[a] The molecular site at which a structural comparison is made is indicated in parentheses. [b] $\Delta\lambda_{em}$ and ΔStokes' shift are expressed as differences in the fluorescence constants of the second compound minus those of the first compound. The intensity ratio is I^{-1} of the second compound divided by that of the first compound. When the intensity ratio is less than unity, the fluorescence intensity of the second compound is increased by the molecular change.

were not occurring. The fluorescence of Solution C was somewhat greater (75% of the intensity of Solution D) than would be accounted for by the dimers of XV formed in this mixture. This finding indicates that the mixed dimer forms (XV–XVII adduct) exhibit some fluorescence, although less intense than that of XV.

The third structural feature that was important in the production of fluorescence by pseudomorphine-like compounds was the furan oxygen bridge. Compounds lacking this group (*e.g.*, levallorphan, pentazocine, and cyclazocine) exhibited no fluorescence under oxidizing conditions. Delocalization of the nonbonding electrons of the furan oxygen into the biphenyl ring system, thereby extending the conjugated system, possibly accounts for the importance of this group.

Table IV—Effects of Substituents on the Fluorescence of Morphine Congeners Oxidized with Potassium Ferro-ferricyanide

Structural[a] Group	Substituent Change	Effect on λ_{em}	Effect on Intensity	Effect on Stokes' Shift
C(3)-OH	C—O-alkyl	Fluorescence not observed	—	—
	C=O	Fluorescence not observed	—	—
Furan oxygen bridge	Elimination	Fluorescence not observed	—	—
		Decrease	Decrease	Decrease
HC(7)=C(8)H	CH_2CH_2	Decrease	Decrease	Decrease
C(14)H	C—OH	None to small increase	Decrease	None to small increase
(N)H	NCH_3	Decrease	Decrease	Decrease
(N)CH_3	$CH_2CH{=}CH_2$ or 	None to small increase	Increase or decrease	None to large increase

[a] The molecular site at which a structural comparison is made is indicated in parenthesis.

Overall, the structural requirements for the production of fluorescence from pseudomorphine-like congeners include the following structural features: an unsubstituted C-3 phenolic group, a furan oxygen bridge, and lack of a C-6 carbonyl group. Thus, the observation by Weinstein *et al.* (8) that a C-6 hydroxyl group is necessary for formation of a fluorescent derivative of XVII under these conditions appears to be incomplete.

Certain structural changes modified λ_{em}, intensity, and the Stokes' shift constant (Table III). Substitution of a larger group for the methyl group at the *N*-substituent position generally produced a shift to longer λ_{em} with a concurrent increase in the Stokes' shift constant. The effect of this change on intensity, however, was varied and could increase or decrease. Saturation of the 7,8-double bond caused a sizable shift to shorter λ_{em}, as well as a decrease in intensity and the Stokes' shift constant.

Changes in the carbinol configuration at C-6 from the α to the β orientation consistently decreased λ_{em}. This change also produced a decrease in intensity and a large decrease in the Stokes' shift constant. Inspection of Dreiding molecular models indicates that the alcoholic group in the β orientation is *anti* to the biphenyl ring system and, thus, would exhibit an electron-withdrawing effect, which would result in a shift to shorter wavelengths and higher energy. However, substitution of an alcoholic group at C-14 for hydrogen caused little change in the fluorescence pattern, probably due to its isolation from the biphenyl system.

Substitution of bulkier groups at R_C in the oripavine series of compounds, XXVII–XXX, caused a decrease in λ_{em} as well as large decreases in intensity.

General trends for effects of substituent changes on the fluorescent properties of the series of morphine agonists and antagonists tested are shown in Table IV. The most pronounced effects resulted from (*a*) structural changes at C-3, where fluorescence was abolished by prevention of dimerization; (*b*) loss of the furan oxygen; and (*c*) structural changes in ring C, where fluorescence could be quenched by the presence of a carbonyl group at C-6. Diminution of intensity was produced by structural changes at C-6, C-7, and C-8.

The structural effects on λ_{em} were so pronounced by epimerization at C-6 that it could provide a means of distinguishing isomers in newly synthesized compounds and metabolites of this series with unknown configurations. Furthermore, the methods used for measurement of fluorescence are readily adaptable for quantitative measurements of drug in biological samples. Thus, a general understanding of the requirements for fluorescence of morphine analogs with the ferricyanide reagent may assist in the development of sensitive and specific assays for these compounds.

High-Performance Liquid Chromatographic Determination of Pilocarpine in Aqueous Humor: Derivatization by Quaternization of Methylimidazole Tertiary Amine Group

A. K. MITRA, C. L. BAUSTIAN, and T. J. MIKKELSON ˣ

Received July 23, 1979, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66044.* Accepted for publication October 1, 1979.

Abstract □ A derivatization procedure and a high-performance liquid chromatographic (HPLC) method of analysis for pilocarpine are described. The method is based on the quaternization of the 3′-tertiary amino group of the methylimidazole ring of pilocarpine with *p*-nitrobenzyl bromide. The HPLC system employs an RP-ODS column with a methanol–water mobile phase containing octanesulfonate as an ion-pairing agent. The sensitivity of the method permits the analysis of pilocarpine in biological fluids such as aqueous humor. The method is selective for pilocarpine in the presence of isopilocarpine. Its applicability to the analysis of aromatic heterocyclic and alkyl tertiary amines is demonstrated.

Keyphrases □ Pilocarpine—high-performance liquid chromatographic determination in aqueous humor, quaternization of the methylimidazole tertiary amine group □ High-performance liquid chromatography—determination of pilocarpine in aqueous humor, quaternization of the methylimidazole tertiary amine group □ Ocular agents—pilocarpine, high-performance liquid chromatographic determination in aqueous humor □ Tertiary amines—derivatization, quaternization, high-performance liquid chromatographic determination

Pilocarpine (I), a parasympathomimetic amine, is used widely as a topical ocular agent for the reduction of the elevated intraocular pressure associated with glaucoma. The UV absorption characteristics of pilocarpine are such that its direct spectrophotometric analysis is an alternative only when high sensitivity is not a requirement.

BACKGROUND

Various analytical methods are available for the determination of pilocarpine, but they are limited relative to sensitivity, specificity, selectivity, and/or reliability. The official colorimetric method (1) utilizes hydroxylamine to cleave the lactone ring. However, the official method is neither selective nor specific.

A kinetic method of analysis was reported (2). In the method, which is based on the imidazole- or substituted imidazole-catalyzed hydrolysis of 2,4-dinitrophenyl acetate, the extent of catalysis is dependent on the pilocarpine concentration. Microgram quantities of pilocarpine are measurable.

GLC methods for pilocarpine have been reported. The most recent utilizes the heptafluorobutyric anhydride acylation of the methylimidazole ring of pilocarpine (3). The method is selective and sensitive and is readily capable of measuring pilocarpine at levels found in biological fluids such as aqueous humor. However, it requires extensive sample handling and workup.

High-performance liquid chromotographic (HPLC) methods for pilocarpine (4) and other imidazole bases (5) have been reported. These methods are based on the direct spectrophotometric measurement of pilocarpine (4) and other imidazole bases (5) at 217 and 208 nm, respectively. Although the approach of direct UV detection of pilocarpine (4) is selective and reliable and is suitable for the analysis of levels contained in pilocarpine dosage forms, it lacks adequate sensitivity for pilocarpine at levels found in aqueous humor following topical administration.

This report describes a derivatization and HPLC procedure for the analysis of pilocarpine in aqueous humor. The method is based on the quaternization of the 3′-tertiary amino group of the methylimidazole ring of pilocarpine with the chromophore *p*-nitrobenzyl bromide. The utilization of a reversed-phase chromatographic system with an ion-pairing agent is described. The method is reliable, because little sample handling is required; the method is selective since pilocarpine and isopilocarpine are separated and determined; and the method is sensitive in that it is applicable to the determination of pilocarpine levels encountered experimentally in aqueous humor. The applicability of the quaternization procedure to the analysis of other tertiary amines, such as aliphatic and aromatic heterocyclic amines, is also described.

EXPERIMENTAL

Materials—Pilocarpine nitrate[1] and isopilocarpine nitrate[2] were used as received. *p*-Nitrobenzyl bromide[2] was recrystallized from water–acetonitrile. The ion-pairing agent, 1-octanesulfonic acid sodium salt[3], was used as received, as was acetonitrile[4]. Methylene chloride[5] (certified ACS grade) was distilled from phosphorus pentoxide prior to use. HPLC grade methanol[5] also was used. All other reagents and chemicals used were analytical reagent grade or high purity.

Equipment—The HPLC system was comprised of a solvent delivery system[6], a septumless injector[7], a UV absorbance detector[8], and a 10-mv strip-chart recorder[9]. Absorbance was measured at 254 nm. Sensitivity settings to 0.005 aufs were used. The column was a 30-cm RP-ODS column with an inside diameter of 3.9 mm and a 10-μm (spherical) particle size[10].

NMR spectra of pilocarpine and the derivative were obtained on a spectrometer[11] in the pulse mode. Spectra were obtained using solutions in deuterium oxide and acetone-d_6, with tetramethylsilane as the internal reference at concentrations of 10–20%.

Chromatographic Conditions—All chromatography was conducted at ambient temperature. The mobile phase consisted of an 80% (v/v) methanol in water mixture containing 1×10^{-3} *M* sodium octanesulfonate. The mobile phase was filtered and degassed prior to use. The flow rate was 1.6 ml/min, which generated a column pressure of 1000–1500 psig.

Glassware—The centrifuge tubes and ampuls used in the derivatization procedure were silanized by soaking for several hours in a solution of 5% dimethyldichlorosilane[1] in toluene and rinsing with toluene, methanol, and methylene chloride (3).

Derivatization—Volumes of 100 μl of either standard aqueous solutions of pilocarpine nitrate or aqueous humor samples were added to 500 μl of 0.3 *M* potassium bicarbonate solutions (pH 8.4) in silanized centrifuge tubes. The resulting solutions were each immediately extracted (vortexed for 1 min and centrifuged at 2000 rpm for 5 min at ambient temperature) with two 1.0-ml volumes of methylene chloride. Aliquots of the two extracts from each sample were combined in silanized glass ampuls and evaporated to dryness under nitrogen at 40°. To the dried samples, a 200-μl volume of a solution of *p*-nitrobenzyl bromide in acetonitrile (0.25 mg/ml) was added.

The ampuls were sealed at ambient pressure under a nitrogen atmosphere, using an oxygen torch flame, and reacted for 24 hr at 40°. Then they were cooled to ambient temperature and opened. The chromatography was conducted by direct injection of an aliquot of the reaction mixture or an internal standard solution was added, the mixture was vortexed, and an aliquot was injected. The internal standard solution was a 10-μl volume of phenylephrine hydrochloride in methanol at 2.0 mg/ml.

Milligram Quantities of Derivative—Pilocarpine nitrate, 50 mg, was dissolved in 25 ml of 0.3 *M* aqueous potassium bicarbonate and extracted with 25 ml of methylene chloride. The organic layer was separated, and the methylene chloride was removed under vacuum. The product obtained was a hydrated pilocarpine base as a clear or very slightly yellow, highly viscous fluid. The pilocarpine base, 50 mg, was combined with 500 mg of *p*-nitrobenzyl bromide in 10 ml of acetonitrile. The resulting solution was reacted at 40° for 24 hr, the reaction mixture was placed in a glass mortar, and the quaternary ammonium reaction product was precipitated by ether addition.

The precipitate was repeatedly washed and purified by trituration in the presence of ether. Then it was dried and stored under vacuum. After thorough drying, the solid was used for UV, mass spectral, and NMR analyses. In addition, the product was used to confirm the chromatographic peak used for quantitation of pilocarpine in the analytical procedure.

Standard Curves—Volumes of 100 μl of aqueous solutions of pilocarpine nitrate ranging in concentration from 0.3 to 10.0 μg/ml were used to develop standard curves. The previously described procedure for derivatization was followed. Standard curves were constructed on a basis of the measured peak heights of the analyte (II), which were compared to both an internal and an external standard. The internal standard, phenylephrine hydrochloride, was used in construction of the standard curve, which was applied to the analysis of samples obtained in *in vitro* transport studies across isolated, mounted corneal membranes.

In vivo pilocarpine absorption studies, where the test solutions were aqueous humor samples obtained as a function of time following topical dosing, and studies using spiked aqueous humor samples resulted in a contaminant that interfered with the internal standard. Therefore, all aqueous humor samples were measured against an external standard of II, which was pure analyte obtained in the milligram quantity preparation procedure described previously. When used, the internal standard was added to the reaction mixture after the derivatization reaction was completed and just prior to injection. This approach was suitable in view of the extraction efficiencies obtained.

Aqueous Humor Samples—New Zealand albino rabbits were sacrificed by marginal ear vein administration of pentobarbital sodium solution. The corneal surface was rinsed with normal saline solution and patted dry with tissue paper. Aqueous humor samples were obtained from the anterior chamber by paracentesis by entering at the limbus with a 1-ml tuberculin syringe fitted with a 27-gauge needle.

RESULTS AND DISCUSSION

Analyte Characteristics—The derivatizing reaction, which is the reaction of pilocarpine (I) with the chromophore *p*-nitrobenzyl bromide to form the quaternary ammonium analyte (II) *p*-nitrobenzyl pilocarpine bromide, is shown in Scheme I. The derivative II displayed a UV absorbance maximum at 263 nm with a molar absorptivity of 1.20×10^4. At 254 nm, this analyte displayed a molar absorptivity of 1.07×10^4.

Under the described chromatographic conditions, the capacity factor, k', for II was 4.87. In comparison, the capacity factor for derivatized isopilocarpine was 5.40. The resulting selectivity was evidenced by a separation factor, α, of 1.11; the degree of separation was evidenced by a resolution, R, of 0.80.

Kinetic experiments were conducted to optimize the reaction conditions in terms of the temperature required and the excess *p*-nitrobenzyl bromide required to achieve complete or near complete production of II in a reasonable time. Reactions forming quaternary salts from tertiary amines and alkyl halides, the Menschutkin reaction (6), are not fast (6–9). They are biomolecular and clearly second order (7). A significant sensitivity to the size and disposition of the nitrogen-substituted alkyl groups has been demonstrated; for example, quinuclidine, which has an exposed nitrogen, is 200-fold more reactive than triethylamine toward methyl chloride (7). Alkyl halide substitutions also significantly alter the quaternization rate. Approximately a 500-fold reduction in the conversion rate was detected through an alkyl series where the following reactivities were found: methyl > ethyl > higher normal alkyls > isopropyl (6, 8). The derivatizing agent, *p*-nitrobenzyl bromide, was chosen because of its UV

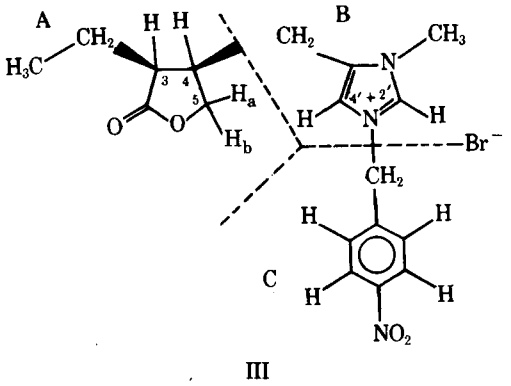
absorption characteristics. However, it was not expected to react rapidly with pilocarpine because of its molecular size, even though the 3′-tertiary nitrogen of the methylimidazole group of pilocarpine is an exposed nitrogen.

Preliminary kinetic studies were conducted at several temperatures, and 40° was chosen for the analytical derivatization. Molar ratios of *p*-nitrobenzyl bromide to I of 40, 125, 420, and 600 were studied. Pseudo-first-order kinetic behavior was observed in each instance, and a decreasing reaction time (10) was observed as a function of increasing molar ratios.

The conditions selected, as described in the procedure for derivatization, corresponded to a molar ratio of *p*-nitrobenzyl bromide to pilocarpine of approximately 600 for a pilocarpine sample solution containing 1.0 μg/ml. These particular conditions were selected because the reaction proceeded with a half-life of ~3 hr without any detectable side reactions. As a result, the reaction was essentially complete in the 24-hr reaction time. In addition, the selected level of *p*-nitrobenzyl bromide did not affect resolution of the analyte or the internal standard.

Comparisons of the NMR spectrum of pilocarpine and the analyte are presented in Table I (the proton numbering system is given in Structure III). The protons of pilocarpine were all accounted for in the derivative. The protons of the ethyl-substituted lactone ring and the methylene bridge were essentially unchanged. However, the protons of the methylimidazole ring demonstrated significant downfield shifts. The *N*-methyl protons, which appeared as a singlet, underwent a downfield shift in the analyte of 0.26 ppm due to the flow of electrons toward the quaternary nitrogen. The 2′- and 4′-protons underwent extensive deshielding. The 2′-proton was found downfield at 11.1 ppm in the analyte compared to 8.6 ppm in pilocarpine. The 4′-proton was at 7.3 ppm in pilocarpine and at 8.1 ppm in the analyte. However, the 4′-proton did not appear as a singlet in the analyte but overlapped as a multiplet with the aromatic protons.



III

Table I—Chemical Shifts in Parts per Million Using Tetramethylsilane Standard for Pilocarpine in Deuterium Oxide and Analyte in Acetone-d_6 [a]

		Pilocarpine[b]	Analyte[b]
Lactone ring with bridge	CH_3–CH_2	1.02 (t)	1.03 (t)
	CH_3–CH_2	1.71 (m)	1.64 (m)
	$-CH_2$-bridge plus 3H,4H	2.81 (m)	3.15 (m)
	$5H_a$	4.17 (dd)	4.31 (dd)
	$5H_b$	4.19 (dd)	4.32 (dd)
Methylimidazole group	N–CH_3	3.77 (s)	4.04 (s)
	2′H	8.60 (s)	11.1 (s)
	4′H	7.30 (s)	8.1 (m)[c]
Chromophore	$-CH_2-$	—	5.96 (s)
	Aromatic	—	8.10 (m)[c]

[a] See Structure III for numbering. [b] s = singlet, dd = double doublet, t = triplet, and m = multiplet. [c] The 4′-proton in the analyte occurs as a multiplet with the aromatic protons.

The integration of the analyte spectrum clearly demonstrated the formation of a one-to-one reaction product. The multiplet at 8.1 ppm was indicative of five protons, the four aromatic protons of the chromophore plus the 4′-proton of the imidazole ring. The singlet at 5.96 ppm, which is the methylene group of the *p*-nitrobenzyl moiety, was indicative of two protons. In comparison, the *N*-methyl group, the lactone–imidazole methylene bridge, the methylene group of the lactone ethyl group at the 3-position, and the methyl group of the lactone ethyl group at the 3-position clearly were indicative of three, two, two, and three protons, respectively.

The mass spectrum of the analyte III did not display a molecular ion peak. The lability of the bond between the quaternary nitrogen of the methylimidazole ring and the methylene of the *p*-nitrobenzyl group was demonstrated by the abundance of *m/e* 208 and 136 fragments, corresponding to a fragment of A + B (pilocarpine), and a fragment of C in III. Further fragmentation was apparent as a function of the abundance of *m/e* 113 (A in III), 84 (A − $-C_2H_5$), 95 (B in III), and 80 (B − $-CH_3$) fragments.

The product sample used to obtain NMR and mass spectral data was isolated and purified from a reaction run at 40° for 24 hr, which indicated that the reaction conditions used to generate the analyte did not result in unexpected side reactions. *p*-Nitrobenzyl bromide and pilocarpine are stable under the conditions of the reaction in that all protons are accounted for and other structural integrity is observed. The reaction follows the expected bimolecular behavior, resulting in the quaternary derivative.

Standard Curve and Detection Limits—Following the procedure for derivatization, plots of calculated peak height ratios, where the analyzed solutions were sample aqueous solutions of pilocarpine nitrate in the concentration range of 0.3–10.0 μg/ml and the internal standard was phenylephrine hydrochloride, were constructed. These plots were linear and reproducible with typical results of $n = 10$, slope = 0.144, intercept = 0.018, and correlation coefficient = 0.995.

Figure 1*a* is the chromatographic result of the derivatization of a standard sample of an aqueous solution containing 6.0 μg/ml of pilocarpine nitrate, approximately equivalent to an injection of 100 ng of pilocarpine. The excess *p*-nitrobenzyl bromide did not interfere with the internal standard or the analyte peaks. Figure 1*b* is the chromatographic result obtained from spiked aqueous humor containing 1.8 μg/ml of pilocarpine nitrate. The internal standard was not added to aqueous humor or spiked aqueous humor samples because of overlapping and interfering substances. For aqueous humor samples, an external standard was employed. Standard curves of peak height plotted against concentration, which were constructed from standard pilocarpine nitrate solutions, from spiked aqueous humor samples, and directly from solutions of known concentrations of analyte, were linear.

The initial step in the derivatization procedure is the double extraction with methylene chloride of the aqueous solutions or samples to which bicarbonate has been added. The efficiency of this extraction was evaluated in two ways. First, several standard pilocarpine solutions were carried through the derivatizing procedure, including the extraction step. The chromatographic results or peak heights obtained were compared to the peak heights obtained from solutions prepared directly with known concentrations of analyte. The chromatographic results were within ±2%, which confirms the extraction efficiency.

Second, aqueous humor samples were spiked with several known concentrations of tritiated pilocarpine and split into two sets. One set

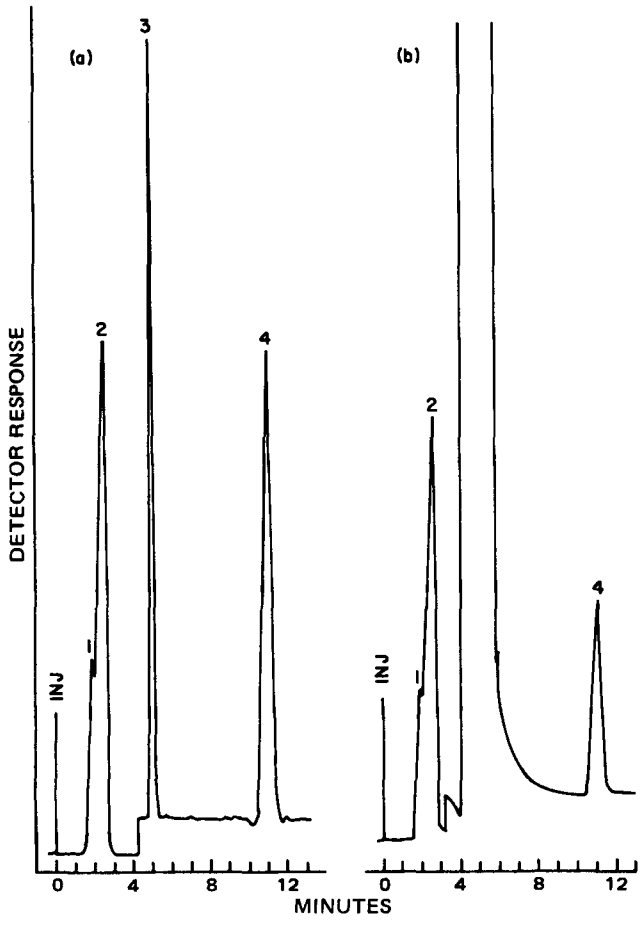


Figure 1—(a) *Chromatogram resulting from a standard pilocarpine nitrate solution. The peaks are: 1, solvent front; 2, excess* p*-nitrobenzyl bromide; 3, internal standard; and 4, analyte.* (b) *Chromatogram resulting from a spiked aqueous humor sample. No internal standard was added because of the broad overlapping contaminant peak.*

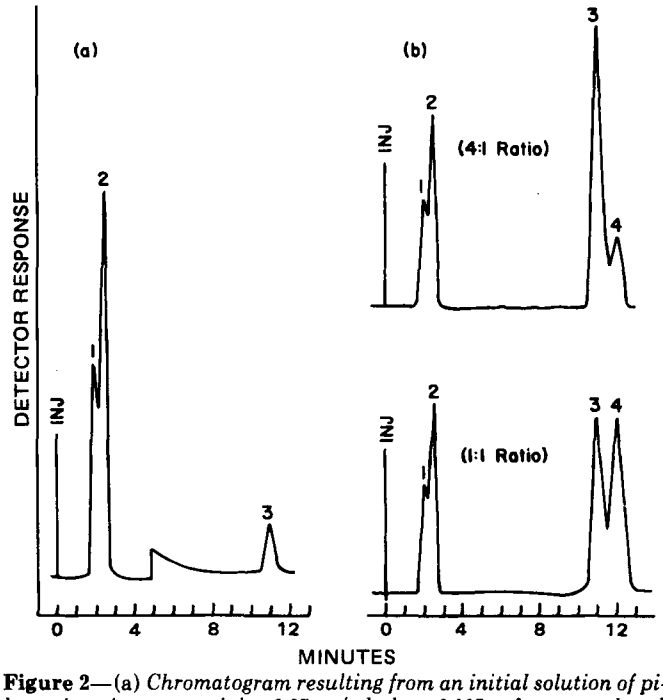

Figure 2—(a) *Chromatogram resulting from an initial solution of pilocarpine nitrate containing 0.05 μg/ml where 0.005 aufs was employed. This amount represents the equivalent of a 3.8-ng injection of pilocarpine. Peak height response linearity was observed at this level.* (b) *Chromatogram resulting from samples containing pilocarpine and isopilocarpine at ratios of 4:1 and 1:1. The peaks in both* a *and* b *are: 1, solvent front; 2, excess* p*-nitrobenzyl bromide; 3, analyte or derivatized pilocarpine (II); and 4, derivatized isopilocarpine.*

was assayed by the derivatization procedure, including the extraction step, and the other set was counted for radioactivity (11). The two sets of analytical results were within ±5%. In the procedure, the solutions containing pilocarpine to which a bicarbonate solution has been added are twice extracted with methylene chloride. The two extractions achieved a total transfer in excess of 98% of the pilocarpine, which is consistent with a previously reported extraction procedure for pilocarpine (2).

The results of the experiments conducted to determine the extraction efficiency support the use of the internal reference standard that is added just prior to injection and not added to the system prior to extraction. Also supported is the use of an external reference standard prepared directly from purified analyte rather than the use of standard solutions of pilocarpine nitrate which are carried through the complete derivatization procedure.

Of the pilocarpine nitrate solutions used to construct standard curves as outlined in the procedure for derivatization, the lowest concentration used was 0.3 μg/ml. To enhance sensitivity, experiments were conducted with 100-μl volumes of the *p*-nitrobenzyl bromide solutions in acetonitrile at 0.5 mg/ml (rather than 200 μl at 0.25 mg/ml). Decreasing the derivatizing reaction volume permitted the volume of the injected aliquot to approach the total volume of the reaction mixture.

Figure 2*a* gives the result of an experiment approximating the practical sensitivity limits of the procedure. The result was obtained from a pilocarpine nitrate solution at 0.05 μg/ml. The injection contained the equivalent of 3.8 ng of pilocarpine. Detection at this level was quantitative. The absolute limits of detection were not determined but are less than the 3.8 ng (or 0.05 μg/ml of pilocarpine nitrate) used previously.

Selectivity—To assess method selectivity, solutions were prepared that contained different ratios (4:1, 1:1, and 1:4) of pilocarine (I) to isopilocarpine (IV). These solutions were run through the described procedure and compared to samples of pure I and IV. A sample result is shown in Fig. 2*b*. The peak height ratios obtained (peak height of I to peak height of IV) were in excellent agreement with the concentration ratios of the initial solutions.

The results suggest that: (*a*) conversion of pilocarpine to isopilocarpine does not occur as a result of the procedure, (*b*) the method is quantitative for isopilocarpine and is applicable to the determination of the amount of isopilocarpine present in pilocarpine as a contaminant, and (*c*) the absorptivity of the pilocarpine and isopilocarpine derivatives is the same at 254 nm. In experiments conducted at the higher pilocarpine nitrate concentrations, *e.g.*, 10 μg/ml, the presence of contaminating isopilocarpine nitrate in the commercial pilocarpine nitrate was observed.

Other Nucleophiles—The primary intent of this study was to develop a method for the low level analysis of pilocarpine in aqueous humor. The method described is based on the reaction between the alkyl halide *p*-nitrobenzyl bromide and the 3′-tertiary amino group of the methylimidazole ring of pilocarpine, which results in the formation of the quaternary ammonium analyte II. Methods are readily available in the literature for the derivatization of primary and secondary amines for purposes of analysis (10, 12, 13), but this is not the case for tertiary amines.

The applicability of this derivatization procedure was investigated for other tertiary amines. Milligram samples of triethylamine, 4-methoxypyridine, and 1-methylimidazole were derivatized and chromatographed. The capacity factors, k', obtained for the resulting quaternary amine derivatives were 5.93, 6.47, and 6.73, respectively. The results indicate that the quaternization reaction using an alkyl halide, such as *p*-nitrobenzyl bromide, can be readily applied to the HPLC analysis of aromatic, heterocyclic, and alkyl tertiary amines in general. There is also flexibility relative to the choice of alkyl halide. An alternative for enhanced UV detection would be the selection of a chromophore with greater molar absorptivity. Another alternative would be the selection of an alkyl halide fluorophore, which would afford the advantage of greater sensitivity of fluorescence.

Dosage Form Design for Improvement of Bioavailability of Levodopa II: Bioavailability of Marketed Levodopa Preparations in Dogs and Parkinsonian Patients

KUNIHIRO SASAHARA ˣ, TAKASHI NITANAI, TAEKO HABARA, TADASHI MORIOKA, and EIICHI NAKAJIMA

Received March 16, 1979, from the *Product Development Laboratories, Sankyo Company, Ltd., 1-2-58, Hiromachi, Shinagawa, Tokyo, Japan.* Accepted for publication September 14, 1979.

Abstract □ To estimate the absolute bioavailability of oral levodopa, plasma concentrations and urinary excretion of levodopa and its metabolites were determined in beagle dogs and in parkinsonian patients after intravenous and oral drug administration. The absolute bioavailability of orally administered levodopa was estimated to be about 35% in both dogs and patients; however, the total amount absorbed of intact drug and levodopa metabolites was estimated to be 80–90% of the administered dose. Due to the similarities of the pharmacokinetic characteristics of levodopa found in beagle dogs and in humans, beagle dogs can serve as a model to study bioavailability, absorption, and metabolic mechanisms.

Keyphrases □ Levodopa—bioavailability, dosage form design, dogs and humans □ Bioavailability—levodopa, dosage form design, dogs and humans □ Antiparkinsonian agents—levodopa, bioavailability, dosage form design, dogs and humans

Much higher oral doses than intravenous doses of levodopa are required to achieve a therapeutic effect in parkinsonian patients, and the resultant plasma levels after oral levodopa are markedly lower than those in patients receiving the drug intravenously.

Rivera-Calimlim *et al.* (1, 2) reported that when levodopa was administered orally to parkinsonian patients, a considerable portion apparently was metabolized *via* reactions in the stomach and intestines before it was absorbed. Other investigators (3–6) reported that 50–70% of the oral doses appeared to be metabolized in the intestinal mucosa of parkinsonian patients.

This paper reports part of a continuing study of levodopa to delineate mechanisms involved in the absorption profile in humans and to develop new dosage form designs to improve the bioavailability of levodopa. The absolute bioavailability of levodopa from marketed conventional preparations was determined by measuring the plasma levels and urinary excretion of levodopa and its metabolites after intravenous and oral administration of single doses to beagle dogs and to parkinsonian patients.

EXPERIMENTAL

Single Intravenous Doses in Dogs—After six healthy male beagle dogs, 10.3–12.5 kg, had been fasted for ~16 hr, levodopa[1] at a 50-mg dose was injected over 30 sec into the brachial vein. Blood samples were withdrawn with a heparinized syringe from the contralateral brachial vein. Samples were obtained 0, 2, 5, 15, and 45 min and 1, 1.5, 2, 3, 4, and 6 hr after dosing. Sodium metabisulfite solution (5% in a saline solution, 0.1 ml/5 ml of blood) and disodium ethylenediaminetetraacetate (2% in a saline solution, 0.1 ml/5 ml of blood) were added to the freshly drawn heparinized blood, and the plasma was separated immediately by centrifugation at 4°. All procedures were conducted in an ice bath.

Urine was collected before dosing and for 48 hr in bottles containing 5 ml of 6 *N* HCl and 3 ml of 0.2 *M* disodium ethylenediaminetetraacetate. The pH of the collected urine was adjusted to 2.0, and the urine was stored at −20° until assayed.

Single Oral Doses in Dogs—The same six beagle dogs used in the single intravenous dose studies were forcefully administered 250 mg of levodopa in capsule form[2] orally with 10 ml of warm water. The dogs' mouths were closed by hand to prevent emesis. Blood samples were withdrawn with a heparinized syringe 0, 0.5, 1, 2, 3, 4, and 6 hr after oral administration.

The blood samples were treated using the same procedures as in the intravenous study. The urine also was collected before dosing and for 48 hr after oral administration following the same procedure used for intravenous administration.

Single Intravenous Doses in Patients—Five parkinsonian patients (three men and two women) were studied. Their mean age was 63 years (range 51–71). Three days prior to the experiment, all levodopa preparations and other drugs that had been administered for the treatment of Parkinson's disease were withdrawn. Levodopa[1], 50 mg, diluted with 200 ml of physiological saline, was infused for 20 min at a constant rate into the brachial vein of these patients. Blood samples were withdrawn with a heparinized syringe at 0, 10, and 20 min during infusion and at 15 and 30 min and 1, 2, and 3 hr after infusion. The blood and urine samples were collected and processed in the same way as were those taken from the dogs.

Single Oral Doses in Patients—Six parkinsonian patients (three men and three women) were studied. Their mean age was 68 years (range 58–74). Three days before drug administration, all levodopa preparations and other drugs that had been administered for the treatment of Par-

kinson's disease were withdrawn. A 1-g dose of levodopa in capsule form[2] was administered to the subjects with 1 cup of water at about 9:00 am.

On the day of the study, the subjects ate breakfast at about 7:00 am, lunch at about 12:00, and dinner at about 5:30 pm. Blood samples were withdrawn with a heparinized syringe before the drug was administered and at 0.5, 1, 2, 3, 4, and 6 hr after oral administration. The blood and urine samples were collected and processed using the same procedures as those used for the dogs.

Assay of Levodopa and Its Metabolites in Plasma and Urine—Levodopa and its metabolites in plasma and urine were assayed according to the methods reported previously (7).

Pharmacokinetics—The plasma levodopa concentration curves following intravenous administration to dogs were analyzed using the program of Hanano *et al.* (8). The plasma levodopa concentration curves following oral administration to dogs, infusion administration to patients, and oral administration to patients were analyzed using the BMDP-3R nonlinear regression program (9).

RESULTS

Absolute Bioavailability of Marketed Levodopa Preparations in Dogs—*Single Intravenous Doses*—The average plasma levels of levodopa and total dopamine[3] following intravenous administration of levodopa at a 50-mg dose to six dogs are presented in Fig. 1. Since the plasma levodopa concentration–time curve appeared to follow biexponential disposition characteristics, the data were fitted to the two-compartment open model using linear kinetics. Table I shows the results of the computer analysis. Visual inspection of the observed points around the fitted curve indicated satisfactory randomness of scatter. The average area under the plasma concentration–time curve (*AUC*) of levodopa corrected for body weight and the average plasma clearance of levodopa corrected for body weight also are shown in Table I to facilitate comparison between these parameters in dogs and in patients.

The average plasma levels of total dopamine formed by the metabolism of levodopa increased with time, reached a maximum value at ~1 hr after intravenous administration, and then decreased more slowly as compared to the elimination of levodopa in the plasma. The average *AUC* of total dopamine corrected for body weight is shown in Table I.

The intravenously administered levodopa was excreted in urine over 48 hr as total levodopa[4], total dopamine, total 3,4-dihydroxyphenylacetic acid[5], and total homovanillic acid[6], which represented 3.1 ± 0.43, 10.6 ± 0.92, 12.3 ± 1.24, and 37.3 ± 3.51% of the dose, respectively. Consequently, 63.3 ± 4.52% of the dose in terms of total urinary excretion[7] was eliminated within 48 hr after intravenous administration. The remainder of the drug probably was excreted in the feces or was undetermined metabolites.

Single Oral Doses—The average plasma levels of levodopa and total dopamine after oral administration of levodopa to six dogs are shown in Fig. 2. The maximum plasma level of 4.32 ± 0.42 mg/liter occurred 1 hr after oral administration. The levels then decreased rapidly to ~0.2 mg/liter 6 hr after oral administration, corresponding to 5% of the maximum plasma levels.

The average plasma levels of total dopamine changed more slowly than did those of levodopa. The elimination of total dopamine from the plasma also was slower compared to that of levodopa, and the plasma level of total dopamine 6 hr after oral administration was 0.42 ± 0.03 mg/liter, corresponding to about 25% of the maximum levels. The average *AUC* values of levodopa and total dopamine were 0.60 ± 0.053 and 0.56 ± 0.046 mg/liter/hr, respectively.

The orally administered levodopa was excreted in urine over 48 hr as total levodopa, total dopamine, total 3,4-dihydroxyphenylacetic acid, and total homovanillic acid, which represented 0.73 ± 0.93, 11.7 ± 1.21, 13.6 ± 0.91, and 25.6 ± 2.62% of the dose, respectively. Consequently, 51.6 ± 3.02% of the dose was excreted within 48 hr after oral administration.

Comparison of the absolute bioavailability of marketed levodopa capsules after oral administration with intravenous injection was accomplished using the plasma levodopa levels to estimate the intact amounts of levodopa absorbed into the circulation system, with the as-

[3] Total dopamine = conjugated dopamine + unconjugated dopamine.

[4] Total levodopa = unconjugated levodopa + conjugated levodopa.

[5] Total 3,4-dihydroxyphenylacetic acid = unconjugated 3,4-dihydroxyphenylacetic acid + conjugated 3,4-dihydroxyphenylacetic acid.

[6] Total homovanillic acid = unconjugated homovanillic acid + conjugated homovanillic acid.

[7] Total urinary excretion = total levodopa + total dopamine + total 3,4-dihydroxyphenylacetic acid + total homovanillic acid.

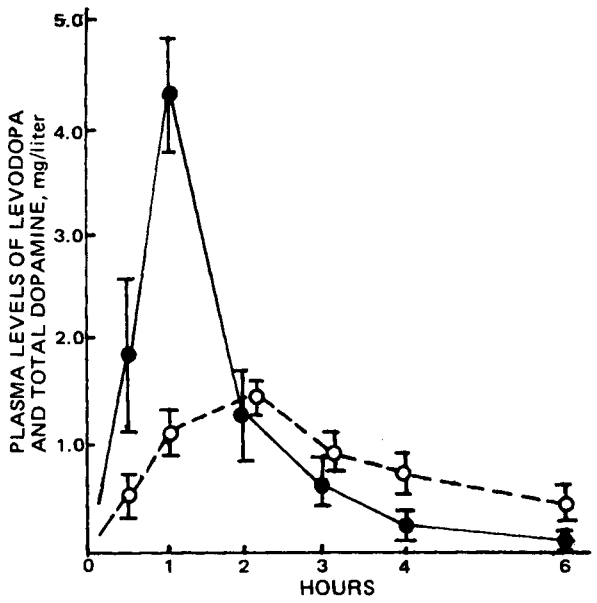

Figure 2—*Average* (±SE) *plasma levels of levodopa* (●) *and total dopamine* (○) *following oral administration of 250-mg doses of levodopa to six dogs.*

sumption that levodopa disposition in the body followed linear kinetics. On the other hand, the total amount absorbed from the GI tract, including levodopa and its metabolites, was calculated by the ratio of the total urinary excretion after oral administration to that after intravenous administration. The absolute bioavailability in the dogs and the total amount absorbed are shown in Table I. These results indicate that the difference between these values is due to presystemic metabolism and/or degradation of the drug.

Absolute Bioavailability of Marketed Levodopa Capsules in Parkinsonian Patients—*Single Intravenous Doses*—The average plasma levels of levodopa and total dopamine for 20 min following intravenous infusion of a 50-mg dose of levodopa to five parkinsonian patients are presented in Fig. 3. The plasma levodopa levels increased during the intravenous infusion and reached a maximum value of 0.89 ± 0.09 mg/liter at the conclusion of the infusion, *i.e.*, 20 min after the beginning of the intravenous infusion. The subsequent plasma levodopa levels decreased rapidly, and levodopa was almost undetectable in the plasma after 200 min. These plasma levodopa concentration–time curves were analyzed by appropriate procedures and linear kinetics presuming a two-compartment open model (Table I). The terminal half-life of levodopa in patients was 39 ± 4.1 min (mean ± *SE*). The *AUC* of levodopa corrected for body weight was 0.0124 ± 0.0012 mg/kg/liter/hr (Table II).

The plasma level of total dopamine increased with time and reached a maximum value of 0.18 ± 0.016 mg/liter 50 min after the intravenous infusion began. The levels then decreased more slowly compared to the elimination of levodopa in the plasma and were approximately 33% of the maximum plasma levels 200 min after the intravenous infusion began. Plasma levodopa and total dopamine were not detectable before dosing. The *AUC* of total dopamine was 0.0099 ± 0.00094 mg/kg/liter/hr.

The infused levodopa was excreted in urine over 8 hr as total levodopa, total dopamine, total 3,4-dihydroxyphenylacetic acid, and total homovanillic acid, which represented 2.5 ± 0.21, 11.2 ± 1.02, 11.8 ± 0.94, and 29.6 ± 2.43% of the dose, respectively. Consequently, 55.1 ± 4.24% of the dose was excreted within 48 hr after infusion.

Single Oral Administration—The average plasma levels of levodopa and total dopamine after oral administration of a 1-g dose of levodopa in capsule form to six patients are shown in Fig. 4. The maximum plasma levels occurred 1 hr after oral administration. The levels then decreased rapidly to <0.2 mg/liter at 6 hr after oral administration. The *AUC* of levodopa was 0.0826 ± 0.0105 mg/kg/liter/hr.

The average plasma levels of total dopamine reached a maximum after 2 hr and then decreased more slowly than did those of levodopa, with the concentration of 0.45 ± 0.05 mg/liter at 6 hr corresponding to about 33% of the maximum levels. The *AUC* of total dopamine was 0.104 ± 0.0102 mg/kg/liter/hr.

Orally administered levodopa was excreted in urine over 24 hr as total levodopa, total dopamine, total 3,4-dihydroxyphenylacetic acid, and total homovanillic acid, which represented 0.58 ± 0.065, 13.5 ± 1.25, 15.1 ± 1.62, and 18.2 ± 1.95% of the dose, respectively. Consequently, 48.4 ± 4.13% of the dose was excreted within 48 hr after oral administration.

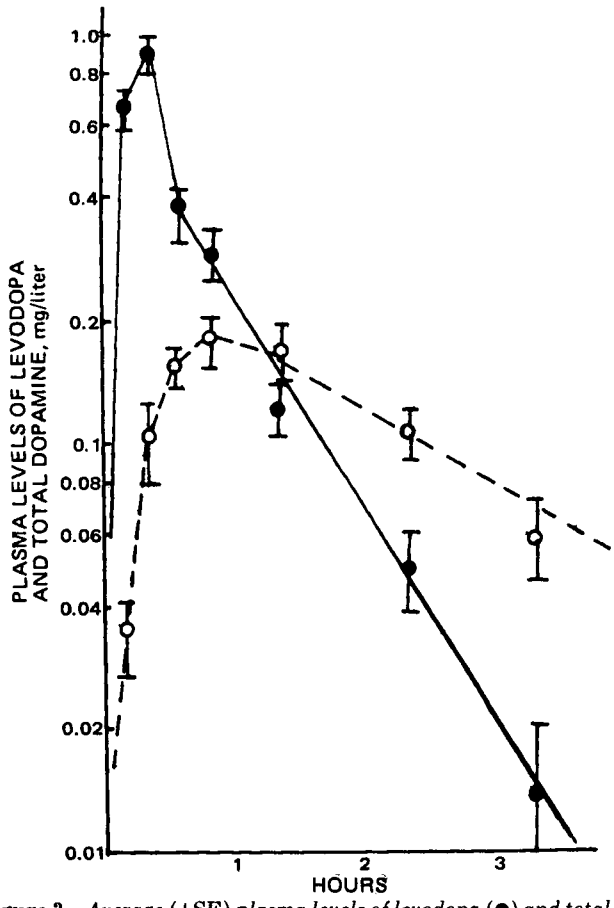

Figure 3—*Average* (±SE) *plasma levels of levodopa* (●) *and total dopamine* (○) *following infusion of 50-mg doses of levodopa to five parkinsonian patients.*

The absolute bioavailability and total percent of oral capsules that were absorbed by patients were calculated on the assumption that levodopa in the body obeys linear kinetics and that the two different population groups were comparable in this study. They are shown in Table II and were in good agreement with the values for the dogs.

DISCUSSION

The plasma concentration–time curves and the estimated pharmacokinetic parameters obtained in these studies compare well with the data obtained by Coutinho *et al.* (10) and Colter *et al.* (11) following intravenous administration of radiolabeled levodopa to dogs. However, Coutinho *et al.* (10) reported that ~75% of the intravenously administered dose, in terms of total radioactivity, was recovered in the urine within 72 hr. In contrast, ~65% of the intravenously administered dose, as the sum of total levodopa, total dopamine, total 3,4-dihydroxyphenylacetic acid, and total homovanillic acid, was excreted in the urine within 48 hr in the present studies. Both results seem to be consistent considering that the data of Coutinho *et al.* (10) involved total radioactivity measurements.

Table II—Absolute Bioavailability and Total Amount Absorbed, Including Metabolites, after Oral Administration of Levodopa to Dogs and Patients

Subject	Dose, mg	Absolute Bioavailability, %[a]	Total Amount Absorbed, %[a]
Dogs	250	36.3 ± 2.9[b]	81.0 ± 4.7
Patients	1000	33.3 ± 4.23	87.8 ± 7.4

[a] Based on the presumed linear kinetics using the dose-corrected *AUC* from the intravenous dose. [b] Average ± *SE*.

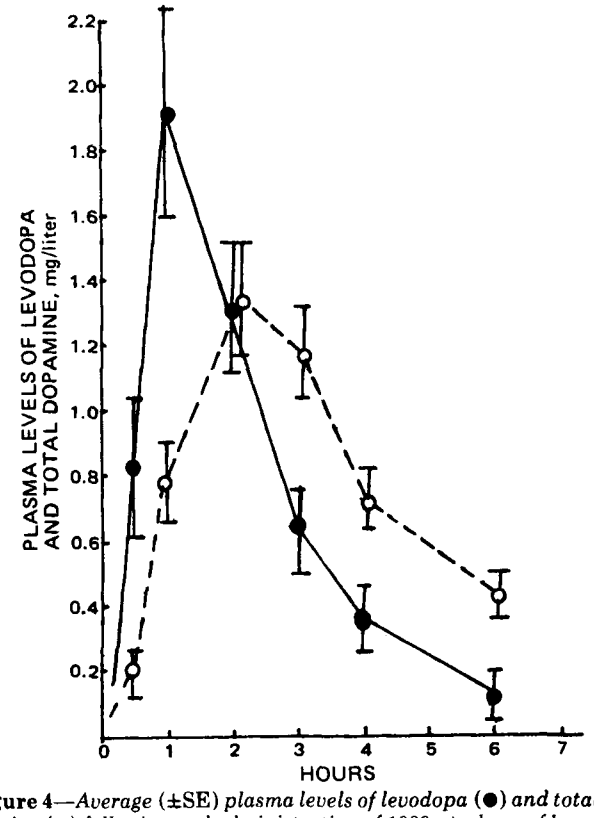

Figure 4—*Average* (±SE) *plasma levels of levodopa* (●) *and total dopamine* (○) *following oral administration of 1000-mg doses of levodopa to six parkinsonian patients.*

The profile of plasma levodopa levels and the pattern of urinary excretion obtained in this experiment following oral administration of levodopa, respectively, agree with the results and the observations reported previously (10–12). In the urine, 44–57% of the oral dose was excreted, including metabolites, but only small amounts of intact levodopa were excreted.

The absolute bioavailability and the extent of total oral absorption including levodopa and its metabolites following oral administration of levodopa to dogs were ~35 and 80%, respectively. These results showed that the bioavailability of levodopa was low but that the extent of total absorption of levodopa was good. It can be inferred that this difference is due to the degradation and/or metabolism of levodopa in the GI tract and liver during absorption. In fact, levodopa decarboxylase, believed to be responsible for metabolizing levodopa, is widely distributed in the liver (13–15), kidney (16), and GI tract (5, 6, 17). The activity of this enzyme is relatively high in the GI tract. Therefore, the proposal of gut and gut wall metabolism of levodopa by this enzyme probably is justified.

One way of evaluating the first-pass effect is to compare the ratio of the *AUC* of the metabolite, total dopamine, to that of the parent drug. These relationships may be represented as follows:

$$AUC_{\text{levodopa}} = FD/Cl_{\text{levodopa}} \qquad \text{(Eq. 1)}$$

$$AUC_{\text{total dopamine}} = fFD/Cl_{\text{total dopamine}} \qquad \text{(Eq. 2)}$$

where Cl_{levodopa} and $Cl_{\text{total dopamine}}$ represent the elimination clearance of the respective compounds, *FD* represents the levodopa dose absorbed, and *f* represents the fraction of the levodopa dose absorbed that is converted to total dopamine. The ratio of Eq. 2 to Eq. 1 gives:

$$\frac{AUC_{\text{total dopamine}}}{AUC_{\text{levodopa}}} = \frac{fCl_{\text{levodopa}}}{Cl_{\text{total dopamine}}} \qquad \text{(Eq. 3)}$$

Thus, the new ratio shown in Eq. 3 cancels out the *FD* term relating to the absorbed dose. The right side of Eq. 3 includes three parameters. The elimination clearance of dopamine, $Cl_{\text{total dopamine}}$, in the denominator should be unaffected by the administration route. Since Eq. 3 eliminates the effect of the absorbed dose, the observed elimination clearance for the parent drug, Cl_{levodopa}, should be unchanged as long as the system obeys linear kinetics.

Finally, Eq. 3 includes a term, *f*, in the numerator that represents the fraction of the parent drug converted to the metabolite, total dopamine. This term should increase after oral administration relative to an intravenous dose. Therefore, comparison of the *AUC* ratios obtained after oral and intravenous studies should reflect the increase in the metabolite formed *via* presystemic metabolism of the drug during oral absorption. The ratio in dogs was 0.56 ± 0.06 after intravenous injection *versus* 0.93 ± 0.10 after oral absorption. Therefore, the first-pass metabolism most likely results in more extensive metabolism of levodopa.

On the other hand, parkinsonian patients administered an intravenous dose of levodopa showed levodopa disposition kinetics similar to those observed in the dogs (Table I). As mentioned before, about 55% of the intravenous dose was recovered from the urine within 8 hr. Imai *et al.* (18) reported that following oral administration of levodopa to parkinsonian patients, >90% of the drug excreted within 24 hr was recovered from the urine within the first 8 hr. Therefore, even though these data are from urine collected within the first 8 hr after dose administration, it seems appropriate to assume that the results would be similar to the 24-hr data. In addition, Bronaugh *et al.* (19) determined the urinary excretion of total levodopa, total dopamine, total 3,4-dihydroxyphenylacetic acid, and total homovanillic acid separately after intravenous administration of radioactive levodopa to patients. They reported about 50% urinary excretion of these metabolites, which is in good agreement with our value. The plasma levodopa levels and the urinary excretion pattern following oral administration of levodopa in the parkinsonian patients in the present study were similar to previous (18, 20, 21) results.

The absolute bioavailability and the extent of total absorption calculated from results of intravenous infusion in parkinsonian patients were ~33 and 88%, respectively (Table II). These results show that bioavailability of levodopa was low in patients but that the extent of total absorption of levodopa was good, as in dogs. Also, the ratio of the *AUC* of total dopamine to the *AUC* of levodopa was 0.81 ± 0.06 after an intravenous dose in patients, while it was 1.26 ± 0.13 after oral administration. These values are consistent with the concept of first-pass metabolism, yielding a more extensive metabolism of levodopa during oral administration in patients as well as in dogs.

Furthermore, the results of these bioavailability studies using both dogs and patients indicate that beagle dogs and patients showed similar pharmacokinetic parameters following intravenous administration of levodopa (Table I) and similar bioavailability of oral levodopa (Table II). Therefore, this study supports the use of beagle dogs as model animals for pharmacokinetic and biopharmaceutical investigations to study the mechanism involved in the low bioavailability of marketed levodopa preparations. A subsequent paper of this series will discuss the possibility of nonlinear kinetics of levodopa in dogs and humans.

Polymers for Sustained Macromolecule Release: Procedures to Fabricate Reproducible Delivery Systems and Control Release Kinetics

WILLIAM D. RHINE, DEAN S. T. HSIEH, and ROBERT LANGER ˣ

Received May 31, 1979, from the *Department of Nutrition and Food Science, Massachusetts Institute of Technology, Cambridge, MA 02139,* and the *Department of Surgery, Childrens' Hospital Medical Center, Boston, MA 02115.* Accepted for publication October 8, 1979.

Abstract □ Matrixes composed of ethylene–vinyl acetate copolymer are useful vehicles for the sustained release of macromolecules such as proteins. A new procedure for fabricating these polymeric delivery systems involved mixing the dry, powdered macromolecule with a polymer solution and casting the mixture at −80°. The resulting matrix was dried in two 48-hr stages, first at −20° and then at 20°. These polymer systems had uniform drug distribution, and their release kinetics were reproducible. Fabrication parameters such as drug particle size, drug loading, and matrix coating all significantly affected release kinetics.

Keyphrases □ Kinetics, drug release—effects of particle size, drug loading, and matrix coating on polymer–drug mixtures □ Polymers—use in sustained-release film formation, preparation methods of polymer–drug matrix, low temperature effects on polymeric matrix □ Controlled-delivery system—preparation methods, polymer–drug matrix, drug release kinetics

A previous study described the first biocompatible polymeric delivery systems capable of continuously delivering macromolecules (mol. wt. > 1000) such as proteins for prolonged periods (1). In that study, a polymer–macromolecule matrix was formed by mixing powdered macromolecules in a polymer solution. This mixture was poured into small, conical, glass molds, and the solvent was evaporated. The resulting pellets, when exposed to an aqueous medium, released macromolecules in biochemically active form for >100 days (2). Although sustained release was achieved, the reproducibility of the release kinetics was poor. Difficulties in obtaining reproducible release rates were compounded when larger volume polymeric delivery systems were fabricated.

Significant drug settling and redistribution occurred during casting and drying due to the insolubility of the incorporated macromolecules in the polymer solvent. At room temperature, the drug migrated vertically, and visible lateral motion was caused by currents (possibly thermal) in the mixture. The low temperature casting procedures described were developed to minimize this drug movement during matrix formation. The reproducibility of release kinetics of matrixes prepared using these low temperature methods was improved markedly.

The reproducible kinetics permitted the study of the effects of certain fabrication factors, including drug particle size, drug loading, and matrix coating, on macromolecule release. The significant effects of these factors on release kinetics suggest possible means of utilizing and modifying macromolecular release systems according to research or clinical needs.

EXPERIMENTAL

Matrix Preparation—Ethylene–vinyl acetate copolymer[1] (40% vinyl acetate by weight) was dissolved in methylene chloride[2] to give a 10% solution (w/v). Protein or another macromolecular powder was sieved[3] to give particles of <75, 75–250, or 250–425 μm. A weighed amount of powder from a single size range was added to 15 ml of the polymer solution in a glass vial[4], and the mixture was vortexed[5] for at least 10 sec to yield a uniform suspension. This mixture was poured quickly into the center of a leveled glass mold (7 × 7 × 0.5 cm), which had been cooled previously on dry ice for 5 min. During precooling, the mold was covered with a glass plate to prevent excess frost formation.

After the mixture was poured, the mold remained on the dry ice for 10 min, and the mixture froze. (The mold was covered again for the last 7 min of this stage.) The frozen slab was easily pried loose with a cold spatula, transferred onto a wire screen[6], and kept at −20° for 2 days. The slab then was dried for 2 more days at room temperature in a desiccator[7] under a mild, houseline vacuum (600 mtorr). Drying caused the slabs to shrink to ~5 × 5 cm. The central 3 × 3-cm square was excised with a scalpel[8] and a straight edge and divided further into nine 1 × 1-cm squares.

Kinetics—Each square was weighed, its thickness was measured with

a micrometer[9], and it was placed in a vial containing 10 ml of saline (0.154 *M* NaCl[10]). Vials were put on a shaker[11] at 20°. At each time point, the squares were transferred with forceps into fresh, saline-containing vials. During these transfers, excess solution on the matrix surface was removed by gentle blotting on a tissue. The concentrations of macromolecules in the vials were determined spectrophotometrically[12].

Release of Macromolecules—Kinetic studies were conducted on the release of three proteins[13]: bovine serum albumin (mol. wt. 68,000), β-lactoglobulin (mol. wt. 18,000), and lysozyme (mol. wt. 14,400). A standard particle size (75–250 μm) and loading (25% of matrix weight as protein) were used in the measurement of release kinetics. Protein concentrations were determined by absorbance at 220 or 280 nm.

Particle Size and Loading—A series of experiments was conducted to compare the release of albumin of three particle sizes (<75, 75–250, and 250–425 μm) at four drug loadings (10, 25, 37.5, and 50% protein by weight). With the smallest particle size, a 67% loading was possible and was tested for release kinetics. (With particle sizes greater than 75 μm, the polymer solution–protein powder mixture would not pour.)

For each particle size and loading, at least two slabs were cast and assayed for release characteristics. Release from each square was monitored for 4–8 weeks. *Table I lists the* weights and thicknesses of matrix squares containing albumin of various particle sizes and loadings.

Isotropic Studies—Experiments were conducted to examine matrix isotropy by comparing release from the top and bottom faces of polymer matrixes containing albumin. Conditions ranged from 25% loading and particle sizes of <75 μm to 50% loading and particle sizes of 250–425 μm. For each matrix square, all surfaces except for one face were covered by dripping molten paraffin wax[14] onto the square. The remaining face was protected by adhesive tape. The excess wax was trimmed off, and the adhesive tape was removed.

Release measurements were conducted with care taken to ensure that the unwaxed face always was exposed to the release medium. Release rates were compared between the top and bottom faces of matrixes for each combination of particle size and loading. Control squares containing albumin were covered completely with wax; these squares showed no effect on the spectrophotometric assay.

Coating—The effect of coating matrixes with an additional polymer layer was examined. Polymeric matrixes, 50% insulin[13] by weight, were prepared by the described procedures, except that the insulin powder was not sieved. (Commercial insulin powder, with a particle size of <50 μm, is more uniform than most protein powder preparations.) After the insulin–polymer matrixes were dried and weighed, the squares were coated by dropping each into a vial containing 15 ml of polymer solution, either 5 or 20% (w/v) ethylene–vinyl acetate in methylene chloride. After 1 min in solution, the square was grasped on its edges with forceps, removed from solution, and held to dry at room temperature for 2 min. The matrix was dried for an additional 24 hr at room temperature under mild vacuum.

Both coated and uncoated samples were measured for release kinetics for over 20 days. Because insulin can bind to glass, release was measured in silicone[15]-coated vials containing saline at 20°. Insulin concentrations were determined by adjusting the pH to 3.0 (50 μl of 1 *N* HCl[10] added/10 ml of saline) and measuring absorbance at 220 nm.

RESULTS

Uniformity and Reproducibility—The improvement in the uniformity of drug distribution using low temperature fabrication methods is shown in Fig. 1. Figure 1*a* is a photograph of a matrix containing albumin (particle size of 75–250 μm, 25% protein by weight), which was cast and dried at low temperature; under these conditions, the drug was distributed uniformly throughout the matrix. Figure 1*b* shows a matrix similarly prepared, except that casting and drying were conducted at room temperature. In this case, drug distribution was irregular, with some areas nearly void of protein (clear zones).

The low temperature fabrication procedure produced polymer matrixes that were essentially isotropic with respect to release. Experiments in which release rates from the top and bottom faces of the polymer matrix were studied separately showed that release rates never differed by more than 25%, which suggests that the low temperatures during the matrix casting and drying prevented significant vertical drug migration.

Figure 2 depicts the reproducibility of release kinetics from matrixes prepared at a low temperature. Three slabs were prepared with albumin, and all 27 1 × 1-cm squares were measured for release for >24 days. The mean daily release rates and their standard deviations are shown in Fig.

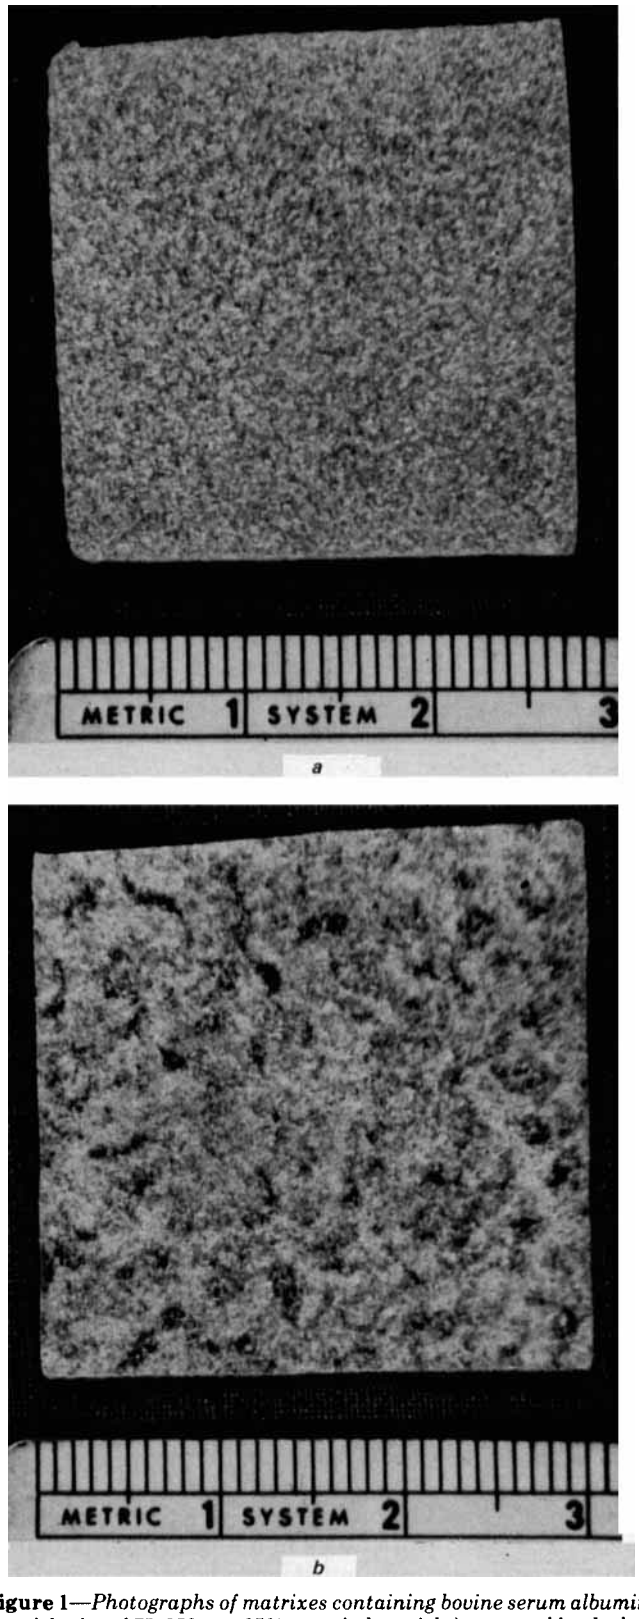

Figure 1—*Photographs of matrixes containing bovine serum albumin (particle size of 75–250 μm, 25% protein by weight) prepared by the low temperature procedure (Fig. 1a) and at room temperature (Fig. 1b). The scale is in centimeters.*

[a] All weights and thicknesses were measured before exposure to saline. Hydration increased the volume by ~5%. [b] $n \geq 8$. [c] This particular combination of particle size and loading was not prepared.

2. Standard deviations of release rates were within 15% of the respective means, except during the early release period (in which the standard deviations were still within 25%). Standard deviations of release rates from matrixes prepared at room temperature were only within 75%. In addition, more than 90% of the total variance of release for matrixes fabricated at a low temperature was due to variability within a single slab.

Other studies using different proteins, particle sizes, and loadings yielded release reproducibilities consistent with the described observation with one exception: at high loadings (≥50%), the center square had a significantly slower release rate than the other eight squares from the same slab. This observation may be because the center is the site of pouring and, therefore, is the last area to be fully cooled.

Figure 3 shows the release of different proteins of the same particle size and loading. In this graph, cumulative percent protein release is plotted *versus* time$^{1/2}$. The standard deviation of cumulative release was within 10% of the mean in all cases.

Particle Size and Loading—Figures 4 and 5 show the effects of drug particle size and loading on release kinetics. The profiles of cumulative release *versus* time$^{1/2}$ first are grouped by common loadings ranging from 10 to 50% (Figs. 4*a*–4*d*). These release profiles then are plotted by similar particle size (Figs. 5*a*–5*c*). In every case, the standard deviation of cumulative release was within 10% of the mean, and there appeared to be a release period roughly linear with respect to time$^{1/2}$. At higher loadings, this period was almost immediate (Fig. 4*d*). At lower loadings, there was an initial, nonlinear burst of release lasting about 48 hr, followed by a linear period (Figs. 4*a* and 4*b*).

Particle size significantly affected the drug release rates. In almost all cases, an increase in particle size increased the release kinetics. The only exception was at the highest loading; in this case, the difference between release rates of polymer matrixes containing protein in the two larger particle-size ranges was minimal. The effect of particle size was most significant at the intermediate loadings (25 and 37.5%). Here, the slopes of the regions linear with respect to time$^{1/2}$ varied as much as sixfold due to a change in particle size.

Increases in drug loading uniformly increased drug release rates (Fig. 5). Not only did total drug release increase, but the cumulative percent of matrix drug released over time increased. As much as a 50-fold increase in the percent released slopes was caused by increasing drug loading from 10 to 50% by weight (Fig. 5*a*).

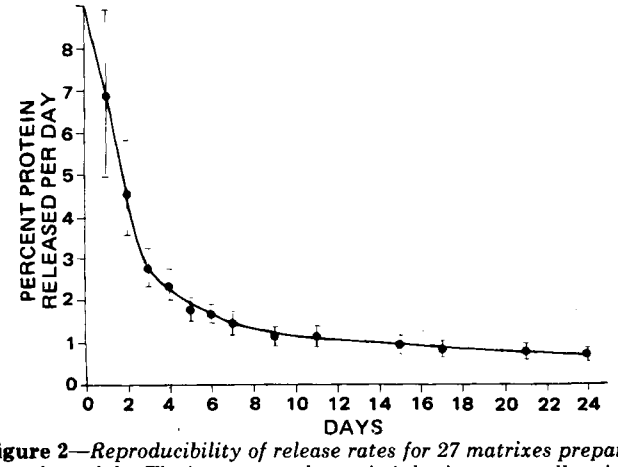

Figure 2—*Reproducibility of release rates for 27 matrixes prepared from three slabs. The incorporated protein is bovine serum albumin at a particle size of 75–250 μm and 25% loading.*

Coating—Coating the matrix also significantly affected drug release rates (Fig. 6). Release in coated matrixes again appeared to follow time$^{1/2}$ kinetics. Release kinetics decreased with increases in coating solution concentrations. A sevenfold difference in release rates was observed between uncoated samples and samples coated with 20% polymer solution. Standard deviations of cumulative release values were within 15% of the means.

DISCUSSION

These results show the effectiveness of low temperature fabrication procedures for the incorporation of macromolecules into polymeric matrixes. Procedures used for the incorporation of low molecular weight drugs (3–7) are inadequate for macromolecules. Compression molding and levigation (3, 4) would subject the relatively less stable proteins or macromolecules to denaturation. Therefore, macromolecules were added to a solution of polymer dissolved in a volatile solvent (methylene chloride). This mixture, when cast and dried, produced matrixes capable of sustained macromolecular release.

Sustained-release films for low molecular weight drugs have been cast from polymer solutions in which the drug also was dissolved (5–7). However, macromolecules such as proteins were insoluble in the polymer solution used and rapidly migrated when cast at room temperature. Low temperature casting and drying reduced protein migration and resulted in matrixes with uniform drug distribution and reproducible release kinetics. Similar low temperature techniques may prove useful in other systems that require uniform distribution of an insoluble compound in a polymer solution.

The reproducibility of release kinetics for matrixes prepared by low temperature methods was demonstrated for different proteins and for a range of particle sizes and loadings. However, it may be more difficult to incorporate some macromolecules uniformly if the drug particle density is much greater than that used in the present study since high density may cause the particles to settle significantly even at low temperatures. This settling may be alleviated by more rapid cooling during casting.

The polymer solution mixed with macromolecules quickly gelled when cast on dry ice at −80°. After 2 days at −20°, enough solvent had evaporated to allow further drying at room temperature (2 days under mild

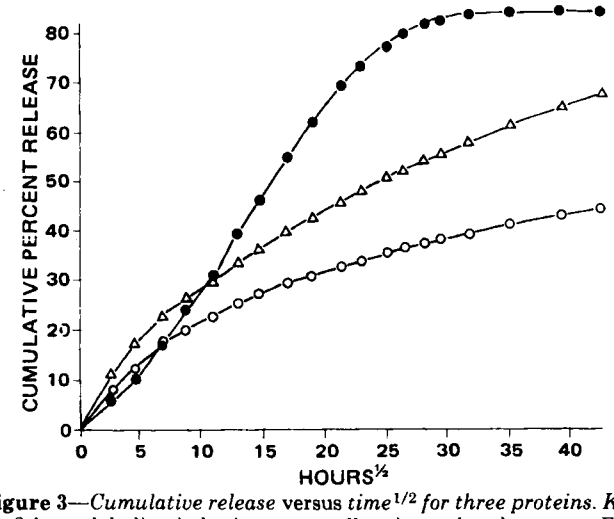

Figure 3—*Cumulative release* versus *time$^{1/2}$ for three proteins. Key: ●, β-lactoglobulin; Δ, bovine serum albumin; and ○, lysozyme. Each point represents the mean of at least eight samples. Standard deviations were <10% of the respective mean values.*

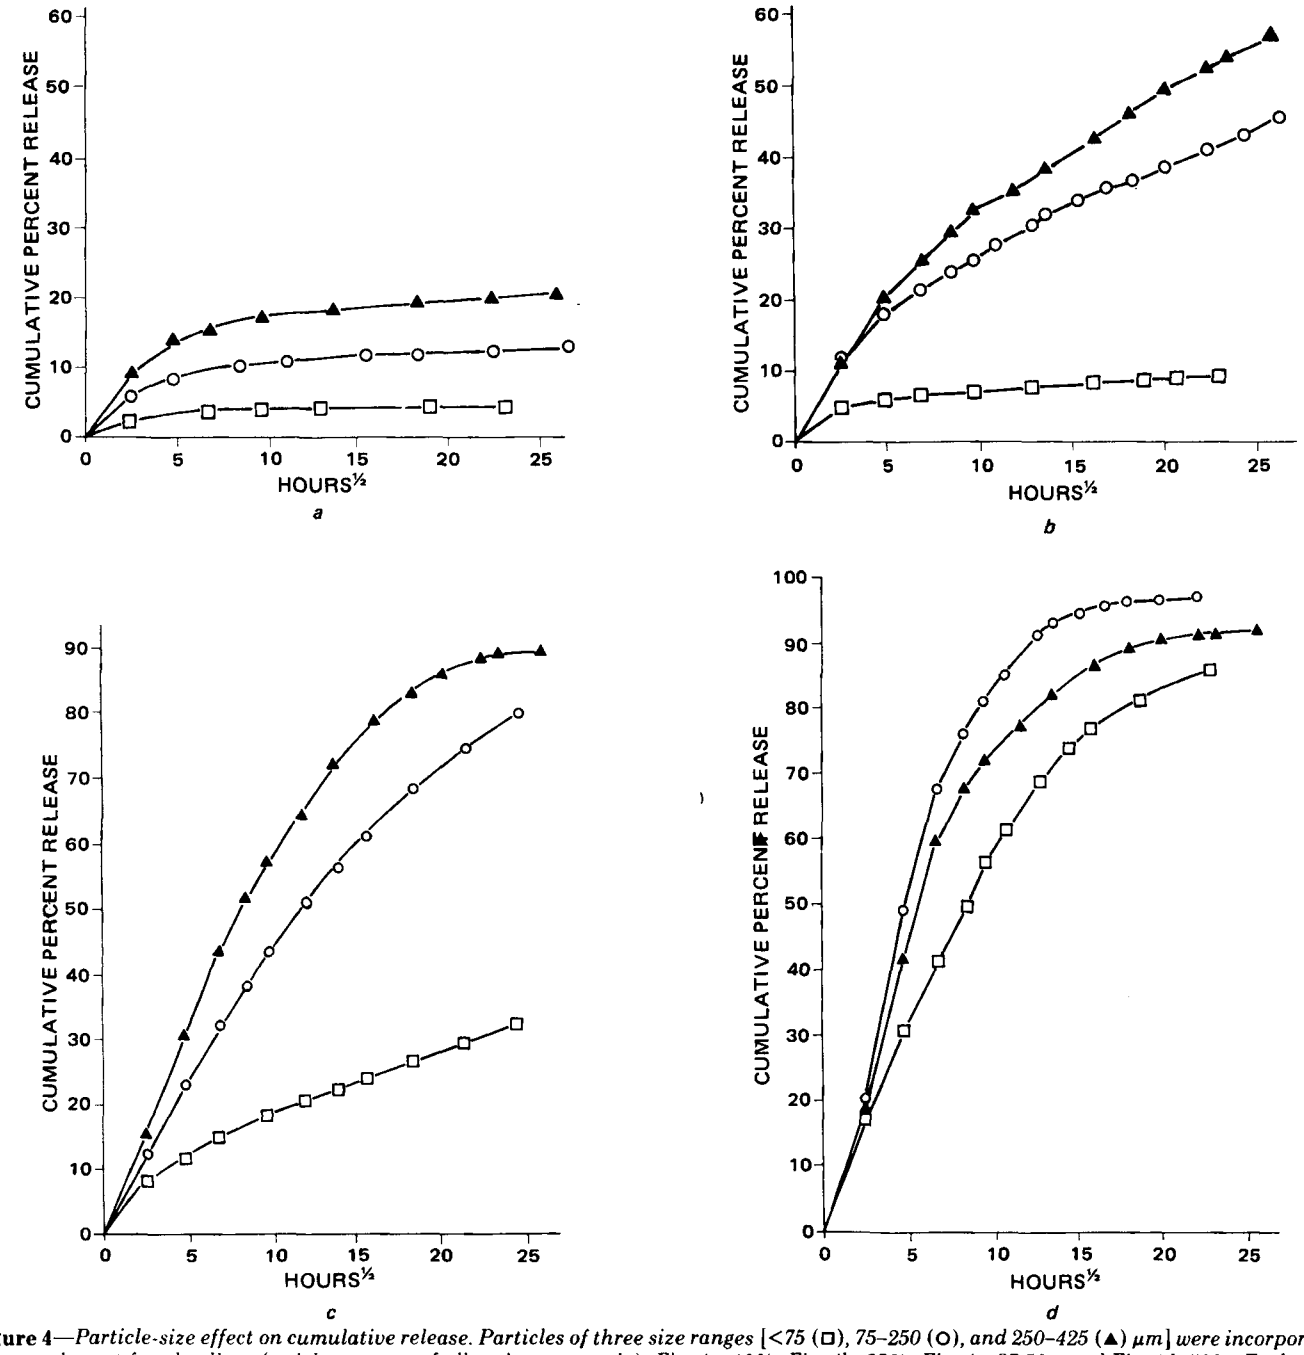

Figure 4—*Particle-size effect on cumulative release. Particles of three size ranges [<75 (□), 75–250 (○), and 250–425 (▲) μm] were incorporated into matrixes at four loadings (weight percent of albumin per matrix): Fig. 4a, 10%; Fig. 4b, 25%; Fig. 4c, 37.5%; and Fig. 4d, 50%. Each point represents the mean of eight samples. Standard deviations were <10% of the respective mean values.*

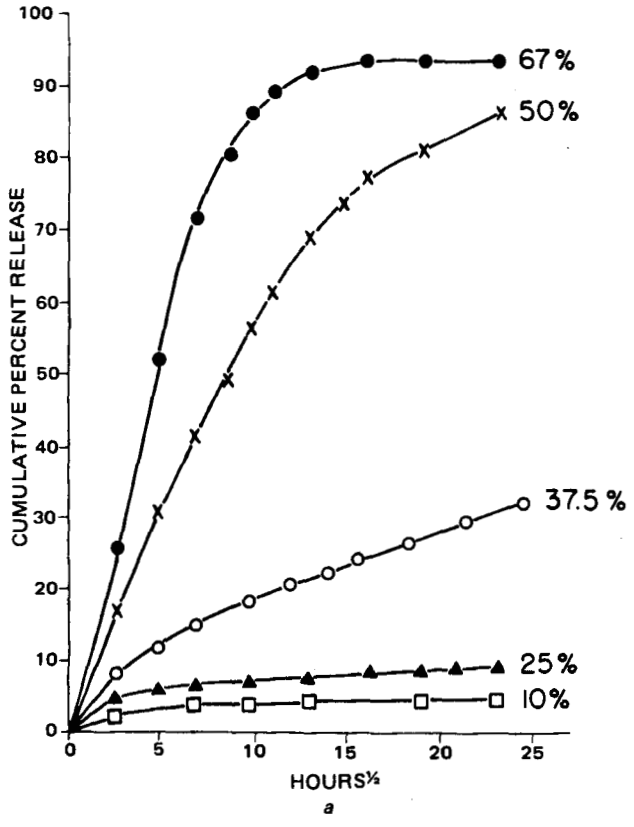
vacuum). In a separate experiment, more extensive drying (up to 60 days under vacuum) did not affect release kinetics.

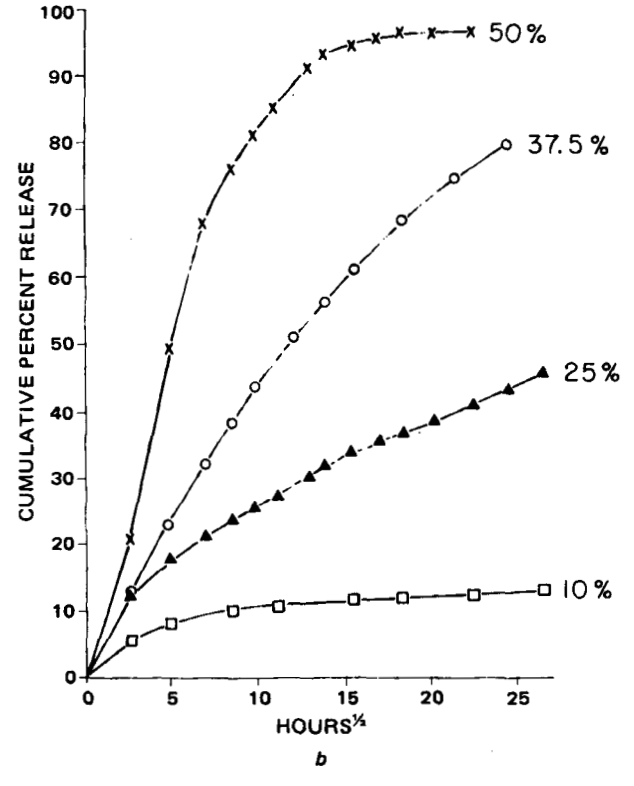
There appeared to be three release phases: (*a*) a burst or initial period of rapid release; (*b*) a period when release was approximately linear with respect to time$^{1/2}$; and (*c*) a final period when release tapered off. The burst effect presumably was due to protein dissolution on the surface and cut edges of the matrix. The intermediate release phase that displayed time$^{1/2}$ kinetics resembled earlier release models of low molecular weight drugs from granular matrixes (8). Because macromolecules are too large to diffuse through a pure polymer film (1), it is possible that sustained release occurs *via* diffusion through channels in the matrix. The incorporation of the macromolecules during casting may introduce such channels through which the dissolved drug can diffuse. In this case, observed differences in release rates for different proteins would be attributable to differences in protein properties (solubility and diffusivity) and matrix characteristics (porosity and tortuosity). For example, the very slow release from the uncoated insulin–polymer matrixes (Fig. 6) may result from the small size of the incorporated insulin powder and the low insulin solubility in the release media.

Drug particle size and loading markedly affected release kinetics of the macromolecular polymeric delivery systems (Figs. 4 and 5). Similar observations have been made for low molecular weight drug release (9, 10), although the effects were not as significant. Release rate increases caused by increases in particle size may result from the formation of larger channels or pores in the polymer matrix. Similarly, increased loadings may provide simpler pathways (lower tortuosity) and greater porosity for diffusion, both of which would facilitate the movement of water into, and proteins out of, the matrix.

A coating also can be used to control macromolecular release kinetics. Its effects may be due to the reduced amount of macromolecule on the matrix surface as well as the decreased surface access of pores for channeled diffusion. It is assumed that the coating procedure does not cause a pure intact polymer film to form around the matrix since that would prevent any macromolecular diffusion into the surrounding media (1).

Systems for the sustained release of macromolecules have potential biological and pharmacological value. For example, these systems provided the basis for bioassays of growth factors derived from tumors (2), cartilage (11), the vitreous body (12), and macrophages (13). They also





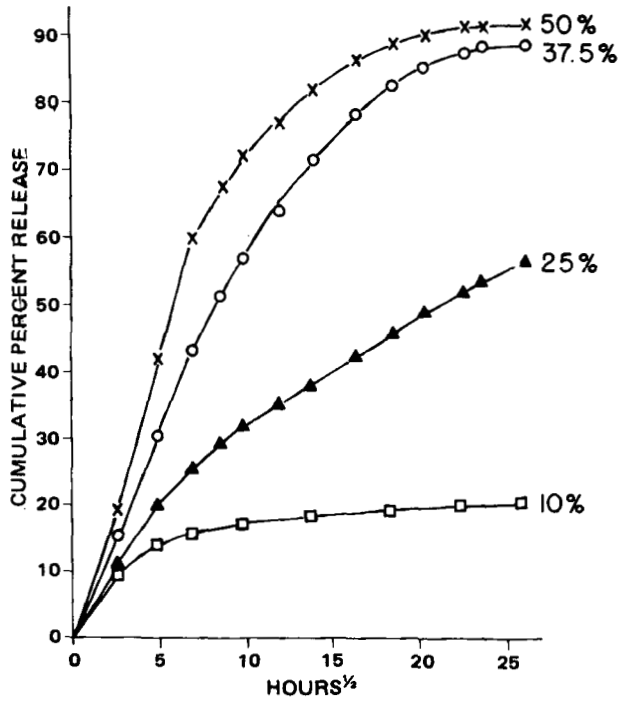


Figure 5—*Loading effect on cumulative release. Matrixes with loadings [10 (□), 25 (▲), 37.5 (○), 50 (×), and 67% (●) of albumin by weight] were made using albumin of three particle-size ranges: Fig. 5a, <75 μm; Fig. 5b, 75–250 μm; and Fig. 5c, 250–425 μm. Each point represents the mean of at least eight samples. Standard deviations were <10% of the respective mean values.*

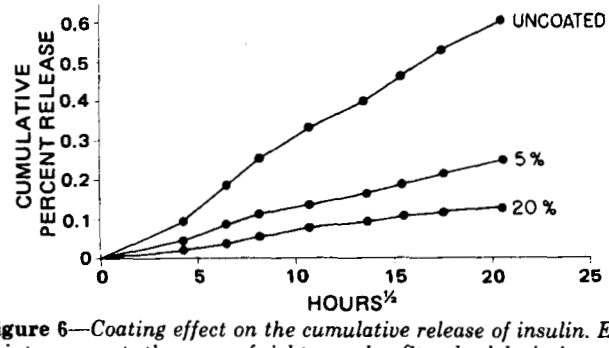

Figure 6—*Coating effect on the cumulative release of insulin. Each point represents the mean of eight samples. Standard deviations were <15% of the respective mean values.*

were used in studies of vascular proliferation (14), vascular regression (15), and chemotaxis (16). Clinically, these systems may prove valuable as single-step methods for immunization (17) or for the continuous delivery of insulin (18) and other high molecular weight drugs.

These low temperature fabrication procedures for macromolecular release systems are easy to perform and require standard, inexpensive laboratory apparatus. A wide spectrum of release rates can be achieved by altering drug particle size and loading and by coating the matrix; thus, these systems can be modified for various applications. Further work is being directed toward the development of physical and mathematical models to describe and predict macromolecular release.

Solvent Effects on IR Spectra of Flurazepam

SAMUEL S. M. NG ˣ and PRANAB K. BHATTACHARYYA

Received April 6, 1979, from the *Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication October 5, 1979.

Abstract □ Differences among the IR spectra of flurazepam samples obtained by recrystallizing flurazepam dihydrochloride from different solvents were studied and found to be caused by different mixtures of flurazepam mono- and dihydrochlorides and the free base; these spectral differences are not caused by polymorphism or decomposition of flurazepam.

Keyphrases □ Flurazepam—IR spectral analysis, effects of various extraction solvents, transformation from dihydrochloride to monohydrochloride and free base, comparison of spectra of extracted, untreated, and solution samples □ Spectroscopy, IR—flurazepam analysis, effect of various extraction solvents □ Sedatives—flurazepam, IR spectroscopy

To identify the active ingredient in flurazepam dihydrochloride capsules, flurazepam dihydrochloride was extracted from the capsules and its IR spectrum was matched with a reference spectrum. The IR spectrum of the extracted substance in potassium bromide was significantly different from the spectrum of untreated flurazepam dihydrochloride in potassium bromide, as well as from that published previously (1). Different spectra also were obtained in potassium bromide when different extraction solvents were used. The observed differences in the IR spectra were investigated to determine their origin.

EXPERIMENTAL

The spectra were recorded by a grating IR spectrophotometer[1]. The samples were measured as potassium bromide disks, as solutions in cells with sodium chloride windows, and as a capillary film between two sodium chloride disks.

The samples were prepared using the following extraction methods.

1. The contents of three 15-mg flurazepam dihydrochloride capsules[2] were extracted with 10 ml of methanol or acetone and filtered. The filtrate was evaporated to dryness under a nitrogen stream, and the residue was collected.
2. Flurazepam dihydrochloride (0.5 g) was dissolved in 3 ml of methanol and evaporated to dryness under nitrogen.
3. Flurazepam dihydrochloride (0.5 g) was dissolved in 100 ml of chloroform with stirring, and the clear solution was evaporated to dryness under nitrogen.
4. Flurazepam dihydrochloride (0.5 g) was dissolved in 2 ml of distilled water and evaporated to dryness under nitrogen. The residue was dried in a vacuum oven at ~50°, if necessary.
5. The contents of two to three flurazepam dihydrochloride capsules (or 100 mg of flurazepam dihydrochloride) were mixed well with 10 ml of distilled water. The mixture was neutralized with 1.0 *N* NaOH, and the milky solution was extracted with 10 ml of chloroform. The chloroform layer (flurazepam free base) was passed through anhydrous sodium sulfate and evaporated to dryness under nitrogen.

RESULTS AND DISCUSSION

The IR spectra of materials (in potassium bromide) extracted from three 15-mg flurazepam dihydrochloride capsules with methanol and acetone are presented in Fig. 1 (curves A and B, respectively). Figure 1 also includes the spectra of untreated flurazepam dihydrochloride, flurazepam monohydrochloride, and flurazepam free base as potassium bromide pellets (curves C, D, and E, respectively). The spectra of the materials extracted with methanol and acetone disagree with each other as well as with the spectra of untreated flurazepam dihydrochloride. At this point, the suggestion of polymorphism arose. The IR spectra (as potassium bromide pellets) of the substances recrystallized by dissolving flurazepam dihydrochloride in methanol, chloroform, and water were obtained (curves A, B, and C, respectively, Fig. 2). Again, these spectra are not identical to one another or to the spectrum of untreated flurazepam dihydrochloride. To investigate whether polymorphism was causing these differences, solution spectra of the same substances were obtained (Fig. 3). Figure 3 also contains the solution spectrum of untreated flurazepam dihydrochloride. Since significant differences were found in the solution spectra as well, these differences could not be attributed to polymorphism.

The differences among curves C–E in Fig. 1 are most pronounced between 1800 and 2500 cm^{-1} and at 1635 cm^{-1}. The 1800–2500-cm^{-1} region contains the absorption bands due to the R_3N^+H and $R_2C{=}N^+H$ ions. Saturated tertiary amine salts (R_3N^+H) exhibit a strong and broad ammonium band (2) centered between 2300 and 2500 cm^{-1}, particularly when a large asymmetric tertiary ammonium ion combines with a relatively small negative ion such as chloride. This band has been observed in many tertiary amine salts of hydrochloric acid and hydrobromic acid.

Unsaturated amine salts ($C{=}N^+H$) exhibit a characteristic immonium band between 1800 and 2000 cm^{-1} in addition to the ammonium band between 2300 and 2500 cm^{-1}, which overlaps with the ammonium band caused by the R_3N^+H ion. The IR spectrum of flurazepam dihydrochloride is characterized by the immonium band between 1800 and 2000 cm^{-1} as well as the ammonium band between 2300 and 2500 cm^{-1} (curve C, Fig. 1). The IR spectrum of flurazepam monohydrochloride is characterized only by the ammonium band between 2300 and 2500 cm^{-1} and the absence of the immonium band between 1800 and 2000 cm^{-1} (curve D, Fig. 1). In flurazepam monohydrochloride, where the hydrochloride

RESULTS AND DISCUSSION

The IR spectra of materials (in potassium bromide) extracted from three 15-mg flurazepam dihydrochloride capsules with methanol and acetone are presented in Fig. 1 (curves A and B, respectively). Figure 1 also includes the spectra of untreated flurazepam dihydrochloride, flurazepam monohydrochloride, and flurazepam free base as potassium bromide pellets (curves C, D, and E, respectively). The spectra of the materials extracted with methanol and acetone disagree with each other as well as with the spectra of untreated flurazepam dihydrochloride. At this point, the suggestion of polymorphism arose. The IR spectra (as potassium bromide pellets) of the substances recrystallized by dissolving flurazepam dihydrochloride in methanol, chloroform, and water were obtained (curves A, B, and C, respectively, Fig. 2). Again, these spectra are not identical to one another or to the spectrum of untreated flurazepam dihydrochloride. To investigate whether polymorphism was causing these differences, solution spectra of the same substances were obtained (Fig. 3). Figure 3 also contains the solution spectrum of untreated flurazepam dihydrochloride. Since significant differences were found in the solution spectra as well, these differences could not be attributed to polymorphism.

The differences among curves C–E in Fig. 1 are most pronounced between 1800 and 2500 cm^{-1} and at 1635 cm^{-1}. The 1800–2500-cm^{-1} region contains the absorption bands due to the R_3N^+H and $R_2C{=}N^+H$ ions. Saturated tertiary amine salts (R_3N^+H) exhibit a strong and broad ammonium band (2) centered between 2300 and 2500 cm^{-1}, particularly when a large asymmetric tertiary ammonium ion combines with a relatively small negative ion such as chloride. This band has been observed in many tertiary amine salts of hydrochloric acid and hydrobromic acid.

Unsaturated amine salts ($C{=}N^+H$) exhibit a characteristic immonium band between 1800 and 2000 cm^{-1} in addition to the ammonium band between 2300 and 2500 cm^{-1}, which overlaps with the ammonium band caused by the R_3N^+H ion. The IR spectrum of flurazepam dihydrochloride is characterized by the immonium band between 1800 and 2000 cm^{-1} as well as the ammonium band between 2300 and 2500 cm^{-1} (curve C, Fig. 1). The IR spectrum of flurazepam monohydrochloride is characterized only by the ammonium band between 2300 and 2500 cm^{-1} and the absence of the immonium band between 1800 and 2000 cm^{-1} (curve D, Fig. 1). In flurazepam monohydrochloride, where the hydrochloride

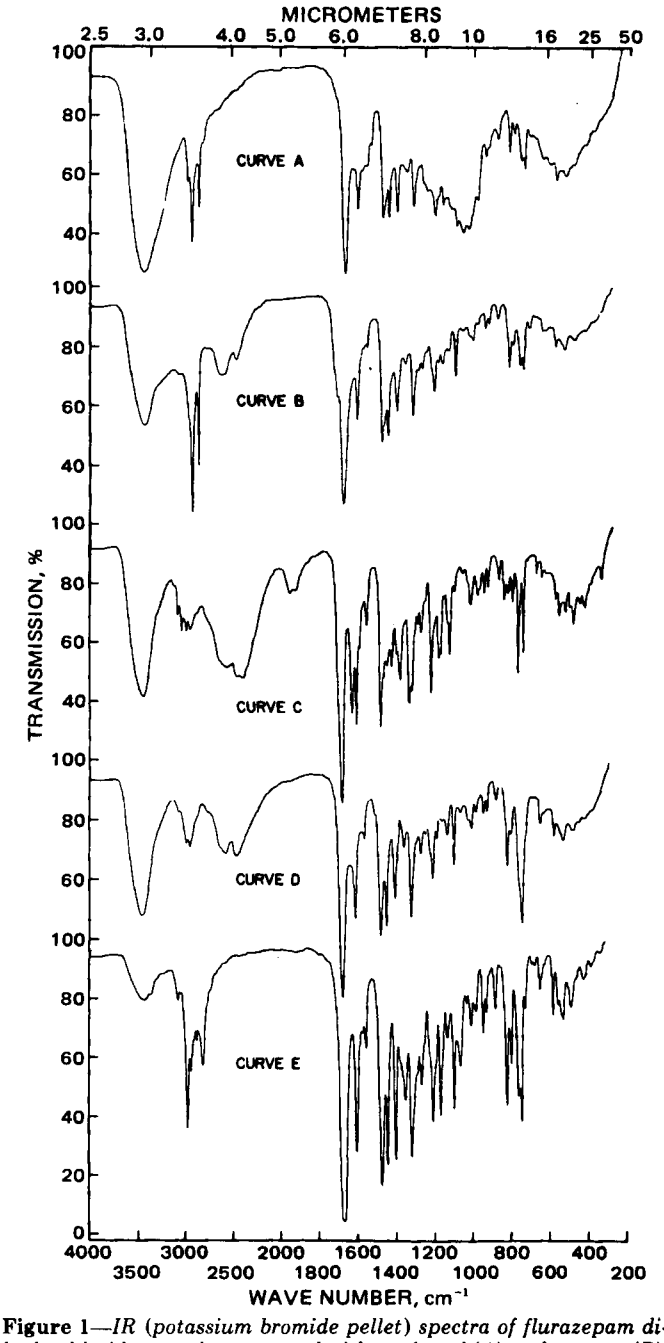

Figure 1—*IR (potassium bromide pellet) spectra of flurazepam dihydrochloride capsules extracted with methanol (A) and acetone (B). Curve C is the spectrum of untreated flurazepam dihydrochloride, curve D is that of flurazepam monohydrochloride, and curve E is that of flurazepam free base.*

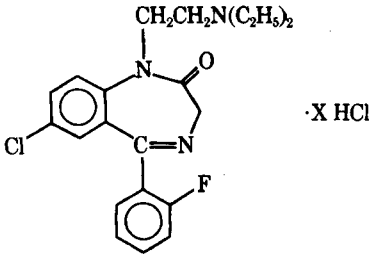

X = 2 (dihydrochloride)
X = 1 (monohydrochloride)
X = 0 (free base)

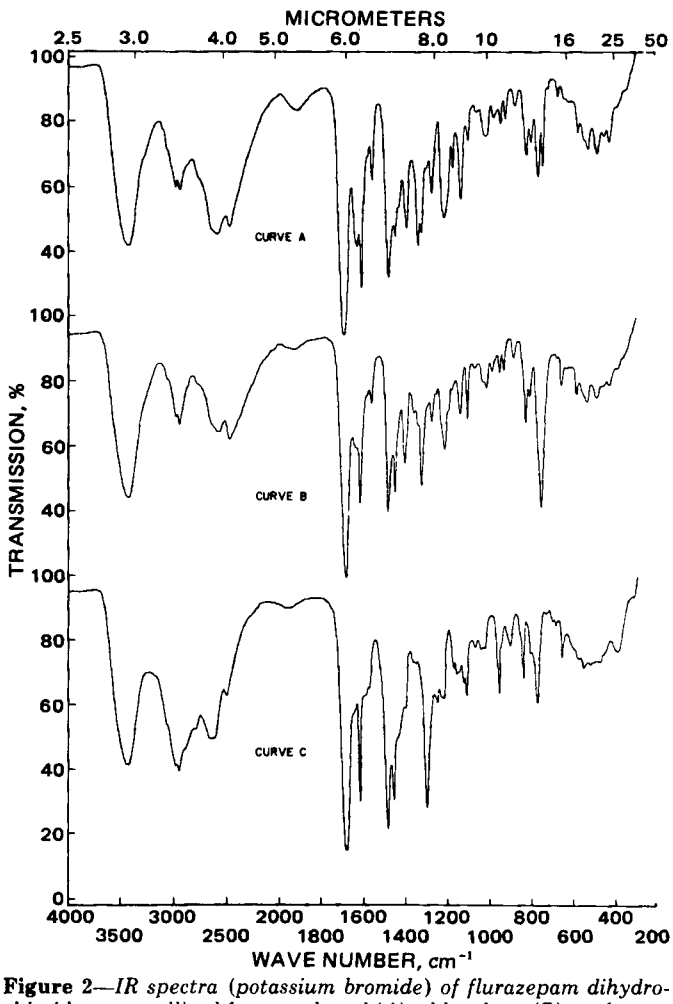

Figure 2—*IR spectra (potassium bromide) of flurazepam dihydrochloride recrystallized from methanol (A), chloroform (B), and water (C).*

concentration is less than that in flurazepam dihydrochloride, the acidic protons in flurazepam monohydrochloride participate in the formation of saturated tertiary ammonium ions (R_3N^+H) only because of the higher basicity of the tertiary amine (R_3N) than the imine (C=N—). The free base is recognized by the absence of such bands in the 1800–2500-cm^{-1} region (curve E, Fig. 1). The next most distinguishing feature of flurazepam dihydrochloride is the sharp band at 1635 cm^{-1} assigned to the $C{=}N^+$ stretching vibration; this band is absent in the spectra of the monohydrochloride and the free base. Furthermore, the carbonyl stretching band shifts from ~1680 cm^{-1} in the monohydrochloride and in the free base, to ~1700 cm^{-1} in the dihydrochloride.

Interpretation of Spectra from Capsules—The spectrum of flurazepam dihydrochloride capsules extracted with methanol lacks the ammonium and immonium absorption bands from 1800 to 2500 cm^{-1} (curve A, Fig. 1); this material is mostly flurazepam free base contaminated by other ingredients extracted from the capsule. The spectrum of flurazepam dihydrochloride capsules extracted with acetone displays only the ammonium band between 2300 and 2500 cm^{-1} (curve B, Fig. 1). Since the intensity of this band is weaker than that observed with the monohydrochloride, this material is a mixture of flurazepam monohydrochloride and flurazepam free base.

The intensities of the observed bands between 1800 and 2500 cm^{-1} and at 1635 cm^{-1} in Fig. 2 show that each spectrum is a linear superposition of the spectra of flurazepam dihydrochloride and flurazepam monohydrochloride, each having a different ratio of dihydrochloride to monohydrochloride. The material recrystallized by dissolving flurazepam dihydrochloride in methanol seemed to be approximately an equal mixture of mono- and dihydrochlorides (curve A, Fig. 2). The substances obtained from chloroform and water contain much more mono- than dihydrochlorides, as evidenced by the reduced intensities of the $C{=}N^+$ band at 1635 cm^{-1} and the immonium band at 1800–2000 cm^{-1} (curves B and C, Fig. 2).

Interpretation of Spectra from Solutions—These spectra (curves

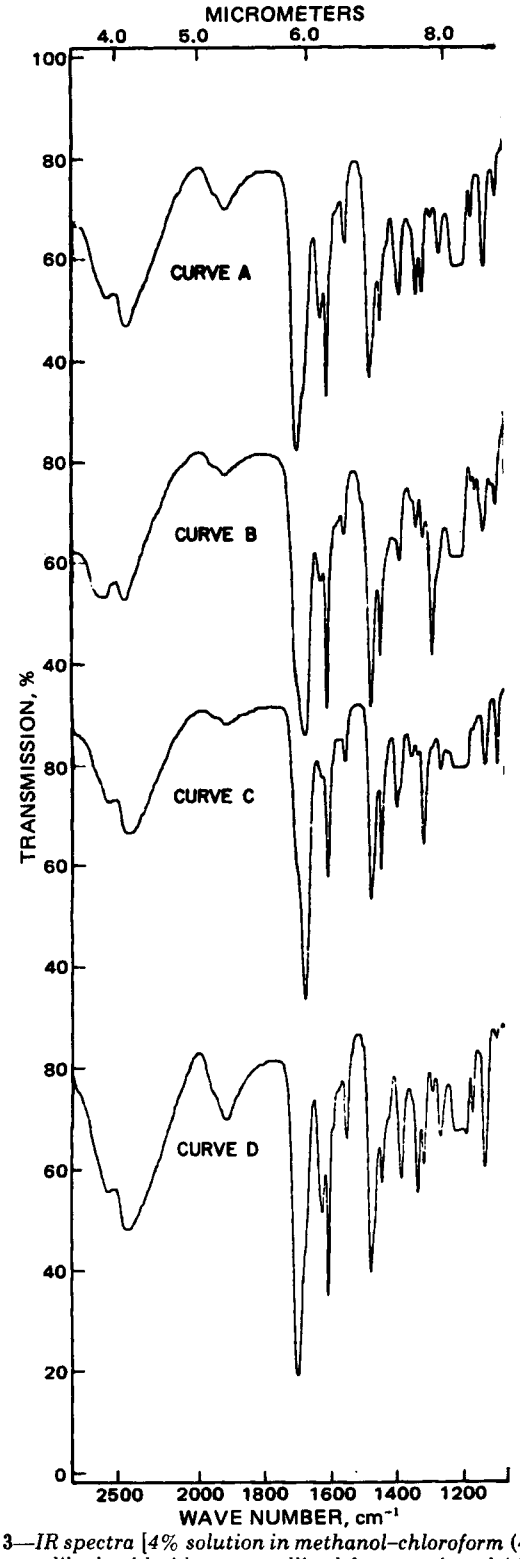

Figure 3—*IR spectra [4% solution in methanol–chloroform (4:96)] of flurazepam dihydrochloride recrystallized from methanol (A), chloroform (B), and water (C). Curve D is the solution spectrum of untreated flurazepam dihydrochloride.*

A–C, Fig. 3) display varying intensities of the ammonium, immonium, and C=N$^+$ bands, which can be attributed to different equilibrium mixtures of the mono- and dihydrochlorides in the materials recrystallized from methanol, chloroform, and water. The material recrystallized from water contained the lowest amount of dihydrochloride. The solution spectra were sharp enough to show the presence of two carbonyl stretching resonances due to the mono- and dihydrochlorides. The shift of the carbonyl band from 1700 to 1680 cm^{-1} provides further evidence of the transformation from the di- to the monohydrochloride.

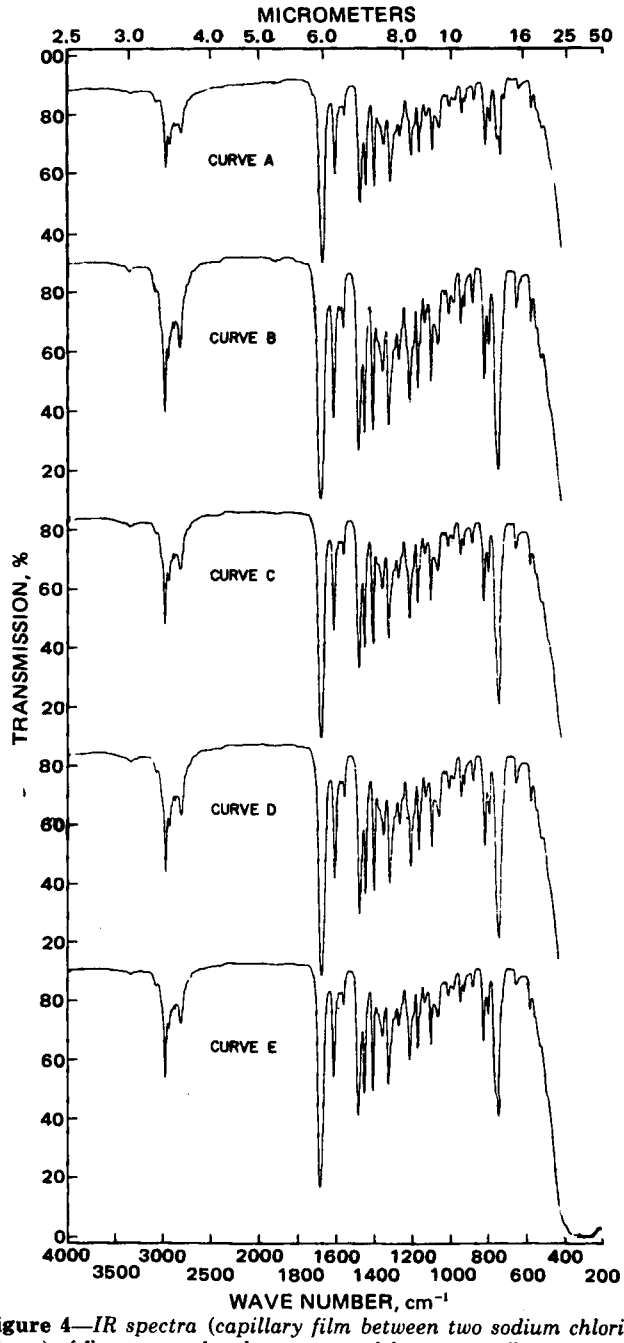

Figure 4—*IR spectra (capillary film between two sodium chloride plates) of flurazepam free base prepared from 15-mg flurazepam dihydrochloride capsules (A) and of flurazepam dihydrochloride recrystallized from methanol (B), chloroform (C), and water (D). Curve E is the spectrum of the free base prepared from untreated flurazepam dihydrochloride.*

In the spectrum (curve A) of the substance recrystallized from methanol, a small shoulder is observable at 1680 cm^{-1} on the right side of the carbonyl band at 1700 cm^{-1}. In the spectra (curves B and C) of the samples recrystallized from chloroform and water, the shoulder becomes the main carbonyl band at 1680 cm^{-1}, while the intensity of the band at 1700 cm^{-1} decreases such that it becomes a shoulder at 1680 cm^{-1} on the left side of the main band. The compatibility of the spectra (Fig. 4) of the flurazepam free base prepared from untreated flurazepam dihydrochloride, flurazepam dihydrochloride capsules, and flurazepam dihydrochloride recrystallized from methanol, chloroform, and water ruled out decomposition of flurazepam in the various studies.

CONCLUSIONS

The immonium and ammonium bands between 1800 and 2500 cm^{-1} and the C=N$^+$ stretching band at 1635 cm^{-1}, as well as the carbonyl band

position (1700 cm^{-1} for dihydrochloride and 1680 cm^{-1} for monohydrochloride and for free base), were the distinguishing diagnostic features used in this investigation to establish that the different IR spectra of flurazepam dihydrochloride recrystallized from different solvents result from different equilibrium mixtures of flurazepam mono- and dihydrochlorides and/or free base in these solvents. The solvent effect on the transformation of flurazepam di- to monohydrochloride was methanol < chloroform < water. The solution spectra also ruled out polymorphism, and the spectra in Fig. 4 show no compound decomposition.

In view of these findings, the IR identity test for the active ingredient in bulk flurazepam dihydrochloride or flurazepam dihydrochloride capsules should be based on extraction of flurazepam free base using the procedure described in the *Experimental* section and then on comparison of its IR spectrum with a spectrum of the free base similarly extracted from a standard flurazepam dihydrochloride sample, which can serve as a reference spectrum for future work.

Determination of Nofedone in Human Serum by Electron-Capture GLC

D. HEUSSE *x, P. POPULAIRE *, A. RENARD *, P. PASQUIER ‡, and J. GREGOIRE ‡

Received February 23, 1979, from the **Institut de Biopharmacie, Rhône-Poulenc, 13 quai Jules Guesde, 94400 Vitry-sur-Seine, France*, and the ‡*Direction des Recherches Thérapeutiques, Rhône-Poulenc, 16 rue Clisson, 75013 Paris, France.* Accepted for publication October 5, 1979.

Abstract □ An electron-capture GLC method to measure nofedone in human serum was developed. A homolog of nofedone was added to the serum as an internal standard before the sample was alkalinized with pH 9.5 phosphate buffer and extracted with ethylene dichloride containing 0.5% isopentyl alcohol. This organic phase was extracted with 0.2 *N* HCl, the acidic aqueous phase was neutralized immediately, and the extraction with ethylene dichloride was repeated. The ethylene dichloride phase was evaporated to dryness, and the residue was reacted with heptafluorobutyric anhydride. The derivatives were chromatographed at 290° on a 1% Dexsil 300 column. Data on apparent recovery, accuracy, and specificity are given. The detection limit was 5 ng/ml of serum. Serum levels over time in one patient after intravenous administration of 1 mg/kg and after oral administration of 50, 100, and 150 mg of nofedone are presented.

Keyphrases □ Nofedone—analysis, electron-capture GLC, human serum □ GLC, electron capture—nofedone, human serum □ Antiarrhythmic agents—nofedone, analysis, electron-capture GLC, human serum

Nofedone[1] (I) fumarate, 3-[2-hydroxy-3-(isopropylamino)propoxy]-2-phenyl-1-isoindolinone B form, shows marked experimental and clinical antiarrhythmic activity after intravenous and oral administration (1). Compound I is under clinical study. To investigate its pharmacokinetics and to establish the optimal dose range, a procedure was developed for the determination of the drug in human serum. The described method involves GLC of a heptafluorobutyrate derivative with ^{63}Ni-electron-capture detection. A similar method was used for the determination of a β-adrenoreceptor antagonist with the same aminohydroxylated chain (2).

EXPERIMENTAL

Reagents—All solvents and reagents (0.2 *N* HCl[2], 1 *N* NaOH[3], and pH 9.5 phosphate buffer prepared from a 0.5 *M* aqueous solution of dibasic sodium phosphate[4]) were analytical grade. Ethylene dichloride[5], UV spectrophotometric grade, was freshly distilled before use. The heptafluorobutyric anhydride[6] was the derivatizing agent for the electron-capture analysis. It was kept at 4° in sealed vials to prevent the ingress of water from the atmosphere. Nofedone and the internal standard, 3-[2-hydroxy-3-(isopropylamino)propoxy]-2-(3-trifluoromethylphenyl)-1-isoindolinone[7] (II), were used as the free bases.

Apparatus and Operating Conditions—The gas chromatograph[8] was equipped with a ^{63}Ni-electron-capture detector[9] and a glass column (2 m long × 6.25 mm i.d.) packed with 1% Dexsil 300 on a 100–120-mesh support[10]. The column temperature was 290°, the injection port temperature was 300°, the detector temperature was 300°, the carrier gas (nitrogen) flow rate was 20 ml/min, and the scavenger gas (nitrogen) flow rate was 80 ml/min.

The column was conditioned for 24 hr by temperature programming from 250 to 350° at 1°/min and was regulated at 350° for 10 min. It was treated before analysis by several injections of the derivatized extract of serum blank with or without I and the internal standard to ensure maximal performance. Under the conditions described, the retention times of the derivatives of I and II were 2 and 1.5 min, respectively.

Glassware—All glassware was cleaned well and tested with an aqueous solution of I·HCl and II of known content.

Procedure—Compound II was used as a 100-μg/ml solution in ethyl acetate[11] and kept from bright light. This solution was diluted (1:100) with ethyl acetate and immediately inserted in a centrifuge tube. Samples of the internal standard, 50, 200, and 500 ng, were commonly used for such analyses. The quantity of the internal standard was selected to give a peak height greater than or equal to that of I. The solvent was evaporated under a nitrogen stream, and 0.25, 0.50, or 1 ml of serum was added. After vibrating for 30 sec, 2 ml of pH 9.5 phosphate buffer was added.

This aqueous solution was extracted with 6 ml of ethylene dichloride containing 0.5% isopentyl alcohol[12], mechanically shaken for 20 min, and centrifuged. The lower organic phase was removed by pipet and washed by shaking for 5 min with 2 ml of distilled water. The organic phase then was extracted with 2 ml of 0.2 *N* HCl and mechanically shaken for 20 min. The acidic aqueous phase was neutralized immediately with 0.5 ml of 1

position (1700 cm^{-1} for dihydrochloride and 1680 cm^{-1} for monohydrochloride and for free base), were the distinguishing diagnostic features used in this investigation to establish that the different IR spectra of flurazepam dihydrochloride recrystallized from different solvents result from different equilibrium mixtures of flurazepam mono- and dihydrochlorides and/or free base in these solvents. The solvent effect on the transformation of flurazepam di- to monohydrochloride was methanol < chloroform < water. The solution spectra also ruled out polymorphism, and the spectra in Fig. 4 show no compound decomposition.

In view of these findings, the IR identity test for the active ingredient in bulk flurazepam dihydrochloride or flurazepam dihydrochloride capsules should be based on extraction of flurazepam free base using the procedure described in the *Experimental* section and then on comparison of its IR spectrum with a spectrum of the free base similarly extracted from a standard flurazepam dihydrochloride sample, which can serve as a reference spectrum for future work.

N NaOH, and 1 ml of pH 9.5 buffer was added. The extraction with ethylene dichloride was repeated.

The organic phase was transferred to a small tube fitted with a glass stopper and evaporated to dryness under a nitrogen stream in a 50° water bath. The residue was dissolved in a mixture of 0.1 ml of ethyl acetate and 0.4 ml of toluene[13]. After shaking for 30 sec, 50 μl of heptafluorobutyric anhydride was added, and the solution was allowed to stand for 5 min at room temperature. The excess reagent was eliminated by adding 1 ml of a 5% aqueous solution of sodium bicarbonate[14]. After gas release, 0.1 ml of isopentyl alcohol was added. The lower aqueous phase was removed by pipet and discarded. The organic phase was washed by shaking with 0.5 ml of a 2% solution of isopentyl alcohol in distilled water. The mixture

was allowed to stand, and 2 or 3 μl of the upper organic phase was injected into the gas chromatograph.

The ratio of the peak heights, H/H_1 (H is the derivative of I and H_1 is the derivative of II), was calculated and compared to a calibration curve. This calibration was obtained by performing derivations on a mixture of 0.025, 0.050, 0.1, or 0.2 ml of a 100-μg/ml stock solution of I in ethyl acetate with 0.1 ml of a 100-μg/ml stock solution of II in ethyl acetate. These reference samples were derivatized and diluted with a mixture of toluene–ethyl acetate–isopentyl alcohol (40:10:10) and were recorded in the best sensitivity range (1:25 dilution for an attenuation of $4 \times 2.5 \times 10^{-10}$). The highest reference sample was not linearly related to the lowest sample when the column was performing properly, but the samples were always derivatized to permit estimation of serum samples added with a too low an amount of internal standard.

To increase reliability, the calibration curve was checked for each series of samples. Each analysis on serum samples and each injection into the chromatograph were repeated at least twice. The injected volume was kept constant during a series of injections.

RESULTS AND DISCUSSION

The use of II as an internal standard was satisfactory because its physicochemical properties are closely related to those of I. The presence of the CF_3 radical in the molecule ensured a higher response for electron-capture detection (Fig. 1).

Several derivatization techniques were tested to form derivatives of I, and the method selected for use in this study was the most rapid. After neutralizing the excess heptafluorobutyric anhydride with sodium bicarbonate, no interfering peaks due to endogenous substances were noted in the upper organic phase. The bis-derivative of I (III) from the serum

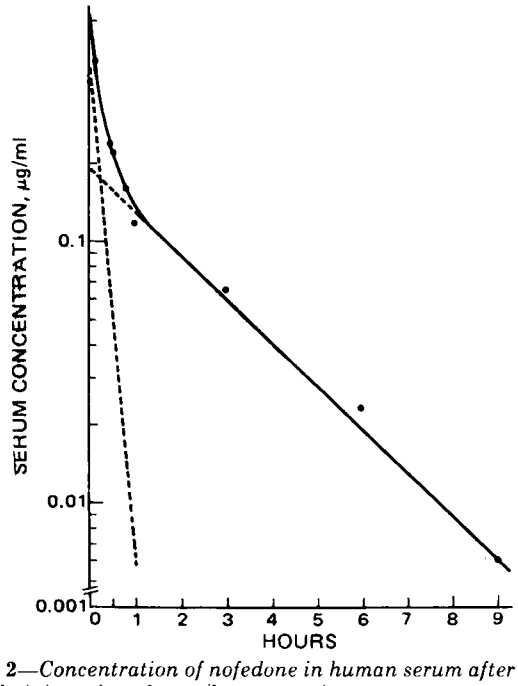

Figure 2—*Concentration of nofedone in human serum after intravenous administration of 1 mg/kg over 2 min.*

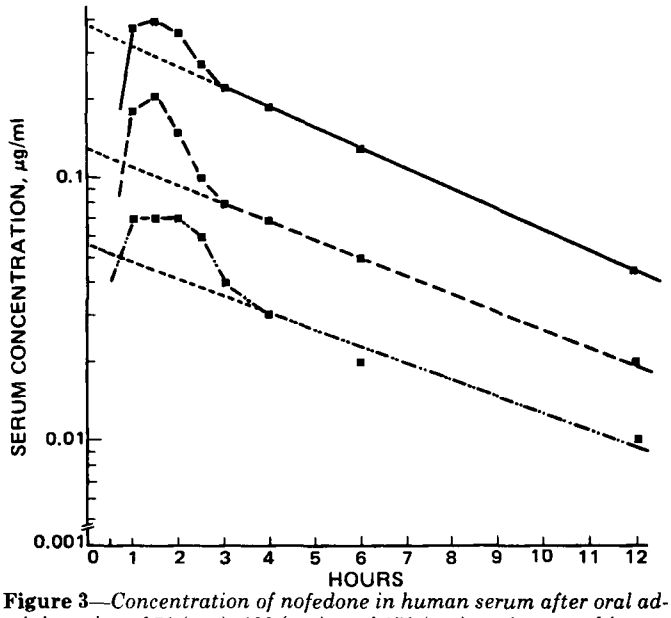

Figure 3—*Concentration of nofedone in human serum after oral administration of 50 (-·-·-), 100 (- - -), and 150 (——) mg in one subject.*

extract had the same chromatographic behavior as the authentic compound. The minimum detectable quantity was 100 pg, and the linearity of the ^{63}Ni-electron-capture detection response was observed from 0.5 to 2 ng in the organic phase injected (attenuation $4 \times 2.5 \times 10^{-10}$).

The theoretical sensitivity initially was 10 ng/ml, but it improved during use. The sensitivity limit for the quantitative determination of I in serum by electron-capture detection was 5 ng/ml of serum after a 2-ml sample extraction. We observed, as did Leitch *et al.* (3), that the sensitivity increased with the number of plasma extracts injected. At the beginning of the GLC analysis, plasma extracts were injected to obtain the plateau of best sensitivity. This plateau was maintained by alternating injections of serum extracts and reference samples. The apparent recovery of I compared with that of the internal standard and the accuracy of the results obtained are shown in Table I. The determinations were repeated seven times for each quantity. The last column in Table I shows the validity of the method. A plot of added drug *versus* found drug had a slope of unity. According to the data provided, a single determination is expected to be within about 12% of the true value, and multiple determinations should vary by ±12% (reproducibility).

The chromatographic analysis of the serum blanks showed that no compound extracted under the conditions described interfered with I or the internal standard (II) (Fig. 1). TLC of derivatized extracts from serum taken from patients treated with nofedone showed that there was no interfering substance with a close R_f value. In the urine of treated patients that contained metabolites, the concentrations of nofedone in the form of bis-derivatives were the same as those measured after elution of a silica plate and GLC analysis.

The sensitivity of this technique allowed determination of serum levels in humans for ~9 hr after an intravenous bolus injection (1 mg/kg in 2 min) and for 12 hr after a single oral dose (50–150 mg in a capsule or tablet). Figures 2 and 3 show the concentrations of nofedone in human serum after an intravenous bolus injection of 1 mg/kg and after an oral dose of 50, 100, and 150 mg in a capsule in another subject. Pharmacokinetic data can be derived from these distribution values. The selectivity of this method allows determination of the compound in saliva, urine, and feces.

Isopentyl alcohol was used because it prevents the molecule from adhering to the glass walls during extraction, derivatization, and GLC analysis. It also prevents tailing peaks and thus increases sensitivity. For serum concentrations below 50 ng/ml, optimal stability of the chromatograph is required to minimize background noise. For higher concentrations, the method provided good reproducibility and allowed calculation of pharmacokinetic parameters up to 9 hr following an intravenous bolus injection (1 mg/kg) and up to 12 and 24 hr after oral doses of 50, 100, and 150 mg.

Fluorometric Determination of Thiazole-Containing Compounds

J.-S. K. SHIM, J. W. TOLAN *, and D. W. FINK ˣ

Received August 9, 1979, from the *Merck Sharp & Dohme Research Laboratories, Rahway, NJ 07065.* Accepted for publication October 11, 1979. *Present address: Ethicon, Somerville, NJ 08876.

Abstract □ Fluorescence spectroscopy was applied to the development of sensitive analytical methods for the determination of thiazole and several congeners that contain substituted thiazole rings. Treatment to yield thionine, previously used spectrophotometrically to measure thiazole and fluorometrically only for sulfur determinations in inorganic systems, is further characterized and illustrated with the determination of the antibiotic thiopeptin. This method is selective for submicrogram quantities of thiazole rings in the presence of fused-ring derivatives and reduced analogs. It has a precision of ±2% *RSD* (n = 11) at the 15-ng/ml thiazole concentration level with a signal-to-noise ratio of 3:1. For thiopeptin, this method has an accuracy of 5% mean relative error (n = 8) over the 5–20-ppm range in medicated feed.

Keyphrases □ Thiazole—thiazole-containing compounds, fluorometry □ Fluorometry—analysis, thiazole-containing compounds □ Spectroscopy, fluorescence—thiazole-containing compounds

The thiazole ring is a common structural element found in many compounds exhibiting biological and therapeutic activity and in several molecules used in agricultural products as well as in pharmaceutical formulations (1, 2). Because of these properties, sensitive analytical methods for thiazole-containing compounds are of interest for application in low concentration level formulations, bioavailability studies, and environmental samples.

Key: 1, absorption spectrum of thionine, 10^{-5} M; 2, absorption spectrum obtained from treatment of thiazole according to the text (a solution containing 6 × 10^{-5} M thiazole was treated; the absorbance of this thionine reaction product represents a chemical yield of 26%); 3, uncorrected emission spectrum, λ_{excite} = 595 nm; and 4, uncorrected excitation spectrum, λ_{emit} = 620 nm.*

The condensation reactions of sulfides with *p*-phenylenediamine or its *N,N*-dimethyl derivative to yield thionine or methylene blue, respectively, have been known for many years. Most previous analytical applications of this reaction sequence primarily have been for spectrophotometric determinations of hydrogen sulfide (3, 4) and other sulfides (5, 6) and for sulfur in inorganic systems such as sulfate after reduction to sulfide (7). A prior inorganic application by luminescence measurement involved the determination of traces of sulfate and sulfite in semiconductors (8, 9).

This inorganic reaction sequence has had only one previous analytical application to the thiazole ring. In work in these laboratories, thiabendazole [2-(4-thiazolyl)-1*H*-benzimidazole] was determined spectrophotometrically by the generation of sulfide *via* pretreatment with zinc in acidic solution (10). The present report describes the extension of this technique to the development of a sensitive general analytical method for the determination of thiazole, substituted thiazoles, and other thiazole-containing compounds. The reaction is characterized further through the examination of model compounds, and its sensitivity is enhanced with the first application of fluorometric measurement instead of absorptiometric analysis for the organic system. Included is the determination of thiopeptin (an antibiotic that contains four thiazole rings) at the low parts-per-million concentration level.

EXPERIMENTAL

Apparatus—A spectrofluorometer[1] equipped with a xenon lamp and a 1P21 photomultiplier tube was used for all fluorescence measurements. The excitation and emission slit widths at the cell were both 1.0 mm, and a 0.2-mm slit was used at the entrance beam to the photomultiplier tube. The sample container was a fused quartz fluorescence cell, 10.5 mm i.d. square × 46 mm high.

All emission intensities were read on the microphotometer[1] and standardized relative to the fluorescence intensity (450 nm) of 1.0-ppm quinine sulfate in 0.1 *N* H_2SO_4 (350-nm excitation). Excitation and emission spectra were recorded on an *x–y* recorder[2] and are uncorrected for frequency dependence of source excitation intensity, photomultiplier output, or monochromators. Absorption spectra were recorded on a spectrophotometer[3].

Reagents and Solutions—Ferric ammonium sulfate[4], *n*-butyl alcohol[4], sodium sulfate[4], pyridine[4], *p*-phenylenediamine[5], zinc dust[6], thiazole[7], thiophene[8], thionine[5], thiabendazole[9], cambendazole[9], and the remaining substituted thiazoles[7] were used as received. Other chemicals were reagent grade.

Procedure—The fluorophore was developed according to the procedure described previously (10). To a 15-ml sample of thiopeptin in 0.15 *N* HCl were added 5.0 ml of 0.5-mg/ml aqueous *p*-phenylenediamine and 150 ± 5 mg of zinc dust, and the sample was mixed. After 7 min, 5.0 ml of ~0.65 *M* aqueous ferric ammonium sulfate was added, and the solution was mixed and allowed to remain at room temperature for 15 min.

The reaction vessel was placed in a water bath at 90 ± 3° for 20 min and then cooled in an ice bath for 5 min. An additional 2.0 ml of ferric ammonium sulfate solution was added, and the mixture was mixed again. After 30 min, ~5 g of sodium sulfate (anhydrous) and 5.0 ml of *n*-butyl alcohol were added, the phases were equilibrated for 2 min, and the fluorescence intensity of the *n*-butyl alcohol phase was measured at 620 nm under 475-nm excitation.

RESULTS AND DISCUSSION

In the present reaction sequence, thiazole was treated with zinc in acidic solution to yield an intermediate that might have been the result of two consecutive reactions, *i.e.*, zinc reduction of the ring followed by hydrolysis to sulfide. This unidentified product added 2 moles of *p*-phenylenediamine; in a ring-closing reaction with ferric ion as the oxidizing agent, the central ring was closed to yield thionine according to standard techniques. A boiling water bath was used for heating the reaction mixture. (When *N,N*-dimethyl-*p*-phenylenediamine was used, the product for colorimetric measurement was methylene blue.)

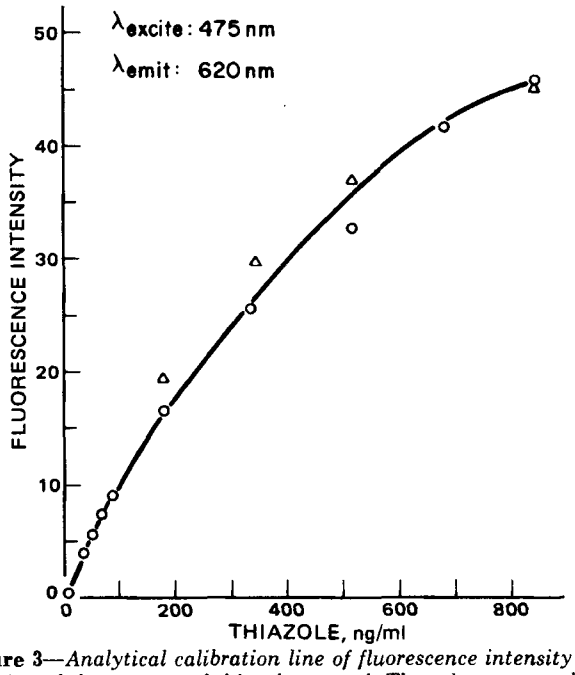

Figure 3—*Analytical calibration line of fluorescence intensity as a function of the amount of thiazole reacted. The solvent was n-butyl alcohol; λ_{excite} = 475 nm, λ_{emit} = 620 nm. Key: O, direct measurement; and Δ, dilutions of a more concentrated reaction product solution. For reaction conditions, see text.*

The identity of the thiazole reaction product was confirmed by chromatographic comparison with authentic thionine in three systems. The R_f values of the reaction product, neutral thionine, and the conjugate acid thionine hydrochloride on silica gel TLC plates[10] were 0.93, 0.91, and 0.17, respectively, with a mobile phase of *p*-dioxane–water (5:1); on silica gel RP-2 with a mobile phase of acetic acid–methanol (100:1), thionine appeared at R_f 0.70, and the reaction product obtained from thiazole appeared at R_f 0.72. This product also eluted with the same retention time as thionine from a silica gel high-pressure liquid chromatographic (HPLC) column[11] with acetic acid–methanol (0.1:200) as the mobile phase.

The first step of this reaction was monitored without the organic coupling reagent and the ferric oxidizing agent by treating thiazole with zinc in acidic solution (Fig. 1). As the reaction proceeded, the single-band, λ_{max} 236-nm electronic absorption spectrum of thiazole decreased in intensity, with no band shifts or new absorption transitions appearing. Eventually, the solution became transparent at λ greater than 210 nm, demonstrating a loss of aromatic π-character. Simultaneously, the intensity of the NMR[12] signals assigned to the three protons of thiazole also diminished and were ultimately lost, with no new NMR signals apparent.

Although proton exchange could have contributed to these lessening NMR signals with time, these results nevertheless were in accord with the UV absorbance spectral changes, confirming that this extremely stable heteroaromatic molecule was broken down by this treatment to furnish the sulfur for the succeeding condensation. This reaction was run with deuterium chloride in deuterium oxide[13]. The ratio of reducing agent to thiazole substrate can be regulated to govern the reaction rate; when microgram quantities of thiazole were treated with milligram quantities of zinc, the reaction proceeded too rapidly to record the UV and/or NMR spectra.

The absorption spectrum of the thionine reaction product is included in Fig. 2. The Beer's law deviation (metachromatic effect) exhibited by this fluorophore has been attributed to self-association to form dimers (or higher polymers) in a stacking, sandwich equilibrium (11–13) that can occur at concentrations as low as 10^{-7} *M* (12). The observed 600-nm λ_{max} in Fig. 2 has been assigned to the monomer, with the dimer evident as the shoulder at 560 nm (12–14).

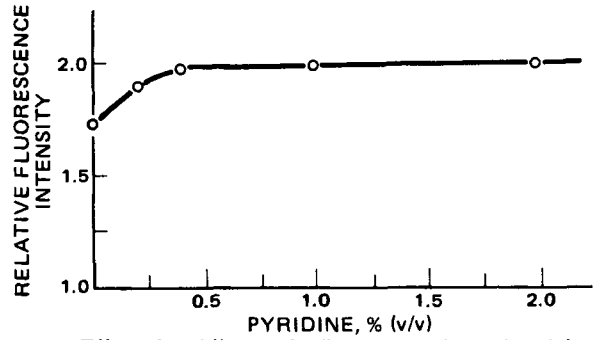

Figure 4—*Effect of pyridine on the fluorescence intensity of the thionine reaction product. The solvent was n-butyl alcohol; λ_{excite} = 475 nm, λ_{emit} = 620 nm. The product was obtained from a solution containing ~0.5μg of thiazole/ml. For reaction conditions, see text.*

The fluorescence spectrum of thionine in *n*-butyl alcohol (Fig. 2) has an emission maximum (uncorrected) at 620 nm, similar to the fluorescence in aqueous and in methanolic solution (13, 15). At least three features of these spectral properties attenuate the analytical signal:

1. The very small Stokes shift and overlap of the absorption and emission spectra cause self-absorption of emitted radiation.
2. Because of the high absorptivity of thionine in butyl alcohol ($\epsilon \sim 6.3 \times 10^4$ liters/mole-cm at 605 nm), the sample is excited at 475 nm so that absorbance at the excitation wavelength is low (Fig. 2) to reduce excitation energy loss near the entrance surface of the cell.
3. Dimerization causes a Beer's law deviation.

Figure 3 presents the fluorescence intensity calibration line as a function of the amount of thiazole treated. This line exhibits the usual attenuation at high concentrations predicted from these spectroscopic properties, although it does furnish a convenient linear range for dilute solutions. Included in Fig. 3 are fluorescence measurements of solutions obtained from dilutions of a more concentrated solution of the reaction product, as in the similar characterization of the Beer's law calibration line by Gustafsson (7). In accordance with the absorbance results, the fluorescence intensity from these solutions near the calibration line confirms that the attenuation results from optical and equilibrium effects and is not the result of decreased reaction yield with larger amounts of thiazole.

Because thionine is not fluorescent in its associated state (12, 13), this dimerization, which also would attenuate the analytical signal, should be avoided over the range of analytical calibration concentrations. To investigate the aggregation of thionine, pyridine was added to the solution to perturb the dimerization equilibrium; similar studies with methylene blue demonstrated that pyridine eliminates the self-association (16). Because of the structural similarity of pyridine to these thiazines, this nitrogen heterocycle can associate with the thionine molecules and thus dissociate the sandwich dimers.

Figure 4 illustrates the small effect pyridine exerts on this system. The increase in fluorescence intensity is only ~15%, suggesting that there is no significant dimerization in this solvent. (Most reports of dimerization have been for aqueous, not alcoholic, solutions.) Moreover, these data also demonstrate that the analytical signal cannot be significantly enhanced by this technique.

Structural Effects—Table I lists a series of model compounds that were examined by this fluorometric procedure using the same reaction conditions. The first column lists single-ring substrates with the fluorescence intensity obtained from thiazole. Thiazole *per se* is not fluorescent (17). Saturation of the aromatic ring inhibits the reaction, as demonstrated by the negative response from thiazolidine. In this aromatic system, the nitrogen heteroatom is necessary for the reaction to proceed; thiophene does not yield the sulfide under these conditions.

The second column of Table I demonstrates that fusing thiazole with a benzene nucleus also inhibits the reaction; neither benzothiazole nor its indicated derivative produced any fluorescence at 620 nm. Each monosubstituted and disubstituted thiazole in Table I gave approximately equimolar (±25%) fluorescence intensity with the parent compound. These compounds are each substituted only in the 2- and/or 4-positions.

Analytical Application—The last disubstituted entry in Table I provides an example of a thiazole-containing compound that was determined by the present method. Thiopeptin is an antibiotic administered to swine and chickens at 10–20 g of drug/ton of feed. The structure of this fermentation product recently was elucidated (18). Thiopeptin has seven

Table I—Relative Fluorescence Intensity from Some Model Compounds[a]

ring systems, including a partially reduced quinoxaline moiety, one piperidine ring, and five five-membered nitrogen–sulfur heterocyclic rings, one of which is a thiazoline nucleus. The remaining four heterocyclic rings are thiazole rings, each bound to the carbon–nitrogen–oxygen skeleton at the 2- and 4-positions.

Because the present reaction sequence is not stoichiometric, it must be optimized (7). Figure 5 presents the effects of four factors on the yield of thionine from thiopeptin, monitored by the absorbance of the fluorophore. Optimal levels for each factor were selected from these data: 2.5 mg of *p*-phenylenediamine was used to minimize the signal from the reagent blank, the amount of zinc and the reaction time were selected at points on the plateaus of each function, and the reaction medium was selected at the peak response for the effect of pH (*i.e.*, 0.15 *M* HCl). The residuals of the linear least-squares calibration line of $A_{605\ nm}$ obtained

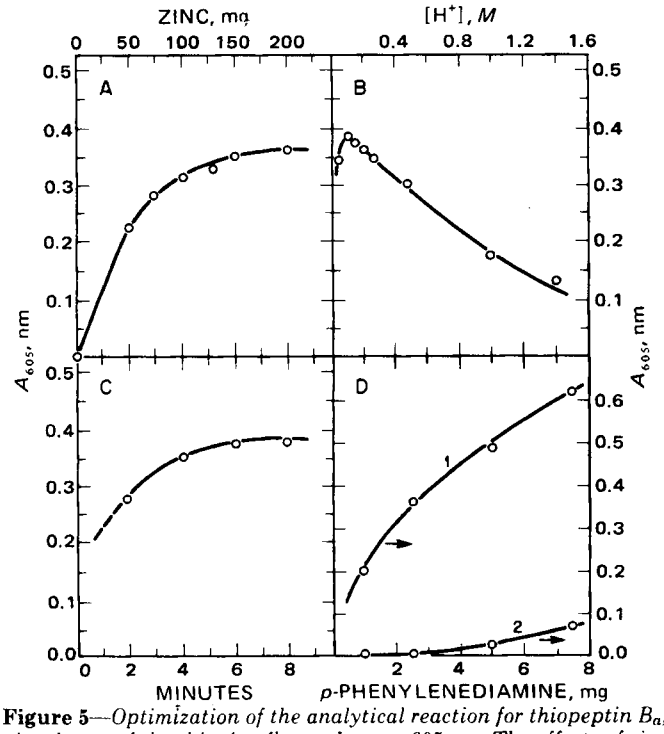

Figure 5—*Optimization of the analytical reaction for thiopeptin B_a; absorbance of the thionine fluorophore at 605 nm. The effects of zinc (A), [H+] (B), time (C), and reagent (D) are shown. Each sample contained ~30 μg of thiopeptin B_a in 15 ml of hydrochloric acid. Zinc, 150 mg, was used in B, C, and D; the reaction mixture was heated 15 min in A, B, and D; 2.5 mg of* p*-phenylenediamine was used in A, B, and C; 0.1 N HCl was used in A; and 0.15 N HCl was used in C and D. In D, line 1 presents the data from thiopeptin and line 2 is the reagent blank response. Each point in this figure is the mean of two, three, or four replicate measurements.*

from seven samples covering the range of 2–15 μg of thiopeptin B_a[14] treated by this procedure averaged 2.9% relative to the line, demonstrating the precision possible with this method.

In the animal feed sample analyzed, thiopeptin was only a trace ingredient in a poorly defined complex matrix. An efficient isolation scheme was required to separate the drug from any other thiazole rings. Furthermore, in addition to thiazole-containing extraneous materials, protein that contains sulfur can also be a significant interference. For instance, these same reactions were used previously for cysteine determinations (19). In the present study, the drug was extracted from the feed into ethyl acetate in the presence of a pH 7 aqueous buffer; the aqueous phase was discarded, and the ethyl acetate extract was charged to the top of a magnesia–silica gel[15] adsorption column. After interfering substances were removed using successive elutions of increasing polarity with petroleum ether, ether, and acetone, the drug was eluted with 5% acetic acid in methanol. The sample was evaporated to dryness under nitrogen and taken up in the 0.15 *N* HCl reaction medium for the fluorogenic reaction, and the thionine fluorophore was partitioned into *n*-butyl alcohol for measurement.

Table II presents some representative analytical results obtained with this procedure. The range of fluorescence intensities from the five analytical reference standards illustrates the precision of replicate measurements. Furthermore, the comparison between the reaction of a pure thiopeptin solution with the same pure solution processed through the analytical isolation demonstrates that there is no loss of thiazole through

[14] Thiopeptin consists of several components, each containing four thiazole rings (18).

[15] Florisil, 100–200 mesh, Floridan Co.

this treatment. The unmedicated feed samples produced fluorescence representing 1–2 ppm of thiopeptin, furnishing sufficient selectivity to determine this drug at the 5-ppm level with an intensity 33% greater than the reagent blank. The mean of the eight analyses covering the 5–20-ppm range in the feed was 95% of the known thiopeptin concentration that was added to the feed. These results demonstrate the use of this treatment for the determination of one thiazole-containing analyte and suggest that this method also should be applicable to other analogous thiazole-containing compounds of pharmaceutical and biological interest.

Decreased Activity of Proteins Adsorbed onto Glass Surfaces with Porous Glass as a Reference

TAKAHARU MIZUTANI

Received April 9, 1979, from the *Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467, Japan.* Accepted for publication October 15, 1979.

Abstract □ The biological activity of proteins bound to controlled-pore glass surfaces was studied as a model of denaturation of biologicals upon storage in glass containers. After adsorption onto the glass for 1 week, the activities of alkaline phosphatase, catalase, and horse-radish peroxidase recovered from the glass column were 88, 63, and 97%, respectively. However, the phosphatase activity recovered after adsorption for 3 months was 14% of the total activity loaded onto the column, and the activities recovered of peroxidase and catalase were 48 and 2%, respectively. Insulin had almost full activity after adsorption for 3 months, but calcitonin activity was absent. The scission of peptide bonds of proteins eluted after adsorption for 3 months was not observed, but dissociation to the subunits was found. The proteins were active in the state adsorbed onto glass surfaces.

Keyphrases □ Adsorption—proteins, glass surfaces, activity decrease □ Proteins—adsorption onto glass surfaces, activity decrease □ Activity—proteins, decrease after adsorption onto glass surfaces

The reaction of biological materials on glass is well known (1–4). By use of controlled-pore glass (5) with a large surface area (97 m^2/g), it was shown that 5 μmoles of basic drugs and materials was adsorbed onto 97 m^2 of glass surface and that adsorption of proteins onto the surfaces was caused by amine–silanol bonding and a cooperative aggregative factor between silica and proteins (6–10). Proteins also were adsorbed in detergent solutions such as urea and guanidine hydrochloride (11). From the value of the maximum amount of protein adsorbed (233 mg/97 m^2), the amount of protein adsorbed onto the surfaces of a glass container (50 cm^2, 20 ml) and a glass injector was estimated to be >12 μg. The 12-μg/20 ml concentration must be a marginal point not affected by adsorption, and the biologicals used at lower concentrations would be affected by adsorption to glass surfaces (10).

Some biologicals composed of proteins are stored or maintained in pharmaceutical glass containers in a water medium (12). However, denaturation of proteins by their adsorptive aggregation on surfaces of glass containers upon storage for long periods is not clear. The purpose of this investigation was to show changes in the biological activity and the structure of proteins adsorbed onto glass surfaces upon storage as a model of denaturation of protein biologicals in glass containers. Enzymes and hormones were studied, and controlled-pore glass was used as a reference standard.

EXPERIMENTAL

Materials and Column Operation—The controlled-pore glass[1] was 96% silica and had a surface area of 97 m^2/g and a particle size of 100 μm. After being washed with water, 0.1% sodium dodecylsulfate, water, chromic acid mixture, and water, the glass was packed in columns (0.6

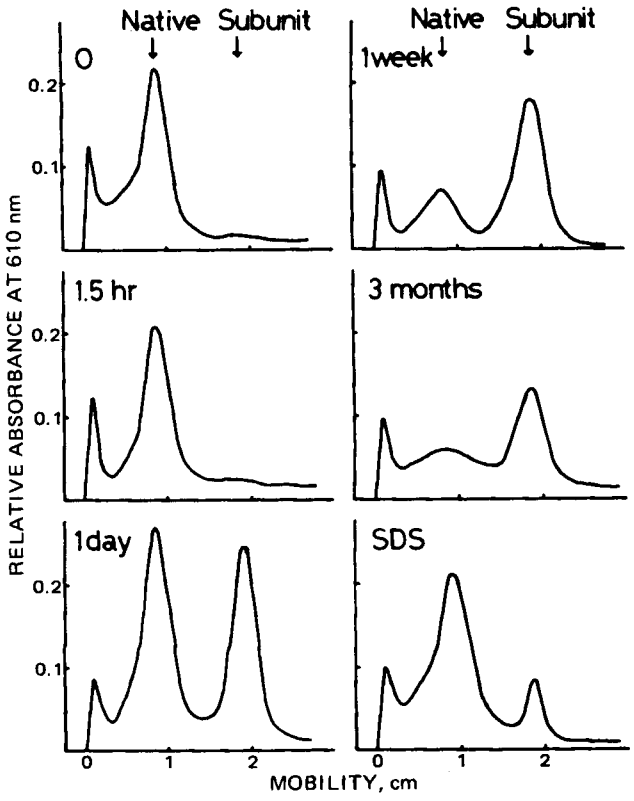

Figure 1—*Densitometric tracing of stained gel patterns of alkaline phosphatase on 10% polyacrylamide gel in the presence of 0.1% sodium dodecylsulfate. The times on the shoulder of each figure are those of adsorption. SDS is the sample incubated in 4* M *urea–0.1% sodium dodecylsulfate solution for 15 hr.*

× 10 cm, 1.3 g), which were used to preserve the proteins in the state in which they were bound to glass. After the column was equilibrated with buffer, the protein solution was applied on the column.

For experiments involving the retention of the activity of proteins bound to porous glass, the protein-bound columns were stored for 1 day, 1 week, 1 month, or 3 months in a cold room at 4°. After storage, the columns were eluted at a flow rate of 0.5 ml/cm^2/min, and 1-ml fractions were collected. Three columns were used for the measurement of each point, and the mean ● *SE* of the three measurements was calculated.

The enzymes and hormones used were alkaline phosphatase from *Escherichia coli*[2], horse-radish peroxidase[3], catalase[3], malate dehydrogenase[3], insulin[4], and porcine calcitonin[5]. For storage for 1 and 3 months, sodium azide was added at 0.1% to the enzyme solution as a preservative.

Activity Measurement—The activity of alkaline phosphatase was measured by the increase of the optical density at 405 nm in an assay mixture containing 0.95 *M* tromethamine [tris(hydroxymethyl)aminomethane] hydrochloride (pH 8.0), 4.8 m*M* *p*-nitrophenyl phosphate, and enzyme. Alkaline phosphatase was used after dialysis of ammonium sulfate contained in the commercial enzyme solution, and the specific activity was 10 units/mg. The activity of malate dehydrogenase was measured by the decrease of the optical density at 340 nm in the mixture of 94 m*M* phosphate buffer (pH 7.5), 0.5 m*M* oxaloacetate, 0.2 m*M* β-nicotinamide adenine dinucleotide in the reduced form, and enzyme. Commercial malate dehydrogenase was used without further purification.

The activity of peroxidase was determined according to a literature method (13) involving measurement of the time required to increase the optical density by 0.05 at 470 nm when 10 μl of 10 m*M* hydrogen peroxide was added to 3 ml of 13 m*M* guaiacol–enzyme. The activity of catalase was determined by direct measurements of the decreased light absorption at 230 nm caused by the decomposition of hydrogen peroxide by catalase.

The insulin activity was determined by measurement of the decreased glucose in rabbit serum. The glucose concentration in the serum derived from a group of six male rabbits was analyzed by a literature method using a mixture of 960 ml of 8% *o*-toluidine in acetic acid and 40 ml of 4% boric acid in water (14). Blood was drawn from the aural vein of six rabbits before and 1 hr after the injection of insulin. The rate of the fall of serum glucose after the injection compared with that before the injection was calculated, and the mean rate was taken as the glucose lowering rate.

The hypocalcemic activity of calcitonin was determined using six male rabbits (15). The sample was injected into the rabbit aural vein, and blood was drawn from another aural vein before and 1 hr after the injection. The calcium concentration in the serum was determined by atomic absorption[6] at 422.7 nm (16). The rate of fall of serum calcium after the injection compared with that before the injection was calculated. Bioassay data are expressed as the mean ± *SE*.

Other Methods—The molecular weights of the proteins were determined by sodium dodecylsulfate–polyacrylamide gel electrophoresis (17). The acrylamide gel concentration was 10% for alkaline phosphatase, peroxidase, and catalase and 20% for insulin and calcitonin. Densitometric tracing of the stained bands on the gel was carried out using an autodensitometer[7], and the ratio of proteins on the gel was calculated from the patterns.

RESULTS AND DISCUSSION

Activity of Proteins Eluted from Porous Glass Columns—Alkaline phosphatase was adsorbed onto a glass column in 0.2 *M* sodium chloride–0.01 *M* phosphate buffer (pH 7.0) and eluted with 0.2 *M* glycine at pH 9.0. After 1 mg of the phosphatase was adsorbed onto the column which can adsorb about 100 mg of protein, the column was washed with five column volumes of buffer, followed by glycine buffer (pH 9.0) for enzyme elution. After adsorption for 1.5 hr, the activity of phosphatase was completely recovered, and the specific activity was identical with that of the untreated enzyme.

The sodium dodecylsulfate–polyacrylamide gel pattern of the eluted enzyme was similar to that of the native enzyme (Fig. 1). After adsorption for 1 day in the sodium chloride–phosphate buffer, 95% of the activity of phosphatase applied on the column was eluted with the glycine solution, but 45% of the enzyme was separated into subunits with a molecular weight of 40,000 (Fig. 1). This separation did not originate from the treatment used in sodium dodecylsulfate electrophoresis, because the native phosphatase did not show the subunit pattern after incubation and treatment for 1 day in the sodium dodecylsulfate solution (Fig. 1).

In the case of adsorption for 1 week, 88% of the activity was recovered, and 61% of the total protein eluted from the column dissociated into subunits (Fig. 1). The phosphatase activity recovered after adsorption for 1 month was 62%. After phosphatase was adsorbed onto the porous glass column for 3 months, elution with glycine yielded the enzyme activity as only 14%; the yield of protein by elution with glycine was 24%. Subunits comprised 70% of the total protein eluted from the column with glycine buffer (Fig. 1).

The relationship between the activity and the binding time on glass surfaces is summarized in Table I. The half-life of the activity of phosphatase adsorbed onto glass surfaces was ~30 days. Phosphatase was eluted easily with glycine after adsorption for 1 week, and the activity was almost completely recovered. The enzyme was adsorbed strongly after standing for 3 months and was not completely eluted with glycine but was eluted with the 0.1% sodium dodecylsulfate solution, which has the strongest eluting force of proteins from the porous glass column among several buffers. The band showing a smaller molecular weight than the subunit was not found on the gel patterns (Fig. 1). Therefore, scission of the peptide bond did not occur on glass surfaces for the long preservation period. The decreased activity recovered from the glass column was believed to depend on a conformational change of proteins or desolubilization by aggregation of proteins on glass surfaces.

After adsorption of catalase for 1 week, 63% of the catalase activity was eluted from the column with the glycine solution, and residual protein was eluted with the 0.1% sodium dodecylsulfate solution. The sodium dodecylsulfate gel pattern of catalase after the 1-week adsorption showed that the subunit with a molecular weight of 6 × 10^4 was 80% of the total protein, even though the native enzyme preparation was comprised of 73% subunits by the gel pattern. The specific activity of catalase adsorbed for 1 week decreased to 75%.

After adsorption for 3 months, the catalase activity recovered from the

Table I—Protein Activity in Eluates after Adsorption onto Porous Glass Columns

Protein	Total Activity Recovered after Adsorption[a], % (Specific Activity, %)		
	1 Week	1 Month	3 Months
Horse-radish peroxidase	97 ± 1.5 (100)	77 ± 2.1 (98)	48 ± 3.1 (90)
Alkaline phosphatase	88 ± 1.1 (98)	62 ± 1.7 (92)	14 ± 1.0 (58)
Catalase	63 ± 3.2 (75)	26 ± 3.0 (73)	2 ± 0.9 (6)
Insulin	—	—	89 ± 2.3 (86)

[a] The values are given as the means of three experiments (±*SE*).

column with glycine buffer (pH 9.0) was only 2% of the total protein applied on the column. Residual catalase adsorbed onto porous glass surfaces was not eluted with the 0.1% sodium dodecylsulfate solution, and the colored band of catalase or heme was found on the top of the column. Catalase was adsorbed onto glass surfaces more strongly than was alkaline phosphatase.

Horse-radish peroxidase was not adsorbed onto the glass column in 0.2 *M* sodium chloride–0.01 *M* phosphate buffer (pH 7.0) but was adsorbed in a distilled water medium. Therefore, peroxidase was eluted with the sodium chloride–phosphate buffer from the column on which the enzyme was loaded in a water medium. After adsorption for 1 week, the recovery of the peroxidase activity was 97% of the initial activity. The recovery of the activity after adsorption for 3 months was 48%, and the residual protein adsorbed onto glass surfaces was eluted with the 0.1% sodium dodecylsulfate solution. The mobility of the eluted peroxidase on a gel did not change from that of the native protein.

The eluting order of proteins by adsorption chromatography was peroxidase, phosphatase, and catalase (7), and the adsorption of peroxidase was weak. The recoveries of the activity after adsorption for 3 months were 48% for peroxidase, 14% for phosphatase, and 2% for catalase (Table I). The stronger the proteins adsorbed onto glass surfaces, the lower was the activity recovery. The retention of the activity of proteins did not relate to the molecular weight and isoelectric point but instead to the inherent properties of proteins such as solubility and aggregative force. Since γ-globulin in serum was adsorbed strongly onto glass and the elution of the γ-globulin fraction from a porous glass column by adsorption chromatography was difficult, as reported previously (7), adsorption of antiserum samples onto the surface of glass containers must be considered. The inactivation of biologicals composed of proteins upon storage must be caused partially by adsorption onto the surface of glass containers.

Insulin (0.5 mg, 10 units) was dissolved in 0.5 ml of 0.01 *N* hydrochloric acid–1.5% glycerin isotonic solution and applied on the porous glass column. Insulin was adsorbed well onto porous glass in this condition (10). After adsorption for 3 months, adsorbed insulin was eluted with 0.2 *M* glycine (pH 9.0), and the pH of the eluate was adjusted with hydrochloric acid to pH 2. For injection, the protein concentration of insulin in the solution was estimated from the absorbance at 280 nm. The solution containing insulin was diluted to a concentration of 0.05 mg/ml with a 1.5% glycerin isotonic solution (pH 2.6), and 0.5 ml was injected subcutaneously into each rabbit. The molecular weight of insulin in the eluate from the column was studied by sodium dodecylsulfate gel electrophoresis using 20% gel, but the mobility on the gel was identical to that of native protein, and the scission to the A-chain and B-chain was not found. In a dose of 0.025 mg/rabbit, native insulin lowered the rabbit serum glucose concentration to 41.7 ± 10.3%, and insulin in the column eluate after adsorption for 3 months lowered the concentration to 36.3 ± 4.1%. The value of 36.3% was less than that of native insulin, but no significant difference between the two values was found. Insulin was not inactivated by adsorption for 3 months.

The calcium lowering rate of native porcine calcitonin was 12.7 ± 0.7% 1 hr after the injection of 4 MRC units/kg of rabbit. Calcitonin (100 MRC units) was dissolved in 1 ml of water and loaded onto a porous glass column, and the column was stored for 3 months at 4°. The column was eluted with 0.2 *M* glycine (pH 9.0), and the eluate of five column volumes was collected. The eluate was used for the hypocalcemic activity assay. The dose of 4 MRC units/kg of rabbit to be injected was calculated on the assumption that the eluate contained the total amount of calcitonin (100 MRC units) applied on the column. However, the hypocalcemic rate at 1 hr after the injection, 2.6 ± 1.4%, was insignificant, even though the band of calcitonin was found on the sodium dodecylsulfate–polyacrylamide gel of the eluate. After elution with glycine, the column was eluted with the 0.1% sodium dodecylsulfate solution, but the gel pattern of the eluate did not contain the band of calcitonin. Finally, active calcitonin was not recovered from the porous glass column after adsorption for 3 months.

These adsorption experiments for long periods showed that enzymes and hormones had a specific strength of activity on glass surfaces. Moreover, drugs might be inactivated on surfaces of glass containers upon storage. In this experiment, 96% silica glass was used, but proteins show different properties on other glass, such as soda-lime glass, from those on 96% silica glass. The stability of enzymes in the buffer at 4° was examined as a control experiment, and the enzymes stored for 3 months in the solution containing 0.1% sodium azide were fully active and the dissociation to the subunit was not found because the commercial enzymes used were stable and pure. Twenty-milliliter glass containers are able to adsorb about 10 μg of proteins. Therefore, for many biologicals composed of proteins at high concentration, the protein drugs in the containers might be inactivated more slowly than the time showed in these experiments.

Activity of Proteins in State Adsorbed onto Glass—After enzymes were adsorbed onto a glass column, the substrate solution was loaded onto the column at a constant flow rate, and the absorbance of the product in the eluate was measured. Malate dehydrogenase (23 μg) in 0.1 *M* phosphate buffer (pH 7.4) was adsorbed onto the column, and the substrate solution containing nicotinamide adenine dinucleotide in the reduced form and oxaloacetic acid was applied on the column at a flow rate of 1.2 ml/min/cm^2. The decreased absorbance in the eluate at 340 nm was 0.41, and thus confirmed that malate dehydrogenase on glass surfaces was active. The reaction rate of the enzyme immobilized on glass was about 1/600 compared with that in the free solution from the flow rate data, the thickness of the band adsorbing the enzyme, and the enzyme concentration in the band.

Alkaline phosphatase (3.4 μg) was adsorbed onto the column, and the column was washed with five column volumes of the 0.2 *M* sodium chloride–0.01 *M* phosphate buffer (pH 7.0). The substrate solution containing 5 m*M* *p*-nitrophenyl phosphate was applied on the column at a flow rate of 1.2 ml/min/cm^2, and the absorbance of the eluate at 405 nm was measured. The apparent reaction rate of the enzyme on glass surfaces was about one-fifth of that in the free solution. The absorbance of the solution was measured at 405 nm at 0 and 1 hr, but it had not changed. Therefore, the enzyme was not eluted and was not contained in the eluate. The change of the absorbance was caused by digestion with the enzyme bound to porous glass surfaces.

Peroxidase (2 mg) dissolved in a water medium was adsorbed onto the glass column, and the substrate solution containing guaiacol and hydrogen peroxide was loaded on the column. The eluate developed a brown color, confirming the reaction with peroxidase on the column. The activity of catalase bound to the porous glass column was ascertained by the evolution of gas (oxygen) with elution of the hydrogen peroxide solution. Bovine serum albumin (1 μmole) bound to glass surfaces adsorbed 0.42 μmole of aspirin and 0.59 μmole of sulfamethoxazole in 0.15 *M* sodium chloride–0.01 *M* phosphate (pH 6.0) by frontal analyses. After adsorption of albumin for 1 week, the amounts of aspirin and sulfamethoxazole bound to albumin (1 μmole) were 0.35 and 0.16 μmole, respectively. The reason for the lower values than those obtained using albumin coupled on agarose (18) must be that the site on albumin which adsorbs drugs was used for adsorption to glass silanol.

Abstract □ To develop nonacidic, nonsteroidal anti-inflammatory agents without GI complications, a series of asymmetric triazines was synthesized and evaluated for anti-inflammatory efficacy in the carrageenan-induced pedal edema assay. Toxicity was estimated by determination of approximate LD_{50} values in mice. Twenty-five compounds possessed activity comparable to the standard, indomethacin. Thirteen of the 25 compounds were selected for dose–response evaluation in the carrageenan assay based on their relative toxicity and anti-inflammatory activity. Neurotoxicity of the 13 triazines was estimated by determination of NTD_{50} values in mice. Five of the 13 compounds tested in the dose–response assay were active in terms of anti-inflammatory efficacy (ED_{50} values) and lack of overt neurotoxicity (NTD_{50} values) when compared to indomethacin. To determine the effect of these five developmental triazines on chronic inflammation, they were evaluated in the adjuvant-induced polyarthritis assay. One was comparable to indomethacin in reducing adjuvant-induced inflammation in this assay.

Keyphrases □ Triazines, asymmetric—synthesis, evaluation of anti-inflammatory activity □ Anti-inflammatory agents—asymmetric triazines, synthesis, evaluation of activity □ Polyarthritis, adjuvant induced—assay, asymmetric triazines

In recent years, the literature on nonsteroidal anti-inflammatory agents has increased dramatically. From 1966 to 1976, 807 new compounds from 262 research laboratories were identified as new nonsteroidal anti-inflammatory agents. However, clinical reports were available on only 65 drugs; and of those that have been marketed, only a few have been commercially successful. GI irritation continues to be the principal complication with most developmental, clinical, and commercial nonsteroidal anti-inflammatory drugs.

The occurrence of GI effects in humans has been demonstrated by numerous investigators with administration of various salicylates (1–4), phenylbutazone (5, 6), indomethacin (7), tolmetin (8), naproxen (9), and ibuprofen (10). The ongoing search for novel classes of nonsteroidal anti-inflammatory agents in part reflects the continued inability to separate anti-inflammatory efficacy from GI toxicity. Although considerable controversy concerns the etiology of this toxicity, it generally is agreed that gastric irritation is associated, directly or indirectly, with the acidic nature of these drugs and their metabolites (11, 12).

DISCUSSION

To eliminate GI complications while maintaining anti-inflammatory activity, a series of 81 asymmetric triazines was synthesized and evaluated for potential anti-inflammatory efficacy. The carrageenan-induced pedal edema assay was utilized to detect primary level activity; acute toxicity was estimated by determination of LD_{50} values in mice. A dose–response carrageenan assay and neurotoxicity evaluation were used to determine the ED_{50} and NTD_{50} values of those compounds active at the primary level. Neurotoxicity was estimated by determination of NTD_{50} values in mice. Compounds that were comparable to indomethacin in the secondary stage of evaluation were tested in the adjuvant-induced polyarthritis assay to determine their effect on a chronic inflammatory condition.

Synthesis—3-Methoxy-5-substituted-1,2,4-triazines (III*a*–III*v*) and 3-alkoxy-5-substituted-phenyl-1,2,4-triazines (IV*a*–IV*l*) were synthesized. Melting points and recrystallization solvents are shown in Tables I–III. The 3-methylthio-1,2,4-triazines (II*a*–II*v*) served as common intermediates in the synthesis of all 3-alkoxy- and 3-aryloxy-1,2,4-triazines (III*a*–III*v*, IV*a*–IV*l*, X*a*–X*h*, and XI*a*–XI*i*). The 3-methylthio intermediates were synthesized according to the method of Paudler and Chen (13) with modifications by Heilman *et al.* (14).

Treatment of II with sodium methoxide in refluxing methanol resulted in nucleophilic displacement of the methylthio function to afford the corresponding 3-methoxy-5-substituted-1,2,4-triazines (III*a*–III*v*). Reaction of II with a variety of sodium alkoxides refluxing in dioxane afforded the corresponding 3-alkoxy-5-phenyl-1,2,4-triazines (IV*a*–IV*l*).

5,6-Disubstituted-3-alkoxy-1,2,4-triazines (VII*a*–VII*h* and VIII*a*–VIII*i*) were synthesized. Melting points and recrystallization solvents are shown in Tables IV and V. Cyclization of symmetrical 1,2-diones (V*a*–V*h*) under basic conditions with methylthiosemicarbazide hydrogen iodide afforded the 3-methylthio-5,6-disubstituted-1,2,4-triazines (VI*a*–VI*h*). Nucleophilic displacement of the methylthio group with the appropriate sodium alkoxide produced the desired 3-alkoxy-5,6-disubstituted-1,2,4-triazines (VII*a*–VII*h* and VIII*a*–VIII*i*).

Biology—The effect of the asymmetric triazines on the inflammatory response was evaluated at the primary level in the carrageenan-induced pedal edema assay (15). Carrageenan injected into the plantar tissue of the hindpaw of Sprague–Dawley rats produces an edematous condition, which simulates in part the inflammatory process found in human arthritis (16–18). Nonsteroidal anti-inflammatory drugs such as indomethacin, phenylbutazone, and aspirin inhibit the formation of this edema (19, 20).

Compounds were administered orally, using 0.25% methylcellulose as the vehicle. Five rats were used per dose, with the reported percent reduction in inflammation represented by the average of the reduction produced in the five animals. Compounds were administered at levels expected to be subtoxic by consideration of their approximate, measured LD_{50} values. The LD_{50} values in mice were determined in a standard,

multidimensional observational assay and calculated according to the method of Litchfield and Wilcoxon (21). The anti-inflammatory and LD_{50} results are shown in Table VI.

Based on the anti-inflammatory performance of each compound relative to the indomethacin standard, 25 of the 81 compounds evaluated gave a reduction in edema equal to or greater than the standard. However, test compounds were administered at 200 mg/kg (unless overt toxicity necessitated a lower dose), while indomethacin was administered at 2.5 mg/kg. Of the 25 active triazines, 13 were selected for secondary evaluation based on their relative toxicity and anti-inflammatory activity. Those compounds selected had LD_{50} values greater than 300 mg/kg and produced a percent reduction in inflammation equal to or greater than the standard, which was run simultaneously.

Within the 3-methylthio-5-substituted-1,2,4-triazine series, seven of the 22 compounds screened were active; two were selected for secondary testing (II*c* and II*f*). Among the 3-methoxy-5-substituted-1,2,4-triazines, eight of the 22 compounds evaluated were active; five were selected for further testing (III*a*, III*b*, III*f*, III*n*, and III*o*). In the 3-alkoxy-5-substituted phenyl series, five of the 12 compounds tested were active; four were selected for secondary evaluation (IV*a*, IV*b*, IV*e*, and IV*i*). Within the 3-methylthio- and 3-methoxy-5,6-disubstituted-1,2,4-triazine series, only two of the 16 compounds evaluated were active; one was selected for secondary testing (VII*g*). In the 3-alkoxy-5,6-disubstituted-1,2,4-triazine

series, two of the nine compounds tested were active; one was selected for subsequent evaluation (VIII*i*).

The secondary evaluation consisted of a dose–response carrageenan assay and the determination of the NTD_{50} value in mice, based on the method of Swinyard *et al.* (22). The compounds were administered in the carrageenan assay at multiple doses (*e.g.*, 100, 30, 10, and 3 mg/kg) to obtain a three-point dose–response curve under identical conditions as used in the primary evaluation. If a dose–response relationship was observed, the ED_{50} value was determined according to the method of Litchfield and Wilcoxon (21). The NTD_{50} values were determined to provide additional information concerning the toxicity of the compounds relative to indomethacin.

The results of the secondary testing are shown in Table VII. Based on 50 determinations, indomethacin had a mean ED_{50} value of 2.5 mg/kg and an NTD_{50} value of 112 mg/kg. To compete successfully with this standard, compounds were expected to be less toxic and yet maintain similar levels of efficacy. Therefore, an NTD_{50} value of >300 mg/kg and an ED_{50} value of <30 mg/kg were established as limits for further testing. Five of the 13 compounds subjected to secondary testing fell within these arbitrary bounds (II*f*, III*o*, IV*b*, IV*e*, and VIII*i*).

To determine the effect of these five developmental compounds on a chronic inflammatory condition, each candidate was evaluated in the adjuvant-induced polyarthritis assay (23). An injection of heat-killed *Mycobacterium tuberculosis*, suspended in mineral oil, produced a highly

[a] Mean percent reduction in inflammation produced by the standard, indomethacin, at a dose of 2.5 mg/kg. An indomethacin standard was run simultaneously with each set of test compounds.

developed arthritic condition after 20 days when injected into the left hindfoot pad of male Wistar–Lewis rats. The developed arthritis was characterized by swelling of all four paws and secondary involvement of the tail and ears (24). The test compounds were administered by gastric intubation in a methylcellulose vehicle on Days 20 and 22. Both left and right hindpaw volumes were recorded daily on Days 20–24. The decrease in mean paw volume per group per day then was calculated as the percent change from Day 20. Efficacy was determined by a percent decrease in the paw volume of test compounds *versus* that of the standard, indomethacin. The test compounds were administered at a dose of 30 mg/kg, and the standard was given at a dose of 1 mg/kg.

The results of this assay are shown in Table VII. Only II*f* was active in the adjuvant-induced polyarthritis assay. This compound appeared to have a rapid onset of action compared to the standard. However, after several days, the activity level began to fall. Additional evaluation is needed to establish whether II*f* possesses a therapeutic advantage over current standards.

Physicochemical Parameters—Since compounds in each series (Tables I–V) differed from others in that series by only one substituent, hydrophobic substituent constants (π values) (25, 26), electronic substituent constants (σ values) (27), and steric substituent constants (E_s values) (28) were utilized to estimate the relative effect of these physicochemical parameters on anti-inflammatory activity. After detailed investigation, it was concluded that within each series, no apparent structure–activity correlation existed between any of these physicochemical parameters and anti-inflammatory activity. Nevertheless, several general trends deserve comment.

First, at the primary screening level, the 5-substituted triazine classes (II*a*–II*v*, III*a*–III*v*, and IV*a*–IV*l*) were inherently more active than the corresponding 5,6-disubstituted triazines (VI*a*–VI*h*, VII*a*–VII*h*, and VIII*a*–VIII*i*). Over 37% of the compounds in the 5-substituted classes were considered active, while only 16% of the compounds in the 5,6-disubstituted classes were active.

Second, the difluorinated triazines (II*i* and III*i*) were among the most toxic derivatives evaluated in this series. Perhaps the toxicity among these fluorinated derivatives is the result of increased susceptibility to nucleophilic attack by the amino and mercapto functions present in DNA

Table VII—ED_{50} Values in Carrageenan-Induced Anti-Inflammatory Assay, NTD_{50} Values in Mice, and Adjuvant-Induced Polyarthritis Activity of Selected 3-Methylthio- and 3-Alkoxy-1,2,4-triazines

Compound	Carrageenan-Induced Anti-Inflammatory Assay		Adjuvant-Induced Polyarthritis Assay[a], % reduction			
	ED_{50}, mg/kg	NTD_{50}, mg/kg	Day 21	Day 22	Day 23	Day 24
II*c*	30	170	NT[b]	NT	NT	NT
II*f*	10	1000	24	19	14	8
III*a*	10	170	NT	NT	NT	NT

Indomethacin	2.5	112	12	19	18	21

[a] All test compounds were administered at 30 mg/kg, while indomethacin was given at 1 mg/kg. [b] Not tested.

and protein structure (29). It may be that the relatively labile fluorine atoms undergo displacement by these functional groups, resulting in interchelation and overt toxic effects.

EXPERIMENTAL[1]

3-Methoxy-5-substituted-1,2,4-triazines (IIIa–IIIv)—In a 1-liter round-bottom flask equipped with condenser and magnetic stirrer was placed the appropriate 3-methylthio-5-substituted-1,2,4-triazine (IIa–IIv) (13,14) dissolved in methanol (500 ml). To this stirred solution was added a molar excess of sodium methoxide, and the mixture was refluxed for 10 hr. (The methanethiol fumes were trapped by a sodium hydroxide scrubber system.) Upon cooling, the mixture was concentrated and treated with hexane–heptane to afford a crystalline product.

Recrystallization from the appropriate solvents (Table II) resulted in the corresponding 3-methoxy-1,2,4-triazine (IIIa–IIIv). The 3-methoxytriazines were characterized by carbon, hydrogen, and nitrogen analyses (Table II) and NMR spectroscopy. This class of triazines was characterized by the following chemical shifts relative to tetramethylsilane in deuterochloroform: δ 4.0–4.2 (s, 3, OCH_3), 7.0–8.2 (m, C-5 aromatic substituent protons), and 9.6–9.8 (s, 1, C-6 triazine proton).

3-Alkoxy-5-substituted-phenyl-1,2,4-triazines (IVa–IVl)—The 3-alkoxy-5-substituted-phenyl-1,2,4-triazines were synthesized in a similar manner as the 3-methoxy-1,2,4-triazines (IIIa–IIIv), except that a molar excess of the desired sodium alkoxide was reacted with the 3-methylthio-1,2,4-triazine (IIa or IIb) and the mixture was refluxed with dioxane. Crude products were recrystallized from the appropriate solvents (Table III) to yield the corresponding 3-alkoxy-1,2,4-triazine (IVa–IVl). The 3-alkoxytriazines were characterized by carbon, hydrogen, and nitrogen analyses (Table III) and NMR spectroscopy; chemical shifts were similar to the 3-methoxytriazines (IIIa–IIIv), but the methoxy shift was replaced by ethyl, *n*-propyl, *n*-pentyl, and higher homologs (Table III).

3-Methylthio-5,6-disubstituted-1,2,4-triazines (VIa–VIh)—In a 1-liter round-bottom flask equipped with a heating mantle, condenser, and magnetic stirrer was placed the appropriate symmetrical 1,2-dione (Va–Vh) dissolved in 80% ethanol (500 ml). To this stirred solution was added an equal molar solution of methylthiosemicarbazide hydrogen iodide and sodium bicarbonate in 80% ethanol. The mixture was refluxed for 10 hr, cooled to ambient temperature, and diluted with water to afford a solid.

The solid material was collected and recrystallized from the appropriate solvents (Table IV) to yield the desired 3-methylthio-5,6-disubstituted-1,2,4-triazine (VIa–VIh). The 3-methylthiotriazines were characterized by carbon, hydrogen, and nitrogen analyses (Table IV) and NMR spectroscopy. This class of triazines was characterized by the following chemical shifts relative to tetramethylsilane in deuterated dimethyl sulfoxide: δ 2.7–2.9 (s, 3, SCH_3) and 7.0–8.2 (m, C-5 and C-6 aromatic substituents).

3-Methoxy-5,6-disubstituted-1,2,4-triazines (VIIa–VIIh)—The 3-methoxy-5,6-disubstituted-1,2,4-triazines (VIIa–VIIh) were synthesized in the same fashion as the corresponding 3-methoxy-5-substituted triazines (IIIa–IIIv). Recrystallization of the solid product from the appropriate solvents (Table IV) afforded the desired 3-methoxy-5,6-disubstituted-1,2,4-triazines (VIIa–VIIh). The carbon, hydrogen, and nitrogen analyses are shown in Table IV; the NMR spectra were identical to those of the 3-methylthio precursor except that the δ 2.7–2.9 (s, 3, SCH_3) signal was replaced by a δ 4.0–4.2 (s, 3, OCH_3) signal further downfield.

3-Alkoxy-5,6-disubstituted-1,2,4-triazines (VIIIa–VIIIi)—The 3-alkoxy-5,6-disubstituted-1,2,4-triazine analogs (VIIIa–VIIIi) were synthesized by the same procedure as the 3-alkoxy-5-substituted-1,2,4-triazines (IVa–IVl). Recrystallization solvents are listed in Table V. The 3-alkoxytriazines (VIIIa–VIIIi) were characterized by carbon, hydrogen, and nitrogen analyses (Table V) and NMR spectroscopy. The 5,6-diphenyl derivatives (VIIIa–VIIIf) produced chemical shifts similar to those of their common precursor VIa, except that the methylthio singlet (δ 2.7–2.9) was replaced by a variety of alkoxy and aryloxy multiplets. The 5,6-dimethyl derivatives (VIIIg–VIIIi) were characterized by the two methyl singlets with δ 2.6–2.5 (s, 3, C-6 methyl) and 2.3–2.5 (s, 3, C-5 methyl) and a variety of multiplets resulting from substituents at C-3.

Carrageenan-Induced Pedal Edema Assay (15)—Male Sprague–Dawley rats, 100–140 g, were used in the pedal edema assay. Five rats were used in each treatment group, the known standard control group, and the vehicle control edema groups. The first and seventh groups were vehicle controls. Therefore, recalibration of the volume differential meter could be done after every 30 animals. All rats were fasted for 2 hr prior to the test, and water was available *ad libitum*.

The experimental drugs and the standard control were given orally and were dissolved or suspended in 0.25% methylcellulose. The volume given was 0.005 cm^3/g of body weight. The edema control groups were administered the vehicle. One hour after the administration of the test compounds, 0.05 cm^3 of a 1% sterile carrageenan solution was injected into the left hindfoot pad of each rat using a 1-cm^3 Cornwall syringe pipet. Three hours after this injection, the paw volumes of the injected paws were measured by means of mercury displacement on a volume differential meter. The apparatus used was a modification of that described by Adamkiewicz *et al.* (30).

The amount of edema was calculated, and the percent reduction of edema from control values was determined. The mean volume ($\pm SD$) of edema based on 50 determinations was 1.24 $\pm$0.226 cm^3. Compounds that reduced edema to a level less than that of indomethacin (dosed at 2.5 mg/kg) were considered active. The ED_{50} values for indomethacin and active test compounds were estimated according to the method of Litchfield and Wilcoxon (21).

Neurotoxicity Determination, NTD_{50} Values (22)—The mean neurotoxic dose was the dose administered orally or intraperitoneally to mice that caused minimal recognizable neurotoxicity in 50% of the animals tested as determined by the following five end-points.

1. Positional sense test: If the hindleg of a normal mouse is lowered gently over the end of a table, it will be lifted quickly back to a normal position. Neurological deficit was indicated by the inability to correct the abnormal position rapidly.
2. Righting test: If a mouse is placed on its back, it will right itself quickly and assume a normal posture. Neurological deficit was indicated by the inability to correct for the abnormal body posture rapidly.
3. Gait and stance test: Neurological deficit was indicated by a circular or zigzag gait, ataxia, abnormal spread of the legs, abnormal body posture, tremor, hyperactivity, lack of exploratory behavior, somnolence, stupor, catalepsy, *etc.*
4. Muscle tone test: Normal animals have a certain amount of skeletal muscle tone that is apparent to the observer on handling. Neurological deficit was indicated by a loss of skeletal muscle tone characterized by hypotonia or flaccidity.
5. Equilibrium test: If a normal mouse is placed on a narrow edge, such as the rim of a cage, it can maintain its equilibrium and walk along the rim. Neurological deficit was indicated by the inability to do so.

Abnormal neurological status disclosed by any of these five tests was taken as the end-point for the NTD_{50} determination. However, if other side effects (*e.g.*, hematuria and hypernea) consistently appeared at doses lower than those causing neurological deficit, they were taken as the end-point.

Adjuvant-Induced Polyarthritis Assay (23, 24)—Five male Wistar–Lewis rats, ~110 g each, were used in each group. On Day 1, 0.1 cm^3 of 3.5-mg/cm^3 suspension of heat-killed *M. tuberculosis* in mineral oil was injected into the left hindfoot pad of each rat. The animals then were kept in cages, with two or three rats per cage for 20 days; food and water were available *ad libitum*. On Day 20, all animals with developed arthritis, *i.e.*, swelling of all four paws and secondary involvement of the tail and ears, were used in the study.

The test compounds and the standard control were dissolved or suspended in methylcellulose and were given orally at doses of 30 and 1 mg/kg, respectively. The volume given was 0.005 cm^3/g of body weight. The control group was administered the vehicle alone. The animals were administered compounds by gavage on Days 20 and 22. The left hindpaw volumes were recorded daily on Days 20–24. The decrease or increase in mean paw volume per group per day was then calculated as the percent change from Day 20. Efficacy was determined by a percent decrease in paw volume of the test compounds compared to indomethocin.

[1] Elemental analyses were performed by the Analytical Group, Diamond Shamrock Corp., Painesville, Ohio. IR spectra were determined on a Perkin-Elmer model 137 spectrophotometer with sodium chloride optics. NMR spectra were recorded on a Varian A56/60D and a Bruker WH-90 spectrometer. Melting points were determined on a Thomas–Hoover capillary melting apparatus and are uncorrected.

Nonisothermal Kinetics with Programmed Temperature Steps

B. EDEL ˣ and M. O. BALTZER

Received April 30, 1979, from *Analytical Research and Development, Pharmaceutical Department, Sandoz Ltd., CH-4002 Basel, Switzerland.* Accepted for publication October 15, 1979.

Abstract □ Data required for predicting the stability of an active principle in solution can be obtained by two kinetic methods. With the isothermal method, the degradation rate constants are determined at different temperatures, which are kept constant throughout the experiment. With the nonisothermal method, the temperature is increased with time. This paper describes a nonisothermal kinetic method in which the temperature is increased in consecutive equal steps. The results are compared with those obtained by the conventional isothermal method. The values for the activation energy are approximately the same by both methods. Although the technique of nonisothermal kinetics demands sophisticated equipment and high experimental accuracy, it provides a continuous picture over a wide temperature range.

Keyphrases □ Stability—prediction, nonisothermal kinetic method, programmed temperature steps, comparison with isothermal kinetic method □ Drug degradation kinetics—nonisothermal method, programmed temperature steps, comparison with isothermal kinetic method □ Kinetics, degradation—nonisothermal method, programmed temperature steps, comparison with isothermal kinetic method

Degradation kinetics usually are studied under isothermal conditions by determining the reaction rate constant at different temperatures. These temperatures generally are fairly high and are kept constant throughout the experiment; in nonisothermal kinetic studies, the temperature changes continuously with time. Several such methods have been described, with the essential difference between them being the equation for the time–temperature relationship (1–3).

Calculations using a continuous temperature increase were carried out previously *via* a multistep model (3). Study of an experimental model with a stepwise temperature profile then was desired. This paper describes the application of nonisothermal kinetics in which the temperature is raised discontinuously in consecutive equal steps, whose number and duration are predetermined. The results are compared with those obtained in conventional isothermal kinetic studies.

EXPERIMENTAL

The investigation was carried out using an active principle, a substituted benzazepine, as a 0.2% solution in pH 5 buffer–ethanol (60:40). This pH was chosen to give appreciable degradation in a relatively short time[1].

The solution of the active principle was introduced into ampuls, which then were sealed and immersed in a thermostatically controlled bath[2] of glycerol–water. At predetermined times coinciding with the end of a temperature stage, ampuls were removed to determine the remaining amount of active ingredient. This determination was done by high-performance liquid chromatography (HPLC) or by spectrophotometry after separation by TLC followed by elution.

TLC—Plates precoated with silica gel and an indicator[3] were used as the stationary phase. The mobile phase was chloroform—ethanol–concentrated ammonia (90:10:0.8). The plates were developed to 12 cm. UV detection was performed at 254 nm with the use of Dragendorff's reagent and peroxide for visualization of degradation after elution.

The R_f values were 0.5 for the active principle and 0.4, 0.7, and 0.9 for the degradation products. After development, the spot corresponding to the unchanged active principle was eluted[4] with 2.50 ml of solvent

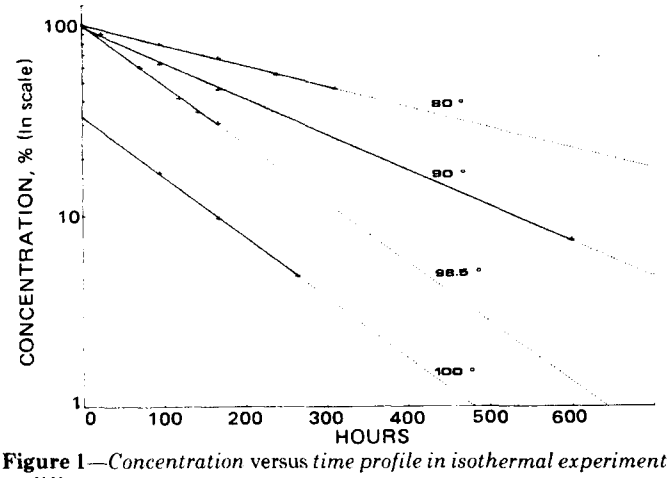

Figure 1—*Concentration* versus *time profile in isothermal experiment at different temperatures.*

(methanol–10% concentrated ammonia). A UV absorption spectrum of this solution was recorded between 200 and 320 nm with a spectrophotometer[5] linked to a recorder[6]. The value was measured at the extinction maximum of 230 nm. The recovery was 97%.

The values are the means of five samples from one ampul. A calibration curve was prepared under the same conditions. The equation was $y = 0.0726x + 0.0111$ ($r = 0.9995$) for concentrations between 1 and 9.5 μg/ml.

HPLC[7]—The stationary phase was Lichrosorb Si 100, 5 μm in a column of 10 cm length and 0.46 i.d. The mobile phase was 95% ethanol–methanol–saturated ammonium carbonate solution (900:100:0.4). A pump[8] maintained the flow rate at 1.5 ml/min with a pressure of ~175 × 10^5 Pa. The chart speed of the recorder[9] was 1 cm/min. The UV detector[10] wavelength was set at 230 nm. The sample loop of the injector[11] had an injection volume of 20 μl. The peak area was obtained by an integration system[12] connected to the detector.

The values are the means of three injections obtained after diluting the sample to give a concentration of unchanged active principle approximating that of the calibration curve. The equation was $y = 0.0258x + 0.0174$ ($r = 0.9999$) for injections from 0.2 to 6 μg.

The kinetic test at 100° carried out using TLC also was performed using HPLC and gave concentrations of 33.7, 19.6, 10.68, and 5.2% at 0, 96, 168, and 264 hr, respectively. These values are close to those shown in Fig. 1. This fact indicates the equivalence of the two methods.

Nonisothermal Temperature Programming—A programmer[13] was used to control the rise of temperature in the bath. This system enables the bath temperature to be altered automatically stepwise from a preset starting temperature over a range of 115° at 10 rates. The kinetic experiments were carried out between 40 and 97.6° in consecutive equal steps, which in this case were temperature changes, ΔT, of 0.3° every 3 hr (Fig. 2). The temperature was increased by 0.3° quickly at the beginning of each step and was kept constant for the remainder of the step time.

RESULTS

Nonisothermal Kinetics—Zoglio *et al.* (3) used a linear progression for temperature. The degradation curve, $f(C)$, is described by a series of straight lines (where the time interval during which the temperature remains constant is reduced) whose individual slopes (or rate constants), k_i, represent the instantaneous degradation rate at a given moment (or temperature). The shorter this time interval, the greater is the chance of the curve being linear in this interval. (For first-order reactions, the curve is log concentration as a function of time.)

This method is based on the hypothesis that the arithmetic mean of these rate constants is equal to the ratio of total degradation, $f(b) - f(a)$,

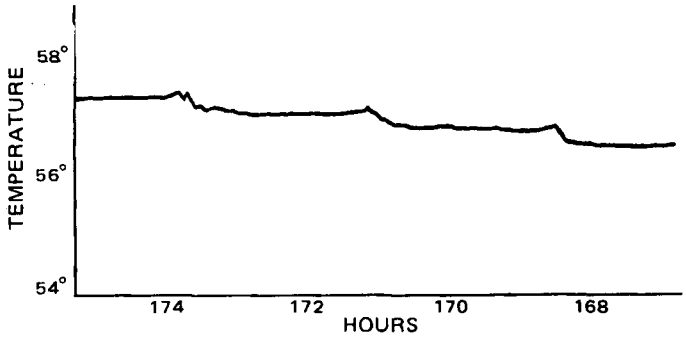

Figure 2—*Section of the experimental temperature profile.*

for the duration of the experiment, $b - a$:

$$\frac{f(b) - f(a)}{b - a} = \frac{k_1 + k_2 + \ldots + k_i + \ldots + k_n}{n} \qquad \text{(Eq. 1)}$$

The size of n is fixed to minimize the error.

The temperature programming in the present experiment represents a special case of this theory. The hypothesis according to which each interval can be described by a straight line becomes a reality. Each temperature stage can be regarded as a miniature isothermal kinetic model. For each step, the degradation is represented by a straight line whose slope corresponds to the rate constant at that temperature. The error due to the time required to raise the temperature between each stage can be regarded as negligible. The equation for the degradation is:

$$\ln C - \ln C_0 = \frac{t}{n}(k_1 + k_2 + \ldots + k_i + \ldots + k_n) \qquad \text{(Eq. 2)}$$

To solve this equation for any rate constant, the constant must be expressed in terms of all of the other constants in the equation. For constant k_i:

$$k_i = Ae^{-E(RT_i)^{-1}} \qquad \text{(Eq. 3)}$$

For constant $k_i + 1$:

$$k_{i+1} = Ae^{-E(RT_{i+1})^{-1}} \qquad \text{(Eq. 4)}$$

By dividing Eq. 4 by Eq. 3, the following expression is obtained:

$$k_{i+1} = k_i e^{E/R[(T_{i+1}-T_i)(T_iT_{i+1})^{-1}]} \qquad \text{(Eq. 5)}$$

Because the increment $T_{i+1} - T_i$ is constant and equal to ΔT, the solution for k_{i+2} with respect to k_i becomes:

$$k_{i+2} = k_i e^{E/R[\Delta T(T_{i+1}T_i)^{-1}]}\, e^{E/R[\Delta T(T_{i+2}T_{i+1})^{-1}]} \qquad \text{(Eq. 6)}$$

In the same way, each constant can be expressed with respect to k_i. The corresponding expressions can be substituted for the values of k_1 to k_n in Eq. 2.

If $k_1 = k_i$, then:

$$\ln C - \ln C_0 = k_1 \frac{t}{n}(1 + e^{E/R[\Delta T(T_1T_2)^{-1}]} + e^{E/R[\Delta T(T_1T_2)^{-1} + \Delta T(T_2T_3)^{-1}]} + \ldots + e^{E/R[\Delta T(T_1T_2)^{-1} + \ldots + \Delta T(T_{n-1}T_n)^{-1}]}) \qquad \text{(Eq. 7)}$$

or:

$$\ln C - \ln C_0 = k_1 \frac{t}{n}\left(1 + \sum_{m=1}^{n-1} \exp\left[E/R\ \Delta T \sum_{i=1}^{m} (T_iT_{i+1})^{-1}\right]\right) \qquad \text{(Eq. 8)}$$

Once the values of $\ln C - \ln C_0$ and t/n are determined experimentally, k_1 can be calculated for any activation energy.

Equations similar to Eq. 8 can be derived and solved for the constants k_2 to k_n in the same way. These constants then are used to plot the theoretical curves [$\ln C = f(t)$] for different activation energies using a scale that corresponds to the order of the degradation reaction (which must be determined).

Since extremely lengthy calculations are needed to solve these equations, a program was elaborated that enables the problem to be solved on a computer[12]. (Automatic calculation takes ~6 hr.) For a first-order reaction and for a particular activation energy, this program calculates (with the aid of Eq. 8) the k' value corresponding to the first temperature stage. With this value, it then is possible to determine the theoretical concentration at the end of this stage, which also is the concentration at the beginning of the next stage. By substituting the values of the con-

480	58.37	4.06680
528	48.36	3.87867
576	35.61	3.57263

[a] Number of stages, n, = 576/3 = 192.

centration and initial temperature in the first stage with those in the second stage and by substituting n with the number of stages remaining, an analogous computation gives the k value corresponding to the second stage and so on to the last one.

The concentrations calculated theoretically are compared with the concentrations obtained experimentally. The value taken for the activation energy then is altered until the calculated concentrations approach the experimental data. Progressively smaller adjustments evaluate the activation energy at best fit to the nearest 100 J. When the sum of the squares of the difference between the experimental values and the theoretical values at the same moment is a minimum, the corresponding activation energy is regarded as the activation energy of the reaction. The constant of the Arrhenius equation is determined at the same time.

Quantitative analysis of the ampul produced the results shown in Table I over 576 hr. Automatic computation of the activation energy after scanning between 40,000 and 70,000 J yielded E = 62.2 kJ/mole. Although this value is purely arbitrary since the n value used corresponds to an actual number of temperature stages during which it remained constant, the same calculation also was performed with n twice the size, and there was no appreciable modification in the activation energy.

The theoretical degradation curves for each activation energy (Fig. 3) were plotted with the concentration values for each ΔT interval given by the computer. The points corresponding to experimental values also were plotted on the graph. One point is marked to show the considerable effect that an error of ±1% can have on the concentration at a given moment.

Isothermal Kinetics—Degradation kinetics were performed isothermally at 80, 90, 98.5, and 100° (Fig. 1). The reaction order was checked in each case as a function of time; the graph of C, ln C, and C^{-1} *versus* t is a straight line for zero-, first-, and second-order reactions, respectively, where C is the concentration of unaltered active ingredient.

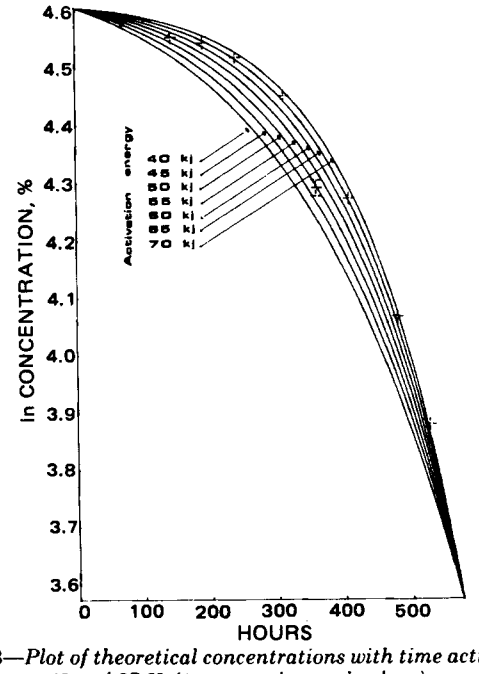

Figure 3—*Plot of theoretical concentrations with time activation energy between 40 and 97.6° (+ = experimental values).*

Table II—Correlation and k Values at Different Temperatures

Parameter	80°	90°	98.5°	100°
Correlation	0.9992	0.9994	0.9989	0.9997
$k \times 10^5$, hr^{-1}	248	431	716	728

When the linear regression was calculated on a programmable computer[14], the best correlation coefficient was obtained for a first-order reaction at the four temperatures. Therefore, the equation for calculating the degradation rate constant is:

$$C = C_0 e^{-kt} \qquad \text{(Eq. 9a)}$$

or:

$$\ln C = \ln C_0 - kt \qquad \text{(Eq. 9b)}$$

where k is the slope of the regression line (Table II).

With the Arrhenius equation, $k = Ae^{-E/RT}$, the graph of ln k as a function of T^{-1} is a straight line with a slope of $-E/R$ (Fig. 4). Calculation of the regression line of ln k as a function of T^{-1} at 80, 90, 98.5, and 100° gave a correlation coefficient of 0.9999. The equation for the straight line was ln k = 14.6 − 7290 T^{-1} in which ln A = 14.6 and E/R = 7290 °K. The activation energy was E = 60.6 kJ/mole.

DISCUSSION AND CONCLUSION

The value for activation energy obtained by the nonisothermal method was similar to that obtained by the isothermal method (62.2 and 60.6 kJ/mole). Therefore, the two methods may be regarded as equivalent with respect to their results. However, they generally are suitable only when the activation energy and the reaction order remain constant throughout the experiment, *i.e.*, the Arrhenius relationship is valid in the particular case.

Given these conditions, the major limitation of the nonisothermal procedure seems to be the experimental accuracy. This limitation is demonstrated by the fact that if the experimental points are measured inaccurately, the experimental and the theoretical degradation curves intersect in too broad a range of activation energies and this effect soon leads to a considerable scattering of the results. To control the experimental accuracy, it is essential to complement the computation by plotting the theoretical curves corresponding to each activation energy to compare them with the experimental curve. It also is necessary to have a prior idea of the degradation rate to select a suitable temperature program; this planning avoids alteration during the experiment.

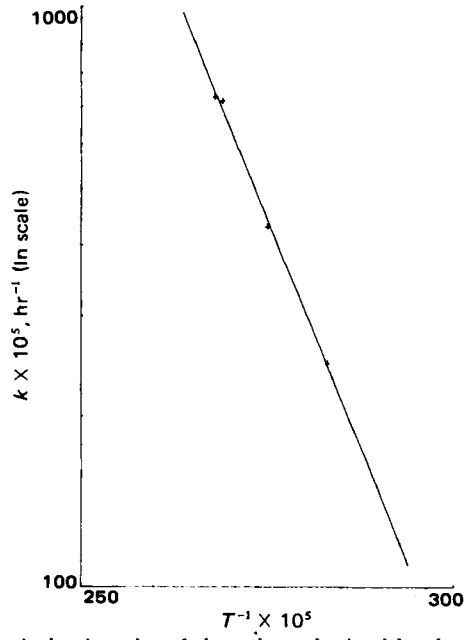

Figure 4—*Arrhenius plot of the values obtained by the isothermal experiment.*

[14] Model 9810 A, Hewlett-Packard.

One advantage of the method is that it examines a wider temperature range than does the isothermal kinetic method. Provided that the tests are sufficiently accurate, it is possible to detect any activation energy change.

Since three temperatures stages and three durations for each stage generally are considered as a minimum for isothermal kinetic studies, the nonisothermal method does not appear to offer any decisive advantage. The definitive need for more sophisticated equipment (temperature programmer, computer, and plotter) is a disadvantage. On the other hand, the nonisothermal method may lead to more precise results with less experimental effort, *e.g.*, data points. Furthermore, it requires only a fraction of the time an isothermal experiment does. Selection of a method depends on the equipment and the time available.

Abstract □ Commercial prednisone tablets were subjected to dissolution tests by USP basket and paddle methods. It was found experimentally that disintegration adheres to an exponential decay law: $\ln(W/W_0) = -d(t - t_i)$, where W is the nondisintegrated weight, d is a disintegration constant, t is time, and t_i is a lag time. Dissolution has been reported to adhere to a similar law, where the dissolution constant, K, follows a pseudo-Arrhenius relationship with changing temperature. Within a certain temperature range, this relationship also exists for the disintegration rate constant, d. A correlation exists in these tablets between K and d. The shaft length in the dissolution apparatus plays a part in the disintegration (and hence dissolution) rate and, therefore, is an important apparatus parameter affecting reproducibility.

Keyphrases □ Disintegration—commercial prednisone tablets, time and temperature dependence, correlation between dissolution and disintegration rate constants □ Prednisone—commercial tablets, time and temperature dependence of disintegration, correlation between dissolution and disintegration rate constants □ Dissolution—commercial prednisone tablets, time and temperature dependence of disintegration, correlation between dissolution and disintegration rate constants

Several recent articles correlated two- or three-component dissolution model parameters with those of disintegration in the same apparatus. These studies were aimed at elucidation of the type of dissolution curve obtained in dissolution experiments both for control and for research purposes. The curves usually are *s*-shaped. Wagner (1) and Wood (2) first recognized the importance of this type of curve, and a probit and a Weibul function were suggested later as a descriptive means (1–4).

Several investigators demonstrated that disintegration and dissolution in an apparatus can be correlated and that these factors lead to *s*-shaped curves (5–11). Carstensen *et al.* (7, 8) suggested that the best general trial function is one in which the weight of undisintegrated tablet is monitored as a function of time. The dimensions of the tablets remaining (such as thickness) as a function of time can be useful in certain cases; but since many tablets swell on contact with water, the functions become complicated. Furthermore, the thickness of a swelling, disintegrating tablet is difficult not only to monitor but also to define.

The simplest model of weight *versus* time that appears compatible with experimental data (8) is a simple exponential decay function. Double exponentials may apply in more complicated systems. This model has been recognized in compendial work, and disintegrating dissolution calibrators have been suggested. This article presents data showing the disintegration–dissolution behavior of a conventional prednisone tablet.

Excellent research and review articles regarding the mechanism of disintegration have been published (12–14), and the effect of temperature on dissolution has been elucidated (15). This article reports the dependence of tablet disintegration on temperature and also the effect of the length of the stirring shaft on dissolution.

EXPERIMENTAL

Commercial prednisone tablets were assayed and found to contain starch, lactose, metallic stearate, and prednisone. Two 20-mg tablets were placed in the basket of a USP basket dissolution apparatus in a thermostated bath. The apparatus was operated at 150 rpm. This agitation speed was chosen because problems with liquid homogeneity exist at lower rotational speeds (9). Samples were taken routinely at appropriate time intervals and, after filtration[1], were assayed using the spectrophotometric absorbance at 242 nm. The amount of prednisone then was determined by comparison with a standard curve of prednisone obtained with a USP reference standard. The experiment was repeated using a different shaft length (Fig. 1), *i.e.*, assembling the shaft onto the motor such that the length of free shaft was different from that first used. The two shaft "lengths" used are denoted as positions I and II (Fig. 1).

A set of experiments was performed (in both positions) to establish the disintegration rate of the tablets in the apparatus. These experiments were done as follows (6, 7). An experiment was carried out for t_i min and then was stopped. The basket was lifted out, and the tablets were removed and dried to constant weight, W, at 100°. This weight was compared with the weight, W_0, of a similarly dried tablet prior to the dissolution test. The experiment then was repeated for other t_i values.

The experiments were repeated using a USP paddle apparatus at 150 rpm. Experiments were carried out at 10, 20, and 30° for the paddle apparatus and at 0, 5, 10, 15, 20, 30, and 37° for the basket apparatus.

RESULTS AND DISCUSSION

All dissolution and disintegration data show s-shaped curves as exemplified in Fig. 2. The data were recast in semilogarithmic form, and, as shown in Fig. 3 and Table I, follow the equations:

$$\ln(W/W_0) = -d(t - t_i) \quad \text{(Eq. 1)}$$

$$\ln(m/m_0) = -K(t - t_i') \quad \text{(Eq. 2)}$$

where m is the amount of undissolved drug, d is a disintegration rate constant ($time^{-1}$), K is a dissolution rate constant ($time^{-1}$), t_i and t_i' are lag times, and the subscript zero denotes zero time.

To present all of the data points graphically, they were converted to reduced parameters in the following fashion. The least-squares parameters d and t_i (and K and t_i') were calculated as shown in Table I. For disintegration, the experimental value of $\ln(W/W_0)$ at time $t^\dagger$ was used as the ordinate (y-axis) in Fig. 4. The corresponding abscissa value, x, then was obtained by inserting the $t^\dagger$ value and the least-squares values of d and t_i into $x = -d(t - t_i)$. A similar procedure was used for dissolution (Fig. 5).

This graphic method allows visualization of how all data points fit the two equations. Essentially straight lines of unit slope and zero intercept are obtained in Figs. 4 and 5. The graphical presentation is not statistical. Usual least-squares methods are not possible by the reduced presentation because both x and y have errors of comparable magnitude, and most methods addressing this situation fail when (as in the described treatment) the error on the y-axis is not independent of the error on the x-axis.

Statistical evidence is confined to comparison of the s_{yx}^2 values of the data treated according to Eq. 1 as compared to other functions, where s_{yx}^2 is the total sum of squares divided by the degrees of freedom ($n - 2$),

						$\Sigma\Delta^2 = 6.04$				$\Sigma\Delta^2 = 3.99$
						$s_{yx}^2 = 2.01$				$s_{yx}^2 = 1.33$
				Slope		1.091				−0.0044
				Intercept		−6.209				0.056
				Correlation coefficient		−0.998				−0.999

which is the equation derived by Kitamori and Iga (11). In logarithmic form, this equation is:

$$z_1 = \ln[1 - (W/W_0)] = n \ln(t) - n \ln(t_d) \qquad \text{(Eq. 3}b\text{)}$$

where n is an equation parameter and t_d is the disintegration time. The least-squares fit for the data is $z_1 = 1.091 \ln t - 6.209$ ($r^2 = 0.996$), where r^2 is the square of the correlation coefficient.

The s_{yx}^2 values are obtained for Eq. 3a first by finding the line values, $\bar{z}_1$, corresponding to Eq. 3b for each t value and then by converting them to $\bar{y}_1$ values (percent disintegrated). These values are shown in Table II. A similar calculation is shown for the data plotted according to Eq. 1 [$z_2 = \ln(W/W_0)$ and $y_2 = 1 - (W/W_0)$]. The sums of squares were equally good whether obtained by Eq. 1 or by Eq. 2. The sums of squares obtained by Eq. 1 were always lower than those calculated from Eq. 3a but only by small amounts, and none of the s_{yx}^2 ratios exceeded the critical F values with (3,3) degrees of freedom.

The derivation of Eq. 3a (10) is based on an assumption (16) that the thickness of a tablet will decrease steadily as it disintegrates. This assumption usually is not the case since swelling initially will cause an increase in thickness. Even if the basis for the derivation of Eq. 3a may not be general, Eq. 3a as shown provides a good trial function. However, Eq. 1 will be used in the remainder of this article.

Correlation between Disintegration and Dissolution—The data in Table I concerning the values of K and d are plotted in Fig. 6. It is graphically evident that there is a correlation and that this correlation is not linear. Many curvilinear functions may fit this curve, one of which ($r = 0.97$) is $\ln[(300 - 10^5 k)] = -0.214 \times 10^3 d + 6.4$. This function is consistent with the theoretical models proposed elsewhere (5–8, 10). At high d values, K should become independent of d (7), and this result probably is the explanation for the curving off at high d values.

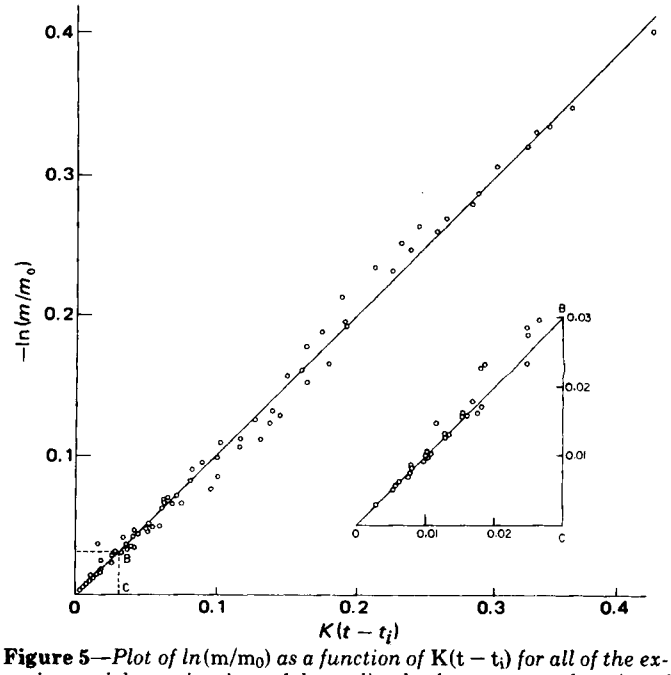

Figure 5—*Plot of* $\ln(m/m_0)$ *as a function of* $K(t - t_i)$ *for all of the experimental determinations of the undissolved amount as a function of time.*

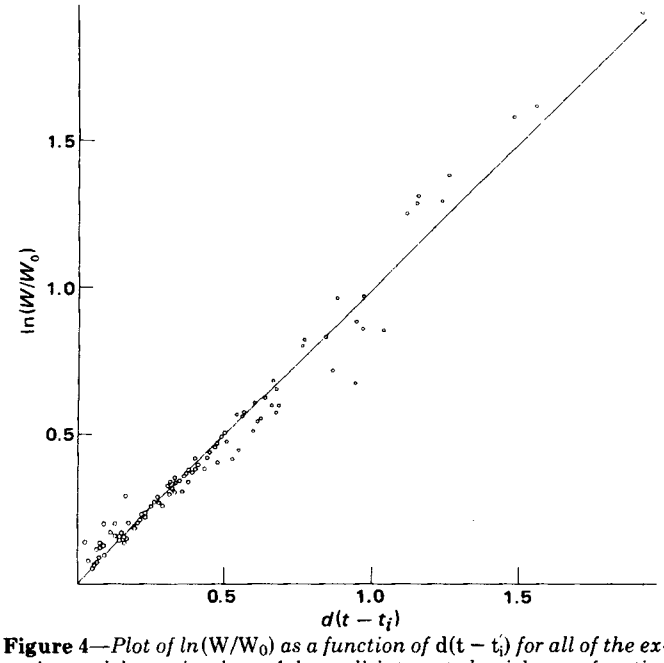

Figure 4—*Plot of* $\ln(W/W_0)$ *as a function of* $d(t - t_i)$ *for all of the experimental determinations of the undisintegrated weight as a function of* t.

Effect of Shaft Length—Table I shows that position II gave significantly ($p > 0.995$) higher results than did position I as far as both disintegration and dissolution are concerned. Since disintegration affects dissolution [$K = f(d)$], it is speculated that the change in disintegration is caused by the longer shaft length and that this effect is the cause for the observed differences.

Effect of Temperature—The logarithm of the disintegration constants, d, is plotted *versus* the reciprocal temperature in Fig. 7. The

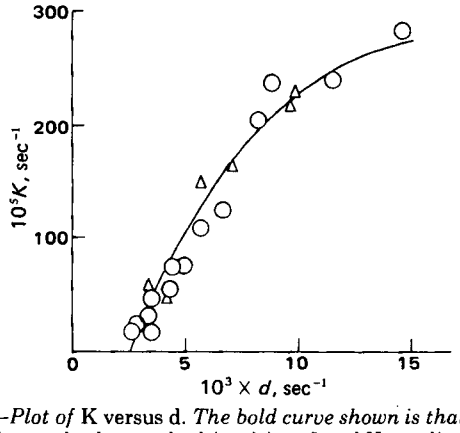

Figure 6—*Plot of* K versus d. *The bold curve shown is that expressed in Eq. 3. Key:* ○, *basket method (positions I and II not distinguished); and* △, *paddle method (positions I and II not distinguished).*

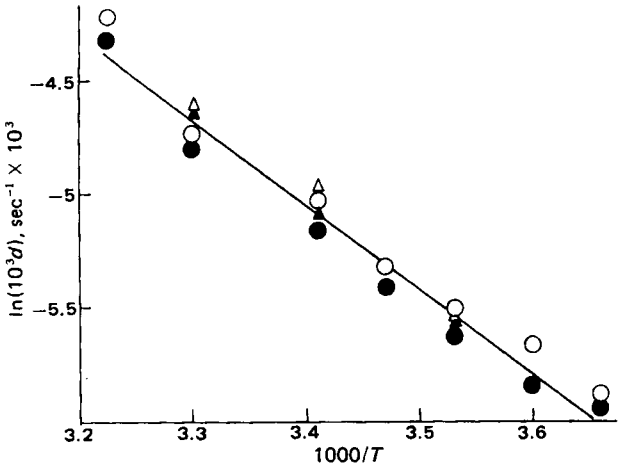

Figure 7—*Temperature dependence of the disintegration constant, d (seconds^{-1}). Key: O, USP basket method; and Δ, USP paddle method. Solid circles are position I, and open circles are position II.*

least-squares equation for the line is:

$$\ln d = -(7000/R)(1/T) - 0.0152 \quad \text{(Eq. 4)}$$

According to previous investigators (12–14), the disintegration of a tablet proceeds *via* two principal mechanisms: (*a*) penetration of liquid into the tablet pores, and (*b*) expansion of the disintegrant exposed in the pore walls. A large pore size facilitates penetration; but if it is too large, the expansion of the disintegrant will not cause sufficient strain to rupture the tablet (12, 17). Therefore, either mechanism or both simultaneously may be the rate-controlling step.

If the rate-controlling process is solely the penetration of pores of a radius *r*, then, as shown previously (12, 18, 19), the length of liquid penetration, *L*, into the capillaries is time dependent according to:

$$L^2 = (r\gamma \cos\theta)/(2\eta)t = q^2t \quad \text{(Eq. 5)}$$

where:

$$q = [r\gamma \cos\theta/(2\eta)]^{1/2} \quad \text{(Eq. 6)}$$

and where γ is the interfacial tension between the liquid and the solid, η is the viscosity, and θ is the contact angle.

If the amount penetrated disintegrates in a certain length of time, t^*, after the time of wetting and if the radius of the tablet is L_0 cm initially, then the weight remaining after t sec would be given by (20, 21):

$$W/W_0 = (L_0 - L)^3/L_0^3 \quad \text{(Eq. 7)}$$

Inserting Eq. 7 into Eq. 5 gives (21):

$$[1 - (W/W_0)^{1/3}]^2 = (q/L_0)^2(t - t^*) \quad \text{(Eq. 8)}$$

Data treated similarly are shown in Table III, and it is apparent that the equation does not hold. However, the model is simple, and more complicated relations could be visualized. But if *d*, the disintegration constant, is related more closely to the volume rate of penetration, then *d* would be expected to be linearly related to q^3, *i.e.*:

$$\ln d = 1.5 \ln(\gamma) + 1.5 \ln(\cos\theta) - 1.5 \ln(\eta) + Q \quad \text{(Eq. 9)}$$

where *Q* is a temperature-independent term.

Table III—Data from Table II Treated by Eq. 8

t, sec	100 (W/W_0), Experimental, %	$[1 - (W/W_0)^{1/3}]^2$	$\widetilde{100(W/W_0)}$, Predicted, %	Δ^2, %^{2}
30	92.1	0.00073	—[a]	—[a]
60	81.8	0.0042	78.7	9.6
90	71.1	0.0116	68.4	7.3
120	63.2	0.0201	61.5	2.9
150	54.3	0.0339	56.2	3.6
				$\Sigma\Delta^2 = 23.4$

[a] Least-squares parameters predicts a negative number for $[1 - (W/W_0)^{1/3}]^2$ at $t = 30$ sec. The least-squares fit was $[1 - (W/W_0)^{1/3}]^2 = 0.000274t - 0.01059$ with $r^2 = 0.95$ and $s^2_{yx} = 23.4/2 = 11.7\%^2$.

The dependence of θ on T is slight (22, 23) as shown. Stepanov *et al.* (24) gave θ values of water on sapphire of:

$$\theta = 8.8 + 8.2 \times 10^{-15}T^6 \quad \text{(Eq. 10)}$$

i.e., $\theta = 11.5$ [or $\ln(\cos\theta) = -0.0206$] at $T = 273°$ ($1/T = 0.00366$) and $\theta = 15.1$ [or $\ln(\cos\theta) = -0.0351$] at $T = 303°$ ($1/T = 0.00333$). On metals, θ decreased with temperature to the same extent (25). Linear Eq. 10 when expressed as $\ln(\cos\theta)$ as a function of $1/T$ is approximately as follows.

For sapphire:

$$\ln(\cos\theta) = 44(1/T) - 0.18 \quad \text{(Eq. 11}a\text{)}$$

For metals:

$$\ln(\cos\theta) = -44(1/T) + 0.13 \quad \text{(Eq. 11}b\text{)}$$

Hence, the activation energy, *E*, is negligible (-88 cal/mole $< E <$ 88 cal/mole). Equations 11*a* and 11*b* are approximations (but acceptable ones) of the experimental Eq. 10. No data exist for the θ values on the tablet matrix used, but it is expected to have a temperature dependence between that of an ionic and that of a covalently bonded surface.

The surface tension, γ, is dependent on temperature by the Ramsay–Shields rule (26):

$$\gamma(M/\rho)^{2/3} = k'(T_c - T - 6) \quad \text{(Eq. 12)}$$

where *M* is the molecular weight, ρ is the density, T_c is the critical temperature of the liquid, and k' is a constant (which equals about 2.1 for liquids that follow Trouton's rule). Since the critical temperature of water is high, γ is virtually temperature independent.

The dependence of viscosity on temperature is given by (25, 26):

$$\ln\eta = (4000/R)(1/T) + \ln\eta_0 \quad \text{(Eq. 13)}$$

This quantity is the only temperature-dependent term in Eq. 9, and it contributes substantially. Equation 9, when Eq. 13 is inserted, becomes:

$$\ln d = (6000/R)(1/T) + Q' \quad \text{(Eq. 14)}$$

where Q' is a nearly temperature-independent term. The slope predicted in Eq. 14 (3000) is on the same order as that found in Eq. 4. Therefore, the data in this case are not contradictory to the disintegration process as being penetration controlled.

Antitumor Agents XLI: Effects of Eupaformosanin on Nucleic Acid, Protein, and Anaerobic and Aerobic Glycolytic Metabolism of Ehrlich Ascites Cells

I. H. HALL ˣ, K. H. LEE, W. L. WILLIAMS, Jr., T. KIMURA, and T. HIRAYAMA

Received August 8, 1979, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication October 16, 1979.

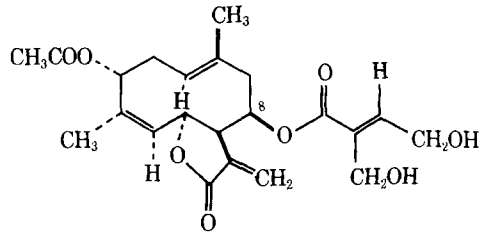
Abstract □ The major effect of eupaformosanin as an antineoplastic agent on Ehrlich ascites cell metabolism was to inhibit deoxyribonucleic acid synthesis, specifically at deoxyribonucleic acid polymerase and thymidylate synthetase enzymatic sites. Both pyrimidine and purine systems of Ehrlich ascites were marginally inhibited. Ribonucleic acid synthesis and messenger and ribosomal polymerase activities also were suppressed. Cyclic adenosine monophosphate levels were increased significantly, which correlated with the drastic reduction of histone phosphorylation. Eupaformosanin also suppressed a number of glycolytic and Krebs cycle enzymes as well as oxidative phosphorylation *in vitro*. All of the inhibited enzymes are known thiol-bearing enzymes that can undergo a Michael-type addition with the α-methylene-γ-lactone moiety of eupaformosanin, as shown with other sesquiterpene lactones.

Keyphrases □ Antitumor agents—eupaformosanin, effect on nucleic acid, protein, and anaerobic and aerobic glycolytic metabolism, Ehrlich ascites cells □ Eupaformosanin—antitumor activity, effect on nucleic acid, protein, and anaerobic and aerobic glycolytic metabolism, Ehrlich ascites cells □ Deoxyribonucleic acid synthesis, inhibitors—eupaformosanin, effect on nucleic acid, protein, and anaerobic and aerobic glycolytic metabolism, Ehrlich ascites cells

A new germacranolide, eupaformosanin (I), has been isolated from the whole plant of *Eupatorium formosanum*, and its stereochemistry and physical characteristics were reported previously (1). As an antineoplastic agent, eupaformosanin is a potent inhibitor of Walker 256 carcinosarcoma cell proliferation at 2.5 mg/kg/day (T/C = 471) and of P-388 lymphocytic leukemia cell proliferation at 25 mg/kg/day (T/C = 147) (2). The effects of eupaformosanin on nucleic acid, chromatin protein, purine, pyrimidine, and protein metabolism, anaerobic and aerobic glycolysis, and oxidative phosphorylation of Ehrlich ascites tumor cells are reported here.

EXPERIMENTAL

Male CF_1 mice, ~30 g, were implanted intraperitoneally on Day 0 with 10^6 Ehrlich ascites tumor cells from donor mice housed in these laboratories. Eupaformosanin suspended by homogenization in 0.05% polysorbate 80–water was administered intraperitoneally at 25 mg/kg/day for 8 days to determine the inhibition of tumor growth (3). For the metabolic studies, mice were treated on Days 7–9 with a subacute dose of 0.25 mg ip. Animals were sacrificed on Day 10, and the ascites fluid was collected from the peritoneal cavity. *In vitro* metabolic studies were determined on untreated, harvested, Day 10 Ehrlich ascites cells. The number of tumor cells per milliliter and the 0.4% trypan blue uptake were determined with a hemocytometer (4).



I

Incorporation of thymidine into deoxyribonucleic acid was determined by the method of Chae *et al.* (5). One hour prior to the animal sacrifice, 10 μCi of [^{14}C-*methyl*]-thymidine[1] (53.2 mCi/mmole) was injected intraperitoneally. The deoxyribonucleic acid was isolated, and the carbon-14 content was determined in two parts of toluene, one part of octoxynol, 0.4% 2,5-diphenyloxazole, and 0.01% 1,4-bis[2-(5-oxazolyl)]-benzene scintillation fluid and corrected for quenching. The deoxyribonucleic acid concentration was determined by UV spectrophotometry at 260 nm with calf thymus deoxyribonucleic acid as a standard.

Uridine incorporation into ribonucleic acid was determined in an analogous manner utilizing 10 μCi of 5-^{3}H-uridine (20.0 Ci/mmole). Ribonucleic acid was extracted by the method of Wilson *et al.* (6). Leucine incorporation into protein was determined by the method of Sartorelli (7) using 8 μCi of 1-^{14}C-leucine (54.4 mCi/mmole). The effect of eupaformosanin on 1-^{14}C-acetic acid (57.8 mCi/mmole) incorporation into cholesterol of Ehrlich ascites cells also was measured (8, 9).

Nuclear deoxyribonucleic acid polymerase activity was determined on isolated nuclei (10). The incubation medium was that of Sawada *et al.* (11), except that [^{3}H-*methyl*]-deoxyribothymidine-5′-triphosphate (53.1 mCi/mmole) was used and the insoluble nucleic acids were collected on glass fiber paper (GF/F) by vacuum suction. Deoxythymidine and deoxythymidylate monophosphate and diphosphate kinase activities were determined by the method of Maley and Ochoa (12), which is based on the disappearance of 0.1 μmole of reduced nicotinamide adenine dinucleotide at 340 nm.

Thymidine synthetase activity was assayed by the method of Kampf *et al.* (13) utilizing a postmitochondrial supernate (9000×*g* for 10 min) and 5 μCi of 5-^{3}H-deoxyuridine monophosphate (11 Ci/mmole). Mes-

senger, ribosomal, and hormone-sensitive ribonucleic acid polymerase activity were determined by the methods of Anderson *et al.* (14) and Hall *et al.* (15). Variation of ammonium sulfate concentrations was used to measure the respective type of ribonucleic acid polymerase. Insoluble ribonucleic acid was collected on nitrocellulose fiber paper by vacuum suction.

Phosphorylation of histones was determined by injecting intraperitoneally 10 μCi of γ-^{32}P-adenosine triphosphate (30.0 Ci/mmole) 1 hr prior to sacrifice. The nuclei were isolated (10), and the histone chromatin protein was extracted by the method of Raineri *et al.* (16). Nonhistone chromatin phosphorylation by nuclear protein kinase (17) was assayed utilizing 2 nmoles of γ-^{32}P-adenosine triphosphate (30.0 Ci/mmole). Chromatin protein was collected on nitrocellulose filter membranes. The effect of eupaformosanin on hydrolytic enzymes also was determined. Deoxyribonuclease activity was measured at pH 5.0 by a modification of the de Duve method (18). Ribonuclease activity and acid cathepsin activity were determined at pH 5.0 by the method of Cho-Chung and Gullino (19).

^{14}C-Formate incorporation into purine was measured by the method of Spassova *et al.* (20) using 0.5 μCi of ^{14}C-formic acid (4.95 mCi/mmole). Separation of purines was carried out on silica gel TLC plates eluted with *n*-butanol–acetic acid–water (4:1:5). The plates were scraped, and the radioactive content was determined. Phosphoribosyl–pyrophosphate amino transferase activity was determined by the method of Wyngaarden and Ashton (21), which is based on the reduction of 0.6 μmole of nicotinamide adenine dinucleotide at 340 nm. Carbamyl phosphate synthetase acitivity was determined with ornithine and ornithine transcarbamylase present by the method of Kalman *et al.* (22).

The colorimetric determination of citrulline was performed according to the method of Archibald (23). Aspartate carbamyl transferase activity was assessed by the method of Kalman *et al.* (22) in the presence of aspartate transcarbamylase. The colorimetric determination of carbamyl aspartate was carried out according to the method of Koritz and Cohen (24). Dihydrofolate reductase activity was determined by the procedure of Ho *et al.* (25), which is based on the disappearance of 0.1 μmole of reduced nicotinamide adenine dinucleotide phosphate at 340 nm. *S*-Adenosyl methionine transferase activity was determined by the method of Borchardt *et al.* (26) utilizing 0.05 μCi of [^{14}C-*methyl*]-*S*-adenosyl-L-methionine (53 mCi/mmole). Ribonucleotide reductase activity was determined by the method of Moore and Hurlbert (27) using 5-^{3}H-cytidine-5-diphosphate (26.1 Ci/mmole).

Cyclic-3′,5′-adenosine monophosphate levels were determined by the method of Gilman (28) using a ^{3}H(G)-adenosine-3′,5′-cyclic phosphate (39.8 Ci/mmole) radioimmunoassay.

UV binding studies (4) were conducted *in vitro* with eupaformosanin (85 μg/ml) with deoxyribonucleic acid or deoxyguanosine monophosphate (38 μg/ml) in 0.1 *M* phosphate buffer, pH 7.2, over a range of 200–340 nm for 24 hr at 22°.

The following *in vitro* glycolytic and Krebs cycle enzymatic activities were determined both for controls and in the presence of 1 μmole of eupaformosanin: hexokinase (29), phosphofructokinase (30), lactic dehydrogenase (31), glucose-6-phosphate dehydrogenase (32), glyceraldehyde-3-phosphate dehydrogenase (33), glucose-6-phosphatase (34), fructose-1,6-diphosphatase (35), malic dehydrogenase (36), succinic dehydrogenase (37), and adenosine phosphatase (38). *In vitro* effects of eupaformosanin on Ehrlich ascites tumor cell oxidative phosphorylation were measured in the presence and absence of adenosine diphosphate utilizing succinate, a flavin adenine dinucleotide-linked dehydrogenase, and α-ketoglutarate, a nicotinamide adenine dinucleotide-linked dehydrogenase (39). The inorganic phosphate was determined by the method of Chen *et al.* (40). The protein content for all assays was determined by the method of Lowry *et al.* (41).

Probable (*p*) significant differences were determined by the Student *t* test. Data are expressed in Tables I and II as percent of the control with standard deviations; *n* equals the number of animals per group.

RESULTS

Daily administration of eupaformosanin resulted in 97% inhibition of Ehrlich ascites tumor growth. The normal number of Ehrlich ascites cells per milliliter on Day 10 was 223 × 10^{6}. Eupaformosanin treatment at a subacute dose of 0.25 mg (12.5 mg/kg) on Days 7–9 reduced the cell count by 82%. Drug treatment resulted in no significant difference in the percentage of nonviable cells or in the size or general morphology of the cell as observed by light microscopy.

For the control animals, the thymidine incorporation into deoxyribonucleic acid was 241,675 dpm/mg of deoxyribonucleic acid. Drug treatment inhibited deoxyribonucleic acid synthesis by 76% (Table I). Uridine incorporation into ribonucleic acid for Day 10 Ehrlich ascites cells was 92,489 dpm/mg of ribonucleic acid. Eupaformosanin treatment reduced ribonucleic acid synthesis by an average of 23%. Leucine incorporation into protein for the control was 2484 dpm/mg of protein, which was not affected by drug treatment. Acetic acid incorporation into cholesterol for membrane synthesis for the control was 273,271 dpm/mg of protein. Drug treatment reduced cholesterol synthesis by 59%.

[a] p = 0.001. [b] p = 0.025. [c] p = 0.005.

In vitro studies of the binding of eupaformosanin with deoxyribonucleic acid and deoxyguanosine monophosphate demonstrated that eupaformosanin possessed a maximum absorption peak at 230 nm. Combination with nucleic acids increased the absorption at 230 nm, indicating nonspecific binding. Untreated Day 10 Ehrlich ascites cells demonstrated a change in absorbance for thymidine kinase activity of 1.328 optical density units/hr/mg of protein. Thymidylate monophosphate kinase activity was 1.361 optical density units/hr/mg of protein, and thymidylate diphosphate kinase activity was 2.100 optical density units/hr/mg of protein. Eupaformosanin treatment had little effect on the kinase activities, with only a 12% reduction of thymidylate monophosphate kinase activity. Nuclear deoxyribonucleic acid polymerase activity, *i.e.*, alpha, beta, and gamma, for the control was 45,734 dpm/mg of nucleoprotein, which was reduced 42% by drug treatment.

^{14}C-Formate incorporation into purines for Day 10 Ehrlich ascites cells was 17,088 dpm/mg of protein, which was reduced 34% by drug therapy. Phosphoribosyl–pyrophosphate amino transferase activity for the control resulted in an absorption increase at 340 nm of 0.376 optical density unit/min/mg of protein based on 0.75 μmole of nicotinamide adenine dinucleotide, which was significantly reduced 13% by eupaformosanin. Dihydrofolate reductase activity for the control was 0.514 optical density unit/hr/mg of protein, which was unaffected by eupaformosanin treatment. *S*-Adenosyl-L-methionine transferase activity for the Day 10 Ehrlich ascites cells was 3268 dpm/mg of protein, which was suppressed 9% by drug treatment. Carbamyl phosphate synthetase activity for the control was 0.128 mg of carbamyl phosphate formed/hr/mg of protein,

Table II—*In Vitro* Effects of Eupaformosanin on Anaerobic and Aerobic Metabolism of Ehrlich Ascites Cells ($n = 6$)

Parameter	Percent Control: Control (0.05% Polysorbate 80), $\bar{x} \pm SD$	Percent Control: Treated on Days 7–9 with Eupaformosanin, $\bar{x} \pm SD$

which was inhibited 27% by eupaformosanin treatment. Aspartate carbamyl transferase activity for the Day 10 Ehrlich ascites cells was 6.245 mg of carbamyl aspartate formed/hr/mg of protein, which was suppressed 23% by eupaformosanin.

Thymidylate synthetase activity for the control was 103,328 dpm/mg of protein, which was reduced 31% by drug treatment. Ribonucleotide reductase activity for the control was 155,065 dpm/mg of protein, which eupaformosanin reduced by 11%. Messenger ribonucleic acid polymerase activity for the control was 6434 dpm/mg of protein, ribosomal ribonucleic acid polymerase activity was 7340 dpm/mg of protein, and hormone-sensitive polymerase activity was 8254 dpm/mg of protein. Eupaformosanin reduced messenger activity by 31% and ribosomal activity by 27% and elevated hormone-sensitive polymerase activity by 183%. The cyclic adenosine monophosphate level for the control was 3.65 pmoles/10^6 cells, whereas the level rose by 152% after drug treatment. Histone phosphorylation of chromatin protein was at a rate of 2954 dpm/mg of chromatin protein, which was reduced 60% by eupaformosanin treatment. Nonhistone phosphorylation of chromatin protein was at a rate of 9803 dpm/mg of chromatin protein, which was inhibited 10% by drug treatment.

The catabolic rate of nucleic acids and proteins also was determined to eliminate the possibility that the drug accelerated hydrolytic enzymatic activity and thus indirectly lowered the incorporation of precursors into nucleic acids and proteins. Deoxyribonuclease activity for Day 10 Ehrlich ascites cells was 247 μg of deoxyribonucleic acid hydrolyzed/hr/mg of protein, which was inhibited 27% by eupaformosanin treatment. Ribonuclease activity for the control tumor cells was 43 μg of ribonucleic acid hydrolyzed/hr/mg of protein, which was unaffected by eupaformosanin. Cathepsin activity for the control was 869 μg of protein hydrolyzed/hr/mg of protein, which was unchanged by drug therapy.

Hexokinase activity for the control Ehrlich ascites tumor cells was calculated as a change in absorbance equal to 0.195 optical density unit/min/mg of protein based on 500 μmoles of nicotinamide adenine dinucleotide phosphate, which was suppressed 15% by 1 μmole of eupaformosanin *in vitro* (Table II). Phosphofructokinase activity for the control was a change of 0.176 optical density unit/min/mg of protein based on 1.125 μmoles of reduced nicotinamide adenine dinucleotide, which was reduced 75% by eupaformosanin presence. Lactic dehydrogenase activity resulted in an optical density unit change of 0.623/min/mg of protein based on 0.12 μmole of reduced nicotinamide adenine dinucleotide, which eupaformosanin reduced by 57%. Glyceraldehyde dehydrogenase activity for the control was 2.623 optical density units/min/mg of protein based on 20.3 μmoles of nicotinamide adenine dinucleotide, which was suppressed 65% by the drug.

Glucose-6-phosphate dehydrogenase activity for the control was 0.284 optical density unit/min/mg of protein based on the presence of 0.0056 μmole of nicotinamide adenine dinucleotide phosphate. Eupaformosanin inhibited this dehydrogenase activity by 97%. Glucose-6-phosphatase activity for the control was 20.15 μg of phosphorus released/hr/mg of protein, which was suppressed 28% by the drug treatment. Fructose-1,6-diphosphatase activity for the control was 24.87 μg of phosphorus released/hr/mg of protein, which was reduced 41% by eupaformosanin. Malic dehydrogenase activity for Day 10 Ehrlich ascites cells was 0.80 optical density unit/min/mg of protein, which was reduced 74% by the drug. Succinic dehydrogenase activity for the control was 0.069 optical density unit/min/mg of protein based on 15 μmoles of potassium ferricyanide, which eupaformosanin suppressed by 89%. Adenosine triphosphatase activity measured as inorganic phosphate released for the control was 17.02 μg of phosphorus hydrolyzed/hr/mg of protein. The presence of eupaformosanin resulted in no change in enzymatic activity.

The basal respiration (state 4) of Day 10 Ehrlich ascites tumor cells with succinate as the substrate was 5.273 μl of oxygen consumed/hr/mg of protein. In the presence of adenosine diphosphate (state 3), stimulated respiration on coupled oxidative phosphorylation was 8.725 μl of oxygen consumed/hr/mg of protein. Eupaformosanin inhibited state 4 and state 3 respiration by 31%. Use of α-ketoglutarate as a substrate resulted in a state 4 respiration of 3.569 μl of oxygen consumed/hr/mg of protein and in a state 3 respiration of 5.156 μl of oxygen consumed/hr/mg of protein. Eupaformosanin inhibited state 4 respiration by 48% and state 3 respiration by 47%.

DISCUSSION

Eupaformosanin administration significantly lowered deoxyribonucleic acid and cholesterol synthesis, whereas ribonucleic acid synthesis was only moderately inhibited in Day 10 Ehrlich ascites cells. One possible explanation of the reduction of radiolabeled precursor into these macromolecules is that drug treatment accelerated catabolism of macromolecules. However, treatment with eupaformosanin did not accelerate hydrolytic enzymatic activity responsible for the catabolism of these macromolecules; rather, the drug moderately reduced deoxyribonuclease activity and had no effect on ribonucleic and cathepsin activities at pH 5.0.

The major site of eupaformosanin inhibition of deoxyribonucleic acid synthesis was on the deoxyribonucleic acid polymerase nuclei enzymes, whereas thymidylate synthetase activity appeared to be reduced moderately. Purine synthesis also was inhibited, but the major site did not appear to be at the regulatory enzyme of the cycle, *i.e.*, phosphoribosylpyrophosphate amino transferase, which was only slightly inhibited. Pyrimidine synthesis was moderately inhibited at the carbamyl phosphate synthetase and aspartate carbamyl transfer steps. *S*-Adenosyl-L-methionine transferase and ribonucleotide reductase activity also were slightly inhibited.

It was demonstrated previously that compounds containing the O=CC=CH_2 system can undergo a rapid Michael-type addition with biological nucleophiles, *e.g.*, sulfhydryl groups (4). Both α- and γ-deoxyribonucleic acid polymerase of the nucleus (42), thymidylate synthetase (43), aspartate carbamyl transferase (44), and ribonucleotide reductase (44) possess exposed sulfhydryl groups which can be alkylated. Contained in the structure of eupaformosanin is the O=CC=CH_2 system both as an α-methylene-γ-lactone and within the C-8 ester side chain. The α-methylene-γ-lactone moiety undergoes a rapid Michael-type addition with L-cysteine and reduced glutathione (4, 45). A similar phenomenon occurs with the sesquiterpene lactones helenalin and tenulin (4, 45) and the germacranolide eupahyssopin (46).

Cellular proliferation is regulated by phosphorylation of chromatin histones, *e.g.*, the F-1 fraction by protein kinase (47). This effect occurs predominantly during G_1 and early S of the cell cycle, when cyclic adenosine monophosphate levels are decreasing and enzymes are synthesized for nucleic acid replication. Eupaformosanin treatment significantly inhibited phosphorylation of histone chromatin protein and increased the intracellular level of cyclic adenosine monophosphate levels in Day 10 Ehrlich ascites cells. The latter effect is associated with reversal of tumor morphology (48), reduced cellular proliferation, and enhanced cellular differentiation (49, 50).

The UV spectral studies suggest that eupaformosanin interacts with deoxyribonucleic acid. The fact that messenger ribonucleotide polymerase activity also was suppressed by drug treatment may indicate that the transcription processes utilizing deoxyribonucleic acid as a template were impaired. The inhibition of purine and pyrimidine nucleotide synthesis is not the reason why messenger and ribosomal ribonucleic acid polymerase activities are inhibited since triphosphate ribonucleotides were added to the medium. Hormone-sensitive ribonucleotide polymerase may be elevated due to the elevated level of cyclic adenosine monophosphate, a modulator of this polymerase (15).

Compounds containing the α-methylene-γ-lactone moiety inhibit

enzymes of the Embden–Meyerhof and Krebs cycles (35, 51–53). Eupaformosanin inhibited phosphofructokinase and lactic acid dehydrogenase significantly and hexokinase marginally *in vitro*. These enzymes contain sulfhydryl groups (35, 51–53) that can be alkylated by the O=CC=CH_2 moiety. Enzymes involved in reversed glycolysis, *e.g.*, glucose-6-phosphatase and fructose-1,6-diphosphatase, were inhibited significantly by eupaformosanin, as was observed previously with other germacranolides (46) and pseudoguaianolides (35). The regulatory enzyme of the hexose monophosphate shunt, glucose-6-phosphate dehydrogenase, was reduced drastically by eupaformosanin. Succinic and malic dehydrogenase activities were suppressed significantly *in vitro*. Dehydrogenases of the Krebs cycle contain sulfhydryl groups in the enzymes and iron inorganic sulfide flavin proteins as integral components of the dehydrogenase enzymes (54). Theoretically, this group also can be alkylated.

Eupaformosanin suppressed basal respiration and coupled oxidative phosphorylation or mitochondrial adenosine triphosphate synthesis *in vitro*, and this suppression was not due to an accelerated adenosine triphosphatase activity brought about by the presence of the drug. The drug inhibited respiration with α-ketoglutarate, a nicotinamide adenine dinucleotide-linked dehydrogenase that contains an iron–sulfur center (55) more than with succinate, which is a flavin adenine dinucleotide-linked enzyme. Numerous antitumor agents inhibit respiration and oxidative phosphorylation of Ehrlich ascites cells (56) including other sesquiterpene lactones (2).

Model-Independent Method of Analyzing Input in Linear Pharmacokinetic Systems Having Polyexponential Impulse Response I: Theoretical Analysis

PETER VENG PEDERSEN

Received September 22, 1978, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication October 11, 1979.

Abstract □ A rigorous treatment of linear compartmental systems is presented, which allows the input rate of drugs into the systemic circulation to be evaluated without assuming a specific kinetic model. The method allows the input to be evaluated in the presence or absence of any combination of intravenous bolus input and infusion input. Only data for the blood drug concentration are required; there are no requirements for specific sampling times. Applications of the equations are given in several examples. The input rate is evaluated with data obtained from a disposition experiment involving an intravenous bolus or zero-order infusion input and an experiment involving the input to be evaluated. The two experiments can be merged so that the input can be evaluated without a washout period between the two drug administrations. The equations also enable model-independent calculations of the optimal drug input control that produces any desirable drug concentration profile. The approach is a useful deconvolution method for any linear pharmacokinetic system where the impulse response can be approximated by a polyexponential expression.

Keyphrases □ Pharmacokinetic models, linear—model-independent method of input analysis, derivation of equations for linear compartmental systems, blood drug levels, polyexponential impulse response □ Blood drug levels—model-independent method of input analysis, linear pharmacokinetic model □ Models, pharmacokinetic—derivation of equations for linear compartmental systems, model-independent method of input analysis

The study of drug input plays such a fundamental role in biopharmaceutics that it has been suggested that biopharmaceutics be defined as the science of drug input (1). Numerous methods of evaluating the pharmacokinetics of drug input have been suggested (2–14), and they can be divided into model-dependent and model-independent methods.

The model-dependent methods assume a specific model for drug input (*e.g.*, first-order or zero-order input) and a specific model for drug disposition (*e.g.*, one- or multiple-compartment models). The blood profile of the drug is analyzed according to the model equation and the specific input parameter(s) that are determined graphically or by a regression technique (15). These methods often do not give a reliable estimate of the input kinetics because they are defined too specifically with respect to drug disposition and because the input is considered to be a simple process that can be described in simple mathematical terms (*e.g.*, zero- and first-order input).

With the many variables affecting the input, particularly in oral administration, it seems unlikely that the input can be approximated well in such simple terms. Nevertheless, it is not uncommon to have good agreement between such model equations and drug level data, as judged by goodness-of-fit when the equations are fitted to the data. However, the good fit may be explained by an inherent flexibility of the equations used. The equations are derived based on a model for the input and a model for the drug disposition. If the input model is wrong, the flexibility of the equation used may compensate for this error in that the disposition parameters in the iterative curve-fitting procedure take values that do not reflect the disposition but provide a good fit. Therefore, it is not uncommon when using model-dependent methods to obtain parameter values of unrealistic magnitude, even when the curve fitting is satisfactory.

Certain methods partly eliminate this problem by combining information about the drug's disposition, obtained from separate intravenous bolus or infusion data, with data resulting from the input to be evaluated. Among these methods are the deconvolution methods (9–14), which have the additional advantage of not assuming a model for the input.

This paper presents a novel method of input analysis; it is applicable to systems with central input and to certain systems with noncentral input. The method is model independent in that it does not assume any specific disposition model. The method enables an unknown input to be evaluated quantitatively in the presence or absence of any combination of intravenous bolus and infusion input. The method requires only blood drug level data with no special requirements for sampling times.

BACKGROUND

Drug input in a subject is studied most accurately by following the blood concentration–time profile. The aim of this theoretical analysis is to derive a suitable method for analyzing blood profiles to quantitate an unknown input.

The total input in the sampleable compartment is the sum of two kinds of input: the primary and the secondary. The primary input is the input into the sampleable compartment of those drug molecules that arrive there for the first time. The secondary input is the input into the sampleable compartment of those drug molecules that previously have been present there. The primary input, the object of this analysis, is of interest for bioavailability studies and for the evaluation of drug delivery systems. The secondary input encompasses ordinary back-transfer from reversible distributions between the sampleable compartment and other compartments, as well as previously presented cyclic processes (recycling) (16).

The present method uses two fundamental properties of linear response systems: the superposition property and the convolution integral property. These properties can be verified only for a known input, *i.e.*, an input made directly into the sampleable compartment. However, the primary input to be evaluated is not a direct input, so it is necessary to assume or verify that the primary input is noninteracting. It must not change the basic linear response property of the system that is evaluated from a direct input but is used to calculate an indirect input.

This requirement is basic for any model-independent and most model-dependent approaches. Its importance cannot be emphasized enough since several factors in the first-pass transfer of a drug may cause a significant interaction. Little attention has been given to this issue. The justification of linear pharmacokinetic principles in drug absorption studies often has been limited to verification of the superposition property. However, it is equally important to test for interaction, *e.g.*, by comparing the concentration profiles of a labeled drug introduced directly into the sampleable compartment in the absence and in the presence of absorption of the unlabeled drug.

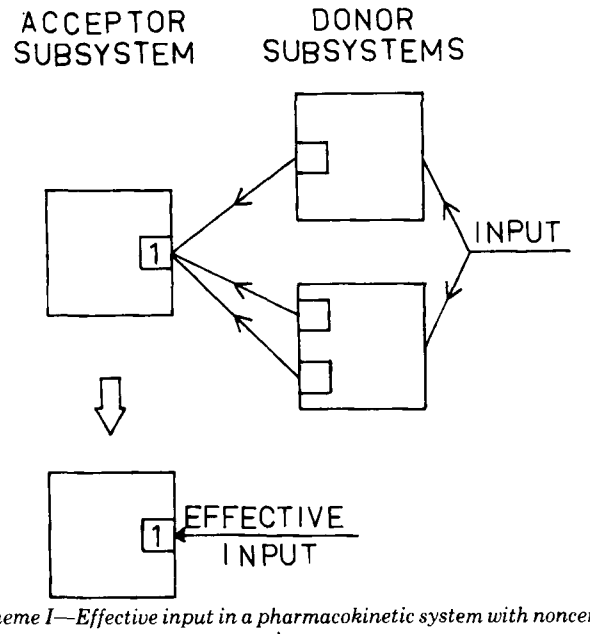

Scheme I—Effective input in a pharmacokinetic system with noncentral input

In the context of the classical linear compartmental systems discussed previously (16), a noninteracting input is either a direct input or an input reaching the sampleable compartment from one or more irreversibly connected donor subsystems (Scheme I).

The following theoretical analysis shows how a noninteracting primary input (subsequently to be referred to as the input) can be rigorously evaluated (blood = sampleable compartment) when blood level data from a known input such as an intravenous bolus or zero-order infusion input are available. The input may be of any linear or nonlinear kinetic form. Although the analysis forms a link to classical linear compartmental pharmacokinetics (16), it is not limited to such systems. The analysis applies to any linear response system where the unit impulse response is appropriately approximated by a polyexponential function with real and/or complex (conjugate) time coefficients.

In the context of compartmental principles (16), the method allows the kinetic processes in irreversibly connected donor subsystems to be of any nonlinear form. In the context of general linear system theory, the method allows individual kinetic processes to be of nonlinear form as long as the total effect of all of the processes results in an approximately linear input–response relationship.

THEORY

In a general treatment of linear compartmental pharmacokinetics, the following matrix–vector equation was presented (16):

$$\mathbf{x} = L^{-1}(\mathbf{Dv}) \qquad \text{(Eq. 1)}$$

where x_i, the ith component of the vector $\mathbf{x}$, is the amount in the ith compartment at time t; and v_i, the ith component of the input vector $\mathbf{v}$, is the sum of the initial amount in the ith compartment and the Laplace transform of the external input rate (*i.e.*, not coming from other compartments) into the ith compartment.

The disposition is defined uniquely by the disposition matrix, **D**. The operator L^{-1} denotes the inverse Laplace transform operator. In the case of central input only, the amount in the central compartment is given by:

$$x_1 = L^{-1}(d_{11}v_1) \qquad \text{(Eq. 2)}$$

where d_{11} is the 1,1 element of the disposition matrix. When a generalized function approach is used in the mathematical analysis, continuous and discontinuous input can be superimposed so that the central input, $v_1(t)$, is written as:

$$v_1(t) = f(t) + f_{bol}(t) + f_{inf}(t) \qquad \text{(Eq. 3)}$$

where $f(t)$ is the unknown input rate to be determined and $f_{bol}(t)$ and $f_{inf}(t)$ are the known bolus input rate and the infusion input rate, respectively. It is most accurate to determine $f(t)$ in the absence of other input. However, this may not always be possible. The following treatment enables $f(t)$ to be determined in the presence or absence of bolus and infusion input.

The bolus input component of Eq. 3 is described in terms of the unit impulse function or Dirac delta function, $\delta(t)$, by:

$$f_{bol}(t) = \sum_{i=1}^{R} q_i\delta(t - \tau_i) \qquad R = 1,2,..,N \qquad \text{(Eq. 4)}$$

where q_i is the quantity of the ith intravenous bolus, τ_i is the time for the ith bolus injection, R is the highest integer for which $\tau_R < t$ is satisfied, and N is the number of bolus inputs. If $\tau_R < t$ cannot be satisfied for any R, then R is defined as zero. Therefore, the right side of Eq. 4 becomes zero by definition. The Laplace transform (bars denote transformed functions) of Eq. 3 is:

$$\bar{v}_1(s) = \bar{f}(s) + \sum_{i=1}^{N} q_i e^{-\tau_i s} + \bar{f}_{inf}(s) \qquad \text{(Eq. 5)}$$

so that Eq. 2 can be written as:

$$c(t) = V^{-1}L^{-1}\left[d_{11}\bar{f}(s) + d_{11}\sum_{i=1}^{N} q_i e^{-\tau_i s} + d_{11}\bar{f}_{inf}(s)\right] \qquad \text{(Eq. 6)}$$

where the conversion from the amount, x_1, to the concentration, $c(t)$, has been done by the central volume term, V. The concentration profile following a single initial intravenous bolus input is:

$$c^*(t) = V^{-1}L^{-1}(d_{11}q^*) \qquad \text{(Eq. 7)}$$

where * distinguishes between the separate intravenous bolus experiment and the input experiment in further derivations. The transforms of Eqs. 6 and 7 are, respectively:

$$\bar{c}(s) = V^{-1}\left[d_{11}\bar{f}(s) + d_{11}\sum_{i=1}^{N} q_i e^{-\tau_i s} + d_{11}\bar{f}_{inf}(s)\right] \qquad \text{(Eq. 8)}$$

$$\bar{c}^*(s) = V^{-1}d_{11}q^* \qquad \text{(Eq. 9)}$$

When $d_{11} = V\bar{c}^*(s)/q^*$ from Eq. 9 is substituted into Eq. 8, Eq. 8 becomes:

$$\bar{c}(s) = \frac{1}{q^*}\left[\bar{c}^*(s)\bar{f}(s) + \bar{c}^*(s)\sum_{i=1}^{N} q_i e^{-\tau_i s} + \bar{c}^*(s)\bar{f}_{inf}(s)\right] \qquad \text{(Eq. 10)}$$

Therefore, the transform of the input rate can be written as:

$$\bar{f}(s) = \frac{\bar{g}(s)}{\bar{c}^*(s)} \qquad \text{(Eq. 11)}$$

where:

$$\bar{g}(s) = q^*\bar{c}(s) - \bar{c}^*(s)\sum_{i=1}^{N} q_i e^{-\tau_i s} - \bar{c}^*(s)\bar{f}_{inf}(s) \qquad \text{(Eq. 12)}$$

To facilitate a suitable solution of Eq. 11, it can be written as:

$$\bar{f}(s) = s\{[s\bar{g}(s)]\bar{h}(s)\} \qquad \text{(Eq. 13)}$$

where:

$$\bar{h}(s) = s^{-2}\bar{c}^*(s)^{-1} \qquad \text{(Eq. 14)}$$

Since $vg(0) = 0$, it follows that:

$$L^{-1}[s\bar{g}(s)] = g'(t) \qquad \text{(Eq. 15)}$$

It will be shown later that $c^*(t)$ has a functional form such that $L^{-1}[s^{-2}\bar{c}^*(s)^{-1}]$ exists. Thus, according to the convolution theorem, Eq. 13 can be transformed to:

$$f(t) = \frac{d}{dt}\int_0^t g'(u)h(t - u)du \qquad \text{(Eq. 16)}$$

According to the Leibnitz rule, Eq. 16 can be written as:

$$f(t) = \int_0^t g'(u)h'(t - u)du + g'(t)h(0) \qquad \text{(Eq. 17)}$$

Integrating by parts and noting that $g(0) = 0$, Eq. 17 becomes:

$$f(t) = h'(0)g(t) + h(0)g'(t) + \int_0^t g(u)h''(t - u)du \qquad \text{(Eq. 18)}$$

Equation 18 forms the basis for further deviations, leading to a final, more specific expression for the input, $f(t)$. The following sections deal with

the problem of deriving specific expressions for $h(0)$, $h'(0)$, $g(0)$, $g'(t)$, and $h''(t)$ in Eq. 18.

If the system has distinct eigenvalues, then the impulse response is given by:

$$c^*(t) = \sum_{i=1}^{n} a_i e^{\lambda_i t} \qquad \text{(Eq. 19)}$$

so that:

$$\bar{c}^*(s) = \sum_{i=1}^{n} \frac{a_i}{s - \lambda_i} \qquad \text{(Eq. 20)}$$

The relationship between the macroparameters in Eq. 19, the coefficient matrix, and the fundamental matrix of the compartmental system is given in the *Appendix*.

According to Eq. 20, Eq. 14 can be written as:

$$\bar{h}(s) = s^{-2}\left[\sum_{i=1}^{n} \frac{a_i}{s - \lambda_i}\right]^{-1} \qquad \text{(Eq. 21)}$$

so that, according to the initial value theorem and L'Hôspital's rule, $h(0)$ in Eq. 18 is:

$$h(0) = \lim_{s \to \infty} s\bar{h}(s) = \left[\sum_{i=1}^{n} a_i\right]^{-1} \qquad \text{(Eq. 22)}$$

Similarly, it can be shown that:

$$h'(0) = \lim_{s \to \infty} s\bar{h'}(s) = \lim_{s \to \infty} [s^2 h(s) - sh(0)] = -\frac{\sum_{i=1}^{n} a_i \lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} \qquad \text{(Eq. 23)}$$

The $h(t)$ function can be written, according to Eq. 21, as:

$$h(t) = L^{-1} \frac{\prod_{i=1}^{n} (s - \lambda_i)}{s^2 \sum_{i=1}^{n} a_i \prod_{\substack{j=1 \\ \neq i}}^{n} (s - \lambda_j)} \qquad \text{(Eq. 24)}$$

where the numerator and denominator are polynomials of nth and $(n + 1)$th degree, respectively. Therefore, according to Heaviside's expansion theorem, Eq. 24 can be written as:

$$h(t) = A_1 t + A_2 + \sum_{i=1}^{n-1} E_i e^{\beta_i t} \qquad \text{(Eq. 25)}$$

where A_1 and A_2 are functions of $\{a_i, \lambda_i\}_1^n$ only and the $\{\beta_i\}_1^{n-1}$ are the roots of the $(n - 1)$th degree polynomial:

$$Q(s) = \sum_{i=1}^{n} a_i \prod_{\substack{j=1 \\ \neq i}}^{n} (s - \lambda_j) \qquad \text{(Eq. 26)}$$

The $\{E_i\}_1^{n-1}$ terms in Eq. 25 are given by:

$$E_\nu = \left.\frac{\prod_{i=1}^{n} (s - \lambda_i)}{\frac{d}{ds}\left[s^2 \sum_{i=1}^{n} a_i \prod_{\substack{j=1 \\ \neq i}}^{n} (s - \lambda_j)\right]}\right|_{s = \beta_\nu} \qquad \text{(Eq. 27)}$$

which leads to:

$$E_\nu = \frac{\prod_{i=1}^{n} (\beta_\nu - \lambda_i)}{2\beta_\nu \sum_{i=1}^{n} a_i \prod_{\substack{j=1 \\ \neq i}}^{n} (\beta_\nu - \lambda_j) + \beta_\nu^2 \sum_{i=1}^{n} a_i \sum_{\substack{j=1 \\ \neq i}}^{n} \prod_{\substack{m=1 \\ \neq i \text{and} j}}^{n} (\beta_\nu - \lambda_m)} \qquad \text{(Eq. 28)}$$

The first term in the denominator of Eq. 28 is equal to zero, according to the property of β_ν since $Q(\beta_\nu) = 0$ (Eq. 26). Therefore, after further simplification, Eq. 28 can be written as:

$$E_\nu = \left[\beta_\nu^2 \sum_{i=1}^{n} \frac{a_i}{\beta_\nu - \lambda_i} \sum_{\substack{j=1 \\ \neq i}}^{n} \frac{1}{\beta_\nu - \lambda_j}\right]^{-1} \qquad \text{(Eq. 29)}$$

For further simplification in later derivations, it is convenient to introduce $b_\nu = \beta_\nu^2 E_\nu$ so that:

$$b_\nu = \left[\sum_{i=1}^{n} \frac{a_i}{\beta_\nu - \lambda_i} \sum_{\substack{j=1 \\ \neq i}}^{n} \frac{1}{\beta_\nu - \lambda_j}\right]^{-1} \qquad \text{(Eq. 30)}$$

According to Eq. 25, h'' in Eq. 18 is given by:

$$h''(t - u) = \sum_{i=1}^{n-1} \beta_i^2 E_i e^{\beta_i t} e^{-\beta_i u} = \sum_{i=1}^{n-1} b_i e^{\beta_i t} e^{-\beta_i u} \qquad \text{(Eq. 31)}$$

By substituting $h''(t - u)$, $h'(0)$, and $h(0)$, as given by Eqs. 31, 23, and 21, respectively, into Eq. 18, this equation becomes:

$$f(t) = -\frac{\sum_{i=1}^{n} a_i \lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} g(t) + \frac{g'(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t g(u) e^{-\beta_i u}\, du \qquad \text{(Eq. 32)}$$

This equation can also be written:

$$f(t) = -\frac{\sum_{i=1}^{n} a_i \lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} g(t) + \frac{g'(t)}{\sum_{i=1}^{n} a_i} + z(t)^* g(t) \qquad \text{(Eq. 33)}$$

where:

$$z(t) = \sum_{i=1}^{n-1} b_i e^{\beta_i t} \qquad \text{(Eq. 34)}$$

and $z(t)^*g(t)$ is the convolution of $z(t)$ and $g(t)$.

The $g(t)$ function remains to be derived and substituted into Eq. 32 to yield the final expression for the input rate, $f(t)$. The $g(t)$ function is obtained as the inverse transform of Eq. 12. It is useful to partition $g(t)$ into a basic component, a bolus component, and an infusion component, according to their origin in Eq. 12, so that it can be written as:

$$g(t) = g_0(t) - g_{bol}(t) - g_{inf}(t) \qquad \text{(Eq. 35)}$$

where:

$$g_0(t) = q^* c(t) \qquad \text{(Eq. 36)}$$

$$g_{bol}(t) = L^{-1}\left[\bar{c}^*(s) \sum_{i=1}^{N} q_i e^{-\tau_i s}\right] \qquad \text{(Eq. 37)}$$

$$g_{inf}(t) = L^{-1}[\bar{c}^*(s)\bar{f}_{inf}(s)] \qquad \text{(Eq. 38)}$$

When each of the three components of $g(t)$ is substituted for $g(t)$ in Eq. 32, this substitution leads to three corresponding components of $f(t)$:

$$f(t) = U_0(t) - U_{bol}(t) - U_{inf}(t) \qquad \text{(Eq. 39)}$$

where $U_0(t)$ is the basic function, and $U_{bol}(t)$ and $U_{inf}(t)$ are the bolus corrector function and the infusion corrector function, respectively, because these functions are subtracted from the basic function if the unknown input rate, $f(t)$, is evaluated in the presence of bolus or infusion input.

The basic function, $U_0(t)$, is obtained by substituting q*c(t) for $g(t)$ in Eq. 32, which yields:

$$U_0(t) = q^*\left[-\frac{\sum_{i=1}^{n} a_i \lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} c(t) + \frac{c'(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t c(u) e^{-\beta_i u}\, du\right] \qquad \text{(Eq. 40)}$$

According to Eq. 20, Eq. 37 can be written as:

$$g_{bol}(t) = \sum_{m=1}^{R} q_m \sum_{j=1}^{n} a_j e^{\lambda_j (t - \tau_m)} \qquad \text{(Eq. 41)}$$

which, when substituted for $g(t)$ in Eq. 32, yields:

$$\begin{aligned} U_{bol}(t) = &-\frac{\sum_{i=1}^{n} a_i \lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} \sum_{m=1}^{R} q_m \sum_{j=1}^{n} a_j e^{\lambda_j (t - \tau_m)} \\ &+ \frac{\sum_{m=1}^{R} q_m \sum_{j=1}^{n} a_j \lambda_j e^{\lambda_j (t - \tau_m)}}{\sum_{i=1}^{n} a_i} \\ &+ \sum_{m=1}^{R} q_m \sum_{i=1}^{n-1} b_i \sum_{j=1}^{n} \frac{a_j}{\lambda_j - \beta_i} e^{\lambda_j (t - \tau_m)} \\ &- \sum_{m=1}^{R} q_m \sum_{i=1}^{n-1} b_i e^{\beta_i (t - \tau_m)} \sum_{j=1}^{n} \frac{a_j}{\lambda_j - \beta_i} \end{aligned} \qquad \text{(Eq. 42)}$$

The last two terms of Eq. 42 are obtained from:

$$\sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t \left[\sum_{m=1}^{R} q_m \sum_{j=1}^{n} a_j e^{\lambda_j(u-\tau_m)}\right] e^{-\beta_i u}\, du$$

$$= \sum_{m=1}^{R} q_m \sum_{i=1}^{n-1} b_i \sum_{j=1}^{n} \frac{a_j}{\lambda_j - \beta_i} e^{\lambda_j(t-\tau_m)}$$

$$- \sum_{m=1}^{R} q_m \sum_{i=1}^{n-1} b_i e^{\beta_i(t-\tau_m)} \sum_{j=1}^{n} \frac{a_j}{\lambda_j - \beta_i} \quad \text{(Eq. 43)}$$

It can be shown that the sum of the first three terms of Eq. 42 is zero[1]:

$$-\frac{\sum_{i=1}^{n} a_i\lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} \sum_{m=1}^{R} q_m \sum_{j=1}^{n} a_j e^{\lambda_j(t-\tau_m)} + \frac{\sum_{m=1}^{R} q_m \sum_{j=1}^{n} a_j\lambda_j e^{\lambda_j(t-\tau_m)}}{\sum_{i=1}^{n} a_i}$$

$$+ \sum_{m=1}^{R} q_m \sum_{i=1}^{n-1} b_i \sum_{j=1}^{n} \frac{a_j}{\lambda_j - \beta_i} e^{\lambda_j(t-\tau_m)} = 0 \quad \text{(Eq. 44)}$$

The fact that the last term of Eq. 42 also equals zero is seen from the innermost summation term, which can be written as:

$$\sum_{j=1}^{n} \frac{a_j}{\lambda_j - \beta_i} = -\frac{\sum_{j=1}^{n} a_j \prod_{\substack{m=1 \\ \neq j}}^{n} (\beta_i - \lambda_m)}{\prod_{j=1}^{n} (\beta_i - \lambda_j)} \quad \text{(Eq. 45)}$$

It is apparent from Eq. 26 and the property of β_i that this term is zero because:

$$\sum_{j=1}^{n} a_j \prod_{\substack{m=1 \\ \neq j}}^{n} (\beta_i - \lambda_m) = Q(\beta_i) = 0 \quad \text{(Eq. 46)}$$

Therefore, the right side of Eq. 42 is zero; *i.e.*, the bolus correction function is zero:

$$U_{bol}(t) = 0 \quad \text{(Eq. 47)}$$

Therefore, the input, $f(t)$ (Eq. 39), can be evaluated in the presence of the bolus input without any correction.

Equation 38 can be written according to Eq. 9 as:

$$g_{inf}(t) = q^* \frac{L^{-1}[d_{11}\bar{f}_{inf}(s)]}{V} \quad \text{(Eq. 48)}$$

According to Eq. 2, the term $L^{-1}[d_{11}\bar{f}_{inf}(s)]/V$ is the blood level, $c_{inf}(t)$, resulting from the infusion input, $f_{inf}(t)$, so Eq. 48 can be written as:

$$g_{inf}(t) = q^* c_{inf}(t) \quad \text{(Eq. 49)}$$

The infusion correction function, $U_{inf}(t)$, is obtained by substituting $g_{inf}(t)$ for $g(t)$ in Eq. 32, which gives:

$$U_{inf}(t) = q^* \times \left[-\frac{\sum_{i=1}^{n} a_i\lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} c_{inf}(t) + \frac{c'_{inf}(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t c_{inf}(u) e^{-\beta_i u}\, du\right] \quad \text{(Eq. 50)}$$

If the infusion input, $f_{inf}(t)$, is considered an unknown input to be evaluated in the absence of other inputs, then by substituting $c_{inf}(t)$ for $c(t)$ in Eq. 40, $f_{inf}(t)$ is given by:

$$f(t) = f_{inf}(t) = U_0(t) = q^* \left[-\frac{\sum_{i=1}^{n} a_i\lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} c_{inf}(t) + \frac{c'_{inf}(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t c_{inf}(u) e^{-\beta_i u}\, du\right] \quad \text{(Eq. 51)}$$

[1] The derivations that show that Eq. 44 holds for $n \geq 1$ are extensive. They are omitted because they are not crucial for understanding the theoretical approach.

By comparing Eqs. 50 and 51, it follows that:

$$U_{inf}(t) = f_{inf}(t) \quad \text{(Eq. 52)}$$

Thus, the infusion correction function is the rate of infusion input. Analogous to Eqs. 48 and 49, it is seen that $g_{bol}(t) = q^* c_{bol}(t)$, where $c_{bol}(t)$ is the drug level resulting from bolus input only. From Eq. 47, it follows that when $c_{bol}(t)$ is substituted for $c(t)$ in Eq. 40, the basic function becomes zero.

To unify these findings in a simple way, it is useful to define the input-generating function, ψ:

$$\psi[c(t)] = q^* \left[-\frac{\sum_{i=1}^{n} a_i\lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} c(t) + \frac{c'(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t c(u) e^{-\beta_i u}\, du\right] \quad \text{(Eq. 53)}$$

This function generates the input from the drug level profile, $c(t)$. It is evident from above that the input-generating function has the following remarkable properties:

$$\psi[c_{bol}(t)] = 0 \qquad t \neq \tau_i \quad \text{(Eq. 54)}$$

$$\psi[c_{inf}(t)] = f_{inf}(t) \quad \text{(Eq. 55)}$$

$$\psi[c(t)] = f(t) + f_{inf}(t) \qquad t \neq \tau_i \quad \text{(Eq. 56)}$$

Equation 54 states that there is no drug input between the bolus input in an experiment only involving bolus input. Equation 56 states that the input-generating function generates the sum of all nonbolus input. Independent of any bolus input, the drug input rate therefore is given by the input-generating function corrected for the rate of superimposed intravenous infusion input that may or may not be present:

$$f(t) = \psi[c(t)] - f_{inf}(t) \qquad t \neq \tau_i \quad \text{(Eq. 57)}$$

which is rewritten as:

$$f(t) = q^* \left[-\frac{\sum_{i=1}^{n} a_i\lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} c(t) + \frac{c'(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t c(u) e^{-\beta_i u}\, du\right] - f_{inf}(t) \qquad t \neq \tau_i \quad \text{(Eq. 58)}$$

RESULTS AND DISCUSSION

If the eigenvalues of the A matrix are distinct, then the impulse response function always is given by Eq. 19. Systems with cyclic structures may give rise to complex conjugate eigenvalues. However, the method still can be applied. An eigenvalue is either zero, due to a subsystem being closed, or is functionally related to the dynamic processes. The input analysis deals with the transport and transition dynamics of drug molecules in a fairly random state. Consequently, nonzero eigenvalues show a stochastic behavior; therefore, the statistical probability of two nonzero eigenvalues being equal is zero.

It is evident that the rank of the coefficient matrix for a closed system is full rank minus one and that a lower rank than that contradicts the randomness condition. Therefore, in an applied (*i.e.*, not theoretical) closed system, there is one and only one zero eigenvalue. Open applied systems are of full rank with no zero eigenvalues (17). The eigenvalues for any applied linear compartmental system are distinct and give rise to a unit impulse response as given by Eq. 19. Therefore, the method of analysis is applicable to any applied linear compartmental system. However, the method is not applicable to every theoretical linear compartmental system because of the possibility of nondistinct eigenvalues, which would result in an equation different from Eq. 19.

The method also could have been derived from the linear system theory for linear systems, where the impulse response can be approximated by a polyexponential expression. As such, it represents a new deconvolution approach. The present derivation method is valuable because it forms a link between classical pharmacokinetics and the linear system approach,

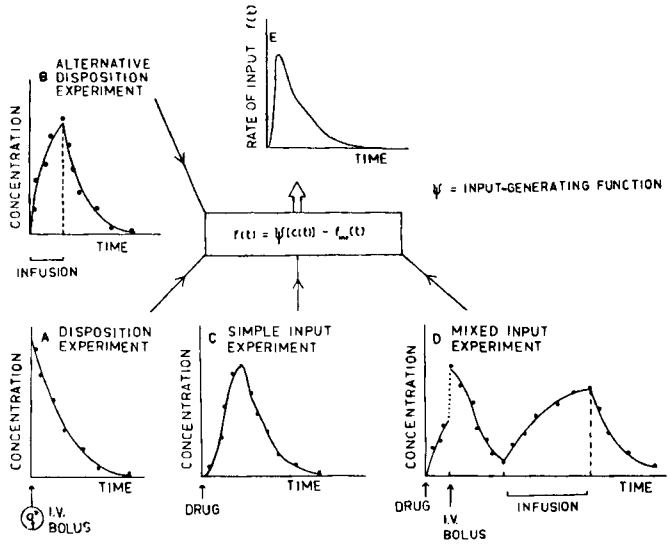

Figure 1—*Summary of model-independent approach of evaluating the drug input rate. The drug is given intravenously either as an initial bolus, q* (A), or alternatively as a zero-order infusion (B) to a subject as a nonprecipitating solution. Equation 19 or Eqs. 75 and 76 are fitted to the respective drug concentration data to give the parameters* $\{a_i, \lambda_i\}_1^n$ *and q* (A and B). The rate of drug input into the blood from a drug delivery system can be evaluated in the same subject in the absence of other input (C) or in the presence of any combination of intravenous bolus and infusion input (D). An appropriate arbitrary function,* c(t) *(e.g., a least-squares spline function), is fitted to the data from the input experiment (C and D). The rate of input is calculated from the parameters* $\{a_i, \lambda_i\}_1^n$, q*, *and the drug level profile,* c(t), *according to the input-generating function and corrected for any superimposed infusion input (E).*

thereby enabling classical pharmacokinetics to be analyzed in a new context.

The input rate can be determined quantitatively in the absence or presence of any combination of intravenous bolus input and infusion input.

The procedure for the evaluation of an input rate is mathematically defined by Eqs. 19, 26, 30, and 58. These equations are used as follows. Equation 19 is fitted to the drug level data from a single intravenous bolus input, q^*, to give $\{a_i, \lambda_i\}_1^n$ (Fig. 1A). If $n > 1$, these parameters are inserted into Eq. 26 to give the auxiliary parameters, $\{\beta_i\}_1^{n-1}$, which when subsequently inserted into Eq. 30 give another set of auxiliary parameters, $\{b_i\}_1^{n-1}$. An arbitrary function is fitted to the drug level data from the input to be evaluated (Fig. 1C). The arbitrary function is denoted briefly as $c(t)$ in the derivations. Since both b and β are functions of $\{a_i, \lambda_i\}_1^n$, only q^*, $\{a_i, \lambda_i\}_1^n$, and $c(t)$ are required to calculate $f(t)$ from Eq. 58. The input-generating function, ψ, is uniquely defined from the disposition experiment by the parameters q^* and $\{a_i, \lambda_i\}_1^n$.

Which arbitrary function, $c(t)$, is chosen to estimate the true drug level profile depends on the accuracy of the data and their general shape as well as any assumptions made about the variation and smoothness of the input process. The method by which a chosen function is fitted to the data should relate to assumptions made about the statistical properties of the errors in the data. For a fairly smooth input process, the best general choice of a function seems to be a weighted or unweighted least-squares spline function. Such a function is particularly suitable because of its smoothness, great flexibility, and optimal properties in estimating the rate of change [the $c'(t)$ term in Eq. 58] and the fact that it readily describes the disturbance(s) caused by bolus input (Fig. 1D). Due to the linear nature of the parameters defining the spline function, it also has desirable computational and statistical properties (18, 19).

If the drug level data are sampled frequently and are not too erratic, then a fitting of an ordinary polynomial may be quite appropriate. To avoid bias in the estimation of the drug level and to avoid an erratic behavior of the first derivative, it has been suggested that the degree of polynomial fitted by least squares should not exceed two times the square root of the number of data points (20). Use of exponential expressions for $c(t)$ can be troublesome because of the problem of getting initial parameter estimates and because of the computational problems associated with nonlinear curve fitting (21). If the drug levels range over several orders of magnitude, it is recommended that a logarithmic transformation or other suitable transformation be applied to the data before the curve fitting (22).

Although Eq. 58 involves an integral, no computational problems should be caused in the evaluation of $f(t)$ since the functions likely to be used for $c(t)$, such as spline functions, ordinary polynomials, and exponential expressions, lead to simple algebraic expressions without an integral that can be evaluated readily and exactly. Although the equations used to calculate $f(t)$ may seem complex, their use is straightforward.

Example 1, $n = 1$—This example represents a drug that behaves in a subject, following a single intravenous bolus, q^*, according to a one-compartment model so the intravenous bolus blood level data are described by:

$$c^*(t) = ae^{\lambda t} \qquad \text{(Eq. 59)}$$

The equation necessary for calculating the input rate of the drug administered to the same subject is simplified in this case with $n = 1$, since the summation term involving a summation to $i = n - 1$ is zero by definition. Thus, in the absence of intravenous infusion input, the input rate is given by:

$$f(t) = \frac{q^*}{a}[c'(t) - \lambda c(t)] \qquad \text{(Eq. 60)}$$

It is of interest to compare this equation with the Wagner–Nelson model-independent method of evaluating the absorption rate in a one-compartment system. The Wagner–Nelson equation is (15):

$$A_t = V\left[c(t) + K\int_0^t c(t)dt\right] \qquad \text{(Eq. 61)}$$

so that:

$$dA_t/dt = V[c'(t) + Kc(t)] \qquad \text{(Eq. 62)}$$

where A_t is the amount absorbed between time zero and time t and K is the first-order elimination rate constant. Since $dA_t/dt = f(t)$, $K = -\lambda$ and $V = q^*/a$, Eq. 62 can be written the same as Eq. 60. Therefore, for $n = 1$, the input-generating function reduces to an expression that is essentially identical to the Wagner–Nelson equation.

Example 2, $n = 2$—In this case, the intravenous bolus data are described by:

$$c^*(t) = a_1e^{\lambda_1 t} + a_2e^{\lambda_2 t} \qquad a_i > 0, \lambda_i < 0 \qquad \text{(Eq. 63)}$$

Equation 26 is used to obtain the auxiliary parameter, β_1:

$$Q(s) = a_1(s - \lambda_2) + a_2(s - \lambda_1) = (a_1 + a_2)s - (a_1\lambda_2 + a_2\lambda_1) \qquad \text{(Eq. 64)}$$

so that:

$$\beta_1 = \frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2} \qquad \text{(Eq. 65)}$$

The other auxiliary parameter, b_1, is obtained from β_1 using Eq. 30:

$$b_1 = \left[\frac{a_1}{(\beta_1 - \lambda_1)}\frac{1}{(\beta_1 - \lambda_2)} + \frac{a_2}{(\beta_1 - \lambda_2)}\frac{1}{(\beta_1 - \lambda_1)}\right]^{-1} = -\frac{a_1a_2(\lambda_1 - \lambda_2)^2}{(a_1 + a_2)^3} \qquad \text{(Eq. 66)}$$

The input-generating function then becomes:

$$\psi[c(t)] = q^*\left\{-\frac{a_1\lambda_1 + a_2\lambda_2}{(a_1 + a_2)^2}c(t) + \frac{c'(t)}{a_1 + a_2} - \frac{a_1a_2(\lambda_1 - \lambda_2)^2}{(a_1 + a_2)^3}\exp\left[\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}t\right] \times \int_0^t c(u)\exp\left[-\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}u\right]du\right\} \qquad \text{(Eq. 67)}$$

Example 3, $n = 3$— The intravenous bolus data are described by:

$$c^*(t) = a_1e^{\lambda_1 t} + a_2e^{\lambda_2 t} + a_3e^{\lambda_3 t} \qquad a_i > 0, \lambda_i < 0 \qquad \text{(Eq. 68)}$$

The $n - 1 = 2$ auxiliary parameters, β_1 and β_2, are obtained as the two roots of Eq. 26:

$$Q(s) = a_1(s - \lambda_2)(s - \lambda_3) + a_2(s - \lambda_1)(s - \lambda_3) + a_3(s - \lambda_1)(s - \lambda_2) \qquad \text{(Eq. 69)}$$

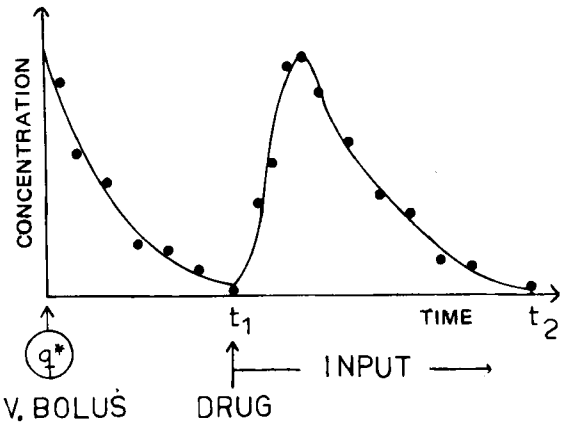

Figure 2—*Summary of input analysis based on a merged bolus and input approach. An initial intravenous bolus solution of the drug is given, and the drug level is followed for a sufficiently long time, t_1, to get proper estimates of $\{a_i, \lambda_i\}_1^n$ by fitting Eq. 19 to the drug level data for $0 < t \leq t_1$. Then, the drug delivery system is administered (t_1) and the drug level is followed for the appropriate length of time (t_2). The input rate is calculated from the input-generating function. The arbitrary function, c(t), fitted to the data must consist of Eq. 19 for the time period $0 < t \leq t_1$ and some other appropriate function (e.g., a least-squares spline function) for $t_1 < t \leq t_2$. This approach of input analysis is powerful because it does not require a washout period between the disposition and the input experiments and because errors arising from changes in the subject's drug disposition with time are reduced to a minimum by bringing the two drug administrations close together.*

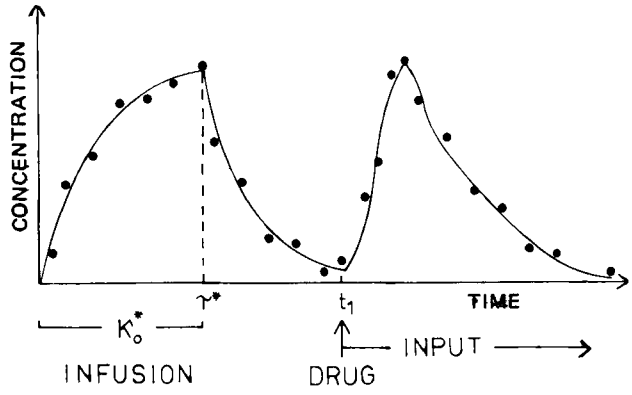

Figure 3—*Summary of input analysis based on a merged infusion and input approach. A zero-order (κ_0^*) infusion is given from $t = 0$ to $t = \tau^*$, and the drug level is allowed to drop to a proper level before the drug delivery system is administered at t_1. Equations 75 and 76 are fitted simultaneously to the data for $0 < t \leq \tau^*$ and $\tau^* < t \leq t_1$, respectively, to give the parameters $\{a_i, \lambda_i\}_1^n$ and q^*. The rate of drug input ($t > t_1$) is calculated from the input-generating function. The arbitrary function, c(t), must consist of Eq. 75 (with the estimated parameters) for $0 < t \leq \tau^*$, of Eq. 76 for $\tau^* < t \leq t_1$, and of some suitable function (e.g., a least-squares spline function) for $t > t_1$.*

so that:

$$Q(s) = [a_1 + a_2 + a_3]s^2 - [a_1(\lambda_2 + \lambda_3) + a_2(\lambda_1 + \lambda_3) + a_3(\lambda_1 + \lambda_2)]s + [a_1\lambda_2\lambda_3 + a_2\lambda_1\lambda_3 + a_3\lambda_1\lambda_2] \quad \text{(Eq. 70)}$$

The two other auxiliary parameters, b_1 and b_2, are obtained from Eq. 30:

$$b_1 = \left[\frac{a_1}{\beta_1 - \lambda_1}\left(\frac{1}{\beta_1 - \lambda_2} + \frac{1}{\beta_1 - \lambda_3}\right) + \frac{a_2}{\beta_1 - \lambda_2}\left(\frac{1}{\beta_1 - \lambda_1} + \frac{1}{\beta_1 - \lambda_3}\right) + \frac{a_3}{\beta_1 - \lambda_3}\left(\frac{1}{\beta_1 - \lambda_1} + \frac{1}{\beta_1 - \lambda_2}\right)\right]^{-1} \quad \text{(Eq. 71)}$$

so that:

$$b_1 = \frac{(\beta_1 - \lambda_1)(\beta_1 - \lambda_2)(\beta_1 - \lambda_3)}{(\beta_1 - \beta_2)(a_1 + a_2 + a_3)} \quad \text{(Eq. 72)}$$

and similarly:

$$b_2 = \frac{(\beta_2 - \lambda_1)(\beta_2 - \lambda_2)(\beta_2 - \lambda_3)}{(\beta_2 - \beta_1)(a_1 + a_2 + a_3)} \quad \text{(Eq. 73)}$$

The input-generating function is:

$$\psi[c(t)] = q^*\left[-\frac{a_1\lambda_1 + a_2\lambda_2 + a_3\lambda_3}{(a_1 + a_2 + a_3)^2}c(t) + \frac{c'(t)}{a_1 + a_2 + a_3} + b_1e^{\beta_1 t}\int_0^t c(u)e^{-\beta_1 u}\,du + b_2e^{\beta_2 t}\int_0^t c(u)e^{-\beta_2 u}\,du\right] \quad \text{(Eq. 74)}$$

where b_1, b_2, β_1, and β_2 are described in terms of $\{a_i, \lambda_i\}_1^2$.

Merged Bolus and Input Approach—The fact that the input-generating function automatically corrects for the disturbance in the drug level profile bolus input makes it particularly suitable for performing an input analysis in a single experiment. For example, it may be of interest to study the input rate from an oral administration. This study can be done by giving an initial intravenous bolus solution of the drug (Fig. 2) and following the drug profile for a sufficiently long time, t_1, to get proper estimates of $\{a_i, \lambda_i\}_1^n$ by fitting Eq. 19. Thereafter, the oral dosage form of the drug is administered and the drug level is followed for the appropriate length of time, t_2.

The input rate ($t > t_1$) is calculated from the input-generating function. The arbitrary function, $c(t)$, representing the data must consist of Eq. 19 for $0 < t \leq t_1$ and of some other appropriate function (*e.g.*, a least-squares spline function) for $t_1 < t \leq t_2$. This input analysis approach is powerful because it does not require a washout period between the disposition and the input experiments and because errors arising from changes in the subject's drug disposition with time are reduced to a minimum by bringing the two drug administrations close together.

Alternative Approach to Intravenous Bolus Input—It is assumed that the intravenous bolus administered to estimate $\{a_i, \lambda_i\}_1^n$ is given in a solution that does not precipitate on dilution with the blood so that it is available immediately to the systemic circulation. Some drugs may be so slightly soluble or so toxic that it is not feasible to administer an intravenous bolus dose to estimate $\{a_i, \lambda_i\}_1^n$. However, this study can be done by an alternative approach. It can be proven that if an intravenous bolus, q^*, produces a concentration profile in a linear pharmacokinetic system as described by Eq. 19, then the profile resulting from a zero-order (κ_0^*) infusion from $t = 0$ to $t = \tau^*$ in the same system is given by:

$$c_0^*(t) = \frac{\kappa_0^*}{q^*}\sum_{i=1}^{n}\frac{a_i}{\lambda_i}[e^{\lambda_i t} - 1] \qquad t \leq \tau^* \quad \text{(Eq. 75)}$$

and:

$$c_0^*(t) = \frac{\kappa_0^*}{q^*}\sum_{i=1}^{n}\frac{a_i e^{\lambda_i t}}{\lambda_i}[1 - e^{-\lambda_i \tau^*}] \qquad t > \tau^* \quad \text{(Eq. 76)}$$

Thus, q^* and $\{a_i, \lambda_i\}_1^n$ required for the calculation of the input rate are obtained by fitting Eqs. 75 and 76 to the infusion data.

Merged Infusion and Input Approach—The infusion disposition experiment can be merged with the input experiment by stopping the infusion after the proper length of time (τ^*, Fig. 3) and then letting the drug level drop to a proper level before the drug delivery system is administered (t_1, Fig. 3). The arbitrary function, $c(t)$, fitted to the data must consist of Eq. 75 (using the estimated parameters) for $0 < t \leq \tau^*$ and Eq. 76 for $\tau^* < t \leq t_1$ and an appropriate arbitrary function for the drug input interval $t > t_1$ (Fig. 3). The rate of drug input, $t > t_1$, is calculated from the input-generating function (without infusion correction). The rate of drug input, $t < t_1$, calculated according to Eq. 58 [with $f_{inf}(t) = \kappa_0^*$ for $0 < t < \tau^*$] is zero if the process has been correctly defined mathematically. This can be used to check the computations when the method is implemented on a computer.

Drug Input Control—Although the presented analysis is directed at a model-independent evaluation of drug input, it is equally applicable to control of drug input. Any desirable drug profile may be produced by a controlled intravenous input according to the equations presented. The application of the theory to model-independent optimized drug input is under investigation.

Although the equations used to calculate the input rate may appear complex, they are presented in a general form that readily allows them to be programmed and implemented on a computer. A general-purpose drug input analysis program can be developed from the equations presented. Ultimately, the investigator will need only to supply the blood level data and information about the experimental design, and the program will automatically compute and plot the drug input rate profile.

The practical application of the drug input analysis presented appears versatile and powerful. It provides some important tools for the evalua-

tion and design of drug delivery systems. In particular, it enables the rate and extent of drug bioavailability to be evaluated in a more intrinsic and accurate way than previous methods for linear systems with a polyexponential impulse response.

APPENDIX

The system of n linear differential equations describing the kinetics after an initial bolus input into a linear pharmacokinetic system is (16):

$$\mathbf{x}' = \mathbf{A}\mathbf{x} \qquad \text{(Eq. A1)}$$

where the square matrix **A** contains the first-order intercompartmental rate constants and the elimination rate constants (16). If the eigenvalues of **A** are distinct, then the solution of Eq. A1 is:

$$\mathbf{x} = \mathbf{P} \exp(t\mathbf{\Lambda})\mathbf{P}^{-1}\mathbf{x}(0) \qquad \text{(Eq. A2)}$$

where $\mathbf{\Lambda}$ is a diagonal matrix of the eigenvalues $\{\lambda_i\}_1^n$ of **A** and the columns of **P** are the corresponding eigenvectors.

From Eq. A2, the following equation is obtained:

$$x_i = \sum_{j=1}^{n} \Omega_{ij} e^{\lambda_j t} \qquad \text{(Eq. A3)}$$

where:

$$\Omega_{ij} = \mathbf{P}_{ij}[\mathbf{P}_{ij}^{-1}\mathbf{x}(0)]_j \qquad \text{(Eq. A4)}$$

An initial bolus input in the central compartment is described by $\mathbf{x}(0)^T = (q^*, 0, 0, \ldots, 0)$, which according to Eqs. A3 and A4 leads to:

$$c^*(t) = \sum_{j=1}^{n} \Omega_{1j} e^{\lambda_j t}/V \qquad \text{(Eq. A5)}$$

Thus, a_i in Eq. 19 is given by:

$$a_i = \Omega_{1i}/V = q^* \mathbf{P}_{1i}\mathbf{P}_{1i}^{-1}/V \qquad \text{(Eq. A6)}$$

Note that:

$$L^{-1}\mathbf{D} = \mathbf{\Phi}(t) = \mathbf{P} \exp(t\mathbf{\Lambda})\mathbf{P}^{-1} \qquad \text{(Eq. A7)}$$

where $\mathbf{\Phi}(t)$, introduced previously (16), is the fundamental matrix of the pharmacokinetic system.

NOTATIONS[2]

a_i = defined by Eq. 19
A_1, A_2 = defined by Eq. 25
A_t = amount absorbed between $t = 0$ and time t
A = coefficient matrix, Eq. A1
b_i = auxiliary parameter defined in terms of $\{a_i, \lambda_i\}_1^n$ by Eq. 30 (see β_i)
β_i = auxiliary parameter defined in terms of $\{a_i, \lambda_i\}_1^n$ by Eq. 26
$c(t)$ = arbitrary function(s) describing the drug concentration
$c^*(t)$ = function (Eq. 19) describing the drug concentration data following an initial intravenous bolus input, q^*
$c_0^*(t)$ = drug concentration resulting from a zero-order infusion starting at $t = 0$
$c_{bol}(t)$ = drug concentration resulting from one or more intravenous bolus input
$c_{inf}(t)$ = drug concentration resulting from continuous or discontinuous intravenous infusion input
d_{ij} = i-, jth element of disposition matrix **D**
D = disposition matrix
$\delta(t)$ = Dirac delta function
e = 2.71828 . . .
E_ν = expression defined by Eq. 27
$f(t)$ = rate of input to be evaluated (amount per unit of time)
$f_{bol}(t)$ = bolus input component
$f_{inf}(t)$ = rate of intravenous infusion input
$g(t)$ = function whose Laplace tranform is defined by Eq. 12
$g_{bol}(t)$ = bolus component of $g(t)$
$g_{inf}(t)$ = infusion component of $g(t)$
$g_0(t)$ = component of $g(t)$ corresponding to $f(t)$
$h(t)$ = function whose Laplace transform is defined by Eq. 16
i = index variable
j = index variable
K = first-order elimination constant in a one-compartment model
κ_0^* = zero-order infusion rate from $t = 0$ to $t = \tau^*$ used in the disposition experiment and in the merged infusion and input approach
λ_i = defined by Eq. 19, ith eigenvalue of matrix **A**
L, L^{-1} = Laplace and inverse Laplace transform operator
$\mathbf{\Lambda}$ = diagonal matrix defined by Eq. A3
m = index variable
n = defined by Eq. 19
N = number of bolus input
ν = index variable
p_{ij} = i-, jth element of the eigenvector matrix
$\mathbf{p}_i$ = ith column vector of the eigenvector matrix
P = eigenvector matrix defined by Eq. A2
π = product operator
q^* = bolus amount injected intravenously initially in the disposition experiment resulting in a drug level described by Eq. 19
q_i = ith bolus injected intravenously
$Q(s)$ = auxiliary function defining β_i (Eq. 26)
R = highest integer for which $\tau_R < t$ is satisfied or defined as zero if inequality cannot be satisfied
s = complex domain variable
t = time
t_1, t_2 = defined in Fig. 2
τ_i = time when the ith intravenous bolus is given
τ^* = time for zero-order infusion stop (Fig. 3)
$U_0(t)$ = basic function
$U_{bol}(t)$ = bolus corrector function
$U_{inf}(t)$ = infusion corrector function
v = input vector
v_1 = first element of input vector
V = constant with dimension of volume
x = vector containing the amounts in the n compartments at time t
x_1 = first element of vector **x**
y = vector defined by Eq. A6
$z(t)$ = auxiliary function defined in terms of $\{a_i, \lambda_i\}_1^n$ by Eq. 34 (see b_i and β_i)
$\Phi(t)$ = fundamental matrix of pharmacokinetic system
$\Psi[c(t)]$ = input-generating function

[2] Bars denote Laplace transforms, bold-faced capital letters denote matrixes, and bold-faced noncapital letters denote vectors.

Model-Independent Method of Analyzing Input in Linear Pharmacokinetic Systems Having Polyexponential Impulse Response II: Numerical Evaluation

PETER VENG PEDERSEN

Received September 22, 1978, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication October 11, 1979.

Abstract □ The investigated method is based on an exact mathematical solution to the deconvolution problem of linear pharmacokinetic systems with a polyexponential impulse response. The accuracy of the method is determined only by how well the curves fitted to the intravenous and absorption data represent the true drug level. Consequently, the method enables objective evaluation of the input. It permits the user to assess whether discrepancies in a calculated input are due to an improper data representation, as judged from the fitted curves, to the inherent nature of the data, or to a violation of the pharmacokinetic assumptions. The method is compared to another method using simulated data containing various degrees of random noise. The accuracy of the two methods was not significantly different and was of the same magnitude as the noise level of the data. The theoretical properties of the two methods and their expected performance in various pharmacokinetic situations are discussed. The method is applied to pentobarbital data from oral and intravenous administrations.

Keyphrases □ Pharmacokinetics—linear systems, polyexponential impulse response, analysis of input, model-independent method □ Model-independent analysis—linear pharmacokinetic systems, polyexponential impulse response, analysis of input □ Drug input—linear pharmacokinetic systems, polyexponential impulse response, analysis by model-independent method

A previous article (1) presented the theoretical derivation and analysis of a novel input analysis method. The method allows a drug input to be evaluated in the presence or absence of any combination of intravenous bolus input and infusion input. Three approaches were discussed: evaluation of the input rate based on a separate intravenous bolus experiment and an input (absorption) experiment, evaluation based on a merged intravenous bolus and input experiment, and evaluation based on a merged infusion and input experiment.

The present work is confined to the first approach and is based on an exact mathematical solution to the deconvolution problem of linear pharmacokinetic systems with a polyexponential impulse response. Several methods for deconvolution have been presented (2–5). The Wagner–Nelson method usually is limited to one-compartment systems (6), and the methods investigated by Benet and Chiang (2) were shown to be very sensitive to errors in the data. The numerical deconvolution method presented by Gamel *et al.* (3) did not provide satisfactory results, possibly due to numerical ill conditioning. Cutler (5) improved Gamel's approach by using orthogonal polynomials to avoid the problem of ill conditioning. The improved method seems to be the most accurate method for numerical deconvolution. It appears to be superior to the many model-dependent methods (6–10) because it is based on fewer assumptions and, therefore, is more likely to result in a meaningful evaluation of the drug input.

This work compares the new method with Cutler's approach using Cutler's simulated test data that contain various degrees of random noise (4, 5).

THEORY

Let the concentration of drug in the blood, $c^*(t)$, following an initial intravenous bolus dose, q^*, be described by a multiexponential relationship (1):

$$c^*(t) = \sum_{i=1}^{n} a_i e^{\lambda_i t} \qquad \text{(Eq. 1)}$$

Let $c(t)$ denote the drug level resulting from an unknown input of a drug that, in the same subject with the same linear relationship between input and response, results in the blood level $c^*(t)$ (Eq. 1) when an intravenous bolus dose, q^*, is given. It has been shown (1) that the rate of input of the drug then is given by:

$$f(t) = q^* \left[-\frac{\sum_{i=1}^{n} a_i \lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} c(t) + \frac{c'(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t c(u) e^{-\beta_i u}\, du \right] \qquad \text{(Eq. 2)}$$

where β_i, $i = 1, 2, \ldots, n-1$ are the roots of the $(n-1)$th-degree polynomial:

$$Q(x) = \sum_{i=1}^{n} a_i \prod_{\substack{j=1 \\ \neq i}}^{n} (x - \lambda_j) \qquad \text{(Eq. 3)}$$

and b_ν, $\nu = 1, 2, \ldots, n-1$ are obtained from:

$$b_\nu = \left[\sum_{i=1}^{n} \frac{a_i}{\beta_\nu - \lambda_i} \sum_{\substack{j=1 \\ \neq i}}^{n} \frac{1}{\beta_\nu - \lambda_j} \right]^{-1} \qquad \text{(Eq. 4)}$$

Integration of $f(t)$ from time zero to time t yields the cumulative amount of input:

$$A(t) = q^* \left[-\left\{ \frac{\sum_{i=1}^{n} a_i \lambda_i}{\left(\sum_{i=1}^{n} a_i\right)^2} + \sum_{i=1}^{n-1} \frac{b_i}{\beta_i} \right\} \int_0^t c(t)\, dt + \frac{c(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} \frac{b_i}{\beta_i} e^{\beta_i t} \int_0^t c(u) e^{-\beta_i u}\, du \right] \qquad \text{(Eq. 5)}$$

Model-Independent Method of Analyzing Input in Linear Pharmacokinetic Systems Having Polyexponential Impulse Response II: Numerical Evaluation

PETER VENG PEDERSEN

Received September 22, 1978, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication October 11, 1979.

Abstract □ The investigated method is based on an exact mathematical solution to the deconvolution problem of linear pharmacokinetic systems with a polyexponential impulse response. The accuracy of the method is determined only by how well the curves fitted to the intravenous and absorption data represent the true drug level. Consequently, the method enables objective evaluation of the input. It permits the user to assess whether discrepancies in a calculated input are due to an improper data representation, as judged from the fitted curves, to the inherent nature of the data, or to a violation of the pharmacokinetic assumptions. The method is compared to another method using simulated data containing various degrees of random noise. The accuracy of the two methods was not significantly different and was of the same magnitude as the noise level of the data. The theoretical properties of the two methods and their expected performance in various pharmacokinetic situations are discussed. The method is applied to pentobarbital data from oral and intravenous administrations.

Keyphrases □ Pharmacokinetics—linear systems, polyexponential impulse response, analysis of input, model-independent method □ Model-independent analysis—linear pharmacokinetic systems, polyexponential impulse response, analysis of input □ Drug input—linear pharmacokinetic systems, polyexponential impulse response, analysis by model-independent method

A previous article (1) presented the theoretical derivation and analysis of a novel input analysis method. The method allows a drug input to be evaluated in the presence or absence of any combination of intravenous bolus input and infusion input. Three approaches were discussed: evaluation of the input rate based on a separate intravenous bolus experiment and an input (absorption) experiment, evaluation based on a merged intravenous bolus and input experiment, and evaluation based on a merged infusion and input experiment.

The present work is confined to the first approach and is based on an exact mathematical solution to the deconvolution problem of linear pharmacokinetic systems with a polyexponential impulse response. Several methods for deconvolution have been presented (2–5). The Wagner–Nelson method usually is limited to one-compartment systems (6), and the methods investigated by Benet and Chiang (2) were shown to be very sensitive to errors in the data. The numerical deconvolution method presented by Gamel *et al.* (3) did not provide satisfactory results, possibly due to numerical ill conditioning. Cutler (5) improved Gamel's approach by using orthogonal polynomials to avoid the problem of ill conditioning. The improved method seems to be the most accurate method for numerical deconvolution. It appears to be superior to the many model-dependent methods (6–10) because it is based on fewer assumptions and, therefore, is more likely to result in a meaningful evaluation of the drug input.

This work compares the new method with Cutler's approach using Cutler's simulated test data that contain various degrees of random noise (4, 5).

THEORY

Let the concentration of drug in the blood, $c^*(t)$, following an initial intravenous bolus dose, q^*, be described by a multiexponential relationship (1):

$$c^*(t) = \sum_{i=1}^{n} a_i e^{\lambda_i t} \qquad \text{(Eq. 1)}$$

Let $c(t)$ denote the drug level resulting from an unknown input of a drug that, in the same subject with the same linear relationship between input and response, results in the blood level $c^*(t)$ (Eq. 1) when an intravenous bolus dose, q^*, is given. It has been shown (1) that the rate of input of the drug then is given by:

$$f(t) = q^* \left[-\frac{\sum_{i=1}^{n} a_i \lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} c(t) + \frac{c'(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i e^{\beta_i t} \int_0^t c(u) e^{-\beta_i u}\, du \right] \qquad \text{(Eq. 2)}$$

where β_i, $i = 1, 2, \ldots, n-1$ are the roots of the $(n-1)$th-degree polynomial:

$$Q(x) = \sum_{i=1}^{n} a_i \prod_{\substack{j=1 \\ \neq i}}^{n} (x - \lambda_j) \qquad \text{(Eq. 3)}$$

and b_ν, $\nu = 1, 2, \ldots, n-1$ are obtained from:

$$b_\nu = \left[\sum_{i=1}^{n} \frac{a_i}{\beta_\nu - \lambda_i} \sum_{\substack{j=1 \\ \neq i}}^{n} \frac{1}{\beta_\nu - \lambda_j} \right]^{-1} \qquad \text{(Eq. 4)}$$

Integration of $f(t)$ from time zero to time t yields the cumulative amount of input:

$$A(t) = q^* \left[-\left\{ \frac{\sum_{i=1}^{n} a_i \lambda_i}{\left(\sum_{i=1}^{n} a_i\right)^2} + \sum_{i=1}^{n-1} \frac{b_i}{\beta_i} \right\} \int_0^t c(t)\, dt + \frac{c(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} \frac{b_i}{\beta_i} e^{\beta_i t} \int_0^t c(u) e^{-\beta_i u}\, du \right] \qquad \text{(Eq. 5)}$$

0022-3549/80/0300-0305$01.00/0
© 1980, American Pharmaceutical Association

It may be more convenient to describe the amount as a percentage of the dose, q, given, *i.e.*:

$$\mathrm{PCT}(t) = 100\frac{q^*}{q}\left[-\left\{\frac{\sum_{i=1}^{n} a_i\lambda_i}{\left(\sum_{i=1}^{n} a_i\right)^2} + \sum_{i=1}^{n-1}\frac{b_i}{\beta_i}\right\}\int_0^t c(t)dt + \frac{c(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1}\frac{b_i}{\beta_i}e^{\beta_i t}\int_0^t c(u)e^{-\beta_i u}\,du\right] \quad \text{(Eq. 6)}$$

Consider as an example the case where the drug level after an intravenous bolus dose, q^*, is described by a two-exponential expression:

$$c^*(t) = a_1e^{\lambda_1 t} + a_2e^{\lambda_2 t} \quad \text{(Eq. 7)}$$

The auxiliary parameters β_1 and b_1, according to Eqs. 3 and 4, are given by:

$$\beta_1 = \frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2} \quad \text{(Eq. 8)}$$

and:

$$b_1 = -\frac{a_1a_2(\lambda_1 - \lambda_2)^2}{(a_1 + a_2)^3} \quad \text{(Eq. 9)}$$

so that the rate of input becomes:

$$f(t) = q^*\left[-\frac{a_1\lambda_1 + a_2\lambda_2}{(a_1 + a_2)^2}c(t) + \frac{c'(t)}{a_1 + a_2} - \frac{a_1a_2(\lambda_1 - \lambda_2)^2}{(a_1 + a_2)^3} \times \exp\left(\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}t\right)\int_0^t c(u)\exp\left(-\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}u\right)du\right] \quad \text{(Eq. 10)}$$

and the cumulative amount of input expressed as a percentage of the dose, q, becomes:

$$\mathrm{PCT}(t) = 100\frac{q^*}{q}\left[-\left\{\frac{a_1\lambda_2 + a_2\lambda_1}{(a_1 + a_2)^2} - \frac{a_1a_2(\lambda_1 - \lambda_2)^2}{(a_1\lambda_2 + a_2\lambda_1)(a_1 + a_2)^2}\right\} \times \int_0^t c(t)dt + \frac{c(t)}{a_1 + a_2} - \frac{a_1a_2(\lambda_1 - \lambda_2)^2}{(a_1\lambda_2 + a_2\lambda_1)(a_1 + a_2)^2}\exp\left(\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}t\right) \times \int_0^t c(u)\exp\left(-\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}u\right)du\right] \quad \text{(Eq. 11)}$$

which simplifies to:

$$\mathrm{PCT}(t) = 100\frac{q^*}{q}\left[-\frac{\lambda_1\lambda_2}{a_1\lambda_2 + a_2\lambda_1}\int_0^t c(t)dt + \frac{c(t)}{a_1 + a_2} - \frac{a_1a_2(\lambda_1 - \lambda_2)^2}{(a_1\lambda_2 + a_2\lambda_1)(a_1 + a_2)^2}\exp\left(\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}t\right) \times \int_0^t c(u)\exp\left(-\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2}u\right)du\right] \quad \text{(Eq. 12)}$$

The procedure for evaluating the input is as follows. The two-exponential expression (Eq. 7) is fitted by nonlinear regression to the intravenous bolus data to estimate a_1, a_2, λ_1, and λ_2. A suitable empirical function[1], $s(t)$, is fitted to the absorption data to estimate the true drug level, $c(t)$. The rate and extent of absorption then are estimated according to Eqs. 10 and 12 using the estimates obtained for a_1, a_2, λ_1, λ_2, and $c(t)$.

The function $s(t)$ chosen to estimate $c(t)$ is an adaptive least-squares cubic spline function (12)[2]. This function is fitted to the data by minimizing the following expression:

$$E = \sum_{i=1}^{m}[w_i|c_i - s(t_i)|]^2 + \sum_{i=2}^{N-1}[\theta_i d_i]^2 \quad \text{(Eq. 13)}$$

where w_i are weights and (c_i, t_i), $i = 1, 2, \ldots, m$ are the absorption data. This expression consists of the usual least-squares term (the first term) and a smoothing term that is determined automatically using statistical tests on errors (16). The function $s(t)$ is a cubic spline with knots $\xi_1, \xi_2, \xi_3, \ldots, \xi_N$ and d_i represents the discontinuity in $s'''(t)$ at ξ_i, *i.e.*:

$$d_i = s'''(\xi_i + 0) - s'''(\xi_i - 0) \quad \text{(Eq. 14)}$$

The θ_i values are weight factors used for smoothing $s(t)$. In the fitting procedure, the number of knots, N, their position, and the smoothing weight factors, θ_i, are optimized automatically so that the fitted spline function attempts to follow trends in the data but ignores random errors (16). The rate of input (Eq. 2) and the extent of input (Eq. 5 or 6) can be evaluated accurately without numerical integration errors[3] when a cubic spline function, $s(t)$, is used to estimate $c(t)$.

This evaluation leads to the following expressions:

$$f(t) = q^*\left[-\frac{\sum_{i=1}^{n} a_i\lambda_i}{\left(\sum_{i=1}^{n} a_i\right)^2}s(t) + \frac{s'(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1} b_i\left\{-\sum_{k=0}^{3}\frac{s^{(k)}(t)}{\beta_i^{k+1}} + e^{\beta_i t}\sum_{k=0}^{3}\frac{s^{(k)}(0)}{\beta_i^{k+1}} + \beta_i^{-4}\sum_{k=2}^{j} e^{\beta_i(t-\xi_k)}d_k\right\}\right] \quad \text{(Eq. 15)}$$

where j is the highest integer for which $t \le \xi_j$ is satisfied, *i.e.*:

$$j = \overset{\sup}{i}\,(t \le \xi_i) \quad \text{(Eq. 16)}$$

and:

$$\mathrm{PCT}(t) = 100\frac{q^*}{q}\left[-\left(\frac{\sum_{i=1}^{n} a_i\lambda_i}{\left[\sum_{i=1}^{n} a_i\right]^2} + \sum_{i=1}^{n-1}\frac{b_i}{\beta_i}\right)\int_0^t s(t)dt + \frac{s(t)}{\sum_{i=1}^{n} a_i} + \sum_{i=1}^{n-1}\frac{b_i}{\beta_i}\left\{-\sum_{k=0}^{3}\frac{s^{(k)}(t)}{\beta_i^{k+1}} + e^{\beta_i t}\sum_{k=0}^{3}\frac{s^{(k)}(0)}{\beta_i^{k+1}} + \beta_i^{-4}\sum_{k=2}^{j} e^{\beta_i(t-\xi_k)}d_k\right\}\right] \quad \text{(Eq. 17)}$$

EXPERIMENTAL

The simulated data used to test the new method consist of four sets of data presented by Cutler (4) and denoted as Data Sets 1–4. Each set consists of a set of 11 simulated unit impulse response data with random noise added and a set of 11 simulated input response data also containing noise from the same linear system. The method of analysis is model independent. Therefore, the models used to simulate data from a linear system to test the method can be chosen arbitrarily.

The models employed by Cutler to generate the test data (Table I) were chosen because of their resemblance to models commonly employed in drug release and drug absorption analyses. They can be considered, in the classical linear pharmacokinetic sense, as a two-compartment model with first-order input (Data Sets 1 and 2) and as a two-compartment model with dissolution rate-limited release from an intramuscular injection, where the drug release follows the well-known cube-root relationship (17) (Data Sets 3 and 4). The results shown for Cutler's method (Tables II–V) were chosen as the best results reported (5).

Data Treatment—Polyexponential expressions of increasing degree n (Eq. 1) were fitted to the unit impulse response data with equal weights using the nonlinear regression program FUNFIT (18). A two-exponential expression fit the data adequately (Table VI). The cubic spline function, $s(t)$, was fitted to the input response data using the subroutine VCO3A from the Harwell subroutine library (12). A subroutine was written that calls VCO3A and calculates, according to Eqs. 15 and 17, the rate and extent of input at the observation times and, optionally, at any number of equally spaced time points from time zero to the last observation time for graphical representation of the input[4]. The pentobarbital data used were those reported by Smith *et al.* (11).

[1] The term empirical function is used here to denote a function that describes empirical data in a low information situation where no specific mathematical model is assumed.

[2] References 13–15 give an introduction to the theory and applications of spline functions in data analysis.

[3] This is the case because analytical expressions exist for $s'(t)$, $s''(t)$, and $s'''(t)$ and because $\int_0^t s(t)dt$ (Eq. 17) leads to a polynomial expression that can be evaluated exactly.

[4] Plotted using a Tektronix 4662 penplotter using a FORTRAN IV graphical software package written by the author.

Table I—Origin of the Simulated Data in Data Sets 1–4 [a]

Data Set	Rate of Input	Amount of Input, $f(t)$	Random Noise Level[b], %	Unit Impulse Response Data	Input Response Data
1	$f(0)e^{-kt}$	$\frac{f(0)}{k}(1-e^{-kt})$	1	$a_1e^{\lambda_1 t}+a_2e^{\lambda_2 t}+\epsilon$	$c^*(t)*f(t)+\epsilon$
2	$f(0)e^{-kt}$	$\frac{f(0)}{k}(1-e^{-kt})$	10	$a_1e^{\lambda_1 t}+a_2e^{\lambda_2 t}+\epsilon$	$c^*(t)*f(t)+\epsilon$
3	$\frac{3D}{t_d}\left(1-\frac{t}{t_d}\right)_+^2$	$D\left[1-\left(1-\frac{t}{t_d}\right)_+^3\right]$	1	$a_1e^{\lambda_1 t}+a_2e^{\lambda_2 t}+\epsilon$	$c^*(t)*f(t)+\epsilon$
4	$\frac{3D}{t_d}\left(1-\frac{t}{t_d}\right)_+^2$	$D\left[1-\left(1-\frac{t}{t_d}\right)_+^3\right]$	10	$a_1e^{\lambda_1 t}+a_2e^{\lambda_2 t}+\epsilon$	$c^*(t)*f(t)+\epsilon$

[a] The following notations are used: $(1-x)_+ = \max(0, 1-x)$; and $c^*(t)*f(t)$ is the convolution of $c^*(t)$ and $f(t)$, where $c^*(t) = a_1\exp(\lambda_1 t) + a_2\exp(\lambda_2 t)$. The parameters used in the simulations are: $a_1 = a_2 = 1$, $\lambda_1 = -5$, $\lambda_2 = -1$, $k = 2$, $D = 0.6$, $t_d = 1.15$, and $f(0) = 1.2$. [b] See Ref. 4 for details.

[a] Calculated as 100 × (calculated rate − exact rate)/1.2, where 1.2 is the initial exact input rate. [b] The mean and the standard deviation of the absolute values of the percent difference.

The data treatment of the pentobarbital data (Table VII) was identical to the treatment of the simulated data with the exception of the additional determination of the absorption lag time. The lag time was determined by linear extrapolation using the line that agreed with the fitted spline function and its slope at the first observation time. The appropriate time transformation then was performed before the rate and extent of input were calculated. Although the intravenously administered pentobarbital was given by a 5-min infusion, it was considered computationally as a bolus input because of the short infusion time relative to the absorption time and the rate of drug elimination.

RESULTS AND DISCUSSION

The analysis method does not require the input of a particular linear or nonlinear form, nor does it assume a specific linear pharmacokinetic model. The method only assumes a time-invariant linearity between input and response and that the impulse response (intravenous bolus input) can be approximated adequately by a polyexponential expression.

The equations for the rate (Eq. 2) and the extent (Eqs. 5 and 6) of input are mathematically exact expressions. The accuracy with which the input is evaluated is determined solely by the accuracy with which $c^*(t)$ (as described by a_i, λ_i, $i = 1, 2, \ldots, n$) and $c(t)$ are estimated. Therefore, the accuracy of the estimation depends on the qualities of two curve fittings. The functional form of $c^*(t)$ has been established as Eq. 1 (1). The method estimates $c^*(t)$ by least-squares regression which, according to the central limit theorem and the Gauss–Markov theorem, can be considered to be statistically the best estimation when no prior information is available about the statistical properties of the errors. Appropriate weighting can be applied if the variances of the errors can be estimated (18).

The estimation of $c(t)$ is the most difficult step. Its functional form is unknown in any model-independent approach. The main problem is to find an empirical function that can be fitted so that it follows the trend and the intrinsic values of the data but ignores the errors. A proper choice of function must be based on assumptions about the properties of the errors and the real behavior of $c(t)$. The function chosen must be able, when fitted, to reflect and demonstrate these properties properly. The present method generally assumes random errors. Although it is difficult to make assumptions about the real behavior of $c(t)$, it seems important

to consider the concept of smoothness. It seems unrealistic to assume $c(t)$ to be as smooth as the functions fitted in model-dependent approaches, considering the natural oscillations in the many body functions affecting absorption. It is more realistic to consider $c(t)$ to have a certain degree of fluctuation.

The adaptive least-squares cubic spline function was chosen to estimate $c(t)$ because it has the following properties. It is flexible enough to follow whatever shape $c(t)$ may have (15). Due to the smoothing term (the second term of Eq. 13), it is not so floppy that it fits to the errors in the data, *i.e.*, by going through all of the data points. The fit of the spline function in one region bears little relationship to its behavior in another region (15). Polynomials and other continuous mathematical functions that are not defined in a piecemeal fashion have just the opposite property. Namely, their behavior in any region determines their behavior everywhere. This unique and important property of the spline function enables it to describe the local behavior of $c(t)$ with no interference from nonlocal data points. The spline function has a smoothness that seems realistic in relation to the response it attempts to describe. It is well recognized in numerical analysis that spline functions are excellent tools for differentiation and integration. Therefore, a spline function representation should provide good estimates for the rate and the extent of drug input, considering the algebraic form of Eqs. 2, 5, and 6. Spline functions, when fitted to data by the least-squares method, conserve the first two moments of the data (19). This statistical property makes spline functions suitable for the analysis of observations with random errors because estimates of the mean, variance, and confidence interval of the true response can be obtained.

The theoretical basis for the described properties of spline functions

and their relationship to their application in empirical data analysis have been discussed extensively (13–15, 19).

Numerical Results—The two linear systems from which the simulated data were generated will be denoted as Systems 1 and 2, corresponding to Data Sets 1 and 2 and 3 and 4, respectively.

Both the rate and the extent of input were evaluated from the four data sets, giving a total of eight determinations (Figs. 1–8 and Tables II–V).

System 1, Data Set 1 (Noise Level 1%)—There was no significant difference in the results obtained by the new method and Cutler's method (t test, $p = 0.95$). The pattern of the errors was similar for the two methods. The average percent relative error was on the same order of magnitude as the percent error added to the data. The methods appeared to be least accurate in the initial stage of the input (Table II and Figs. 1 and 2).

System 1, Data Set 2 (Noise Level 10%)—Raising the error level from 1 to 10% did not differentiate between the two methods. The pattern of the errors again was similar, and the average percent error was of the same order of magnitude as the noise added to the data (Table III and Figs. 3 and 4).

System 2, Data Set 3 (Noise Level 1%)—Although the Cutler method appeared to perform better in the initial stage of the input, it did not estimate the input as accurately as did the new method at later sampling times. The difference was particularly great at the last sampling point. The new method seemed to give an overall better estimate of the input (Table IV and Figs. 5 and 6).

System 2, Data Set 4 (Noise Level 10%)—The two methods did not seem to be significantly different in their overall accuracy when the error level was raised from 1 to 10%. However, the new method appeared to determine the input rate more accurately at the later sampling times. The average percent error for the two methods was on the same order of magnitude as the noise level and came close to the averages obtained for System 1 where the same degree of noise was added to the data (Table V and Figs. 7 and 8).

It is not possible to differentiate between the two methods on the basis of the test data. They both performed well considering that the average relative error in all estimations was of the same magnitude as the noise added to the simulated data. However, both methods appeared to underestimate the initial release rate consistently. Cutler's test problems could not discriminate between the two methods because the test data simulate rather ideal, somewhat synthetic cases. In practice, it is uncommon to have so many points sampled in the absorption phase, and the sampling is rarely taken so evenly and at the same times after intravenous and oral administrations. Also, it is uncommon not to have a lag time in the absorption phase.

An excessive number of simulation tests is required to establish experimentally, using a variety of linear systems and sampling schemes, the relative performance of the two methods. However, the following theoretical considerations should give an assessment of the methods and how they may perform in various situations.

Both methods use empirical functions. The Cutler method uses polynomials of various degrees to represent the input function and the unit impulse response. The new method uses an adaptive least-squares cubic spline function to represent the input response and a polyexponential expression (Eq. 1) to represent the impulse response. It is important to recognize the properties of polynomials relative to the properties of a

least-squares cubic spline function and a polyexponential expression since the differences may explain and predict how the two methods perform under various conditions. Least-squares polynomials usually give a good data representation when the data points are fairly equally spaced and do not change too rapidly or contain excessive errors as in the described simulation study. They then interpolate well but perform poorly when used for extrapolation beyond the end-points. The extrapolation error frequently increases rapidly with the distance from the end-point. Cutler used a polynomial to represent the impulse response (the intravenous bolus response). The polynomial is extrapolated from the first sampling time to time zero to calculate the convolution integral (p. 249, Ref. 5) that plays an essential role in his method. The chance of introducing a substantial error in this way becomes particularly significant if early intravenous data are lacking.

It sometimes is desirable to evaluate the absorption of a drug that has been sampled longer than its intravenous bolus response. Inaccurate results may be expected using Cutler's method in such cases because it requires a polynomial extrapolation beyond the last intravenous bolus data point to calculate the convolution integral. It is well known that polynomials may interpolate badly and show large oscillations between some data points if the data are not spaced fairly equally or contain one or more large gaps, due to missing data for example. The Cutler method is expected to be deficient when applied to such data. It is well known in empirical data fittings that cubic spline functions are superior to polynomials with respect to interpolation and extrapolation (20). It also is evident that the polyexponential expression, Eq. 1, is superior to a polynomial for interpolation and especially for extrapolation of the intravenous bolus response, considering the well-documented and successful use of Eq. 1 in pharmacokinetics. Therefore, the new method is expected to be more accurate with respect to the interpolations and the extrapolations that greatly influence the accuracy of the two methods.

Cutler's method should perform at its best when the sampling times from intravenous and nonintravenous administrations coincide as in the test examples. This result occurs because the polynomial representation of the input function is best defined under this condition, due to the local emphasis inherent in the sum of squares expression being minimized. The accuracy of the new method does not depend on whether the sampling times coincide because of the different approach used. Most absorption data in pharmacokinetics contain a lag time. Cutler did not discuss how his method should be applied to take this factor into account.

It seems apparent from the discussion that the test data used tend to give an optimistically biased evaluation of the performance of Cutler's method. A differentiation of the two methods may result if more realistic simulation studies are performed.

The user of Cutler's method is faced with several different estimations of the input corresponding to the various degrees of the polynomial used in the approximations of the input rate. The problem of picking the "best" results is complicated by possible multiple minima of the residual mean square function (5). If a polynomial of too high a degree is used, it will fit to the errors in the data and produce unreliable results. In favor-

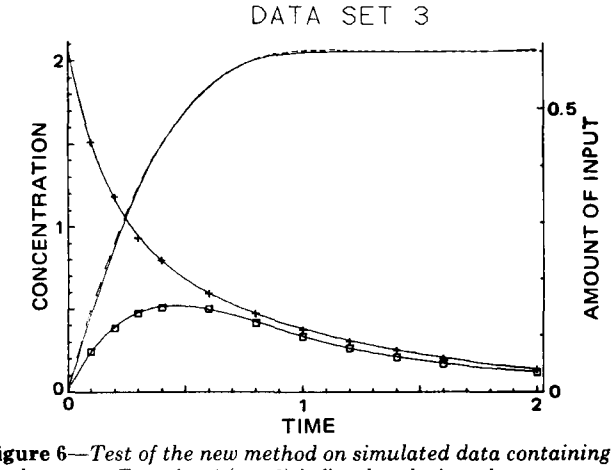

Figure 6—*Test of the new method on simulated data containing 1% random error. Equation 1* (n = 2) *is fitted to the plasma drug level data* (+) *from intravenous administration. An adaptive least-squares cubic spline function,* s(t), *is fitted to the oral absorption data* (□). *The drug input (upper curves) is calculated from* a_i, λ_i, i = *1, 2 and* s(t) *according to Eq. 17.*

able cases, a suitable, well-defined minimum may exist, but the problem is expected to be particularly difficult in more realistic situations. The additional problem of choosing the proper polynomial to represent the impulse response was not discussed by Cutler. The number of multiple solutions is multiplied for each possible polynomial, thereby making a choice even more difficult.

The new method seems more appealing from the user's point of view because it gives clear, unambiguous results. It has the advantage that, contrary to Cutler's approximation method, it is based on an exact mathematical solution to the deconvolution problem of linear compartmental pharmacokinetics. The method also provides, as a by-product of the least-squares spline fitting to the absorption data, estimates of the important model-independent quantities, *i.e.*, time to the peak, maximum response, and area under the curve (truncated).

Pentobarbital Input—The pentobarbital data are difficult to treat because the absorption phase is defined by only three or four data points and because the absorption lag time is not well defined due to the lack of early sampling points (Fig. 9). Although the lag times for the absorption by Subjects R.B. and B.G. (0.36 and 0.46 hr, respectively) came close, it was not possible to detect a significant lag time for the absorption by Subject R.M. due to the low information density of the data in the absorption phase. It is satisfactory that the extent of absorption for R.M. and R.B. both came close to the label claim (100 and 96%, respectively) judged from the maximum of the percent absorbed curves (Fig. 9). However, the excessive value for Subject B.G. (144%) and the significant decline of the percent absorbed curves for all subjects indicate a pronounced violation of the assumption of time-invariant linearity between input and response.

The observed discrepancy was not caused by the method of analysis or the numerical treatment. The rate of decline of the absorption data after the absorption phase was significantly larger than the rate for the intravenous data, indicating apparently faster elimination after the oral administration. Under the given assumptions, this effect will computationally result in a negative input, *i.e.*, a decline in the percent absorbed curve after the absorption phase as shown due to an elimination rate that is faster than that expected judging from the intravenous data.

Several explanations may be investigated to explain this discrepancy between the oral and intravenous data. One possibility is that the linearity between input and response is only of a relatively short duration so that it changes significantly between administrations but not within the duration of a single administration. The merged intravenous bolus and input approach or the merged infusion and input approach (1) can be applied in such cases. These methods do not require a washout period between the intravenous and nonintravenous administrations. Therefore, the two administrations can be brought close together to minimize errors arising from a time-dependent input–response linearity. This ability should result in a more reliable drug input evaluation than is possible with other model-independent methods because these methods are based on a complete washout of drug between the administrations.

The new method appears to be a potentially powerful tool for the evaluation of drug input and bioavailability. It is based on an exact mathematical solution to the deconvolution problem of linear compartmental pharmacokinetics. The accuracy of the method is determined by how well the fitted curves represent the true response. The superimposed graphical representation of the estimated impulse and input responses and the calculated input, provided by the method (Fig. 9), consequently is of significant conceptual value. It enables the user to evaluate visually whether discrepancies or peculiarities in a calculated input are due to an improper data representation, judged from the fitted curves, or to the inherent nature of the impulse and input response data. The method is not used as a "black box" but enables the user to be critical about the results obtained and the assumptions made about the pharmacokinetics. Hopefully, this work will lead to a less assumptive and more objective approach in bioavailability testing.

Novel Deconvolution Method for Linear Pharmacokinetic Systems with Polyexponential Impulse Response

PETER VENG PEDERSEN

Received November 15, 1978, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication March 28, 1979.

Abstract □ A novel least-squares deconvolution method for estimating the rate and the extent of drug input into the systemic circulation is presented. The method is based on a polyexponential approximation of the impulse response and a polynomial approximation of the input rate. The method, which is readily implemented on a computer using any multiple linear regression program with a zero-intercept option, is compared to two other deconvolution methods using simulated data with various degrees of random noise added. It appears to have several significant advantages. The method is applied to plasma pentobarbital level data from oral and intravenous administration. The assumptions and limitations of deconvolution methods for analyzing drug input into the blood are discussed.

Keyphrases □ Pharmacokinetics—deconvolution method, linear pharmacokinetics, polyexponential impulse response, drug input into blood □ Blood—drug input, deconvolution method for pharmacokinetic estimation □ Deconvolutions—pharmacokinetic estimation of drug input into blood □ Drug bioavailability—blood, deconvolution method for pharmacokinetic estimation

Drug input analysis is of utmost importance in biopharmaceutics because of its fundamental role in drug design, evaluation, and administration. Accurate quantitation of a drug's input–response relationship in a subject or patient population is, therefore, important. The relevant response is usually the drug concentration in the blood, in a certain tissue, or in an organ, but it may be a pharmacological or toxicological response.

The response environment is the destination for the input to be quantitated. There are two kinds of response environments: sampleable, *i.e.*, environments that can be quantitatively sampled for the drug, and nonsampleable. The blood, a tissue, or an organ are sampleable environments. Drug receptors and other biochemical structures responsible for a drug's pharmacological–toxicological response are usually nonsampleable environments. A drug's input can be experimentally verified only for sampleable environments. The evaluation of a drug's input into a nonsampleable environment would be based on some hypothesis about the quantitative relationship between the drug concentration in the nonsampleable response environment and the sampleable response. Therefore, it is not possible to quantitate drug input from pharmacological measurements if the input is defined with respect to a nonsampleable response environment, *e.g.*, drug receptors or "the biophase" (1).

For only a few drugs is it possible to establish experimentally a quantitative functional relationship between the drug concentration in a sampleable environment (*e.g.*, the blood) and the pharmacological response. In such cases, the pharmacological response may be used to evaluate the input into the sampleable environment. The possibility of noninvasive, nonanalytical techniques to quantitate drug input from pharmacological response measurements is exciting (1). However, the sources of errors are enormous and generally result in very inaccurate results. The blood is usually not the "site of action" for a drug and, therefore, may not represent the ultimate destination for the drug input. However, the transfer of a drug to the site of action from the blood is often direct, or the barriers involved are often insignificant compared to the physical, chemical, and biological barriers the drug encounters to get into the blood. Thus, it is adequate in most cases to evaluate the drug input with the blood as the response environment, as in the present approach.

The treatment presented is limited to linear pharmacokinetic systems, *i.e.*, systems where the input–response relationship follows the linear superposition principle. The classical linear compartmental systems (2, 3) belong to the family of linear systems. The method presented can be characterized in the classical (linear compartmental) pharmacokinetic sense as model independent. The various published approaches for evaluating drug input were discussed previously (4, 5).

THEORY

The drug level in the blood, $c^*(t)$, after an intravenous bolus dose, q^*, can often be well described by a polyexponential expression:

$$c^*(t) = \sum_{i=1}^{n} a_i e^{\lambda_i t} \qquad \text{(Eq. 1)}$$

If the blood drug level behaves linearly with respect to input into the blood, then the unit impulse response is $c^*(t)/q^*$, and the response to an arbitrary input rate, $f(t)$, is given by the general expression:

$$c(t) = \frac{1}{q^*} \int_0^t f(t-u)c^*(u)du \qquad \text{(Eq. 2)}$$

Keyphrases □ Pharmacokinetics—deconvolution method, linear pharmacokinetics, polyexponential impulse response, drug input into blood □ Blood—drug input, deconvolution method for pharmacokinetic estimation □ Deconvolutions—pharmacokinetic estimation of drug input into blood □ Drug bioavailability—blood, deconvolution method for pharmacokinetic estimation

Drug input analysis is of utmost importance in biopharmaceutics because of its fundamental role in drug design, evaluation, and administration. Accurate quantitation of a drug's input–response relationship in a subject or patient population is, therefore, important. The relevant response is usually the drug concentration in the blood, in a certain tissue, or in an organ, but it may be a pharmacological or toxicological response.

The response environment is the destination for the input to be quantitated. There are two kinds of response environments: sampleable, *i.e.*, environments that can be quantitatively sampled for the drug, and nonsampleable. The blood, a tissue, or an organ are sampleable environments. Drug receptors and other biochemical structures responsible for a drug's pharmacological–toxicological response are usually nonsampleable environments. A drug's input can be experimentally verified only for sampleable environments. The evaluation of a drug's input into a nonsampleable environment would be based on some hypothesis about the quantitative relationship between the drug concentration in the nonsampleable response environment and the sampleable response. Therefore, it is not possible to quantitate drug input from pharmacological measurements if the input is defined with respect to a nonsampleable response environment, *e.g.*, drug receptors or "the biophase" (1).

For only a few drugs is it possible to establish experimentally a quantitative functional relationship between the drug concentration in a sampleable environment (*e.g.*, the blood) and the pharmacological response. In such cases, the pharmacological response may be used to evaluate the input into the sampleable environment. The possibility of noninvasive, nonanalytical techniques to quantitate drug input from pharmacological response measurements is exciting (1). However, the sources of errors are enormous and generally result in very inaccurate results. The blood is usually not the "site of action" for a drug and, therefore, may not represent the ultimate destination for the drug input. However, the transfer of a drug to the site of action from the blood is often direct, or the barriers involved are often insignificant compared to the physical, chemical, and biological barriers the drug encounters to get into the blood. Thus, it is adequate in most cases to evaluate the drug input with the blood as the response environment, as in the present approach.

The treatment presented is limited to linear pharmacokinetic systems, *i.e.*, systems where the input–response relationship follows the linear superposition principle. The classical linear compartmental systems (2, 3) belong to the family of linear systems. The method presented can be characterized in the classical (linear compartmental) pharmacokinetic sense as model independent. The various published approaches for evaluating drug input were discussed previously (4, 5).

THEORY

The drug level in the blood, $c^*(t)$, after an intravenous bolus dose, q^*, can often be well described by a polyexponential expression:

$$c^*(t) = \sum_{i=1}^{n} a_i e^{\lambda_i t} \qquad \text{(Eq. 1)}$$

If the blood drug level behaves linearly with respect to input into the blood, then the unit impulse response is $c^*(t)/q^*$, and the response to an arbitrary input rate, $f(t)$, is given by the general expression:

$$c(t) = \frac{1}{q^*} \int_0^t f(t-u)c^*(u)du \qquad \text{(Eq. 2)}$$

0022-3549/80/0300-0312$01.00/0
© 1980, American Pharmaceutical Association

A suitable method is to be derived whereby $f(t)$ can be estimated from samples of the bolus response, $c^*(t)$, and the input (absorption) response, $c(t)$.

Considering the many factors influencing the absorption process, it may be appropriate to approximate $f(t)$ with a model-independent empirical equation such as a polynomial:

$$f(t) = \sum_{i=0}^{N} x_i t^i \qquad \text{(Eq. 3)}$$

The problem is then to determine the polynomial coefficients $x_0, x_1, \ldots, x_N$. The following derivations (Eqs. 4–15) lead to an equation, Eq. 16, that is linear with respect to the coefficients. This equation can be used to calculate the coefficients by standard multiple linear regression techniques.

Inserting Eqs. 1 and 3 into Eq. 2 leads to:

$$c(t) = \frac{1}{q^*} \int_0^t \sum_{i=0}^{N} x_i (t-u)^i \sum_{j=1}^{n} a_j e^{\lambda_j t}\, du \qquad \text{(Eq. 4)}$$

The binomial expansion for $(t-u)^i$ leads to:

$$c(t) = \frac{1}{q^*} \int_0^t \sum_{i=0}^{N} x_i \sum_{j=0}^{i} \binom{i}{j} t^j (-1)^{i-j} u^{i-j} \sum_{k=1}^{n} a_k e^{\lambda_k u}\, du \qquad \text{(Eq. 5)}$$

so that:

$$c(t) = \frac{1}{q^*} \sum_{i=0}^{N} x_i \sum_{j=0}^{i} \binom{i}{j} t^j (-1)^{i-j} \sum_{k=1}^{n} a_k \int_0^t u^{i-j} e^{\lambda_k u}\, du \qquad \text{(Eq. 6)}$$

The following useful integral formula can be derived readily:

$$\int_0^t x^n e^{ax}\, dx = \frac{e^{at}}{a} \sum_{i=0}^{n} (-1)^i \frac{n!}{a^i (n-i)!} t^{n-i} - (-1)^n \frac{n!}{a^{n+1}} \qquad n \geq 0 \qquad \text{(Eq. 7)}$$

By applying this formula to the integral in Eq. 6, this equation becomes:

$$q^* c(t) = \sum_{i=0}^{N} x_i \sum_{j=0}^{i} \binom{i}{j} t^j (-1)^{i-j} \sum_{k=1}^{n} \frac{a_k}{\lambda_k} e^{\lambda_k t} \sum_{m=0}^{i-j} (-1)^m \times \frac{(i-j)!}{\lambda_k^m (i-j-m)!} t^{i-j-m} - \left[\sum_{i=0}^{N} x_i \sum_{j=0}^{i} \binom{i}{j} t^j (-1)^{i-j} \sum_{k=1}^{n} a_k (-1)^{i-j} \frac{(i-j)!}{\lambda_k^{i-j+1}} \right] \qquad \text{(Eq. 8)}$$

The second term in Eq. 8, indicated by a bracket, simplifies to:

$$\text{second term} = -\sum_{i=0}^{N} x_i i! \sum_{j=0}^{i} \frac{t^j}{j!} \sum_{k=1}^{n} \frac{a_k}{\lambda_k^{i-j+1}} \qquad \text{(Eq. 9)}$$

Multiplying through with t^j and rearranging terms in the first term of Eq. 8 lead to:

$$\text{first term} = \sum_{i=0}^{N} x_i i! \sum_{j=0}^{i} \frac{(-1)^{i-j}}{j!} \sum_{k=1}^{n} \frac{a_k}{\lambda_k} e^{\lambda_k t} \sum_{m=0}^{i-j} \frac{(-1)^{i-j-m}}{\lambda_k^m (i-j-m)!} t^{i-m} \qquad \text{(Eq. 10)}$$

By changing the order of the summation and rearranging terms, this expression becomes:

$$\text{first term} = \sum_{i=0}^{N} x_i i! \sum_{k=1}^{n} \frac{a_k}{\lambda_k} e^{\lambda_k t} \sum_{j=0}^{i} \sum_{m=0}^{i-j} \frac{(-1)^{i-j+m}}{\lambda_k^m j! (i-j-m)!} t^{i-m} \qquad \text{(Eq. 11)}$$

The coefficient to t^{i-m} resulting from the two innermost summations in Eq. 11 is:

$$\frac{1}{\lambda_k^m} \sum_{j=0}^{i-m} \frac{(-1)^{i-m-j}}{j!(i-m-j)!} = 0 \qquad m < i \qquad \text{(Eq. 12)}$$

Thus, only the term $1/\lambda_k^i (m = i)$ is left from the two innermost summations, which results in a substantial simplification of Eq. 11:

$$\text{first term} = \sum_{i=0}^{N} x_i i! \sum_{k=1}^{n} \frac{a_k}{\lambda_k^{i+1}} e^{\lambda_k t} \qquad \text{(Eq. 13)}$$

Equation 8, according to Eqs. 9 and 13, simplifies considerably to:

$$c(t) = \frac{1}{q^*} \sum_{i=0}^{N} x_i i! \left[\sum_{k=1}^{n} \frac{a_k}{\lambda_k^{i+1}} e^{\lambda_k t} - \sum_{j=0}^{i} \frac{t^j}{j!} \sum_{k=1}^{n} \frac{a_k}{\lambda_k^{i-j+1}} \right] \qquad \text{(Eq. 14)}$$

which also can be rearranged to give:

$$c(t) = \sum_{i=0}^{N} x_i \frac{1}{q^*} i! \sum_{j=1}^{n} \frac{a_j}{\lambda_j^{i+1}} \left[e^{\lambda_j t} - \sum_{k=0}^{i} \frac{(\lambda_j t)^k}{k!} \right] \qquad \text{(Eq. 15)}$$

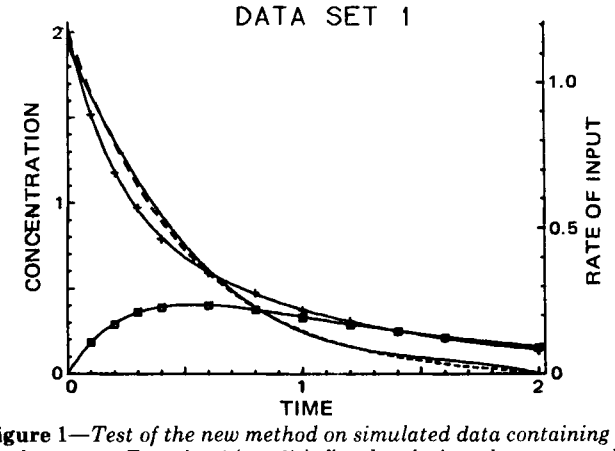

Figure 1—*Test of the new method on simulated data containing 1% random errors. Equation 1* (n = 2) *is fitted to the impulse response data* (+). *The curve representing the input response data* (□) *is calculated from Eq. 16 using the parameters* $x_0, x_1, \ldots, x_N$ *estimated by multiple linear regression and the parameters estimated from Eq. 1. The input curve is the input rate calculated according to Eq. 3. The broken curve is the exact input rate.*

For further simplification and to illustrate the linearity of $c(t)$ with respect to the polynomial coefficients $x_0, x_1, \ldots, x_N$, Eq. 15 can be written:

$$c(t) = \sum_{i=0}^{N} x_i \theta_i(t) \qquad \text{(Eq. 16)}$$

where:

$$\theta_i(t) = \frac{1}{q^*} i! \sum_{j=1}^{n} \frac{a_j}{\lambda_j^{i+1}} \left[e^{\lambda_j t} - \sum_{k=0}^{i} \frac{(\lambda_j t)^k}{k!} \right] \qquad \text{(Eq. 17)}$$

The expression inside the brackets in Eq. 17 is recognized as the difference between $e^{\lambda_j t}$ and a truncated Maclaurin series expansion of $e^{\lambda_j t}$. This difference becomes smaller when $\lambda_j t \to 0$ and when i increases, which may result in subtraction cancellation and loss of significant figures in the calculations. However, this result can be avoided by using alternative formulas for $\theta_i(t)$. When $|\lambda_j t|$ is small (<0.1), $\theta_i(t)$ is calculated most accurately from the tail of the Maclaurin series:

$$\theta_i(t) \doteq \frac{1}{q^*} i! \sum_{j=1}^{n} \frac{a_j}{\lambda_j^{i+1}} \sum_{k=i+1}^{K} \frac{(\lambda_j t)^k}{k!} \qquad \text{(Eq. 18)}$$

If the computer used represents floating-point numbers to m significant decimal digits, then K in Eq. 18 should be equal to $i + m + 1$ to get the best accuracy ($|\lambda_j t| < 0.1$). (The first neglected term in the summation of the series gives a strict error estimate because the series is alternating.) In the extreme cases where i (N) is large and $|\lambda_j t|$ is not small, $\theta_i(t)$ can be accurately evaluated using the integral representation of the tail of the Maclaurin series, which is:

$$\theta_i(t) = \frac{1}{q^*} \sum_{j=1}^{n} \frac{a_j}{(-\lambda_j)^{i+1}} \int_{\lambda_j t}^{0} e^u (u - \lambda_j t)^i\, du \qquad \text{(Eq. 19)}$$

where the integral is evaluated numerically. However, in most cases, it would not be necessary to use Eq. 19 because Eq. 17 is sufficiently accurate, particularly if the calculations are done in double precision. Furthermore, the number of sampling points in the absorption phase is frequently small. To avoid "fitting to the errors in the data," it is not advisable to use a polynomial of high degree in the approximation of the input rate $f(t)$ so N will not be large.

EXPERIMENTAL

The method presented was tested using the same simulated and real pharmacokinetic data used previously (5) so that it could be compared to two other deconvolution methods tested on the same data (5, 6). A function subprogram was written in FORTRAN IV which evaluated the theta function $\theta_i(t)$[1]. The subprogram algorithm automatically chooses among Eqs. 17–19 so that the best accuracy is obtained. The integral in Eq. 19 was evaluated using a product-type two-point Gauss–Legendre–

[1] A listing of the subprogram is available from the author.

Simpson algorithm compounded 50 times (7), which gave excellent accuracy.

The subprogram was used to generate, from the M observations c_i, t_i, $i = 1, 2, \ldots, M$, an $M \times (M + 1)$ data matrix $\{d_{ij}\}$ for input to the multiple linear regression program that calculated $x_0, x_1, \ldots, x_N$ (Eq. 3). The first data matrix column contains the M observations of the dependent variable, *i.e.*, the observed drug concentrations $d_{i1} = c_i$, $i = 1, 2, \ldots, M$. The other data matrix columns contain the independent variables $d_{ij} = \theta_{j-2}(t_i)$, $i = 1, \ldots, M$, $j = 2, \ldots, M + 1$. The highest degree possible for the polynomial that approximates $f(t)$ is $N = M - 1$, which corresponds to a collocation approximation (zero residual sum of squares). Most of the many multiple linear regression programs available for statistical computations can be used to calculate the parameters $x_0, x_1, \ldots, x_N$ of the input function from this data matrix. The only requirement is that the regression program must have a zero-intercept option that is to be used in this regression situation (Eq. 16)[2].

The program P9R, "All Possible Subset Regression," from the BMDP-77 biomedical computer program package (9) was used with the zero-option and TOL = 10^{-5}. The program was used to automatically find, among $x_0, x_1, \ldots, x_{M-1}$, the best subset based on Mallow's criterion (10). The parameters of the polyexponential expression, Eq. 1, fitted to the intravenous bolus data were reported previously (5) and were determined using the FUNFIT nonlinear regression program (11). The drawings (Figs. 1–9) were done by a penplotter driven by a computer[3] using a software package written by the author. The lag times used in the calculation of the pentobarbital input were those reported earlier (5).

The input curve is the input rate calculated according to Eq. 3. The broken curve is the exact input rate.*

RESULTS AND DISCUSSION

The proposed method is a least-squares deconvolution method, as is the method presented by Cutler (6). Both methods are based on a polynomial approximation of the input rate. However, the present method offers four significant advantages over Cutler's method:

1. The impulse response (bolus input response) is approximated by a polyexponential expression and not by a polynomial. A polyexponential expression does not tend to "fit to the errors" in the data as a polynomial

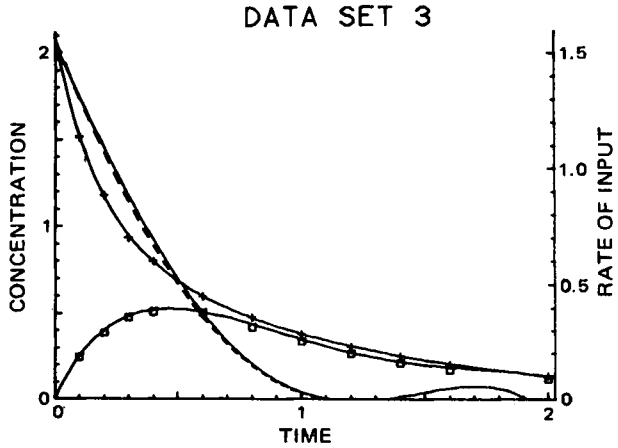

Figure 5—*Test of the new method on simulated data containing 1% random errors. Equation 1* (n = 2) *is fitted to the impulse response data* (+). *The curve representing the input response data* (□) *is calculated from Eq. 16 using the parameters* $x_0, x_1, \ldots, x_N$ *estimated by multiple linear regression and the parameters estimated from Eq. 1. The input curve is the input rate calculated according to Eq. 3. The broken curve is the exact input rate.*

[2] The two most widely used statistical software packages SPSS (8) and BMDP (9) contain several multiple linear regression programs. However, only the BMDP programs have the zero-intercept option. These programs allow the data to be weighted.

does. It is smoother and does not oscillate between data points as a polynomial often does. It is also superior to a polynomial with respect to the extrapolation to time zero, which plays an important role in the accuracy of any deconvolution method. Polyexponential expressions have been used successfully and extensively in pharmacokinetics to describe intravenous bolus data, and many application programs are available for this curve-fitting procedure (8, 11, 12).

2. The rate and extent of input are given in a simple, explicit mathematical form by the new method. Cutler (6) expressed the input rate as a sum of polynomial functions which, through a linear transformation, gives a set of orthogonal functions. Although a back-transformation and summation of terms may provide a single polynomial expression, this approach substantially increases the complexity of the method.

3. The present method requires very little programming on a computer. Only a short program is needed that, according to Eq. 17 or 18 (or Eq. 19 in rare cases), generates the data matrix for input to a standard multiple linear regression program. This programming can be done even using an ordinary programmable pocket calculator. The input function is calculated directly by the linear regression program in terms of the polynomial coefficients. Implementation of Cutler's method requires the

development of a fairly extensive and specialized program. Moreover, the user would not have many of the valuable statistical options that are supplied by the standard multiple linear regression programs (9).

4. The present method is computationally efficient and fast. With Cutler's method, a convolution integral (Ref. 6, p. 249) is evaluated numerically several times during the computations. The integration may introduce significant errors and may add significant cost to the computations if the results are to be presented graphically.

Simulation Results—The present results and comparisons are related to a similar investigation recently published (5). Comparing Tables I–IV with Tables II–V in Ref. 5 shows that the present method and Cutler's method do not differ significantly in the accuracy of estimating the input for Data Sets 1, 2, and 4 (Tables I, II, and IV). However, the present method appears to be significantly more accurate for Data Set 3 (Table III). Both methods perform well, considering that the average relative error in all estimations is of the same magnitude as the noise added to the simulated data.

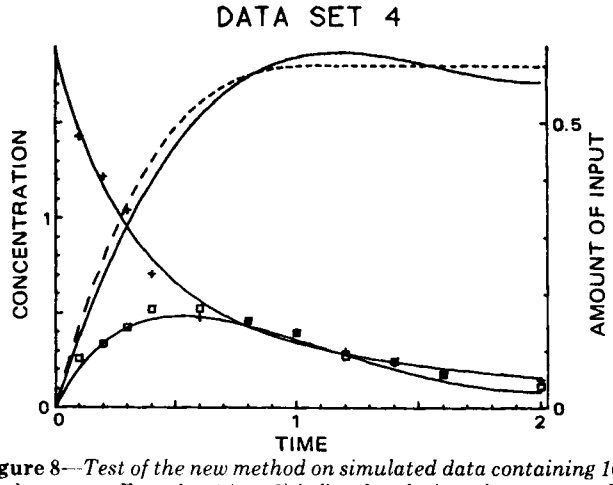

Figure 8—*Test of the new method on simulated data containing 10% random errors. Equation 1* (n = 2) *is fitted to the impulse response data* (+). *The curve representing the input response data* (□) *is calculated from Eq. 16 using the parameters* $x_0, x_1, \ldots, x_N$ *estimated by multiple linear regression and the parameters estimated from Eq. 1. Each method tends consistently to underestimate the initial input rate. This trend is probably related to the use of a polynomial in the input approximation. It may be explained theoretically ["Runge's phenomenon" (13)]. A special sampling procedure may eliminate or reduce this trend and give an overall better estimation. This procedure, based on the min–max principle using a Tschebyscheff sampling (13), is as follows. Let it be known from preliminary investigations that the absorption of the drug is completed (*e.g.*, 95%) in approximately T hr after the lag time and that the lag time is approximately t_{lag} hr. If the experimental protocol allows m samples to be drawn, then these samples should be taken at the following times:

$$t_i = t_{lag} + \frac{T}{2}\left[1 + \cos\frac{(2i-1)\pi}{2m}\right] \qquad i = 1, 2, \ldots, m \quad \text{(Eq. 20)}$$

A few additional samples are required after $T + t_{lag}$ hr to check for a change in the disposition kinetics between the intravenous and the absorption experiments. However, these points should not be included in the actual calculation of the input because they may interact unfavorably with the curve fitting in the absorption region.

Calculation of Pentobarbital Input—It is of interest to compare the present method with the other deconvolution method presented by the author (Ref. 5, Fig. 9). The pentobarbital data are rather difficult to treat, because the absorption phase is defined by only three or four data points and the data contain rather large errors. However, it is surprising how similarly the two methods perform in the absorption region. The total percent absorbed, measured by the maximum of the percent absorbed curve, does not differ much between the methods. The times for the absorption are also rather close.

However, the present method does not perform as well with respect

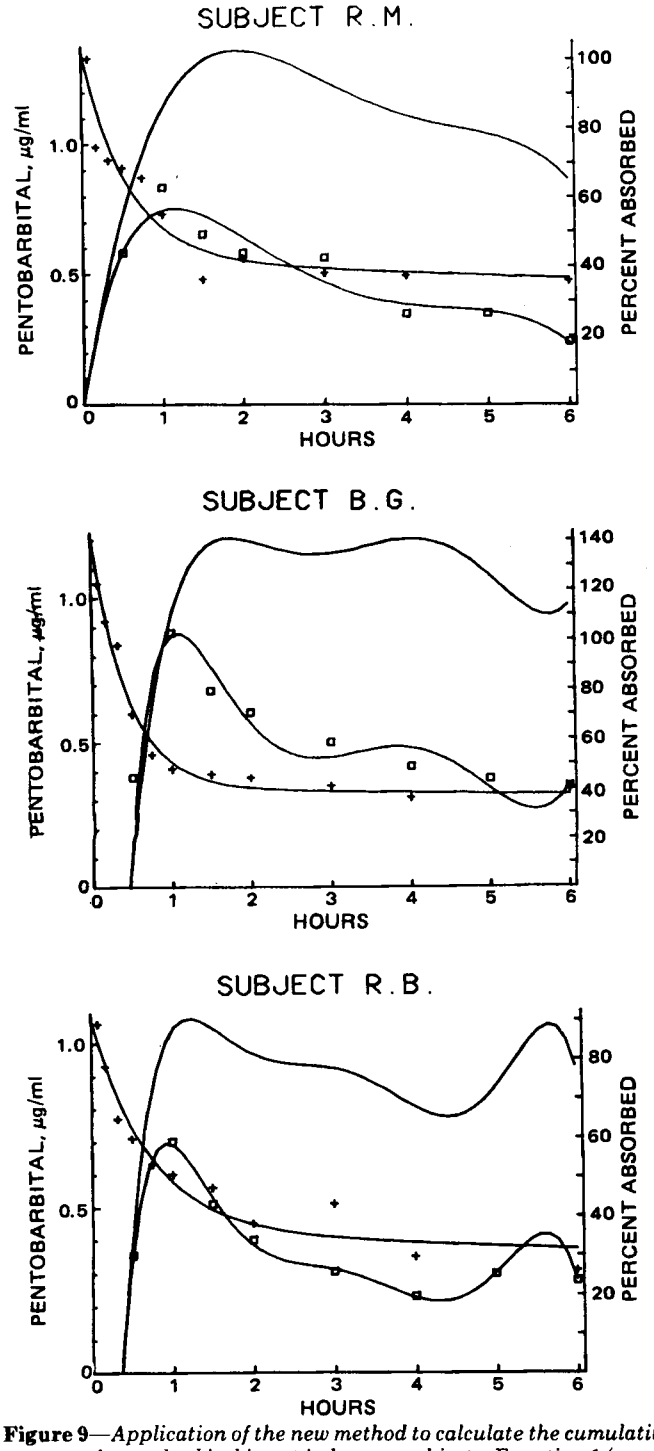

Figure 9—*Application of the new method to calculate the cumulative amount of pentobarbital input in human subjects. Equation 1* (n = 2) *is fitted to the plasma drug level data* (+) *from intravenous administration. The curve representing oral absorption data* (□) *is calculated from Eq. 16 using the parameters* $x_0, x_1, \ldots, x_N$ *estimated by multiple linear regression and the parameters estimated from Eq. 1. The input is calculated according to the integrated form of Eq. 3.*

to the curve fitting after the absorption phase. It demonstrates some of the undesirable effects originating from the polynomial approximation of the input rate; the absorption curve for Subject R.B. passes too close to all of the points, probably resulting in a poor filtering of the errors in the data. The curve for Subject B.G. shows excessive oscillations. However, the curve for Subject R.M. seems satisfactory overall. The same discrepancies between the intravenous and the absorption data reported previously (5) are also observed using the present method.

It is important to note that the calculation of the rate and extent of drug input at a given time, $t = t_0$, depends only on the fitted curves up to that time, t_0, according to the fundamental convolution integral equation (Eq. 2). Thus, the accuracy of the calculated input depends only on the goodness of the fit in the absorption phase. The goodness of the fit in the postabsorptive phase has no influence on the calculations. A fitting in this region is not required, but it provides a means of detecting discrepancies between the intravenous and absorption data (5). The fits in the absorption phase (Fig. 9) appear satisfactory considering the sparseness of the data in this region.

Table V—Calculated Polynomials that Describe the Rate of Input [a]

Data Set	Rate of Input

4	$f(t) = 1.322 - 1.794t + 0.5682t^2$

[a] $0.1 \leq t \leq 2.0$.

Assumptions and Limitations of Deconvolution Methods of Analysis of Drug Input into Blood—The deconvolution methods are based on the assumption of a time-invariant linearity between input and response in the sampleable response environment (the blood). A necessary condition for an environment to be linear is that the principle of superposition applies; *i.e.*, the sum or superposition of any two inputs, $f_1(t) + f_2(t)$, results in a response that is the superposition, $c_1(t) + c_2(t)$, of the individual responses (14). Corollaries to the superposition principle are:

1. No input affects the response of other inputs.
2. There is no interaction among the responses caused by different inputs.
3. The total response of several inputs into the environment can be determined by determining separately the response of the environment to each individual input and then superimposing the responses to get the total response.

These principles are well known from linear system theory (14). However, the real problem in applying these principles to pharmacokinetics apparently has not been discussed, namely, the effect of the input path on the response. The deconvolution methods can be used only if the response to a well-defined input is determined. The input is only well defined if it is direct intravenous (bolus and/or infusion). Consequently, the information about the system's input–response relationship is based only on a direct intravenous input. However, the inputs that are of interest are not direct intravenous. Therefore, the validity of the deconvolution approach is directly related to Corollary 1.

The crucial question is: Does the drug in its indirect path to the sampleable response environment affect the change in the concentration of the drug already in the environment so that the concentration change is different from that predicted had the input been direct? This question is identical to the question posed previously in dealing with the evaluation of input into linear compartmental systems (4): Is the input interacting?

Deconvolution methods can only be used to evaluate a noninteracting, primary input (4). Therefore, to verify the validity of the deconvolution approach, the system must be tested not only with respect to superposition but also with respect to interaction. A superposition test requires a minimum of two different direct intravenous bolus or intravenous infusion inputs. A test for interaction requires two experiments, one involving only a direct intravenous input and the other involving the indirect and direct inputs combined, where the drug in either the indirect or the direct input must be labeled in order to evaluate a possible interaction between the two inputs.

In spite of the crucial role that these aspects play in drug input evaluation, there does not seem to have been any work done in this fundamental area.

Table VI—Rate of Input of Pentobarbital

Subject	Rate[a], mg/hr	Lag Time, hr
B.G.	$f(t) = 159 - 266T + 150T^2 - 34.7T^3 + 2.77T^4$	0.46
R.M.	$f(t) = 69.9 - 64.7T + 17.8T^2 - 1.54T^3$	0.0
R.B.	$f(t) = 149 - 365T + 313T^2 - 122T^3 + 22.1T^4 - 1.49T^5$	0.36

[a] T = time − lag time.

The method presented, when applied with care, should be a valuable tool in drug absorption investigations. It seems to have some distinct advantages over the method proposed by Cutler (6). The simulation data generated by Cutler do not differentiate between the two approaches. However, these data represent rather ideal, somewhat unrealistic cases. More realistic tests might result in a definite distinction of the methods. The relative accuracy of the two approaches in practice is closely related to the issue of whether the impulse response data (*i.e.*, the intravenous bolus data) are best approximated by a polynomial or a polyexponential expression. It seems quite evident that the latter is the case, so the present method should be generally more accurate. Although this method seems promising, it appears from previous theoretical considerations (4) that the other deconvolution method presented by the author (5) is superior. However, the new method has the advantage that the rate and the amount (cumulative) of input are summarized in a simple polynomial form (Tables V and VI).

Novel Approach to Bioavailability Testing: Statistical Method for Comparing Drug Input Calculated by a Least-Squares Deconvolution Technique

PETER VENG PEDERSEN

Received January 29, 1979, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication July 18, 1979.

Abstract □ A novel approach to bioavailability testing is presented. The approach is model independent because it does not assume a specific pharmacokinetic model and does not use absorption, distribution, or elimination rate constants or a volume term. The method, which requires intravenous administration, is compared to classical bioavailability evaluation methods. Evaluation of drug input is based on the same assumptions required for using the area under the curve. No extrapolation beyond the last data point is required. Two statistics are derived that enable a comparison of the rate and the cumulative amount of input of two inputs for various times. A differential confidence profile is calculated that allows a more detailed and intrinsic bioavailability comparison than previous methods. The approach is demonstrated on simulated data containing random noise and shows satisfactory performance.

Keyphrases □ Bioavailability—testing, drug input, least-squares deconvolution technique □ Deconvolution—least-squares technique, bioavailability testing, drug input □ Drug availability—testing, least-squares deconvolution technique

The quality of a drug product as a drug delivery system is determined by the rate and extent of delivery of the active form to the biological environment responsible for the pharmacological effect. In most cases, this environment is neither known nor may be sampled for the drug. However, a close relationship usually exists between the drug concentration in a sampled environment (*e.g.*, blood) and its pharmacological response. Therefore, this environment may be a useful indicator of the drug input into the response environment.

Drug delivery usually is characterized in bioavailability terms with the blood as the sampleable environment. Bioavailability commonly is defined by the rate and the extent of drug input into the systemic circulation (1). Bioavailability comparisons usually are based on three parameters from a single-dose blood level curve: (*a*) the area under the curve, AUC (extrapolated); (*b*) the time of the peak concentration, t_{max}; and (*c*) the peak concentration, C_{max} (2).

These parameters are associated conceptually with the extent (AUC) and the rate (t_{max} and C_{max}) of input. This association is related to linear pharmacokinetic assumptions. For example, AUC is a proper measure of the total input only if the response (concentration) is linear with respect to the input (3, 4). If the system is not linear, a larger AUC does not guarantee greater input. Comparisons of the drug input on the basis of AUC may be inaccurate for several reasons:

1. The tail area must be estimated by extrapolation. Consequently, this area can be determined only by a model-dependent approach that assumes a certain functional form for the tail or the total curve.

2. The tail area frequently is estimated from the last observations (*e.g.*, log-linear extrapolation), based on the assumption that these points predict the behavior in the tail. The tail area usually is determined poorly in this way due to low information density of the terminal set of points. This problem is complicated further by constraints in time and the number of samples when dealing with human subjects. The experimenter must decide whether more samples should be taken in the terminal phase, where little or no input takes place, to predict the tail area better or whether these samples would be more valuable in the input phase where the real information about the input is present and where C_{max} and t_{max} are to be estimated.

3. The problem is complicated by the fact that the tail

Novel Approach to Bioavailability Testing: Statistical Method for Comparing Drug Input Calculated by a Least-Squares Deconvolution Technique

PETER VENG PEDERSEN

Received January 29, 1979, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication July 18, 1979.

Abstract □ A novel approach to bioavailability testing is presented. The approach is model independent because it does not assume a specific pharmacokinetic model and does not use absorption, distribution, or elimination rate constants or a volume term. The method, which requires intravenous administration, is compared to classical bioavailability evaluation methods. Evaluation of drug input is based on the same assumptions required for using the area under the curve. No extrapolation beyond the last data point is required. Two statistics are derived that enable a comparison of the rate and the cumulative amount of input of two inputs for various times. A differential confidence profile is calculated that allows a more detailed and intrinsic bioavailability comparison than previous methods. The approach is demonstrated on simulated data containing random noise and shows satisfactory performance.

Keyphrases □ Bioavailability—testing, drug input, least-squares deconvolution technique □ Deconvolution—least-squares technique, bioavailability testing, drug input □ Drug availability—testing, least-squares deconvolution technique

The quality of a drug product as a drug delivery system is determined by the rate and extent of delivery of the active form to the biological environment responsible for the pharmacological effect. In most cases, this environment is neither known nor may be sampled for the drug. However, a close relationship usually exists between the drug concentration in a sampled environment (*e.g.*, blood) and its pharmacological response. Therefore, this environment may be a useful indicator of the drug input into the response environment.

Drug delivery usually is characterized in bioavailability terms with the blood as the sampleable environment. Bioavailability commonly is defined by the rate and the extent of drug input into the systemic circulation (1). Bioavailability comparisons usually are based on three parameters from a single-dose blood level curve: (*a*) the area under the curve, AUC (extrapolated); (*b*) the time of the peak concentration, t_{max}; and (*c*) the peak concentration, C_{max} (2).

These parameters are associated conceptually with the extent (AUC) and the rate (t_{max} and C_{max}) of input. This association is related to linear pharmacokinetic assumptions. For example, AUC is a proper measure of the total input only if the response (concentration) is linear with respect to the input (3, 4). If the system is not linear, a larger AUC does not guarantee greater input. Comparisons of the drug input on the basis of AUC may be inaccurate for several reasons:

1. The tail area must be estimated by extrapolation. Consequently, this area can be determined only by a model-dependent approach that assumes a certain functional form for the tail or the total curve.

2. The tail area frequently is estimated from the last observations (*e.g.*, log-linear extrapolation), based on the assumption that these points predict the behavior in the tail. The tail area usually is determined poorly in this way due to low information density of the terminal set of points. This problem is complicated further by constraints in time and the number of samples when dealing with human subjects. The experimenter must decide whether more samples should be taken in the terminal phase, where little or no input takes place, to predict the tail area better or whether these samples would be more valuable in the input phase where the real information about the input is present and where C_{max} and t_{max} are to be estimated.

3. The problem is complicated by the fact that the tail

0022-3549/80/0300-0318$01.00/0

© 1980, American Pharmaceutical Association

area is determined by an asymptotic-type infinite extrapolation that is more complex than an intercept-type extrapolation.

A new approach to bioavailability testing is presented that enables a more detailed comparison of the rate and the extent of drug input than conventional methods. The method does not use *AUC* and does not require extrapolation beyond the last data point. The approach is model independent in the classical linear pharmacokinetic sense because it does not assume a specific pharmacokinetic model and does not use absorption, distribution, or elimination rate constants or a volume term. This method of evaluating drug input is based on the same assumptions as those required for using *AUC* as a proper measure of the drug input. These assumptions are: (*a*) the input evaluated is a noninteracting primary input, and (*b*) there is a time-invariant linearity between the response (concentration) measured in the sampled environment (the blood) and the input (4). These assumptions can be tested experimentally as discussed previously (4). Their violation invalidates the classical linear approaches to bioavailability testing (5) under the current bioavailability definition (1, 6).

THEORY

It was shown (4) that if the input rate into a linear response environment is given in polynomial form by[1]:

$$f(t) = \sum_{i=1}^{N} \beta_i t^{i-1} \qquad \text{(Eq. 1)}$$

and the unit impulse response (the characteristic response) of the environment is given by:

$$c_u(t) = \sum_{i=1}^{n} a_i e^{\lambda_i t} \qquad \text{(Eq. 2)}$$

then the response to $f(t)$ is:

$$c(t) = \sum_{i=1}^{N} \beta_i \phi_i(t) \qquad \text{(Eq. 3)}$$

which is linear with respect to the unknown parameters $\beta_1, \beta_2, \ldots, \beta_N$, and:

$$\phi_i(t) = (i-1)! \sum_{j=1}^{n} \frac{a_j}{\lambda_j^i} \left[e^{\lambda_j t} - \sum_{k=0}^{i-1} \frac{(\lambda_j t)^k}{k!} \right] \qquad \text{(Eq. 4)}$$

Without loss of generality, two brands or drug delivery systems may be compared by assuming the blood to be the response environment, the response to be the drug concentration, $c(t)$, and $c_m(t_{mi})$ to be the response measured at the time t_{mi}, $i = 1, 2, \ldots, M_m$, for the mth drug product ($m = 1, 2$). To facilitate the statistical analysis, the measured responses can be written in the form:

$$y_{mi} = \sum_{j=1}^{N_m} \beta_{mj} x_{mij} + \epsilon_{mi} \qquad \begin{matrix} i = 1, 2, \ldots, M_m \\ m = 1, 2 \end{matrix} \qquad \text{(Eq. 5)}$$

where:

$$x_{mij} = \phi_{mj}(t_{mi}) \qquad \begin{matrix} i = 1, 2, \ldots, M_m \\ j = 1, 2, \ldots, N_m \\ m = 1, 2 \end{matrix} \qquad \text{(Eq. 6)}$$

and:

$$y_{mi} = c(t_{mi}) \qquad \begin{matrix} i = 1, 2, \ldots, M_m \\ m = 1, 2 \end{matrix} \qquad \text{(Eq. 7)}$$

Equations 1 and 4 may be written similarly:

$$f_m(t) = \sum_{i=1}^{N_m} \beta_{mi} t^{i-1} \qquad m = 1, 2 \qquad \text{(Eq. 8)}$$

$$\phi_{mi}(t) = (i-1)! \sum_{j=1}^{n_m} \frac{a_{mj}}{\lambda_{mj}^i} \left[e^{\lambda_{mj} t} - \sum_{k=0}^{i-1} \frac{(\lambda_{mj} t)^k}{k!} \right] \qquad m = 1, 2 \qquad \text{(Eq. 9)}$$

It is of interest in bioavailability studies to test the significance of differences in the rate and/or extent of drug input between drug products. This is equivalent to testing the null hypothesis:

$$H_0: \quad \mu_1|t_0 = \mu_2|t_0 \qquad \text{(Eq. 10)}$$

against:

$$H_1: \quad \mu_1|t_0 \neq \mu_2|t_0 \qquad \text{(Eq. 11)}$$

where:

$$\mu_m|t_0 = f_m(t_0) = \sum_{i=1}^{N_m} \beta_{mi} t_0^{i-1} \qquad m = 1, 2 \qquad \text{(Eq. 12)}$$

for various values of $t = t_0$.

In matrix–vector notation, Eq. 5 is:

$$\mathbf{y}_m = \mathbf{X}_m \boldsymbol{\beta}_m + \boldsymbol{\epsilon}_m \qquad m = 1, 2 \qquad \text{(Eq. 13)}$$

The statistics to be derived for testing H_0 will be based on a normality assumption about the errors; *i.e.*, $\boldsymbol{\epsilon}_m$ is a random vector distributed $N(\mathbf{0}, \sigma_m^2 \mathbf{I})$, where $\mathbf{I}$ is the identity matrix and σ_m^2 is unknown. The unknown $N_m \times 1$ parameter vector, $\boldsymbol{\beta}_m$, is estimated by a multiple linear regression technique (4). It is assumed that the observed data are sufficient to ensure that the rank of the $M_m \times N_m$ matrix, $\mathbf{X}_m$, is $N_m \leq M_m$.

For this statistical model the least-squares estimates, denoted by $\hat{}$, are given by:

$$\hat{\boldsymbol{\beta}}_m = \mathbf{V}_m \mathbf{X}_m' \mathbf{y}_m \qquad m = 1, 2 \qquad \text{(Eq. 14)}$$

and:

$$\hat{\sigma}_m = \mathbf{e}_m' \mathbf{e}_m / (M_m - N_m) \qquad m = 1, 2 \qquad \text{(Eq. 15)}$$

where:

$$\mathbf{V}_m = (\mathbf{X}_m' \mathbf{X}_m)^{-1} \qquad m = 1, 2 \qquad \text{(Eq. 16)}$$

and:

$$\mathbf{e}_m = \mathbf{y}_m - \mathbf{X}_m \hat{\boldsymbol{\beta}}_m \qquad m = 1, 2 \qquad \text{(Eq. 17)}$$

are best linear unbiased estimates (BLUE) of $\boldsymbol{\beta}_m$ and σ_m^2. They are sufficient, efficient, complete, and consistent estimators. Furthermore, $\hat{\boldsymbol{\beta}}_m$ and $\hat{\sigma}_m$ are stochastically independent and $\hat{\boldsymbol{\beta}}_m$ is distributed $N(\boldsymbol{\beta}_m, \sigma_m^2 \mathbf{V}_m)$. Consequently, the least-squares estimate of the input rate at $t = t_0$ is the best linear unbiased estimate and is distributed:

$$\hat{f}_m(t_0) = \boldsymbol{\tau}_m' \hat{\boldsymbol{\beta}}_m \sim N(\mu_m|t_0, \sigma_m^2 \boldsymbol{\tau}_m' \mathbf{V}_m \boldsymbol{\tau}_m) \qquad m = 1, 2 \qquad \text{(Eq. 18)}$$

where:

$$\boldsymbol{\tau}_m' = (1, t_0, t_0^2, \ldots, t_0^{N_m - 1}) \qquad m = 1, 2 \qquad \text{(Eq. 19)}$$

Since $[\hat{f}_1(t_0) - \mu_1|t_0]$ and $[\hat{f}_2(t_0) - \mu_2|t_0]$ are stochastically independent, the random variable Q_1 given by:

$$Q_1 = \frac{[\hat{f}_1(t_0) - \hat{f}_2(t_0)] - (\mu_1|t_0 - \mu_2|t_0)}{[\sigma_1^2 \boldsymbol{\tau}_1' \mathbf{V}_1 \boldsymbol{\tau}_1 + \sigma_2^2 \boldsymbol{\tau}_2' \mathbf{V}_2 \boldsymbol{\tau}_2]^{1/2}} \qquad \text{(Eq. 20)}$$

is standard and normally distributed. Furthermore, $(M_m - N_m)\hat{\sigma}_m^2 / \sigma_m^2$ is χ^2-distributed with $(M_m - N_m)$ degrees of freedom. Thus, the random variable Q_2 given by:

$$Q_2 = (M_1 - N_1)\hat{\sigma}_1^2 / \sigma_1^2 + (M_2 - N_2)\hat{\sigma}_2^2 / \sigma_2^2 = \frac{\mathbf{e}_1' \mathbf{e}_1}{\sigma_1^2} + \frac{\mathbf{e}_2' \mathbf{e}_2}{\sigma_2^2} \qquad \text{(Eq. 21)}$$

is χ^2-distributed with $(M_1 - N_1) + (M_2 - N_2)$ degrees of freedom because $(M_1 - N_1)\hat{\sigma}_1^2 / \sigma_1^2$ and $(M_2 - N_2)\hat{\sigma}_2^2 / \sigma_2^2$ are stochastically independent. It can be shown that the standard normal random variable Q_1 and the χ^2-distributed random variable Q_2 are stochastically independent. Consequently, by definition, the random variable $T = Q_1 / [Q_2 / (M_1 - N_1 + M_2 - N_2)]^{1/2}$ is t-distributed with $(M_1 - N_1 + M_2 - N_2)$ degrees of freedom. If the two population variances are equal, $\sigma_1^2 = \sigma_2^2$, then T becomes independent of σ^2, so that the H_0-hypothesis can be tested by a t-test:

$$T = \frac{\hat{f}_1(t_0) - \hat{f}_2(t_0)}{\left[\dfrac{\mathbf{e}_1' \mathbf{e}_1 + \mathbf{e}_2' \mathbf{e}_2}{M_1 - N_1 + M_2 - N_2} (\boldsymbol{\tau}_1' \mathbf{V}_1 \boldsymbol{\tau}_1 + \boldsymbol{\tau}_2' \mathbf{V}_2 \boldsymbol{\tau}_2) \right]^{1/2}} \qquad \text{(Eq. 22)}$$

[1] Note that the notational expressions for the input rate (Eq. 1), the impulse response (Eq. 2), and the input response (Eq. 3) were changed from previous notations (4) to facilitate the present statistical analysis.

Table I—Origin of the Simulated Data Used

Data Set	Unit Impulse Response $a_1e^{\lambda_1 t} + a_2e^{\lambda_2 t}$				Input Rate $f(t) = kKe^{-kt}$	
	a_1	a_2	λ_1	λ_2	K	k
1	1	1	−4	−1	Unit impulse	
2	1.727	7.523	−16.30	−2.134	Unit impulse	
3	1	1	−4	−3	Unit impulse	
4	1	1	−4	−1	3.0	1.5
5	1.727	7.523	−16.30	−2.134	1.0	1.0
6	1	1	−4	−3	3.0	1.5

with a critical region (H_0 rejection region) $|T| > t\ (\alpha/2, M_1 - N_1 + M_2 - N_2)$ for a type 1 error probability α.

The equality of the population variances can be tested according to an F-test:

$$F = \frac{\mathbf{e}_1'\mathbf{e}_1}{\mathbf{e}_2'\mathbf{e}_2} \qquad \text{(Eq. 23)}$$

with a critical region $F > F\ (\alpha, M_1 - N_1, M_2 - N_2)$, since $\mathbf{e}_1'\mathbf{e}_1/\sigma^2$ and $\mathbf{e}_2'\mathbf{e}_2/\sigma^2$ are stochastically independent, χ^2-distributed, random variables with the respective degrees of freedom.

If the F-test shows that the variances are not equal, then the t-test (Eq. 22) should not be used. For such cases, the H_0-hypothesis can be tested using the following statistic (see *Appendix*):

$$w = \frac{\hat{f}_1(t_0) - \hat{f}_2(t_0)}{\left[\dfrac{\mathbf{e}_1'\mathbf{e}_1\tau_1'\mathbf{V}_1\tau_1}{M_1 - N_1} + \dfrac{\mathbf{e}_2'\mathbf{e}_2\tau_2'\mathbf{V}_2\tau_2}{M_2 - N_2}\right]^{1/2}} \qquad \text{(Eq. 24)}$$

The w-statistic is approximated by a t-distribution with degrees of freedom, DF, given by[2]:

$$DF = \left[\frac{u^2}{M_1 - N_1} + \frac{1 - u^2}{M_2 - N_2}\right]^{-1} \qquad \text{(Eq. 25)}$$

where:

$$u = \frac{\mathbf{e}_1'\mathbf{e}_1\tau_1'\mathbf{V}_1\tau_1/(M_1 - N_1)}{\mathbf{e}_1'\mathbf{e}_1\tau_1'\mathbf{V}_1\tau_1/(M_1 - N_1) + \mathbf{e}_2'\mathbf{e}_2\tau_2'\mathbf{V}_2\tau_2/(M_2 - N_2)} \qquad \text{(Eq. 26)}$$

The critical region (H_0 rejection region) is $|w| > t(\alpha/2, DF)$. A $100(1 - \alpha)$-percent confidence interval for the drug input rate at time $t = t_0$ is:

$$\hat{f}_m(t_0) - t\left(\frac{\alpha}{2}, M_m - N_m\right)\left[\frac{\mathbf{e}_m'\mathbf{e}_m\tau_m'\mathbf{V}_m\tau_m}{M_m - N_m}\right]^{1/2} \le \mu_m|t_0 \le \hat{f}_m(t_0) + t\left(\frac{\alpha}{2}, M_m - N_m\right)\left[\frac{\mathbf{e}_m'\mathbf{e}_m\tau_m'\mathbf{V}_m\tau_m}{M_m - N_m}\right]^{1/2} \qquad m = 1, 2 \quad \text{(Eq. 27)}$$

This treatment dealt with a statistical analysis of the *rate* of drug input.

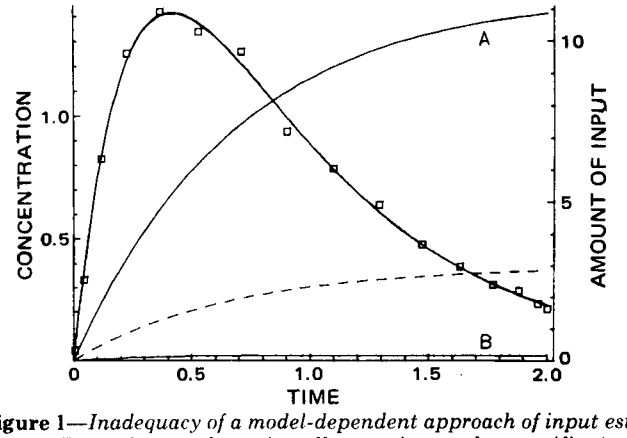

Figure 1—*Inadequacy of a model-dependent approach of input estimation. Examples are of two virtually superimposed curves (fits 1 and 2 in Table IV) fitted to Data Set 6. Curves A and B are the inputs calculated from the two fitted curves. The broken curve is the true input.*

[2] The degrees of freedom thereby is a real number, requiring interpolation in the t-table. However, most computer routines for the t-distribution permit noninteger degrees of freedom.

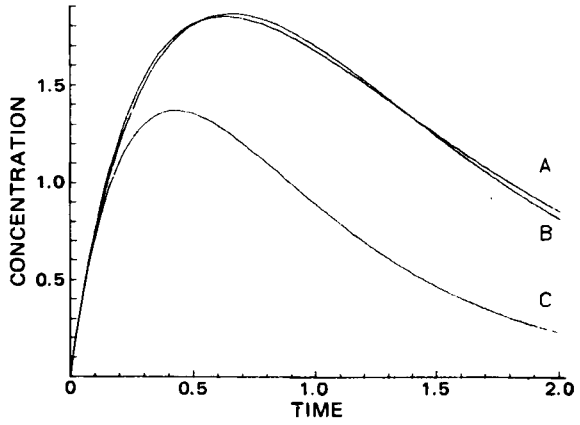

Figure 2—*Response curves A, B, and C from which the simulated Data Sets 4, 5, and 6, respectively, are derived by adding 5% random, normally distributed error. Curves A and B have widely different inputs; curves A and C have the same input (Table I).*

However, the *extent* of drug input given by:

$$A_m(t) = \int_0^t f_m(t)\,dt = \sum_{i=1}^{N_m} \frac{\beta_{mi}}{i!}\,t^i \qquad m = 1, 2 \qquad \text{(Eq. 28)}$$

can be treated similarly by replacing $f_m(t)$ with $A_m(t)$ in the respective equations and redefining τ_m' (Eq. 19) as:

$$\tau_m' = \left(t_0, \frac{t_0^2}{2}, \frac{t_0^3}{3}, \ldots, \frac{t_0^{Nm}}{N_m}\right) \qquad m = 1, 2 \qquad \text{(Eq. 29)}$$

The analysis was based on the ordinary least-squares Gauss–Markov statistical model. It is extended readily by standard means (7) to the generalized linear regression model involving correlated and/or heteroscedatic errors. The Gauss–Markov statistical model assumes no error in the independent variables, which is not true in the present case. However, the independent variables are stochastically independent random variables that do not depend on the β parameters, so the above estimation, testing, and prediction still apply. Only two aspects of the analysis are affected: (*a*) the probability in the t- and F-tests is not exact but only approximate, and (*b*) the power of the tests is different. The effect of these modifications becomes smaller the more accurately the unit impulse response is determined.

EXPERIMENTAL

The rate and the cumulative amount of input were determined by the least-squares deconvolution method presented previously (4). The data used for the demonstration of the proposed approach were generated from an arbitrarily chosen linear model with a two-exponential unit impulse response and a first-order input (Table I). Random, normally dis-

[a] The data were generated from the equations in Table I, and random normally distributed noise was added.

tributed noise was added to the exact concentration data at the 5% level, *i.e.*, with an expected coefficient of variation of 5%, using a pseudo-random normal generator based on the polar method (8) (Table II). To demonstrate the method, the unit impulse response parameters for Data Set 2 (Table I) were calculated by a nonlinear optimization technique so that Data Sets 4 and 5 (having different input) would not differ significantly. The parameters for Data Set 6 were chosen for the same reason so that Data Sets 4 and 6 would differ significantly but would have the same input (Tables I and II). The 16 sampling times for Data Sets 4–6 were chosen according to a Tschebyscheff sampling (Eq. 20 in Ref. 4) to avoid the "Runge effect" occurring in some linear regressions with fairly equally spaced sampling points.

The data matrix for the linear regression was generated from the simulated data as discussed previously (4). The matrix was executed stepwise with the BMDP-77 linear regression program P9R with a zero-intercept option and the option METHOD = NONE resulting in double-precision computations (9). The regression subsets were chosen on the basis of Mallow's criterion (10).

None of the BMDP linear regression programs provides output of the unscaled variance–covariance matrix required in the statistical computations. Therefore, a program was written to assemble the cross-product matrix and invert it using a Cholesky decomposition. A subroutine was written in FORTRAN IV to calculate and compare the rate and the cumulative amount of input of two inputs. The routine tests for heteroscedatic errors (Eq. 23) and chooses the appropriate type of statistic (Eq. 22 or 24) to calculate the significance of the input difference for various times. The α-values for the t-statistic were calculated according to the algorithm presented by Hill (11). The α-values for the F-statistic were calculated according to algorithms 26.6.15 and 26.2.17 reported in the literature (12). The parameters in Tables III and IV were obtained by nonlinear regression using the interactive program FUNFIT (13). All drawings were done by a penplotter[3] driven by a computer[4] using a software package written by the author.

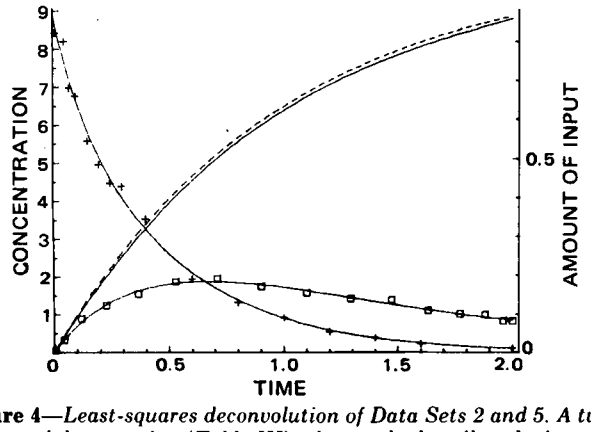

Figure 4—*Least-squares deconvolution of Data Sets 2 and 5. A two-exponential expression (Table III) adequately describes the impulse response data (+). The input function Eq. 1 is estimated subsequently by fitting Eq. 3 to the response data (□) by multiple linear regression. The continuously increasing curve is the calculated input amount (Table V). The broken curve is the exact input.*

RESULTS AND DISCUSSION

Simulated Model—Data Sets 1–3 (Tables I and II) can be considered to simulate, in the classical linear compartmental sense, intravenous bolus data normalized with respect to the dose for three subjects showing two-compartmental pharmacokinetic behavior with respect to a given drug. Data Sets 4–6 (Tables I and II) can be considered similarly as simulated first-order absorption blood concentration data adjusted for a possible lag time for the three subjects.

Comparison of Model-Dependent and Model-Independent Approaches—It is often impossible to administer a drug intravenously. It is of interest to see how accurately the drug input can be determined by a model-dependent approach from absorption blood level data alone, without knowledge of the system's response to intravenous administration of the drug. Data Sets 4–6 are generated from the convolution of $a_1 \exp(\lambda_1 t) + a_2 \exp(\lambda_2 t)$ and $kK \exp(-kt)$. The three data sets are based on:

$$c(t) = kK\left[\frac{a_1}{\lambda_1 + k}(e^{\lambda_1 t} - e^{-kt}) + \frac{a_2}{\lambda_2 + k}(e^{\lambda_2 t} - e^{-kt})\right] \qquad \lambda_1, \lambda_2 < 0 \quad \text{(Eq. 30)}$$

where K corresponds to FD (F = fraction of dose D available) and k corresponds to k_a (the first-order absorption rate constant) in classical linear compartmental modeling. This equation was fitted several times to Data Set 6 using the FUNFIT program (13) with the initial parameter estimates randomly chosen in a feasible parameter space. It is evident (Table IV and Fig. 1) that the parameters for the rate, k, and the extent, K, of input describe the input inadequately, even though the correct model is fitted to the data, the fits are excellent (Table IV and Fig. 1), and the data are as accurate as can be expected in a pharmacokinetic experiment. The input is determined poorly primarily because the parameters a_1, a_2, λ_1, and λ_2 from the unit impulse response $a_1 \exp(\lambda_1 t) + a_2 \exp(\lambda_2 t)$ (the characteristic response) are free to take nearly any values in the

[a] Residual sum of squares. [b] The parameters a_1 and λ_1 were fixed as zero in the fitting procedure corresponding to a one-compartment model.

curve-fitting procedure at the expense of k and K. Furthermore, the nonlinear parameters are not unique due to the presence of multiple minima of the residual sum of the squares function (13). (The six fits in Table IV represent different local minima.)

The input could have been determined more accurately if the unit impulse response parameters had been determined first from an intravenous administration and then used as constants in the fitting of Eq. 30. However, this approach has the disadvantage of being model dependent since it assumes a first-order input $f(t) = kK \exp(-kt)$. Since many variables affect the input *via* the GI route (gastric emptying, GI motility, pH, blood flow, *etc.*), it may seem unreasonable that the input is described in such a smooth, functional form. The present least-squares deconvolution approach is more general. The input is approximated by a polynomial. As such, it is more flexible and can adapt to whatever fluctuations or functional form the input may have. Furthermore, the input is determined by linear rather than nonlinear regression, so it is easier to apply computationally (*e.g.*, no initial parameter estimates are required). The problem with multiple minima is eliminated, and the approach is more suitable for a statistical analysis of the input.

The present method requires the unit impulse response parameters to be determined by nonlinear regression. However, the nonuniqueness of these parameters and their actual values as such have no influence on the accuracy of the input determination. The input is not calculated from the parameters individually but collectively in the way that together they represent the unit impulse response. In estimating these parameters from data from an intravenous bolus or intravenous infusion administration, two or more sets of widely different parameters may be obtained that give nearly superimposed curves as in Fig. 1 (Table IV). However, contrary to a model-dependent approach, the individual parameter values are irrelevant. The important consideration is how well the curve fits the data. There are several methods for automatically handling this curve-fitting problem (14, 15).

Deficiencies in Using C_{max}, t_{max}, and AUC in Bioavailability Testing—Data Sets 4, 5, and 6 are generated from Fig. 2 curves A, B, and C, respectively, by adding 5% normally distributed noise to the exact concentration data (Table II). Curves A and B are very close, but the rate and the extent of input resulting in these curves differ substantially (Table I; A: $k = 1.5$, $K = 3.0$; B: $k = 1.0$, $K = 1.0$). Curves A and C differ widely, but they result from the same input (Table I; $k = 1.5$, $K = 3.0$). A comparison of the extent and the rate of input for Data Sets 4 and 5 (A and B, Fig. 2) on the basis of AUC, t_{max}, and C_{max} will not show a significant difference in their input. Furthermore, a comparison of Data Sets 4 and 6 (A and C, Fig. 2) by AUC, t_{max}, and C_{max} is likely to show a significant difference in both the rate and the extent of input when, in fact, there is no difference.

Because AUC, t_{max}, and C_{max} depend both on the input and the response properties of the system, they can be misleading measures of bioavailability if the comparison is not done within subjects, *i.e.*, for a constant unit impulse response. The deconvolution approach does not have this disadvantage. The response properties of the system are deconvoluted from the measured response to give a pure measure of the rate and the extent of input.

Deconvolution Approach—Deconvolution of Data Sets 4, 5, and 6 (corresponding to A, B, and C in Fig. 2) is done (Figs. 3, 4, and 5, respectively) using the responses measured for the three systems from a bolus input (Data Sets 1, 2, and 3, respectively)[5]. There is excellent agreement between the exact input and that calculated by deconvolution (Figs. 3–5). The regression function, Eq. 3, fits Data Sets 4–6 well. A Durbin–Watson analysis (16) and a runs test (17) show no systematic deviations among the residuals. The Tschebyscheff sampling strategy for Data Sets 4–6 appears to give a more stable behavior for the fitted curve (Eq. 3) and the calculated input for an increase in N (Eqs. 1 and 3) than the sampling scheme used previously (4).

Statistical Comparison of Input—The input rate calculated from Data Sets 1 and 4 and 3 and 6 (A and B, respectively, Fig. 6) does not appear to differ significantly throughout the input period $t = 0$–2. The differential confidence profile (curve C, Fig. 6) is largest in the initial input phase but shows no significant [$100(1 - \alpha) < 95$] difference in the input rate. The same is the case in comparing the cumulative input amount (Fig. 7). The input rates calculated from Data Sets 2 and 5 and 3 and 6 (A and B, respectively, Fig. 8) differ significantly in most of the input period. The respective cumulative input amounts differ significantly during the entire input period (Fig. 9). The input calculated from Data Sets 1 and 4 and 2 and 5 shows the same general behavior as the input calculated from Data Sets 2 and 5 and 3 and 6 (Figs. 10 and 11).

The method proposed performs satisfactorily. The inputs are well determined[6], and the method properly differentiates between the input

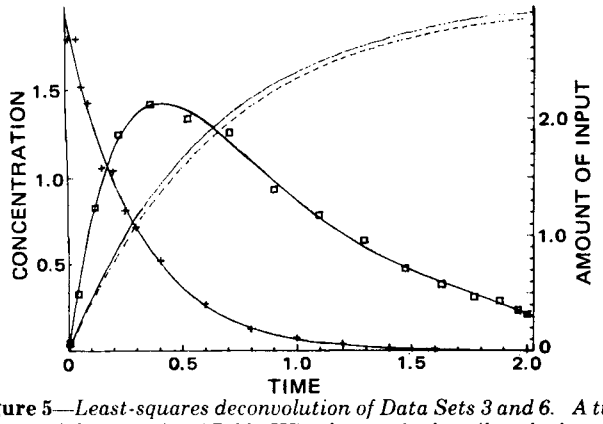

Figure 5—*Least-squares deconvolution of Data Sets 3 and 6. A two-exponential expression (Table III) adequately describes the impulse response data (+). The input function Eq. 1 is estimated subsequently by fitting Eq. 3 to the response data (□) by multiple linear regression. The continuously increasing curve is the calculated input amount (Table V). The broken curve is the exact input.*

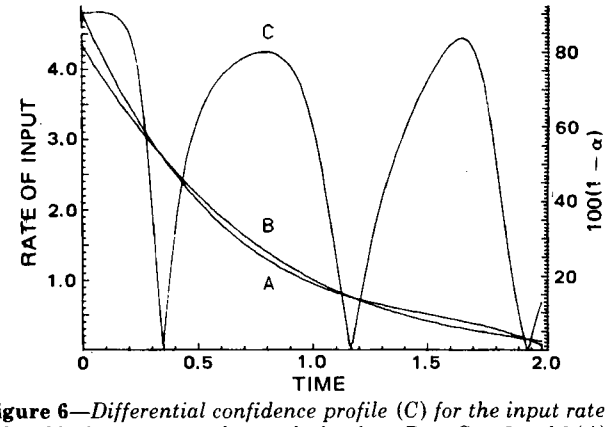

Figure 6—*Differential confidence profile (C) for the input rate calculated by least-squares deconvolution from Data Sets 3 and 6 (A) and 1 and 4 (B).*

[5] An infusion input also could have been used to obtain the unit impulse response parameters.

[6] The input might not have been approximated so well if the analysis had been performed using data extending substantially beyond the absorption phase. However, a beginning oscillatory behavior around zero of $f(t)$ in the postabsorption phase would result, indicating that the fitting is extended too far.

Table V—Input Rate Estimated by the Least-Squares Deconvolution Method, $0 \leq t \leq 2$

Data Sets	
1 and 4	$f(t) = 4.35 - 5.37t + 2.43t^2 - 0.403t^3$
2 and 5	$f(t) = 0.937 - 0.754t + 0.184t^2$
3 and 6	$f(t) = 4.81 - 7.32t + 4.45t^2 - 0.988t^3$

for the similar Data Sets 4 and 5. It also shows no significant difference between the widely different Data Sets 4 and 6 having the same input. However, the statistics appear rather sensitive (Figs. 6 and 7), as expected, since they are based on normality assumptions. Therefore, it would be appropriate to choose a more conservative hypothesis testing such as:

$$H_1: \quad \mu_1|t_0 \leq \mu_2^*|t_0 \qquad \text{(Eq. 31)}$$

against:

$$H_0: \quad \mu_1|t_0 > \mu_2^*|t_0 \qquad \text{(Eq. 32)}$$

$$\mu_2^*|t_0 = \frac{100 + D}{100}\mu_2|t_0 \qquad \text{(Eq. 33)}$$

where D, the differential index, is chosen appropriately. For example, with the differential index equal to 25, the hypothesis that the rate or cumulative amount of input differs by more than 25% could then be tested at various times by a simple extension of the present method. This approach seems to be more rational considering the large intersubject variations observed in the pharmacological response for many drugs. The application of the method to analyze real pharmacokinetic data is in progress.

APPENDIX

Several statistics have been proposed to test the equality of means for normal populations with unequal variances (18–21). Monte Carlo simulation studies comparing several of these statistics (21) indicate that the statistic proposed by Welch (19) is the most robust and appropriate for small samples.

This statistic can be stated for a two population problem in the following simplified form:

Theorem I: Let x_{ij} be the jth observation from the ith population, where $j = 1, \ldots, n_i$ and $i = 1, 2$. If x_{ij} are stochastically independent normal variates with expected values of μ_i and the variance σ_i^2, then the probability distribution of the statistic:

$$w = \frac{\bar{x}_1 - \bar{x}_2}{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)^{1/2}} \qquad \text{(Eq. A1)}$$

is approximated by a t-distribution with degrees of freedom given by:

$$DF = \left[\frac{u^2}{n_1 - 1} + \frac{1 - u^2}{n_2 - 1}\right]^{-1} \qquad \text{(Eq. A2)}$$

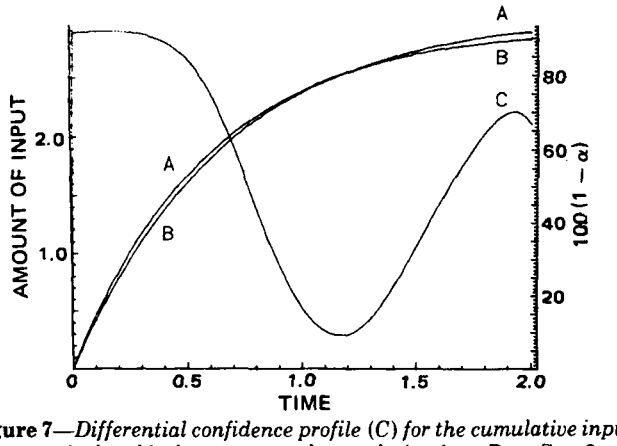

Figure 7—*Differential confidence profile (C) for the cumulative input amount calculated by least-squares deconvolution from Data Sets 3 and 6 (A) and 1 and 4 (B).*

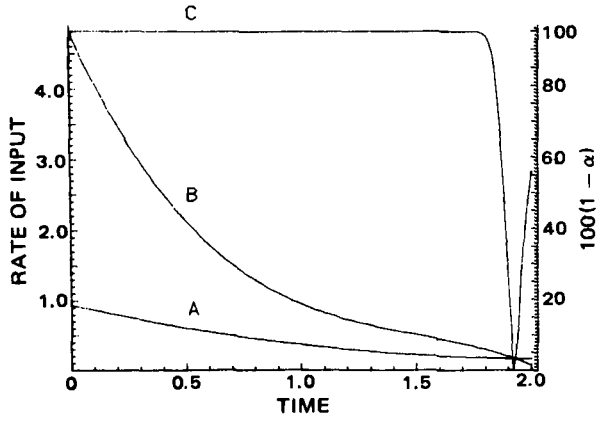

Figure 8—*Differential confidence profile (C) for the input rate calculated by least-squares deconvolution from Data Sets 2 and 5 (A) and 3 and 6 (B).*

where:

$$u = \frac{s_1^2/n_1}{s_1^2/n_1 + s_2^2/n_2} \qquad \text{(Eq. A3)}$$

$$s_i^2 = \sum_{j=1}^{n_i} (\bar{x}_i - x_{ij})^2/(n_i - 1) \qquad i = 1, 2 \qquad \text{(Eq. A4)}$$

and:

$$\bar{x}_i = \sum_{j=1}^{n_i} x_{ij}/n_i \qquad i = 1, 2 \qquad \text{(Eq. A5)}$$

This theorem deals with a differently formulated statistical problem than that of interest. However, the following extension of the theorem can be applied to test H_0 (Eq. 10) in the case of unequal population variances:

Corollary I: Let z_1 and z_2 be stochastically independent random variables distributed $N(\mu_1, \sigma_1^2)$ and $N(\mu_2, \sigma_2^2)$, respectively. Further, let s_{z1}^2 and s_{z2}^2 be stochastically independent random variables with moment-generating functions:

$$G_1(t) = \left(1 - 2\frac{\sigma_1^2}{\nu_1}t\right)^{-\nu_1/2} \qquad \nu_1 > 0 \qquad \text{(Eq. A6)}$$

$$G_2(t) = \left(1 - 2\frac{\sigma_2^2}{\nu_2}t\right)^{-\nu_2/2} \qquad \nu_2 > 0 \qquad \text{(Eq. A7)}$$

Then the probability distribution of the statistic:

$$w = \frac{z_1 - z_2}{(s_{z1}^2 + s_{z2}^2)^{1/2}} \qquad \text{(Eq. A8)}$$

is approximated by a t-distribution with degrees of freedom given by:

$$DF = \left[\frac{u^2}{\nu_1} + \frac{1 - u^2}{\nu_2}\right]^{-1} \qquad \text{(Eq. A9)}$$

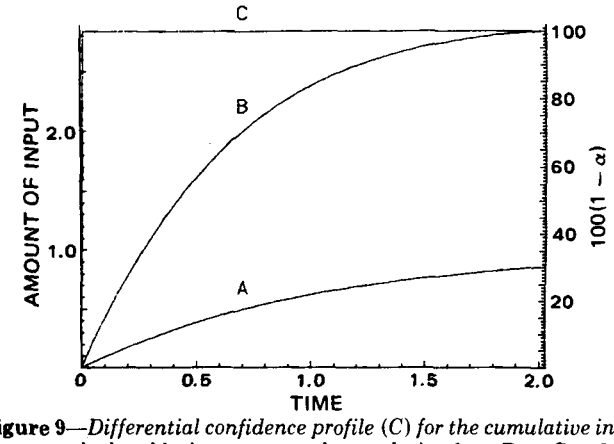

Figure 9—*Differential confidence profile (C) for the cumulative input amount calculated by least-squares deconvolution from Data Sets 2 and 5 (A) and 3 and 6 (B).*

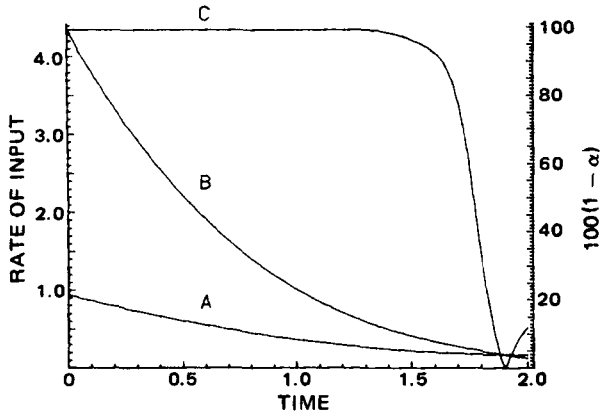

Figure 10—*Differential confidence profile (C) for the input rate calculated by least-squares deconvolution from Data Sets 2 and 5 (A) and 1 and 4 (B).*

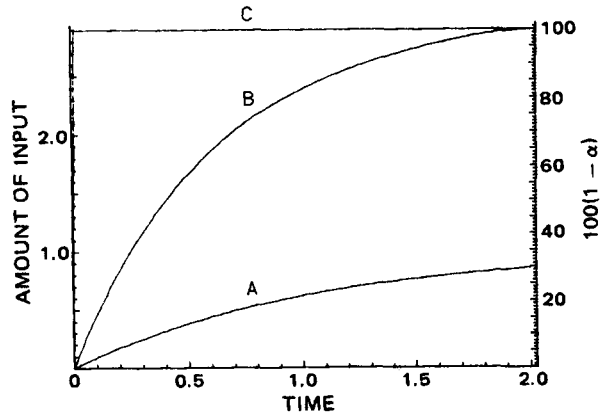

Figure 11—*Differential confidence profile (C) for the cumulative input amount calculated by least-squares deconvolution from Data Sets 2 and 5 (A) and 1 and 4 (B).*

where:

$$u = \frac{s_{z1}^2}{s_{z1}^2 + s_{z2}^2} \qquad \text{(Eq. A10)}$$

Proof: The random variables $z_i = \bar{x}_i$, $i = 1, 2$ (Eq. A5), are distributed $N(\mu_i, \sigma_i^2/n_i)$. The random variables $s_{zi}^2 = s_i^2/n_i$ have the moment-generating functions:

$$G_i(t) = \left(1 - 2\frac{\sigma_i^2/n_i}{n_i - 1}t\right)^{-(n_i-1)/2} \qquad i = 1, 2 \qquad \text{(Eq. A11)}$$

because $(n_i - 1)s_i^2/\sigma_i^2$ is χ^2-distributed with $n_i - 1$ degrees of freedom[7]. Equation A11 uniquely defines the probability distribution of s_{zi}^2. Letting $\nu_i = n_i - 1$ and replacing σ_i^2/n_i by σ_i^2 lead to the corollary.

The applicability of the corollary to test H_0 (Eq. 10) is seen as follows. With:

$$z_m = \hat{f}_m(t_0) \sim N(\mu_m | t_0, \sigma_m^2 \tau_m' \mathbf{V}_m \tau_m) \qquad m = 1, 2 \qquad \text{(Eq. A12)}$$

the moment-generating function of:

$$s_{zm}^2 = \hat{\sigma}_m^2 \tau_m' \mathbf{V}_m \tau_m = \frac{\mathbf{e}_m' \mathbf{e}_m}{M_m - N_m} \tau_m' \mathbf{V}_m \tau_m \qquad m = 1, 2 \qquad \text{(Eq. A13)}$$

is:

$$G_m(t) = \left(1 - 2\frac{\sigma_m^2 \tau_m' \mathbf{V}_m \tau_m}{M_m - N_m}t\right)^{-(M_m - N_m)/2} \qquad m = 1, 2 \qquad \text{(Eq. A14)}$$

because $(M_m - N_m)\hat{\sigma}_m^2/\sigma_m^2$ is χ^2-distributed with $M_m - N_m$ degrees of freedom. Comparison of Eqs. A12 and A14 in relation to Corollary I leads to Eqs. 24–26.

[7] The moment-generating function of a χ^2-distributed variable with n degrees of freedom is $(1 - 2t)^{-n/2}$.

Kinetic Ratio as a Parameter for Product Stability Calculations

MARVIN SCHER

Received May 17, 1979, from *Miles Laboratories, Elkhart, IN 46515.* Accepted for publication October 12, 1979.

Abstract □ A new parameter, the kinetic ratio, is suggested for estimating product potency during storage under ambient warehouse temperatures. Actual warehouse temperature data were integrated using Arrhenius kinetics, and the resulting potency errors, due both to the integration method and to temperature averaging, were evaluated. Kinetic ratios and virtual temperatures then were compared to show seasonal and Arrhenius constant effects. Equations interrelating the kinetic ratio and virtual temperature are given. Finally, sample calculations using typical vitamin A data were analyzed to demonstrate the calculational and interpretation characteristics of the kinetic ratio compared to the virtual temperature.

Keyphrases □ Stability—product potency, calculation, kinetic ratio parameter □ Drug potency—product stability, calculation, kinetic ratio parameter □ Expiration dating—product stability, calculation, kinetic ratio parameter □ Arrhenius equation—calculation of product stability, kinetic ratio parameter

The useful concept of a single measurement, virtual temperature, to reflect the pattern of changing temperatures in a warehouse was introduced in 1971 (1). Since then, virtual temperature has been used widely in stability calculations. Although the physical meaning of virtual temperature is easily understood, it tends to be misleading and difficult to use because it causes a change two exponentiations away from the focus of interest.

Because temperature is a misleading criterion for kinetic change and is difficult to use in calculations, and because reference potencies commonly were calculated based on a reference temperature anyway, a new parameter, the kinetic ratio, was defined. Compared to virtual temperature, the kinetic ratio appears to relate more directly to potency, to separate temperature effects more effectively, to reflect important changes more sensitively, and to yield calculated results more conveniently.

EXPERIMENTAL

Data obtained at a Dallas warehouse were selected for analysis because this location offered extreme temperature variation. Temperature readings were used weekly from a circular chart recorder at 6-hr intervals for 364 days (September 1, 1975 through August 31, 1976). The data were collected as part of an ongoing stability evaluation program by a quality assurance unit.

In addition to the temperature data, typical constants for vitamin A in multivitamin tablets at a reference temperature of 24° were obtained from the same source and used in sample calculations. These constants were: Arrhenius "activation" constant (b_1), 13185.0 °K; Arrhenius factor (b_0), 2.0361×10^{16} weeks^{-1}; reference rate constant (T_{ref}), 297.16 °K; reference rate constant (k_{ref}), 0.0010943 week^{-1}; initial potency (P_0), 7300 units; reference potency at 52 weeks (P_{52}), 6896 units; reference potency at 78 weeks (P_{78}), 6703 units; reference potency at 156 weeks (P_{156}), 6154 units; and reference shelflife (τ_{sl}), 442 weeks.

RESULTS

Definitions and Relationships—Virtual temperature is the fixed temperature that produces the same kinetic constant as that which results from evaluating temperature that changes with time[1]. The kinetic ratio is a ratio of a rate constant that results from evaluating temperature that changes with time to the rate constant at a fixed reference temperature.

Quantitative relationships are given in Table I, and the nomenclature is appended. Both virtual temperature and the kinetic ratio are independent of reaction order for the simple models used in most cases. In this paper, temperature response is assumed to follow Arrhenius's law (Eq. 1). Mathematical definitions of the virtual temperature and kinetic ratio (Eqs. 2*a* and 2*b*, respectively) allow for temperature variation with time. At a given location, the observed temperature values can be integrated numerically to yield values of the two parameters. The remaining relationships in Table I are the result of combining and relating kinetic-order effects with the Arrhenius equation. Because reference temperature constants are a common form of reporting stability data, these constants normally would be readily available for the indicated calculations.

The resulting equations for α may be verified by direct derivation using definitions and kinetic relationships. For example, if a ratio of the first-order kinetic equations, $\ln(P_\tau/P_0) = -k\tau$ and $\ln(P_\tau/P_0)_{ref} = -k_{ref}\tau$, is formed and the definition of the kinetic ratio, $\alpha = k/k_{ref}$, is substituted therein, Eq. 3*b* results after antilogs are taken.

Temperature Data—Many questions might be asked about the process of transforming temperature data into a potency change. How frequently must temperature be measured? What errors are introduced by averaging temperatures to daily, weekly, and monthly values? What methods might be used to convert temperature–time data into potency effects? These questions are not fully answered here, but an efficient approach to the problem is suggested and the relative importance of several factors is weighed.

Potency changes were evaluated for two sets of Arrhenius constants, one set typical of vitamin A in a multivitamin tablet and another set arbitrarily formulated to approach the upper temperature–instability limit likely to be encountered in products stored at ambient temperatures. The conventional Arrhenius equation and first-order kinetics were combined as in Eq. 3*a*, except that actual temperatures were used in place of virtual temperature. The result was integrated numerically over time. With temperature readings at 6-hr intervals, three numerical integration methods were compared: Simpson's rule, the trapezoidal rule, and a fifth-order quadrature method[2]. Although errors resulting from all methods were small (Table II), the fifth-order quadrature method was used for subsequent comparisons because it reduced integration errors to insignificantly small values.

The effect of temperature averaging on the observed error in potency also was considered. Results for averaged temperature values for each day, week, and month showed very small errors for moderately stable materials, but these values would be subject to noticeable errors at the limit of practical stability. This effect has a direct bearing on the use of virtual temperature, the kinetic ratio, or any other temperature-averaging method. Either correction factors or averages over smaller time intervals probably would be required to reflect accurately the potency of very heat-sensitive materials stored at ambient temperatures.

Daily averaged temperatures and fifth-order quadrature were used with Eq. 2*a* from Table I to evaluate virtual temperatures. Kinetic ratios were determined similarly from Eq. 2*b* with a reference temperature of 24°. Results are presented in Table III.

DISCUSSION

Virtual Temperature and Kinetic Ratio—Close examination of Eq. 3*b* reveals that, for first-order kinetics, the kinetic ratio has an interpretation similar to the elasticity in economics. For every small percent change in the reference potency, the actual percent potency changes by a factor of approximately α times. Thus, with reference to Table III, a compound with an activation constant of 15,000 will drop approximately 13.24% for a 10% annual loss observed at the reference temperature. Actual calculation from Eq. 3*b* yields 13.02%. Although this simple interpretation of α becomes subject to larger errors with larger potency

[1] This statement is a general application of Haynes' definition, which related virtual temperature to a monthly average temperature (1).

Table I—Relationships of Virtual Temperature and Kinetic Ratio Parameters [Arrhenius's Law: $k = b_0 e^{-b_1/T}$ (Eq. 1)]

Definition	Virtual Temperature		Kinetic Ratio	
	$T_v = \dfrac{-b_1}{\ln\left(\frac{1}{\tau}\int_0^\tau e^{-b_1/T}\,d\theta\right)}$	(Eq. 2a)	$\alpha = \dfrac{\frac{1}{\tau}\int_0^\tau e^{-b_1/T}\,d\theta}{e^{-b_1/T_{ref}}}$	(Eq. 2b)
	where $T = g(\theta)$ is an unspecified function of time			
First-order potency	$P_\tau = P_0 e^{-(b_0 e^{-b_1/T_v})\tau}$	(Eq. 3a)	$P_\tau = P_0\left(\frac{P_\tau}{P_0}\right)^\alpha_{ref}$	(Eq. 3b)
First-order shelflife	$\tau_{sl} = \dfrac{\ln(P_0/P_\tau)_{sl}}{b_0 e^{-b_1/T_v}}$	(Eq. 4a)	$\tau_{sl} = \dfrac{\ln(P_0/P_\tau)_{sl}}{\alpha k_{ref}}$	(Eq. 4b)
Zero-order potency	$(P_0 - P_\tau) = (b_0 e^{-b_1/T_v})\tau$	(Eq. 5a)	$(P_0 - P_\tau) = \alpha(P_0 - P_\tau)_{ref}$	(Eq. 5b)
Zero-order shelflife	$\tau_{sl} = \dfrac{(P_0 - P_\tau)_{sl}}{b_0 e^{-b_1/T_v}}$	(Eq. 6a)	$\tau_{sl} = \dfrac{(P_0 - P_\tau)_{sl}}{\alpha k_{ref}}$	(Eq. 6b)
For equal cumulative time periods	$(-b_1/T_v)_\tau = \ln\frac{1}{\tau}\sum_{i=1}^{\tau}(e^{-b_1/T_{vi}})$	(Eq. 7a)	$\alpha_\tau = \frac{1}{\tau}\sum_{i=1}^{\tau}\alpha_i$	(Eq. 7b)
Conversion, T_v/α	$T_v = \dfrac{b_1}{b_1/T_{ref} - \ln\alpha}$	(Eq. 8a)	$\ln\alpha = b_1\left(\frac{1}{T_{ref}} - \frac{1}{T_v}\right)$	(Eq. 8b)
Conversion, reference T	$k_v = \alpha k_{ref}$	(Eq. 9a)	$\alpha_{T_2} = \alpha_{T_1} e^{-b_1(1/T_1 - 1/T_2)}$	(Eq. 9b)

Table II—Annual Percent Error in Potency Calculations Relative to the Best Estimate Based on a Dallas Warehouse

Constants		Percent Potency Remaining, $100\,(P_\tau/P_0)_y$	Percent Error in Fraction Potency Remaining[a] by Time Interval/Method[b]					
			6 hr			Daily	Weekly	Monthly
b_0	b_1		DQSF	SIMP	TRAP	DQSF	DQSF	DQSF
2.0361×10^{16}	13,185	93.1	0	<0.01	−0.02	0.06	0.18	0.50
8.46×10^{33}	25,000	74.3	0	0.09	−0.30	1.5	5.5	12.6

[a] Percent error = $100\,[(P_\tau/P_0)_y - (P_\tau^{\sim}/P_0)_y]/(P_\tau/P_0)_y$. [b] DQSF is a fifth-order quadrature subroutine from IBM's Scientific Subroutine Package, and SIMP and TRAP are mnemonics for Simpson's rule and the trapezoidal rule, respectively.

Table III—Yearly and Quarterly Arrhenius Kinetic Parameters for a Dallas Warehouse [T_{ref} = 297.16 (24°)]

	Kinetic Ratios					Virtual Temperatures				
b_1	α_y	α_1	α_2	α_3	α_4	T_{vy}	T_{v1}	T_{v2}	T_{v3}	T_{v4}
5,000	1.009	0.708	0.998	1.404	0.927	297.32	291.17	297.13	303.27	295.83
10,000	1.112	0.507	1.027	1.999	0.915	298.15	291.28	297.39	303.41	296.37
15,000	1.324	0.367	1.088	2.886	0.955	298.82	291.38	297.66	303.53	296.89
20,000	1.679	0.270	1.187	4.214	1.046	299.47	291.48	297.92	303.64	297.36
25,000	2.236	0.200	1.331	6.221	1.190	300.03	291.58	298.17	303.76	297.77

changes, it is a quick and easy estimator and has a readily understood relationship to potency.

Seasonal effects are relatively easy to discern in the kinetic ratio (Table III). A compound with an activation constant of 15,000 and a warehouse potency loss of 13% for the year will have experienced a cycle of changes relative to the constant-temperature reference. In the cold winter months of the first quarter, the α value of 0.367 suggests a change of slightly more than one-third of the change of the reference potency. During the spring and fall, the reference and warehouse potencies change by about the same amount. However, in the summer, the warehouse potency loss was just under three times the reference loss.

For zero-order kinetics, the kinetic ratio is directly proportional to the drop in potency (Eq. 5b). Thus, if the reference potency for the example drops 500 units in a year, that same compound would drop $1.324 \times 500 = 662$ units in the Dallas warehouse.

Comparison of Virtual Temperature and Kinetic Ratio—No obvious deductions regarding potency changes can be made from the virtual temperatures in Table III. Interpolation may be used to obtain intermediate values for both parameters. Linear interpolation in Table III produced a maximum positive error of ~0.01. Because of the additional exponentiation, virtual temperature calculations require greater care. The constancy of virtual temperature has been emphasized as offering a special advantage (1). This constancy is an artifact of double exponentiation and demonstrates the insensitivity of virtual temperature to changes that can significantly affect potency. For example, according to Eq. 3a, a relatively small change in T_v will, after being exponentiated twice, magnify into a substantial potency change.

The interrelationship between the kinetic ratio and virtual temperature is given by Eqs. 8a and 8b, which quantify the relative sensitivity of α observed in Table III. Specifically, the entire range of virtual temperatures here changes by only 4%, while the corresponding range of the kinetic ratio changes by 3100%. It is evident that numerous significant digits must be carried for virtual temperature and that the leading constant digits tend to screen information.

Computation of virtual temperature and the kinetic ratio is similar, except that a reference temperature must be declared for the latter (Eq. 2b). This requirement is the only price paid for later ease of use, and reference temperature calculations appear to be widely used throughout the pharmaceutical industry. Because both parameters are dependent on ambient temperatures, which, in turn, are a function of the specific

Table IV—Comparison of Calculations for Potency at a Dallas Warehouse

Calculation	Virtual Temperature	Kinetic Ratio	Number of Arithmetic Operations: Virtual Temperature	Number of Arithmetic Operations: Kinetic Ratio	Vitamin A Results
Potency after 3 years	Eqs. 1 and 3*a*	Eq. 3*b*	6	3	5914 units
Potency after 18 months (six quarters) using seasonal values	Eqs. 7*a*, 1, and 3*a*	Eqs. 7*b* and 3*b*	17	8	664 units
Potency after 18 months (six quarters) using annual values	Eqs. 1 and 3*a*	Eq. 3*b*	6	3	6570 units
Shelflife	Eq. 4*a*	Eq. 4*b*	6	4	358 weeks

warehouse location and construction, each company would have to determine its individual parameters. The inclusion of a reference temperature in these calculations is a small matter. In addition, conversion from one reference temperature to another, should this be necessary, is straightforward (Eq. 9*b*).

Sample Calculations—Constants and reference data were combined with the data from Table III for sample calculations. Twice as many arithmetic operations usually are required for calculations involving virtual temperature (Table IV). The use of reference potencies eliminates the need to calculate rate constants. The kinetic ratio reference potency and initial potency are all that are required for direct calculations. Once the reference values are calculated, they remain constant and may be used to calculate potencies at each warehouse with the appropriate α value. Virtual temperature calculations invariably require exponentiation to obtain a rate constant needed for subsequent calculations. As also can be seen from Table IV, the seasonal effect over six quarters is not significant for vitamin A in multivitamin tablets (1.5%). Shelflife calculations using the kinetic ratio are particularly easy because they only involve dividing a constant by a different α for each warehouse.

CONCLUSIONS

Although it is only a simple extension of a generalized virtual temperature definition, the kinetic ratio offers clear practical advantages. The parameter has a direct, easily understood physical relationship to potency, and commonly performed calculations are simplified greatly.

NOMENCLATURE

α = kinetic ratio (dimensionless)
b_0 = Arrhenius factor, defined by Eq. 1 (weeks^{-1})
b_1 = Arrhenius activation factor, E/R, defined by Eq. 1 (°K)
θ = time (weeks)
g = general unspecified function
k = Arrhenius kinetic constant (weeks^{-1})
P = potency or concentration variable (units)
τ = specific time (weeks)
T = temperature (°K)

Subscripts:

0 = initial value of a variable
1, 2, 3, 4 = either a specific value denoted by the number or values that relate to enumerated quarters of the year
ref = reference value of a variable or quantity enclosed in brackets
sl = value of variables corresponding to the shelflife
v = virtual value
y = cumulative annual value

Synthesis and Skeletal Muscle Relaxant Activity of Quaternary Ammonium Salts of Dantrolene and Clodanolene

K. O. ELLIS ˣ, R. L. WHITE, Jr., G. C. WRIGHT, and F. L. WESSELS

Received July 16, 1979, from the *Scientific Affairs Department, Norwich-Eaton Pharmaceuticals, Division of Morton-Norwich Products, Inc., Norwich, NY 13815.* Accepted for publication October 16, 1979.

Abstract □ A series of quaternary ammonium salts of dantrolene and clodanolene was prepared and evaluated for skeletal muscle relaxant activity. The quaternary ammonium salts exhibit greater aqueous solubility and, therefore, facilitate intravenous administration. One member of this series, although less effective orally, exhibited greater aqueous solubility than the sodium salt. When administered intravenously, it was a more potent antagonist of skeletal muscle contraction and yielded comparable therapeutic and muscle relaxant efficacy indexes.

Keyphrases □ Dantrolene—quaternary ammonium salts, synthesis, skeletal muscle relaxant activity □ Clodanolene—quaternary ammonium salts, synthesis, skeletal muscle relaxant activity □ Relaxants, skeletal muscle—dantrolene and clodanolene, quaternary ammonium salts, synthesis, activity

Several hydantoins have skeletal muscle relaxant activity (1). One member of this series, dantrolene[1], was shown subsequently to cause skeletal muscle relaxation by a unique mechanism involving direct action on the skeletal muscle (2, 3). Dantrolene sodium has been hypothesized to act by preventing the release of calcium ion (Ca^{2+}) from the sarcoplasmic reticulum (4, 5).

Dantrolene sodium recently was shown to have potential

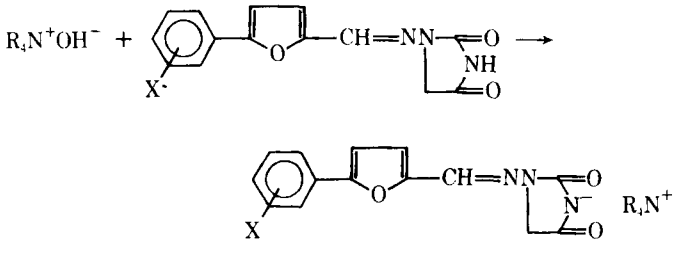
[a] The water solubility is greater than 1%.

utility for the treatment of malignant hyperthermia (6–8). The fulminating nature of this condition requires rapid institution of therapeutic measures including intravenous muscle relaxants. Because dantrolene sodium is relatively insoluble in aqueous solutions, other soluble salts have been synthesized for evaluation (Table I). This paper reports the preparation of a series of quaternary ammonium salts (9) of dantrolene and clodanolene and their pharmacological evaluation for skeletal muscle relaxant activity.

Salts of dantrolene and clodanolene, other than the sodium salts, were desired for comparative pharmacological evaluation. Since the hydantoin moiety of the two parent compounds is weakly acidic, a strong base was sought for salt formation. The broad class of quaternary ammonium hydroxides fills the requirement of a strong base and also provides versatility in selection of an organic cation. In practice, the acid–base reaction of dantrolene or clodanolene with quaternary ammonium hydroxides proceeded rapidly, and the salt products were stable to recrystallization from various solvents (Scheme I). The quaternary ammonium hydroxides were prepared from the appropriate quaternary ammonium halides by ion-exchange chromatography and then were used directly. Success of



dantrolene: X = *p*-NO_2
clodanolene: X = 3,4-Cl

the acid–base reaction was easily discernible upon isolation of the product. The carbonyl bands of the hydantoins at 5.65 and 5.8 μm in the IR spectrum shifted to 5.9 and 6.2 μm.

EXPERIMENTAL

Chemistry[2]—*Quaternary Halides*—The following salts were prepared by literature methods: diethyldimethylammonium iodide (10), 1,3-dimethylimidazolium iodide (11), *N*-methylpyridinium iodide (12), 1,1-dimethyl-2-hydroxyethyltrimethylammonium iodide (13), 2-carbamyl-1-methylpyridinium iodide (14), aminopyridine methiodide (15), quinolizinium bromide (16), and 2-(2,3-dihydroxypropylamino)quinolizinium bromide (17). Tetramethylammonium hydroxide, benzyltrimethylammonium hydroxide, tetramethylammonium chloride, tetrabutylammonium iodide, benzyltrimethylammonium chloride, and Safranine O were purchased[3]. Choline chloride was obtained commercially[4].

The following four methods were used for preparation of quaternary salts of dantrolene and clodanolene, with dantrolene salts given as examples (Table II).

Dantrolene [1-[[5-(p-Nitrophenyl)furfurylidene]amino]hydantoin] Quinolizinium Salt Hemihydrate (VII) (Method A)—Resin[5] (65 ml) was activated by elution with 10% NaOH, and the column was washed with water to bring to pH 7–8. Quinolizinium bromide (4.7 g, 0.021 mole) (7) was passed through the basic anion-exchange resin with water (75 ml) at ~1 drop/sec until the eluent (pH 10–11) returned to pH 8–9.

Dantrolene (5.1 g, 0.016 mole) was added slowly to the quaternary hydroxide solution at room temperature to bring to pH 8–9. The resultant yellow solid was collected and washed with cold water (3 × 5 ml) and 2-propanol (2 × 5 ml) and then was allowed to dry to give 5.1 g (70% yield), mp 184–196° dec.; IR (mineral oil): 5.9 and 6.2–6.3 μm.

Dantrolene Diethyldimethylammonium Salt (XI) (Method B)—A resin[5] column (115 ml) was prepared as in Method A. Methanol (400 ml) was eluted slowly through the column followed by a solution of diethyldimethylammonium iodide in methanol (50 ml). The column was eluted to neutrality with methanol. The methanolic solution was added to dantrolene (15.7 g, 0.050 mole) in methanol (100 ml), and the mixture was stirred for 1.0 hr.

The mixture was filtered, and the filtrate was concentrated under reduced pressure to a red solid. Recrystallization from 2-propanol (150 ml) with activated charcoal[6] yielded 16.5 g (72% yield) of product, mp 198–200°. A sample again was recrystallized from 2-propanol to analytical purity, mp 201–202°; IR (mineral oil): 5.9 and 6.2–6.3 μm.

Dantrolene Tetramethylammonium Salt (II) (Method C)—To a stirred mixture of dantrolene (21 g, 0.066 mole) in 1.0 liter of methanol was added tetramethylammonium hydroxide (50 ml of 20% solution in methanol, 0.10 mole). The mixture was stirred for 1.0 hr and then heated while methanol (400 ml) was added to complete dissolution. Filtration and cooling allowed isolation of 15 g (59% yield) of a red product. Recrystallization from methanol gave analytical material, mp 218–220°; NMR: δ 3.23 (s, 12H, methyl CH), 3.80 (s, 2H, hydantoin CH), 6.87 (d, 1H, furan CH, J = 3.5 Hz), 7.46 (d, 1H, furan CH, J = 3.5 Hz), 7.58 (s, 1H, azomethine CH), 8.00 (d, 2H, phenyl CH, J = 8 Hz), and 8.32 (d, 2H, phenyl CH, J = 8 Hz); IR (mineral oil): 5.9 and 6.2 (broad) μm.

Dantrolene Benzyltrimethylammonium Salt (I) (Method D)—To a refluxing stirred solution of dantrolene (16 g, 0.050 mole) in methanol (1.0 liter) was added rapidly benzyltrimethylammonium hydroxide (25 ml of 40% solution in methanol, 0.060 mole). The solution was filtered and concentrated under reduced pressure to ~250 ml. Ether (750 ml) was added to the cooled solution, and the resulting red solid was collected and rinsed with ether (100 ml) to give 22 g (95% yield) of product, mp 150–160° dec.; IR (mineral oil): 5.9 and 6.25 μm.

Pharmacology—Initially selected quaternary ammonium salts were evaluated intravenously in rats by gross observation for skeletal muscle relaxant activity (cholinergic and/or toxic signs). Direct effects on skeletal

[2] Melting points were determined on a Mel-Temp apparatus and are uncorrected. A Varian Associates A-60A instrument was used for NMR spectra. All spectra were run in dimethyl sulfoxide-d_6 with tetramethylsilane as the internal standard. A Perkin-Elmer model 137B recording spectrophotometer was used for IR spectra. Solubilities were determined by agitation of a sample in water at room temperature, filtration of the saturated aqueous solution, and UV comparison with a standard sample (Table I).

[a] The recrystallization solvents were methanol (F), acetone (G), ethanol (H), nitromethane (J), acetonitrile (K), and 2-propanol (L), or no recrystallization solvent was used (E). [b] Sample was rinsed with 2-propanol after recrystallization, and the NMR spectrum indicated the presence of 0.167 mole of 2-propanol.

Table III—Acute Lethality of Quaternary Salts Used to Prepare Dantrolene and Clodanolene Salts

Quaternary Salt	Gastrocnemius Muscle Twitch Response, maximum % change at 25 mg/kg	Acute Oral Lethality in Mice
Benzyltrimethylammonium chloride	+10.1 ± 1.5	100% at 1600 mg/kg
Tetramethylammonium chloride	+8 ± 0.9	100% at 125 mg/kg
N-Methylpyridinium iodide	+3 ± 3.0	30% at 1600 mg/kg
Tetrabutylammonium iodide	+14.2 ± 6.5	60% at 1600 mg/kg
2-(2,3-Dihydroxy-1-propylamino)quinolizinium bromide	−5.6 ± 5.6	10% at 1600 mg/kg
Safranine O	+5 ± 1.7	10% at 1600 mg/kg
Quinolizinium bromide	+18.7 ± 6.3	100% at 1600 mg/kg
2-Carbamoyl-1-methylpyridinium iodide	+7 ± 1.4	>1600 mg/kg
2,3-Dimethyl-1-phenyl-4-trimethylammonium-3-pyrazolin-5-one iodide	−1 ± 2.1	>1600 mg/kg
Diethyldimethylammonium iodide	+7 ± 4.5	LD_{50} = 712 mg/kg (584–853)
1,3-Dimethylimidazolium iodide	+3 ± 0.1	10% at 1600 mg/kg
Choline chloride	+7.5 ± 0.5	>1600 mg/kg
2-(1-Hydroxy-2-methyl)propyltrimethylammonium iodide	+20 ± 2.7	>1600 mg/kg

muscle also were evaluated in the gastrocnemius muscle preparation by the method to be described later. Only compounds (Table III) devoid of skeletal muscle relaxant activity were used for the preparation of the imidazolidinedione compounds.

Gross Observation—Groups of unfasted male mice (TAC:SWfBr), 20–27 g, were used. The drugs were administered orally as 2% concentrations suspended in 0.5% methylcellulose 4000 cps. Gross observations for pharmacological effects were made for 2 hr, utilizing a rating of drug effect signs similar to that described by Irwin (18). Muscle relaxation was rated on a scale from 0 to 4 with 0 = no effect, 1 = slight, 2 = moderate, 3 = marked, and 4 = extreme.

Pithed Rat Gastrocnemius Muscle Preparation—A literature method was used for direct stimulation of the gastrocnemius muscle in rats (TAC:SD/NfBr) (19). The test drugs were administered intravenously at logarithmically spaced doses in tetrahydrofurfuryl alcohol, and ED_{50} values for inhibition of skeletal muscle contractions were estimated by the method of Litchfield and Wilcoxon (20).

Rotarod Testing in Mice—A method similar to that described by Dunham and Miya (21) was used to test the effect of drugs on motor coordination. Male mice (TAC:SWfBr) were trained to walk a revolving rod (20 rpm) for over 1 min. The test drugs were administered orally at logarithmically spaced doses in methylcellulose[7] to the previously trained mice, and performance trials were conducted 30 min following drug administration. The inability of an animal to stay on the rotarod for more than 30 sec was considered a positive drug effect. The ED_{50} values (the drug dose that caused 50% of the animals to fall off the revolving rod within the 30 sec) were calculated using the method of Litchfield and Wilcoxon (20).

[a] $n = 4$ for each compound: drugs were administered in tetrahydrofurfuryl alcohol at a maximum cumulative dose of 36.6 mg/kg. [b] Drug dose causing 50% inhibition of gastrocnemius muscle twitch tension. [c] Gross effects in rats following a 30-mg/kg dose in tetrahydrofurfuryl alcohol. [d] Drug dose causing 50% inhibition of morphine-induced Straub tail in mice. [e] Not tested further because of undesirable side effects. [f] Not tested further because of solubility. [g] Insoluble in tetrahydrofurfuryl alcohol or dimethyl sulfoxide.

Straub Tail in Mice—The method used was similar to that reported by Ellis and Carpenter (22). The drugs were administered either orally in 0.5% methylcellulose or intravenously in distilled water 20 min after the subcutaneous morphine injection to male mice (TAC:SWfBr). The drugs administered orally were evaluated 30 min after drug dosing, while the compounds administered intravenously were evaluated 5 min after drug administration. The drugs were judged effective if they caused the elevated Straub tail to lie flat on the table. The compounds were administered in logarithmically spaced doses, and ED_{50} values were obtained by the Litchfield and Wilcoxon method (20).

LD_{50} in Mice—The test compounds were administered orally or intravenously to groups of unfasted male mice (TAC:SWfBr). The drugs administered orally were suspended in saline to prevent the gel formation that occurred occasionally in methylcellulose at the higher concentrations. Drugs administered intravenously were dissolved in distilled water. The animals were held in cages for 72 hr, and deaths were recorded. The LD_{50} values were calculated using the Litchfield and Wilcoxon method (20).

Intravenous Injections in Rats—Adult male rats (TAC:SD/NfBr) were used to determine the intravenous muscle relaxant potential of each drug in unanesthetized animals. The drugs were injected intravenously at a dose of 30 mg/kg (0.25 ml) in 100% tetrahydrofurfuryl alcohol into the tail vein. This dose was more than three times the effective muscle relaxant dose and was selected to uncover undesirable cholinergic and/or toxic effects of the drug. The drugs were evaluated by gross observation for skeletal muscle relaxation, gross changes, and acute toxicity.

Intravenous LD_{50} in Rats—Groups of five male rats (TAC:SD/NfBr) were administered the drug intravenously in distilled water for acute toxicity. The animals were held in their cages for 72 hr, and all deaths were recorded. The LD_{50} values were calculated using the method of Litchfield and Wilcoxon (20).

RESULTS AND DISCUSSION

To increase the aqueous solubility of dantrolene and clodanolene, quaternary ammonium salts of these compounds were synthesized. Initially, representative quaternary ammonium halide salts were evaluated for skeletal muscle relaxant activity (cholinergic and toxic signs such as loss of the righting reflex and death), and only compounds devoid of these pharmacological activities were used to form salts (Table III).

Fifteen compounds were synthesized and evaluated, including four salts of clodanolene and 11 salts of dantrolene (Table I). The aqueous solubilities for these compounds as well as those for dantrolene sodium and clodanolene sodium are listed in Table I. The compounds were evaluated initially by gross observation in mice, and 12 of the 15 compounds were effective oral muscle relaxants (Table IV). Dantrolene sodium has been shown to relax the tail in the Straub tail mouse (22). The 12 active compounds then were tested orally in the Straub tail mouse, and six compounds were effective (Table IV). These six compounds then were evaluated for motor incoordination (rotating rod), and the activities of these compounds were compared to the parent structures (Table IV). From these data, VI and XII yielded muscle relaxant efficacy indexes equal to those of dantrolene and slightly superior to those of clodanolene.

The objective in the synthesis and pharmacological evaluation of these compounds was to increase aqueous solubility. This objective was achieved since the solubilities for the respective compounds represent increases in solubilities of 10–50 times over those of the parent sodium salts. This increased solubility facilitates the dosage flexibility, specifically for intravenous administration of a skeletal muscle contraction antagonist required for conditions such as malignant hyperthermia (6–8).

The compounds were tested intravenously for inhibition of the gastrocnemius muscle twitch response and for gross effects including cholinergic symptoms and skeletal muscle relaxation. Fourteen of the 15 compounds tested were equally effective in inhibiting the gastrocnemius muscle twitch tension (IX was insoluble in the standard solvents, tetrahydrofurfuryl alcohol and dimethyl sulfoxide) (Table V). Six compounds caused cholinergic effects and were not tested further.

The six compounds without cholinergic properties that exhibited sufficient aqueous solubility were evaluated further. The LD_{50} intravenous values in rats were calculated, and therapeutic indexes were calculated using the ED_{50} for gastrocnemius muscle twitch tension inhibition (Table V). All six compounds were effective intravenously in abolishing the Straub tail phenomenon (Table V). The LD_{50} intravenous values in mice were estimated for these active compounds, and the resulting therapeutic indexes were calculated (Table V).

Effects of *N*-Demethylated Carbachol on Iris and Ciliary Muscles

JEROME TRZECIAKOWSKI *§ **and GEORGE C. Y. CHIOU** ‡x

Received November 27, 1978, from the *Department of Pharmacology & Therapeutics, College of Medicine, University of Florida, Gainesville, FL 32610, and the ‡Department of Medical Pharmacology, College of Medicine, Texas A&M University, College Station, TX 77843. Accepted for publication October 18, 1979. §Present address: Department of Pharmacology, College of Medicine, Cornell University, New York, NY 10021.

Abstract □ The tertiary nitrogen derivative of carbachol, *N*-demethylated carbachol, was synthesized to produce a drug that could be used as an alternative to pilocarpine in the treatment of open-angle glaucoma. Unlike pilocarpine, *N*-demethylated carbachol appeared to be stable in alkaline solutions. Since pilocarpine has to be dissolved in an acidic medium (pH 5.5) to prevent its destruction, <10% of its molecules are in an unionized form. On the other hand, *N*-demethylated carbachol is very stable at pH values higher than 7.4 and thus has more molecules (>10%) in an unionized, penetrable form than does pilocarpine in high pH media. *N*-Demethylated carbachol acted as a full agonist on isolated dog iris and ciliary muscle preparations, whereas pilocarpine produced only 49 and 38% of the maximum tissue responses, respectively. These findings suggest that *N*-demethylated carbachol may be able to affect the outflow facility to a greater extent than is achievable with pilocarpine at high doses.

Keyphrases □ Carbachol, *N*-demethylated derivative—effect on iris and ciliary muscles, treatment of open-angle glaucoma □ *N*-Demethylated carbachol—effect on iris and ciliary muscles, treatment of open-angle glaucoma □ Antiglaucoma agents—*N*-demethylated carbachol, effect on iris and ciliary muscles, treatment of open-angle glaucoma □ Ophthalmic preparations—*N*-demethylated carbachol, effect on iris and ciliary muscles, treatment of open-angle glaucoma

Pilocarpine is one of the oldest antiglaucoma agents used in ophthalmology (1). It exerts its action primarily through the increase of aqueous humor outflow (2). However, it induces some side effects such as miosis, exocrine gland secretions, and local irritations, which prevent it from being used continuously in some patients (3).

N-Demethylated carbachol recently was reported to possess a potency similar to that of pilocarpine in its ability to lower the intraocular pressure of glaucomatous dogs but to cause only minor miotic effects and to be devoid of other untoward actions produced by pilocarpine (4). Therefore, the effects of these two antiglaucoma drugs in the isolated ocular tissues, iris, and ciliary muscles were compared. The pKa value of *N*-demethylated carbachol was determined, and the ionization curves were constructed for comparison with its penetrability.

EXPERIMENTAL

Chemistry—*N*-Demethylated carbachol hydrochloride was synthesized in this laboratory by a modification (4) of the method of Hazard *et al.* (5). Dimethylaminoethanol was refluxed with an excess of ethyl carbamate in toluene for 2 hr to remove water by using a trap receiver. Aluminum methoxide was added to catalyze the reaction, and the reaction mixture was refluxed for an additional 12 hr. The reaction by-product, ethanol, was removed by distillation along with toluene at a rate of 2–5 ml/min for 10 hr. Fresh toluene was added periodically to replenish the lost volume. Aluminum methoxide then was filtered off while the reaction mixture was still hot.

The product, *N*-demethylated carbachol base, was distilled with fractional distillation under vacuum to avoid overheating. (The distillation temperature should not exceed 130° to avoid polymerization and reduction in the yield.) The base product then was converted into the hydrochloride salt with dry hydrogen chloride gas in ether. The final product was recrystallized with absolute ethanol. *N*-Demethylated carbachol was tritiated commercially[1] with a specific activity of 31 mCi/mmole. The ^{3}H-*N*-demethylated carbachol was stored as a dried powder and was dissolved in an aqueous medium immediately before use to avoid tritium exchange. Pilocarpine nitrate and carbachol chloride were purchased from commercial sources.

The stability of aqueous solutions of *N*-demethylated carbachol was studied with NMR spectroscopy. Free *N*-demethylated carbachol base and its salt were dissolved in heavy water for NMR analysis.

The acid dissociation constants, pKa, of *N*-demethylated carbachol and pilocarpine were determined with a potentiometric titration method. The standardized carbonate-free potassium hydroxide solution (0.1 *M*) was obtained commercially[2] for titration. The drug quantities employed were selected to achieve concentrations of 1×10^{-5} *M* at the point of half-neutralization. Values of pKa and their scatter were calculated as described in the literature (6).

Penetrability—^{3}H-*N*-Demethylated carbachol solution (25 μl of 0.128 *M* and 31 mCi/mmole at pH 7.4) was instilled into the eyes of conscious rabbits, and the eyelids were held closed for 1 min. Rabbits were killed at 10, 20, 60, and 180 min after instillation. The eyes were rinsed with saline to remove surface radioactivity, and the tissues were obtained in the order of aqueous humor, cornea, iris, and ciliary body. All tissues were weighed, digested with a solubilizer[3], and counted in a scintillation medium[4] with a scintillation counter[5]. The tissue uptake of ^{3}H-*N*-demethylated carbachol was expressed in picomoles per milligram of tissue. The amount of *N*-demethylated carbachol taken up by ocular tissues at the approximate peak time was tabulated.

Isolated Iris and Ciliary Muscle Preparation—Mongrel dogs, 13–17 kg, were sacrificed with an intravenous injection of pentobarbital sodium. The eyes were removed and placed on a moist gauze, and the iris was dissected according to a literature method (7). After removal of the iris, an incision was made in the sclera to expose the interior of the glove. The lens and adhering vitreous humor were removed, and a shallow incision was made in the uvea anterior to the ora serrata. A strip of ciliary muscle, 4–5 mm wide and approximately 25 mm long, was carefully lifted free of the sclera. Sections of iris and ciliary muscles were suspended in 6-ml organ baths containing a Ringer solution (119.8 m*M* NaCl, 4.02 m*M* KCl, 1.98 m*M* $CaCl_2$, 1.27 m*M* $MgSO_4$, 26.2 m*M* $NaHCO_3$, 1.0 m*M* KH_2PO_4, and 11.1 m*M* glucose at pH 7.4) oxygenated with 95% O_2–5% CO_2 at 32°.

A microdisplacement force transducer[6] was used to detect the muscle contraction, and the contraction was recorded on a polygraph[7]. The initial tension placed on the iris was 100 mg and that on the ciliary muscle was 300 mg. Effects of *N*-demethylated carbachol were compared with those of pilocarpine and carbachol. The maximum contraction induced by carbachol was designated as the 100% response, and other responses induced were calculated as a percent of that maximum response.

RESULTS

The NMR spectrum of *N*-demethylated carbachol dissolved in heavy water produced the expected chemical shifts and splitting patterns. The spectrum consisted of a singlet at δ 4.72 (NH_2), two triplets at δ 4.27 and 2.65 (CH_2CH_2), and another singlet at δ 2.27 [$N(CH_3)_2$] relative to Tiers' salt, $(CH_3)_3Si(CH_2)_3SO_3Na$. The NMR spectra of the salt and free base of *N*-demethylated carbachol obtained at regular intervals after the compounds were dissolved in heavy water remained unchanged at room temperature for at least 3 months.

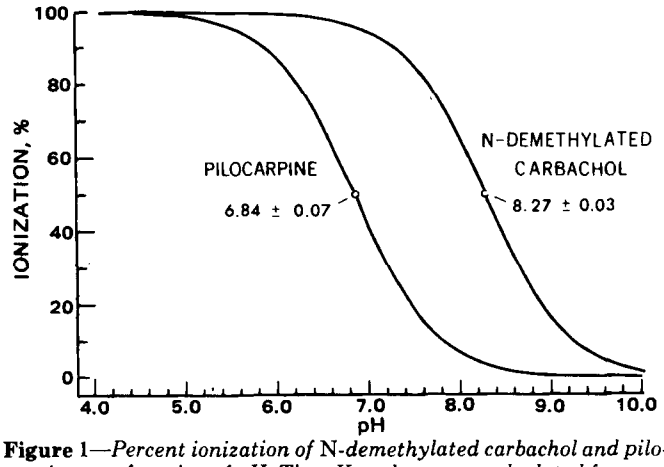

Figure 1—*Percent ionization of* N-*demethylated carbachol and pilocarpine as a function of pH. The pKa values were calculated from experimentally determined values at 25°* (n = 9).

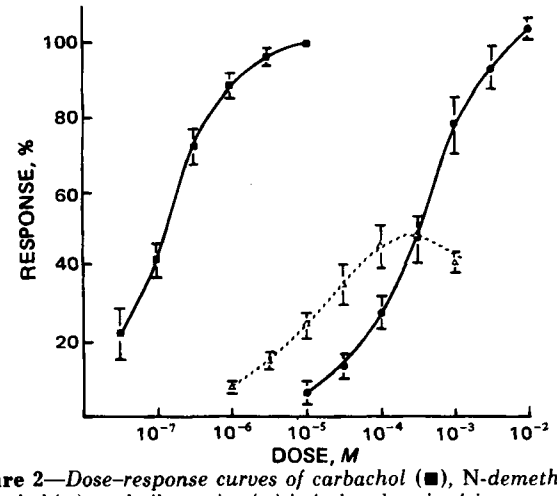

Figure 2—*Dose–response curves of carbachol* (■), N-*demethylated carbachol* (●), *and pilocarpine* (△) *in isolated canine iris preparations. Each point is the mean of four values, and the bars indicate standard errors.*

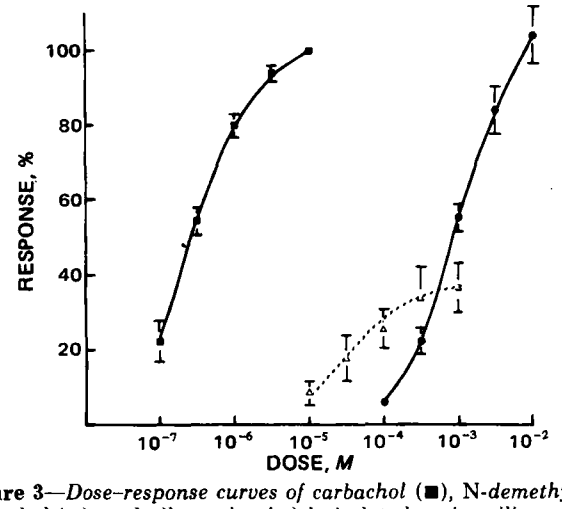

Figure 3—*Dose–response curves of carbachol* (■), N-*demethylated carbachol* (●), *and pilocarpine* (△) *in isolated canine ciliary muscle preparations. Each point is the mean of four values, and the bars indicate standard errors.*

The pKa values of *N*-demethylated carbachol and pilocarpine and the ionization curves constructed from these values are shown in Fig. 1. An additional pKa value for pilocarpine should be at 12.57 (8), but it was not observed in this laboratory. Titrations of *N*-demethylated carbachol revealed that this compound has a single pKa value of 8.27.

The penetrability of *N*-demethylated carbachol into the eyes is presented in Table I. The peak time for *N*-demethylated carbachol to reach intraocular tissues was ~20 min, and the penetrability was about the same as that of pilocarpine (9).

N-Demethylated carbachol contracted the isolated dog iris at doses of 1×10^{-5}–1×10^{-2} *M* (Fig. 2). The dose–response curve paralleled that of carbachol. Pilocarpine was more potent at lower doses (1×10^{-6}–1×10^{-4} *M*) than *N*-demethylated carbachol, but the maximum effect attainable with this drug was only 49% of that produced by carbachol or *N*-demethylated carbachol. Pilocarpine doses greater than 3×10^{-4} *M* decreased muscle tension.

The overall shape of the dose–response curves of *N*-demethylated carbachol, carbachol, and pilocarpine obtained with ciliary muscle was similar to that obtained with the iris preparation, except that the ciliary muscle appeared to be less sensitive to these agents (Fig. 3). The maximum response produced by pilocarpine was only 38% of that produced by *N*-demethylated carbachol or carbachol.

DISCUSSION

The usefulness of a drug as eye drops in the treatment of glaucoma depends primarily on its penetrability across the cornea. Although pilocarpine is a much less potent muscarinic agent than carbachol, it is more widely used than carbachol as an antiglaucoma agent because it can penetrate the cornea better than carbachol.

At the physiological pH of 7.4, 78% of pilocarpine is in the unionized, penetrable form (Fig. 1). However, pilocarpine is not stable at this pH because it undergoes base-catalyzed epimerization or is cleaved at the lactone ring (10, 11). For this reason, the pH of most ophthalmic preparations of pilocarpine is adjusted to 4.5–5.5 (12). At these pH values, >95% of the drug is ionized.

The ester linkage in *N*-demethylated carbachol is the same as that in carbachol, which is known to be quite stable in aqueous solution. This structure was confirmed in this laboratory with NMR studies. Thus, an ophthalmic solution of *N*-demethylated carbachol at pH 7.4 can be made.

Table I—Penetration of *N*-Demethylated Carbachol into Ocular Tissues

Tissue	Peak Time, min	Quantity at Peak, pmoles/mg	Tissue Weight, mg	Total Amount in Tissue, nmoles	Percent Absorbed[a]
Cornea	10	129[b]	64[c]	8.26	0.26
Iris	20	20	35	0.70	0.02
Ciliary muscle	20	15	27	0.41	0.01
Aqueous humor	20	21	287	6.03	0.20

[a] The calculation was based on the total amount of *N*-demethylated carbachol instilled (3.19 μmoles). [b] $n = 6$. [c] $n = 19$.

At pH 7.4, <90% of *N*-demethylated carbachol is ionized. Thus, in clinical situations (*N*-demethylated carbachol at pH 7.4, pilocarpine at pH 5.5 or less), *N*-demethylated carbachol could be more effective than pilocarpine because it has greater penetration. Moreover, a drug solution with a pH range of 6.6–8.7 may be instilled into the eye without producing unpleasant sensations (13). Therefore, it should be possible to increase the effectiveness of *N*-demethylated carbachol even further by administering it in solutions having pH values greater than 7.4 but less than 8.7. At pH 8.7, 70% of *N*-demethylated carbachol is unionized and penetrable.

In actual experimentation with ^{3}H-*N*-demethylated carbachol, the drug was absorbed to reach a concentration in the aqueous humor of 2.1×10^{-5} *M* 20 min after topical administration at pH 7.4.

Experiments with isolated iris and ciliary muscles demonstrated that *N*-demethylated carbachol has a greater intrinsic activity or efficacy than pilocarpine. However, pilocarpine possesses higher sensitivity to these muscles at lower doses (1×10^{-6}–1×10^{-4} *M* in the iris preparation and 1×10^{-5}–2×10^{-4} *M* in ciliary muscle). The combination of these two factors could explain the fact that, in *in vivo* studies, *N*-demethylated carbachol is as potent as pilocarpine in lowering the intraocular pressure but causes less miosis in the glaucomatous beagle eye.

Effect of Low and High Relative Humidity on Metered-Dose Bronchodilator Solution and Powder Aerosols

F. CHARLES HILLER ˣ, MALAY K. MAZUMDER, J. DOUGLAS WILSON, and ROGER C. BONE

Received August 9, 1979, from the *University of Arkansas for Medical Sciences, Little Rock, AR 72201.* Accepted for publication October 19, 1979.

Abstract □ Physical properties of two metered-dose bronchodilator aerosols packaged as solutions and two aerosols packaged as finely ground powders were measured at low and high relative humidity. The aerodynamic size distribution and particle concentration were measured in real time using the single-particle aerodynamic relaxation time analyzer, which can measure the aerodynamic diameter of single suspended particles in the respirable size range. The count median aerodynamic diameter, the mass median aerodynamic diameter, the total particles per dose, and the total aerodynamic mass per dose were calculated. Significant increases were noted in the count median aerodynamic diameter for three aerosols and in the mass median aerodynamic diameter for two aerosols. The number of particles in the measured size range increased 3.6- and 4.1-fold for the droplet aerosols and 1.4-fold for the powder preparations. The aerodynamic mass per dose in the measured size range increased 5.7- and 11.4-fold for the droplet aerosols and 3.1- and 1.6-fold for the powder aerosols. These data indicate that all aerosols tested increased in size at high humidity and that aerosols dispensed as droplets may be more unstable than those dispensed as powders.

Keyphrases □ Bronchodilators—metered-dose solution and powder aerosols, effect of low and high humidity □ Aerosols—bronchodilators, metered-dose solution and powder preparations, effect of low and high humidity □ Asthma products—metered-dose solution and powder aerosols, effect of low and high humidity □ Metered-dose aerosols—bronchodilators, solution and powder preparations, effect of low and high humidity

Metered-dose bronchodilator aerosols are used widely to treat obstructive lung disease. The efficacy of these medications is determined by their quantity and site of pulmonary deposition. Factors that affect pulmonary retention and distribution are the inhalation technique, airway patency, and particle size.

BACKGROUND

The particle-size distributions of aerosols produced by some of these devices have been reported (1–3), but the effect of hygroscopicity on particle size was not included. Any particle may grow by water condensation or shrink by water evaporation, depending on the humidity and physical characteristics of the particle. Such changes may affect the mass and site of aerosol deposition in the respiratory tract. Although particle growth during exposure to high humidity such as that occurring in the respiratory tract has been predicted for therapeutic aerosols (4) and the effect of humidity on the size of propylene glycol aerosols has been described (5), there is no information documenting or quantitating the effect of high humidity on bronchodilator aerosols.

Measurement of aerosol particle size is most relevant for prediction of deposition when the size is expressed as the aerodynamic diameter, defined as the diameter of a unit density spherical particle having the same terminal settling velocity as the particle in question. Methods currently used to measure the aerodynamic size distribution of aerosols require particle impaction and subsequent analysis of the quantity deposited (4, 6). The instability of water-containing particles has been described (7), and size changes may occur in <1 sec (8). This instability precludes extrapolation of the particle-size measurement following precipitation of unstable particles to the particle size in the suspended state. Measurement in the suspended state is necessary to assess accurately the effect of humidity on the size of unstable particles.

The purpose of this study was to determine the effect of high humidity, similar to that encountered in the respiratory tract, on the particle-size distribution of four commonly used metered-dose aerosol devices. Humidity in the trachea and more distal airways generally is regarded to be in the 99.0–99.8% range (9). The mass median aerodynamic diameter and count median aerodynamic diameter (the sizes below which are 50% of the particles by mass and number, respectively), the geometric standard deviation (84.1% size divided by 50% size), the mass per dose, and the number of particles per dose were measured. A new device, the single-particle aerodynamic relaxation time analyzer (hereafter called the analyzer) that measures the aerodynamic diameter of single particles in real time, was used for these studies.

EXPERIMENTAL

The following medications were studied: isoproterenol hydrochloride[1] and isoetharine mesylate[2], both packaged as solutions, and metaproterenol sulfate[3] and isoproterenol sulfate[4], both packaged as finely ground powders. In each case, the commercially available preparation was used. Each medication was injected into an environmental chamber for subsequent sampling by the analyzer.

The analyzer (Fig. 1) and the theoretical basis for its operation were described previously (3, 10, 11). The sensing volume, in which the signal

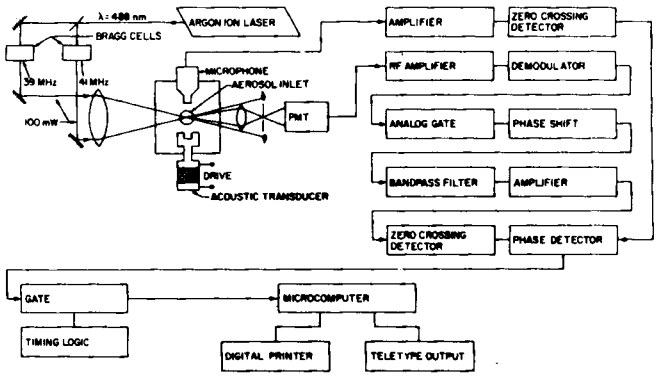

Figure 1—*Schematic outline of the SPART analyzer. The analyzer and ancillary signal processing equipment are shown.*

for particle-size measurement is generated, is formed by the intersection of two laser beams of slightly different frequencies (Fig. 2). Each particle entering the sensing volume is subjected to acoustic oscillation at 24.25 kHz. Particle oscillation lags behind acoustic field oscillation; this delay, the phase lag, is directly related to the aerodynamic diameter.

Particle oscillation is measured by a laser Doppler velocimeter using the Doppler principle (7). The Doppler frequency shift in the light scattered by a particle oscillating in this sensing volume is detected by a photomultiplier, which generates a frequency-modulated (FM) signal. The FM signal, which transmits particle velocity information, is demodulated and compared using data processing circuitry to the acoustic signal generated by a microphone to determine the phase lag. A microprocessor determines the aerodynamic diameter from the phase lag and stores the data for analysis (Fig. 1). The stored data are processed by a minicomputer to determine the count median aerodynamic diameter, mass median aerodynamic diameter, and geometric standard deviation (σg) and to plot the following distributions: (*a*) derivative of the number with respect to the aerodynamic diameter, (*b*) derivative of the aerodynamic mass with respect to the aerodynamic diameter, (*c*) the cumulative number, and (*d*) the cumulative aerodynamic mass. The aerodynamic mass is calculated from the aerodynamic diameter by:

$$\text{aerodynamic mass} = \tfrac{2}{3}\,\pi \text{ aerodynamic diameter}^3 \times \text{density} \quad \text{(Eq. 1)}$$

The density is assumed to be unity. The actual density of these multicomponent particles is difficult to determine. The actual mass differs from the aerodynamic mass as the difference between the actual and assumed density increases. There also is some error introduced for particles with an aerodynamic diameter of <1 μm since those particles behave somewhat differently than larger particles. For these studies, the error should be small since most of the mass is in particles with an aerodynamic diameter of <1 μm. The geometric standard deviation (Table I) was calculated by a computer from the cumulative aerodynamic mass distributions and was only slightly different from the geometric standard deviation calculated from cumulative number distributions.

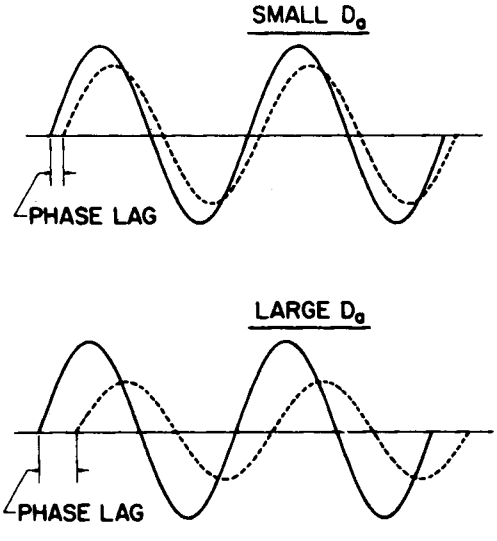

Figure 2—*The solid lines represent the wave form of the oscillatory motion of air caused by acoustic excitation. The broken lines represent particle motion, which lags behind air motion. The relative phase lag depends on the aerodynamic diameter of the particulate.* D_a = *aerodynamic diameter. (Reprinted from Ref. 3 with permission of the publisher.)*

The aerosol is drawn from the environmental chamber to the analyzer at a rate of 55 cm^3/min. Only a portion of this sample passes through the sensing volume. The sensing volume is 1.3×10^{-6} cm^3, and the quantity of aerosol passing through it is 1.3×10^{-2} cm^3/sec. The analyzer coincidence loss is <2% at a counting rate of 40 particles/sec or less. In the present study, the count rate was maintained below this level by maintaining aerosol concentrations in the environmental chamber at <3000 particles/cm^3.

The environmental chamber was a 200-liter insulated plastic box. The temperature was maintained at 37 ± 0.5° by applying thermostatically controlled heat strips to the chamber walls and was monitored using a digital thermometer. The chamber was humidified for high humidity studies by bubbling chamber air through a heated water bath and was monitored with a hygrometer[5]. Ambient humidity studies were at 16–21% relative humidity (RH), and high humidity studies were at 95–98% RH. The analyzer was operated at 37°, and the relative humidity of the efflux from the analyzer was monitored[6] to ensure that no significant loss of humidity occurred during transport of the aerosol to the sensing volume.

Prior to each study, the environmental chamber was checked to ensure that it was free of residual aerosol. The aerosol and thermal mixing was provided using a fan inside the chamber. The decay rate for this chamber has been measured as a function of the aerodynamic diameter and is sufficiently low for the particle sizes involved in this study so as to be insignificant for the sampling time used. During testing, the environmental chamber was placed above the analyzer. The aerosol was sampled vertically with laminar flow in the sampling tubes to minimize particle loss from impaction in the sampling tubing.

For each of the four metered-dose devices, seven trials were performed. When appropriate environmental conditions were attained, the drug was injected into the chamber. The count rate was assessed, and the injection was repeated until the chamber concentration reached 3000 particles/cm^3. Injection was completed in <1 min. Following loading of the chamber with the aerosol, 30 sec was allowed for mixing; the analyzer sampling then was begun and continued for 5 min.

RESULTS

Seven trials were performed for each study, with 5000–9000 individual particles sized in each trial. The data reported are the average of these

trials. The average results for the count median aerodynamic diameter, mass median aerodynamic diameter, and geometric standard deviation for each preparation at low and high humidity are shown in Table I. Also shown is the statistical significance of the comparison between the values at low and high humidity. The information indicates that there was a significant increase at high humidity in the count median aerodynamic diameter for isoetharine mesylate, isoproterenol hydrochloride, and metaproterenol sulfate but not for isoproterenol sulfate. Significant increases in the mass median aerodynamic diameter were noted for isoproterenol hydrochloride and metaproterenol sulfate. The geometric standard deviation for all of the aerosols was similar, did not change much with high humidity, and indicated a heterodisperse aerosol.

Table II describes the total number of particles and the total mass per dose of the aerosol measured in the 0.30–6.0-μm range. At high humidity, the total particles and total mass per dose of all aerosols increased significantly. The increase in total particles was 3.6- and 4.1-fold for isoetharine mesylate and isoproterenol hydrochloride, respectively, an increase considerably greater than the 1.4-fold change noted for both powdered preparations. The increases in total mass of 5.7- and 11.4-fold for isoetharine mesylate and isoproterenol hydrochloride were greater than the 3.4- and 1.6-fold increases in mass noted with the metaproterenol sulfate and isoproterenol sulfate powders.

Representative aerodynamic size distribution curves are shown in Figs. 3 and 4. In Fig. 3, the number distribution of the droplet isoproterenol hydrochloride aerosol measured at low humidity is compared to the number distribution measured at high humidity. The area under each curve represents the total number of particles measured at each humidity.

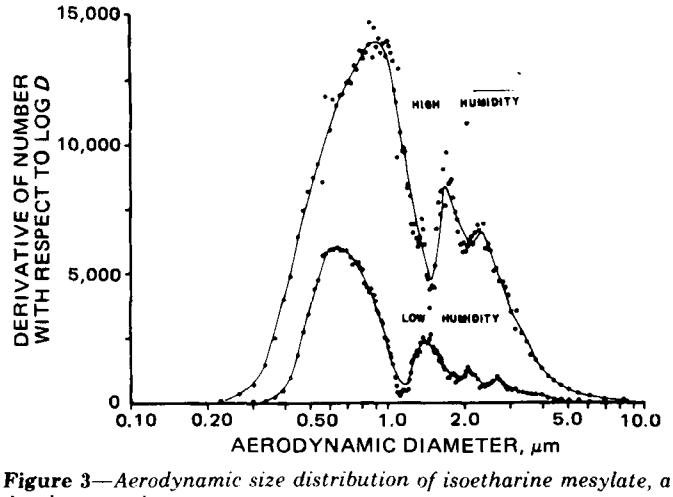

Figure 3—*Aerodynamic size distribution of isoetharine mesylate, a droplet aerosol.*

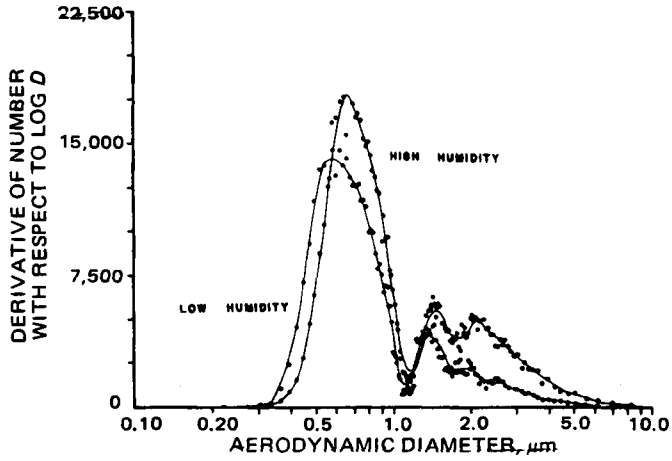

Figure 4—*Aerodynamic size distribution of isoproterenol sulfate, a powdered aerosol.*

The aerodynamic size distribution curves for the powdered isoproterenol sulfate aerosol are shown in Fig. 4, which is arranged similarly to Fig. 3. These figures illustrate the considerably smaller difference in the area under the curve between studies done at low and high relative humidity for the powdered aerosol compared to the droplet aerosol, a difference also shown in the particles per dose column of Table II.

DISCUSSION

The physical properties of all aerosols tested were different at low humidity compared to high humidity. In general, physical properties reflecting particle size increased at high humidity, and these increases were greater for droplet aerosols than for powder aerosols.

The number of particles per dose increased significantly for all four aerosols tested. The increase in particles per dose was especially marked for droplet aerosols. The number of particles per dose increased from 1.23×10^8 to 4.47×10^8 for isoetharine mesylate and from 4.0×10^7 to 2.02×10^8 for isoproterenol hydrochloride. One possible explanation for the increase in the particle number per dose is that many small particles exist at low humidity below the resolution limit (0.3 μm) of the analyzer and that these particles grow into the measurable size range at high humidity.

The mass per dose also increased significantly at high humidity for all four aerosols. The increase was greatest for droplet aerosols, changing from 334 to 1016 μg for isoproterenol hydrochloride at low and high humidity, respectively. The count median aerodynamic diameter increased significantly for three aerosols, while the mass median aerodynamic diameter increased for two aerosols.

The increase in the total mass and the number of particles per dose observed in these studies was considerable, especially for droplet aerosols, and may seem inconsistent with the modest increases in the count median aerodynamic diameter and mass median aerodynamic diameter. There are several possible explanations. At low humidity, the aerosol may contain many particles smaller than the lowest size the analyzer can measure. When the humidity increases, these particles grow and become measurable. Thus, in the measurable size range, there is an apparent increase in the number of particles in the smaller size range. This increase in the number of small particles would offset the increase in the count median aerodynamic diameter and the mass median aerodynamic diameter that would be expected had the aerosol not contained at low humidity many particles below the measurable size range. The size attained by a particle subjected to a given set of conditions is called the equilibrium diameter. The equilibrium diameter is determined by the relative humidity, hygroscopicity of the particle, and size of the dry particle. The severalfold increase in the total aerosol mass per dose without a significant change in the mass median aerodynamic diameter may be due in part to the fact that small hygroscopic particles have larger surface-to-mass ratios than do larger particles and undergo a higher relative growth when exposed to high humidity.

Another phenomenon pertains to the fact that the measured aerodynamic diameter depends in part on the particle density, ρ. If ρ of the dry particle is greater than 1 g/cm^3, then water absorbed by the particle increases the volume but reduces ρ, and, consequently, the aerodynamic diameter does not increase in proportion to the geometric diameter.

Therefore, the total particulate volume may increase out of proportion to the observed change in the mass median aerodynamic diameter. In considering these data and the hypothesized explanations, it is important to recognize that the relative contribution to particle growth at high humidity in a complex system of multicomponent particles, air, water vapor, and other vapors such as fluorocarbons and ethanol is not clear.

The increase in the number density and the mass of aerosol particles at high humidity must not be interpreted as an increase in the content of active ingredients. Although the growth is caused by the water uptake, any accompanying change in the mass distribution of the active ingredient may significantly change the amount and site of deposition of the active ingredient inside the lung. Additional information is needed to determine the content of the active ingredient at various size intervals, especially at high humidity.

The total mass of dry aerosol in the 0.30–6.0-μm range shown in Table II is similar for three of the four aerosols to the mass of the active ingredient claimed by the manufacturer to be dispensed from each device per valve activation. All aerosols contain stabilizing and dispensing agents that may contribute to the total mass. The portion of the active ingredient in the aerosol mass is not known. The active ingredient of droplet aerosols is dissolved in alcohol, which may contribute to the aerosol mass, although it probably evaporates fairly rapidly. The fluorocarbon propellants also contribute to the particle size as these aerosols leave the metered-dose device, but most are highly volatile and evaporate almost immediately upon aerosolization. In addition, all of these devices contain a dispersing agent present in variable quantities. The mass of isoproterenol sulfate measured in this study was greater than the mass of active ingredient reported to be dispensed per dose by the manufacturer. This difference probably was due to the relatively high ratio of dispersing agent to active ingredient for isoproterenol sulfate (~2.5:1) compared to metaproterenol sulfate (~1:1)[7].

The increase in particle size found in this study probably was not greatly influenced by particle aggregation since the aerosol concentration after injection into the environmental chamber was relatively dilute. Aggregation, which is related to the square of the concentration, may contribute along with water condensation to particle growth in the respiratory tract where the concentration should be much higher than in the chamber used for these studies.

Although the content of active ingredient per particle at high humidity is not known, the increase in total aerosol mass, which is considerable for the droplet aerosols, implies that the content of active ingredient shifts to particles of a larger size. A size shift similar to that observed in these high humidity studies may occur when these aerosols are inhaled into the human respiratory tract. Failure to consider particle-size changes may result in inaccurate prediction of respiratory tract deposition, especially for apparently highly unstable droplet aerosols.

Substituent Constants of Azulene

M. R. LICHTENWALNER * and T. J. SPEAKER ˣ

Received September 4, 1979, from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication October 24, 1979. *Present address: Center for Laboratory Medicine, Trevose, PA 19047.

Abstract □ The ionization constants in water for six 3-substituted azuloic acids were determined spectrophotometrically. Conversion of these physical constants to their pKa values allowed a set of Hammett-type σ values for the substituents on these acids to be calculated. Determination of partition coefficients for nine 1-substituted azulenes allowed Hansch-type π values to be determined, using azulene as the model compound.

Keyphrases □ Azulenes, various—substituent constants, ionization and partition coefficients, spectral characteristics □ Substituent constants—various azulenes □ Ionization constants—various azuloic acids □ Partition constants—various azulenes

The σ constant of Hammett (1) and the π constant of Hansch *et al.* (2) are useful in estimating the relative effects of substituents on the reactivity (σ) and partitioning (π) characteristics (3) of aromatic compounds. There are extensive collections of correlations of biological activity with these substituent values within one or another series of benzenoid compounds (4–6). Thus, they can guide the selection of substituents with which to modify the bioactivity and other properties of benzenoid compounds (7).

BACKGROUND

Replacement of the benzenoid nucleus with nonbenzenoid aromatic systems has been used to prepare local anesthetic esters, amides, and carboxamides (8–10) and oxidative enzyme inhibitors (11). Few experimentally determined σ or π values are available for nonbenzenoid aromatic systems. Except for the work of McDonald *et al.* (12), only scattered reports of pKa and σ values and even fewer reports of partition coefficients and π values for nonbenzenoid aromatic compounds are available. These studies include the ionization constants of azuloic acids as determined in 50% aqueous ethanol (12, 13), the ionization constants of variously substituted ferrocenecarboxylic acids (14), and the octanol–water partition coefficient of azulene (15). This small set of values is restricted further in utility because, as Bright and Briscoe (16) reported, apparent

pKa values and apparent σ constants calculated from them change substantially as the ethanol concentration in hydroalcoholic solutions changes. They showed that an apparent σ value could change sign as the alcohol concentration of the solution changed.

The present work involved the determination of σ and π values for azulene substituents for use in selecting candidate substances in drug design and the elucidation of drug action.

Although an acidic functional group is not essential (17), Hammett σ values are determined conveniently when the model substance is an acid. The ionization constants of some 3-substituted azuloic acids (Table I) and the partition coefficients of some 1-substituted azulenes (Table II) were measured spectrophotometrically. The corresponding σ and π constants for the azulene series were calculated from the experimental values.

EXPERIMENTAL

Materials—Azulene[1], reagents[1,2], and solvents[3] were purchased commercially. The following compounds were prepared by previously described methods: azuloic acid (18), 3-acetylazuloic acid (19), 3-bromoazuloic acid (19), 3-chloroazuloic acid (19), 3-formylazuloic acid (20), 3-nitroazuloic acid (9), acetamidoazulene (21), acetylazulene (21), azulenecarboxaldehyde (22), nitroazulene (21), and ethyl azuloate (18).

Ionization Constants—The method employed for the determination of ionization constants was adapted from that of Albert and Serjeant (23). The acid of interest was dissolved in 0.01 *N* HCl, 0.01 *N* NaOH, or a graded series of buffers having pH values that bracketed the anticipated pKa. The pH values of the resulting solutions were recorded to a thousandth of a pH unit[4], and the desired spectral characteristics were measured using a recording spectrophotometer[5]. All measurements were made between 20 and 25° to eliminate making temperature corrections (24).

All solutions except buffers were prepared fresh daily. Buffer solutions were prepared as needed from 0.1 *M* stock solutions of acetic acid, hydrochloric acid, sodium acetate, and sodium hydroxide. All water for the preparation of solutions was purified by ion exchange and reverse osmosis and then distilled in glass.

Saturated solutions of the azuloic acids in water containing 1% ethanol (to assist wetting) (23) were prepared as stock solutions from which exact 1:5 dilutions were made with 0.01 *N* HCl, acetate buffer, or NaOH. Volumes of 1% ethanol in water were similarly diluted to provide blanks. Spectra were recorded between 700 and 220 nm using cells with 10-cm light paths.

The absorption spectra of the most basic and most acidic solutions were recorded as superimposed traces on the same section of calibrated chart paper. With the aid of dividers, the optimal wavelength was found; the checklist of priorities regarding selection of this wavelength as described by Albert and Serjeant (23) was observed. All subsequent measurements were made at this wavelength.

In all instances, the pH value of each solution was measured just prior to measuring the absorbance. Sufficient time was allowed for electrode equilibration so that not more than a 0.001-pH unit drift occurred in 1 min.

Since the pKa values were assumed and found to lie between 4 and 5, acetate buffer was used; it has useful buffering properties between pH 4.1 and 5.3. The ionic strength of the buffer in the final measured solution was 8×10^{-3}. The molarity of the acids varied but was never greater than 1.5×10^{-4} mole/liter. A trial determination at pH 4.5 was made to obtain a first measure of the pKa of each acid. Once this value was obtained, a series of buffers with pH values bracketing it was used to provide a set of seven values for each compound. The averages of the K_a and pKa values determined for each compound are given in Table I together with the calculated σ values.

Partition Coefficients—The method for partition coefficients used was derived from that of Hansch and coworkers (25). Monosubstituted azulenes were partitioned between *n*-octanol and water. For the determination of the partition coefficient of azuloic acid only, the water was adjusted with acetic acid to a final acid concentration of 0.01 *N*; the resulting pH was about 3.4. This acid concentration was low enough that it did not interfere with the analysis but was sufficiently high to ensure that azuloic acid was <2% ionized.

Because the specific method employed is critical to the accuracy of the values determined, the procedure is described in detail. The octanol was purified by sequentially washing with nominally 2 *N* NaOH, 4 *N* H_2SO_4, 2 *N* Na_2CO_3, and water followed by distillation under reduced pressure. The water used for partitioning studies was purified by ion exchange, reverse osmosis, and distillation in glass and then was vigorously shaken with purified octanol to ensure saturation. The resulting milky suspension was passed through two 0.22-μm filters[6] saturated with octanol to assist in breaking the emulsion. The phases were separated and stored in ground-glass stoppered bottles.

A few milligrams of each purified 1-substituted azulene was dissolved separately in about 25 ml of water-saturated octanol. These solutions were used as stock solutions. Beer's law plots were established for each compound; correlations between absorbance values and concentration typically had values of r^2 greater than 0.999. A 5.00-ml aliquot of the stock solution and two dilutions of it were pipetted into volumetric flasks containing 1000.0 ml of octanol-saturated water. The mixtures were hand inverted 400 times and allowed to separate, and as much of each octanol layer as possible was withdrawn with the aid of a Pasteur pipet. The octanol layers were clarified by centrifugation at 1000×*g* for 30 min. The absorbances of the octanol solutions were measured immediately at three different absorbance maxima of the azulenoid, and the azulenoid concentration was calculated. Results are reported as the average of these nine values in Table II, expressed as partition coefficients, together with the corresponding values of π.

RESULTS AND DISCUSSION

The ionization constants of six azuloic acids were determined spectrophotometricallly using the method of Albert and Serjeant (23), and the corresponding pKa and Hammett σ values were calculated. These values are presented in Table I together with the corresponding benzenoid σ values. Azuloic acid, with a pKa of 5.11, is a weaker acid than naphthoic acid (pKa 4.17) (27), which is an isomer, or than benzoic acid (pKa 4.18) (27). This finding is consistent with the relatively high charge density of the parent hydrocarbon, azulene, as calculated by the Hückle LCAO–MO (linear combination of atomic orbitals–molecular orbitals) approach (28).

The observation that azuloic acid is about 10-fold weaker as an acid than either naphthoic or benzoic acid was confirmed indirectly by Leermakers and Bowman (13) who determined the apparent pKa of azuloic acid in 50% ethanol to be 6.67. A similar determination of the apparent pKa of benzoic acid gave 5.78.

Comparison of the σ values of the benzene and azulene series shows them to be substantially different. It is possible that inductive and resonance components may correlate with these values; however, the limited number of compounds in this study precludes such a test. The reversal

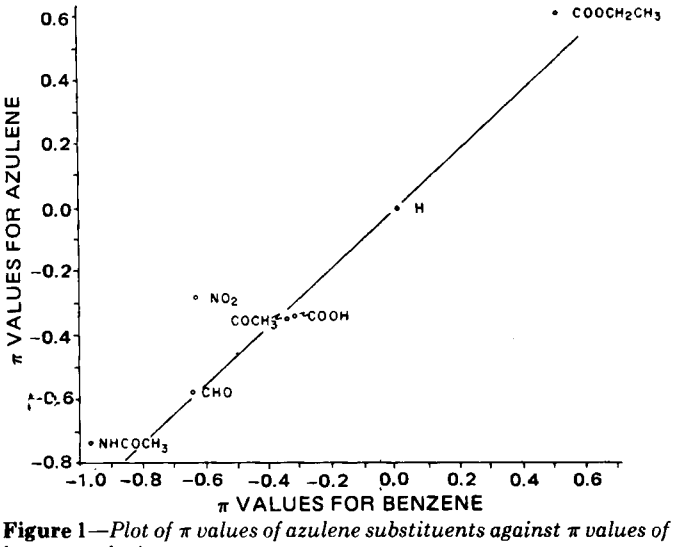

Figure 1—*Plot of π values of azulene substituents against π values of benzene substituents.*

of rank for the acetyl and formyl groups compared to σ_p is deserving of comment since the acetyl and formyl groups usually are considered similar in electronic behavior. They are, however, sterically different, and the difference in σ values may be attributed to a steric interaction between the methyl portion of the acetyl group and the *peri*-proton. Such steric interaction can reduce the coplanarity of the acetyl group with the ring bearing it, thereby decreasing the conjugation between the ring and the carbonyl function. Such a reduction of conjugation would reduce the electron-withdrawing ability of the carbonyl group. This interpretation is consistent with the observation that the UV absorbance maximum of acetylazulene shows a hypsochromic shift of about 7 nm with respect to that of formylazulene.

Another disparity between azulenoid and benzenoid σ values is seen with the bromo and chloro substituents. The benzenoid σ values for these substituents are nearly identical, but the azulenoid values differ distinctly. While this effect may be attributable to differing degrees of steric interaction with the *peri*-proton on the adjacent ring, it is explained more satisfactorily by the greater conjugative effect of the chloro over the bromo substituent.

The octanol–water partition coefficients of seven azulenoid compounds were determined spectrophotometrically, and the corresponding π values (2) were calculated. These values, together with the corresponding benzenoid π values, are presented in Table II.

Comparison of the azulenoid and benzenoid π values in Table II and Fig. 1 shows that a fair correlation exists between the two values (r^2 = 0.841). The correlation improves markedly (r^2 = 0.966) if the values for the nitro substituent are omitted from the regression equation:

$$\pi_{Az} = 0.925\ \pi_{Bz} + 0.041 \qquad \text{(Eq. 1)}$$

where the subscripts Az and Bz indicate azulenoid and benzenoid values, respectively. It is reasoned that the strongly electron-withdrawing character of the nitro group further accentuates the charge separation that exists in azulene itself (μ = 1*D*), thus increasing both its dipole moment and its water solubility.

In summary, while the π constants for azulene may be predicted reasonably and accurately from benzene π values except when the substituents are highly polar, the values of the azulene σ constants may not be inferred reliably from σ values of their benzenoid counterparts.

Antimicrobial Activity of *N*-Substituted *N*-(Triphenylstannyl)cyanamides and Triethylammonium (Organocyanoamino)chlorotriphenylstannates

EUGENE J. KUPCHIK *x, MICHAEL A. PISANO ‡, ANN M. CARROLL ‡, JOHN R. LUMPP ‡, and JOSEPH A. FEICCABRINO *

Received July 18, 1979, from the *Department of Chemistry and the ‡Department of Biological Sciences, St. John's University, New York, NY 11439. Accepted for publication September 21, 1979.

Abstract □ *N*-Substituted *N*-(triphenylstannyl)cyanamides were studied and found to be better antifungal agents than the previously tested *N*-substituted *N'*-cyano-*S*-(triphenylstannyl)isothioureas and *N*-substituted *N'*-cyano-*O*-(triphenylstannyl)isoureas. They were similar in activity to the previously tested ethyl *N*-aryl-*S*-(triphenylstannyl)-isothiocarbamates. The antifungal activity of triethylammonium (organocyanoamino)chlorotriphenylstannates, which are the triethylammonium chloride complexes of *N*-substituted *N*-(triphenylstannyl)-cyanamides, was similar to or better than that of the *N*-substituted *N*-(triphenylstannyl)cyanamides. Triethylammonium (acetylcyanoamino)chlorotriphenylstannate and triethylammonium dichlorotriphenylstannate were highly inhibitory toward Gram-positive bacteria.

Keyphrases □ *N*-(Triphenylstannyl)cyanamides, *N*-substituted—evaluated for antifungal activity □ Triethylammonium (organocyanoamino)chlorotriphenylstannates—evaluated for antifungal and antibacterial activity □ Antifungal activity—*N*-substituted *N*-(triphenylstannyl)cyanamides and triethylammonium (organocyanoamino)-chlorotriphenylstannates evaluated □ Antibacterial activity—triethylammonium (acetylcyanoamino)chlorotriphenylstannate and triethylammonium dichlorotriphenylstannate evaluated □ Organotin compounds—*N*-substituted *N*-(triphenylstannyl)cyanamides and triethylammonium (organocyanoamino)triphenylstannates evaluated for antibacterial activity, triethylammonium (acetylcyanoamino)triphenylstannate and triethylammonium dichlorostannate evaluated for antibacterial activity □ Structure–activity relationships—cyanamides evaluated for antifungal activity, chlorotriphenylstannates evaluated for antifungal and antibacterial activity

Many biocidal applications have been found or suggested for organotin compounds (1). The biological effects of organotin compounds were stressed in a recent symposium (2). Their use in agriculture as fungicides and pesticides is of special interest because they degrade to nontoxic inorganic compounds and, therefore, appear to pose little threat to the environment (3–7). Recently, ethyl *N*-aryl-*S*-(triphenylstannyl)isothiocarbamates (Series I) (8), which contain a tin–sulfur bond, were found to be generally better antifungal agents than another class of compounds having a tin–sulfur bond, namely, *N*-substituted *N'*-cyano-(triphenylstannyl)isothioureas (Series II) (9). The former compounds were also generally better antifungal agents than some previously studied compounds having a tin–oxygen bond, namely, *N*-substituted *N'*-cyano-*O*-(triphenylstannyl)isoureas (Series III) (10).

The purpose of the present study was to evaluate the antimicrobial activity of some recently reported compounds (11, 12) having a tin–nitrogen bond, namely, *N*-substituted *N*-(triphenylstannyl)cyanamides (Series IV) and triethylammonium (organocyanoamino)chlorotriphenylstannates (Series V). The latter compounds are anionic organotin complexes. The anionic organotin complex, triethylammonium dichlorotriphenylstannate (VI) (12), which is structurally simpler than V, also was evaluated.

RESULTS AND DISCUSSION

The data in Table I show that each of the Series IV compounds behaved essentially identically toward *Cladosporium carpophilum* (ATCC 12117), *Fusarium monoliforme* (ATCC 10052), *Myrothecium verrucaria* (ATCC 9095), *Penicillium notatum* (ATCC 9179), *Rhizopus stolonifer* (ATCC 10404), *Saccharomyces cerevisiae* (ATCC 9896), and *Trichoderma viride* (ATCC 8678). In the case of *C. carpophilum*, *F. monoliforme*, *M. verrucaria*, *P. notatum*, and *R. stolonifer*, each compound partially inhibited fungal growth at all three concentrations, with the exception of IV*a*, IV*c*, IV*e*, IV*f*, and IV*i*. Compounds IV*a*, IV*c*, and IV*f* were inactive toward *C. carpophilum* at 1 μg/ml, IV*i* was inactive toward both *P. notatum* and *R. stolonifer* at 1 μg/ml, and IV*e* was inactive toward *S. cerevisiae* at 10 μg/ml.

Each Series IV compound partially inhibited *Aspergillus niger* (ATCC 12845) at both 1 and 10 μg/ml. Each compound also completely inhibited growth at 100 μg/ml, with the exception of IV*e*–IV*g* and IV*i*, which only partially inhibited growth. The Series IV compounds exhibited partial inhibition of growth of *Chaetomium globosum* (ATCC 6205) at all concentrations, with the exception of IV*a*, IV*e*, and IV*i*, which completely inhibited growth at 100 μg/ml. The Series IV compounds showed the greatest activity toward *Trichophyton mentagrophytes* (ATCC 9129), with seven compounds completely inhibiting growth at 100 μg/ml.

In general, the Series IV compounds were much better antifungal agents than the previously tested Series II compounds and, with the exception of *T. mentagrophytes* toward which the antifungal activity was the same, were better fungal inhibitors than the Series III compounds. The Series IV compounds were more effective against *A. niger* but less effective against *C. globosum*, *T. mentagrophytes*, and *C. carpophilum* than the Series I compounds; the Series IV and Series I compounds exhibited essentially identical activity toward the other six fungi.

The antifungal activity of the Series V compounds (Table II), which are the triethylammonium chloride complexes of the Series IV compounds, was similar to or better than that of the Series IV compounds. The Series V compounds were more active than the Series IV compounds toward *C. globosum*, *P. notatum*, *S. cerevisiae*, and *T. viride*. For ex-

Table III—Antibacterial Activity of Triethylammonium (Acetylcyanoamino)chlorotriphenylstannate and Triethylammonium Dichlorotriphenylstannate

Compound	*B. subtilis*[a]			*E. coli*			*S. aureus*		
	1[b]	10	100	1	10	100	1	10	100
Va	2+	2+	2+	—	—	+	2+	2+	2+
VI	2+	2+	2+	—	—	+	+	2+	2+

[a] Bacteria were obtained from the culture collection of the Department of Biological Sciences, St. John's University. [b] Indicates concentration of compounds employed in micrograms per milliliter; — indicates no inhibition of growth, + indicates partial inhibition of growth, and 2+ indicates complete inhibition of growth.

ample, only three of the Series IV compounds completely inhibited *C. globosum* at 100 μg/ml, whereas five of the Series V compounds exhibited this activity. Furthermore, none of the Series IV compounds inhibited *P. notatum* at 100 μg/ml, whereas two of the Series V compounds exhibited this activity. Furthermore, none of the Series IV compounds showed activity against *S. cerevisiae* and *T. viride* at 1 μg/ml, whereas four of the Series V compounds were partially active against *S. cerevisiae* and all of the Series V compounds were partially active against *T. viride* at this concentration. In addition, two of the Series V compounds completely inhibited *S. cerevisiae* at 100 μg/ml. The simple anionic complex, VI, exhibited equal or less activity than the Series V compounds.

The data in Table III show that Va and VI behaved in an almost identical manner toward specific test bacteria. Both compounds completely inhibited *Bacillus subtilus* at the lowest level (1 μg/ml) of organotin compound. Both compounds were equal to the previously tested *N*-phenyl-*N'*-cyano-*S*-(triphenylstannyl)isothioureas (II, R = C_6H_5) in this regard (9). On the other hand, the previously tested Series I compounds (8) were completely inactive at this concentration, while the previously tested *N*-phenyl-*N'*-cyano-*O*-(triphenylstannyl)isourea (III, R = C_6H_5) (10) only partially inhibited growth at this concentration. Compound Va behaved identically to the Series I compounds and to II (R = C_6H_5) in that it completely inhibited the growth of *Staphylococcus aureus* at 1 μg/ml. Compound III (R = C_6H_5) was inactive at this concentration (10). Compounds Va and VI were no more active than some previously studied compounds toward *Escherichia coli* (8–10).

EXPERIMENTAL

The Series IV compounds were individually dissolved in tetrahydrofuran. The Series V compounds and VI were individually dissolved in acetone. The preparation of sterile solutions of the compounds, the fungi employed, the antimicrobial testing procedures, and the determination of growth inhibition were reported previously (10).

Compounds Va and VI also were investigated for antibacterial activity according to the procedure reported earlier (10).

Determination of Isophenindamine in Phenindamine Tartrate Using an Argentated High-Performance Liquid Chromatographic Mobile Phase

RONALD J. TSCHERNE ˣ and HERMINIA UMAGAT

Received May 7, 1979, from the *Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication September 13, 1979.

Abstract □ A high-performance liquid chromatographic procedure was developed for the determination of isophenindamine in phenindamine tartrate bulk powder. The method employs a reversed-phase column and a mobile phase containing methanol, 0.001 *M* HNO_3, and silver nitrate.

Keyphrases □ Isophenindamine—analysis, high-performance liquid chromatography, argentated mobile phase, phenindamine tartrate bulk powder □ High-performance liquid chromatography—isophenindamine, analysis in phenindamine tartrate bulk powder □ Phenindamine tartrate—analysis of isophenindamine in bulk powder, high-performance liquid chromatography, argentated mobile phase □ Antihistaminics—phenindamine tartrate, analysis of bulk powder for isophenindamine, high-performance liquid chromatography, argentated mobile phase

The role of histamine in anaphylactic shock and allergic conditions stimulated research for specific histamine antagonists. A series of antihistaminics including phenindamine (I) was synthesized (1). Distinct differences were observed between I and isophenindamine (II) when administered intravenously.

Because of the possible formation of II during the manufacture of phenindamine tartrate, a method for the determination of II was desired. A UV spectrophotometric procedure based on the fact that the wavelength of maximum absorbance for each compound is slightly different

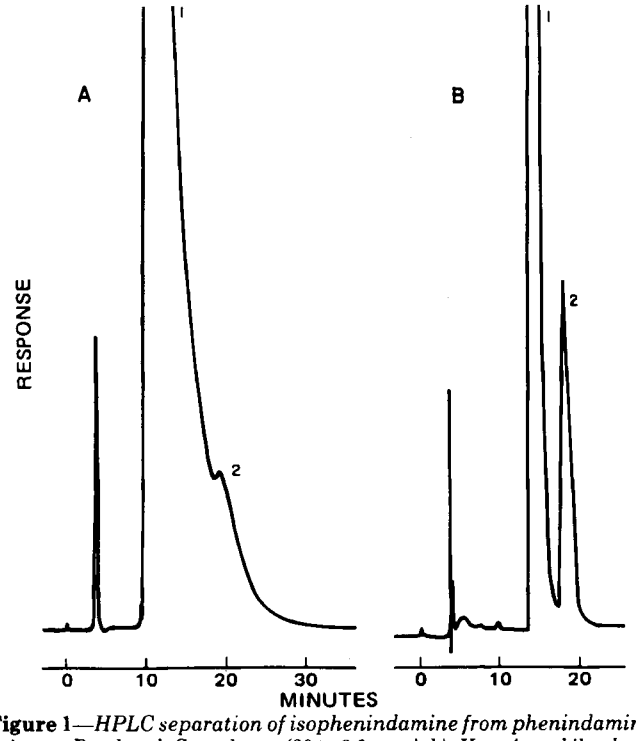

Figure 1—*HPLC separation of isophenindamine from phenindamine using a μBondapak C_{18} column (30 × 3.9 mm i.d.). Key: A, mobile phase of 0.001 M HNO_3–methanol (1:1) and a flow rate of 0.8 ml/min; B, mobile phase of 0.001 M HNO_3–methanol (1:1) containing 2% $AgNO_3$ (w/v) and a flow rate of 0.8 ml/min; 1, phenindamine; and 2, isophenindamine.*

(2) would allow quantitation using simultaneous equation treatment. NMR spectroscopy might be used for II detection, but quantitative results have not been reported[1].

A high-performance liquid chromatographic (HPLC) procedure that enables separation and quantitation of II in the presence of phenindamine tartrate bulk powder is described.

EXPERIMENTAL

Reagents and Chemicals—Glass-distilled water, methanol, nitric acid, and silver nitrate[2] were used for preparation of the mobile phase. The mobile phase was filtered[3] prior to use. Samples and standards were prepared using low-actinic glassware. Isophenindamine nitrate[4] was used for standard preparations.

Instrumentation and Apparatus—A constant-volume pump[5] was used in conjunction with a septum-type injector[6] and a variable-wavelength detector[7]. The separation was accomplished using a permanently bonded octadecylsilane partition column[8]. A high-pressure syringe[9] was used for injection of all samples and standards.

Mobile Phase—The mobile phase was prepared by dissolving 20 g of silver nitrate in 500 ml of 0.001 *M* HNO_3 and diluting with 500 ml of methanol. It was prepared fresh daily using low-actinic glassware and filtered through a 0.45-μm filter prior to use.

Standard Preparation—To prepare the standard solution, 13 mg of isophenindamine nitrate reference standard was weighed accurately into a 25-ml low-actinic volumetric flask, and 12.5 ml of 0.001 *M* HNO_3 was added. The flask was shaken until dissolution was nearly or totally complete (~5 min). Then 12.5 ml of methanol was added, and the flask was shaken again until dissolution occurred. A small degree of sonication usually was necessary to solubilize the reference material.

Sample Preparation—To prepare the sample solution, ~100 mg of phenindamine tartrate powder was weighed accurately into a low-actinic 10-ml volumetric flask. The sample was dispersed in 5 ml of 0.001 *M* HNO_3 by gentle shaking of the flask. Then 5 ml of methanol was added, and the solution was shaken until complete dissolution was observed.

Procedure—Five microliters each of the standard and sample solutions were injected alternately into the chromatograph. The peak heights of the isophenindamine standard and the peak that corresponded to it in retention time in the sample chromatogram were measured. The percent isophenindamine (as tartrate) was calculated by:

$$\%\ \text{isophenindamine (as tartrate)} = \left(\frac{W_{ISTD}}{P_{ISTD}}\right)\left(\frac{P_{ISAM}}{W_{SAM}}\right)\left(\frac{MW_{ITAR}}{MW_{INO3}}\right)\left(\frac{1000}{25}\right) \quad \text{(Eq. 1)}$$

where W_{ISTD} is the weight of isophenindamine nitrate standard in milligrams; W_{SAM} is the weight of the sample in milligrams; P_{ISTD} and P_{ISAM} are the heights, in millimeters, of isophenindamine in the standard and sample runs, respectively; and MW_{ITAR} and MW_{INO3} are the molecular weights of isophenindamine tartrate (411.44) and isophenindamine nitrate (324.37), respectively. The factor 1000/25 is a combination of the dilution factor (10/25) and the conversion to percent (×100).

Table I—Comparison of Results Obtained Using UV and Chromatographic Methods

Lot	Percent Isophenindamine	
	HPLC Determination	UV Determination
A	5.6	3.5
B	5.1	3.1
C	5.3	3.9
D	6.3	3.4
E	7.6	4.2

RESULTS AND DISCUSSION

The chromatographic separation of isophenindamine in the presence of phenindamine tartrate was obtained using a μBondapak C_{18} column and an argentated mobile phase. A 2% $AgNO_3$ (w/v) concentration in the mobile phase was necessary for complete compound separation. Lower silver nitrate concentrations reduced the resolution between I and II, while increased silver nitrate concentrations yielded little additional separation. Typical chromatograms using argentated and nonargentated mobile phases are shown in Fig. 1. Ion-pairing systems employing octanesulfonic acid and lauryl sulfate as pairing reagents were tried but did not produce resolution equivalent to the system containing 2% $AgNO_3$.

Several phenindamine tartrate samples were tested for their isophenindamine content using this method, and the results were compared with those obtained using a UV spectrophotometric procedure based on UV absorbance differences (Table I). Since poor correlation of results was found between the two methods, a standard addition study was done using the HPLC procedure. A straight line through the origin (within experimental error) was obtained for a plot of peak height response *versus* amount of isophenindamine added. This experiment showed conclusively that: (*a*) response *versus* concentration was linear between 0 and 10% isophenindamine in the samples and (*b*) discrepancy in results between the two methods must be linked to the inaccuracy of the UV procedure. Intuitively, these conclusions seem logical because the UV procedure suffers inherently from overlapping absorption bands in the measurement region. The relative standard deviation for 10 injections of the same solution into the chromatograph was 2.2%.

When using both the UV and the chromatographic procedures for quantitation studies, isophenindamine nitrate was the reference standard because no isophenindamine tartrate was available. Sample results were corrected for molecular weight differences between the tartrate and the nitrate salts.

Samples of phenindamine free base also were assayed for their isophenindamine content when the sample preparation was modified slightly. Free base samples had to be dissolved in methanol instead of 0.001 *M* HNO_3–methanol (1:1). This alteration did not affect method reliability.

A rechromatographed portion of an eluted phenindamine peak showed that no detectable amount of the iso-compound formed during the analysis. Also, a stability study on prepared solutions indicated that a

small degree of transformation of isophenindamine to phenindamine occurred after standing in the mobile phase for ~1 day.

To take advantage of the properties of silver nitrate, it was necessary to ensure that all materials in contact with the mobile phase were made of 316 stainless steel or other noncorrodible material. The detector balance had to be electronically offset to monitor the effluent at 254 nm because of the relatively high absorbance of the mobile phase. By observing these relatively simple directions and precautions, the system was safe and reliable, producing no column deterioration over ~3 months of use.

Effect of Exercise on Renal Clearance of Atenolol

WILLIAM D. MASON *x, GREGORY KOCHAK *, NATHANIEL WINER *, and IRVING COHEN ‡

Received April 30, 1979, from the **Pharmacokinetics Laboratory, Schools of Pharmacy and Medicine, University of Missouri-Kansas City, Kansas City, MO 64108,* and the ‡*Clinical Research Department, ICI Americas, Inc., Wilmington, DE 19897.* Accepted for publication October 1, 1979.

Abstract □ The effect of exercise on plasma atenolol was evaluated using a two-phase complete crossover study in 12 healthy volunteers. In one phase, the volunteers were subjected to physical exertion on a treadmill; in the other phase, they remained in a sitting or standing position. Following a single 100-mg atenolol dose, frequent blood samples and a complete urine collection were obtained over 24 hr. Plasma and urine atenolol levels were assayed by high-pressure liquid chromatography. Plasma atenolol was significantly ($p < 0.05$) higher during the exercise phase of the study, and this result was associated with approximately an 8% decrease in the renal clearance of the drug, probably due to decreased renal blood flow during exercise.

Keyphrases □ Atenolol—effect of exercise on renal clearance □ Pharmacokinetics—atenolol, effect of exercise on renal clearance □ Renal clearance—atenolol, effect of exercise □ β-Adrenergic blocking agents—atenolol, effect of exercise on renal clearance

Recently published reports described the pharmacokinetics (1) and pharmacodynamics (2) of atenolol, 2-[*p*-[2-hydroxy-3-(isopropylamino)propoxy]phenyl]acetamide, a new cardioselective (3–5) β-adrenergic blocking agent. More than 90% of the bioavailable dose of atenolol is excreted unchanged in the urine within 48 hr of dosing (6). To study the relationship of pharmacokinetics to pharmacodynamics, a two-phase complete crossover design was employed, with the phases differing only in the amount of exercise required of the subjects. A difference in the kinetics of atenolol between the two phases (exercise *versus* nonexercise) is reported.

EXPERIMENTAL

The 12 healthy male volunteers were 20–28 years old and weighed 63.6–85.5 kg (140–188 lb). Each subject was judged healthy based on the absence of any abnormality in his history, physical examination, ECG, hemogram, blood chemistries, and urinalysis.

The study design was a two-phase complete crossover, with the treatments being identical except for the exercise performed by each subject. Following a 10-hr fast, each subject received 100 mg of atenolol as an oral solution in 240 ml of water. The fast continued until after the 4th-hr blood sample was drawn; a standard meal was served at the 5th hr. Following the meal, water was allowed *ad libitum*. Blood samples were collected at 0, 0.5, 1.0, 2.0, 3.0, 4.0, 6.0, 8.0, 10.0, 12.0, 14.0, and 24.0 hr. Urine was collected prior to dosing, from 0.0 to 12.0 hr, and from 12.0 to 24.0 hr.

Plasma and urine atenolol levels were determined by a high-pressure liquid chromatographic (HPLC) method described previously (7) and modified as follows. The mobile phase consisted of a 4.00 m*M* solution of 1-heptanesulfonic acid sodium salt, 1.0% acetic acid, and 60.0% methanol in distilled water. The mobile phase was pumped at 1.5 ml/min and 20° through a stainless steel column packed with a high efficiency bonded-phase packing[1]. Aliquots of 150 μl of the reextraction solution were injected directly on-column through the injector. The atenolol peak was well separated from the procainamide internal standard peak and from artifacts. The retention times of atenolol and procainamide were 5.8 and 12.3 min, respectively.

X_u^{12}[d], mg	39.4	13.4	42.0	13.3	NS
Cl_R[e], ml/min	150	18.6	139	14.3	S

[a] S denotes significant difference at 0.05 significance level by analysis of variance; NS denotes no significant difference. [b] Area under the plasma concentration–time profile from 0 to 24 hr. [c] Amount of drug collected in the urine in 24 hr. [d] Amount of drug collected in the urine in 12 hr. [e] Renal clearance = $X_u^{0\rightarrow 24}/AUC^{0\rightarrow 24}$ hr.

During the nonexercise phase, the subjects remained in a sitting or standing position while confined to a small room. Subjects were confined for the entire 24-hr period of each phase of the study. The exercise phase consisted of the four stages of the Bruce protocol (8) (Table I) prior to dosing and at 4, 8, and 24 hr following each dose.

The mean heart rate for the 12 subjects prior to atenolol administration was 174 beats/min at Stage 4 of exercise. Volunteers in the exercise group were subjected to further physical exertion by the need to walk from their location up one flight of stairs to the treadmill, a distance of 114.3 m (375 ft). The subjects then rested until a resting pulse was attained, and treadmill exercise was then performed.

RESULTS AND DISCUSSION

Table II and Fig. 1 present the mean plasma and urine atenolol with the individual and mean areas under the plasma–time profiles and the calculated renal clearances for each treatment with the corresponding statistics. Analysis of variance showed differences at the 4-, 6-, 8-, and 10-hr times in plasma atenolol ($p < 0.05$) such that plasma atenolol was higher during exercise. The $AUC^{0\rightarrow 24}$ and Cl_R also showed significant ($p < 0.05$) differences. All other times and $X_u^{0\rightarrow 24}$ did not show significant differences. Since the total amount of atenolol excreted in 24 hr did not differ between exercised and nonexercised subjects and the area under the curve ($AUC^{0\rightarrow 24}$) was significantly increased during exercise ($p < 0.05$), the computed renal clearance decreased during exercise.

With the commencement of exercise at 4 hr, a change in plasma atenolol was attained. This result is consistent with the fact that the change in $AUC^{0\rightarrow 24}$ and Cl_R with exercise is due to the exercising condition and not some other factor. Urinary recovery of atenolol verified previous recoveries (1), consistent with published results showing orally administered atenolol to be 0.58 ± 0.16 bioavailable.

The decrease in renal clearance of atenolol of ~8% can possibly be explained by changes in renal plasma flow. Decreases of up to 35% normal renal plasma flow were noted in a similar treadmill test as the Bruce treadmill protocol (9–11). During exercise, neurogenic and hormonal influences shunt blood away from the kidney to other areas (*i.e.*, heart, brain, and skeletal muscle). Since atenolol is essentially totally eliminated *via* the kidney, a decrease in renal clearance, Cl_R, would be expected during exercise.

A review (12) of the interrelationships among renal hemodynamics, drug kinetics, and drug action described the potential effects of reduced renal blood flow on the clearance and distribution of drugs but did not directly address the potential effects of exercise. Little is known of the effects of exercise on drug kinetics. An 8% increase in plasma atenolol during exercise would probably not be therapeutically significant, but it does demonstrate the importance of controlling exercise levels during pharmacokinetic and bioavailability studies.

Colorimetric Determination of Procaine Hydrochloride in Pharmaceutical Preparations

R. B. SALAMA *x and A. I. H. OMER ‡

Received June 16, 1978, from the **Department of Pharmaceutical Chemistry, University of Khartoum, Khartoum, Sudan,* and the ‡*Chemical Laboratories, Ministry of Health, Khartoum, Sudan.* Accepted for publication October 1, 1979.

Abstract □ A new rapid, specific, and convenient colorimetric method for the determination of procaine hydrochloride in pharmaceutical preparations is described. This method is based on measurement of the intensity of the orange-red color developed when procaine hydrochloride is allowed to react with 1,2-naphthoquinone-4-sulfonic acid sodium salt in aqueous solution. Beer's law is followed over 6.0–20.0 μg/ml. The method was applied to the determination of procaine hydrochloride in procaine hydrochloride, procaine hydrochloride injection with or without epinephrine, penicillin G procaine, penicillin G procaine injection, and fortified procaine penicillin injection (BP). The results were comparable to those obtained by official procedures. Because of its simplicity, sensitivity, and accuracy, this method is particularly suited for routine analysis of official preparations of procaine hydrochloride.

Keyphrases □ Procaine hydrochloride—colorimetric assay using 1,2-naphthoquinone-4-sulfonic acid sodium salt □ Colorimetry—analysis, procaine hydrochloride reaction with 1,2-naphthoquinone-4-sulfonic acid sodium salt

The USP (1) and BP (2) methods for the determination of procaine hydrochloride depend on diazotization and titration of the compound with standard sodium nitrite solution. For procaine hydrochloride injection, the USP assay requires prior isolation of the procaine by solvent extraction and then determination of the procaine spectrophotometrically (3). The BP (4) method for the determination of procaine hydrochloride in procaine hydrochloride injection depends on solvent extraction of the procaine from alkaline solution followed by acid–base titration. Both methods are lengthy and involve solvent extractions.

The BP (5) methods for the determination of procaine in penicillin G procaine, penicillin G procaine injection, and fortified procaine penicillin injection are all similar, depending on solvent extraction followed by acid–base titration. The method is lengthy and lacks sensitivity.

A colorimetric method for the determination of procaine hydrochloride was developed recently (6) based on the interaction of procaine hydrochloride with *p*-dimethylaminocinnamaldehyde in the presence of trichloroacetic acid in absolute methanol. This method requires a nonaqueous acidic medium.

A simple, time-saving, and sensitive method for the determination of procaine in pharmaceutical preparations is needed. The proposed method depends on the reaction between procaine hydrochloride and 1,2-naphthoquinone-4-sulfonic acid sodium salt in aqueous solution. 1,2-Naphthoquinone-4-sulfonic acid sodium salt was reported previously (7) to be a detecting agent for aromatic amines on TLC plates.

EXPERIMENTAL

Instruments—A visible UV spectrophotometer[1] was used.

Materials and Reagents—The following were used: procaine hydrochloride[2]; a 0.1% solution of 1,2-naphthoquinone-4-sulfonic acid sodium salt in water[3]; a 2% procaine hydrochloride injection; a 2% procaine hydrochloride injection containing 0.002% epinephrine; a procaine and epinephrine injection[4] containing 2.0% procaine hydrochloride, 0.002% epinephrine, 0.2% sodium chloride, 0.3% potassium sulfate, and 0.002% phenylmercuric nitrate; penicillin G procaine[5]; a penicillin G procaine injection containing 300 mg of penicillin G procaine; fortified penicillin and penicillin G (sodium salt), 60 mg; and fortified penicillin G injection BP[6].

Calibration Curve Preparation—Several aliquots of exactly 2.0–10.0 ml of procaine hydrochloride solution (100 μg/ml) were pipetted into 50-ml volumetric flasks. Then 20 ml of water and 2.0 ml of 1,2-naphthoquinone-4-sulfonic acid sodium salt were added. Each flask was mixed well, let stand for 60 min, and diluted to volume with water. The absorbance was measured at 482 nm in a 1-cm cell against a blank prepared under the same conditions but without procaine hydrochloride.

Table V—Recovery of Procaine Hydrochloride

Preparation	Procaine Hydrochloride, mg	Found, mg	Added, mg	Found after Addition, mg	Recovery, %
Injection (without epinephrine)	20	20.05	10.0	30.1	100.5
Injection (with epinephrine)	20	19.95	20.0	39.9	99.75
Solution	50	50.15	50.0	100.4	100.5

Procaine Hydrochloride—One hundred milligrams, accurately weighed, of procaine hydrochloride was dissolved in water to produce 100 ml. Then 0.8 ml of this solution was pipetted into a 50-ml volumetric flask, and the procedure described for the calibration curve was followed. The amount of procaine hydrochloride was calculated from the calibration curve.

Procaine Hydrochloride Injection with or without Epinephrine—Five milliliters of a 2% procaine hydrochloride injection was pipetted into a 100-ml volumetric flask and diluted to volume with water. Then 0.8 ml of this solution was pipetted into a 50-ml volumetric flask, and the procedure described for the calibration curve was followed. The amount of procaine hydrochloride was calculated from the calibration curve.

Penicillin G Procaine—Three hundred milligrams[7] of penicillin G procaine was dissolved in water to produce 100 ml. Then 0.5 ml of this solution was pipetted into a 50-ml volumetric flask, and the procedure described for the calibration curve was followed. The amount of procaine hydrochloride was calculated from the calibration curve.

Penicillin G Procaine Injection—An accurately measured volume of a well-shaken suspension, equivalent to 300 mg of penicillin G procaine, was diluted to 100 ml with water. Then 0.5 ml of this solution was pipetted into a 50-ml volumetric flask, and the procedure described for the calibration curve was followed. The amount of procaine hydrochloride was calculated from the calibration curve.

Fortified Procaine Penicillin Injection (BP)—The contents of the vial (containing 300 mg of penicillin procaine and 60 mg of penicillin G) were dissolved in water to produce 100 ml. Then 0.5 ml of this solution was pipetted into a 50-ml volumetric flask, and the procedure described for the calibration curve was followed. The amount of procaine hydrochloride was calculated from the calibration curve.

Interferences—The effect of epinephrine, sodium chloride, potassium sulfate, phenylmercuric nitrate, chlorocresol, and sodium metabisulfite on the determination of procaine hydrochloride was determined by preparing solutions containing these substances plus a known amount of procaine hydrochloride and performing the analysis according to the procedure for procaine hydrochloride. The effect of penicillin G on the determination of procaine in penicillin G procaine preparation was studied similarly.

RESULTS AND DISCUSSION

A characteristic orange-red color with an absorbance maximum at 482 nm developed when procaine hydrochloride was reacted with 1,2-naphthoquinone-4-sulfonic acid sodium salt in aqueous medium. When the observed absorbances were plotted against concentrations, a linear calibration curve with a slope of 0.01636 was obtained over the concentration range of 6.0–20.0 μg/ml, indicating obedience to Beer's law. This linearity was also confirmed when the correlation coefficient, r, was calculated from the values of absorbances and concentrations and was 0.9991.

The color reached maximum intensity after 60 min and remained stable for at least an additional 2 hr (Table I).

The effect of pH on the color intensity was studied. It was stable between pH 4 and 9 but dropped suddenly at pH 10 (Table II). Therefore, buffers were not used to adjust the pH since the method could be used at any pH between 4 and 9.

The concentration optimum of the color reagent was determined by adding various volumes of 0.1% 1,2-naphthoquinone-4-sulfonic acid sodium salt reagent to a series of 50-ml volumetric flasks, each containing 800 μg of procaine hydrochloride, diluting to volume with water, and measuring the absorbance of each solution at 482 nm against a blank[8]. Maximum color intensity was obtained with 1.5 ml of the reagent. Increasing the volume to 4.0 ml did not increase the absorbance. Therefore, it was decided to use 2.0 ml as the optimum concentration.

The precision study was performed at three different concentrations, 6, 12, and 18 μg/ml, by running 10 replicates of each. The coefficients of variation were 1.190, 0.684, and 0.452%, respectively (Table III).

The proposed method was compared to the official methods for prepared and commercially available procaine hydrochloride pharmaceutical preparations. There was a close relationship between the results obtained by the official procedures and those obtained by the suggested method (Table IV).

Samples of procaine hydrochloride preparation were analyzed before and after the addition of known quantities of procaine hydrochloride solution (Table V). The recovery data obtained proved that the suggested method is accurate. Temperature change had an insignificant effect on chromophore formation.

The presence of epinephrine, penicillin G, sodium chloride, potassium sulfate, phenylmercuric nitrate, chlorocresol, and sodium metabisulfite in the concentrations used produced no effect on the development, intensity, or stability of the color and, therefore, had no effect on the colorimetric assay.

Quantitation of Acetazolamide in Plasma by High-Performance Liquid Chromatography

R. D. HOSSIE ˣ, N. MOUSSEAU, S. SVED, and R. BRIEN

Received August 20, 1979, from the *Drug Research Laboratories, Health Protection Branch, Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario K1A 0L2, Canada.* Accepted for publication October 5, 1979.

Abstract □ A method for estimating acetazolamide concentrations in human plasma is described. Buffered plasma (pH 4.8) containing chlorothiazide as an internal standard is extracted twice with ethyl acetate. The extract is evaporated, redissolved, and chromatographed on silica gel with hexane–chloroform–methanol–acetic acid (65:25:10:0.25) as the mobile phase. The extraction efficiencies were >90%, the coefficients of variation at 1 and 30 μg/ml of plasma were 3.5 and 2.0%, respectively, and the calibration curves were linear and had an intercept of essentially zero. The suitability of the method for pharmacokinetic studies was verified in a normal volunteer dosed with 250-mg (solution) and 500-mg (sustained-release tablet) acetazolamide formulations.

Keyphrases □ Acetazolamide—analysis, high-performance liquid chromatography, plasma □ High-performance liquid chromatography—analysis, acetazolamide, plasma □ Carbonic anhydrase inhibitors—acetazolamide, high-performance liquid chromatography, plasma

Acetazolamide, a carbonic anhydrase inhibitor, is used to decrease the ocular aqueous humor secretion in certain types of glaucoma. Methods for the quantitation of this drug in biological fluids include measurement of the carbonic anhydrase inhibition (1, 2), colorimetry (3, 4), electron-capture GLC (5), and high-performance liquid chromatography (HPLC) (6). However, the GLC and HPLC procedures are time consuming (2), the colorimetric method is only partially successful (4, 6), and the modified enzymatic assay (2) lacks sufficient precision.

The present study was undertaken to develop an assay without the described deficiencies that could be used to quantitate acetazolamide in human or animal plasma following administration of single doses of 250 mg of a regular acetazolamide formulation or 500 mg of a sustained-release formulation.

EXPERIMENTAL

Materials—Hexane, chloroform, and methanol were HPLC grade[1,2]. Acetazolamide and chlorothiazide were USP reference standards. Sodium acetate, ethyl acetate, sodium bicarbonate, sodium hydroxide, and acetic acid were reagent grade.

One oral acetazolamide solution, used in the plasma profile experiments, was prepared by dissolving 250 mg of the USP standard in 20 ml of ethanol and diluting to 200 ml with fresh aqueous sodium bicarbonate (0.1 *M*). The final pH was 8. Another oral solution, used in determining the absence of interference, was prepared by dissolving a commercial parenteral preparation[3] in water.

Subjects—After an overnight fast, a healthy, 40-year-old male subject (90 kg) was administered 200 ml of the solution (250 mg) and separately one commercial 500-mg sustained-release formulation[3] with 150–250 ml of water at a 1-week interval.

Blood samples (10 ml) were collected in heparinized evacuated containers[4] at the various times (Figs. 1 and 2). The samples were centrifuged at 1000×*g*, and the separated plasma was stored at −18° until analysis.

Method—To tubes containing 1 ml of plasma were added 0.5 ml of internal standard (20 μg of chlorothiazide/ml of water), 2 ml of sodium acetate buffer (0.05 *M*, pH 4.8), and 10 ml of ethyl acetate. After mixing[5] for 10 min and centrifuging for 10 min at 1000×*g*, the organic layer was removed, and the extraction steps were repeated. The combined organic layers were evaporated at 60° to dryness using a nitrogen stream. After the residue was dissolved in 10 μl of 0.45 *N* NaOH by mixing[6], 1 ml of ethyl acetate was added, and the contents were mixed again. Aliquots (200 μl) of this solution were chromatographed.

The HPLC system consisted of a pump, an injector, and a detector[7] set at 280 nm. The silica gel column[8] (5 μm, 3.2 × 250 mm) was packed using a balanced density slurry method. The mobile phase was hexane–chloroform–methanol–acetic acid (65:25:10:0.25) at a flow rate of 3 ml/min (2900 psi). Quantitation was achieved by measuring the peak height ratio of the drug to the internal standard.

Calibration Curve—The linearity of the calibration curve was determined by adding 0.5, 2, 4, 8, and 12 μg of acetazolamide/ml to blank plasma samples. Two aliquots of each concentration were assayed as described. The coefficients of variation were determined using replicate samples of plasma standards containing 1 and 30 μg of acetazolamide/ml.

Determination of Extraction Efficiency—The extraction efficiency for the drug was estimated from the change in the peak height ratio when the drug was added to the plasma while the internal standard was added to the final extract compared to the peak height ratio when both were added to the final extract. The extraction efficiency for the internal standard was estimated from the change in the peak height ratio when the internal standard was added to the plasma while the drug was added to the final extract compared to the peak height ratio when both were added to the final extract.

Absence of Interferences—To verify the absence of metabolites and naturally occurring plasma constituents interfering with the internal standard or drug, plasma samples obtained from another volunteer 2 and 2.5 hr after ingestion of 500 mg of acetazolamide solution were pooled and extracted without the internal standard and chromatographed.

The effluents containing acetazolamide were combined and evaporated. One aliquot was rechromatographed on the same column using hexane–chloroform–methanol–acetic acid (70:25:5:0.25) as the mobile phase at a flow rate of 3 ml/min. Another aliquot was injected onto a bonded amino-silica gel column[9] (10 μm, 4.0 × 300 mm) using a mobile

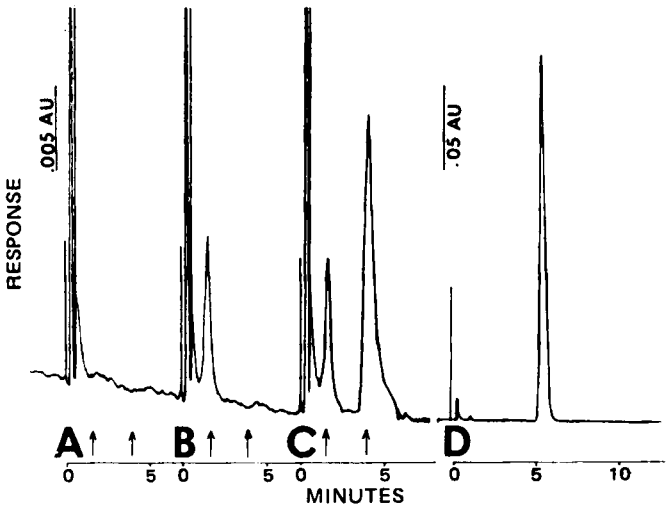

Figure 1—*Chromatograms of plasma extracts. Key: A, blank plasma; B and C, plasma of a human volunteer 4.5 hr after administration of 250 mg of an oral acetazolamide solution without (B) and with (C) the internal standard (estimated concentration, 6.03 μg/ml); and D, rechromatography of pooled acetazolamide peaks. Samples A, B, and C were chromatographed on a silica gel column with a mobile phase of hexane–chloroform–methanol–acetic acid (65:25:10:0.25). Sample D was chromatographed on a bonded amino-silica gel column with a mobile phase of 20% methanol in 0.01* M *ammonium formate. The expected locations of the drug and the internal standard are marked by arrows.*

phase of 20% methanol in 0.01 *M* aqueous ammonium formate at a flow rate of 2 ml/min.

RESULTS AND DISCUSSION

Preliminary experiments demonstrated the need for acetic acid in the mobile phase. In its absence, the peak height ratio of the drug to the internal standard diminished on successive injections of plasma extract, which may have been due to an accumulation of interfering substances. However, inclusion of acetic acid maintained the constancy of the peak height ratio in new columns, and old columns were restored to their original conditions by thorough flushing with the acidic mobile phase. Bayne *et al.* (6) had a similar problem with their acetazolamide assay. They attempted to overcome the problem by injecting alcohol between injections of the plasma extract. Unfortunately, in the present investigation this alcohol injection increased the analysis time and was not always successful.

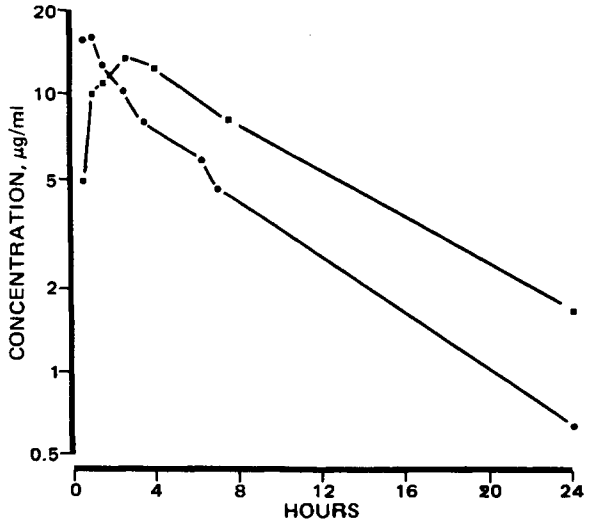

Figure 2—*Plasma concentration profiles of acetazolamide in a volunteer following the oral administration of 250 mg in solution (●) and a 500-mg sustained-release tablet (■).*

Table I—Typical Acetazolamide Calibration Curve

Drug Added, μg/ml	Peak Height Ratio[a]	Ratio[b]
0.5	0.062	0.125
2.0	0.264	0.132
4.0	0.521	0.130
8.0	1.043	0.130
12.0	1.595	0.133

[a] Ratio of the drug to the internal standard. [b] Ratio of the peak height ratio to the drug concentration.

The final method was evaluated in terms of extraction efficiency, interferences, linearity, and precision. The extraction efficiency of acetazolamide from plasma to ethyl acetate was 94% while that for chlorothiazide was 91%. Neither naturally occurring plasma constituents nor metabolites interfered with the peak height determination of either the drug or the internal standard. With blank plasma, when the internal standard was eliminated from the assay, no peaks absorbing at 280 nm and having the same retention times as acetazolamide or chlorothiazide were observed (Fig. 1A). Plasma extracts from a volunteer 4.5 hr after ingestion of 250 mg of drug (Fig. 1B) showed no peak with a retention time similar to that of the internal standard. Furthermore, the pooled effluents corresponding to the acetazolamide peak from the plasma of a volunteer 2–2.5 hr after a 500-mg drug dose showed a single peak when rechromatographed using a different column and mobile phase (Fig. 1D).

A typical calibration curve is shown in Table I. The excellent linearity of the method is illustrated by the constant values of the ratio of the peak height ratio to the drug concentration. The regression of the peak height ratio against drug concentrations gave a slope (±95% confidence interval) of 0.13 (±0.003) ml/μg and a peak height ratio intercept of nearly zero (−0.006 ± 0.02). In another series of experiments, the coefficients of variation determined at 1 and 30 μg/ml (n = 5 and 6, respectively) were 3.5 and 2.0%, respectively.

The suitability of the method for studying acetazolamide pharmacokinetics following single-dose administration was ascertained by administering separately 250 mg of the drug in solution and 500 mg in a sustained-release formulation to a normal human volunteer (Fig. 2). The solution showed rapid absorption with apparently biphasic elimination. A peak concentration of 16 μg/ml was produced at 1 hr compared to the lower peak concentration (13 μg/ml) produced at 2.5 hr with the larger dose, sustained-release product. These figures are in good agreement with values published previously (7).

This assay is relatively quick and precise and is not subject to interference either from metabolites or from naturally occurring plasma constituents.

Effect of Hyperthermically Elevated Serum Prolactin on Epididymal Cyclic AMP (Adenosine 3′,5′-Cyclic Monophosphate) Levels in Rats

J. M. ROSENBERG ×, I. S. KAMPA *, V. REID, J. M. HUNDERTMARK *, D. W. FRASCELLA ‡, and C. A. LAU-CAM §

Received June 21, 1979, from the *Arnold and Marie Schwartz College of Pharmacy and Health Sciences, Brooklyn, NY 11201.* Accepted for publication October 5, 1979. *Department of Pathology, Valley Hospital, Ridgewood, NJ 07451. ‡Hoechst-Roussel Pharmaceuticals, Somerville, NJ 08876. §Department of Pharmaceutical Sciences, St. John's University College of Pharmacy and Allied Health Professions, Jamaica, NY 11439.

Abstract □ To investigate whether increased blood prolactin concentration affects epididymal cyclic AMP (adenosine 3′,5′-cyclic monophosphate) levels during hyperthermic stress, a study was conducted on 40 Sprague–Dawley male rats divided into four equal groups. Two groups were injected intraperitoneally with bromocriptine, a potent inhibitor of prolactin release. Under identical experimental conditions, one group was subjected to hyperthermic stress, and the other group was maintained at room temperature. Two additional groups were injected with a control vehicle; one group was subjected to hyperthermic stress, and the other group was kept at normal body temperature. Blood samples were analyzed for serum prolactin, and epididymal fat pads were assayed for cyclic AMP. Serum prolactin levels increased significantly ($p < 0.01$) in hyperthermic rats, but this effect was suppressed completely by bromocriptine. Cyclic AMP levels were increased ($p < 0.01$) during elevated body temperature in all animals examined, with no significant difference ($p > 0.05$) occurring between the nonbromocriptine-treated and bromocriptine–prolactin-suppressed groups. This investigation suggested that elevation of epididymal fat cyclic AMP during hyperthermia is not the result of increased prolactin levels.

Keyphrases □ Cyclic AMP—epididymal levels, effect of hyperthermically elevated serum prolactin, rats □ Hyperthermia—elevation of serum prolactin, effect on epididymal cyclic AMP levels, rats □ Prolactin, serum—hyperthermic elevation, effect on epididymal cyclic AMP levels, rats

Hyperthermic stress induces changes in lipid metabolism, including a rise in epididymal fat pad cyclic AMP (adenosine 3′,5′-cyclic monophosphate) (1–3). It has been shown that insulin exerts an inhibiting effect on the rise of epididymal fat pad cyclic AMP during hyperthermia (1). However, the rise in cyclic AMP may result from a concomitant decrease in blood insulin (1), an increase in extrapituitary lipolytic hormones such as glucagon (1), and/or an increase in pituitary lipolytic hormones such as prolactin (4–6). The present study was designed to elucidate the role of prolactin on the elevation of epididymal cyclic AMP during hyperthermic stress.

EXPERIMENTAL

Animals—Forty male Sprague–Dawley adult rats[1], 225–300 g, were divided into four equal groups. They were housed for 21 days prior to the study in a temperature-controlled (23 ± 3°), artificially illuminated (lights on from 7:00 am to 7:00 pm daily) room. During this period, the rats were given food[2] and water *ad libitum*. Prior to all experiments, the animals were fasted for 12 hr.

Effect of Hyperthermia on Epididymal Fat Pad Cyclic AMP and Serum Prolactin—The first 10 animals (hyperthermic bromocriptine group) were injected intraperitoneally with 1 mg of bromocriptine[3], a known potent inhibitor of prolactin (7), in 0.5 ml of 5% ethanol. A second group of animals (hyperthermic control group) was injected intraperitoneally with 5% ethanol vehicle. Thirty minutes after injection, both groups were placed in an environmental chamber[4]. The relative humidity was maintained between 40 and 45% within the chamber, and the ambient temperature was controlled to allow the rectal temperature[5] to increase ~1°/30 min until a value of 42 ± 0.1° was reached. This rectal temperature was maintained for approximately 30 min, at which time blood samples were obtained by decapitation. A small portion of epididymal fat was removed immediately from each animal and frozen in liquid nitrogen.

The third group of animals (normothermic bromocriptine group) was treated as described for the first group, and the remaining 10 animals (normothermic control group) were treated identically to the second group. For the latter two groups, the temperature in the environmental chamber was maintained at 23 ± 3° for the 3 hr that the animals were contained in it. Blood and epididymal fat samples then were obtained.

Sample Collection and Assay—All decapitations were conducted between 3:30 and 5:00 pm. Blood was collected from the trunk portion and allowed to stand for 10 min at 4°, and the serum was separated and frozen at −40° until hormone analysis could be performed. Serum prolactin levels were measured using a double antibody radioimmunoassay kit[6] according to the instructions supplied. The rat prolactin was iodinated by a modification of the Hunter–Greenwood method (8). Each serum sample was assayed in duplicate, and the average was taken as representative of the true prolactin concentration. All results are expressed in terms of nanograms per milliliter of NIAMDD rat prolactin.

Cyclic AMP was extracted from the epididymal fat pads by a method described by Steiner *et al.* (9), and the concentrations were determined by radioimmunoassay[7] using a modification of a method reported by the same investigators (10). Each sample was assayed in duplicate, and the average was taken as representative of the concentration. Cyclic AMP results are expressed in picomoles per gram of wet epididymal fat tissue.

Statistical comparisons were determined by the Student t test (11).

RESULTS

Figure 1 shows the results of hyperthermic stress on serum prolactin levels following treatment with bromocriptine or control vehicle. Prolactin levels were elevated significantly ($p < 0.01$) in the hyperthermic control group compared to the normothermic control group [124.3 ± 20.6 (*SE*) *versus* 44.8 ± 7.7 (*SE*) ng/ml, respectively; $t = 3.4$, $df = 18$]. Prolactin levels were depressed significantly ($p < 0.01$) in the hyperthermic bromocriptine group compared to the hyperthermic control group [11.2 ± 1.2 (*SE*) *versus* 124.3 ± 20.6 (*SE*) ng/ml, respectively; $t = 39.0$, $df = 18$] and in the normothermic bromocriptine group compared to the normothermic control group [44.8 ± 7.7 (*SE*) *versus* 13.4 ± 1.2 (*SE*) ng/ml, respectively; $t = 3.5$, $df = 18$], with no significant difference ($p > 0.05$) between the bromocriptine–prolactin-suppressed groups [11.2 ± 1.2 (*SE*) *versus* 13.4 ■ 1.2 (*SE*) ng/ml, respectively; $t = 1.2$, $df = 18$].

Figure 2 indicates that epididymal cyclic AMP levels were elevated significantly ($p < 0.01$) in the hyperthermic control group compared to

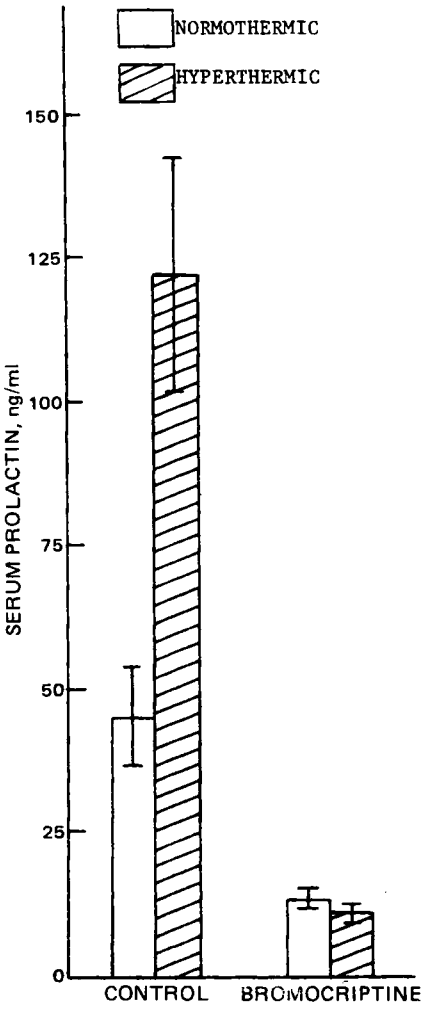

Figure 1—*Serum prolactin levels in rats treated with bromocriptine or vehicle during normal and elevated rectal temperatures. Each vertical bar represents the mean of 10 observations. The vertical brackets indicate standard errors of the mean. Prolactin levels in the hyperthermic control rats were significantly ($p < 0.01$) elevated compared to normothermic controls. Bromocriptine treatment significantly depressed serum prolactin levels in both hyperthermic and normothermic animals.*

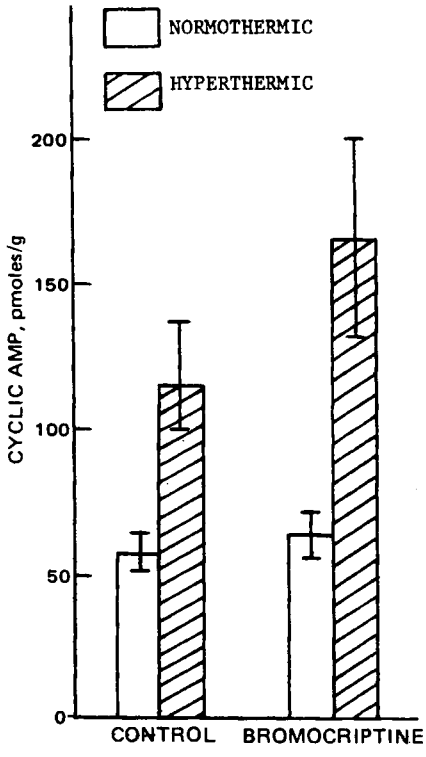

Figure 2—*Cyclic AMP concentrations in rats treated with bromocriptine or control vehicle during normal and elevated rectal temperatures. Each vertical bar represents the mean of 10 observations. The vertical brackets indicate standard errors of the mean. Hyperthermia significantly ($p < 0.01$) elevated cyclic AMP in both bromocriptine- and control vehicle-treated animals with no significant difference ($p > 0.05$) in the concentration of both groups.*

the normothermic control group [115.2 ± 20.9 (*SE*) *versus* 56.1 ± 6.7 (*SE*) pmoles/g, respectively; $t = 3.8$, $df = 18$] and in the hyperthermic bromocriptine group compared to the normothermic bromocriptine animals [165.7 ± 33.8 (*SE*) *versus* 63.4 ± 8.3 (*SE*) pmoles/g, respectively; $t = 3.9$, $df = 18$]. The cyclic AMP concentrations of the normothermic control and the normothermic bromocriptine groups were not significantly different ($p > 0.05$) [56.1 ± 6.7 (*SE*) *versus* 63.4 ± 8.3 (*SE*) pmoles/g, respectively; $t = 2.0$, $df = 18$], and there also was no significant difference ($p > 0.05$) in concentration between the hyperthermic control and the hyperthermic bromocriptine groups [115.2 ± 20.9 (*SE*) *versus* 165.7 ± 33.8 (*SE*) pmoles/g, respectively; $t = 1.2$, $df = 18$].

DISCUSSION

Serum prolactin levels are largely controlled by a hypothalamic prolactin-inhibiting factor related to dopamine which, indeed, may be dopamine (12). Pharmacological agents that reduce serum prolactin levels include dopamine agonists such as bromocriptine (7). Although bromocriptine also may transiently increase the prolactin clearance from plasma by stimulating its uptake into peripheral receptor sites, its exact inhibitory mechanism is not fully known (13).

In the present study, serum prolactin levels significantly increased in hyperthermic rats. Bromocriptine-treated animals exhibited suppressed serum prolactin levels, and no elevation of prolactin levels occurred during hyperthermia (Fig. 1). Previous studies (14, 15) showed that increased temperature raises blood prolactin. However, these changes were not attributed simply to stress since lowered temperature significantly decreased serum prolactin and elevated temperature produced the opposite effect (14, 15). Although it was reported previously that prolactin increases lipolysis in adipose tissue from mature rats, as indicated by an increased free fatty acid and glycerol release (16, 17), this effect has not been observed in young rats (16).

Prolactin also is known to increase cyclic AMP in some tissues but not in others (16). Since no significant change in the levels of cyclic AMP occurred among the bromocriptine-treated hyperthermic animals in contrast to nonbromocriptine-treated rats (Fig. 2), it appears that epididymal fat cyclic AMP elevations during hyperthermia occur independently of increases in serum prolactin levels. The role of extrapituitary lipolytic hormones such as glucagon is now being investigated to determine if they play a part in the epididymal fat cyclic AMP increase observed during elevated body temperature.

In Vitro Adsorption Studies of Cimetidine

F. GANJIAN, A. J. CUTIE, and T. JOCHSBERGER ˣ

Received August 8, 1979, from the *Arnold & Marie Schwartz College of Pharmacy and Health Sciences, Brooklyn, NY 11201.* Accepted for publication October 5, 1979.

Abstract □ The adsorption of cimetidine on selected pharmaceuticals including kaolin, activated charcoal, talc, and nonsystemic antacids was determined at pH 5.0 and 25°. The Langmuir and Freundlich adsorption isotherms showed that cimetidine adsorption was significant with activated charcoal, kaolin, talc, and magnesium trisilicate and was virtually nonexistent with magnesium hydroxide and aluminum hydroxide. Equations expressing the Freundlich and Langmuir adsorption isotherms were evaluated for each adsorbent. The approximate amounts of cimetidine adsorbed per gram of adsorbent were 25.6, 0.402, 0.291, and 0.343 mg for charcoal, kaolin, talc, and magnesium trisilicate, respectively. These *in vitro* studies indicate that some cimetidine may be lost when it is administered concomitantly with pharmaceutical adsorbents.

Keyphrases □ Cimetidine—adsorption onto various pharmaceutical adsorbents, *in vitro* □ Adsorption—cimetidine, various pharmaceutical adsorbents, *in vitro* □ Interactions—adsorption of cimetidine onto various pharmaceutical adsorbents

Numerous pharmaceuticals contain substances that are capable of adsorbing various drugs and other compounds (1–8). These substances include clays such as kaolin and talc and silicates found in some antacid–antiflatulent preparations. The purpose of this study was to determine if any adsorption interaction occurred with some commonly employed pharmaceutical ingredients including kaolin, talc, magnesium trisilicate, aluminum hydroxide, magnesium hydroxide, activated charcoal, and the H_2-receptor antagonist cimetidine used for the treatment of duodenal ulcers and gastric hypersecretion. Since antacids are recommended commonly for concurrent therapy with cimetidine, it was of interest to determine if any *in vitro* interaction was evident. To evaluate the efficiency of the adsorption, activated charcoal was employed as a standard.

EXPERIMENTAL

Reagents—Activated charcoal[1], kaolin[1], talc[2], aluminum hydroxide[1], magnesium hydroxide[1], and magnesium trisilicate[3] were reagent grade. Cimetidine[4] was compendial grade and was used without further purification. Methanol was certified ACS spectroanalyzed grade[1].

Procedure—All potential adsorbents (aluminum hydroxide, charcoal, kaolin, magnesium hydroxide, magnesium trisilicate, and talc) employed were washed repeatedly with distilled water followed by spectroanalytical grade methanol until the wash solution exhibited no absorbance at 226 nm (the wavelength of maximum cimetidine absorption). The adsorbents were passed through a 20-mesh sieve[1] while still moist and permitted to dry in an oven at approximately 45°. The dried materials then were passed through a 100-mesh sieve to ensure that the particle sizes of all of the adsorbents were 100 mesh or smaller. One gram of adsorbent was used in all cases, except for charcoal where only 50 mg was utilized.

Adsorbate mixtures were prepared by diluting aqueous cimetidine solutions (~12 mg/liter) with appropriate amounts of distilled water. The final pH of the solutions was 5.0[1]. The solutions then were agitated vigorously[5] for 10 min at 25° and allowed to stand for 20 min. Twenty-five-milliliter aliquots of the supernate were drawn from each solution, centrifuged[6] for 20 min, and assayed spectrophotometrically[7] at 226 nm. The reference solutions were prepared in an identical manner as the sample, with the cimetidine solution replaced by distilled water.

RESULTS AND DISCUSSION

The results of the *in vitro* adsorption of cimetidine onto various substances are given in Tables I–III and Figs. 1 and 2. The data are presented as both Freundlich constants (Eq. 1) and Langmuir constants (Eq. 2) as well as in terms of the adsorption rate:

$$\frac{x}{m} = kC^n \qquad \text{(Eq. 1)}$$

$$\frac{x}{m} = \frac{\alpha C}{1 + \beta C} \qquad \text{(Eq. 2)}$$

Table I—Freundlich Constants for Adsorption of Cimetidine onto Various Adsorbents

Adsorbent	$k \times 10^4$, g (adsorbed)/g (adsorbent)	n
Kaolin	4.02	0.621
Magnesium trisilicate	3.43	0.943
Talc	2.91	0.384
Charcoal	256	0.347

Table II—Langmuir Constants for Adsorption of Cimetidine onto Various Adsorbents

Adsorbent	$\alpha \times 10^{-1}$, g (adsorbed)/mg (adsorbent)	$\beta \times 10^{-4}\ M^{-1}$
Kaolin	5.68	3.72
Talc	4.63	6.57
Magnesium trisilicate	3.83	0.475
Charcoal	877	21.6

where x/m is the grams of drug adsorbed per gram of adsorbent, C is the equilibrium concentration of the unbound drug, and k, n, α, and β are constants.

The data indicate that activated charcoal is about two orders of magnitude more efficient in the adsorption of cimetidine than are kaolin, talc, and magnesium trisilicate. Magnesium hydroxide and aluminum hydroxide did not adsorb cimetidine to any significant extent. This lack of adsorption is reflected in the adsorption rate as well as in the Freundlich constant k and the Langmuir constants α and β. These latter constants

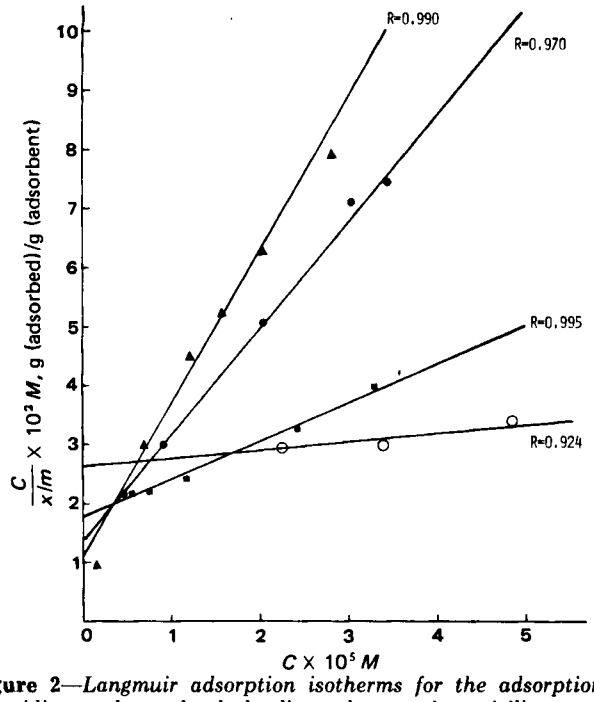

Figure 2—*Langmuir adsorption isotherms for the adsorption of cimetidine on charcoal, talc, kaolin, and magnesium trisilicate at 25°. Key: ▲, charcoal (values × 10⁴); ●, talc; ■, kaolin; and ○, magnesium trisilicate.*

Table III—Adsorption Rate of Cimetidine [a] with Different Adsorbents

Adsorbent	$(x/m)^b \times 10^4$, g (adsorbed)/ g (adsorbent)	Adsorption Rate $\times 10^3$, g (adsorbed)/ g(adsorbent) hr
Charcoal	118	35.4
Kaolin	4.69	1.41
Magnesium trisilicate	4.23	1.27
Talc	3.33	1.00
Magnesium hydroxide	0.00	0.00
Aluminum hydroxide	0.00	0.00

[a] The initial concentration was $3.20 \times 10^{-5}\ M$. [b] At equilibrium.

are directly related to the adsorption rate and inversely to the desorption rate. Therefore, the larger their values, the more efficient is the adsorbent. The Freundlich constant k represents the drug amount adsorbed per unit weight of adsorbent at a unit drug concentration (Eq. 1).

The Freundlich constant n is always less than unity (9) and represents the drug amount adsorbed for a given concentration change. Larger n values reflect a greater fraction of adsorbed drug to unbound drug. This value, in turn, reflects the ratio of the rate of adsorption to desorption and the relative strength of the bond between the drug and the binding site. The n value is largest for magnesium trisilicate, which appears to indicate that while the number of sites available on this adsorbent are somewhat less than for charcoal, as reflected in a lower per gram adsorption, the interaction of the magnesium trisilicate with cimetidine is stronger. This interaction could be the result of an electrostatic interaction between anionic silicate and the positive charge on the cimetidine molecules. The pKa of cimetidine (10) is 6.8; at pH 5.0, the drug exists almost entirely in the cationic form. Khalil (11) showed that adsorption of materials on magnesium trisilicate diminishes its uptake of hydrochloric acid, which could be significant in the use of antacids utilizing magnesium trisilicate concomitantly with cimetidine.

The results of aluminum hydroxide and magnesium hydroxide, although negative, are interesting. Bodemar *et al.* (12) showed that blood cimetidine levels are reduced in the presence of both compounds. The present work indicates that the source of this reduction is not due to the cimetidine adsorption.

The *in vitro* results with kaolin and talc indicate possible interference with cimetidine therapy by these substances. However, the clinical significance of this interaction has not been demonstrated.

Serum Protein Binding Alterations of Selected Cephalosporin Antibiotics by Fatty Acids and Their Derivatives

D. H. PITKIN ˣ, P. ACTOR, and J. A. WEISBACH

Received June 11, 1979, from *Smith Kline Corp., Philadelphia, PA 19101.* Accepted for publication October 15, 1979.

Abstract □ Saturated fatty acids containing 10–14 carbon atoms were more potent inhibitors of serum protein binding than those containing shorter or longer carbon chains. Introduction of unsaturation into chains containing 16 or 18 carbons increased their inhibitory potency. Triglycerides and fatty acid esters, chlorides, thiols, and amides had no inhibitory activity. When inhibition was observed, it was concentration dependent and occurred when the molar ratio of fatty acid to protein equaled or exceeded three. The change in percent serum protein binding in the presence of an effective inhibitor was the greatest with cephalosporins that were most highly bound in the absence of an inhibitor.

Keyphrases □ Antibiotics—cephalosporins, serum protein binding, alteration by fatty acids and their derivatives □ Cephalosporins—serum protein binding, alteration by fatty acids and their derivatives □ Protein binding—cephalosporin antibiotics, alteration by fatty acids and their derivatives, serum

Serum protein binding can be diminished in several disease states, after administration of certain hormones, anticoagulants, and sulfa drugs, or by alteration of the levels of normally occurring metabolites such as bilirubin or fatty acids (1–6). Even small changes in serum protein binding can produce clinically significant physiological effects, particularly with drugs that are highly bound. These changes may affect not only the amount of free drug in the plasma but also its tissue concentration, tissue distribution, and elimination pharmacokinetics (1, 5, 7–9).

Kunin (4) showed that the content of free penicillin analogs in humans may be increased by coadministration of sulfamethoxypyridazine or sulfaethidole (sulfaethylthiadiazole), two *in vitro* inhibitors of serum protein binding. Spector (8) stressed the need to determine if the ability of albumin to transport a second compound can be influenced by free fatty acid concentrations in plasma. In this paper, data are presented on the relationship between the structure and serum protein binding inhibition of seven saturated and four unsaturated fatty acids in addition to the effects of chemical substituents on the carboxy terminus.

EXPERIMENTAL

Cephalothin and cefazolin were obtained from commercial sources. Cefonicid sodium [(6*R*,7*R*)-7-[(*R*)-mandelamido]-8-oxo-3-[[[1-(sulfomethyl)-1*H*-tetrazol-5-yl]thio]methyl]-5-thia -1- azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid disodium salt], a new, long-acting parenteral cephalosporin (10), was synthesized[1]. Fatty acids were obtained commercially at a stated purity of >98%, while analogs were obtained at a stated purity of >95%. Fatty acids and their analogs were dissolved at high concentrations in ethanol or ethanol–chloroform, depending on solubility.

Human serum was obtained from a local commercial supplier of blood products. Serum pH was adjusted to 7.2–7.4 with carbon dioxide before use. Small volumes of fatty acid or other stock solutions or the diluent used in their preparation were added in varying concentrations to the serum, which was then held at 4° for 16–18 hr before use. This storage permitted the additive to interact with the serum proteins (9, 11). The additives to the serum were present at molar ratios of fatty acid to serum protein of 0:1, 1:1, 3:1, 5:1, 7.5:1, or 10:1, whereas the fatty acid analogs were tested at ratios of 0:1, 3:1, and 10:1 (5, 12, 13).

Samples were assayed using a disk agar diffusion test employing *Bacillus subtilis* (ATCC 6633) grown in penicillin assay seed agar as the indicator. Corrections were made for intergroup variation in the indicator response by assaying an internal standard. Serum protein binding determinations were made using the standard response line offset technique. In this technique, the response of the indicator to five concentrations of the selected antibiotic in 1% pH 7.4 phosphate buffer was compared to the response produced when the antibiotic was diluted in serum. The concentration of antibiotic in serum, S, producing a specified response was compared to the concentration of antibiotic in buffer, B, producing the identical response. The value $(1 - B)/S \times 100$ was computed and reported as the percent serum protein binding (11, 14).

RESULTS

The three antibiotics used, cephalothin, cefazolin, and cefonicid, were chosen in control experiments on the basis of their serum protein binding as being representatives of moderately, highly, and very highly bound cephalosporins.

The effects of adding C_6–C_{18}-saturated fatty acids at various fatty acid to protein molar ratios on the serum protein binding of the three cephalosporins are shown in Figs. 1–3. The data show the difference in percent serum protein binding with and without an inhibitor in the serum as a function of inhibitor chain length. The amount of inhibition was dependent on fatty acid concentrations and occurred at ratios of 3:1 or greater. The various fatty acids differed in their ability to inhibit serum protein binding. With cephalothin, maximal inhibition occurred at C_{10} (Fig. 1); it occurred at C_{10}–C_{12} (Fig. 2) for cefazolin and at C_{12} for cefonicid (Fig. 3).

Results obtained using the standard curve offset technique were confirmed using ultrafiltration techniques and radiolabeled cefonicid with intermediate or high concentrations of a C_{10}-fatty acid as a serum additive. These results indicate that data obtained using the standard curve offset technique are not attributable to artifacts introduced by the assay system. Fatty acids exerted their greatest effect on cephalosporins that were most highly bound in the absence of an inhibitor. The carbon chain length requirements for inhibition of cefazolin appear to be slightly less

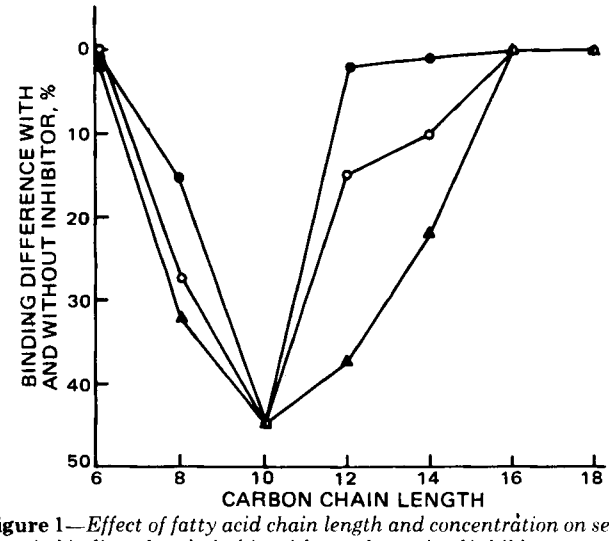

Figure 1—*Effect of fatty acid chain length and concentration on serum protein binding of cephalothin with a molar ratio of inhibitor to protein of 3:1 (●), 5:1 (○), and 10:1 (△).*

stringent than those for inhibition of cephalothin or cefonicid. In all cases, adding a potential inhibitor at inhibitor to serum protein ratios of 1:1 failed to affect the serum protein binding significantly.

The effect of structural modification of saturated fatty acids on their ability to act as serum protein binding inhibitors was examined. Fatty acids having carbon chain lengths of 16 (poorly effective) or 18 (ineffective) were used as examples. Introduction of monounsaturation or multiple unsaturation into these compounds profoundly changed their potency as serum protein binding inhibitors (Table I).

The next structural modification examined was substitution at the carboxy terminus. Fatty acids with a 12 carbon chain (lauric acid) and a monounsaturated 18 carbon chain (oleic acid) were studied. The results of substituting the carboxy group with sodium, alcohol, amide, chloride, methyl ester, or thiol groups or of using the triglyceride on the serum protein binding of the three cephalosporins are shown in Table II. These tests were carried out with a 10:1 inhibitor to protein ratio. Only the acid and its sodium salt were effective serum protein inhibitors.

DISCUSSION

These results show that saturated fatty acids having 10–14 carbon atom chains markedly inhibited serum protein binding of all tested cephalosporins whereas fatty acids with shorter or longer carbon chains were less effective. Introduction of unsaturation or substitution at the carboxy terminus also altered their potency. This effect suggests that the interaction is structure dependent and possibly is due to the degree of lipophilicity of the inhibitor. This idea is supported by the findings that introduction of unsaturation into 16–18 carbon atom chains markedly increase their inhibitory ability while substitution at the carboxy terminus with any of several negatively charged groups or esterification in the presence or absence of glycerol eliminated the serum protein binding inhibitory effect.

These findings are in agreement with earlier work (8) which indicated that the bond between fatty acids and human serum albumin was due

predominantly to lipophilic rather than electrostatic or hydrogen bond interactions. Fatty acid esters or triglycerides were not inhibitory (8). The findings of Vallner (12) and Rudman *et al.* (5) were verified in that maximal inhibitory effects were observed when the fatty acid to protein ratio was three or greater. Previous findings that highly bound drugs show a more pronounced response than drugs with lower binding also were confirmed (1).

In related studies, probenecid and novobiocin, both organic acids that are highly serum protein bound, also were effective *in vitro* inhibitors of serum protein binding using the three cephalosporins. These findings suggest that variation in the fatty acid content of human serum or coadministration of other highly serum protein bound compounds have the potential to affect dramatically the serum protein binding of commonly used antibiotics.

Changes in serum protein binding can be important clinically with regard to potential toxicity of highly bound drugs having a narrow therapeutic ratio. In addition, alterations in serum protein binding may affect

Absorption of Sodium γ-Hydroxybutyrate and Its Prodrug γ-Butyrolactone: Relationship between *In Vitro* Transport and *In Vivo* Absorption

C. ARENA and HO-LEUNG FUNG ˣ

Received August 20, 1979, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication October 11, 1979.

Abstract □ A qualitative relationship between *in vitro* transport and *in vivo* absorption of sodium γ-hydroxybutyrate and γ-butyrolactone was demonstrated. As with other short-chain acids, sodium γ-hydroxybutyrate showed capacity-limited transport *in vitro*, consistent with the previous observation that this drug exhibited slower *in vivo* absorption with increasing dose. The prodrug lactone, on the other hand, showed a higher intestinal flux than the acid in the everted gut, and *in vivo* absorption also was more rapid. Capacity-limited transport and absorption of the lactone appeared less evident. Thus, the increased oral hypnotic activity of the lactone over that of the acid most likely is a result of its more favorable intestinal transport characteristics.

Keyphrases □ Sodium γ-hydroxybutyrate—relationship between *in vitro* transport and *in vivo* absorption □ γ-Butyrolactone—prodrug for sodium γ-hydroxybutyrate, relationship between *in vitro* transport and *in vivo* absorption □ Hypnotic agents—sodium γ-hydroxybutyrate and γ-butyrolactone, relationship between *in vitro* transport and *in vivo* absorption

γ-Hydroxybutyrate (I), a metabolite of γ-aminobutyric acid, is found endogenously in the human brain (1). When introduced intravenously, I is a useful anesthetic (2) and is beneficial in Parkinson's disease (3). However, oral administration of this compound results in decreased and variable pharmacological activity (4–6). Recently, oral doses of I totaling 50 mg/kg were shown to be useful in the treatment of narcolepsy and cataplexy in patients, but the duration of sleep induction after each oral dose lasted only for ~2 hr (7).

BACKGROUND

In previous animal studies in these laboratories (8–10), orally administered I was shown to be subject to first-pass metabolism at low doses (≤200 mg/kg) in rats. At higher doses (400–1600 mg/kg), systemic availability approached 100%, presumably due to saturation of first-pass metabolism, but the relative absorption rate appeared to decrease with increasing dose. Thus, although the extent of drug absorption was almost complete, peak plasma I concentrations were relatively insensitive to increases in the oral dose and, in most animals, threshold hypnotic concentrations in plasma were not reached in spite of high oral doses.

The lactone analog of I, γ-butyrolactone (II), is hydrolyzed rapidly and exclusively *in vivo* to I (11, 12) and, therefore, can be classified as a prodrug. Compound II is rapidly and completely absorbed *in vivo* after oral administration over a wide dose range. In contrast to I, the peak drug concentration after oral dosing of II was proportional to the dose, and II was equally effective as a hypnotic whether given orally or intravenously (9).

The reason for the apparent difference in *in vivo* absorption characteristics between I and II has not been delineated. In this paper, *in vitro* experiments that compared the transport properties of these two compounds across the everted rat gut are described.

EXPERIMENTAL

Reagents—Compound I, obtained as the sodium salt[1], and II[1] were used without purification. The buffer and assay reagents[1–3] were all reagent or analytical grade.

Everted Rat Gut Preparation—Male Sprague–Dawley rats, 260–310 g, were sacrificed by decapitation. An intestinal segment, ~12 cm long, was taken from a region 20 cm from the pylorus sphincter; it was everted and mounted according to the technique originally devised by Wilson and Wiseman (13) and modified by Crane and Wilson (14).

Flux Experiment—The everted gut was placed inside a test tube with the mucosal side exposed to 90 ml of a 0.05 *M* physiological tromethamine buffer (pH 7.4) containing the appropriate drug concentration. All flux studies were carried out at 37°. At 5-min intervals up to 25 min, the serosal solution (~1 ml) was removed for the assay and replaced with an equal volume of fresh buffer. Three or four replicate flux experiments were conducted at each initial mucosal concentration.

Spectrophotometric Analysis—The Hestrin (15) assay for short-chain *O*-acyl derivatives as adopted for I and II by Guidotti and Ballotti (16) was employed. Conversion of I to II was effected by reaction with two parts of concentrated sulfuric acid[2] and subsequent neutralization with 10 parts of 6 *N* NaOH[2].

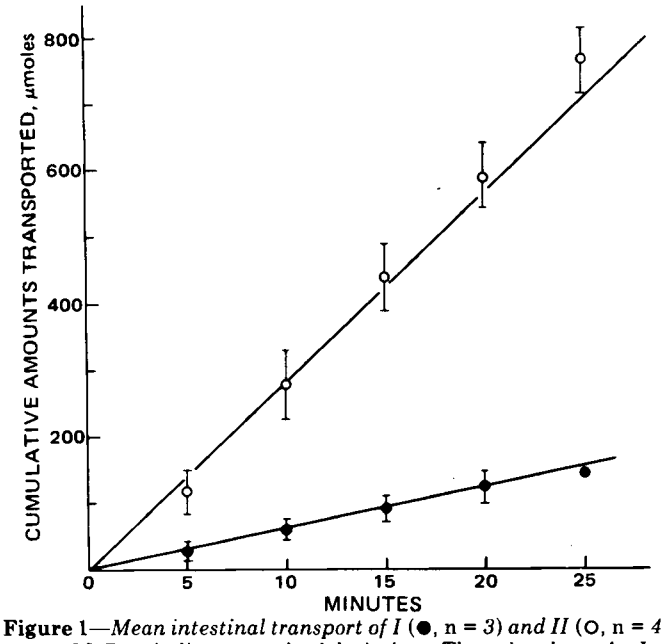

Figure 1—*Mean intestinal transport of I (●, n = 3) and II (○, n = 4) at 0.40* M. *Bars indicate standard deviations. The point shown for I at 25 min represents the mean value of two measurements.*

RESULTS AND DISCUSSION

Transport of I and II through the everted rat gut was examined at various initial mucosal drug concentrations. Intestinal flux was determined for each animal preparation by linear regression of a plot of cumulative amount transported to the serosal side *versus* time. Representative plots showing intestinal transport of I and II at 0.40 *M* are given in Fig. 1. At low mucosal concentrations, linearity of flux was maintained throughout the experiment. However, at high I concentrations, positive deviations (increased flux) occurred at the later time points, suggesting possible tissue damage with prolonged drug exposure. In these instances, initial rates of transport restricted to the linear portion of the curve (usually 0–20 min) were used to calculate flux. In all experiments, the total amounts transported to the serosal side were small (<0.4% for I and <2.5% for II) compared to the total drug available from the mucosal pool. Thus, the initial mucosal concentration remained essentially unchanged throughout each experiment.

Figure 2 shows the relationships between intestinal flux of I and II and their respective mucosal concentrations. Over the concentration range studied, intestinal transport of II was considerably more rapid than that of I. At equimolar mucosal concentrations, the differences in flux between I and II were statistically significant at $p < 0.001$ using the Student t test. Compound II fluxes were ~5, 7, and 10 times higher than I fluxes at 0.40, 0.79, and 1.19 *M*, respectively. In addition, I transport leveled off at concentrations above 0.40 *M*. If nonspecific effects on intestinal permeability could be ruled out, this flux behavior suggested the presence of a capacity-limited transport system for I in the rat intestine. In comparison, concentration-dependent transport of II was less evident.

In these experiments, the ionic strength in the mucosal solution was not constant over the concentration range studied. Although the mucosal solution was prepared with buffer, high I concentrations also could affect the pH slightly because I, as its sodium salt, is mildly basic. The leveling in I flux could, in principle, have been partially contributed to by nonspecific ionic strength and/or pH effects created by increasing mucosal concentrations of the ionic drug. The possibility of this artifact was ruled out by the following experiment.

Flux studies were carried out at 0.08 *M* I under two sets of conditions. In one case, no pH or salt adjustments were made (Condition A: pH 7.4, $\mu = 0.23$ *M*); in the other case, sodium chloride and sodium hydroxide were added so that the pH and ionic conditions were equivalent to those present when flux was studied at 1.19 *M* I (Condition B: pH 8.1, $\mu = 1.34$ *M*). If ionic strength and pH affected flux significantly, then the observed fluxes under Conditions A and B would be different, with the flux of B similar to that observed at 1.19 *M* I. In fact, the flux of I was identical whether or not additional salt or alkalinizing agents were added.

In duplicate determinations, the fluxes obtained under Condition A were 2.2 and 2.3 μ*M*/min; those under Condition B both were 2.4 μ*M*/min. Thus, minor differences in pH and ionic strength contributed by changes

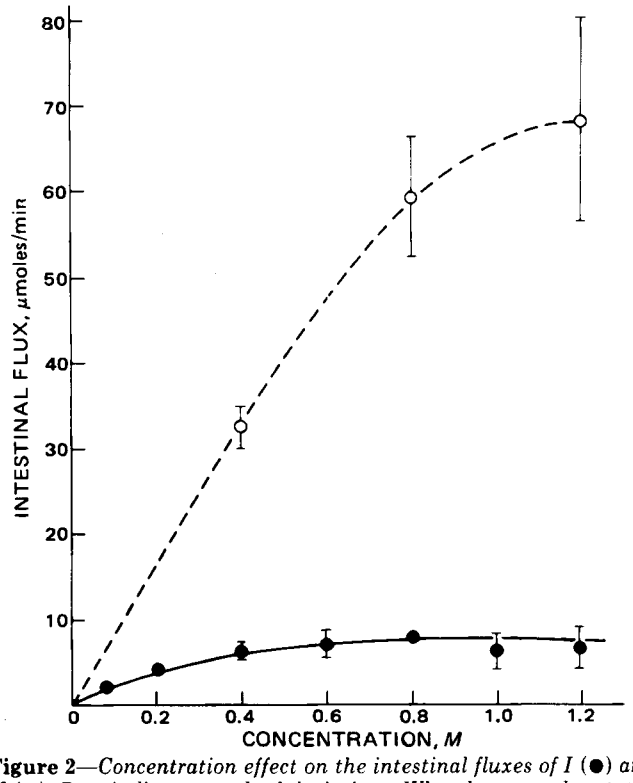

Figure 2—*Concentration effect on the intestinal fluxes of I (●) and II (○). Bars indicate standard deviations. When bars are absent, the standard deviations were too small to be shown.*

in the mucosal I concentration did not affect flux significantly. Since II is nonionic, ionic strength and pH effects produced by increasing II concentrations were presumed to be negligible. Bender *et al.* (17) found the second-order alkaline hydrolytic constant of II to be ~0.2 liter/mole-sec at 25°. At pH 7.4, the hydrolysis half-life would be about 1000 days. Thus, conversion of II to I in the buffered mucosal solution was insignificant during the experiment.

The *in vitro* transport characteristics of I and II are consistent with their *in vivo* absorption properties reported previously (8–10). Compound I, which showed capacity-limited transport *in vitro*, also exhibited relatively slower *in vivo* absorption rates with increasing oral dose (10). Other short-chain acids, such as acetic and butyric acids, also have been shown to be transported *via* an active system (18, 19). Therefore, a capacity-limited absorption mechanism might be a reason for the decreased and variable activity of I when given in high oral doses to humans (4–7). The prodrug lactone II, on the other hand, showed a much higher intestinal flux than I in the everted gut and was almost instantaneously absorbed when orally administered (9). Capacity-limited transport of II, if existent, appeared to occur at much higher drug concentrations.

The present study demonstrated a qualitative relationship between *in vitro* transport and *in vivo* absorption of the two compounds studied. Thus, the increased oral activity of the lactone over that of its open-chain hydroxy acid is most likely a result of its more favorable intestinal transport characteristics. The usefulness of II has not been investigated in humans.

Temporal Variations in Trough Serum Theophylline Concentrations at Steady State

L. J. LESKO *x, D. BROUSSEAU ‡, A. T. CANADA *, and G. EASTWOOD *

Received June 21, 1979, from the **Drug Concentration Laboratory, University of Massachusetts Medical Center, Worcester, MA 01605*, and ‡*Fisons Corporation, Bedford, MA 01730.* Accepted for publication October 11, 1979.

Abstract □ Temporal variations in serum theophylline concentrations were observed in 14 healthy volunteers receiving multiple doses of theophylline. After repeated oral doses (6.9–18.2 mg/kg/day) of theophylline as either a nonalcoholic aminophylline solution or a controlled-release capsule, trough theophylline levels at steady state were significantly higher ($p < 0.05$) in the morning than in the afternoon or evening. With the solution, the mean ($\pm SE$) trough serum level at 7 am was 11.1 ± 0.9 μg/ml, and at 1 pm it was 9.6 ± 0.8 μg/ml. With the capsule, the mean ($\pm SE$) trough serum level at 8 am was 13.8 ± 0.9 μg/ml, and at 8 pm it was 10.7 ± 0.9 μg/ml. Temporal variations in serum theophylline concentrations have not been reported previously and may be important in therapeutic monitoring.

Keyphrases □ Theophylline—trough serum concentrations at steady state, temporal variations □ Bronchodilators—theophylline, trough serum concentrations at steady state, temporal variations □ Pharmacokinetics—theophylline, trough serum concentrations at steady state, temporal variations

Temporal variation in the absorption and disposition of drugs is an area of pharmacokinetics about which relatively little is known. In the few studies performed, the findings have not been consistent. For example, Shirley and Vesell (1) reported that temporal variations in the disposition of acetaminophen and phenacetin occur. However, Vesell *et al.* (2) observed no temporal variations in the pharmacokinetics of antipyrine (2), and Nakano and Hollister (3) reported no time-related changes in the disposition of nortriptyline. The causes of temporal variations in drug pharmacokinetics may be varied. Circadian rhythm apparently influences the distribution of potassium between body compartments (4), while changes in body posture alter the absorption of cephradine (5) and erythromycin (6) from the GI tract.

One mechanism suggested to account for the temporal variations in the disposition of phenacetin and acetaminophen was the occurrence of diurnal changes in the amount and activity of hepatic microsomal oxidases (1). Theophylline is a drug whose disposition also is determined by microsomal oxidases, so it seemed possible that temporal variations in theophylline disposition may occur. Since this aspect of theophylline kinetics had not been reported previously, one objective of this study was to determine if temporal variations exist.

EXPERIMENTAL

Subjects—The seven male and seven female volunteers were 21–40 years old, and their average weight was 67.5 kg. All volunteers were nonsmokers and were in good physical health with no history of alcoholism or cardiovascular disease.

Drug Administration and Blood Sampling—The volunteers randomly received either a nonalcoholic aminophylline solution or a controlled-release theophylline capsule. The oral theophylline dose was individualized for each volunteer, based on single-dose kinetics, to produce peak serum theophylline concentrations no larger than 18 μg/ml after repeated dosing. The daily doses ranged from 6.9 to 18.2 mg/kg. The solution was administered at 7 am, 1 pm, 7 pm, and 1 am, and the capsule was given at 8 am and 8 pm. Dosing was continued for 6 days prior to each study day. The study days were separated by 1 week during which the volunteers took the alternate formulation.

On each study day, 1 ml of serum was obtained immediately before the morning dose of each dosage form and 6 or 12 hr after administration of the solution or capsule, respectively.

Theophylline Assay—Serum theophylline determinations were made by high-pressure liquid chromatography using a method described previously (7).

Data Analysis—A paired t test was used to analyze within-subject differences between the am and pm trough theophylline concentrations observed for each dosage form.

RESULTS AND DISCUSSION

The am and pm trough serum theophylline concentrations determined for each dosage form are listed in Table I. The percentage changes in trough level are noted for each volunteer. The mean ($\pm SE$) serum theophylline concentration at 7 am for the solution was 11.1 ± 0.9 μg/ml, while at 1 pm the serum theophylline concentration was 9.6 ± 0.8 μg/ml, representing a change of 13%. For the capsule, the mean ($\pm SE$) serum theophylline concentration at 8 am was 13.8 ± 0.9 μg/ml, and at 8 pm it was 10.7 ± 0.9 μg/ml, reflecting a decrease of 24%. The differences between the am and pm serum theophylline concentrations were significant ($p < 0.05$) for each dosage form.

Based on these results, there appear to be temporal variations in theophylline pharmacokinetics. Higher trough levels at 7 or 8 am compared to those at 1 or 8 pm may be related to a shorter plasma half-life at the latter times. Indeed, Shirley and Vesell (1) reported that plasma half-lives of phenacetin and acetaminophen were ~15% shorter at 2 pm than at 6 am. Another possible cause of higher am trough levels may be

Temporal Variations in Trough Serum Theophylline Concentrations at Steady State

L. J. LESKO *x, D. BROUSSEAU ‡, A. T. CANADA *, and G. EASTWOOD *

Received June 21, 1979, from the **Drug Concentration Laboratory, University of Massachusetts Medical Center, Worcester, MA 01605*, and ‡*Fisons Corporation, Bedford, MA 01730.* Accepted for publication October 11, 1979.

Abstract □ Temporal variations in serum theophylline concentrations were observed in 14 healthy volunteers receiving multiple doses of theophylline. After repeated oral doses (6.9–18.2 mg/kg/day) of theophylline as either a nonalcoholic aminophylline solution or a controlled-release capsule, trough theophylline levels at steady state were significantly higher ($p < 0.05$) in the morning than in the afternoon or evening. With the solution, the mean ($\pm SE$) trough serum level at 7 am was 11.1 ± 0.9 μg/ml, and at 1 pm it was 9.6 ± 0.8 μg/ml. With the capsule, the mean ($\pm SE$) trough serum level at 8 am was 13.8 ± 0.9 μg/ml, and at 8 pm it was 10.7 ± 0.9 μg/ml. Temporal variations in serum theophylline concentrations have not been reported previously and may be important in therapeutic monitoring.

Keyphrases □ Theophylline—trough serum concentrations at steady state, temporal variations □ Bronchodilators—theophylline, trough serum concentrations at steady state, temporal variations □ Pharmacokinetics—theophylline, trough serum concentrations at steady state, temporal variations

Temporal variation in the absorption and disposition of drugs is an area of pharmacokinetics about which relatively little is known. In the few studies performed, the findings have not been consistent. For example, Shirley and Vesell (1) reported that temporal variations in the disposition of acetaminophen and phenacetin occur. However, Vesell *et al.* (2) observed no temporal variations in the pharmacokinetics of antipyrine (2), and Nakano and Hollister (3) reported no time-related changes in the disposition of nortriptyline. The causes of temporal variations in drug pharmacokinetics may be varied. Circadian rhythm apparently influences the distribution of potassium between body compartments (4), while changes in body posture alter the absorption of cephradine (5) and erythromycin (6) from the GI tract.

One mechanism suggested to account for the temporal variations in the disposition of phenacetin and acetaminophen was the occurrence of diurnal changes in the amount and activity of hepatic microsomal oxidases (1). Theophylline is a drug whose disposition also is determined by microsomal oxidases, so it seemed possible that temporal variations in theophylline disposition may occur. Since this aspect of theophylline kinetics had not been reported previously, one objective of this study was to determine if temporal variations exist.

EXPERIMENTAL

Subjects—The seven male and seven female volunteers were 21–40 years old, and their average weight was 67.5 kg. All volunteers were nonsmokers and were in good physical health with no history of alcoholism or cardiovascular disease.

Drug Administration and Blood Sampling—The volunteers randomly received either a nonalcoholic aminophylline solution or a controlled-release theophylline capsule. The oral theophylline dose was individualized for each volunteer, based on single-dose kinetics, to produce peak serum theophylline concentrations no larger than 18 μg/ml after repeated dosing. The daily doses ranged from 6.9 to 18.2 mg/kg. The solution was administered at 7 am, 1 pm, 7 pm, and 1 am, and the capsule was given at 8 am and 8 pm. Dosing was continued for 6 days prior to each study day. The study days were separated by 1 week during which the volunteers took the alternate formulation.

On each study day, 1 ml of serum was obtained immediately before the morning dose of each dosage form and 6 or 12 hr after administration of the solution or capsule, respectively.

Theophylline Assay—Serum theophylline determinations were made by high-pressure liquid chromatography using a method described previously (7).

Data Analysis—A paired t test was used to analyze within-subject differences between the am and pm trough theophylline concentrations observed for each dosage form.

RESULTS AND DISCUSSION

The am and pm trough serum theophylline concentrations determined for each dosage form are listed in Table I. The percentage changes in trough level are noted for each volunteer. The mean ($\pm SE$) serum theophylline concentration at 7 am for the solution was 11.1 ± 0.9 μg/ml, while at 1 pm the serum theophylline concentration was 9.6 ± 0.8 μg/ml, representing a change of 13%. For the capsule, the mean ($\pm SE$) serum theophylline concentration at 8 am was 13.8 ± 0.9 μg/ml, and at 8 pm it was 10.7 ± 0.9 μg/ml, reflecting a decrease of 24%. The differences between the am and pm serum theophylline concentrations were significant ($p < 0.05$) for each dosage form.

Based on these results, there appear to be temporal variations in theophylline pharmacokinetics. Higher trough levels at 7 or 8 am compared to those at 1 or 8 pm may be related to a shorter plasma half-life at the latter times. Indeed, Shirley and Vesell (1) reported that plasma half-lives of phenacetin and acetaminophen were ~15% shorter at 2 pm than at 6 am. Another possible cause of higher am trough levels may be

[a] Percent decrease in trough level from the am to pm period.

slower absorption of the nighttime dose. Nakano and Hollister (3) reported that nortriptyline was absorbed slower after an evening oral dose than after a morning dose. In this study of theophylline, the volunteers were primarily in the supine position after the 1-am and 8-pm doses, which may have slowed absorption. The supine position has been shown to account for slowed absorption of cephradine (5) and erythromycin (6).

Since serum level determinations are widely used to monitor theophylline therapy, temporal variations in theophylline kinetics may be important in the clinical setting. The results emphasize the importance of timing in therapeutic drug monitoring. Serum theophylline concentrations vary with time during a dosage interval at steady state and, based on this study, from one dosage interval to the next. In monitoring theophylline therapy from 1 day to another, it is important to obtain a trough serum theophylline concentration at the same time on each day.

Chemical Constituents of *Curatella americana* (Dilleniaceae)

M. M. EL-AZIZI *, A. M. ATEYA *, G. H. SVOBODA ‡, P. L. SCHIFF, Jr. *, D. J. SLATKIN *, and J. E. KNAPP *x

Received July 16, 1979, from the **Department of Pharmacognosy, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15261*, and the ‡*Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46206.* Accepted for publication October 15, 1979.

Abstract □ A phytochemical investigation of an ethanolic extract of the leaves of *Curatella americana* Linn. (Dilleniaceae) resulted in the isolation and identification of the flavonol glycoside avicularin and gallic acid.

Keyphrases □ *Curatella americana*—chemical constituents, isolation and identification □ Medicinal plants—*Curatella americana*, chemical constituents, isolation and identification □ Avicularin—isolation from *Curatella americana*, identification □ Gallic acid—isolation from *Curatella americana*, identification

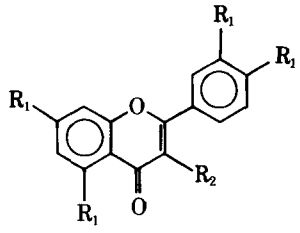
Curatella americana Linn. (Dilleniaceae) (1) is a shrub indigenous to Australasia and the tropical Americas (2). The plant has been used in Mexico medicinally for unidentified conditions (3). This use, along with reports of the medicinal and/or toxic potential among other members of the Dilleniaceae (3), and the scarcity of in-depth phytochemical studies on the plant prompted this study.

DISCUSSION

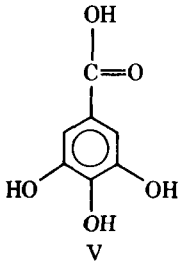
The plant material was extracted by percolation with ethanol to exhaustion. The ethanolic extract was fractionated by successive solvent partitioning and precipitation to yield a fraction that was separated further by chromatography over a polyamide column. Elution of this column with methanol–water afforded avicularin (II) and gallic acid (V).

Compound II was identified by consideration of its physical properties as well as those of derivatives and hydrolysis products. Hydrolysis of II afforded quercetin (I) and L-arabinose. Methylation of II with diazomethane followed by acid hydrolysis afforded 5,7,3′,4′-*O*-methylquercetin (III) and L-arabinose. The identity of III was deduced largely from its mass spectrum, which readily differentiates it from the other tetra-*O*-methylquercetins (4). Peracetylation showed that II was a monoarabinoside.

The NMR spectrum of the peracetate (IV) clearly indicated the presence of phenolic and aliphatic acetate groups in a 4:3 ratio. The mass spectrum of IV showed a weak, but discernible, molecular ion at *m/e* 728, confirming the presence of a single arabinose residue.



I: $R_1 = R_2 = OH$
II: $R_1 = OH$, R_2 = L-arabinose
III: $R_1 = OCH_3$, $R_2 = OH$
IV: $R_1 = CH_3COO$, $R_2 = CH_3COO$—L-arabinose



V

The identity of gallic acid (V) was established by comparison of its physical properties with those of an authentic sample.

The presence of a quercetin glycoside in *C. americana* was not unexpected since quercetin (I) was detected chromatographically in *Curatella* species previously (5). Avicularin (II), although not widely distributed in nature, was reported previously in *Polygonum aviculare* var. *buxifolium* (Polygonaceae), *Psidium guaijava* (Myrtaceae), and *Vaccinium myrtillus* (Ericaceae) (6–8). Compound II possesses antibiotic properties (6), which may account for some of the reputed medicinal activity of *C. americana*.

EXPERIMENTAL[1]

Plant Material—The leaves of *C. Americana* (Dilleniaceae) were used[2].

Extraction—The air-dried ground plant material (1.56 kg) was extracted by percolation with ethanol (20 liters). The extract was evaporated *in vacuo* at 40° to yield a syrupy extract (508 g).

Fractionation—The extract was partitioned between chloroform (2 liters) and water (2 liters). The aqueous layer was partitioned further with ethyl acetate (2 liters), and the solvents were removed from each layer to afford Fractions A (chloroform) (175 g), B (water) (268 g), and C (ethyl acetate) (59 g). Fraction C was dissolved in 100 ml of methanol, and 200 ml of chloroform was added. The resulting suspension was filtered to remove the insoluble matter (8.0 g), and the filtrate was evaporated to a residue. This residue was dissolved in 100 ml of ethyl acetate, and 1 liter of petroleum ether was added to the solution. The resulting precipitate (Fraction D) (9.22 g) was recovered by filtration, and the filtrate was set aside.

Chromatography—The precipitated Fraction D was dissolved in methanol (100 ml) and was adsorbed onto 20 g of polyamide[3] by evaporation of the solvent. The dry powder was packed on top of a column (5 × 23 cm, 100 g) of polyamide packed in water. The column was rinsed with 6 liters of water, and elution was carried out first with methanol–water and then with methanol. One-liter fractions were collected.

Isolation of II—Elution of the column with methanol–water (1:1) afforded a fraction (2.86 g) from which II (307 mg) was obtained by crystallization from methanol. The compound had a melting point of 224° [lit. (6) mp 217° (dilute ethanol) and 222° (dehydrated)]; $[\alpha]_D^{30}$ −60° (c 0.2, water); UV (CH_3OH): λ_{max} 215 (log ϵ 4.36), 258 (4.31), 296 (sh) (3.88), and 357 (4.27) nm; IR (KBr): ν_{max} 3420–3200 (br), 1650, 1600, 1500, 1450, 1120, 1050, and 1015 cm^{-1}; NMR (dimethyl sulfoxide): δ 5.35 (1H, d, J = 5 Hz), 6.20 (1H, d, J = 2 Hz), 6.40 (1H, d, J = 2 Hz), 6.85 (1H, d, J = 8 Hz), 7.52 (1H, s), and 7.60 (1H, d, J = 8 Hz).

The mass spectrum did not show a molecular ion. However, characteristic of flavonol glycosides (4), the spectrum was that of the aglycone, showing peaks at *m/e* 302 (100%), 286 (10), 237 (7), 153 (6), 151 (3), 137 (9), and 109 (5). Since no physical data on II other than the melting point have been reported and since a reference sample was unavailable, comparison of physical constants was not possible.

[1] Melting points were taken on a Thomas-Hoover Uni-Melt capillary apparatus and are corrected. IR spectra were determined on a Perkin-Elmer model 257 spectrometer in potassium bromide pellets. UV spectra were obtained on a Perkin-Elmer model 202 spectrometer. Optical rotations were measured on a Perkin-Elmer 241 automatic polarimeter. Mass spectra were taken with an LKB-9000 mass spectrometer. NMR spectra were obtained on a Perkin-Elmer R-24 spectrometer in the solvents specified with tetramethylsilane as the internal standard. Chemical shifts are reported as δ units (parts per million). GLC analysis was performed on a Perkin-Elmer model 3920B instrument operated isothermally at 150°. The column (2 × 0.0004 m, glass) was packed with 3% OV-17 on 80–100-mesh Supelcoport. Nitrogen was the carrier gas at a flow rate of 30 ml/min.

[2] Collected in Brazil and identified by Dr. Basset McGuire of the New York Botanical Gardens. A voucher specimen is on deposit at Eli Lilly and Co., Indianapolis, IN 46206.

Hydrolysis of II—Compound II (80 mg) was dissolved in 20 ml of 6% aqueous HCl, and the solution was refluxed for 45 min. The solution was cooled and filtered to separate the precipitated I from the soluble sugar. The filtrate was extracted with chloroform (4 × 50 ml), the extract was dried (sodium sulfate) and evaporated to a residue, and the residue was added to the precipitated I to afford a total of 35 mg. The I obtained (mp 300°) was identical in all respects (UV, IR, NMR, and mass spectra, melting point, and mixed melting point) to an authentic sample[4].

The aqueous filtrate was evaporated to dryness to yield a residue (31 mg) of crude L-arabinose; $[\alpha]_D^{29}$ +34.1° (c 1.1, water). TLC of the material (silica gel G, *n*-butanol–acetic acid–ether–water 9:6:3:1) indicated that it was homogeneous. A comparison of the R_f value (0.42) and color reaction with anisaldehyde spray reagent (9) given by the material with known sugars indicated that it was arabinose. This conclusion was confirmed by converting the sugar to its trimethylsilyl derivative (10) and subjecting it, along with the trimethylsilyl derivatives of other known sugars, to GLC analysis. The trimethylsilyl derivative of the isolated sugar showed an identical retention time (7.5 min) to that of the trimethylsilyl derivative of L-arabinose when analyzed individually or as a mixture and was clearly different from the trimethylsilyl derivatives of other sugars.

5,7,3′,4′-*O*-Methylquercetin (III)—Compound II (50 mg) was treated for 48 hr with 30 ml of ethereal diazomethane solution prepared from 21.5 g of *N*-methyl-*N*-nitrosó-*p*-toluenesulfonamide[5]. The solution then was evaporated to give a residue (56 mg), the residue was suspended in 10 ml of 7% aqueous H_2SO_4, and the suspension was refluxed for 1 hr. The reaction mixture was cooled and extracted with ether (4 × 20 ml), and the ether extract was evaporated to yield 5,7,3′,4′-*O*-methylquercetin (III) (20 mg).

The compound had a melting point of 186–188° [lit. (8) mp 195–196°]; IR (KBr): ν_{max} 3290, 3000, 2925, 2820, 1635 (sh), 1615, 1570, 1515, 1490, 1090, and 1025 cm^{-1}; mass spectrum: *m/e* 358 (M^+) (85%), 312 (100), 181 (17), 197 (75), 165 (65), 150 (43), 149 (34), 142 (30), 137 (30), 135 (42), 122 (30), 119 (32), 107 (28), 92 (33), 79 (52), and 77 (48); NMR ($CDCl_3$): δ 3.90 (1H, s), 3.95 (9H, s), 6.26 (1H, d, J = 2 Hz), 6.43 (1H, d, J = 2 Hz), 6.90 (1H, d, J = 9 Hz), 7.70 (1H, d, J = 9 Hz), and 7.73 (1H, bs); UV: λ_{max} (methanol) 224 (log ε 4.54), 257 (4.43), 300 (6.65), and 3.61 (4.30) nm; λ_{max} (aluminum chloride–methanol) 227 (log ε 4.52), 265 (4.49), and 422 (4.40) nm; and λ_{max} (aluminum chloride–hydrochloric acid–methanol) 220 log ε 4.50), 262 (4.38), 360 (4.05), and 420 (4.03) nm. The UV spectrum was indicative of a 3-hydroxy flavonoid (11).

Avicularin Heptaacetate (IV)—Compound II (15 mg) was treated at room temperature with acetic anhydride and pyridine (5 ml each) for 16 hr. Water, 2 ml, was added to the reaction mixture, and the mixture was evaporated to a residue. This residue was dissolved in 1 ml of acetone, and 5 ml of hexane was added. The precipitated heptaacetate (IV) (16 mg) was recovered by filtration.

The compound had a melting point of 175° [lit. (4) mp 187°]; $[\alpha]_D^{28}$ −95.1° (c 1.20, chloroform) [lit. (4) $[\alpha]_D$ −136° (c 1.22, chloroform)]; IR (KBr): ν_{max} 2920, 1725, 1630, 1615, 1500, 1420, 1370, 1215, and 1070 cm^{-1}; mass spectrum: *m/e* 728 (M^+) (0.2%), 686 (1.0), 644 (0.3), 470 (2.0), 428 (30), 386 (53), 344 (67), 328 (10), 302 (100), 286 (30), 273 (17), 259 (77), 233 (27), 199 (13), 157 (43), 153 (10), 137 (27), 134 (7), and 109 (7). The NMR spectrum ($CDCl_3$) showed singlets at δ 2.10 (12H) and 2.30 (9H), attributable to aromatic and aliphatic acetate groups, respectively.

Isolation of Gallic Acid (V)—Elution of the polyamide column with methanol–water (3:1) afforded a fraction (332 mg) containing V. Treatment of this fraction with methanol–chloroform afforded crystals of V (12 mg) with a melting point of 230–235° whose physical properties (IR, UV, NMR, and mass spectra) were identical to those of an authentic sample[5].

Improved GLC Determination of Ethambutol

Keyphrases □ Ethambutol—GLC analysis in biological fluids □ GLC—analysis, ethambutol in biological fluids □ Tuberculostatic antibacterials—ethambutol, GLC analysis in biological fluids

To the Editor:

Several GLC procedures have been reported for the determination of ethambutol in biological fluids (1–4). Only the methods (3, 4) using electron-capture detection are sensitive enough to measure ethambutol concentrations in patient samples of plasma and dialysate. We modified the previously published method (3, 4) to provide a more sensitive and precise procedure that is particularly useful for the determination of low ethambutol levels in biological samples.

Appropriate plasma aliquots (10–100 μl) were mixed with 50 μl of the internal standard [(+)-2,2′-(ethylenediimino)di-1-propanol] solution (10 μg/ml) and deionized water to give a final volume of 0.5 ml. The mixtures were extracted with 5 ml of chloroform for 10 min under alkaline conditions. Portions of the chloroform extract were transferred to another tube and evaporated to dryness under nitrogen. Residues were dissolved in 0.5 ml of spectroquality ethyl acetate.

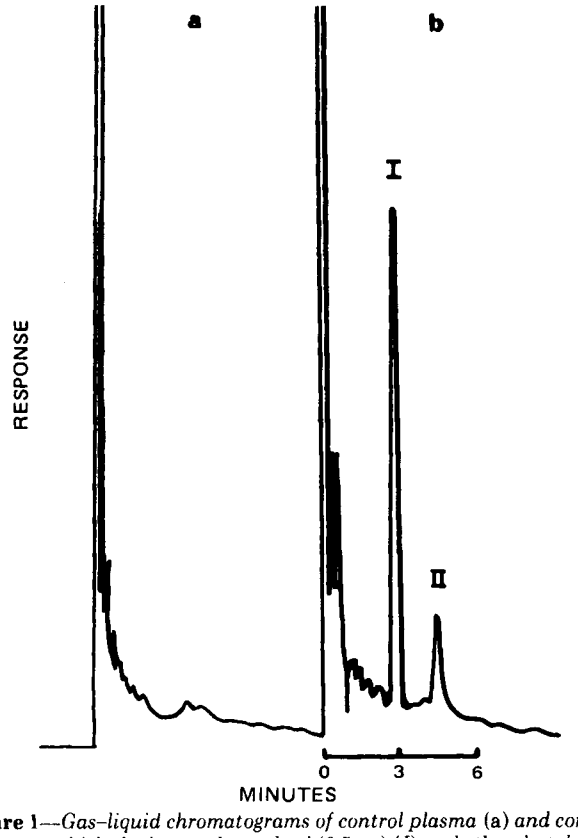

Figure 1—*Gas–liquid chromatograms of control plasma* (a) *and control plasma to which the internal standard (0.5 μg) (I) and ethambutol (0.01 μg) (II) were added* (b).

Table I—Recovery of Ethambutol from Plasma using Electron-Capture Detection (n = 5)

Ethambutol Added, ng	Ethambutol Found, ng	Recovery[a], %
10	9.37 ± 0.84	93.7 ± 8.4
20	18.79 ± 1.13	93.4 ± 5.7
30	30.15 ± 2.72	103.5 ± 9.1
50	51.19 ± 1.13	102.4 ± 2.3
70	68.49 ± 5.02	97.8 ± 7.2
100	98.70 ± 4.92	98.7 ± 4.9
10–100[b]	—	98.3 ± 4.2

[a] Expressed as mean ± *SD*. [b] n = 30.

Derivatization was initiated by adding 20 μl of trifluoroacetic anhydride and was complete in 1 hr at 50°. The contents of the tube were dried with a nitrogen stream to remove excess trifluoroacetic anhydride. Residues of the trifluoroacyl derivatives were reconstituted in 0.5 ml of anhydrous ethyl acetate, and 1–2 μl was injected into the gas–liquid chromatograph equipped with a ^{63}Ni-electron-capture detector. GLC conditions were the same as those described previously (3, 4).

Figure 1 presents gas–liquid chromatograms of control and blank plasma to which 0.01 μg of ethambutol and 0.5 μg of the internal standard were added. Retention times of 3 and 5 min were observed for the internal standard and the drug, respectively. No interfering peaks were found in the control plasma specimens (Fig. 1*a*). Table I summarizes the results obtained following electron-capture analysis of various amounts of ethambutol (10–100 ng) added to plasma. The mean recovery of ethambutol from control plasma in the 10–100-ng range was 98.3 ± 4.2% (n = 30).

The modified procedure offers the following advantages:

1. No catalyst is needed for derivatization. In the old procedure, pyridine is required.
2. The excess trifluoroacetic anhydride can be eliminated by direct evaporation. In the old procedure, the excess derivatizing agent was decomposed by the addition of 0.01 *M* HCl. The acid hydrolysis may adversely affect the yield of the trifluoroacyl derivative.
3. The detection sensitivity of the modified method, 10 ng/ml of plasma, is a significant improvement over that of the previous procedure, 100 ng/ml of plasma. Therefore, only a very small biological sample volume is required for ethambutol detection.

The minimum detectable quantity for ethambutol using this procedure is 10 ng. The optimal therapeutic plasma level in humans was reported as 3–5 μg/ml for ethambutol (5). In this concentration range, only 1–2 μl of plasma would be adequate for an accurate determination of the ethambutol content. This procedure would be helpful in pharmacokinetic studies where low ethambutol concentrations are encountered (6). It should be particularly useful for the microdetermination of ethambutol in bio-

Pharmacokinetic Studies of Propoxyphene IV: Effect of Renal Failure on Systemic Clearance in Rats

Keyphrases □ Propoxyphene—pharmacokinetics, effect of renal failure on systemic clearance, rats □ Pharmacokinetics—propoxyphene, effect of renal failure on systemic clearance, rats □ Analgesics—propoxyphene, pharmacokinetics, effect of renal failure on systemic clearance, rats

To the Editor:

There is considerable concern about the safety of the widely used analgesic agent propoxyphene (dextropropoxyphene) (1). Under certain circumstances, death from propoxyphene may occur following ingestion of quantities only slightly larger than the upper limit of the recommended therapeutic dosage (1).

Propoxyphene is subject to pronounced presystemic ("first-pass") biotransformation; only a small fraction of the absorbed dose enters the general circulation in unmetabolized form (2–4). This effect may be due to both hepatic and prehepatic biotransformation of the drug during absorption (5). Plasma concentrations of propoxyphene in patients without functioning kidneys are considerably higher than in normal subjects after oral administration of the drug (6). Indirect evidence suggests that this result is due to decreased presystemic biotransformation in the patients (6). However, since propoxyphene could not be administered by intravenous injection, a decreased systemic clearance or apparent volume of distribution of the drug in anephric patients could not be excluded definitively. For this reason, the systemic clearance and apparent volume of distribution of propoxyphene after intravenous injection have now been determined in normal rats and in rats with renal failure.

Male Sprague–Dawley rats, 260–350 g, received a single 5-mg/kg iv dose of either uranyl nitrate (7) or an equal volume of saline solution. Five days later, when serum urea nitrogen concentrations had increased to 150 ± 37 mg/100 ml (mean ± *SD*) in the uranyl nitrate-treated animals (as compared to 15 ± 8 mg/100 ml in normal rats), all animals received a single dose of tritium-labeled propoxyphene, 8.3 ± 1.9 μg/kg (mean ± *SD*), through an indwelling cannula in the jugular vein (8).

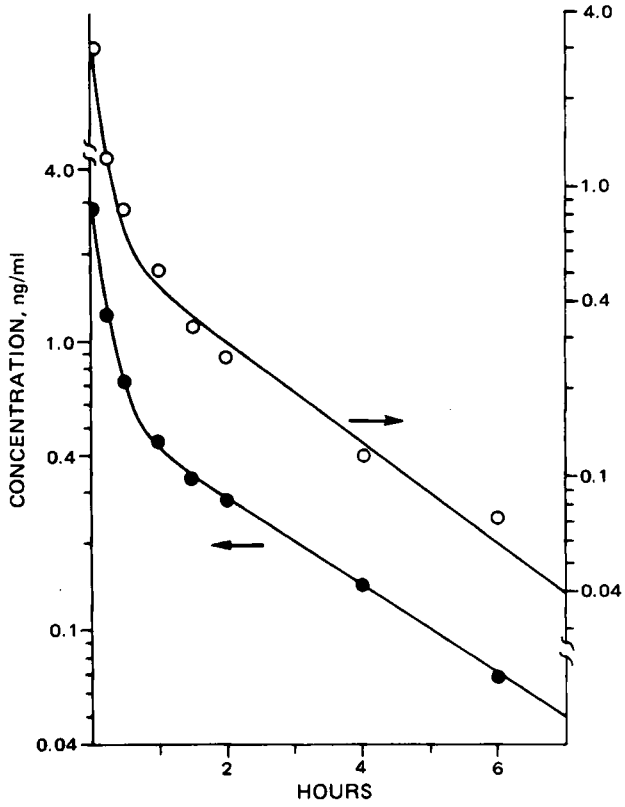

Figure 1—*Serum concentrations of propoxyphene as a function of time after intravenous injection of ^{3}H-propoxyphene at ~8 μg/kg. Key: ●, normal rat; and ○, rat with experimental renal failure. The curves were fitted to the data by nonlinear least-squares regression analysis. (The two vertical axes are displaced relative to one another.)*

Blood samples (0.25–1 ml) were obtained serially for 6–8 hr after injection. Serum was separated, adjusted to pH 9.8, and extracted with butyl chloride; the unmetabolized drug was isolated by TLC (9) and quantified by scintillation spectrometry. An aliquot of the injected solution was assayed similarly. The concentration–time curve was fitted to a biexponential equation by a digital computer (10), with the concentrations weighted as their reciprocals (Fig. 1). The systemic clearance was calculated from the injected dose and the area under the concentration–time curve. The apparent volume of distribution was calculated by dividing the systemic clearance by β.

Compared to surgical methods, injection of uranyl nitrate produces a more reproducible (as determined by serum creatinine and urea nitrogen concentrations) renal failure model. The animals appear to be in better health than after surgery. There was no evidence of hepatocellular damage after a single injection of uranyl nitrate in that glutamic–pyruvic transaminase concentrations in serum were normal[1]. Concomitant injection of tritium-labeled and unlabeled propoxyphene and assay of serum samples by scintillation spectrometry (after TLC) and by GLC

Table I—Effect of Renal Failure on Pharmacokinetics of Propoxyphene in Rats

Pharmacokinetic Constant	Normal Rats	Renal Failure Rats
Systemic clearance, ml/min/kg	61.4 ± 11.7[a] (47.8–75.1)	59.1 ± 13.2 (38.5–78.0)
Apparent volume of distribution, liters/kg	10.4 ± 3.2 (6.24–13.4)	8.3 ± 2.1 (6.22–11.9)

[a] Mean ± SD, $n = 6$; the range is given in parentheses.

yielded essentially identical results, showing that the tritium exchange was negligible.

The propoxyphene clearance and apparent volume of distribution values for normal rats and rats with experimental renal failure are listed in Table I. Clearance was high and comparable in magnitude to the hepatic plasma flow rate (11). The apparent volume of distribution was very large and comparable to that reported for humans (4). There were no significant differences in the kinetic constants between rats with normal and impaired renal function.

Rats, like humans, eliminate propoxyphene almost exclusively by biotransformation (12). Systemic clearance of propoxyphene in humans is somewhat higher than the hepatic plasma flow rate (4); the two values are similar in the rat. Therefore, the systemic clearance of propoxyphene is primarily a function of the hepatic blood flow rate and should be relatively insensitive to changes in the activity of hepatic drug metabolizing enzyme systems. Hepatic blood flow is not reduced, and the blood plasma flow rate may actually increase in renal failure (13). The results of this study are consistent with these considerations in that the systemic clearance of propoxyphene was not affected by experimental renal dysfunction. This finding and the apparent lack of effect of renal dysfunction on the volume of distribution of propoxyphene support the conclusion that higher plasma propoxyphene concentrations in anephric patients following oral administration are probably due to decreased presystemic biotransformation of the drug (6).

Reaction of *cis*-Platinum with Sodium Bisulfite

Keyphrases □ *cis*-Platinum—reaction with sodium bisulfite □ Sodium bisulfite—reaction with *cis*-platinum □ Antitumor agents, potential—*cis*-platinum(II) diaminedichloride, reaction of *cis*-platinum with sodium bisulfite

To the Editor:

cis-Platinum(II) diaminedichloride is a promising antitumor agent for the treatment of testicular cancer. Although the exact mechanism of its action is not fully understood, it is known that the agent reacts with DNA (1) and inhibits DNA synthesis (2). Recent studies showed that the antitumor agent reacts with DNA bases to form complexes of different composition (3).

In our study of the reaction of *cis*-platinum with pharmaceutical additives, we observed a rather unusual reaction between the antitumor agent and sodium bisulfite. When sodium bisulfite solutions (0.005–0.2 *M*) were mixed directly in the spectrophotometric cell with freshly prepared *cis*-platinum solution (10^{-4} *M*) in pH 4.2, 0.5 *M* acetate buffer, the absorbance at 280 nm increased. At this wavelength and concentration, *cis*-platinum has no absorbance; sodium bisulfite was present in both the sample and the blank.

The increase in the absorbance at 280 nm exhibited a lag time, followed by a rapid change, and finally leveled off (Fig. 1). However, the rate of change in absorbance varied

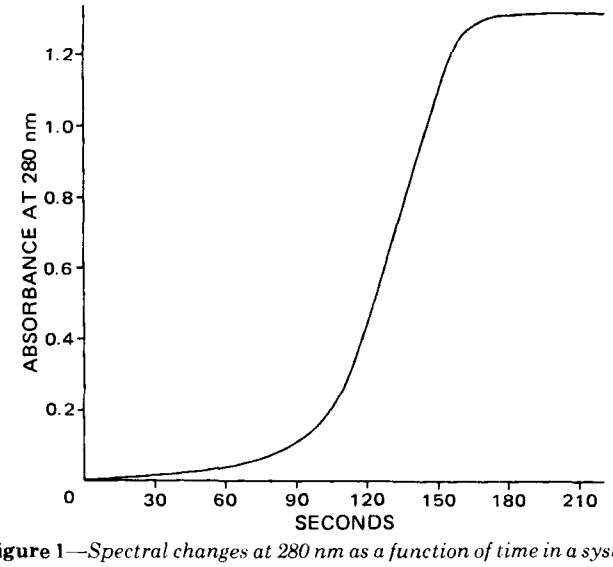

Figure 1—*Spectral changes at 280 nm as a function of time in a system containing 2 × 10^{-4} M cis-platinum and 0.01 M sodium bisulfite at pH 4.2 and 25°.*

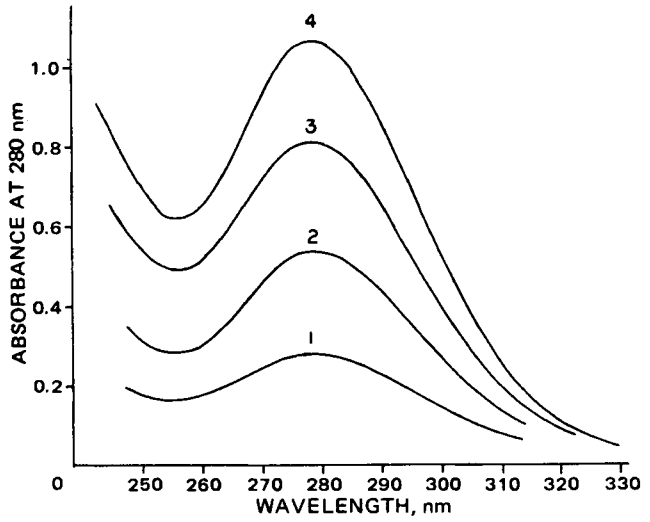

Figure 2—*UV spectra of solutions containing 1 × 10^{-2} M sodium bisulfite and varying amounts of* cis-*platinum. Key: 1, 4 μg/ml; 2, 8 μg/ml; 3, 12 μg/ml; and 4, 16 μg/ml.*

in nonlinear fashion as a function of the bisulfite concentration. Furthermore, in the presence of nitrogen or concentrations of ethanol or methanol as low as 1 × 10^{-3} *M*, no reaction was observed indicating autoxidation.

When 0.5 ml of 1 *M* sodium bisulfite (pH 4.2) was added to different concentrations of *cis*-platinum (0.1–0.5 ml of 1 mg of *cis*-platinum/ml) in water and the reaction mixture was left for 5 min at room temperature and diluted with pH 4.2 acetate buffer to 25 ml, the maximum absorbance at 280 nm varied linearly with the *cis*-platinum concentration (Fig. 2).

The absorbance at 280 nm remained constant for several hours. Although the exact mechanism of this interesting reaction is not known at this time, such a chemical reaction possibly may occur *in vivo* between the antitumor agent and the enzymes containing a sulfhydryl group found in the body.

Furthermore, in view of the enhancement of the UV absorbance of *cis*-platinum in the presence of bisulfite, this reaction can be used for the analysis of the drug in dosage forms. This observation also is important from the pharmaceutical standpoint when the drug is added to intravenous fluids containing antioxidants such as sodium bisulfite. It may be possible that the antioxidant will inactivate the drug in the intravenous fluids prior to administration.

Percutaneous Absorption of Nitroglycerin

Keyphrases □ Nitroglycerin—percutaneous absorption, rhesus monkeys □ Absorption, percutaneous—nitroglycerin, rhesus monkeys □ Vasodilators—nitroglycerin, percutaneous absorption, rhesus monkeys

To the Editor:

We wish to report the percutaneous absorption of nitroglycerin in the rhesus monkey, an animal model that has been shown to be similar to humans (1, 2).

Sublingual nitroglycerin therapy has been the principal treatment for the symptomatic relief of angina pectoris. Sublingual nitrates are very effective, but their symptomatic improvements are not long lasting. Recently, nitroglycerin administered topically as an ointment was shown to be clinically effective for angina (3), and the slower absorption rate after topical administration results in a longer duration of action than after sublingual administration. Oral administration of nitroglycerin is not effective.

Our objective was to study some parameters of the percutaneous absorption of nitroglycerin. We wanted first to determine if there is an optimal site for absorption because the anatomical site of application affects skin absorption (4, 5). We then wanted to ascertain if the size of the application area affects the absorption of nitroglycerin.

The study was done *in vivo* with the rhesus monkey (*Macaca mulata*). Nitroglycerin (40 mg, 5 μCi) labeled with carbon 14 was applied to a 2-cm^2 area of skin. The areas tested were the chest, arm (upper inside), inner thigh, and postauricular region. After the application, each area was occluded with aluminum foil and adhesive tape for 24 hr. Then the occlusion was removed, and the site was washed with soap and water.

In addition, absorption of an identical dose was determined on the chest using a surface area of 50 cm^2. For this larger surface area, it was necessary to dissolve the dose in 250 μl of absolute ethanol. This solution was applied, and the ethanol was gently evaporated. Alcohol does not significantly alter nitroglycerin absorption (6). Percutaneous absorption was determined by the urinary excretion of carbon 14.

Absorption was quantified on the basis of the percent of radioactivity excreted in urine for 5 days following application of a known amount of the labeled compound to the skin. Daily urinary excretion values were corrected for excretion of radioactivity by other routes and retention of radioactivity in the body by administration of an intravenous dose of [^{14}C]nitroglycerin (1). Urinary radioactivity represents only the apparent nitroglycerin absorption. The potential for skin metabolism of nitroglycerin during absorption is unknown.

After intravenous administration of [^{14}C]nitroglycerin, 59.0 ± 1.9 (*SEM*) % of the dose was excreted in the urine in 5 days. Percent absorptions were 13.4 ± 1.2 (chest), 12.9 ± 1.2 (arm), 8.9 ± 1.4 (postauricular), and 14.8 ± 2.2 (thigh). None of the absorption values for doses applied to the 2-cm^2 areas was statistically different from each other. The majority of the unabsorbed dose in each case was recovered in the wash. Absorption of an identical dose

in nonlinear fashion as a function of the bisulfite concentration. Furthermore, in the presence of nitrogen or concentrations of ethanol or methanol as low as 1 × 10^{-3} *M*, no reaction was observed indicating autoxidation.

When 0.5 ml of 1 *M* sodium bisulfite (pH 4.2) was added to different concentrations of *cis*-platinum (0.1–0.5 ml of 1 mg of *cis*-platinum/ml) in water and the reaction mixture was left for 5 min at room temperature and diluted with pH 4.2 acetate buffer to 25 ml, the maximum absorbance at 280 nm varied linearly with the *cis*-platinum concentration (Fig. 2).

The absorbance at 280 nm remained constant for several hours. Although the exact mechanism of this interesting reaction is not known at this time, such a chemical reaction possibly may occur *in vivo* between the antitumor agent and the enzymes containing a sulfhydryl group found in the body.

Furthermore, in view of the enhancement of the UV absorbance of *cis*-platinum in the presence of bisulfite, this reaction can be used for the analysis of the drug in dosage forms. This observation also is important from the pharmaceutical standpoint when the drug is added to intravenous fluids containing antioxidants such as sodium bisulfite. It may be possible that the antioxidant will inactivate the drug in the intravenous fluids prior to administration.

Percutaneous Absorption of Nitroglycerin

Keyphrases □ Nitroglycerin—percutaneous absorption, rhesus monkeys □ Absorption, percutaneous—nitroglycerin, rhesus monkeys □ Vasodilators—nitroglycerin, percutaneous absorption, rhesus monkeys

To the Editor:

We wish to report the percutaneous absorption of nitroglycerin in the rhesus monkey, an animal model that has been shown to be similar to humans (1, 2).

Sublingual nitroglycerin therapy has been the principal treatment for the symptomatic relief of angina pectoris. Sublingual nitrates are very effective, but their symptomatic improvements are not long lasting. Recently, nitroglycerin administered topically as an ointment was shown to be clinically effective for angina (3), and the slower absorption rate after topical administration results in a longer duration of action than after sublingual administration. Oral administration of nitroglycerin is not effective.

Our objective was to study some parameters of the percutaneous absorption of nitroglycerin. We wanted first to determine if there is an optimal site for absorption because the anatomical site of application affects skin absorption (4, 5). We then wanted to ascertain if the size of the application area affects the absorption of nitroglycerin.

The study was done *in vivo* with the rhesus monkey (*Macaca mulata*). Nitroglycerin (40 mg, 5 μCi) labeled with carbon 14 was applied to a 2-cm^2 area of skin. The areas tested were the chest, arm (upper inside), inner thigh, and postauricular region. After the application, each area was occluded with aluminum foil and adhesive tape for 24 hr. Then the occlusion was removed, and the site was washed with soap and water.

In addition, absorption of an identical dose was determined on the chest using a surface area of 50 cm^2. For this larger surface area, it was necessary to dissolve the dose in 250 μl of absolute ethanol. This solution was applied, and the ethanol was gently evaporated. Alcohol does not significantly alter nitroglycerin absorption (6). Percutaneous absorption was determined by the urinary excretion of carbon 14.

Absorption was quantified on the basis of the percent of radioactivity excreted in urine for 5 days following application of a known amount of the labeled compound to the skin. Daily urinary excretion values were corrected for excretion of radioactivity by other routes and retention of radioactivity in the body by administration of an intravenous dose of [^{14}C]nitroglycerin (1). Urinary radioactivity represents only the apparent nitroglycerin absorption. The potential for skin metabolism of nitroglycerin during absorption is unknown.

After intravenous administration of [^{14}C]nitroglycerin, 59.0 ± 1.9 (*SEM*) % of the dose was excreted in the urine in 5 days. Percent absorptions were 13.4 ± 1.2 (chest), 12.9 ± 1.2 (arm), 8.9 ± 1.4 (postauricular), and 14.8 ± 2.2 (thigh). None of the absorption values for doses applied to the 2-cm^2 areas was statistically different from each other. The majority of the unabsorbed dose in each case was recovered in the wash. Absorption of an identical dose

0022-3549/80/0300-0365$01.00/0
© 1980, American Pharmaceutical Association

on the chest from a surface area of 50 cm^2 was significantly ($p < 0.002$) greater (36.4 ± 4.3%) than the absorption from the smaller surface area. Therefore, differences in these anatomical sites did not affect absorption, but increasing the size of the skin surface area did increase absorption.

The anatomical site of application has been shown to affect the percutaneous absorption of compounds in humans (4, 5) and the rhesus monkey (7). Site dependence for absorption of nitroglycerin has been reported in the rat (8) and humans (9). In the human study, the topical dose and the surface area were not controlled, but both of these parameters affect absorption (2).

Two points should be stressed. First, the topical dose and the surface area must be controlled in percutaneous absorption studies. Second, future studies may show that nitroglycerin absorption can vary with some anatomical sites. However, there also will be anatomical sites where absorption is similar. Therefore, a patient may have the convenience of choosing a preferred site.

BOOKS

REVIEWS

GLC and HPLC Determination of Therapeutic Agents, Parts I–III. (Chromatographic Science Series, Vol. 9).

Part I edited by K. TSUJI and W. MOROZOWICH.

Parts II and III edited by K. TSUJI.

Dekker, 270 Madison Ave., New York, NY 10016.

Part I: 1978, 415 pp., 18 × 26 cm, Price $37.50.

Part II: 1978, 432 pp., 18 × 26 cm, Price $45.00.

Part III: 1979, 528 pp., 18 × 26 cm, Price $45.00.

Part I has chapters entitled: Theory and Instrumentation, Column Selection in GLC, Column Selection in HPLC, Derivatization Techniques in Gas–Liquid Chromatography, Derivatization Techniques in HPLC, The Mass Spectrometer as a Detector for Gas–Liquid Chromatography, Isolation of Samples Prior to Chromatography, Preparative HPLC: Small Scale and Trace Collection, Preparative HPLC: Milligram Quantities, Quality Control in GLC, Automation and Quality Control in HPLC, Computer Interfacing, and Data Processing. Much new material as well as an exhaustive critical review of the literature is included. The writing has an immediacy and authority which are most welcome, indicating that the authors are directly involved with the techniques they describe. The volume is recommended to all in the field who wish to update their knowledge of the theory and practice of GLC and HPLC. It is particularly recommended to graduate students and would make an excellent course text except for one problem: an index is available only in Part III. Use of the index is made more annoying since the three parts are successively paginated so that the index does not immediately indicate the volume to open.

Part II is devoted to therapeutic drug monitoring with GLC and HPLC. It contains chapters 14–24, which give scientific methods and detailed directions for individual drugs. In addition to the literature review, there are author-preferred-and-tested methods for each drug. The drug classes covered are: narcotic analgesics, narcotic antagonists and related drugs, central nervous system (CNS) depressants, cocaine and phenylethylamines, hallucinogens, cannabis preparations, barbiturates, anticonvulsants, salicylates, aniline derivatives, pyrazolones, synthetic opiate-like drugs of low potency and low addictive potential, analgesic combinations, nonbarbiturate hypnotics, glutethimide, methaqualone, anorexigenics, antipsychotics, antianxiety agents, antidepressives, stimulants, antihypertensives, pulmonary and vasoactive drugs, antimicrobials, antimycotics, antiparasitics, adrenocorticosteroids, androgens, estrogens, and antifertility steroids. In addition, there are chapters on preservatives and on the determination of residues in gaseous sterilants.

The editor has been extremely careless in Part II, allowing the same material about the same drug to appear in two different chapters. For example, Fig. 9 of Chapter 14, showing GLC analysis of opium alkaloids, is reproduced as Fig. 15 of Chapter 16. The duplicated information involves the narcotic analgesics, barbiturates, amphetamine, papaverine, and, perhaps, others.

Part III continues with the drugs used in metabolic diseases, those that affect endocrine functions and nutritional agents. Drug classes included are: nonsteroidal anti-inflammatories, prostaglandins, cardiac glycosides, antiarrhythmics, vasodilators, oral anticoagulants (there are no methods for heparin in this collection), antidiabetics, diuretics, lipid- and cholesterol-lowering agents, thyroid agents, X-ray contrast agents, nucleosides and nucleotides, alkaloids, antihistamines and antitussives, water-soluble vitamins, fat-soluble vitamins, amino acids and peptides, sugar and sugar alcohols, and saccharin. The last chapter deals with serum lipid and fatty acid analysis.

The methods reported in Parts II and III include sample preparation (including separation from clinical samples or drug formulations and derivatization) as well as the determinations. Most chapters contain a summary table of the drugs included in it, choosing between GLC and HPLC as the method of choice and giving the chromatographic conditions.

It is an amusing coincidence that while this review was being prepared, the August issue of "Chromatography Newsletter" was received, which was devoted entirely (15 pages) to drug analysis, thus showing again that reviews, no matter how well done, can only supplement and not substitute for current periodicals.

These three volumes are an indispensible reference to all scientists who use or intend to use GLC and HPLC, particularly drug analysts, forensic scientists, clinical chemists, and biochemists. Good use of the collection will be made by "anyone concerned with the potency, purity, stability,

on the chest from a surface area of 50 cm^2 was significantly ($p < 0.002$) greater (36.4 ± 4.3%) than the absorption from the smaller surface area. Therefore, differences in these anatomical sites did not affect absorption, but increasing the size of the skin surface area did increase absorption.

The anatomical site of application has been shown to affect the percutaneous absorption of compounds in humans (4, 5) and the rhesus monkey (7). The Chemistry of Antitumor Antibiotics, Vol. 1. By WILLIAM A. REMERS. Wiley–Interscience, One Wiley Drive, Somerset, NJ 08873. 1979. 289 pp. 15 × 22.5 cm.

A lack of fundamental knowledge concerning many aspects of the biological sciences still restricts most oncologists to dealing with the treatment rather than the causes of cancer. Nevertheless, encouraging results have been attained with many drugs in the treatment of certain neoplastic diseases such as acute lymphocytic leukemia, Burkitt's lymphoma, choriocarcinoma, Hodgkin's disease, squamous cell cancer, and Wilm's tumor, Many of these remissions were achieved by the use of antitumor antibiotics.

Antibiotics are unique in their extreme diversity of chemical structures and in the fact that the "rational approach" followed so enthusiastically in the design of other classes of antineoplastic agents has played only a minor role in the discovery of their striking effects. As a result, information gained by assessing the antitumor activity of these antibiotics may be more objective than studies of more conventional drug classes. There can be little doubt that the information will contribute significantly to the future design of better antineoplastic agents and will provide a guide to the proper selection of agents for use in combination chemotherapy.

Since the discovery in 1952 that actinomycin D (dactinomycin) shows activity against experimental tumors, antibiotics have gained firm ground as a unique class of agents for the management of cancer. As a result, numerous studies on this subject mushroomed, and publications were scattered in every possible chemical, biological, pharmacological, and medical journal. Although some reviews and chapters were published occasionally on certain antitumor antibiotics, this book is the first of its type in which pertinent information in this area has been assembled in a comprehensive yet precise and clear manner. Dr. Remers' effort should be appreciated by investigators working in this field. His achievement is particularly admired by those who have tried to compile similar information, even on a smaller scale.

Volume 1 of this book is divided into five chapters: the actinomycins, the anthracyclines, the aureolic acid group, the bleomycins and phleomycins, and the mitomycins and porfiromycins. At least one member of each of these categories has recognition in cancer chemotherapy [*e.g.*, actinomycin D, adriamycin (doxorubicin), mithramycin, bleomycin B_2, and mitomycin C, respectively]. Each chapter has a concise, general introduction and is divided further into specific discussions including the discovery, isolation, and characterization, structural elucidation, possible mode of action, chemical synthesis and biosynthesis, and structure–activity relationships. Three of these five chapters also include the chemical transformations among related antibiotics.

Since many antibiotics discussed in this book tend to form chelates or complexes with certain metal ions, the author has emphasized repeatedly a significant point which, if not noticed, would cause confusion and misinterpretation by other investigators. This point is that physical properties such as optical rotation often are influenced by traces of metals and other impurities that are difficult to separate or remove from the pure compound. This case is especially true with antibiotics of the aureolic acid group in which samples with the same chemical structure were assigned as different antibiotics based on the observed discrepancy in specific rotation values.

This reviewer agrees with the author's comment that in a field where anticancer activity is the primary goal of synthesis and structural modification, it is surprising that not enough data have been published on the inhibition of experimental tumors. Judging from the many elegant total or partial syntheses recorded in this book, I cannot help but wonder whether the lengthy ones under the name of an alternate synthesis or a novel approach are of value to other investigators. Indeed, the aim of a chemical synthesis is to identify the structural assignment, to devise a practical method for more plentiful procurement of a specific antibiotic, or to facilitate analog synthesis. With the current limited funding in research, perhaps now is the best time for every dedicated investigator to reassess the true value and implication of his or her own work.

The order of tetracyclic rings in the anthracycline antibiotics (Chapter 2) given in this book was from the aromatic ring (ring A) toward the alicyclic ring (ring D) in which the glycoside is attached. However, on p. 88 and p. 102, ring A was designated as the alicyclic ring. In the literature, the conflicting order of rings A → D or D ← A has been assigned and has aroused unnecessary confusion. Since the original Italian investigators [Arcamone *et al.*, *Gazz. Chim. Ital.*, **100**, 949 (1970)] designated the alicyclic ring on the aglycone portion as ring A, perhaps such assignment should be honored rather than the general order of assignment in this book. The author also may wish to change the cell line of He La to HeLa in forthcoming books.

This reviewer also would like to add one piece of interesting information concerning the phleomycin antibiotics. Although it is known that the low therapeutic indexes of phleomycins hamper their use as antibacterial or antitumor agents, the addition of certain thioethers of purine or related heterocyclic compounds as potentiators ("amplifiers") permits the use of phleomycins at much lower levels, thereby raising their therapeutic indexes to potentially useful levels [Grigg *et al.*, *J. Bacteriol.*, **107**, 599 (1971); and Brown *et al.*, *Austr. J. Chem.*, **31**, 397 (1978) and the references cited therein].

All in all, this is a well-written and valuable book. Readers can follow easily the historical development of important antibiotics and recognize the work that has been accomplished as well as areas that still need to be studied. This book should be of interest to chemists, biochemists, toxicologists, pharmacologists, and clinicians who are interested in research.

The Alkaloids: The Fundamental Chemistry—A Biogenetic Approach. (Studies in Organic Chemistry Series, Vol. 7). By D. R. DALTON. 270 Madison Ave., New York, NY 10016. 1979. x + 789 pp. 18 × 26 cm. Price $49.50 (A special price of $29.50 is available in the United States and Canada on orders of five or more copies).

The alkaloids represent the largest and most diverse group of plant-derived natural products, with well over 10,000 known members of the class involving 300 different ring systems. In view of their importance, including their significance in pharmacy and medicine, it is surprising that few textbooks on alkaloids have appeared in recent years. Thus, apart from reviews in "The Alkaloids" series, the Chemical Society Specialist Periodical Reports of the same name, and specialized reviews such as the one by Shamma and Moniot on isoquinoline alkaloids, no comprehensive general treatment of the alkaloids has appeared since that edited by Pelletier almost a decade ago. The publication of the book that is the subject of this review is thus a timely event and one that will be welcomed by all researchers involved in the alkaloid field.

The book is an outgrowth of a course taught by the author at Temple University, and this is the origin of its greatest strength and its greatest weakness. The strength of the book is that it provides for the first time, in one place, a unified account of the biosynthesis and chemistry of the alkaloids. It is organized along biosynthetic lines rather than along the traditional lines of previous works. Thus, instead of chapters on subjects such as the ipecac (ipecacuanha) alkaloids or the cinchona alkaloids, there are chapters on alkaloids derived from ornithine, lysine, nicotinic acid, tyrosine, and tryptophan and on alkaloids derived by introduction of nitrogen into a terpenoid skeleton. Although the traditional classification, largely by plant of origin, does group alkaloids of similar type, our present understanding of alkaloid biosynthesis makes the approach adopted in this book logical and desirable. Furthermore, the discussion of the biosynthesis and the chemistry of each alkaloid is integrated within each chapter rather than having the biosynthesis discussed in a separate chapter. This feature allows the reader to appreciate the synthetic approaches to the alkaloids more readily, particularly those that are modeled on an actual or presumed biosynthetic pathway.

The major weakness of the book as a standard reference on the alka-

pharmacokinetics and mechanisms of actions of drugs. . . ."

The type is clear and readable. The books have glossy paper covered boards, are easy to open, and lie flat, as are typical of Marcel Dekker volumes.

Despite the nuisances and repetitiveness noted, the set is highly recommended.

This reviewer also would like to add one piece of interesting information concerning the phleomycin antibiotics. Although it is known that the low therapeutic indexes of phleomycins hamper their use as antibacterial or antitumor agents, the addition of certain thioethers of purine or related heterocyclic compounds as potentiators ("amplifiers") permits the use of phleomycins at much lower levels, thereby raising their therapeutic indexes to potentially useful levels [Grigg *et al.*, *J. Bacteriol.*, **107**, 599 (1971); and Brown *et al.*, *Austr. J. Chem.*, **31**, 397 (1978) and the references cited therein].

All in all, this is a well-written and valuable book. Readers can follow easily the historical development of important antibiotics and recognize the work that has been accomplished as well as areas that still need to be studied. This book should be of interest to chemists, biochemists, toxicologists, pharmacologists, and clinicians who are interested in research.

The Alkaloids: The Fundamental Chemistry—A Biogenetic Approach. (Studies in Organic Chemistry Series, Vol. 7). By D. R. DALTON. 270 Madison Ave., New York, NY 10016. 1979. x + 789 pp. 18 × 26 cm. Price $49.50 (A special price of $29.50 is available in the United States and Canada on orders of five or more copies).

The alkaloids represent the largest and most diverse group of plant-derived natural products, with well over 10,000 known members of the class involving 300 different ring systems. In view of their importance, including their significance in pharmacy and medicine, it is surprising that few textbooks on alkaloids have appeared in recent years. Thus, apart from reviews in "The Alkaloids" series, the Chemical Society Specialist Periodical Reports of the same name, and specialized reviews such as the one by Shamma and Moniot on isoquinoline alkaloids, no comprehensive general treatment of the alkaloids has appeared since that edited by Pelletier almost a decade ago. The publication of the book that is the subject of this review is thus a timely event and one that will be welcomed by all researchers involved in the alkaloid field.

The book is an outgrowth of a course taught by the author at Temple University, and this is the origin of its greatest strength and its greatest weakness. The strength of the book is that it provides for the first time, in one place, a unified account of the biosynthesis and chemistry of the alkaloids. It is organized along biosynthetic lines rather than along the traditional lines of previous works. Thus, instead of chapters on subjects such as the ipecac (ipecacuanha) alkaloids or the cinchona alkaloids, there are chapters on alkaloids derived from ornithine, lysine, nicotinic acid, tyrosine, and tryptophan and on alkaloids derived by introduction of nitrogen into a terpenoid skeleton. Although the traditional classification, largely by plant of origin, does group alkaloids of similar type, our present understanding of alkaloid biosynthesis makes the approach adopted in this book logical and desirable. Furthermore, the discussion of the biosynthesis and the chemistry of each alkaloid is integrated within each chapter rather than having the biosynthesis discussed in a separate chapter. This feature allows the reader to appreciate the synthetic approaches to the alkaloids more readily, particularly those that are modeled on an actual or presumed biosynthetic pathway.

The major weakness of the book as a standard reference on the alka-

pharmacokinetics and mechanisms of actions of drugs. . . ."

The type is clear and readable. The books have glossy paper covered boards, are easy to open, and lie flat, as are typical of Marcel Dekker volumes.

Despite the nuisances and repetitiveness noted, the set is highly recommended.

The Chemistry of Antitumor Antibiotics, Vol. 1. By WILLIAM A. REMERS. Wiley–Interscience, One Wiley Drive, Somerset, NJ 08873. 1979. 289 pp. 15 × 22.5 cm.

A lack of fundamental knowledge concerning many aspects of the biological sciences still restricts most oncologists to dealing with the treatment rather than the causes of cancer. Nevertheless, encouraging results have been attained with many drugs in the treatment of certain neoplastic diseases such as acute lymphocytic leukemia, Burkitt's lymphoma, choriocarcinoma, Hodgkin's disease, squamous cell cancer, and Wilm's tumor, Many of these remissions were achieved by the use of antitumor antibiotics.

Antibiotics are unique in their extreme diversity of chemical structures and in the fact that the "rational approach" followed so enthusiastically in the design of other classes of antineoplastic agents has played only a minor role in the discovery of their striking effects. As a result, information gained by assessing the antitumor activity of these antibiotics may be more objective than studies of more conventional drug classes. There can be little doubt that the information will contribute significantly to the future design of better antineoplastic agents and will provide a guide to the proper selection of agents for use in combination chemotherapy.

Since the discovery in 1952 that actinomycin D (dactinomycin) shows activity against experimental tumors, antibiotics have gained firm ground as a unique class of agents for the management of cancer. As a result, numerous studies on this subject mushroomed, and publications were scattered in every possible chemical, biological, pharmacological, and medical journal. Although some reviews and chapters were published occasionally on certain antitumor antibiotics, this book is the first of its type in which pertinent information in this area has been assembled in a comprehensive yet precise and clear manner. Dr. Remers' effort should be appreciated by investigators working in this field. His achievement is particularly admired by those who have tried to compile similar information, even on a smaller scale.

Volume 1 of this book is divided into five chapters: the actinomycins, the anthracyclines, the aureolic acid group, the bleomycins and phleomycins, and the mitomycins and porfiromycins. At least one member of each of these categories has recognition in cancer chemotherapy [*e.g.*, actinomycin D, adriamycin (doxorubicin), mithramycin, bleomycin B_2, and mitomycin C, respectively]. Each chapter has a concise, general introduction and is divided further into specific discussions including the discovery, isolation, and characterization, structural elucidation, possible mode of action, chemical synthesis and biosynthesis, and structure–activity relationships. Three of these five chapters also include the chemical transformations among related antibiotics.

Since many antibiotics discussed in this book tend to form chelates or complexes with certain metal ions, the author has emphasized repeatedly a significant point which, if not noticed, would cause confusion and misinterpretation by other investigators. This point is that physical properties such as optical rotation often are influenced by traces of metals and other impurities that are difficult to separate or remove from the pure compound. This case is especially true with antibiotics of the aureolic acid group in which samples with the same chemical structure were assigned as different antibiotics based on the observed discrepancy in specific rotation values.

This reviewer agrees with the author's comment that in a field where anticancer activity is the primary goal of synthesis and structural modification, it is surprising that not enough data have been published on the inhibition of experimental tumors. Judging from the many elegant total or partial syntheses recorded in this book, I cannot help but wonder whether the lengthy ones under the name of an alternate synthesis or a novel approach are of value to other investigators. Indeed, the aim of a chemical synthesis is to identify the structural assignment, to devise a practical method for more plentiful procurement of a specific antibiotic, or to facilitate analog synthesis. With the current limited funding in research, perhaps now is the best time for every dedicated investigator to reassess the true value and implication of his or her own work.

The order of tetracyclic rings in the anthracycline antibiotics (Chapter 2) given in this book was from the aromatic ring (ring A) toward the alicyclic ring (ring D) in which the glycoside is attached. However, on p. 88 and p. 102, ring A was designated as the alicyclic ring. In the literature, the conflicting order of rings A → D or D ← A has been assigned and has aroused unnecessary confusion. Since the original Italian investigators [Arcamone *et al.*, *Gazz. Chim. Ital.*, **100**, 949 (1970)] designated the alicyclic ring on the aglycone portion as ring A, perhaps such assignment should be honored rather than the general order of assignment in this book. The author also may wish to change the cell line of He La to HeLa in forthcoming books.

This reviewer also would like to add one piece of interesting information concerning the phleomycin antibiotics. Although it is known that the low therapeutic indexes of phleomycins hamper their use as antibacterial or antitumor agents, the addition of certain thioethers of purine or related heterocyclic compounds as potentiators ("amplifiers") permits the use of phleomycins at much lower levels, thereby raising their therapeutic indexes to potentially useful levels [Grigg *et al.*, *J. Bacteriol.*, **107**, 599 (1971); and Brown *et al.*, *Austr. J. Chem.*, **31**, 397 (1978) and the references cited therein].

All in all, this is a well-written and valuable book. Readers can follow easily the historical development of important antibiotics and recognize the work that has been accomplished as well as areas that still need to be studied. This book should be of interest to chemists, biochemists, toxicologists, pharmacologists, and clinicians who are interested in research.

The Alkaloids: The Fundamental Chemistry—A Biogenetic Approach. (Studies in Organic Chemistry Series, Vol. 7). By D. R. DALTON. 270 Madison Ave., New York, NY 10016. 1979. x + 789 pp. 18 × 26 cm. Price $49.50 (A special price of $29.50 is available in the United States and Canada on orders of five or more copies).

The alkaloids represent the largest and most diverse group of plant-derived natural products, with well over 10,000 known members of the class involving 300 different ring systems. In view of their importance, including their significance in pharmacy and medicine, it is surprising that few textbooks on alkaloids have appeared in recent years. Thus, apart from reviews in "The Alkaloids" series, the Chemical Society Specialist Periodical Reports of the same name, and specialized reviews such as the one by Shamma and Moniot on isoquinoline alkaloids, no comprehensive general treatment of the alkaloids has appeared since that edited by Pelletier almost a decade ago. The publication of the book that is the subject of this review is thus a timely event and one that will be welcomed by all researchers involved in the alkaloid field.

The book is an outgrowth of a course taught by the author at Temple University, and this is the origin of its greatest strength and its greatest weakness. The strength of the book is that it provides for the first time, in one place, a unified account of the biosynthesis and chemistry of the alkaloids. It is organized along biosynthetic lines rather than along the traditional lines of previous works. Thus, instead of chapters on subjects such as the ipecac (ipecacuanha) alkaloids or the cinchona alkaloids, there are chapters on alkaloids derived from ornithine, lysine, nicotinic acid, tyrosine, and tryptophan and on alkaloids derived by introduction of nitrogen into a terpenoid skeleton. Although the traditional classification, largely by plant of origin, does group alkaloids of similar type, our present understanding of alkaloid biosynthesis makes the approach adopted in this book logical and desirable. Furthermore, the discussion of the biosynthesis and the chemistry of each alkaloid is integrated within each chapter rather than having the biosynthesis discussed in a separate chapter. This feature allows the reader to appreciate the synthetic approaches to the alkaloids more readily, particularly those that are modeled on an actual or presumed biosynthetic pathway.

The major weakness of the book as a standard reference on the alka-

loids is that is is not thoroughly referenced. It only has 480 references, fewer than 20 of which are from 1975 or later. In contrast, the earlier and somewhat shorter work by Pelletier, which dealt largely with alkaloid chemistry, boasted 1750 references. In the present work, the lack of references is made up to some extent by references to review articles at the end of each chapter, but these reviews are, of course, of even earlier vintage than the book itself. The book thus is not a good source for the latest information in alkaloid research, particularly in such rapidly developing fields as indole alkaloid biosynthesis. In addition, it also is not comprehensive; several classes of alkaloids are not discussed at all.

The book sets out to be a textbook, however, and it is within this framework that it should be judged. As the author modestly states in the epilogue, "The major objective . . . is to provide the beginning student with an appreciation of order in structure type and biogenetic reasoning. Hopefully, some chemistry was also learned." Any person who takes the time to work through this book is certain to achieve these objectives and much more. The discussion of both biosynthesis and chemistry is lucid and concise, and the structural diagrams are excellent in quality and abundant in quantity. The only minor improvements that could be suggested would be for the initial diagrams to carry the numbering system for that structural type and for more diagrams to be oriented so that the reader does not have to turn the book around to see them.

In conclusion, the author has written an excellent textbook on the alkaloids, and it can be recommended as the book of choice for any scientist wishing to become acquainted with this fascinating area of natural products. Persons needing detailed and up-to-date information in a specific area will have to supplement this book with material from review articles and the recent literature.

The Pharmaceutical Codex, 11th Ed. The Pharmaceutical Press, One Lambeth High St., London SE1 7JN, England. 1979. 1101 pp. 17 × 25 cm. Price £27.

The 11th edition of "The British Pharmaceutical Codex," now called "The Pharmaceutical Codex," contains over 1400 entries in a single alphabetical sequence. Over 900 monographs on synthetic drug substances and natural products used in medicine are included. A typical drug substance monograph features the full chemical name, structural and molecular formulas, molecular weights, synonyms and trade names, physical characteristics such as solubility and specific rotation, stability and storage information, identification tests, metabolism, actions and uses, and preparations. Entries for drug classes also are included.

Diseases and minor ailments are discussed with respect to the cause and nature of the disorder, its major signs and symptoms, and its treatment with reference to the use of drugs. Entries on analytical techniques such as IR and UV spectrophotometry are included.

The first appendix describes the analytical reagents mentioned in the text. The second appendix gives reduced facsimile reproductions of IR spectra for more than 300 drug substances to aid in their identification. A comprehensive index with over 10,000 entries concludes the book.

This book is a useful reference for those concerned with the manufacture, formulation, distribution, dispensing, and quality control of drugs and medicines for human or veterinary use.

IDENTIFYING "THE BAD CHARACTERS"

The so-called "Lannett decision" threw into question the authority of the Food and Drug Administration to require its approval of a duplicative drug product before that product is placed in distribution on the open market. At this writing, the effect of the court decision is still in question for various reasons including FDA appeals and differing decisions by courts in other judicial districts.

In the meantime, however, certain manufacturers have proceeded to market products without submitting them for FDA review and approval. The FDA has been seizing many of these products—particularly in those judicial districts where decisions have not been handed down that are adverse to its claim that federal law gives it the authority to require premarketing drug approval.

Nevertheless, at least a few unapproved products have gotten into general distribution. Moreover, according to the FDA, several of these products have been poorly formulated in a manner to make them less than satisfactory for their intended clinical uses, and the problem presented by these defective products has been widely publicized.

In an effort to avoid creating therapeutic problems for patients, pharmacists have been strongly advised to avoid purchasing and dispensing any products lacking FDA's approval. Indeed, pharmacists have been warned that they expose themselves to potential legal liability and to possible malpractice suits by using such products—particularly if patient injury were to result.

This well-intended advice has been offered from a variety of sources. In addition to a veritable bombarding of mailings from certain major pharmaceutical companies, pharmacists have gotten such cautions from state boards of pharmacy, from editors in the pharmaceutical press, from various professional associations, from attorney-pharmacists at conferences and symposia, and so on.

Indeed, a report in the drug press even quoted FDA Commissioner Jere E. Goyan as telling his Bureau of Drugs staff in mid-February that the situation concerning "unapproved generics"—the problem that some manufacturers may be marketing drugs illegally—is one that calls for an information campaign directed at the pharmacist. According to the Commissioner, "We have to go very heavily to pharmacy and say, 'Look, you're taking a terrible risk.' "

We do not quarrel in the least with the Commissioner's assessment that dispensing unapproved drugs constitutes a very serious risk to both the pharmacist and the patient. But what we do wonder is whether the Commissioner, and all the other well-meaning dispensors of "Dutch-uncle advice" noted above, recognize or appreciate the pharmacist's real problem.

We are personally convinced that virtually all pharmacists would shun such unapproved drug products *if*—and that's a very big "if"—they could immediately identify which products are approved or which are not. Fully 99% of the nation's pharmacists have the integrity and intelligence to avoid dealing with products of such questionable quality; and most of the other 1% are at least wise enough to do so, even if they are not motivated out of professional integrity.

Imagine for a moment the confusion that would reign if the millions and millions of automobiles in this country were all being driven around without license plates. The vehicles themselves still might be properly registered with the respective state vehicle departments, but there would be no outward evidence of such registration, or verification of registration, or means of identification, or the like, displayed on each automobile for all to see. To say that this would be a chaotic situation is a gross understatement.

And yet, when it comes to marketed drug products, we have no reliable system—short of telephoning the FDA offices in Washington concerning each individual drug product—for identifying those that have been so approved. Hence, there is no ready means of being able to distinguish them from products that may be on the market without having gone through the FDA's new drug application (NDA) or abbreviated new drug application (ANDA) approval process.

In mid-December, APhA President William S. Apple and this writer met with FDA officials and made a strong pitch for the agency to permit (or to require) drug manufacturers to carry the NDA or ANDA approval number in the labeling of those drug products that do, in fact, have such approval. In the past, and continuing at least to the time of this writing, FDA has prohibited the inclusion of such information as part of the product labeling on grounds that it constituted a form of inappropriate advertising; that is, the FDA was concerned that the approval number would be interpreted by consumers as an FDA endorsement of the product or that the product had a "seal of approval" from the federal government.

However justified this prohibition may have been in the past, present circumstances have drastically changed. In our opinion, if pharmacists are going to be able to exercise due care in product selection and dispensing, and if the health and welfare of patients are to be duly guarded, then it is essential that the FDA rescind its restriction and permit approved products to be appropriately identified for the benefit of all pertinent parties. —EGF

Determination of Extent of Hydration of Water-Miscible Organic Liquids in Aqueous Solution from Viscosity Data

HANS SCHOTT

Received March 12, 1979, from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication September 20, 1979.

Abstract □ Three viscometric methods for estimating the extent of association in binary liquid mixtures were employed to determine the maximum hydration of acetone, dimethyl sulfoxide, dioxane, 1-propanol, and 2-pyrrolidinone in aqueous solution. Two of the methods are based on the increase in viscosity or the decrease in fluidity of binary aqueous solutions caused by association between water and the second component, *i.e.*, by hydration of the second component. The composition of maximum hydration is that at which the deviation of experimental viscosities or fluidities from additive viscosities or fluidities reaches a maximum. Additive values are calculated by interpolation between the viscosities or fluidities of water and the second liquid component. Additivity would be observed in ideal solutions, *i.e.*, in the absence of hydration. The first method of interpolation uses the Kendall equation, $\phi_{12calc} = \phi_1^{x_1}\phi_2^{x_2}$, to calculate the fluidities, ϕ, of the mixtures (subscript 12) from the fluidities and mole fractions, x, of water (subscript 1) and the second liquid (subscript 2). The Kendall equation has a theoretical basis and is applicable where the viscosities, η, of water and the second liquid are of the same order of magnitude, differing by less than a factor of five. The maximum number of bound water molecules per molecule of the second component was 3 for acetone and dimethyl sulfoxide, 4 for dioxane, and 5.7 for propanol. The second method of interpolation is based on the empirical Kendall–Monroe equation, $\eta_{12\,calc}^{1/3} = x_1\eta_1^{1/3} + x_2\eta_2^{1/3}$, which is applicable to mixtures where the viscosities of the two pure components differ by a factor of 10 or more. The resultant hydration ratio of one water molecule per molecule of pyrrolidinone is confirmed by the separation of the solid monohydrate at lower temperatures. A novel and universal method determines the maximum hydration as the composition at which the activation energy for viscous flow of the mixtures, indicative of the size of the flow units, goes through a maximum. This method requires viscosity data of higher accuracy and at more than one temperature. Its hydration results agreed with those of the other two methods where the latter were applicable. The change in the activation energy of water with temperature was used to obtain a relative measure of the degree of self-association in liquid water as a function of temperature.

Keyphrases □ Hydration—water-miscible organic liquids in aqueous solution, determination using three viscometric methods □ Binary liquid mixtures—extent of hydration, three viscometric methods □ Viscosity—determination of extent of hydration of water-miscible organic liquids in aqueous solution □ Organic solvents—extent of hydration in aqueous solution, viscosity data

The extent of hydration of water-miscible organic liquids is of interest because it affords estimates of the number of water molecules associated with the organic functional groups present in the molecules of these liquids as well as in other compounds containing the same functional groups, including drugs, polymers, and constituents of biological membranes and cells.

For example, a knowledge of the maximum number of water molecules associated with an ether group, obtained from studies of binary liquid systems comprising water and model ethers (1), was essential to understanding the hydration of micelles of nonionic polyoxyethylated surfactants, making it possible to distinguish between water molecules bound to ether groups by hydrogen bonding and those mechanically trapped in the coiled and interpenetrating chains of the polyoxyethylene moieties of the surfactants (2). Information concerning the maximum hydration of hydroxyl groups (3) may lead to a better understanding of the transport properties of aqueous solutions of natural or synthetic polyhydroxylated polymers and of the water vapor permeability of their films (4).

Finally, the composition of maximum hydration of solvents such as dimethyl sulfoxide (5) is important in connection with their use as vehicles for drugs and as reaction media.

THEORETICAL

Association in a binary liquid system usually can be detected by the deviation of the experimental values of an intensive property of the solutions from the additive values of the property. Additive values are calculated by linear interpolation between the two values of that property belonging to the two pure components as a function of composition. Additive values are observed experimentally in the absence of association between molecules of the two liquids in their binary mixtures. Association leads to deviations from additivity. Such deviations frequently reach maximum values at a stoichiometric composition corresponding to the complex formed between the two components or at the composition of maximum hydration when water is one of the two liquid components.

Among the properties tested as suitable indicators are density and partial molar volume, refractive index and molar refraction, dielectric

© 1980, American Pharmaceutical Association

constant, magnetic susceptibility, IR and UV absorption spectra, and heat of mixing (6). Fluidity, ϕ, or its reciprocal, viscosity, η, is a reliable and sensitive property for detecting association between strongly (7) and weakly (1, 3, 5, 8, 9) interacting components.

Kendall and Kendall–Monroe Equations—The first equation used to calculate the fluidities of binary aqueous mixtures by interpolation between the fluidity of water and that of the second liquid component was the Kendall equation (10):

$$\log \phi_{12\ \text{calc}} = x_1 \log \phi_1 + x_2 \log \phi_2 \qquad \text{(Eq. 1)}$$

where x represents mole fraction and subscripts 1, 2, and 12 refer to water, the second liquid component, and their mixtures, respectively. This equation is obeyed by ideal or nearly ideal solutions (11).

Association between the two components causes the observed fluidity of their mixtures to be smaller than that calculated by Eq. 1. The composition corresponding to the greatest deviation of the experimental fluidity from that calculated by Eq. 1 is the composition at which the association between the two liquids is most extensive. Deviations in fluidity are defined as:

$$\Delta\phi = \phi_{12\ \text{calc}} - \phi_{12\ \text{exp}} \qquad \text{(Eq. 2)}$$

while percent relative deviations in fluidity are calculated as:

$$\text{relative deviation } \phi = 100\Delta\phi/\phi_{12\ \text{exp}} \qquad \text{(Eq. 3)}$$

The Kendall equation is easily derived from Eyring's theory of the viscosity of liquids (12) for the case where the molar volumes and, hence, the viscosities of the two pure liquid components are of comparable orders of magnitude. Molar volume refers to the volume of 1 mole of the kinetic or flow unit. If the liquid is self-associated, *e.g.*, a dimer, the molar volume to be used is twice the ratio of the monomeric molecular weight to density. Molar volume is then related to the size of the holes or vacant sites which, according to the relaxation theory of transport phenomena, exist in liquids and determine their transport properties (13).

The Kendall equation is applicable to pairs of miscible liquids whose viscosities do not differ by too much, *e.g.*, by less than a factor of 5. In that case, the fluidities of the mixtures calculated by means of Eq. 1 are correct in the absence of association between the two components. Therefore, where association does occur, the composition of maximum interaction is that corresponding to the maximum difference, $\Delta\phi$, between calculated and observed fluidities.

When the fluidities of the two liquid components differ appreciably, Kendall and Monroe (14) proposed the following empirical equation to calculate the viscosities of binary mixtures by interpolation between the viscosities of the pure components:

$$\eta_{12\ \text{calc}}^{1/3} = x_1\eta_1^{1/3} + x_2\eta_2^{1/3} \qquad \text{(Eq. 4)}$$

Equation 4 correctly predicts the viscosity of binary mixtures of nonassociated liquids when there is an appreciable difference between the viscosities and, hence, the molar volumes of the two liquids (7, 14). Deviations of the observed viscosities of aqueous solutions from the viscosities calculated by means of Eq. 4 can be used to determine the composition corresponding to maximum hydration only if the second liquid is considerably more viscous than water, having a viscosity at room temperature of at least 10 or 15 cps. Deviations in viscosity are defined as:

$$\Delta\eta = \eta_{12\ \text{exp}} - \eta_{12\ \text{calc}} \qquad \text{(Eq. 5)}$$

while percent relative deviations in viscosity are calculated as:

$$\text{relative deviation } \eta = 100\ \Delta\eta/\eta_{12\ \text{exp}} \qquad \text{(Eq. 6)}$$

Neither Eq. 1 nor 4 is universally applicable. They are mutually exclusive; furthermore, Eq. 4 lacks a theoretical basis. Therefore, there is a need for a general method of determining the composition of most extensive hydration of binary systems. Such a method, while still based on rheology because of the large relative deviations observed, does not employ deviations from viscosities calculated by interpolation.

Activation Energy for Viscous Flow as a Measure of Association—The activation energy for viscous flow, ΔE, is defined by the Arrhenius–Gusman–Andrade equation (11):

$$\eta = A \exp(\Delta E/RT) \qquad \text{(Eq. 7)}$$

or:

$$\frac{d \log \eta}{d(1/T)} = \frac{\Delta E}{2.3026R} \qquad \text{(Eq. 8)}$$

where T is the absolute temperature; R is the gas constant, 1.98717 cal/mole/degree; A is another constant; and ΔE is expressed in calories per mole.

Mixtures of simple liquids generally exhibit Newtonian flow behavior, so that η and, hence, ΔE are independent of shear stress. Plots of log η *versus* $1/T$ are sometimes very slightly convex toward the reciprocal temperature axis, especially over temperature ranges broader than ~30°. The ΔE values used in the present study were calculated from viscosity data taken within temperature ranges of ≤20°. The Arrhenius equation was obeyed over these narrow ranges, and ΔE was calculated by the method of least squares.

When viscosity data at only two temperatures, T_1 and T_2, were considered, ΔE was calculated from the integrated form of Eq. 8:

$$\Delta E = \frac{(2.3026)(1.98717)}{\left(\frac{1}{T_2} - \frac{1}{T_1}\right)} \log \frac{(\eta_{12\ \text{exp}})_{T_2}}{(\eta_{12\ \text{exp}})_{T_1}} \qquad \text{(Eq. 9)}$$

The energy of activation for viscous flow of a single liquid is related to its latent heat of vaporization. Liquids are mobile because of the presence of holes or vacant sites. According to Eyring's theory for viscous flow, the flow of liquids in shear consists of molecules squeezing past their neighbors to occupy such vacant sites. The activation energy for viscous flow is used mostly to form new holes (11–13). The size of the holes and, hence, the magnitude of the activation energy must increase as the flow unit increases. For binary aqueous mixtures, more extensive hydration of the second liquid increases the size of the flow unit and should increase the activation energy. Accordingly, the activation energy should go through a maximum at the composition at which the association is most extensive, *i.e.*, at which the greatest number of water molecules are associated with each molecule of the second liquid. The composition corresponding to the highest activation energy is the composition of maximum hydration.

EXPERIMENTAL

Materials—Purification methods and properties of dimethyl sulfoxide (5), 1,4-dioxane (1, 15), and 1-propanol (3) were described previously; 2-pyrrolidinone[1] (also called 2-pyrrolidone or γ-butyrolactam) was purified by fractional distillation and repeated crystallization by freezing until the freezing point could not be increased further. The final value of 25.64° is in good agreement with the published values of 25.57° (16) and 25.67° (17). Because solid pyrrolidinone monohydrate separates at room temperature over a wide range of compositions (16), measurements for the water–pyrrolidinone system were made at temperatures above its melting point of 30.4°.

Acetone[2] was dried with anhydrous sodium sulfate and distilled twice from a 4-Å molecular sieve. Its normal boiling point, refractive index, and density at 25° (Table I) are in good agreement with published values (18, 19).

Water was double distilled. Water–solvent mixtures were prepared in batches of ~100 g by weighing the two liquids to the nearest milligram. Selected properties of the six purified liquids are listed in Table I.

Methods—The temperatures during the measurements were maintained constant within ±0.01°. Viscosities were measured with Cannon–Fenske glass capillary viscometers for which the flow times exceeded 250 sec. The kinetic energy correction was thus too small to be considered. Duplicate measurements, made on fresh portions of the solutions, agreed within 0.2 sec. Densities were determined with a Sprengel–Ostwald pycnometer of 25-ml capacity. Duplicate measurements were identical within ±0.00003 g/ml or better.

RESULTS

Evaluation of Three Methods—The three viscometric methods for determining the composition at which binary mixtures of miscible liquids are most extensively associated were applied to aqueous solutions of acetone, dimethyl sulfoxide, dioxane, propanol, and pyrrolidinone. The data are plotted in Figs. 1–9 and summarized in Table II.

The activation energies for viscous flow for the various aqueous solvent systems were computed as follows. For acetone, new viscosity data at 20 and 25° were obtained because the ΔE values calculated from Ref. 19 as a function of x_2 were too irregular. While ΔE went through a maximum at $x_2 = 0.24$, $\Delta\phi$ went through maxima at $x_2 = 0.26$ for 20° and at $x_2 =$

0.25 for 25° (Figs. 1 and 3). These three values of x_2 are identical within the precision of the methods.

The ΔE values for water–dimethyl sulfoxide mixtures (Fig. 3) are based on viscosity data of Ref. 20 at 25 , 35, and 45°; of Ref. 21 at 25 and 45°; and on new data at 20° combined with published data at 25° (5). The three sets of data agree well with one another. The ΔE values for water–dioxane mixtures (Fig. 6) are based on data of Ref. 22 at 20, 25, and 30° plus new data at 20° combined with published data at 25° (1, 23).

The viscosity data of Refs. 3 and 24 for water–propanol mixtures are in good agreement. The ΔE values are based on data of both references at 25 and 30°. The melting points of solid pyrrolidinone and its monohydrate, 25.6 and 30.4°, respectively (16, 17), require higher working temperatures. Published viscosity data at 31, 35, 40, 45, and 50° (17) were supplemented by new data at 37 and 45°, especially for determining ΔE (Fig. 8).

The disparity between the viscosities of the second liquid and water is relatively small for acetone (1:3 ratio; seventh column of Table II), dimethyl sulfoxide and propanol (2:1 ratio), and dioxane (approximately equal). Therefore, the Kendall equation (Eq. 1) should provide the correct fluidity or viscosity in the absence of association. Consequently, the composition of maximum deviation, $\Delta\phi$, defined by Eq. 2 should be the composition corresponding to the highest hydration.

The applicability of the method based on the Kendall equation is corroborated by the excellent agreement between the composition of maximum hydration, x_2, obtained from $\Delta\phi$ and ΔE for the first four liquids in Table II (compare the x_2 values in the second and sixth columns). The x_2 values calculated by the Kendall–Monroe equation (Eq. 4) and $\Delta\eta$ (Eq. 5), shown in the fourth column, disagree with the x_2 values determined by the other two methods.

The following additional point confirms the use of $\Delta\phi$ rather than $\Delta\eta$ for the first four systems. The maximum deviation in $\Delta\phi$ and ΔE for water–dioxane mixtures occurred at $x_2 = 0.20$ and 0.19, corresponding to a maximum hydration ratio of four water molecules per dioxane molecule or two water molecules per ether group. This hydration ratio of two is to be expected because each ether oxygen has two lone or unshared electron pairs. The same ratio also was found experimentally for linear polyfunctional ethers (1, 8). The x_2 value corresponding to a maximum in $\Delta\eta$, 0.23, would result in a hydration ratio of 3.35 or only 1.67 water molecules per ether group.

The viscosity of pyrrolidinone is 12–13 times higher than that of water at comparable temperatures, indicating that the Kendall–Monroe equation and $\Delta\eta$ rather than the Kendall equation and $\Delta\phi$ should provide the composition corresponding to maximum hydration. Both ΔE and $\Delta\eta$ result in $x_2 = 0.51$ for maximum hydration, compared to $x_2 = 0.15$ from $\Delta\phi$. The following is direct evidence for the correctness of the unit hydration ratio in liquid water–pyrrolidinone mixtures and of the methods for determining this ratio. The solid monohydrate has a congruent melting point at 30.4°. The maximum in the water–pyrrolidinone phase diagram corresponding to this compound is relatively sharp rather than flat (16). These facts indicate that the monohydrate is stable in the liquid state above the melting point as well as in the solid state below it and that dissociation in the melt at temperatures close to the melting point is not extensive (25). Hence, the monohydrate largely persists over the 31–45° range in which the viscosity measurements were conducted.

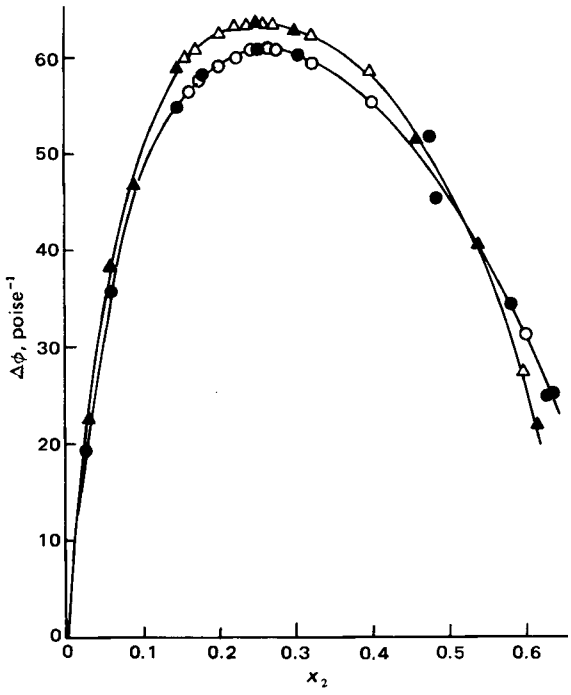

Figure 1—*Difference between calculated and experimental fluidities of water–acetone mixtures as a function of the mole fraction,* x_2, *of acetone. Key:* ●, *Ref. 19 at 20°;* ○, *present work at 20°;* ▲, *Ref. 19 at 25°; and* △, *present work at 25°.*

Precision of Three Methods—The points of most plots of $\Delta\phi$ and $\Delta\eta$ *versus* x_2 fell right on the curves because the usual experimental errors have only moderate effects on $\Delta\phi$ and $\Delta\eta$. Compositions of maximum deviation can be located with a precision of 0.005. Extensive sets of viscosity data by different investigators agreed within 0.01 of the x_2 value corresponding to maximum hydration.

The viscosities of water and the other five pure solvents were determined by five or more measurements each and were practically identical with the literature values reported for the carefully purified liquids at comparable temperatures. If the viscosities of the pure components are assumed to be free of experimental error, the standard deviation of $\Delta\eta$ is the same as that of $\eta_{12\ exp}$ according to Eq. 5. Since fluidity is the reciprocal of viscosity, the standard deviation of $\phi_{12\ exp}$ and $\Delta\phi$ is equal to the standard deviation of $\eta_{12\ exp}$ divided by the square of that viscosity (26).

Experimental errors in the viscosity and temperature measurements greatly affect the activation energy values. Points of ΔE *versus* x_2 plots were more widely scattered about the curves than those of the other two methods, and some published sets of η *versus* x_2 values at different temperatures could not be used due to lack of precision in the viscosity measurements.

The experimental errors in maintaining and measuring temperatures were small compared to those incurred in measuring viscosities. Since ΔE and T are exponential terms in Eq. 7 or, alternatively, since viscosity appears as a logarithmic term in Eqs. 8 and 9, the experimental errors in η affect ΔE less than would comparable errors in T (26). However, two

or more pairs of η, T measurements are required to determine each value of the dependent variable ΔE to eliminate the unknown preexponential factor A, which varies with composition. This requirement raises the standard deviation of ΔE substantially, increasing it above the standard deviations of $\Delta\phi$ and $\Delta\eta$.

Use of the activation energy for viscous flow to determine the composition of maximum association between two liquids thus requires a larger number of more accurate viscosity measurements than does use of the maximum deviation in fluidity or viscosity. The present values for x_2 of maximum hydration obtained from maxima in activation energies are only good to ±0.015. The greatest uncertainty is in the water–dimethyl sulfoxide and water–pyrrolidinone systems, where the curves have flat peaks.

STRUCTURAL CONSIDERATIONS

Possible structures for the most extensively hydrated species prevalent in the water–solvent systems are discussed here. The 3:1 hydration ratio found in the acetone and dimethyl sulfoxide systems is probably represented (5) by Structure I, where two water molecules are hydrogen bonded to the carbonyl or sulfoxide oxygen while a third water molecule is associated with the organic molecule by attraction between the negative end of its dipole and the positive end of the carbonyl or sulfoxide dipole.

IR studies (27) showed that carbonyl groups can bind two water molecules through their two lone electron pairs. Hydrogen bonding increases

II

the dipole moment of the carbonyl group, enhancing its binding of a third water molecule by dipole–dipole attraction.

The three aprotic solvents acetone, dimethyl sulfoxide, and dioxane can only act as proton acceptors in hydrogen bonding with water. The simple and integer hydration ratios of 3:1 for the carbonyl and sulfoxide groups and 2:1 for the ether group may be due to this fact. The high and fractional hydration ratio of propanol probably results because this solvent acts as a proton donor as well as acceptor, forming hydrogen-bonded clusters consisting, on the average, of 5.67 water molecules for each propanol molecule. Hydrophobic interaction (28) probably plays a role in forming such clusters—*viz.*, the structure of the water molecules surrounding the normal propyl chain is enhanced or tightened. Accordingly, such clusters may consist of water molecules hydrogen bonded to the hydroxyl group of propanol and other water molecules bunched around its hydrocarbon chain and hydrogen bonded to each other.

The following two experimental observations are consistent with the existence of such clusters and with the enhancement of the water structure around the propyl chain (3). In the homologous series of lower alcohols, the hydration ratio at 25° decreases with the hydrocarbon chain length of the alcohol, from 5.7 for 1-propanol to 4.0 for ethanol and 1.4 for methanol. For propanol, the hydration ratio or cluster size decreases with increasing temperature, being 5.7, 5.3, 4.9, and 4.6 at 25, 30, 40, and 50°, respectively. The hydration ratio of ethanol decreases merely from 4.0 to 3.7 while that of methanol remains practically constant, increasing from 1.4 to 1.5 between 25 and 50° (3). The effect of alkyl chain length on the hydration of monofunctional alcohols and aprotic solvents is under investigation.

The monohydrate of pyrrolidinone is probably represented chiefly by Structure II, where the hydrogen-bonded water molecule participates in a six-membered ring.

COMPARISON WITH OTHER METHODS

Other Viscometric Methods—Viscosity maxima for binary liquid mixtures have frequently been reported. For instance, the compilation of Raridon and Kraus (29) covered 39 aqueous mixtures of organic sol-

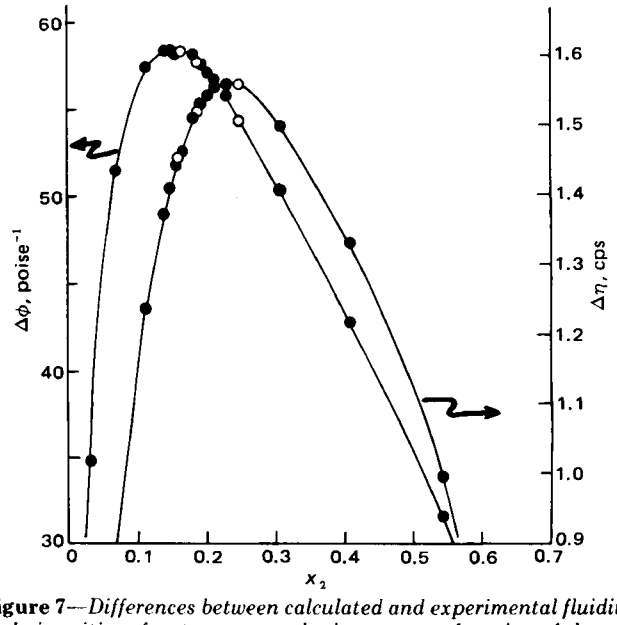

Figure 7—*Differences between calculated and experimental fluidities and viscosities of water–propanol mixtures as a function of the mole fraction,* x_2, *of propanol at 25°. Key:* ○, *Ref. 3; and* ●, *Ref. 24.*

vents at 25°. Viscosities were measured at only five compositions for each binary system, making the determination of the composition of maximum viscosity by interpolation uncertain. Their estimated x_2 values corresponding to maximum viscosity were 0.14 for acetone, 0.35 for dimethyl sulfoxide, 0.24 for dioxane, and 0.29 for propanol (29).

Viscosity maxima in binary solvent mixtures are of practical importance, *e.g.*, when using such mixtures as reaction media, but do not necessarily coincide with the maximum association between the two solvents. As was pointed out in several publications as early as 1913 and 1917, the most extensive association between two liquids, as well as the possible formation of stoichiometric complexes of the highest solvation number between them, occurs at the composition at which the *deviation* of the experimental viscosity function goes through a maximum rather than at the composition of the viscosity maximum (1, 7, 10, 14, 22). Furthermore, the choice of the correct viscosity function for calculating additive viscosities is important. This requirement was demonstrated in the present work by the discrepancies between the compositions of maximum deviation from experimental viscosities or fluidities calculated with the Kendall (Eq. 1) and Kendall–Monroe (Eq. 4) equations.

Despite these considerations, the maximum in the viscosity of water–dimethyl sulfoxide mixtures at approximately $x_2 = 0.35$ (20, 21, 30–32) has been attributed to a 2:1 association complex (20, 21, 30, 31).

The following are additional arguments against equating the composition of maximum viscosity with the composition of maximum association. With water–acetone mixtures, maximum viscosity at room temperature was reached at $x_2 = 0.14$ (19, 29). This composition would correspond to a hydration ratio of 6, which is improbable, because six water molecules cannot be in close contact with a single carbonyl group. In the water–pyrrolidinone system, the highest viscosity is that of pure pyrrolidinone; *i.e.*, there is no viscosity maximum at an intermediate composition. However, there is a pronounced association maximum at the composition of the monohydrate, signaled by a maximum in the deviation of the experimental viscosity from that calculated by Eq. 4 at $x_2 = 0.50$, which amounts to one-half of the experimental viscosity.

Fort and Moore (32) introduced a correction term into the Kendall equation (Eq. 1), changing it to:

$$\log \eta_{12\,\mathrm{exp}} = x_1 \log \eta_1 + x_2 \log \eta_2 + x_1 x_2 d \qquad \text{(Eq. 10)}$$

Comparison of Eq. 10 with Eq. 1 results in:

$$d = \frac{\log (\phi_{12\,\mathrm{calc}}/\phi_{12\,\mathrm{exp}})}{x_1 x_2} \qquad \text{(Eq. 11)}$$

They claimed that the empirical parameter d provides a useful measure of the interaction between pairs of liquids, reaching a maximum at the composition of strongest interaction (32). One shortcoming of their work is that only four mixtures were determined for each of the 14 binary systems, making the location of the composition corresponding to the maximum value of d for each system vague.

A more serious shortcoming is that the 14 pairs of liquids studied all had viscosities of the same order of magnitude. If the present data for the water–pyrrolidinone system are used to calculate d by Eq. 11, the maximum value of d is reached at a mole fraction of pyrrolidinone close to unity, corresponding to a hydration ratio close to zero. Thus, Fort and Moore's treatment has the same shortcoming as the Kendall equation, which it resembles. It fails for binary systems where one of the two components has an appreciably higher viscosity than the other. The only universal viscometric method for determining the composition of maximum association, applicable to pairs of liquids of widely differing as well as of comparable viscosities, is the one based on the activation energies of viscous flow described previously.

Other Transport Properties—Differential diffusion coefficients in the water–acetone system at 25° (33, 34), as well as at 35, 45, and 55° (33), went through minima at a mole fraction of acetone of about 0.25, confirming the maximum hydration ratio of 3:1 obtained by the viscometric methods. Relative deviation, in percent, is defined by equations analogous to Eqs. 5 and 6, with viscosity replaced by the differential diffusion coefficient. The relative deviations of the latter at the composition of maximum deviation were in the −200 to −300% range.

For the systems of deuterated water–dimethyl sulfoxide and water–deuterated dimethyl sulfoxide at 26°, self-diffusion measurements were made in x_2 increments of 0.1. Minima in the self-diffusion coefficients of water and of dimethyl sulfoxide were observed at a mole fraction of dimethyl sulfoxide of ~0.3. This composition could correspond either to the present 3:1 or to the lower 2:1 hydration ratio. The measurements were made by NMR, using a pulsed magnetic field-gradient spin-echo technique (35).

Compound Formation—The most direct corroboration for the maximum hydration ratio is the existence, on the binary phase diagram, of a solid hydrate with a congruent melting point stable at lower temperatures. In agreement with the present hydration ratios of 3:1 for dimethyl sulfoxide and 1:1 for pyrrolidinone, a solid trihydrate was isolated for the former (36) and a monohydrate was isolated for the latter (16). The other solvents form no stable solid hydrates (37).

Thermodynamic Parameters—When water is mixed with aprotic solvents, hydrogen bonds between water molecules are broken while hydrogen bonds between water and solvent molecules are formed. Hydrogen bonds of protonated solvents like propanol are broken as well. The enthalpy of mixing depends in part on the difference between the numbers and energies of these two or three kinds of hydrogen bonds. The breaking up of clusters of water molecules when adding solvent or of clusters of solvent molecules when adding water increases the entropy of mixing while the association between water and solvent molecules decreases it. The net entropy change of mixing depends in part on the difference between the numbers and sizes of these two or three types of clusters. Enthalpy and entropy of mixing thus depend on the difference between two opposite processes, and their variation with composition does not provide a good indication of the composition of maximum association between water and the solvent.

Dimethyl sulfoxide and acetone can bind only two water molecules by hydrogen bonding (Ref. 27 and below). The third water molecule is held by Keesom forces, which are considerably weaker than hydrogen bonds and are probably not detected in calorimetric measurements. This difference in bond energies is another reason why thermodynamic functions are not reliable parameters for determining the maximum hydration of solvents. Excess functions are used in the discussion here since they represent the magnitude of deviation from ideality.

The maximum hydration ratio of dioxane is 4:1, with two water molecules hydrogen bonded to each ether group (1, 8, and present results, Table II). The excess enthalpy of mixing goes through a minimum at a mole fraction of dioxane of 0.14 or 0.15 (37–39), which would correspond to a hydration ratio of 6.1 or 5.7:1, while the excess entropy of mixing goes through a minimum at $x_2 = 0.27$ (37). Excess enthalpy and entropy of mixing are thus at variance with one another and with previous and present results.

Mixing of water and dimethyl sulfoxide is noticeably exothermic. The excess enthalpy of mixing at 25° goes through a minimum at mole frac-

Table III—Maximum Deviations of Density and Dielectric Constant for Five Water–Solvent Systems

	Maximum Deviations According to									
	Density					Dielectric Constant				
Solvent	Temperature	x_2	Hydration Ratio[a]	Relative Deviation[b], %	Reference	Temperature	x_2	Hydration Ratio[a]	Relative Deviation[b], %	Reference
Acetone	20°	0.45	1.2	−4.3	18, 19, p[c]	25°	0.39	1.6	−49	58
Dimethyl sulfoxide	25°	0.30	2.3	+5.6	5	25°	0.25	3.0	+4.1	5, 59

	40°	0.31	2.2	+4.6	17, p	40°	0.50	1.0	−17	17

[a] Ratio water molecules to molecule solvent. [b] Calculated with equations analogous to Eqs. 5 and 6. [c] Present work.

tions of dimethyl sulfoxide of 0.34 (40, 41) or 0.36 (42), which would translate into hydration ratios of 1.9 or 1.8:1. The excess enthalpy of mixing in the water–acetone system at 20° goes through a minimum at a mole fraction of acetone of 0.18 (43). This composition would correspond to a hydration ratio of 4.6:1.

Heat capacities of liquid mixtures are perhaps more pertinent than enthalpies since they depend in part on the size of the clusters of associated molecules. The excess molal heat capacity at 25° goes through a maximum at a mole fraction of acetone of 0.24, corresponding to the present hydration ratio of 3:1. It is much smaller and nearly independent of composition in the water–dimethyl sulfoxide system (44). The cohesive energy density of binary mixtures depends in part on the extent of association since it represents the energy of vaporization per molar volume. The excess cohesive energy density at 25° goes through a maximum at a mole fraction of dimethyl sulfoxide of 0.25 (45), corresponding to the present hydration ratio of 3:1.

Spectroscopic Methods—The main difficulty in using absorption spectroscopy to determine the maximum hydration of organic solvents in binary mixtures with water is that spectroscopic methods are restricted almost exclusively to the strongest intermolecular bonds—*viz.*, hydrogen bonds. Dipole–dipole interactions between molecules have, in most cases, only minor effects on their IR, UV, Raman, and NMR spectra and usually go undetected. Additional reasons why spectroscopic methods are not well suited for determining maximum hydration are the frequent use of a third, "inert" solvent and the difficulty of proper band assignment.

The maximum hydration ratio of pyrrolidinone was identified correctly as unity from the IR spectra (46) because the attraction between water and pyrrolidinone is based mainly on hydrogen bonds. In the water–acetone system, a maximum of two water molecules can be bound to the carbonyl group by hydrogen bonds (27), which is to be expected in view of the fact that the carbonyl oxygen has two unshared electron pairs. IR (47–49), UV (49), and NMR (50) measurements have identified mainly water–acetone "complexes" of 1:1 and 1:2 molar ratios, in part because this was the range of compositions in which most spectra were investigated. Both 2:1 and 3:1 or 4:1 complexes were reported also, although it is difficult to reconcile the binding of more than two water molecules by hydrogen bonds to one carbonyl oxygen having two lone electron pairs. Water molecules bound to acetone by dipole–dipole forces (Structure I) could not have been detected by the spectroscopic techniques used in Refs. 47–50.

In the water–dimethyl sulfoxide system, IR (41, 51), UV (41), Raman (52, 53), and NMR (54) spectra have identified 2:1, 1:1, and 1:2 complexes. The third water molecule, bound to dimethyl sulfoxide by dipole–dipole forces (5, 36), cannot be disclosed by these spectroscopic techniques.

NMR relaxation techniques are better suited to determine maximum hydration because they depend largely on the size and symmetry of water–solvent clusters. The reorientation of these clusters or complexes is the most important motion in the relaxation process. In particular, excess nuclear spin-lattice relaxation times, T_1, reach a minimum and excess relaxation rates, $1/T_1$, reach a maximum at the composition corresponding to the maximum intermolecular association (55, 56). Use of mixtures of deuterated acetone with water and heavy water with acetone resulted in a maximum relaxation rate at 25° at a mole fraction of acetone of ~0.20 (55). Since the authors only studied compositions of $x_2 = 0.10$, 0.20, and 0.40 in the pertinent range, the maximum could equally well be located at $x_2 = 0.25$ but not as high as 0.33. Accordingly, the maximum hydration ratio of acetone lies between 4 and 2.7:1, a result compatible with the present 3.0:1 value. The use of excess functions might have shifted the x_2 value corresponding to maximum hydration.

The water–dimethyl sulfoxide system was investigated over narrower composition intervals. The absolute value of the excess relaxation time went through a maximum at a mole fraction of dimethyl sulfoxide of 0.25, leading the author to describe "compound formation" resulting in a 3:1 molecular complex (56). While this result does not preclude the existence of a 2:1 complex in mixtures of lower water content, the most highly hydrated complex has a 3:1 hydration ratio, in agreement with the present results. Other studies of proton spin-lattice plus spin-spin relaxation times over a range of temperatures found maxima in relaxation rates at a mole fraction of dimethyl sulfoxide of about 0.35 (57), but these authors used $1/T_1$. The use of excess relaxation rates would shift the maxima toward somewhat lower dimethyl sulfoxide mole fractions or higher hydration ratios.

Density—Compositions of maximum deviations and relative deviations of calculated from experimental densities for the five binary systems are summarized in Table III. Positive relative deviations indicate that experimental densities were higher than calculated densities, *i.e.*, that volume contractions occurred during mixing. In aqueous mixtures of acetone and propanol, experimental densities were actually smaller than those calculated. The absolute values of the relative deviations are small, ranging from 3 to 6%.

If the compositions of maximum density deviation corresponded to maximum hydration ratios, these would be quite different from the ratios obtained by viscometry. However, excess densities do not necessarily reach maxima at the composition of most extensive association for the following reason. When two highly structured liquids like water, propanol, or pyrrolidinone are mixed, the structures of both liquids are broken up and new structures or association complexes are formed. Even acetone and dioxane, which have little structure of their own in the pure state,

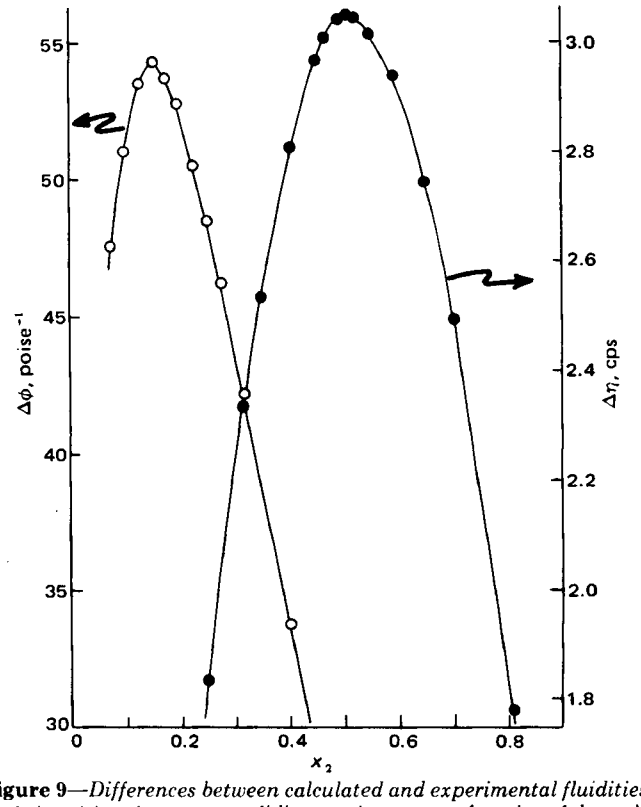

Figure 9—*Differences between calculated and experimental fluidities and viscosities of water–pyrrolidinone mixtures as a function of the mole fraction,* x_2, *of pyrrolidinone at 37°. Key:* ○, $\Delta\phi$; *and* ●, $\Delta\eta$.

are effective in breaking up the structure of water in aqueous mixtures. Calculated densities depend on the density and, hence, on the short-range order and structure in pure water and in the second pure liquid. These properties of one pure liquid are unrelated to corresponding properties of the second pure liquid and of the clusters formed by association between the two. A highly structured liquid like propanol and a liquid with little association like acetone both caused monotonic decreases in density when mixed with water while aqueous mixtures of the nonpolar dioxane had a density maximum at an intermediate composition. Therefore, excess density does not constitute a suitable property for determining the composition of maximum association, contrary to what had been assumed by the author (15).

Dielectric Constants—Deviations of experimental dielectric constants from those interpolated according to equations analogous to Eqs. 5 and 6 were calculated from literature data for the five aqueous systems. Compositions corresponding to the maximum deviations, hydration ratios corresponding to these compositions, and relative deviations are listed in Table III. Hydration ratios agree with those obtained from the viscometric methods in the cases of dimethyl sulfoxide and pyrrolidinone. However, in the former system, the experimental dielectric constants were higher than those calculated for the corresponding compositions, resulting in positive relative deviations; in the latter system and in the other three, the calculated dielectric constants were higher than the corresponding experimental values.

Pure propanol and, presumably, liquid pyrrolidinone as well have high values for the Kirkwood correlation factor (62). Those of the aprotic solvents acetone and dimethyl sulfoxide are low, namely, close to unity, while dioxane has a zero dipole moment (62). When added to water in low concentrations, propanol, acetone, and dioxane decrease the dielectric constant of water. In the water–acetone and water–dioxane systems, the correlation factors (62) and the experimental dielectric constants (58, 60, 61) decrease monotonically with increasing mole fraction of the organic component over the entire range of compositions. The addition of water to propanol and of propanol to water break their respective structures, and the correlation factor of the mixtures reaches a minimum around $x_2 = 0.5$ (62). Surprisingly, the experimental dielectric constants of water–propanol (58) and water–pyrrolidinone (17) mixtures decrease monotonically with increasing x_2 over the entire range of compositions.

The case of dimethyl sulfoxide is even more puzzling since its aqueous mixtures constitute the only one of the five systems studied in which experimental dielectric constants are larger than the corresponding calculated values. The cause for the high dielectric constant of pure dimethyl sulfoxide (46.4 at 25° from Ref. 59) is poorly understood (63). Therefore, it seems useless to speculate on why the deviations of the dielectric constants are positive in the water–dimethyl sulfoxide system and negative in the other four systems. The agreement between the compositions corresponding to a maximum positive deviation in the dimethyl sulfoxide mixtures and a maximum negative deviation in the pyrrolidinone mixtures and the compositions of maximum hydration obtained by the viscometric methods may be fortuitous. Until the theory for dielectric constants of aqueous solutions of nonelectrolytes is better understood (62), it seems preferable not to use the excess dielectric constants of such mixtures for determining the composition of maximum hydration.

Miscellaneous Methods—Ultrasonic velocity in water–dimethyl sulfoxide mixtures reaches a maximum at a mole fraction of dimethyl sulfoxide of 0.27 at 20° (64). The excess velocity, *i.e.*, the deviation of the experimental velocity from the velocity calculated by equations analogous to Eqs. 5 and 6, reaches a maximum at $x_2 = 0.25$. The maximum relative deviation, which occurs at that composition, amounts to 16%.

The adiabatic compressibility at 20°, calculated as the reciprocal of the product of density and the square of the sound velocity, goes through a minimum at $x_2 = 0.27$ (64). The excess adiabatic compressibility goes through a minimum at a slightly lower x_2 value. The relative deviation reaches a maximum value of −42% at that composition. The excess compressibility of a mixture is expected to reach a minimum and the excess sound velocity is expected to reach a maximum at the composition at which the intermolecular association is most extensive. Therefore, these data confirm the present hydration ratio of 3:1.

The solubility of hydrogen at 25° and a constant partial pressure of 1 atm in water–dimethyl sulfoxide mixtures goes through a minimum at a mole fraction of dimethyl sulfoxide of about 0.28 (65). Since solubilities were measured in mole fraction increments of 0.2, the minimum could be located equally well at $x_2 = 0.25$ or 0.33, corresponding to hydration ratios of 3:1 or 2:1. The hydrogen molecule, as a small and nonpolar probe, should cause only minimal disturbance of the association clusters between water and dimethyl sulfoxide molecules, so the minimum solubility should occur at the composition of maximum association. Symons (65) interprets his measurements in terms of an equilibrium between a 3:1 and a 2:1 water–dimethyl sulfoxide complex. His maximum hydration of 3:1 is in agreement with the present findings.

The reason why excess molar refraction is not suitable for determining the composition of maximum hydration is given in Ref. 5.

CONCLUSION

The composition at which water and the second liquid component are most extensively associated is marked by a minimum or maximum in an excess property of the binary mixture that expresses the difference between the experimental and the calculated values of this property rather than by a minimum or maximum in the experimental value of the property. Excess enthalpy and entropy of mixing as well as absorption spectroscopy methods only detect intermolecular association by hydrogen bonding but not by dipole–dipole attraction. When the two components interact mainly by hydrogen bonding, as in the water–pyrrolidinone system, maximum hydration ratios obtained from excess thermodynamic functions or by absorption spectroscopy agree with those obtained by viscometric methods. When additional water molecules are bound by dipole forces, spectroscopic methods result in erroneously low maximum hydration ratios comprising only hydrogen-bonded water molecules. This is the case with the water–dimethyl sulfoxide and water–acetone systems, where absorption spectra and thermodynamic excess functions identified the 2:1 hydrogen-bonded complex as possessing the highest hydration ratio, whereas transport and relaxation methods revealed the existence of the 3:1 complex.

Relaxation methods that depend on the size of the clusters or complexes give maximum hydration ratios in good agreement with viscometric methods. Since all transport properties depend on cluster size, they result in identical maximum hydration ratios when properly interpreted. These hydration ratios are relevant to chemical and biological processes affected by the solvation of functional groups.

The most direct validation of the hydration ratios determined by viscometric methods is that they agreed with the composition of solid hydrates stable at lower temperatures in the two instances where such solid hydrates exist. For instance, the fact that a solid dimethyl sulfoxide trihydrate was found demonstrates that dimethyl sulfoxide possesses the bonding capacity and geometric requirements to bind three water molecules. Any method producing a hydration ratio of <3:1 as the *maximum* ratio is in error.

The use of the activation energy for viscous flow of binary mixtures to determine the composition of maximum association requires a greater number and more accurate viscosity measurements than the use of isothermal viscosities or fluidities. By comparison with the other suitable methods already discussed, viscometric techniques require less elaborate equipment that is easier to operate, have comparable or better reproducibility, and result in relative deviations that are as large or larger.

APPENDIX: VARIATION IN SELF-ASSOCIATION OF LIQUID WATER WITH TEMPERATURE DETERMINED FROM TEMPERATURE DEPENDENCE OF ACTIVATION ENERGY FOR VISCOUS FLOW

In this section, the variation of the activation energy for viscous flow of water with temperature is used to provide a relative estimate of the degree of self-association in the pure liquid as a function of temperature. The activation energy of water, unlike that of most liquids, depends markedly on temperature because of an exceptionally extensive self-association (66–68).

The activation energies for viscous flow at constant volume of nonassociated liquids are small and independent of temperature. The experimental activation energies, ΔE, measured at constant pressure and defined by Eqs. 7–9 vary with temperature to the same limited extent as do the specific volumes and, hence, the free space or volume of the holes in these liquids (11, 13, 69). For associated liquids, the size of the holes and, therefore, the viscosities and activation energies for viscous flow are larger than for nonassociated liquids of comparable molecular size because the flow units are larger.

The degree of association decreases with increasing temperature. Since the activation energy for viscous flow is primarily expended in creating the holes or vacant sites required for flow, it too should decrease with increasing temperature. The activation energy is proportional to the size of a hole which, in turn, is proportional to the size of a flow unit and the degree of association. Therefore, any decrease of the latter with increasing

Table IV—Activation Energy for Viscous Flow, Slope of the ΔE *versus* Temperature Curve, and Median Cluster Size for Liquid Water

100°	2.9		4.5[c]

[a] Median cluster size [b] From Ref. 68. [c] Calculated by Eq. 12.

temperature should be reflected in a comparable decrease in the activation energy. The variation of the activation energy with temperature can, therefore, be used as a measure of the variation in the degree of association of the liquid with temperature.

Three sets of data for the viscosity of water at 1 atm from 0 to 100° in increments of 5° are reported in the literature (66, 70). The activation energies for viscous flow derived from the three sets are in good agreement up to 70°. Table IV lists the best values of ΔE as a function of temperature and the values of the slope of the ΔE *versus* temperature curve, $\Delta(\Delta E)/\Delta T$, in kcal/mole/°K. As shown, ΔE decreases fast with increasing temperature near the melting point where the association of water molecules is extensive and, consequently, the reduction in association per degree temperature increase is appreciable. This reduction and the slope of the ΔE *versus* temperature curve level off as the temperature approaches the normal boiling point. Considering the association in liquid water in the range between its freezing point and normal boiling point, over half of the association disappears between 0 and 20° because over half of the drop in ΔE occurs over that temperature range.

The extensive dissociation of clusters of associated water molecules over a relatively narrow temperature interval above the melting point of ice is confirmed qualitatively by several techniques. Most of the investigations dealing with self-association in water are based on spectroscopic methods and provide estimates mainly for the fraction of unbonded and hydrogen-bonded protons. The various results differ considerably (51).

In a statistical thermodynamic treatment, water was assumed to consist of clusters in equilibrium having a continuous size distribution. The median cluster size, j, was calculated from partition functions and found to decrease with increasing temperature (68). These values of j, estimated between 0 and 60°, are included in Table IV. The following linear relation between ΔE and j is obtained from the tabulated data, with a correlation coefficient of 0.9995:

$$j = -2.884 + 2.555\,\Delta E \qquad \text{(Eq. A1)}$$

The close correlation between cluster size and activation energy for viscous flow corroborates the use of the latter in estimating the relative size of the flow unit and its variation with temperature for pure, extensively associated liquids like water.

Spectra of Radical Cations of Phenothiazine Derivatives in Solution and Solid State

A. ORTIZ, A. PARDO, and J. I. FERNÁNDEZ-ALONSO ˣ

Received July 21, 1978, from the *Departamento de Química Física y Química Cuántica, Centro Coordinado CSIC-UAM, Facultad de Ciencias C-XIV, Cantoblanco, Madrid 34, Spain.* Accepted for publication October 1, 1979.

Abstract □ The UV and visible spectra of radical cations of several phenothiazine derivatives were studied using different solvents. The establishment of a relationship between these bands and the R_2 and R_{10} substituents was attempted. The influence of the disolvents on the bands also was studied. The characteristic charge transfer band was observed in the solid state using diffuse reflectance spectroscopy. The R_2 substituent did not appear to influence the band, while the R_{10} substituent influenced the band considerably, probably due to steric effects.

Keyphrases □ Phenothiazine—derivatives, spectra in solution and solid state, effect of R_2 and R_{10} substituents □ Psychotropic drugs—phenothiazine derivatives, spectra in solution and solid state, effect of R_2 and R_{10} substituents □ Spectroscopy—UV and visible spectra of phenothiazine derivatives, solution and solid state

Psychotropic drugs are fundamental in the treatment of mental disorders. Increased knowledge of the physicochemical properties of these products would help in understanding their interaction with live organisms.

One important property of these drugs is that they are oxidized easily (1). The idea that phenothiazines could act in humans in an oxidized form (2) was supported by the fact that several oxidized compounds are observed in the degradation products (3). This paper describes a study of the oxidized form of these phenothiazine derivatives in solution and in the solid state.

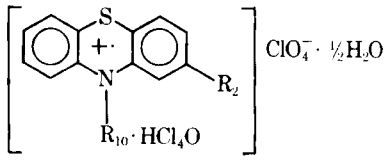
An attempt was made to relate the derivatives according to their R_2 and R_{10} substituents, semiconductor properties, dissociation constants (4), and ability to form complexes (5). The phenothiazine derivative cation radicals were prepared in a solid state, and their diffuse reflectance spectra were studied. The UV and visible spectra of these radicals in solution also were studied.

EXPERIMENTAL

Materials—Phenothiazine derivatives with R_2 and R_{10} substituents were used (Table I). The products were pharmacologically pure and were used as supplied commercially. Perchloric acid (70%) and potassium dichromate were the oxidizing agents. The solvents were distilled water, acetonitrile, and sulfuric acid (2 and 9 *N*).

A UV–visible spectrophotometer was used to obtain the solution spectra; for the diffuse reflectance spectra, the corresponding attachment was used.

Method—A literature method (6) was used to obtain the cation radicals in the solid state. The proposed formula for these products is (6):



The melting points of the products ranged from 175 to 223°. The radicals rapidly dissolved in all of the solvents used. An intense color appeared, corresponding to the oxidized form. The radicals remained indefinitely stable only with 9 *N* H_2SO_4 due to its high acidity.

The formation of charge transfer complexes in the solid state was studied by diffuse reflectance spectroscopy. Tablet preparation was the same as that used for the IR method except that naphthalene (7) was the solvent.

RESULTS

Solutions were prepared from polycrystalline powder of the cation radicals in 9 *N* H_2SO_4. Table II gives the wavelengths corresponding to the absorption peaks of the radicals in 9 *N* H_2SO_4, both in the visible and the UV range (Fig. 1). The reference used to study the effect of the substituents was promazine.

UV Spectra—The UV spectra of derivatives with a constant R_2 substituent and various R_{10} substituents were studied. Derivatives with R_2 = H and various R_{10} substituents (I–V) showed no change from the reference spectrum. This observation showed that the R_{10} substituent does not influence the UV electron transitions. In derivatives with R_2 = Cl and various R_{10} substituents, the R_2 substituent caused a bathochromic shift of 4 nm throughout the spectrum (Table II). The second peak in the spectra of derivatives with R_2 = CF_3 and various R_{10} substituents disappeared.

Derivatives with a constant R_{10} substituent and various R_2 substituents were considered. The effect of the R_2 substituent was observed in the promazine (I and VI–VIII) and perazine (V and X–XIII) families (Table II). The chlorine derivatives featured a 4-nm bathochromic shift in all bands. The other substituents caused more pronounced shifts throughout the spectrum, together with the disappearance of the second peak [derivatives with R_2 = OCH_3 or $SO_2N(CH_3)_2$].

Table I—Products and Their Characteristics

	Product	R_2	R_{10}	Salt	Clinical Use
I	Promazine[a]	H	$(CH_2)_3N(CH_3)_2$	HCl	Tranquilizer
II	Trimeprazine[b]	H	$CH_2CHCH_2N(CH_3)_2$ | CH_3	Tartrate	Antipruritic
III	Ethopropazine[b]	H	$CH_2CHN(CH_2CH_3)_2$ | CH_3	HCl	Antiparkinsonian, anticholinergic
IV	Diethazine[b]	H	$(CH_2)_2N(CH_2CH_3)_2$	HCl	Antiparkinsonian, anticholinergic
V	Perazine[c]	H		HCl	Tranquilizer
VI	Chlorpromazine[b]	Cl	$(CH_2)_3N(CH_3)_2$	HCl	Tranquilizer
VII	Triflupromazine[d]	CF_3	$(CH_2)_3N(CH_3)_2$	HCl	Tranquilizer
VIII	Methoxypromazine[b]	OCH_3	$(CH_2)_3N(CH_3)_2$	Maleate	Tranquilizer
IX	Methotrimeprazine[b]	OCH_3	$CH_2CHCH_2N(CH_3)_2$ | CH_3	Maleate	Analgesic
X	Prochlorperazine[e]	Cl		HCl	Tranquilizer
XI	Trifluoperazine[d]	CF_3		2 HCl	Tranquilizer
XII	Thiethylperazine[f]	SCH_2CH_3		Dimaleate	Antiemetic
XIII	Thioproperazine[b]	$SO_2N(CH_3)_2$		Maleate	Tranquilizer
XIV	Perphenazine[g]	Cl		HCl	Tranquilizer
XV	Fluphenazine[a]	CF_3		2 HCl	Tranquilizer
XVI	Properiziazine	CN		Base	—
XVII	Thioridazine[h]	SCH_3		HCl	Tranquilizer

[a] Rhodia. [b] Specia. [c] Promonta. [d] Squibb. [e] Upjohn. [f] Sandoz. [g] Schering USA. [h] Bayer.

In derivatives where $R_2 = CF_3$, no shift was produced in the bands compared to the same derivatives with $R_2 = H$, but the second peak disappeared.

For derivatives where $R_2 = SCH_3$ or SC_2H_5, an intense bathochromic shift was present in the first peak, the second peak remained at 265 nm, and a transition peak appeared (245–228 nm) that seemed to represent a vibratory structure. This transition could have been caused by the sulfur atom in the substituent [the same bands also appeared at the same wavelengths in the spectra of identical neutral products (8)].

Visible Spectra—The influence of the R_2 substituent on the first band was studied.

For the molecular series of I and VI–VIII, the results in Table II indicate that the substituents caused bathochromic shifts except for $R_2 = CF_3$, where a hypsochromic effect existed in the first band. The same shift occurred with the perazine-derived molecules (V and X–XIII).

The effect of the R_{10} substituent in the first band of the visible zone was observed in I–V. The values in Table II for these compounds show that not only the reduction in the number of carbons between the two nitrogens of the alkyl chain and of the nucleus, but also the introduction of substituents in the chain, produced small bathochromic shifts.

For the second and third bands, where a vibratory structure appeared to exist, the R_{10} substituent produced bathochromic effects. Contrary to the case with the first band, the R_2 substituent did not exert such a pronounced effect as the R_{10} substituent (5).

Analysis of Spectra with Different Solvents—A comparison of spectra using different solvents showed that the characteristic bands did not undergo any change. As a result, it was deduced that a difference in the polarity of the solvent did not produce a shift in the bands assigned to these compounds. It follows that the transition cannot be of the $n-\pi$ type where any influence of the solvent polarity would be pronounced. Therefore, these bands correspond to $\pi-\pi^*$ transitions (with the exception of the SR type, which was not studied).

The bathochromic shifts could have been produced by an instability in the fundamental state caused by the substituent and possible stability in the excited state. Where bands remained unaltered, it was assumed that the substituents did not interact with the π-structure of the ring. It is difficult to explain the effect of certain substituents, such as OCH_3 and CF_3, which caused the disappearance of some bands. The influence

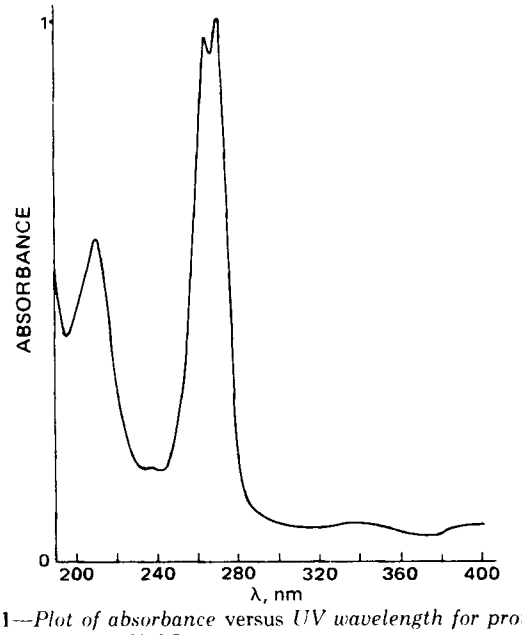

Figure 1—*Plot of absorbance* versus *UV wavelength for promazine radical cation in 9* N H_2SO_4.

of the R_{10} substituent appears on the electronic transition of the lowest energy transitions (with vibrational structure) in the visible range. This fact was attributed to the effect of the R_{10} interaction on the vibrational states.

Solid-State Spectra of Cation Radicals—The diffuse reflection spectra contained one band at 500 nm and another very wide band of equal intensity at 600–1200 nm. There were no other transitions in the field until 2000 nm.

A comparison was made with the visible spectrum of a cation radical in solution (curve e, Fig. 2). The location of the first band corresponded with the spectrum of the same radical in solution (515 nm), although it was slightly displaced toward the blue zone. These transitions of the monomer were affected by the field of the other cations and caused a shift in the π–π^* bands. The second band, wide and equal in intensity to the first band, was attributed to a charge transfer transition and appeared to superimpose on the electronic transition of the monomer in solution that appeared at 750–870 nm. This band exhibited the typical characteristics of a charge transfer; it was wide and without defined maxima.

To study the influence of the R_{10} substituent, I, II, IV, and V were considered (Fig. 2). If the maximum of this band is considered to be ~1000 nm, the promazine and perazine maxima were shifted toward the blue zone while the maxima of trimeprazine and diethazine were shifted toward the red zone.

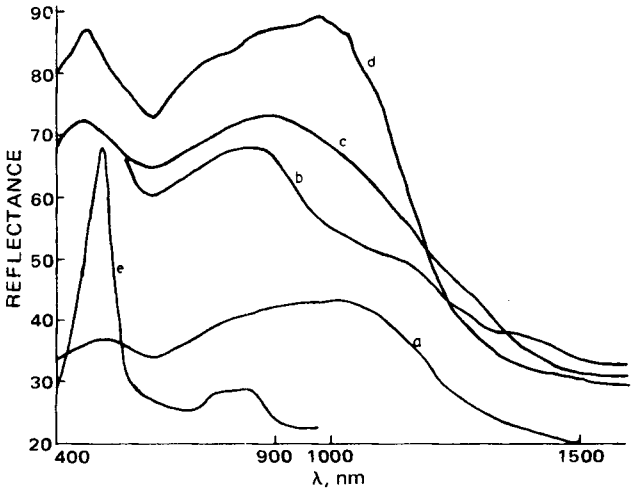

Figure 2—*Solid-state reflectance spectra of radical cations* (*reflectance* versus λ). *Key: a, diethazine; b, promazine; c, perazine; and d, trimeprazine. The visible spectrum of the perazine radical cation in sulfuric acid also is shown (e).*

Study of the influence of the R_2 substituent in the perazine family showed that the absorption peak varied slightly from 900 nm. Therefore, the R_{10} lateral chain appears to exert a greater effect than the R_2 substituents in the solid state. The influence of the R_{10} chain could be due to steric effects. This steric effect is augmented by an increase in the chain length and the different configurations that may result. This chain could insert itself between two radicals in the same column and the separation between them would increase, thus diminishing the possibility of a charge transfer and shifting the maximum toward the blue zone. Magnetic susceptibility studies could be conducted to verify this supposition. Promazine and perazine compounds should exhibit greater paramagnetism than the trimeprazine and diethazine compounds[1].

The transition was attributed to a charge transfer in the solid state and is thought to be caused through those ion radicals that are sufficiently close to overlap their half-complete π-orbitals.

Phenothiazine and its derivatives in neutral form are puckered by the heteroatoms (9).

In phenothazine oxidation, the positive charge is distributed throughout the nucleus, and the phenothiazine ion subsequently has to adopt a plane spatial structure for stability. On the other hand, it was concluded from electron–proton resonance studies (10, 11) that the positive charge is centered on the hetero ring. A definitive solution could be achieved by an X-ray diffraction study of these ions in the solid state. These ions could be in the form of infinitely long columns (12); this type of structure has been proposed for several ion salts (13).

The columns are believed to be formed by equidistant ion radicals (14). The separation of these ion radicals within the same column also could be studied by X-ray analysis. The columnar structure and the interplanar distance between the ions comprising the column can lead to charge transfer complexes. Here, the bond can be described as being formed by the overlap of half-complete π-orbitals of a donor molecule, *D*, and an acceptor, *A*. In this case, *A* and *D* are equal, and it follows that each molecule participates in the formation of overlapping orbitals. With two identical radicals, greatest interaction would take place when the two ions are superimposed.

The existence of distinct substituents capable of producing a large steric effect when interposed between two radicals of the same column appeared to have a marked influence on the packing distance of the cation derivatives in this study.

The apparent opposition that exists between the formation of solid structures with the participation of charge transfer bonding forces and the existence of unpaired electrons of these ion radicals, which in turn exhibit semiconductor properties associated with the unpaired electrons (15), should be considered. Likewise, the decrease in paramagnetic properties as a result of charge transfer interactions should be noted.

Antifungal Properties of n-Alkanols, α,ω-n-Alkanediols, and ω-Chloro-α-alkanols

HERMAN GERSHON [x] **and LARRY SHANKS**

Received March 6, 1979, from the *Boyce Thompson Institute, Cornell University, Ithaca, NY 14853.* Accepted for publication October 22, 1979.

Abstract □ Fourteen n-alkanols (C_1–C_{12}, C_{14}, and C_{16}), 13 α,ω-n-alkanediols (C_2–C_{12}, C_{14}, and C_{16}), and 13 ω-chloro-α-alkanols (C_2–C_{12}, C_{14}, and C_{16}) were tested against *Aspergillus niger*, *Trichoderma viride*, and *Myrothecium verrucaria* in Sabouraud dextrose agar at pH 4.0 and 5.6. Toxicity to *Candida albicans*, *Trichophyton mentagrophytes*, and *Mucor mucedo* was determined in the same medium at pH 5.6 and 7.0 in the absence and presence of 10% beef serum. The fungitoxicity of these alcohols was influenced by chain length and insignificantly by the pH of the medium and the presence of beef serum. The C_{10}-member of each series was most active; the order of activity of the three groups was chloroalkanols > alkanols > alkanediols. Compared to the fatty acids, the order of fungitoxicity on a weight basis was 2-alkynoic acids > 2-alkenoic acids > ω-chloroalkanols > alkanoic acids > 2-bromoalkanoic acids > 2-fluoroalkanoic acids > n-alkoxyacetic acids > n-alkanols > α,ω-n-alkanediols.

Keyphrases □ Antifungal activity—n-alkanols, α,ω-n-alkanediols, and ω-chloro-α-alkanols, *in vitro*, effect of chain length, pH, and adsorbents □ Structure–activity relationships—n-alkanols, α,ω-n-alkanediols, and ω-chloro-α-alkanols, antifungal activity, *in vitro*, effect of chain length □ n-Alkanols—antifungal activity, *in vitro*, effect of chain length, pH, and adsorbents □ α,ω-n-Alkanediols—antifungal activity, *in vitro*, effect of chain length, pH, and adsorbents □ ω-Chloro-α-alkanols—antifungal activity, *in vitro*, effect of chain length, pH, and adsorbents

In the examination in these laboratories of the effect of structural modification on the antifungal activity of fatty acids, systematic studies were made on the fungitoxicity of alkanoic acids (1), 2-alkenoic acids (2), 2-alkynoic acids (3), 2-fluoroalkanoic acids (1), 2-bromoalkanoic acids (2), α,ω-alkanedicarboxylic acids (4), and alkoxyacetic acids (5). Two major factors that influence the fungitoxicity of fatty acids are the partition coefficient and the absence or presence of adsorbents such as albumin in the growth medium. Among the factors that determine the partition coefficient are chain length, pKa, and pH of the medium (3).

BACKGROUND

It was established that the intact carboxyl group was not essential for fungitoxicity. The alkyl carboxamides were less toxic than the carboxylic acids at pH 4.0 but were equally toxic at pH 5.6. The pH of the medium had little effect on the activity of the amides, but beef serum had a deactivating effect on both the acids and amides. Chain length was a determining factor for the toxicity of the amides as well as the acids (6).

Esters were reported to be markedly less fungitoxic than the acids (7). This finding was confirmed for the methyl esters of the alkanoic and 2-fluoroalkanoic acids (8) and 2-alkynoic acids (3). An exception to these observations was that *Trichophyton mentagrophytes* was inhibited equally by the esters and free acids. The pH of the medium and the absence or presence of beef serum in the medium did not greatly affect the toxicity of the esters to the fungus.

The antifungal activity of nonionizing compounds is affected only slightly by the pH of the medium. The serum effect on fatty acids, amides, and esters can be rationalized on the basis of hydrogen bonding. Compounds containing carboxyl and carboxamide functions are bound more strongly by beef serum because they possess both donor hydrogen atoms and acceptor oxygen atoms, whereas the esters possess only acceptor oxygen atoms (9).

The purpose of the present study was to examine the fungitoxic action of the n-alkanols, α,ω-n-alkanediols, and ω-chloro-α-alkanols. These nonionizing compounds would not be expected to undergo strong hydrogen bonding with adsorbents.

It was reported previously that the wood-destroying fungus, Madison 517 on an agar malt extract medium, was inhibited by n-alkanols. n-Decanol was the most inhibitory of the series (10). The same effect was observed for *Penicillium glaucum* in an inorganic medium containing sucrose or lactose as the carbon source (11). This observation was confirmed in agar media, but n-dodecanol was the most effective alcohol for the protection of wood (12). No systematic studies of the α,ω-n-alkanediols or ω-chloro-α-alkanols have been reported.

The present work concerns the *in vitro* testing of 14 n-alkanols (C_1–C_{12}, C_{14}, and C_{16}), 13 α,ω-n-alkanediols (C_2–C_{12}, C_{14}, and C_{16}), and 13 ω-chloro-α-alkanols (C_2–C_{12}, C_{14}, and C_{16}) against *Aspergillus niger*, *Trichoderma viride*, and *Myrothecium verrucaria* in Sabouraud dextrose agar at pH 4.0 and 5.6. *Candida albicans*, *T. mentagrophytes*, and *Mucor mucedo* also were tested in the same medium at pH 5.6 and 7.0 in the absence or presence of 10% beef serum. Also included in these tests were 11-bromo-1-undecanol for comparison of analogous chloro and bromo compounds and 1,6-dichlorohexane and 1,9-dichlorononane for comparisons with the corresponding chloroalkanols.

EXPERIMENTAL

Some compounds were obtained from commercial sources[1]. The ω-chloroalkanols [C_5 and C_7–C_{10} (13), C_{11} (14), and C_{12}, C_{14}, and C_{16} (15)] were prepared by published methods.

The test fungi included *A. niger* (ATCC 1004), *T. viride* (ATCC 8678), *M. verrucaria* (ATCC 9095C), *C. albicans* (ATCC 10231), *T. mentagrophytes* (ATCC 9129), and *M. mucedo* (ATCC 7941).

The compounds were tested against *A. niger*, *T. viride*, and *M. verrucari* in Sabouraud dextrose agar[2] at pH 4.0 and 5.6 according to published methods (1). Graded levels of test compound dissolved in dimethyl sulfoxide (I) were incorporated into the growth medium, which then was inoculated with the respective fungus. The inoculum consisted of 1 drop of spore suspension delivered from a 5-ml Mohr pipet containing 6×10^6 spores/ml in 0.85% NaCl solution. Incubation took place at 28° for 5 days.

For *T. mentagrophytes*, *C. albicans*, and *M. mucedo*, the methods described previously were used (16). Graded levels of test compounds dissolved in I were added to Sabouraud dextrose agar at pH 5.6 and 7.0 alone and supplemented with 10% beef serum[3]. The inocula of *T. mentagrophytes* and *M. mucedo* consisted of 1 drop of spore suspension containing 6×10^6 spores/ml, and the inoculum of *C. albicans* was 1 drop of a suspension obtained from a 20-hr culture in Sabouraud dextrose broth[2] incubated at 37°. The test plates with *T. mentagrophytes* were incubated at 28° for 5 days, and those with *C. albicans* and *M. mucedo* were incubated at 37° for 20 hr.

The results reported are the number of levels of compounds causing 100% inhibition of the test organisms. The compounds were tested at 10^4, 10^3, and 10^2 μg/ml. All tests were carried out in I-plate petri dishes[4].

The results were weighted by calculating the antifungal spectrum index, defined as the sum of the number of levels of complete inhibition multiplied by the number of organisms inhibited within the defined system (17, 18).

[1] The C_1-, C_3–C_{12}-, C_{14}-, C_{16}-, and C_{18}-alkanols, the C_2–C_{12}- and C_{16}-α,ω-alkanediols, and 3-chloro-1-propanol, 6-chloro-1-hexanol, 11-bromo-1-undecanol, 1,6-dichlorohexane, and 1,9-dichlorononane were obtained from Aldrich Chemical Co., Milwaukee, Wis. The C_2-alkanol was obtained from U.S. Industrial Chemicals Co., New York, N.Y. The C_{14}-α,ω-alkanediol was obtained from Eastman Kodak Co., Rochester, N.Y. 2-Chloro-1-ethanol and 4-chloro-1-butanol were obtained from Matheson, Coleman and Bell, Norwood, Ohio.

[a] Compounds were incorporated in the test medium at 10^4, 10^3, and 10^2 μg/ml. Key to inhibition levels: 3 = inhibition at all levels of the compound, 2 = inhibition at the two highest levels, 1 = inhibition at the highest level only, and 0 = compound inactive at the highest level tested. [b] Number of methylene groups in the chain. [c] Sum of the number of levels of inhibition multiplied by the number of organisms inhibited.

RESULTS

The results of the tests of the *n*-alkanols, α,ω-*n*-alkanediols, and ω-chloro-α-alkanols against *A. niger*, *T. viride*, and *M. verrucaria* are given in Table I; the results of the tests against *C. albicans*, *T. mentagrophytes*, and *M. mucedo* are given in Table II.

A comparison of the fungitoxicity of the alkanols based on the combined antifungal spectrum indexes at pH 4.0 and 5.6 (Table I) reveals that the homologs of chain length C_5–C_{12} were most active against *A. niger*, *T. viride*, and *M. verrucaria*. The order of activity of the compounds tested was $C_{10} > C_{11} > C_9 > C_{12} > C_8 = C_7 = C_6 = C_5 > C_4 > C_3 = C_2$. Similarly, for the alkanediols, the most active members of the series were the C_7–C_{11}-compounds; the order of activity was $C_{10} > C_9 > C_{11} = C_8 > C_7$. For the ω-chloro-α-alkanols, the most fungitoxic compounds were between C_8 and C_{14}; the order of activity was $C_{10} = C_9 > C_{11} > C_8 = C_7 > C_6 > C_{12} > C_5 = C_4 = C_3 > C_{14} > C_2$. Varying the pH between 4.0 and 5.6 did not affect the fungitoxicity of the three classes of compounds significantly.

The most fungitoxic alkanols against *C. albicans*, *T. mentagrophytes*, and *M. mucedo* were the C_5–C_{12}-compounds; the overall order of toxicity was $C_{11} = C_{10} > C_{12} > C_9 = C_8 > C_7 > C_6 = C_5 > C_4 > C_{14} = C_3$. For the alkanediols, the C_7–C_{12}-compounds were the most toxic; the order of toxicity was $C_{10} > C_{11} > C_9 = C_8 = C_7 > C_{12}$. The chloroalkanols were most fungitoxic at chain lengths between C_2 and C_{11} in the order $C_{10} = C_9 > C_{11} = C_8 = C_7 > C_6 = C_5 = C_2 > C_4 = C_3 > C_{12}$. Raising the pH from 5.6 to 7.0 and adding beef serum to the growth medium caused no significant deactivation of the antifungal activity of the three classes of compounds.

11-Bromo-1-undecanol was less fungitoxic than the analogous alkanol, chloroalkanol, and alkanediol. 1,6-Dichlorohexane and 1,9-dichlorononane were markedly less toxic than the analogous alkanols, chloroalkanols, and alkanediols, with the 6-carbon compound being more active than the 9-carbon compound.

DISCUSSION

It is apparent (Tables I and II) that the chain length influences antifungal activity in each homologous series of compounds. A chain length of 10 carbon atoms seems to be optimal for maximal fungitoxicity. This result was observed previously for the alkanols (10–12). The relationship between the chain length and the partition coefficient with respect to the antifungal activity of fatty acids was discussed previously (3). This constant was employed in the application of regression analysis to fungitoxicity (19).

Table II—Antifungal Activity of *n*-Alkanols, α,ω-*n*-Alkanediols, and ω-Chloro-α-alkanols at pH 5.6 and 7.0 against *C. albicans*, *T. mentagrophytes*, and *M. mucedo* in Sabouraud Dextrose Agar in the Absence and Presence of Beef Serum [a]

[a] *C. albicans* and *M. mucedo* were incubated at 37° for 30 hr, and *T. mentagrophytes* was incubated at 28° for 5 days. [b] Compounds were incorporated in the test medium at 10^4, 10^3, and 10^2 μg/ml. Key to inhibition levels: 3 = inhibition at all levels of the compound, 2 = inhibition at the two highest levels, 1 = inhibition at the highest level only, and 0 = compound inactive at the highest level tested. [c] Number of methylene groups in the chain. [d] Sum of the number of levels of inhibition multiplied by the number of organisms inhibited.

The order of fungitoxicity of the three classes of compounds was chloroalkanols > alkanols > alkanediols. This finding suggests that, in addition to possessing a certain degree of amphiphilicity, each compound also should have a lipophilic and a hydrophilic end. These concepts are consistent with the results obtained with the fatty acids and derivatives (1–6, 8).

Although these data do not indicate a mechanism of action for the alkanols and related compounds, it is clear that alkylation plays no part in the fungitoxic reaction. The bromoalkanol, which is a better alkylating agent than the corresponding chloro compound, is a poorer antifungal agent.

The antifungal activity of alkanols can be modified by altering the ω-end of the molecule. Conceivably, an ω-substituted alkanol could be prepared with superior antifungal activity. Such a compound also would have the advantage of its activity not being affected significantly by a pH change or the presence of serum.

Since an attempt is being made at generalizing the antifungal activity of the substituted straight-chain alkanes, it is not unreasonable to compare the activity of the alkanols with the carboxylic acids. Totaling the antifungal spectrum indexes of the seven most active members of each series of compounds at pH 4.0 and 5.6 for *A. niger*, *T. viride*, and *M. verrucaria* gives the order of fungitoxicity for six types of fatty acids and three types of alcohols, on a weight basis, as 2-alkynoic acids (336) > 2-alkenoic acids (288) > ω-chloroalkanols (266) > alkanoic acids (264) > 2-bromoalkanoic acids (253) > 2-fluoroalkanoic acids (228) > *n*-alkoxyacetic acids (220) > alkanols (205) > α,ω-alkanediols (98) (3, 5).

New Instrumentation for Determining Flexure Breaking Strength of Capsule-Shaped Tablets

GERALD GOLD ˣ, RONALD N. DUVALL, and BLAZE T. PALERMO

Received June 14, 1978, from the *Applied Pharmaceutics Laboratory, Miles Laboratories, Inc., Elkhart, IN 46514.* Accepted for publication October 22, 1979.

Abstract □ New instrumentation to measure the flexure breaking strength of capsule-shaped tablets was developed. It consisted of a mechanical linkage to apply the breaking load at a uniform rate and a strain-gauge instrumented cantilever beam to convert the load to a proportional millivolt response on a recorder. A recorder tracing was obtained of increasing load with time, with a break in the tracing denoting the tablet's flexure breaking strength. Measurements were made for different tablet hardnesses, and a plot of tablet hardness *versus* flexure breaking strength yielded a profile of the mechanical strength of the tablet. The instrumentation was shown to have application for determining the effects of tablet thicknesses, tablet ingredients, tablet sizes, cup depths, and bisect dimensions on tablet strength.

Keyphrases □ Flexure breaking strength—determination for capsule-shaped tablets, new instrumentation □ Tablet breakage—capsule-shaped tablets, determination of flexure breaking strength, new instrumentation □ Hardness, tablets—flexure breaking strength, determination for capsule-shaped tablets, new instrumentation

Although tablet breakage is a problem often encountered in the manufacture, packaging, and distribution of capsule-shaped tablets, little information is available on the subject. Several factors that need to be studied for their effects on breakage are the ingredients, size, shape, and dimensions of the tablets. To evaluate these factors, the flexure breaking strength of the tablet must be determined. At present, there is no generally accepted mechanical method to measure the flexure breaking strength of tablets with sufficient accuracy and precision.

BACKGROUND

A widely used but subjective flexure test employed in practice is to break the tablet between the thumb and fingers and to evaluate both the force necessary to break the tablet and the sharpness of the snap. An instrument constructed to simulate the manual method was described (1) in which a pneumatic tablet hardness tester was modified by the addition of two auxiliary pieces, one attached to the plunger and the other to the anvil. Increasing pressure is applied through the plunger on the center of the tablet face until it breaks to measure the fracture resistance. These investigators found that the fracture resistance was directly proportional to tablet thickness and pointed out the importance of this finding for reducing tablet breakage. They also indicated that additional research was necessary to design an instrument that would be more versatile and accurate.

In another study, a flexure tester was constructed by attaching a knife edge and two fulcrums to the platens of a motorized tablet hardness tester (2). The flexure tester was found to be a rapid, reproducible instrument for determining the tablet tensile strength of very strong tablets but could not be used for very weak tablets.

Two related procedures have been developed to measure resistance to bending. In one procedure, mercury is added to provide the weight to break the tablet (3). In the other procedure, a special tablet form is used that is unrelated to the manufactured product (4). Both procedures, however, are impractical for use in industry.

The objective of this study was to develop new instrumentation that can be calibrated readily for increased accuracy, measure a wide range of tablet strengths, and be of practical use in a product development laboratory. This paper describes the instrument developed and indicates

how the measurements may be used in product development to evaluate factors affecting tablet breakage.

EXPERIMENTAL

The flexure tester (Fig. 1) was constructed by modifying the plunger tip and anvil of instrumentation described previously for measuring granule strength (5). Dimensions of the modified plunger tip and anvil are given in Fig. 2.

The flexure tester consists of a mechanical linkage for applying the load at a uniform rate and a strain-gauge instrumented cantilever beam and recorder for measuring the magnitude of the applied load. To measure flexure breaking strength, a single capsule-shaped tablet (C) is placed on the anvil (D), and the cam (A) is rotated at a uniform rate. Rotation of the cam at one revolution per 45 sec is controlled by a link chain, gear motor[1], and speed control switch[2].

The plunger (B) presses down across the middle of the tablet and bends the instrumented cantilever beam (E), thereby deforming the strain gauges (F). This deformation results in a millivolt response across the strain-gauge bridge circuit, which is measured on a recorder[3] with a 0–2-mv range for 25.4-cm full scale and a chart speed of 0.33 cm/sec. A tracing is obtained of increasing load with time, and a measurement of the tablet breaking strength is obtained at tablet breakage. The cam makes one complete revolution for each measurement.

The calibration procedure is built into the instrumentation and is performed each time the instrument is operated. A linear relationship exists between the weight on the calibration platform and the millivolt response on the recorder. The instrument is calibrated by adding weights to the calibration platform and adjusting the gain and zero controls to obtain the desired full-scale deflection on the recorder. Full-scale deflection can be varied from 200 g to 10 kg.

A typical recorder tracing of a flexure breaking strength measurement is shown in Fig. 3. The load is applied at a uniform rate by the speed control switch, which regulates the descent rate of the plunger. A break in the tracing of the increasing load with time indicates the tablet flexure breaking strength. In this tracing, the flexure breaking strength is 3 kg.

Table I—Typical Flexure Breaking Strength and Tablet Hardness Values (±*SD*)

Tablet Thickness[a], mm	Tablet Weight, mg	Flexure Breaking Strength ± *SD*, kg[b]	Tablet Hardness ± *SD*, kg[c]
6.299	588	1.25 ± 0.05	4.97 ± 0.08
6.325	620	1.97 ± 0.15	7.80 ± 0.21
6.325	650	2.79 ± 0.14	11.01 ± 0.66
6.350	680	3.99 ± 0.30	15.34 ± 0.78

[a] All tablets were 7.035 mm wide and 17.900 mm long. [b] Mean of six measurements. [c] Mean of 10 measurements.

After the breaking point, the backswing develops because the load is relieved abruptly and the cantilever beam rapidly rises until it contacts the plunger. Six replicate measurements were made, and the mean is reported.

Tablet hardness[4] measurements were made by the diametral compression of capsule-shaped tablets through their major axes. Ten replicate measurements were made, and the mean is reported. Typical tablet hardness and flexure breaking strength measurements and their relative standard deviations are listed in Table I. The tablet mechanical strength profile was obtained by a least-squares line plot of tablet hardness *versus* flexure breaking strength.

Materials used in this study were USP, NF, or pharmaceutical grade. Lactose tablets contained 89.5% direct-compression lactose, 10% cornstarch, and 0.5% magnesium stearate. Capsule-shaped tablets, 7.035 × 17.900 mm, were prepared with one punch of a rotary tablet press[5] at a rate of 24 tablets/min using one station to minimize tooling variations. Tablets of other sizes were prepared on a modified single-punch tablet press[6].

RESULTS AND DISCUSSION

The effects of four different tablet thicknesses on the mechanical strength profile of lactose capsule-shaped tablets are shown in Fig. 4. From this profile, it is apparent that, at the same tablet hardness, an increase in tablet thickness resulted in an increase in flexure breaking strength. At 10-kg tablet hardness, for example, tablets prepared at a thickness of 5.08 mm (line A) had a flexure breaking strength of 2.2 kg, whereas tablets prepared at a thickness of 7.62 mm (line D) had a breaking strength of 3.4 kg.

The effects of various tablet formulations on the mechanical strength profile of tablets prepared at a constant thickness were studied. Measurements on 10 formulations are shown in Fig. 5. The formulations were prepared by either direct compression or wet granulation, and an attempt was made to vary the type and concentrations of fillers, binders, disintegrants, and lubricants. The formulation and ingredients did not significantly alter the mechanical strength of the tablet. The data indicate

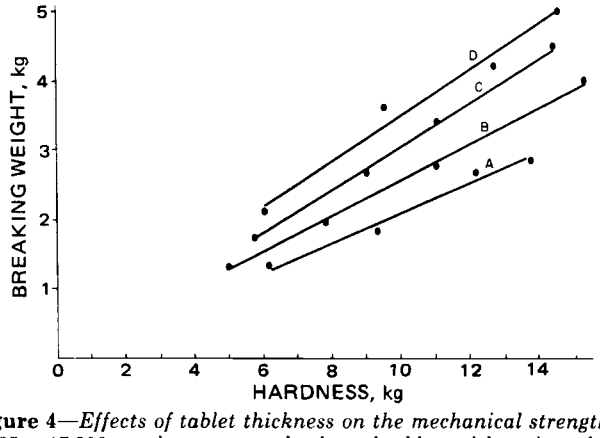

Figure 4—*Effects of tablet thickness on the mechanical strength of 7.035 × 17.900-mm lactose capsule-shaped tablets with various thicknesses. Key: A, 5.088 mm thick; B, 5.715 mm thick; C, 6.350 mm thick; and D, 7.620 mm thick.*

that, for this specific tablet configuration, there is a linear relationship between the tablet crushing strength as determined by the tablet hardness measurement and the flexure breaking strength.

The mechanical strength of different size lactose tablets is shown in Fig. 6. At the lower tablet hardness values, the differences in breaking strengths between the different size tablets were small; at the higher tablet hardness values, the differences were significantly greater. The oval tablet (line D) had greater breaking strength than the capsule-shaped tablet. Since each breakage problem represents a unique set of conditions,

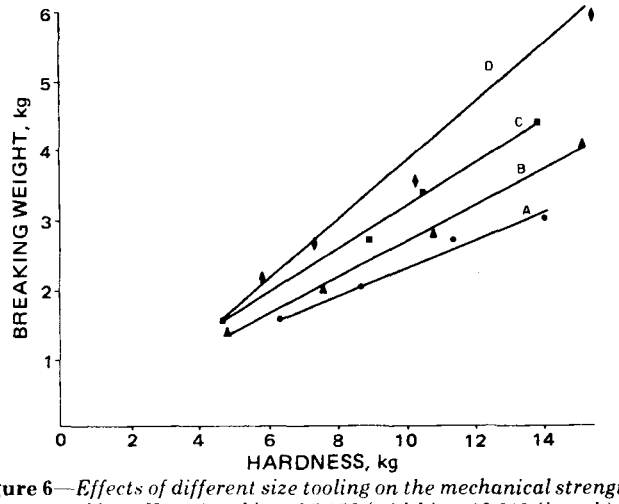

Figure 6—*Effects of different size tooling on the mechanical strength of lactose tablets. Key: A, tablet of 5.156 (width) × 16.612 (length) × 5.105 (thickness) mm; B, tablet of 7.035 (width) × 17.900 (length) × 6.350 (thickness) mm; C, tablet of 7.112 (width) × 22.987 (length) × 7.239 (thickness) mm; and D, oval-shaped tablet of 7.976 (width) × 19.177 (length) × 6.655 (thickness) mm.*

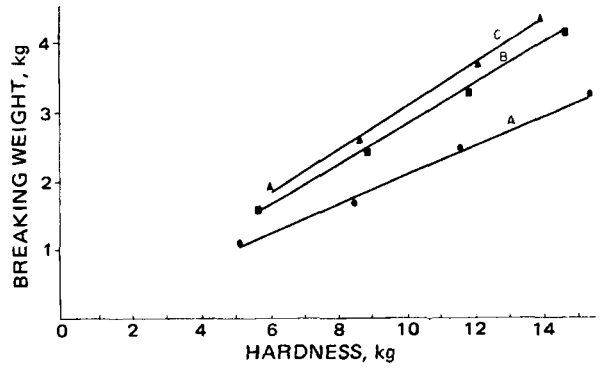

Figure 7—*Effects of tablet concavity on the mechanical strength of a 7.035-mm wide × 17.900-mm long × 6.350-mm thick lactose capsule-shaped tablet. Key: A, 1.143 mm deep; B, 1.8034 mm deep; and C, 2.235 mm deep.*

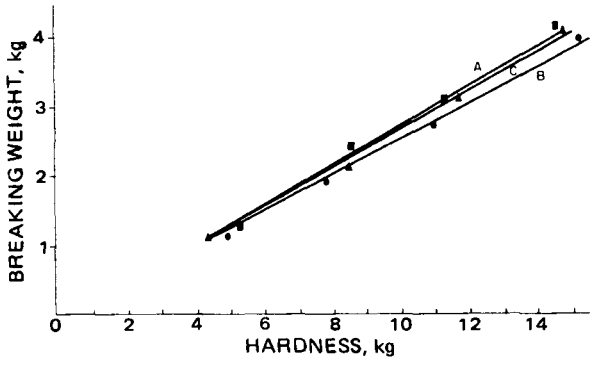

Figure 8—*Effects of the bisect bar dimensions on the mechanical strength of a 7.035-mm wide × 17.900-mm long × 6.350-mm thick lactose capsule-shaped tablet. Key: A, no bisect bar; B, 0.762-mm wide and 0.381-mm deep bisect bar; and C, 1.524-mm wide and 0.381-mm deep bisect bar.*

the size and configuration of the tablet must be evaluated in terms of the specific problem. Where the cross-sectional area of the tablet may be the critical parameter in coating tablets, the length may be the critical parameter in a bottle-filling operation.

The effect of the concavity of the tablet on the mechanical strength of lactose tablets was evaluated (Fig. 7). Tablets were prepared with shallow (1.143 mm), medium (1.803 mm), and deep (2.235 mm) cups in which the overall dimensions of the tablet were maintained at 7.035 × 17.900 × 6.350 mm. Tablets made with the shallow cup had significantly less breaking strength at the same tablet hardness than did either the medium or deep cup tablets. At 12-kg tablet hardness, the shallow cup had a breaking strength of only 2.4 kg compared to the standard cup value of 3.3 kg and the deep cup value of 3.6 kg.

The effect of the bisect on the mechanical strength of lactose tablets also was evaluated (Fig. 8). Using the same size tooling, tablets were prepared with no bisect, a 0.762-mm wide and 0.381-mm deep bisect, and a 1.524-mm wide and 0.381-mm deep bisect. Surprisingly, the bisect did not significantly alter the mechanical strength of these tablets.

Vehicle Effects in Percutaneous Absorption: *In Vitro* Study of Influence of Solvent Power and Microscopic Viscosity of Vehicle on Benzocaine Release from Suspension Hydrogels

G. DI COLO ˣ, V. CARELLI, B. GIANNACCINI, M. F. SERAFINI, and F. BOTTARI

Received April 11, 1979, from the *Pharmaceutical Technology Laboratory, Institute of Pharmaceutical Chemistry, University of Pisa, 56100 Pisa, Italy.* Accepted for publication October 23, 1979.

Abstract □ The release through silicone rubber membranes of benzocaine suspended in carbomer hydrogels containing different concentrations of low molecular weight polyols (ethylene glycol, propylene glycol, glycerol, and sorbitol) was studied to establish general principles and procedures for control of the effects on percutaneous absorption caused by changes in drug solubility and/or diffusivity in the vehicle. The effect of the additives on the release is expressed in terms of the relative released amount, *i.e.*, the ratio, Q/Q_W, of the amount of drug released from each additive-containing gel to the amount released at the same time from the additive-free gel. The experimental Q/Q_W values are correlated with values calculated by a simple equation involving known or readily measurable parameters such as the drug concentration in the gel, the drug solubility in the pure liquid phase, and the viscosity of this phase. Derivation of such a relationship from a known equation describing the vehicle-controlled release of suspended drugs was possible because an inverse proportionality was observed between drug diffusivity in the gels and the viscosity of the respective solvents. This relationship is interpreted with respect to current theories on drug diffusion in diluted gels.

Low molecular weight polyols are used extensively as humidity conditioners in dermatological hydrogels. Propylene glycol, glycerol, and sorbitol usually are introduced in these dosage forms to prevent undesirable solid films from forming on the skin following water evaporation. In addition to vehicle stability, drug bioavailability can be affected profoundly by these additives through their effect on physicochemical factors controlling passive absorption, such as the solubility and diffusivity of the drug in the vehicle and the resistance of the skin barrier to drug penetration.

The effect of varying the solubility of the penetrant in the vehicle on transepidermal penetration was investigated thoroughly (1–3). Other investigators (4) found that drug diffusion in the vehicle may provide a rate-limiting step in absorption if the drug is suspended in the vehicle. On the other hand, *in vivo* studies have not fully clarified, except in certain cases, the effect of excipients on skin resistance to drug penetration.

From the results of *in vivo* studies on propylene glycol, the most studied of these polyols (5), a precise conclusion cannot be drawn as to whether this substance exerts its effect on drug penetration by influencing the physicochemical properties of the vehicle or those of the skin or both. This uncertainty is due to the fact that, in most of these studies, the physicochemical parameters relative to the vehicle and the drug, namely, the solubility and apparent diffusivity of the drug in the vehicle, were not controlled suitably to allow assessment of the effects of the excipient on the skin barrier. These parameters must be considered for an appropriate evaluation of the release properties of topical vehicles.

This paper discusses an *in vitro* study of drug release from hydrogels containing low molecular weight polyols. The purpose of this study was to establish general principles and procedures for control of the effects on percutaneous absorption caused by the additive-induced changes in drug solubility and diffusivity in these vehicles. Although convenient methods for determining the solubility and the diffusion coefficient of drugs in semisolid media have been developed (6–9), investigation of possible correlations of these parameters with the more readily measurable drug solubility in the liquid phase of gels and the viscosity of this phase, respectively, was desired.

Propylene glycol, ethylene glycol, glycerol, and sorbitol were the additives studied because they are used widely in commercial preparations. Benzocaine (ethyl *p*-aminobenzoate) was selected as a model of a neutral, topical drug with low water solubility.

THEORETICAL

The effect on drug release to the skin by variations of the solubility and/or diffusivity of the drug in the vehicle depends on whether the rate-controlling step of release occurs in the skin (Case A), in the vehicle (Case B), or in both the skin and the vehicle (Case C).

In Case A, such variations are expected to exert no effect on the release rate since this rate depends on skin parameters, which are presumed constant, and on the thermodynamic activity of the drug in the vehicle, which is independent of the vehicle properties, above saturation (10). For two vehicles characterized by different values of drug solubility and/or diffusivity, $Q_2/Q_1 = 1$, where the ratio Q_2/Q_1 of the amount of drug released per unit area at any given time from Vehicle 2 to that released at the same time from Vehicle 1 is defined as the relative released amount from Vehicle 2 with respect to Vehicle 1.

Higuchi (11) derived the following equation for Case B:

$$Q = \sqrt{(2A - S)SDt} \qquad \text{(Eq. 1)}$$

where D, A, and S are the apparent diffusivity, the total concentration, and the solubility of the drug in the vehicle, respectively. Equation 1 is valid for vehicles in which the apparent diffusion coefficient is constant, the suspended drug is finely dispersed, the dissolution of the drug is much faster than its diffusion through the vehicle, and the total drug concentration is at least threefold greater than the solubility. With Eq. 1, the following expression for the relative released amount can be derived:

0022-3549/80/0400-0387$01.00/0
© 1980, American Pharmaceutical Association

$$Q_2/Q_1 = \sqrt{\frac{(2A - S_2)S_2D_2}{(2A - S_1)S_1D_1}} \quad \text{(Eq. 2)}$$

where the drug concentration is assumed to be the same in the two vehicles.

In Case C, Q_2/Q_1 is expected to vary from 1 to the value expressed by Eq. 2, depending on the resistance the drug encounters in its diffusion through the respective vehicles relative to that in the skin[1].

Equation 2 should be suitable for evaluating the maximum effect on the *in vivo* release of a drug to the skin attributable to variations of drug solubility and/or diffusivity in the vehicle. Greater or opposite effects should be ascribed to modifications of the barrier properties of skin due to skin–vehicle interactions.

The convenience of Eq. 2 for controlling the solubility and diffusivity effects obviously is connected with the ease of determination of these parameters. For gels, Eq. 2 can be modified to contain such readily measurable parameters as drug solubility in the solvent of the gel and the viscosity of this solvent. If the gel substance does not interact significantly with the drug, the solubility and diffusion coefficient of the drug in the gel should be practically the same as in the pure liquid. The diffusivity in homogeneous liquids, D_l, can be expressed through the viscosity of the liquid, η, and can be expected to range from:

$$D_l = \frac{kT}{4\pi\eta}\left(\frac{4\pi}{3v}\right)^{1/3} \quad \text{(Eq. 3)}$$

for solutes whose molar volume, v, is equal to the molar volume of the solvent, to:

$$D_l = \frac{kT}{6\pi\eta}\left(\frac{4\pi}{3v}\right)^{1/3} \quad \text{(Eq. 4)}$$

when the molar volume of the solute is significantly greater than that of the solvent[2] (12).

Substitution in Eq. 2 of the appropriate expressions of D_l (*i.e.*, Eq. 3 or 4) in place of the respective D and of the drug solubility in the solvent of the gel, Sl, in place of the respective S leads to:

$$Q_2/Q_1 = \sqrt{\frac{(2A - Sl_2)Sl_2\eta_1}{(2A - Sl_1)Sl_1\eta_2}} \quad \text{(Eq. 5)}$$

for Solvents 1 and 2, having either similar or different molecular volumes approximately equal to or smaller than that of the drug in the former case and considerably smaller than that of the drug in the latter, or to:

$$Q_2/Q_1 = \sqrt{\frac{2(2A - Sl_2)Sl_2\eta_1}{3(2A - Sl_1)Sl_1\eta_2}} \quad \text{(Eq. 6)}$$

where the molecular volume of Solvent 1 is significantly greater than that of Solvent 2 and approaches the value of the diffusing particle.

As stated, Eqs. 5 and 6 are applicable to gels where the interactions of the drug with the chains of the gel polymer are either absent or unimportant. Actually, these equations also are valid where such interactions are strictly mechanical if the volume fraction of the gel substance is the same in Gels 1 and 2, and is not so high that the diameter of the gel pores approaches the diffusing particle diameter. In these conditions, the diffusion coefficient in the gel is proportional to that in the solvent, D_l (12):

$$D = \frac{D_l}{1 + 2/3\phi} \quad \text{(Eq. 7)}$$

If ϕ, the volume fraction of the gel substance, is the same in Gels 1 and 2, then Eq. 2 for these gels again may be transformed into Eq. 5 or 6. On the other hand, the complications arising when the drug or some components of the liquid phase undergo complexation by the gel polymer rule out the application of simple Eq. 5 or 6 to such systems.

EXPERIMENTAL

Materials—Ethylene glycol[3], propylene glycol[3], glycerol[3], sorbitol[4], and carboxypolymethylene[5] (carboxyvinyl polymer) were used as received. The neutral sodium salt of carboxypolymethylene was prepared as described in the literature (13). Benzocaine[3] was crystallized to a constant melting point of 91.5° and micronized[6]. The average diameter of the particles (microscopic analysis) was 2.0 μm (geometric). Simethicone[7] (dimethyl polysiloxane, silicone rubber) sheeting in a labeled thickness of ~127 μm was used as the membrane.

Vehicles, Apparatus, and Procedures—Hydrophilic gels containing 1% (w/v) carboxypolymethylene sodium salt were obtained from water (Gel W) and from the following aqueous polyols: 25% (w/w) ethylene glycol (Gel EG 25), 36% (w/w) ethylene glycol (Gel EG 36), 17.5% (w/w) propylene glycol (Gel PG 17.5), 30% (w/w) propylene glycol (Gel PG 30), 50% (w/w) glycerol (Gel G 50), 66% (w/w) glycerol (Gel G 66), and 54.5% (w/w) sorbitol (Gel S 54.5).

Solution gels, each containing benzocaine concentrations corresponding to 20 and 40% of the solubility in the respective solvents, and suspension gels, each containing 11 mg of micronized benzocaine/ml, were prepared following literature procedures (7, 8). The apparatus and procedures used for the release experiments with the solution (9) and suspension (7) gels were reported previously.

The apparent impermeability of the membrane to the polyols was demonstrated by the use of a previously described permeation cell and an apparatus (14) where the nongelled polyol–water mixtures without the drug were the internal solutions and water was the external phase. The periodic acid test (15) performed on this phase after 8-hr runs gave a negative result in all cases. Each release experiment was performed at least three times, and the averaged data were used for the individual plots.

Solubility Determinations—Benzocaine solubility in the solvent systems of the gels was determined by equilibrating excess benzocaine with the solvent at 30°. Samples then were withdrawn and rapidly filtered through a 0.22-μm pore filter[8]. The clear solutions were diluted with distilled water and spectrophotometrically[9] analyzed at 286 nm.

Diffusivity Determinations—The diffusion coefficient of benzocaine in the gels at 30° was calculated from the release data obtained from the solution gels according to a reported numerical method of analysis (9). The computations were executed with a computer[10].

Table I—Solubility, Diffusivity, and Viscosity Data at 30°

Gel	Drug Solubility in Solvent, Sl, mg/ml	Drug Diffusivity in Gel, D, $cm^2/sec \times 10^6$	Solvent Viscosity, η, cps	$D\eta$, cm^2/sec cps $\times 10^6$
W[a]	1.31	8.6	0.8	6.88
EG 25	2.37	4.5	1.60	7.2

S 54.5[a]	1.05	—	12.3	—

[a] The solubility and diffusivity data for this gel were obtained from previous reports (7–9).

RESULTS AND DISCUSSION

Solubility of Drug, Microscopic Viscosity of Gels, and Drug Diffusivity in Gels—The values of the solubility, Sl, of benzocaine in the solvents of the gels studied are listed in Table I, together with the viscosity[11] of the solvents, η, and the diffusion coefficient, D, of drug in the gels. These values were determined by a recently developed method based on numerical analysis of release data (9). Accordingly, two drug concentrations, corresponding to 20 and 40% solubility in the solvent, were run for each gel; the respective values of diffusivity obtained from the computations were compared to ascertain the independence of concentration. This independence existed for all gels investigated since the diffusivity values determined at the two drug concentrations were within experimental error. Table I reports the average values. The diffusion coefficient of benzocaine in the gel containing sorbitol was not determined since previous work showed concentration dependence of this parameter (9).

[1] This analysis assumes the same release mechanism for the two vehicles being compared. The case of different mechanisms is not considered since it generally would require large variations of solubility and diffusivity.

[2] Strictly speaking, a correction for nonsphericity of the diffusant should be introduced in the expression of D for large particles. However, this correction has been ignored since it amounts to <10% for all but the most elongated structures (12).

The concentration independence of diffusivity in Gels W, G 50, G 66, EG 25, EG 36, PG 17.5, and PG 30 points to the absence of self-aggregation of the benzocaine molecules over the concentration ranges investigated (12). Complexation of the drug by the gel substance also can be excluded, because previous work indicated that the addition of carboxypolymethylene sodium salt to solutions of benzocaine in water or in water–glycerol did not alter the thermodynamic activity of the drug (8). Then the values reported in Table I for the solubility in the solvents also may be referred to as the drug solubility in the corresponding gels.

The dependence of the parameters in Table I on solvent composition can be visualized best in Figs. 1–3. Table I and Fig. 1 show that the solubility of benzocaine in the solvent mixtures increased with increasing content of propylene glycol, ethylene glycol, or glycerol, but the opposite effect was produced by sorbitol. For a given composition of the water–additive mixture, ascent in the polyol series from ethylene glycol to sorbitol resulted in a progressive solubility decrease. Such a decrease was more evident for higher additive concentrations. The greater solvent power of propylene glycol with respect to ethylene glycol probably was due to the moderately lower polarity of the propylene glycol molecule.

A substantial inverse proportionality between the diffusion coefficient in the gels and the viscosity of the respective solvents can be noticed on comparing the data in Figs. 2 and 3. This relationship is confirmed in Table I by the $D\eta$ products approximating a constant and in Fig. 4 by the linear trend of the D *versus* $1/\eta$ plot with a least-squares intercept approximating zero. Such a relationship agrees with the theory. Once complexation is excluded, only mechanical interactions between the diffusing species and the gel substance can be anticipated. Then, at the low concentrations of the gel polymer used in the present work, a proportionality between the diffusion coefficient of the drug in the gel and that in the solvent should exist and should be expressed by Eq. 7. Compliance of the latter coefficient with (or, in fact, an approximation to) Eq. 3 or 4 should account for the relationship between D and η emerging from the present data. Equation 4 seems more appropriate since the molecular volume either of water or of the polyols is in all cases smaller than that of the diffusing particle.

According to the foregoing considerations, the viscosity of the solvent mixtures should represent the effective microscopic viscosity of the respective gels; in turn, the composition of the liquid phase of gels should be substantially the same as that of the corresponding nongelled solvents. The assumption of an inverse proportionality between D and η, although substantially reasonable, is in fact an approximation. The nonzero intercept of the D *versus* $1/\eta$ plot in Fig. 4 hardly is attributable only to experimental errors. This observation may be better explained by admitting that in the presence of increasing additive concentrations, the diffusion coefficient in the liquid phase of gels deviates toward higher values than those expressed by Eq. 4. Furthermore, the volume fraction of solvent immobilized by the polymer might decrease, thus causing a decrease of the mechanical interactions of the diffusing particle with the gel network and, consequently, an increase of the diffusion coefficient in the gel with respect to that in the solvent (Eq. 7).

Influence of Solubility and Microscopic Viscosity on Release—Silicone rubber membranes similar to those used in this investigation were employed previously (4) for simulating skin. Their permeability to the drug is not supposed to be influenced by the polyols since none of them was found in the receiving phase. The degree of fineness of the suspended benzocaine, the concentration of the drug, and the concentration of the gel polymer all were kept constant so that the differences in release could not be attributed to these variables.

The plots in Fig. 5 show that either the solubility of the drug or the microscopic viscosity of the gels markedly affected release. Substantially

The linear regression parameters are slope = 6.65 and intercept = 0.44.*

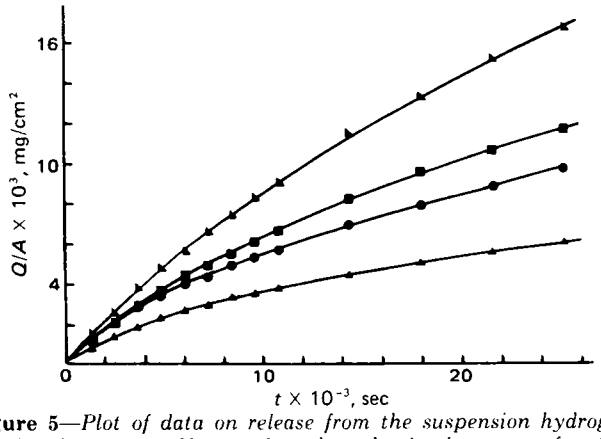

Figure 5—*Plot of data on release from the suspension hydrogels showing the amount of benzocaine released per unit area as a function of time. The total drug concentration was 11 mg/ml. Key: ◣, Gel W; ▲, Gel S 54.5; ●, Gel G 66; and ■, Gel G 50. The plots for Gels EG 25, EG 36, PG 17.5, and PG 30 are nearly superimposable on that for Gel W.*

distinct release patterns were shown by gels differing only in a single parameter (compare the data in Table I and Fig. 5 for Gels G 66 and S 54.5 and for Gels PG 17.5 and G 50). The data also indicate that the drug solubility and the gel microviscosity exerted their effects in opposite directions, with the former related directly and the latter related inversely to release. This effect can explain the substantially identical release pattern shown by gels differing in both parameters such as Gels W, EG 25 (or PG 17.5), and PG 30 (or EG 36) since any increase in the drug solubility was paralleled by an increase in the microscopic viscosity.

In light of the considerations stated under *Theoretical*, the results point to possible utilization of Eq. 5 for controlling the effect on release of varying the described parameters. Such an effect may be represented through the relative released amount, *i.e.*, the ratio, Q/Q_W, of the amount of drug released from each additive-containing gel to the amount released at the same time from the additive-free Gel W. The plots in Fig. 6 were intended to verify the time dependence of Q/Q_W for each gel; a comparison of the values of Q/Q_W determined at the end of the release experiments ($t = 25.2 \times 10^3$ sec) with those calculated by Eq. 5 is given in Table II.

The relative released amount was time dependent for gels (G 50, G 66, and S 54.5) that showed a marked deviation from the Q/Q_W value of unity determined at $t = 25.2 \times 10^3$ sec. Such a deviation was essentially less than that calculated by Eq. 5. On the other hand, a fair correspondence existed at all times between the experimental and the calculated Q/Q_W values when the latter value approximated one (see the data for PG 17.5, PG 30, EG 25, and EG 36). These results are in compliance with the theoretical considerations for Case C, and they appear to substantiate a vehicle–membrane-controlled release for the present gels. The increasing deviation of Q/Q_W from unity with time toward the value ex-

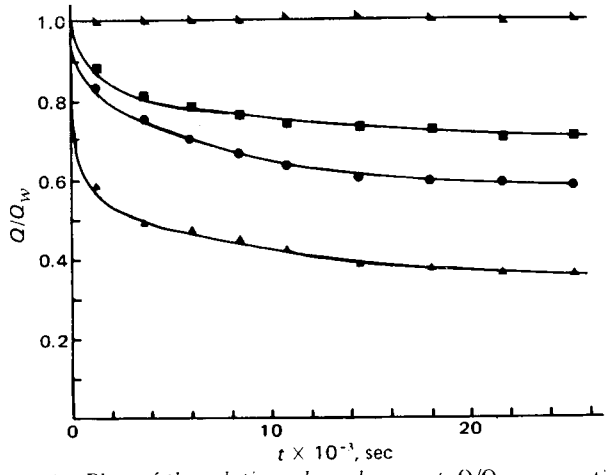

Figure 6—*Plots of the relative released amount, Q/Q_W, versus time. Key: ▲, Gel S 54.5; ●, Gel G 66; ■, Gel G 50; and ◣, Gel PG 17.5. The plots for Gels PG 30, EG 25, and EG 36 are nearly superimposable on that for Gel PG 17.5.*

Table II—Comparison of Experimental Relative Released Amount, Q/Q_W, with Values Calculated by Eq. 5

Gel	Experimental ($t = 25.2 \times 10^3$ sec)	Calculated
EG 25	1.04	0.93
EG 36	1.07	0.94
PG 17.5	1.01	0.94
PG 30	1.06	0.99
G 50	0.69	0.56
G 66	0.58	0.41
S 54.5	0.36	0.22

pressed by Eq. 5 is in agreement with the statement in previous reports (7, 16) that the vehicle–membrane-controlled release model evolves with time toward the vehicle-controlled model. Also, the present experimental evidence supports the view that Eq. 5 expresses the maximum effect on release produced by variations of the drug solubility and/or the gel microviscosity.

In Fig. 7, the experimental values of the relative released amount determined at $t = 1.2 \times 10^3$ sec, $t = 3.6 \times 10^3$ sec, and $t = 25.2 \times 10^3$ sec for all gels are plotted *versus* the values calculated by Eq. 5. The alignment of points clearly indicates that a definite relationship existed between the experimental vehicle–membrane-controlled Q/Q_W and the calculated vehicle-controlled values. This result points to the usefulness of such plots as calibration curves of the effects of the solubility and the diffusivity of the drug in the applied phase on quasi-steady-state[12] drug penetration through a membrane. Curves of this type, if obtained from *in vivo* experiments, should be indicative of the absence of vehicle-induced changes in skin permeability to drug; in this event, they could enable the prediction of the relative released amount once the parameters in Eq. 5 are determined. The more general Eq. 2 should be used to construct similar calibration curves when dealing with vehicles not meeting the requirements of Eq. 5.

CONCLUSIONS

In summary, Eq. 5 is proposed as a tool for controlling the effects of polyol additives, usually introduced in dermatological hydrogels, on important physicochemical factors influencing drug release such as the solubility and diffusivity of the drug in the vehicle. This equation has been shown to predict the maximum effect on benzocaine penetration through silicone rubber membranes associated with changes in the described parameters. A precise correlation exists between the experimental values of the relative released amount and the values calculated by Eq. 5. This finding points to the potential usefulness of this equation for constructing calibration curves of the effects of drug solubility and diffusivity in the vehicle on quasi-steady-state drug penetration through skin.

Although a silicone rubber membrane is far from being perfectly rep-

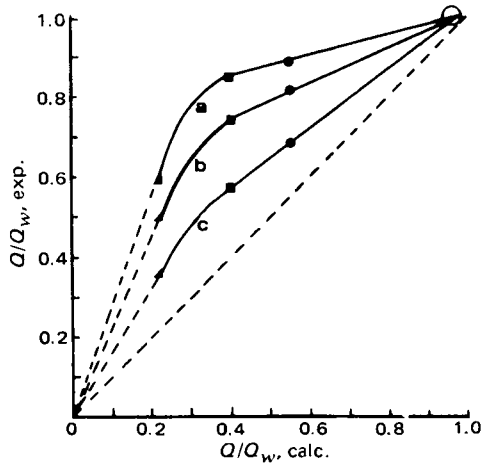

Figure 7—*Plots of the experimental relative released amount, Q/Q_W, versus the values calculated by Eq. 5. Key: a, $t = 1.2 \times 10^3$ sec; b, $t = 3.6 \times 10^3$ sec; c, $t = 25.2 \times 10^3$ sec; ○, Gels EG 25, EG 36, PG 17.5, and PG 30; ■, Gel G 66; ▲, Gel S 54.5; and ●, Gel G 50.*

[12] According to the results of a previous work (7), linear concentration gradients of the drug in the membrane should exist after the early times of the release experiments.

resentative of skin with regard to drug penetration, it nevertheless provides the requirements for the present comparative study where the following assumptions were made:

1. Skin transport is passive.
2. The skin parameters relevant to drug penetration are not influenced by the vehicle.
3. The vehicle composition does not change significantly during release.

Derivation of Eq. 5 from Higuchi's Eq. 1 (11) was possible because an inverse proportionality was observed between the diffusivity of drug in gels and the viscosity of the respective solvents. Such a relationship is justifiable considering the current theories on diffusion in diluted gels, as long as the viscosity of each solvent is accepted as the microscopic viscosity of the corresponding gel and self-aggregation or complexation of the drug is excluded. All of the gels studied in the present work (except, perhaps, the gel containing sorbitol) met the requirement of Eq. 5 that the molecular volume of the components of the liquid phase be substantially smaller than that of the diffusing drug. The cases of molecular volume of solvent approaching or exceeding that of the drug might deserve investigation for the applicability of Eq. 5 or 6.

It is hoped that the present study will help to rationalize the compounding of pharmaceutical gels and, furthermore, that the suggested principles and procedures for controlling the vehicle parameters will be useful in *in vivo* studies intended to assess the effects of excipients on skin permeability to drugs.

Effect of Particle Size on Ophthalmic Bioavailability of Dexamethasone Suspensions in Rabbits

R. D. SCHOENWALD ˣ and P. STEWART *

Received June 25, 1979, from the *Pharmaceutics Division, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication October 24, 1979. *Present address: Department of Pharmacy, University of Queensland, St. Lucia 4067, Queensland, Australia.

Abstract □ Three suspensions of 0.1% [^{3}H]dexamethasone were prepared with mean particle sizes of 5.75, 11.5, and 22.0 μm. The suspensions were dosed topically to the right eyes of rabbits. Their bioavailability was compared by measuring aqueous humor and corneal levels over 5 hr. A statistically significant rank-order correlation was observed between increasing drug levels and decreasing particle size.

Keyphrases □ Dexamethasone—ophthalmic suspensions, bioavailability, effect of particle size, rabbits □ Bioavailability—dexamethasone, ophthalmic suspensions, effect of particle size, rabbits □ Ophthalmic preparations—dexamethasone suspensions, bioavailability, effect of particle size, rabbits

In the development of an aqueous suspension for topical use in the eye, the size of the suspended particles often is governed by their irritation potential. Although the particle size is an important consideration in irritation and comfort, the ophthalmic bioavailability of the drug can be influenced by particle size according to one or two possible *in vivo* mechanisms. If the particle induces tearing, rapid drainage of the instilled dose could reduce bioavailability (1, 2). In addition, the dissolution rate of particles residing in the conjunctival sac just after dose instillation should influence ophthalmic bioavailability.

Few published articles have indicated the importance of particle size in ophthalmic bioavailability. Sieg and Robinson (2) studied the bioavailability of a 0.1% ophthalmic fluorometholone suspension and demonstrated that the particles were retained within the conjunctival sac longer than the corresponding saturated solution and contributed significantly to the quantity of drug penetrating the cornea. By comparing the area under the aqueous humor–time curve for the 0.1% suspension and the saturated solution, ~78% of the area was determined to come from the retained particles. Therefore, the dissolution rate for poorly soluble drugs may influence the rate and extent of penetration into eye fluids.

The present study was conducted in rabbits to determine the importance of particle size in the ophthalmic bioavailability of a 0.1% dexamethasone suspension. Dexamethasone was chosen because of its clinical significance and because of the availability of tritiated dexa-

A statistically significant rank-order correlation was observed between increasing drug levels and decreasing particle size.

In the development of an aqueous suspension for topical use in the eye, the size of the suspended particles often is governed by their irritation potential. Although the particle size is an important consideration in irritation and comfort, the ophthalmic bioavailability of the drug can be influenced by particle size according to one or two possible *in vivo* mechanisms. If the particle induces tearing, rapid drainage of the instilled dose could reduce bioavailability (1, 2). In addition, the dissolution rate of particles residing in the conjunctival sac just after dose instillation should influence ophthalmic bioavailability.

Few published articles have indicated the importance of particle size in ophthalmic bioavailability. Sieg and Robinson (2) studied the bioavailability of a 0.1% ophthalmic fluorometholone suspension and demonstrated that the particles were retained within the conjunctival sac longer than the corresponding saturated solution and contributed significantly to the quantity of drug penetrating the cornea. By comparing the area under the aqueous humor–time curve for the 0.1% suspension and the saturated solution, ~78% of the area was determined to come from the retained particles. Therefore, the dissolution rate for poorly soluble drugs may influence the rate and extent of penetration into eye fluids.

The present study was conducted in rabbits to determine the importance of particle size in the ophthalmic bioavailability of a 0.1% dexamethasone suspension. Dexamethasone was chosen because of its clinical significance and because of the availability of tritiated dexa-

methasone, which permits determination of low drug levels in aqueous humor.

EXPERIMENTAL

Materials—Two millicuries of tritiated dexamethasone dissolved in benzene–ethanol (9:1) was obtained commercially[1]. Nontritiated dexamethasone[2] was used as received. Other chemicals were reagent grade.

Preparation of Particle-Size Dexamethasone Fractions—Tritiated dexamethasone in benzene–ethanol (9:1) was evaporated to dryness using a nitrogen stream and was redissolved in 0.5 ml of absolute alcohol. An alcoholic solution containing 120 mg of nontritiated dexamethasone in 5.6 ml was heated to 65° and was added to 0.4 ml of the tritiated alcoholic dexamethasone solution. This supersaturated solution was transferred to a test tube, submerged in an ice bath at 0°, and sonified[3] for 10 min until crystallization occurred.

Crystals were harvested 2, 9, and 24 hr following sonification by removing 2 ml of the resulting suspension at each time increment and filtering through a 0.45-μm membrane[4]. The three fractions of dexamethasone crystals were air dried and removed carefully from the membrane. The dried microfine powder was assumed to contain tracer homogeneously throughout its crystalline structure.

Suspension Preparation—Five milliliters of 0.1% dexamethasone suspension was prepared separately from the three microfine powder fractions using a vehicle consisting of 0.9% NaCl, 0.05% polysorbate 80, and water for injection. Each suspension was sonified for 30 sec to achieve uniform dispersion of the particles and was stored in several small vials at 4° for <4 weeks.

Particle-Size Measurement—Several suspensions were formulated with narrow and nearly nonoverlapping particle-size distributions using an adapted sonification technique (3–5). The suspensions were formulated as simply as possible. Viscosity-inducing agents were omitted because their effect on particle-size growth is not known. Particle-size distributions of each suspension were performed with a research microscope[5]. The eye-piece micrometer had been calibrated previously using a stage micrometer.

At least 300 particles were measured for each determination of the particle-size distribution. Microscopic examinations confirmed that the particles were well dispersed with no evidence of agglomeration. At the end of the study, the suspensions were examined again for the mean particle size and distribution; no differences were noted as a function of storage conditions.

Procedure—New Zealand White rabbits without observable eye defects, 1.5–3.0 kg[6] and 2–3 months old, were used. Four to six rabbits were studied at each time interval for each preparation. The animals were randomized with respect to the formulation each received. A single 50-μl dose[7] was administered to the right eye. The lower lid was pulled away from the globe, and the drop was allowed to fall onto the cornea, with the excess falling into the conjunctival sac. The eyelid was returned carefully to its normal position.

The rabbits were sacrificed by rapid injection of 20 cm of air into the marginal ear vein at intervals of 0, 0.33, 0.67, 1, 1.67, 2.5, and 5 hr. Aqueous humor samples of about 0.15 ml were removed from the anterior chamber with a 27-gauge needle attached to a 1-ml tuberculin syringe and were added quantitatively to a counting vial[8] in volumes of 0.125–0.175 ml. Ten milliliters of scintillation fluid[9] was added to each vial.

Immediately following removal of the aqueous humor samples, 8-mm corneal buttons were removed with the use of a trephine[10], blotted once on each side, weighed, and immediately place in a counting vial containing 1.0 ml of tissue solubilizer[11]. The mixture was allowed to stand overnight to permit dissolution of the cornea. Ten milliliters of scintillation fluid[12] then was added to each vial. The vials were allowed to adapt to the dark overnight before counting. A minimum of 10,000 counts was obtained (2% counting error) for each sample. The internal standardization method (6) was used to determine counting efficiencies and, therefore, permitted the quantity of steroid[13] present in each sample to be calculated.

Table I—Particle Statistics for Dexamethasone Suspensions

[a] Length number diameter or arithmetic mean, $\Sigma nd/\Sigma n$. [b] Volume number diameter, $(\Sigma nd^3/\Sigma n)^{1/3}$. [c] Volume surface diameter, $\Sigma nd^3/\Sigma nd^2$. [d] Calculated from the particle number, $6/\pi d_{vn}^3 p$. [e] Calculated from $\sigma = \sqrt{N}$ (from Ref. 7).

RESULTS AND DISCUSSION

The specific activities of Suspensions A, B, and C were 10.3, 11.4, and 11.2 μCi/mg, respectively. The radiochemical purity of each tracer before and after preparation of each suspension as well as at the end of the study was approximately 98%[14]. A particle-size analysis was performed on each suspension prior to use (Fig. 1).

The particle statistics and diameters of each 0.1% dexamethasone suspension are shown in Table I. The mean volume surface diameter, d_{vs}, which emphasizes surface characteristics (7), was used to express the mean particle size. Measurements of 5.75, 11.5, and 22.0 μm were obtained for Suspensions A, B, and C, respectively. The d_{vs} parameter was considered appropriate since the GI absorption rate of poorly soluble, weakly acidic, and, particularly, neutral drugs has been shown to be dissolution rate limited (8–10). After sonification, crystallization continued. The

[a] Mean particle size = 5.75 μm. [b] Mean particle size = 11.5 μm. [c] Mean particle size = 22.0 μm. [d] Number in parentheses represent 1 *SD*. [e] Determined by one-way analysis of variance for heterogeneous variances; all other data sets were determined by the standard one-way analysis of variance for homogeneous variances. NS = not significant or $p > 0.05$.

particle size increased after 2 hr. Relatively narrow distributions were achieved, but some overlap occurred. Removal of crystals from the filter after drying and subsequent handling produced some particle comminution that contributed to this overlap.

The averaged aqueous humor levels of dexamethasone obtained after dosing with the 0.1% preparations are shown in Fig. 2. A rank-order correlation is observed between increasing drug levels and decreasing particle size.

Because of the small sample size used at certain time intervals, a heterogeneous variance resulted. The assumption of homogeneous variances, which is required by a standard one-way analysis of variance, was tested with the use of Bartlett's test of homogeneity of variances (11). Of the 12 time points, five produced χ^2 distributions of $p < 0.05$, indicating heterogeneous variances for these data sets. The remaining seven data sets could be treated with the standard one-way analysis of variance (Table II).

When an equal number of cases (or eyes) is used in each treatment population, the effect of heterogeneous variances is less important in producing erroneous F distributions (12, 13). Nevertheless, an analysis of variance for heterogeneous variances was applied to the appropriate data sets (12, 13). This method differs from the standard method in that the means are weighted according to the reciprocal of the sample variance, and a corrected error mean square term takes the weighting into account (12). An analysis of variance indicated a statistically significant difference for the aqueous humor levels of dexamethasone at each sampling time except the 1.67- and 5-hr intervals. Table II lists the probability values calculated for the data.

Although dissolution rates were not determined for each formulation, the results agree with the expected findings. Suspension A, with its smaller particle size, would be expected to have a more rapid dissolution rate and, providing absorption is dissolution rate controlled, would show a higher C_{max} and an earlier time to peak than Suspension B or C. In comparing Suspensions B and C, Suspension B, which had a smaller particle size, showed a higher C_{max} but had an identical apparent time to peak. More frequent sampling may have permitted a separation of time to peak for Suspensions B and C. The area under the aqueous humor–time curves through the five sampling periods diminished for Suspensions A–C. This effect would occur if the residence time of particles in the conjunctival sac for each suspension was relatively short in comparison to their respective dissolution rates.

Figure 3 shows similar results obtained for corneal levels of drug with time. A statistical difference also was determined between Suspensions A–C for corneal drug levels for most sampling times (Table II). An apparent time to peak was observed at 0.33 hr; however, earlier sampling periods might have indicated an earlier time to peak. The area under each curve shows reduced absorption as the particle size increased.

Suspensions A and B, but not C, showed a parallel decline from 2.5 to 5 hr for the aqueous humor levels. For the corneal data, Suspensions A and C, but not B, showed a parallel decline. The reason for this observation may be related to each suspension; however, more data points in this region are needed to draw a firm conclusion.

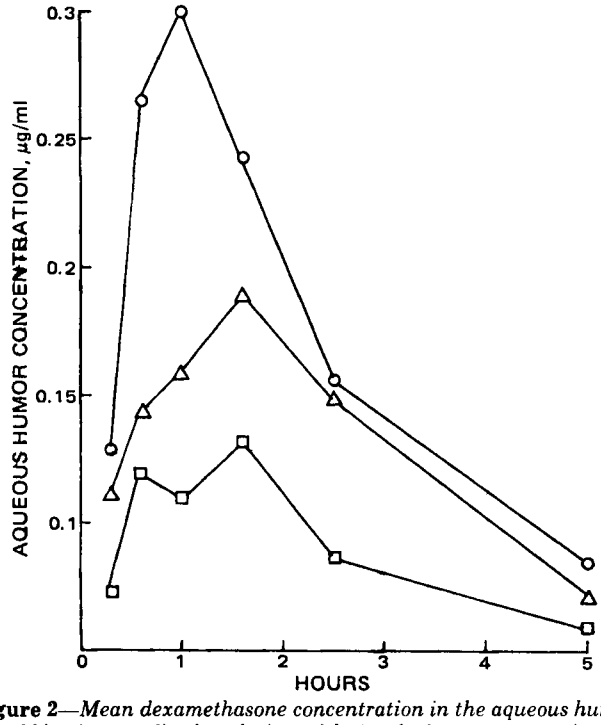

Figure 2—*Mean dexamethasone concentration in the aqueous humor of rabbits* (n = 4–6) *after dosing with 50 μl of 0.1% suspensions of varying particle size. Key:* ○, d_{vs} = *5.75 μm (Suspension A);* △, d_{vs} = *11.5 μm (Suspension B); and* □, d_{vs} = *22.0 μm (Suspension C).*

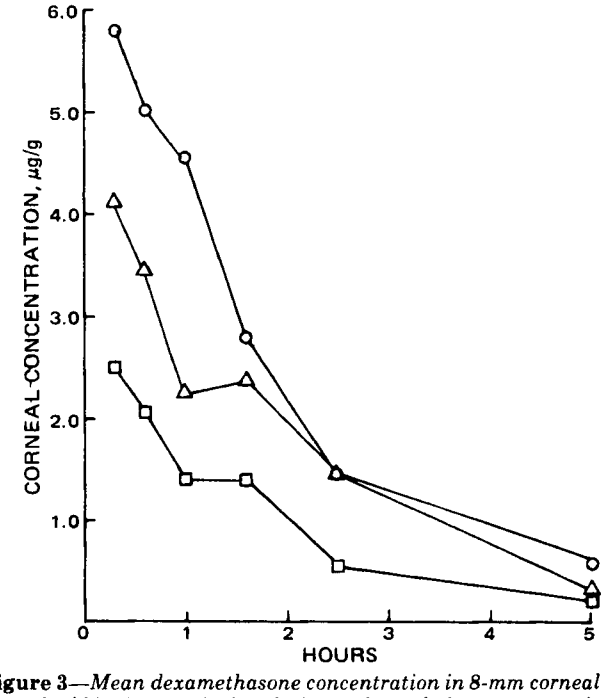

Figure 3—*Mean dexamethasone concentration in 8-mm corneal buttons of rabbits* (n = 4–6) *after dosing with 50 μl of 0.1% suspensions of varying particle size. Key:* ○, d_{vs} = *5.75 μm (Suspension A);* △, d_{vs} = *11.5 μm (Suspension B); and* □, d_{vs} = *22.0 μm (Suspension C).*

According to the data presented, Figs. 2 and 3 suggest that as the particles increase in size, the *in vivo* dissolution rate decreases such that the particles are removed from the conjunctival sac before dissolution is completed. Therefore, both the rate and the extent of penetration into aqueous humor are decreased.

It is possible that as particle size increases, a potential for discomfort is created. As a consequence, tearing could be induced and a progressively decreasing residence time might occur. No clear distinction has been made regarding an upper limit in particle size that would be considered comfortable and, therefore, would not induce tearing. Sieg and Robinson (2) stated that the particle size should be <10 μm to minimize particle irritation in the eye. However, shape and concentration are additional factors that make it difficult to select a specific particle size above which irritation or discomfort might result. From observing the animals during the study, there was no reason to believe that dexamethasone induced tearing at a concentration of 0.1% and an average size of 5.75–22 μm. Nevertheless, the present data do not rule out this possibility.

A potential source of variability between ophthalmic suspensions with different particle sizes could be differences in the amount of the administered dose. Table I lists the volume number diameter, d_{vn}, from which the number of particles per dose can be calculated. In low-strength suspensions such as 0.1% dexamethasone, as the drug particle size increases the number of particles per dose falls rapidly (*i.e.*, inversely with the cube of d_{vn}), potentially increasing the standard deviation of the drug concentration in a randomized dose. The last column in Table I illustrates this point.

Although a limited number of animals was used in the study, the results suggest that ophthalmic dexamethasone suspensions can be optimized for bioavailability by using suspensions with particles as small as possible. This approach would promote a rapid dissolution rate and reduce the chance of tearing and, therefore, would minimize rapid drainage as well as the variability in the quantity of dose administered.

Pharmacokinetics and Bioavailability of Cimetidine in Humans

PETER VENG PEDERSEN [*x] **and RAYMOND MILLER** [‡§]

Received August 28, 1979, from the [*]*Department of Pharmacy, School of Pharmacy, and the* [‡]*Division of Clinical Pharmacology, Department of Medicine, University of California, San Francisco, CA 94143.* Accepted for publication October 18, 1979. [§]Present address: Department of Pharmacology, University of Potchefstroom, Potchefstroom 2520, South Africa.

Abstract □ Cimetidine given orally without food after an overnight fast produces a blood concentration curve with a pronounced second peak that does not appear after parenteral administration or when the drug is taken with food. The following interpretation of this kinetic phenomenon is proposed: 1. The drug cumulates in a tissue or organ that is well perfused in the first-pass transfer. 2. The hepatic parenchymal tissue and the bile phase are the most likely storage areas. 3. The high capacity of the cumulation may be due to the formation of conjugates or other modifications of the drug with a pronounced affinity for the hepatic–biliary system. 4. The rate of cumulation is much higher in the first-pass transfer than from the systemic circulation, possibly due to the difference in the drug concentrations and the conjugation rate. 5. The cumulation appears to occur by a competitive process. 6. Absorbed elements of food seem to compete in this process. 7. The second peak apparently is the result of a rapid release of drug and bioreversible drug compounds from the hepatic–biliary system with subsequent reabsorption. 8. This release may occur spontaneously but appears to be triggered by food intake. A pharmacokinetic model constructed according to this interpretation showed good agreement with data from oral, intravenous, and intramuscular administration. The special problems associated with the evaluation of bioavailability in the presence of reabsorption are discussed.

Keyphrases □ Cimetidine—pharmacokinetics, bioavailability, humans □ Pharmacokinetics—cimetidine, humans □ Bioavailability—cimetidine, humans

Blood levels of cimetidine in humans after oral dosing (1–8) and intravenous administration (2, 5, 6) have been analyzed with respect to the pharmacological response (2), influence of a meal on absorption (3), biliary distribution and secretion (4), and bioavailability (1, 5, 6). The drug shows unusual pharmacokinetic behavior in producing a significant secondary peak in the drug concentration profile after oral dosing on a fasting stomach but not after intravenous administration (5–7). No attempts have been made to describe the pharmacokinetics of the phenomenon.

A conventional two-exponential model has been applied (6), but such a model does not account for the secondary peaks. Bodemar *et al.* (8) stated that: "A second absorption peak could be explained by enterohepatic circulation of cimetidine, although a preliminary report by Spence *et al.* (4) seems almost to exclude this possibility." Considering the possibility of delayed absorption of some of the cimetidine or a varying absorption rate at different segments of the GI tract (6), the same authors (1) stated that: "Calculations from the present results indicate that the consideration from a hypothetical delayed absorption is as much as 50% of total *AUC* in some patients. Delayed absorption of this magnitude, however, is unlikely and this second peak following oral administration of cimetidine remains to be explained."

This study was intended to evaluate the pharmacokinetics of cimetidine and to explain its kinetic discrepancy using the data of Walkenstein *et al.* (5). It is proposed that the phenomenon can be described best in terms of discontinuous reabsorption. The special problems associated with the evaluation of bioavailability in the presence of reabsorption are discussed.

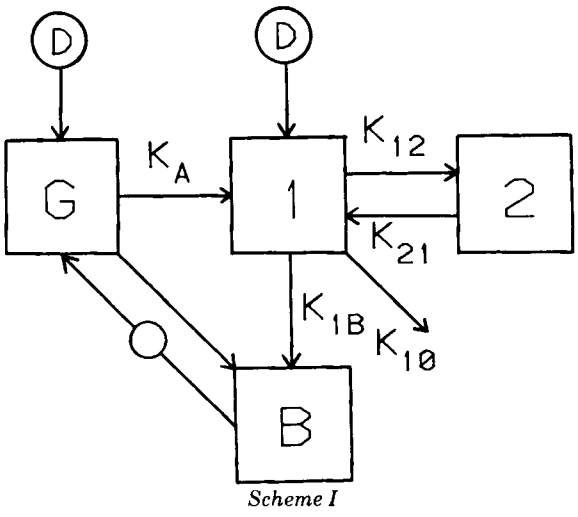

Scheme I

THEORY

The proposed pharmacokinetic model (Scheme I) was developed considering the reported kinetic behavior of cimetidine and encompasses the kinetics after oral, intravenous, and intramuscular administration.

Oral Administration—The drug is presented into the absorption compartment, G (the gut), where a fraction, F_{G1}, of the dose, D, is absorbed by a first-order process into the central, sampleable compartment, 1. The remaining fraction, $1 - F_{G1}$, of the drug goes into a compartment, B, in the first-pass transfer process. No assumptions are made about the type of transfer process from G to B because the kinetic behavior of the system does not depend on the rate of input into B but only on the amount of drug in B at a particular time, T_B. At this time, a fraction, F_B, of the drug cumulated in B is released momentarily into the absorption compartment.

The first-pass elimination reported for cimetidine (5, 6) is incorporated into $1 - F_{G1}$ for simplification. The drug is eliminated from the central compartment and transferred into compartment B and a peripheral compartment, 2, by first-order processes.

Intravenous and Intramuscular Administration—It has been shown that there are no significant differences in the blood level profiles between intravenous and intramuscular administration (5). The absorption from an intramuscular injection appears so rapidly that kinetically it can be considered as an intravenous administration. Therefore, the same model was applied for the two administrations. It is the same model as discussed, except that the input is a bolus input into the central compartment.

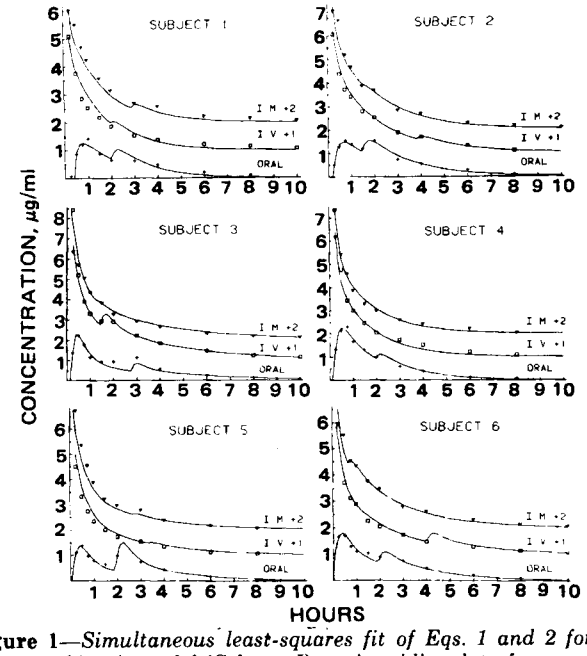

Figure 1—*Simultaneous least-squares fit of Eqs. 1 and 2 for the pharmacokinetic model (Scheme I) to cimetidine data from oral, intravenous, and intramuscular administration. The curves and data are staggered vertically one unit for clarity.*

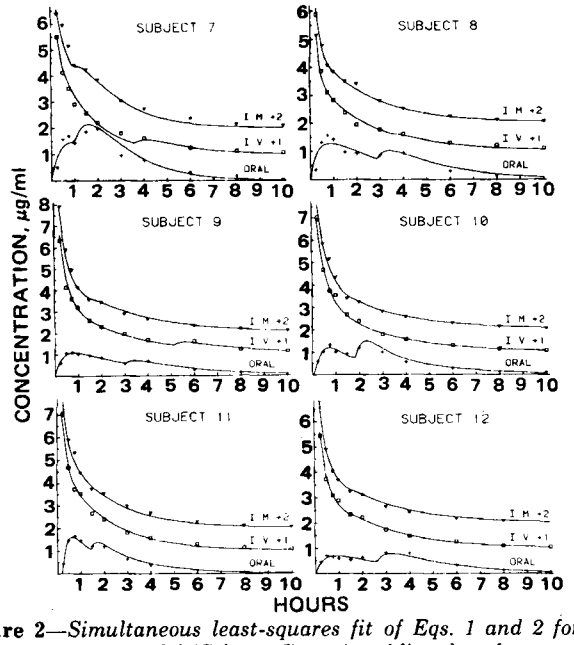

Figure 2—*Simultaneous least-squares fit of Eqs. 1 and 2 for the pharmacokinetic model (Scheme I) to cimetidine data from oral, intravenous, and intramuscular administration. The curves and data are staggered vertically one unit for clarity.*

The differences in the response profiles with respect to the presence or the absence of the secondary peak from an oral or parenteral administration is accounted for by the relative magnitude of the transfer rate of the drug from G to B and from 1 to B. A significant G to B transfer gives rise to a pronounced secondary peak. However, a slow 1 to B transfer, competing with elimination and distribution, results in only a small drug cumulation in B and an insignificant secondary peak, which may be difficult to detect in the blood level data (Figs. 1 and 2).

The choice of a discontinuous cyclic transfer process in the model is justified from physiological considerations (9, 10). Theoretical as well as simulation studies also indicate that secondary peaks cannot be obtained from linear compartmental systems with continuous cyclic transfer processes (11, 12).

Regression Equations—The following response equations are readily derived by standard means (13). After intravenous and intramuscular administration:

$$c = \frac{D}{V}[a_1e^{-\lambda_1 t} + a_2e^{-\lambda_2 t}] + \frac{K_A F_B D_B}{V}[a_3e^{-K_A(t-T_B)+} - a_4e^{-\lambda_1(t-T_B)+} - a_5e^{-\lambda_2(t-T_B)+}] \quad \text{(Eq. 1)}$$

and after oral administration:

$$c = \frac{K_A}{V}[F_{G1}D(a_3e^{-K_A(t-T_L)+} - a_4e^{-\lambda_1(t-T_L)+} - a_5e^{-\lambda_2(t-T_L)+}) + F_B D_B(a_3e^{-K_A(t-T_B)+} - a_4e^{-\lambda_1(t-T_B)+} - a_5e^{-\lambda_2(t-T_B)+})] \quad \text{(Eq. 2)}$$

where:

$$a_1 = (K_{21} - \lambda_1)/(\lambda_2 - \lambda_1) \quad \text{(Eq. 3)}$$

$$a_2 = (K_{21} - \lambda_2)/(\lambda_1 - \lambda_2) \quad \text{(Eq. 4)}$$

$$a_3 = (K_{21} - K_A)/(\lambda_1 - K_A)(\lambda_2 - K_A) \quad \text{(Eq. 5)}$$

$$a_4 = (K_{21} - \lambda_1)/(\lambda_1 - K_A)(\lambda_2 - \lambda_1) \quad \text{(Eq. 6)}$$

$$a_5 = (K_{21} - \lambda_2)/(\lambda_2 - K_A)(\lambda_1 - \lambda_2) \quad \text{(Eq. 7)}$$

and where after intravenous and intramuscular administration:

$$D_B = K_{1B}D\left[\frac{a_1}{\lambda_1}(1 - e^{-\lambda_1 T_B}) + \frac{a_2}{\lambda_2}(1 - e^{-\lambda_2 T_B})\right] \quad \text{(Eq. 8)}$$

while after oral administration:

$$D_B = X_B + (1 - F_{G1})D \quad \text{(Eq. 9)}$$

The truncation function used in Eqs. 1 and 2 is defined by:

$$(x)_+ = \max(0,x) \quad \text{(Eq. 11)}$$

Data Treatment[1]—With the interactive program FUNFIT (14), Eqs. 1 and 2 were fitted simultaneously by nonlinear least-squares regression to the oral, intravenous, and intramuscular data for each of the 12 subjects (5). All estimated microparameters are common for the functions describing the intravenous, intramuscular, and oral data except for the time, T_B, and the fraction, F_B, of drug release from B (Table I).

RESULTS AND DISCUSSION

To elucidate the unusual kinetic behavior of cimetidine, it is appropriate to summarize the most pertinent findings in the literature:

F1. Cimetidine taken orally without food after an overnight fast produces a pronounced secondary peak in most subjects (1, 5).

F2. The secondary peak does not seem to be present when the drug is taken orally with food (1).

F3. Intravenous and intramuscular administrations of cimetidine do not result in secondary peaks as occur after oral administration (1, 5).

F4. With food, the initial rise in plasma cimetidine concentration appears more slowly than if the drug is taken without food on a fasting stomach (1, 3).

F5. Mean blood levels after equal doses of cimetidine given orally or parenterally do not differ significantly after 4 hr (5, 6).

F6. The drug appears to be completely and rapidly absorbed in the therapeutic dosing range after oral administration (1, 5).

F7. The extent of absorption apparently does not differ when the drug is administered on a fasting stomach with or without food (1).

F8. The bioavailability of the drug after oral administration is ~70% of the intravenous bioavailability. The reduction appears to be due to a first-pass effect rather than a drug release rate-limited absorption (1, 5).

F9. The *AUC* appears to be proportional to the oral dose in the therapeutic dosing range (1, 6).

F10. Cimetidine is eliminated mainly *via* the kidneys (2). An average of 0.75 of the drug is recovered unchanged in the urine after parenteral administration, while only 0.5 of it is recovered after oral administration (5).

F11. A small amount of material derived from cimetidine is excreted in the feces after intravenous administration of radiolabeled drug (6).

F12. The fecal radioactivity accounts for an average of 10% of orally administered labeled cimetidine regardless of the dose (400 or 800 mg) (6).

F13. An average of 70% of the radioactivity administered is recovered in the urine of healthy human subjects after an oral dose of 200 mg of labeled cimetidine.

F14. The concentration of cimetidine is approximately five times higher in the bile than in the blood of patients undergoing exploratory surgery of the common bile duct (4).

F15. The conjugation reaction is of considerable significance for the biliary excretion of a drug since it produces a substrate with particularly suitable properties for the hepatic system (15–17).

F16. Several isolated studies on the fate of orally administered conjugates indicate that they are reabsorbed largely after hydrolysis in the gut and that this step is important in relation to the enterohepatic cycle (15, 17, 18).

F17. Substances showing a bile–blood concentration ratio substantially larger than one appear to be transferred into the bile across the parenchymal cell wall by an active transport process (4, 15).

F18. Substances actively transferred by the liver cells compete for transport across the hepatic membrane into the bile (15, 19–22).

F19. Many compounds secreted in the bile have a marked affinity for localizing in hepatic parenchymal tissue (22–24).

F20. The gallbladder releases most of its bile content into the duodenum shortly after the intake of a meal, particularly when the meal is eaten on a fasting stomach (9, 10).

F21. The release of bile into the duodenum stimulates the flow of pancreatic juice (25).

F22. Spontaneous contractions of the gallbladder occur in the fasting stage (9).

F23. The volume difference between a full and contracted gallbladder is ~30–50 cm^3 (9).

F24. It takes the gallbladder 1.5–2 hr to fill after a full contraction (9).

F25. Cimetidine results in marked inhibition of both gastric acid and pepsin secretion (2).

Kinetic Interpretation—In studying the cimetidine data from intravenous, intramuscular, and oral administrations (1, 5) together with the described findings, the following interpretation of this drug's unusual kinetic behavior was reached:

1. The secondary peak appears to be due to a rapid release from a drug depot. The depot is located in a tissue or organ that is well perfused by the drug in the first-pass transfer. The bile and the hepatic parenchymal tissues are the most likely primary storage areas (F11, F14, F15, F19, and F20) (26).

2. The time for the release appears to coincide with the intake of food in most cases. The 2-hr interval between oral drug intake and breakfast agrees well with the start of the second peak (Figs. 1 and 2). The mean value of T_B is 2.1 hr (Table I) (F20 and F22).

3. Drug transfer into the depot occurs mainly in the first-pass process (F1 and F3).

4. This transfer is significantly inhibited, possibly by the way of competitive active membrane transport, when the drug is taken with food (F2, F17, and F18). The excretion of bile in response to food also may play a role if the smaller amount of bile in the hepatic system reduces the uptake rate or capacity of the system.

5. The transfer rate of drug into the depot from the systemic circulation is slow compared to the first-pass transfer (F1 and F3). This effect possibly is due to a pronounced drug concentration difference at the depot site for the two administration routes. The drug concentration is large in the first-pass perfusion of the depot organ before the drug reaches the general systemic circulation. However, when the drug is introduced parenterally in the systemic circulation, a substantial dilution takes place before it reaches the depot organ. The higher metabolic activity at the first-pass route also may contribute to a larger uptake of drug by the

depot (F8, F15, and F16).

6. Cimetidine possibly is stored in the depot both in the parent form and as conjugates or complexes. The large capacity of the hepatic system for storage and biliary excretion of conjugates may explain the magnitude of the secondary peak (F15 and F16).

Capacity of Hepatic System for Recycling—The theory of enterohepatic recycling to explain the second peak phenomenon has been criticized mainly because of the magnitude of the peak relative to the concentration of cimetidine found in the bile (4) and the estimated amount of bile secreted by the hepatic system into the intestine (9). However, it is difficult to evaluate the mechanism and capacity of the hepatic system for drug recycling. Data obtained with chronic biliary fistulas or with draining T-tubes after cholecystectomy may have to be interpreted with caution because of the inevitable loss of bile salts (27). In addition, liver disease in humans is a collection of functional and structural disabilities including inflammatory, neoplastic, and degenerative disorders in which the parenchyma, the biliary tree, and the vascular supply may be substantially affected (28, 29). Therefore, the disease state of the patient would play a significant role in the biliary excretion of the drug.

The studies of biliary secretion of cimetidine involved patients undergoing exploratory surgery of the common bile duct (4). Presumably, the patients did not have a normal hepatic–biliary function. The surgery seems to have had a pronounced effect on the pharmacokinetics since the peak venous concentration of cimetidine often differed by more than 100% in the same individual during the study. In contrast, the nonoperative studies involving healthy subjects showed a remarkably small intraindividual variation in the blood drug levels (1, 5). The concentration of cimetidine in the bile found in the operative study (4) apparently was based on an assay that considers only free, untransformed drugs (3). Conjugates or other modifications that may be present in high concentrations (F15) and may be responsible for a significant recycling (F16) apparently were not included.

Pharmacokinetic Model—The pharmacokinetic model proposed (Scheme I) is a highly simplified functional model constructed according to the given interpretation. The *B* compartment represents the depot of the drug that is partly released, F_B, at some time, T_B, soon after or during a meal or spontaneously before a meal (F22). The model appears to agree well with the data (Figs. 1 and 2) and shows that the transfer of the drug into *B* in the first pass (*G* to *B*) is primarily responsible for the cumulation of the drug in *B* while the systemic transfer (1 to *B*) only plays a minor role (Figs. 1 and 2 and Table I).

The least-squares estimate of T_B after oral administration is 2.1 hr, which is not significantly different from the time (2 hr) for the intake of food after oral drug administration (F20). Although it is difficult to detect a secondary peak or hump in the data from the parenteral administrations, nonlinear regression analysis indicates a small degree of recycling in some cases (Figs. 1 and 2). However, due to the sparseness and limited accuracy of the data, it is difficult to determine T_B and the magnitude of the recycling effect after parenteral administration. This situation is reflected in the coefficients of variation of the T_B values; they are approximately the same for intravenous and intramuscular administrations but significantly larger than those for oral administration (Table I).

Bioavailability—An interesting aspect of the recycling phenomenon is its influence on the *AUC* values and the interpretation of bioavailability calculations based on comparisons of such values. The ratio between *AUC* values in such cases cannot be used as a relative measure of the extent of drug absorption since the *AUC* is dependent on the extent of recycling. Therefore, the *AUC* does not properly reflect the extent of primary absorption. Thus, the evaluation of the extent of first-pass effect and the evaluation of bioequivalency of oral drug delivery systems are complicated using the model-independent *AUC* approach, so other techniques may be worth considering. However, the *AUC* still is a useful parameter since, physiologically and pharmacologically, it is a more meaningful parameter than a parameter that measures the extent of primary absorption.

By using the intravenous and intramuscular administrations as reference dosage forms and the integrated form of the regression equations to calculate the *AUC* values, the bioavailability of the oral dosage was 0.61 in both cases (Table II). This value corresponds well to the reported values of 0.62 and 0.59 obtained by log-linear trapezoidal integration (5).

It is evident that in the presence of recycling it is not possible to calculate *F*, the fraction of the dose given that reaches the systemic circulation, by a model-independent approach. With the present model, *F* can be calculated according to:

$$F = (F_{G1}D + F_B D_B)/D \qquad \text{(Eq. 12)}$$

The mean value of 0.64 obtained in this way (Table II) agrees with the quantities of drug and drug metabolites found in the urine and the feces (F10, F12, and F13).

The oral data showing the pronounced secondary peak were from an oral administration taken on a fasting stomach without food. Two hours was allowed to pass before food intake. Other investigations indicated that the second peak will not be present when cimetidine is taken orally with food (1). It has been recommended that cimetidine be taken with food to obtain the best therapeutic effect. Thus, the second peak seems to be an artifact from the experimental design and may not be of much significance in the practical therapeutic setting. This result raises the question of how appropriate it is to fast a subject before and during a pharmacokinetic study. It may not be appropriate if the objective is to estimate the normal pharmacokinetic behavior of a population or to provide practical guidelines for dosage regimens.

However, the particular experimental design does reveal an interesting pharmacokinetic phenomenon that may be of significance in organ and

tissue specific drug delivery, chemotherapy, and treatment of inflammatory and infectious diseases of the liver and biliary system.

NOTATIONS

$AUC = \int_0^\infty c\,dt$
B = drug depot compartment
c = blood cimetidine concentration
D = dose
$D_B = X_B + (1 - F_{G1})D$
$D_T = F_{G1}D + F_BD_B$, the apparent amount of the dose absorbed
$F = (F_{G1}D + F_BD_B)/D$, the apparent fraction of the dose absorbed
F_B = fraction of drug cumulated in B that is released to G at time $t = T_B$
F_{G1} = fraction of D absorbed by first-order absorption into the central compartment
$1 - F_{G1}$ = fraction of D transferred from G to B
G = compartment from which absorption takes place
K_{xx} = first-order transfer rate constants
$-\lambda_1, -\lambda_2$ = eigenvalues of the linear system
t = time
T_L = lag time
T_B = time when a part (F_BD_B) of the drug cumulated in B is released to G
V = volume of distribution
X_B = amount of drug transferred from compartment 1 to compartment B at time $t = T_B$

Human Pharmacokinetics of a New Broad-Spectrum Parenteral Cephalosporin Antibiotic, Ceforanide

MORRIS PFEFFER ˣ, ROBERT C. GAVER, and DONALD R. VAN HARKEN

Received July 14, 1977, from the *Department of Drug Metabolism and Pharmacokinetics, Bristol Laboratories, Syracuse, NY 13201.* Accepted for publication October 26, 1979.

Abstract □ The pharmacokinetics of the *l*-lysine salt of ceforanide were studied after intravenous administration of 1132 and 2264 mg as 30-min constant-rate infusions and after intramuscular administration of 556 and 1132 mg. The peak intravenous plasma concentrations were 136 and 222 μg/ml at termination of infusion, and 12-hr trough concentrations were 5.9 and 9.0 μg/ml, respectively. The peak intramuscular plasma concentrations were 38 and 74 μg/ml at 1.0–1.3 hr after dosing, and 12-hr trough concentrations were 3.9 and 6.7 μg/ml, respectively. When 19 successive intravenous and intramuscular doses at these levels were administered at 12-hr intervals, there was no tendency toward drug accumulation. The major drug elimination route was urinary excretion; 85% of the dose was excreted unchanged in the urine within 12 hr, and no metabolites with antibiotic activity were observed in urine. The mean terminal plasma half-life was 2.98 hr, the mean plasma protein binding was 80.6%, the steady-state volume of distribution was 12 liters, the plasma clearance was 45.9 ml/min/1.73 m^2, and the renal clearance was 34.9 ml/min/1.73 m^2. The pharmacokinetic properties and antibacterial activity spectrum indicate that this antibiotic should be effective in treating human bacterial infections when administered at 12-hr intervals. It is presently under clinical investigation.

NOTATIONS

$AUC = \int_0^\infty c\,dt$
B = drug depot compartment
c = blood cimetidine concentration
D = dose
$D_B = X_B + (1 - F_{G1})D$
$D_T = F_{G1}D + F_BD_B$, the apparent amount of the dose absorbed
$F = (F_{G1}D + F_BD_B)/D$, the apparent fraction of the dose absorbed
F_B = fraction of drug cumulated in B that is released to G at time $t = T_B$
F_{G1} = fraction of D absorbed by first-order absorption into the central compartment
$1 - F_{G1}$ = fraction of D transferred from G to B
G = compartment from which absorption takes place
K_{xx} = first-order transfer rate constants
$-\lambda_1, -\lambda_2$ = eigenvalues of the linear system
t = time
T_L = lag time
T_B = time when a part (F_BD_B) of the drug cumulated in B is released to G
V = volume of distribution
X_B = amount of drug transferred from compartment 1 to compartment B at time $t = T_B$

Human Pharmacokinetics of a New Broad-Spectrum Parenteral Cephalosporin Antibiotic, Ceforanide

MORRIS PFEFFER ˣ, ROBERT C. GAVER, and DONALD R. VAN HARKEN

Received July 14, 1977, from the *Department of Drug Metabolism and Pharmacokinetics, Bristol Laboratories, Syracuse, NY 13201.* Accepted for publication October 26, 1979.

Abstract □ The pharmacokinetics of the *l*-lysine salt of ceforanide were studied after intravenous administration of 1132 and 2264 mg as 30-min constant-rate infusions and after intramuscular administration of 556 and 1132 mg. The peak intravenous plasma concentrations were 136 and 222 μg/ml at termination of infusion, and 12-hr trough concentrations were 5.9 and 9.0 μg/ml, respectively. The peak intramuscular plasma concentrations were 38 and 74 μg/ml at 1.0–1.3 hr after dosing, and 12-hr trough concentrations were 3.9 and 6.7 μg/ml, respectively. When 19 successive intravenous and intramuscular doses at these levels were administered at 12-hr intervals, there was no tendency toward drug accumulation. The major drug elimination route was urinary excretion; 85% of the dose was excreted unchanged in the urine within 12 hr, and no metabolites with antibiotic activity were observed in urine. The mean terminal plasma half-life was 2.98 hr, the mean plasma protein binding was 80.6%, the steady-state volume of distribution was 12 liters, the plasma clearance was 45.9 ml/min/1.73 m^2, and the renal clearance was 34.9 ml/min/1.73 m^2. The pharmacokinetic properties and antibacterial activity spectrum indicate that this antibiotic should be effective in treating human bacterial infections when administered at 12-hr intervals. It is presently under clinical investigation.

I

administered cephalosporin antibiotic, have been described in detail and compared with those of cephalothin, cephaloridine, and cefazolin (1). With few exceptions, ceforanide was more active than these reference antibiotics against major Gram-negative pathogens, and it inhibited their growth at plasma and urinary concentrations readily achievable in humans.

This report describes the pharmacokinetics of the lysine salt (I) of this cephalosporin antibiotic in normal subjects following single and multiple intravenous and intramuscular doses.

EXPERIMENTAL

Drug Doses and Administration Routes—All doses are expressed in terms of free acid equivalents of ceforanide. The drug was prepared immediately before administration as sterile solutions in vials containing 283 mg of drug. For intramuscular injection, the vial contents were reconstituted with sterile water USP to yield concentrations of 283 mg/ml. The intramuscular injections were administered in the outer quadrant of the gluteal muscle as 2 ml of solution for the 566-mg dose and as 4 ml of solution for the 1132-mg dose. For intravenous administration, the antibiotic was reconstituted in sterile physiological saline solution USP to give a final concentration of 1132 or 2264 mg in 50 ml of solution. Fifty milliliters of either solution was administered into an antecubital vein by 30-min constant-rate infusion using a compact infusion pump[1].

Volunteers and Study Design—The drug was administered to 24 normal adult males, 22–40 years old, with an average weight ($\pm SE$) of 72.5 ± 1.3 kg and an average body surface area ($\pm SE$) of 1.90 ± 0.02 m^2.

Six randomly selected subjects were given 556 and 1132 mg im and 1132 and 2264 mg iv twice daily at 12-hr intervals for a total of 19 successive doses over 10 dosing days (a second dose was not administered on the last dosing day). The morning dose was given before breakfast.

Sample Collection—Plasma and urine specimens were collected after the first, ninth, and 19th doses. Plasma samples were collected from the intravenous subjects immediately before dosing (zero time), at 15 and 30 min during the infusion (the 30-min sample was collected at the end of the infusion and also constituted the zero-time postinfusion sample), and then at 0.25, 0.50, 1.0, 2.0, 4.0, 6.0. 8.0, and 11.5 hr after infusion termination. Plasma samples were collected from the intramuscular subjects immediately before dosing (zero time) and at 0.25, 0.50, 0.75, 1.0, 1.5, 2.5, 4.0, 6.0, 9.0, and 12 hr after dosing.

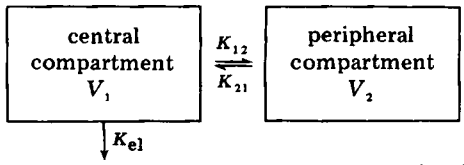
Complete urine samples were collected from all subjects over the 0–2-, 2–4-, 4–6-, 6–9-, and 9–12-hr intervals after the start of dosing. After the 19th dose, a 12–24-hr urine sample also was collected.

Heparinized blood samples, 10 ml, were collected by venipuncture[2]. The contents of the tubes were mixed gently and then immediately placed in a chipped ice bath where they were kept until plasma was separated by centrifugation at 4°. At least 3 ml of plasma was withdrawn and placed in polypropylene tubes with caps.

The urine samples were refrigerated at 4° while being collected. The subjects were instructed to empty their bladders at the end of each collection interval. The total volume and pH of each urine sample were measured and recorded. Immediately thereafter, 10-ml aliquots of each urine sample were transferred to polypropylene bottles.

The plasma and urine samples were flash frozen by immersion in an ethanol–dry ice bath and stored at or below −20° until they were thawed for assay.

Antibiotic Assay—Plasma and urine concentrations of ceforanide were determined by standard cup-plate bioassay techniques (2) using *Klebsiella pneumoniae* (Bristol A9977)[3] as the bioassay organism. Other microorganisms cannot be expected to yield equivalent, valid results for the bioassay of ceforanide. All bioassay results are expressed in terms of free acid equivalent concentrations.



Scheme I—Open, first-order, two-compartment model of drug distribution

The lower sensitivity limit of the assay was equivalent to a plasma concentration of 2.0 μg/ml. The linear concentration ranges for the cup-plate assay were 0.5–5.0 μg/ml for plasma and 1–10 μg/ml for urine. The mean coefficient of variation [(standard deviation of zone diameter/mean zone diameter) × 100] of replicate cup-plate assays of the standards was 3.10%.

Determination of Plasma Protein Binding—Ceforanide was added to fresh, pooled, heparinized 90% human plasma at concentrations of 27, 53, 99, and 200 μg/ml, and the samples were incubated at 37° for 15 min with gentle shaking. Replicate solutions were prepared in aqueous pH 7.40 buffer containing 0.05 *M* NaCl and 0.10 *M* *N*-tris(hydroxymethyl)-methyl-2-aminoethanesulfonic acid[4] and were treated similarly. These samples were subjected to centrifugal ultrafiltration[5].

The drug concentrations in the filtrates were determined by the same cup-plate assay technique used for plasma and urine analyses. The concentration in the plasma filtrate as a percentage of the total concentration in the unfiltered plasma sample was subtracted from 100% to determine the percentage bound to plasma protein. Ceforanide did not bind to the ultrafiltration membrane.

Bioautographic Analysis for Urinary Metabolites with Antibiotic Activity—Urine samples were diluted with 0.1 *M* potassium phosphate buffer (pH 7.0) and spotted on 1.2 × 57-cm strips of filter paper[6]. The strips were developed overnight in the descending mode using *n*-butanol–acetic acid–water (60:15:25). Then they were air dried, overlaid on seed agar inoculated with *Bacillus subtilis* (A9506A), and incubated overnight at 28°. Inhibition zones were visualized by spraying with 1.2% triphenyltetrazolium chloride in 1.25% dextrose solution. The R_f value of ceforanide was 0.3.

Pharmacokinetic Analysis—Mean plasma concentrations during and after intravenous infusion of the first doses were fitted to an open, first-order, two-compartment model of drug distribution (Scheme I) (3). The fitting was performed according to Marquardt's algorithm (4) using a digital computer program. The best-fit parameters found by this procedure were corrected by the Loo–Riegelman procedure (5) to obtain the equivalent parameters that could be found on instantaneous bolus intravenous administration of the same drug doses. This procedure yielded an equation of the form $C = A \exp(-\alpha t) + B \exp(-\beta t)$, where C is the plasma concentration, t is time, A and B are coefficients, and α and β are exponents. The A, B, α, and β parameters and the urinary excretion data were processed further, allowing the various pharmacokinetic parameters to be calculated by standard procedures (6).

The individual subject's observed peak plasma concentrations, C_{max}, and the time to peak plasma concentrations, t_{max}, by both dosing routes and at all dose levels were tabulated, and the mean values and standard errors were calculated. The individual area under the plasma concentration–time curves from $t = 0$ to $t = \infty$ (AUC) were calculated for the first dose by the trapezoidal rule:

$$AUC = \sum_{i=1}^{n-1} (C_{i+1} + C_i)(t_{i+1} - t_i)/2 + C_n/\beta \qquad \text{(Eq. 1)}$$

where $C_1 = 0$ at $t_1 = 0$. The β term is the slope of a plot of the natural logarithms of the 3–12-hr plasma concentrations *versus* time as determined by linear regression analysis. The AUC values for the ninth and 19th doses were calculated between 0 and 12 hr. The observed terminal plasma half-life, $t_{1/2}$, was calculated from β by:

$$t_{1/2} = 0.693/\beta \qquad \text{(Eq. 2)}$$

for all subjects. The individual AUC and $t_{1/2}$ values also were tabulated, and their means and standard errors were calculated.

Table I—Ceforanide Binding to Human Plasma Proteins

Plasma Concentration, μg/ml	Percent Bound[a]
27	83.0 (0.0)
53	82.8 (0.2)
99	80.7 (0.0)
200	76.0 (1.1)

[a] Mean (±*SE*) of triplicate determinations.

The absorption profile following intramuscular administration was determined from the mean plasma concentration data using the Loo–Riegelman method (7).

The absolute percentage bioavailability following intramuscular administration was determined by linear regression analysis of a plot of *AUC versus* dose for the intravenous and intramuscular data and by:

$$100F = (U_{im}/U_{iv}) \times 100 \qquad \text{(Eq. 3)}$$

where $100F$ is the absolute percentage bioavailability and U is the fraction of the dose excreted in the urine in 12 hr.

Statistical Analysis—The various observed and calculated pharmacokinetic parameters by each dosing route and at each dose level were compared between dosing groups by the *t* test for group comparisons. The statistical tests (both the *t* test and linear regression analyses) were analyzed for significance at $p = 0.05$. All references to significant or nonsignificant results refer to the tests for statistical significance.

When comparisons were performed between study days within a given dosing group, a *t* test for paired comparisons was used, except in one case. Since there were data for only four subjects for the first 1132-mg iv infusion dose but there were data for all six subjects for the ninth and 19th doses, these data sets also were compared by a *t* test for group comparisons so that two subjects did not have to be omitted at the ninth and 19th doses. These *t* tests for group comparisons yielded the same results as the *t* tests for paired comparisons.

The results of the absolute bioavailability analyses of urinary excretion data were subjected to a *t* test of the null hypothesis that the true mean bioavailability was 100%. These tests also were analyzed for significance at $p = 0.05$.

RESULTS

Plasma Protein Binding—These results are summarized in Table I. The binding over the 27–200-μg/ml range was essentially constant at 80.6%. Investigations of the binding of other cephalosporin antibiotics, using the same technique and the same pooled plasma sample as for ceforanide, indicated 89.7% protein binding for cefazolin between 25 and 205 μg/ml, 50.0% for cefoxitin between 11 and 88 μg/ml, 44.7% for cefuroxime between 9 and 75 μg/ml, and 82.7% for cefamandole (either as the sodium salt or as cefamandole nafate) between 8 and 88 μg/ml.

Bioautographic Analysis—No evidence was found for the presence of any ceforanide metabolite(s) with antibiotic activity in urine.

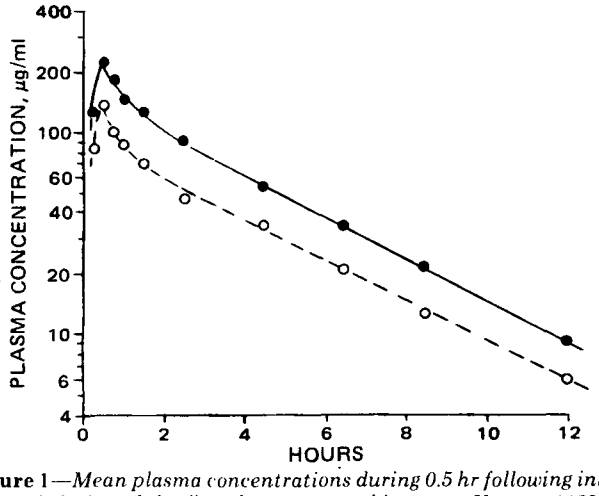

Figure 1—*Mean plasma concentrations during 0.5 hr following intravenous infusion of the first dose to normal humans. Key:* ○, *1132-mg dose; and* ●, *2264-mg dose.*

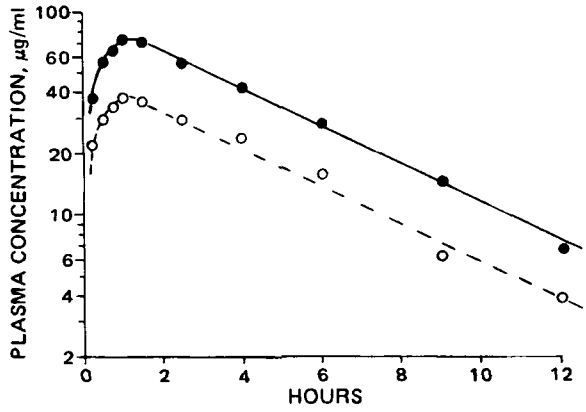

Figure 2—*Mean plasma concentrations following intramuscular administration of the first dose to normal humans. Key:* ○, *566-mg dose; and* ●, *1132-mg dose.*

Plasma and Urine Levels—Figures 1 and 2 are semilogarithmic plots of the mean concentration *versus* time data for the first intravenous and intramuscular doses. There were data from six subjects for each dosage route and dosage level on all dosing days, except for the first 1132-mg iv dose where there were only four subjects. At that time, one infusion pump developed a minor mechanical problem. Therefore, the starting time and exact dose administered to two of the subjects were unknown, although it was estimated that they received ~85% of the dose. Neither plasma nor urine samples were collected from these two subjects on the 1st day. The mechanical problem was resolved immediately, and there were no other difficulties with dosing throughout the study.

The various observed mean plasma parameters after intravenous and intramuscular administration are listed in Table II. The mean peak concentrations did not change significantly over the 19 drug doses by either route or at any given dose level, indicating that there was no tendency toward accumulation of ceforanide when administered every 12 hr, even though there was an appreciably detectable trough plasma concentration immediately before the next dose was given. The mean time of peak concentrations after intramuscular dosing did not change significantly over the duration of the study, indicating that the absorption profile of ceforanide did not change on repeated administration.

The terminal plasma half-lives (2.7–3.2 hr) remained essentially constant throughout the study by both routes and dose levels. Figure 3 is a rectilinear plot of the mean area under the plasma concentration–time curve *versus* dose for the intravenous and intramuscular data from the first, ninth, and 19th doses. Linear regression analysis indicated that the areas by the two dosage routes were on the same statistically significant straight line and that the *y* intercept was not significantly different from zero ($p = 0.05$). Therefore, the absolute bioavailability was 100% following intramuscular administration. The reciprocal of the slope of this line was the plasma clearance, Cl_p, of the drug, 50.2 ml/min/1.73 m^2.

The mean urinary recoveries are listed in Table III. The compound was excreted through the kidneys at high concentrations. On the average, 85% of the administered dose was recovered in the urine within 12 hr of the start of injection. There were no statistically significant differences in total excretion after intramuscular or intravenous administration, which

[a] Standard errors in parentheses. [b] Sample not collected.

also is indicative of 100% bioavailability of ceforanide on intramuscular administration.

The data in Table III were converted to urinary excretion rates during each urine collection interval and plotted *versus* the plasma concentrations at the midpoints of the collection intervals (Fig. 4). The data yielded a statistically significant straight line by linear regression analysis. The y intercept was not significantly different from zero. Therefore, urinary excretion of ceforanide may be treated as a reaction following apparent first-order kinetics. The slope of the plot was equivalent to the renal clearance, Cl_r, of ceforanide, 34.9 ml/min/1.73 m^2.

The mean plasma concentrations for the first intravenous doses of ceforanide were analyzed using the open, two-compartment model of drug distribution (Scheme I). The central compartment, with a volume of distribution of V_1, is comprised of well-perfused tissues and includes the blood plasma. The peripheral compartment, with a volume of distribution of V_2, is comprised of more poorly perfused tissues. Both K_{12} and K_{21} are first-order rate constants for drug transfer between the central and peripheral compartments; K_{el} is the first-order rate constant for drug elimination, which occurs only from the central compartment. The total volume of the drug distribution in the body is V_{dss} (the volume of distribution at steady state). If it is assumed that drug clearances from the central to the peripheral compartments and from the peripheral to the central compartments are equal (*i.e.*, $V_1K_{12} = V_2K_{21}$), then $V_2 = K_{12}V_1/K_{21}$ and V_{dss} can be calculated as $V_{dss} = V_1 + V_2$. According to this model, the plasma clearance can be calculated as $Cl_p = V_1K_{el}$.

The best-fit values for the pharmacokinetic parameters are listed in Table IV. The results for the 1132- and 2264-mg iv doses were essentially identical; the differences between doses were attributed to normal intersubject differences between two panels of subjects. The half-lives (3.08 and 2.89 hr) were almost identical to those found by direct linear regression analysis of the data of individual subjects (3.06 and 2.88 hr, Table II). The overall Cl_p found by direct pharmacokinetic analysis of the mean intravenous infusion data, 45.9 ml/min/1.73 m^2, was close to the Cl_p of 50.2 ml/min/1.73 m^2 found by plotting the area under the curve *versus* dose for all subjects for both the intravenous and intramuscular data.

The most important, but not exclusive, factor controlling the terminal half-life of ceforanide was the elimination rate constant, K_{el}. The rate constant for drug transfer from the peripheral to the central compartment, K_{21}, was about three times larger than K_{el} and, therefore, cannot be process limiting.

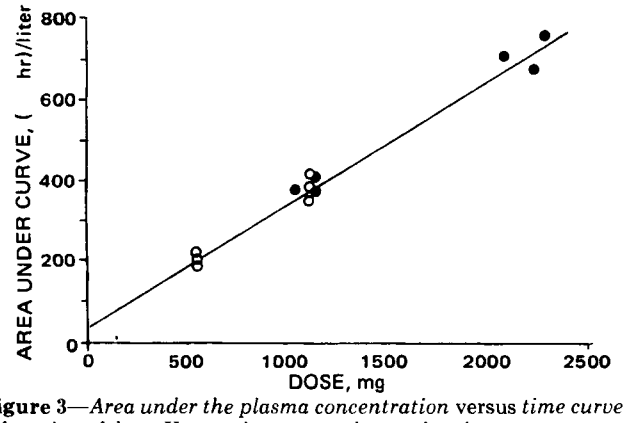

Figure 3—*Area under the plasma concentration* versus *time curve as a function of dose. Key:* ○, *intramuscular; and* ●, *intravenous.*

The mean values listed for the pharmacokinetic parameters in Table IV were used to determine the intrinsic intramuscular absorption profile according to the Loo–Riegelman procedure (7). The results are presented in Fig. 5 as a semilogarithmic plot of the percentage of dose unabsorbed *versus* time. The values for the 566- and 1132-mg doses essentially were superimposable and formed a straight line. Intramuscular absorption of the drug can be considered to be a passive process proceeding by apparent first-order kinetics. The first-order intramuscular absorption rate constant, K_a, was 1.19 hr^{-1}, yielding an absorption half-time of 35 min. Intramuscular absorption of ceforanide had no dose-dependent features.

DISCUSSION

Ceforanide has linear, dose-independent pharmacokinetic properties in humans. These properties are compared to those of several other parenteral cephalosporin antibiotics in Table V. Its plasma half-life, 2.9 hr, is the longest of any of these antibiotics; cefazolin, at 1.8 hr, has the next longest plasma half-life. Concomitant with its extended half-life, ceforanide has the lowest rates of plasma and renal clearance. These factors result in the prolonged *in vivo* duration of ceforanide. Peak plasma levels of ceforanide following intramuscular administration would be higher than those reported for equivalent doses of cephalothin, cephaloridine, cefoxitin, cefuroxime, and cefamandole and should be similar to peak plasma concentrations following the intramuscular administration of cefazolin. Volumes of distribution are in the range of the values of the two-compartment model reported for cephalothin and cefoxitin and are 1.4- to 1.8-fold higher than these volumes of distribution for cefazolin. These relatively high volumes of distribution, coupled with high peak plasma concentrations and prolonged duration, suggest favorable distribution of the drug to tissue sites. Ceforanide was excreted in the urine in 12 hr, suggesting little or no contribution of biliary excretion or metabolism to drug elimination.

The linear, dose-independent kinetics of ceforanide permit prediction of plasma concentrations that would result from different dosage regimens. For instance, the predicted mean peak plasma concentrations after intramuscular injection of 500 and 1000 mg should be about 34 and 66 μg/ml, respectively. The peak plasma concentration and time to peak on intravenous administration can be controlled by controlling the size and

Table IV—Pharmacokinetic Parameters for Ceforanide from Mean Plasma Concentration Data for First Intravenous Doses

[a] Protein binding values for ceforanide, cefazolin, cefoxitin, cefuroxime, and cefamandole were obtained in this laboratory. All other cefuroxime values are from Ref. 8. All other cefamandole values are from Refs. 9 and 10. All other values for cephalothin, cephaloridine, cefazolin, and cefoxitin are from Ref. 11.

Table VI—Estimated Mean Duration of Plasma Ceforanide Concentrations

Mode of Administration	Dose, mg	Duration (hr) at Plasma Concentrations Greater Than or Equal to 6.25 μg/ml	8.0 μg/ml	12.5 μg/ml
Intramuscular	500	9.6	8.2	6.2
	1000	12.8	11.6	9.4
Intravenous bolus	1000	10.4	9.3	7.4
	2000	13.3	12.3	10.4
Constant rate intravenous infusion for 30 min	1000	10.5	9.5	7.6
	2000	13.5	12.5	10.5
Constant rate intravenous infusion for 60 min	1000	10.8	9.7	7.8
	2000	13.8	12.7	10.8

mode of the intravenous injection. The predicted mean peak plasma concentrations resulting from a 0.5-hr constant-rate infusion would occur at 0.5 hr and would be 103 μg/ml for a 1000-mg dose and 205 μg/ml for a 2000-mg dose. If the doses remain the same and are infused over 1 hr, the peak concentrations at 1 hr should be 88 μg/ml for 1000 mg and 176 μg/ml for 2000 mg. If these doses are given by true bolus intravenous injection, the immediate peak plasma concentrations should be 126 μg/ml at 1000 mg and 252 μg/ml at 2000 mg.

The varying modes of administration also would affect the periods over which observed plasma concentrations would exceed the given minimum

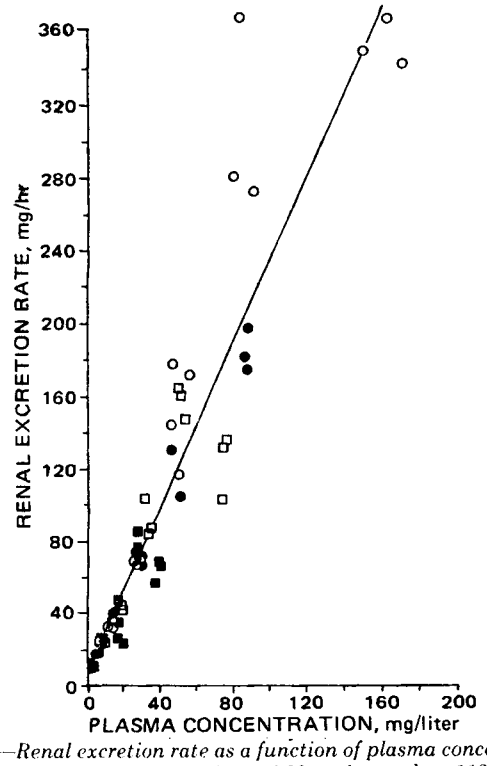

Figure 4—*Renal excretion rate as a function of plasma concentration. Key:* ●, *1132 mg iv;* ○, *2264 mg iv;* ■, *566 mg im; and* □, *1132 mg im.*

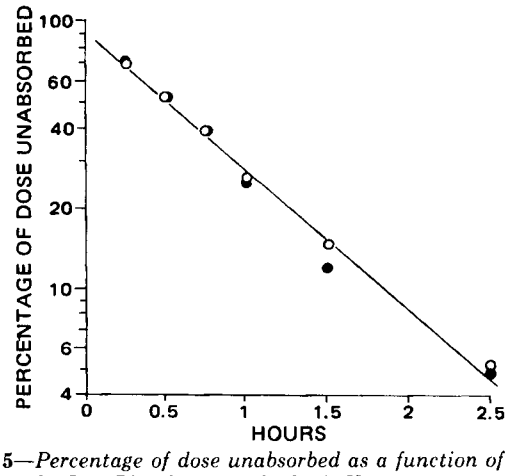

Figure 5—*Percentage of dose unabsorbed as a function of time according to the Loo–Riegelman method (7). Key:* ○, *566-mg dose; and* ●, *1132-mg dose.*

plasma concentrations. Table VI lists the estimated periods that plasma concentrations would exceed 6.25, 8.0, and 12.5 μg/ml (standard concentrations in a geometrically diluted minimum inhibitory concentration series) using these modes of parenteral administration. If ceforanide is dosed at 12-hr intervals, a 500-mg im dose would exceed 6.25 μg/ml for about 80% of that period and would exceed 12.5 μg/ml for about 52% of that period. If the intramuscular dose is increased to 1000 mg, the plasma concentration would exceed 6.25 μg/ml for the entire 12-hr period and would exceed 12.5 μg/ml for about 78% of that period. From the point of view of maintaining a proper peak-to-trough plasma concentration relationship, a 500-mg im dose every 12 hr is reasonable. The kinetic relationships pertaining to constant-rate intravenous infusion of ceforanide are such that increasing the infusion time for a given dose from 0.5 to 1 hr would lower the peak concentration without appreciably lengthening the duration of plasma concentrations above the given minimum levels.

Ceforanide demonstrated no tendency to accumulate. It yielded high and prolonged plasma concentrations and has useful distribution properties. These favorable properties, together with its good antibacterial activity, suggest that it could be effective in treating bacterial infections in humans when administered at 12-hr intervals. This regimen is undergoing clinical trials.

Influence of Viscosity on Absorption from Nitrofurantoin Suspensions

M. MIRTA SOCI * and EUGENE L. PARROTT ˣ

Received July 23, 1979, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication October 31, 1979. *Present address: Caracas, Venezuela.

Abstract □ Nitrofurantoin, 200 mg, was administered orally to 11 subjects in an aqueous reference dispersion and in five suspensions having the same rheogram. Algin, carbomer, guar gum, methylcellulose, and colloidal magnesium aluminum silicate were the five suspending agents employed. Complexation was demonstrated by dialysis between nitrofurantoin and methylcellulose and between nitrofurantoin and carbomer; however, physiological availability was not altered by the interaction. The viscosity increase slowed absorption and urinary excretion, thus delaying the time of the maximum excretion rate without a decrease in bioavailability. A clinically acceptable urinary nitrofurantoin concentration was maintained for at least 2 hr longer by a viscosity increase.

Keyphrases □ Nitrofurantoin—suspensions, effect of viscosity on absorption □ Suspensions—nitrofurantoin, effect of viscosity on absorption □ Bioavailability—nitrofurantoin suspensions, effect of viscosity on absorption □ Antibacterial agents—nitrofurantoin suspensions, effect of viscosity on absorption

Based on the few literature reports, it is difficult to generalize the effect of viscosity on the absorption and availability of medicinal compounds from oral liquids. Malone *et al.* (1) noted that increasing viscosity by increasing the concentration of sucrose in aqueous solutions of phenobarbital sodium progressively lengthened the induction time of narcosis in rats. Davison *et al.* (2) found that methylcellulose delayed the absorption from orally administered sodium salicylate solutions as demonstrated by the reduction of brain and plasma salicylate levels.

Levy and Jusko (3) concluded that the decrease in absorption by the ligated rat stomach of alcohol and salicylic acid from solutions containing methylcellulose was due to the slower movement of the drug molecule to the absorbing membrane. Harper and Wordan (4) reported that the LD_{50} values of isoniazid (isonicotinic acid hydrazide) in rats were 3300, 2650, and 2000 mg/kg in acacia solution, gelatin solution, and water, respectively, and they concluded that the apparent toxicity was influenced by the vehicle. Hewitt and Levy (5) reported that, contrary to expectation, the oral administration of thiamine and riboflavin in highly viscous methylcellulose solutions did not affect the rate and extent of absorption. Ashley and Levy (6) showed that the absorption of phenolsulfonphthalein was decreased during the 1st hr by the addition of algin (sodium alginate) to the solution but that the total amount absorbed was unchanged.

BACKGROUND

Suspending agents are added to suspensions to increase the viscosity so that the sedimentation rate is slowed and the measurement of a proper dose is simplified. Because a suspending agent improves the physical properties of a suspension, it may concomitantly affect the absorption of the medicinal compound by the increased viscosity or by complexation. It has been shown that the dissolution rate of a solid is inversely proportional to the viscosity of the dissolution medium (7).

Since the dissolution rate often is the limiting factor in availability of a relatively insoluble medicinal compound in an orally administered suspension, viscosity would be expected to affect absorption. Seager (8) found that methylcellulose affected the excretion after the oral administration of a nitrofurantoin suspension so that less nitrofurantoin was excreted and the time of maximum excretion was delayed by 1 hr.

This study was conducted to determine, by a urinary recovery technique, the effect of suspending agents (algin, carbomer, guar gum, methylcellulose, and colloidal magnesium aluminum silicate) on the absorption of nitrofurantoin. Because the main concern was to determine if the viscosity affected GI absorption, all formulations containing a suspending agent had the same viscosity.

EXPERIMENTAL

Suspension Preparation—Nitrofurantoin[1] was classified by a sonic sifter[2], and the 70–140-mesh fraction (157 μm) was used. Nitrofurantoin, 200 mg, was dispersed in 20 g of vehicle. Each vehicle was prepared by making dispersions of various concentrations of the suspending agent, and their viscosities were measured by a rotational viscometer[3]. Guided by these results, more appropriate concentrations then were prepared, and their viscosities were measured. For each suspending agent, a concentration was found experimentally that provided a rheogram similar to that of a 2% aqueous solution of methylcellulose, 4000 cps.

Dialysis—Dialysis was carried out at 37° in cellophane tubing[4] tied into a sac with distilled water as the dialysis medium. The nitrofurantoin dispersion, 50 ml, was placed in the cellophane sac, which was soaked previously for 24 hr to achieve hydration; then the open end was tied. The sac was immersed in 100 ml of distilled water, sealed in the container, and attached to a submersion rotator[5].

At 3, 6, 12, 24, and 36 hr, one dialysis sac of a series was removed, fluid volume inside and outside of the sac was measured, and the nitrofurantoin concentration in the fluid inside and outside of the sac was determined from spectrophotometric measurements at 367 nm. Equilibrium was always attained in <36 hr.

Protocol—All suspensions were coded and distributed according to the Latin square law (9) so that two of the initial 12 volunteers received

the same suspension. Two weeks elapsed between each urinary study. One subject did not complete the study; the study was completed with two healthy female and nine healthy male subjects, 24–35 years old and 40–70 kg.

Each subject drank 300 ml of water upon arising. After 30 min, the bladder was voided, and the suspension was swallowed. The participants were instructed to allow adequate time for the suspension to drain from the container. Two 5-ml portions of water were used to rinse any residue from the container, and each portion was swallowed. No food or fluids were ingested for 6 hr.

Urine samples were collected at 1-hr intervals for 12 hr. Volumes were measured, and aliquots were retained in amber vials for analysis. The urinary pH was determined at the time of each sample collection, and the values ranged from 5.3 to 7.0. For a given subject, the pH fluctuation did not exceed 1 pH unit. No attempt was made to control the urinary pH.

Analytical Method—The urine analysis was carried out in duplicate by the method of Conklin and Hollifield (10) on the collection day. To protect the nitrofurantoin from light, amber glassware was used.

Statistics—The significance of the difference between suspensions containing different suspending agents and the reference dispersion was calculated using the Student two-tailed t test ($p = 0.05$).

RESULTS AND DISCUSSION

To compare the effect of several suspending agents on the absorption and urinary excretion of nitrofurantoin from an oral suspension, the viscosity should be the same for all suspensions. A 2% aqueous solution of methylcellulose, 4000 cps, was selected because it had a moderately high viscosity. This selection accented the factor of viscosity, but the suspension was pourable from the container. Figure 1 shows that the rheological characteristics of a 1.6% algin[6] solution, a 0.3% carbomer[7] solution, a 1.0% guar gum[8] solution, a 2.0% methylcellulose[9] solution, and a 5.0% colloidal magnesium aluminum silicate[10] dispersion are similar.

Shah and Sheth (11) demonstrated *in vitro* that the dialysis rate of nitrofurantoin was reduced by the presence of methylcellulose. They thought that this effect was due to the drug complexation in solution with

the polymer. A nitrofurantoin–suspending agent interaction (complexation) possibly could affect absorption and urinary excretion. Nitrofurantoin and each suspending agent were dialyzed until equilibrium was attained. Aqueous dispersions of nitrofurantoin with carbomer and with methylcellulose gave ratios of the concentration in the internal compartment to that in the external compartment of 1.22 and 1.26, respectively, thus indicating interaction between nitrofurantoin and carbomer and between nitrofurantoin and methylcellulose such that less nitrofurantoin diffused through the membrane. Such an interaction could interfere with absorption and subsequent urinary excretion. No interaction occurred with algin, guar gum, and colloidal magnesium aluminum silicate.

In a blind study, 11 subjects ingested 200 mg of nitrofurantoin in various suspensions of the same viscosity and in an aqueous dispersion at 2-week intervals. No nitrofurantoin was detected in the urine of any subject after 12 hr. The half-life was determined by plotting the logarithm of the amount excreted after administration of the aqueous dispersion against time (12). The average half-life was 1.03 ± 0.45 hr. This result agrees with the literature values that range from 0.3 to 1.0 hr (13).

The excretion rate and the cumulative milligrams excreted were determined and plotted for each subject. From these data, the percent of the orally administered dose excreted in the urine and the time of the maximum excretion rate were determined for each subject. Data for each individual are not given to conserve space. The mean ($\pm SD$) excretion rate and the cumulative amount ($\pm SD$) excreted for 11 subjects are given in Table I for the aqueous reference dispersion and for the five suspensions. Figure 2 shows the mean cumulative amount of nitrofurantoin excreted as a function of time for each suspension.

The mean percent ($\pm SD$) of the oral dose excreted is given in Table II. The significance of the difference between the aqueous reference dispersion and the means in Table II was calculated using the Student t test. The percent of the oral dose recovered in the urine was not diminished significantly by any suspending agent, even though *in vitro* interaction had been demonstrated between nitrofurantoin and methylcellulose and between nitrofurantoin and carbomer. This result indicates that under physiological conditions, complexation, as demonstrated by dialysis, does not interfere with GI absorption. Because complexation did not alter physiological availability, any changes in urinary excretion may be attributed to the effect of viscosity.

The excretion rates were plotted against time for each subject. The times of the maximum excretion rate for each of the 11 subjects were averaged to give the mean time ($\pm SD$) of the maximum excretion rate given in Table II. The significance of the difference between the mean time of the maximum excretion rate of the aqueous reference dispersion and the suspensions with various suspending agents (Table II) was determined using the Student t test. The differences between the time of the maximum excretion rate of the aqueous reference dispersion and the test suspensions were significant.

Nitrofurantoin suspended with methylcellulose reportedly (8) delays the maximum absorption time by 1 hr relative to an aqueous reference dispersion. In this study, the time at which the average maximum excretion rate occurred for the preparation containing methylcellulose was only 0.3 hr longer than that of the aqueous reference dispersion, with the time of the maximum excretion rate varying from 1 to 6 hr for the 11 subjects. The reason for this wide variation without a significant difference between the aqueous reference dispersion and the suspension containing methylcellulose is unknown.

As shown in Table II, the mean time of the maximum excretion rate was increased by 1.4 hr for the experimental viscosity induced by algin, carbomer, guar gum, and colloidal magnesium aluminum silicate in comparison to an aqueous dispersion. Thus, the increased viscosity of these oral suspensions delayed absorption and excretion but did not diminish total absorption. Since increasing viscosity slows diffusion, mobility, and the dissolution rate, one would anticipate slower absorption and excretion.

Because nitrofurantoin is rapidly excreted in the urine, slower absorption could maintain a clinically recommended concentration of 1:100,000-1:200,000 (14) in the urine for a longer time. The mean nitrofurantoin concentration in the urine of 11 subjects after the oral administration of 200 mg of nitrofurantoin is given in Table III. With 1:100,000 as the nitrofurantoin concentration needed for the clinically acceptable bacteriostatic effect, the reference dispersion is acceptable for 6 hr. The suspensions containing carbomer, guar gum, and colloidal magnesium aluminum silicate are acceptable for 8 hr. The suspensions containing methylcellulose and algin are acceptable for 7 and 11 hr, respectively.

An increase in viscosity of the investigated suspensions delayed absorption; consequently, urinary excretion was delayed without a decrease in availability. As a result, the concentration in the urine was maintained

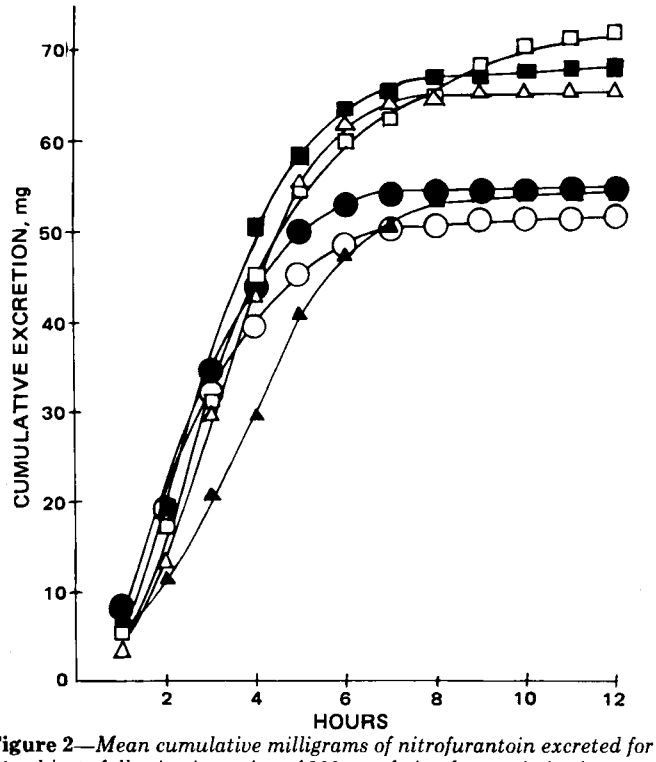

Figure 2—*Mean cumulative milligrams of nitrofurantoin excreted for 11 subjects following ingestion of 200 mg of nitrofurantoin in six preparations. at a clinically useful concentration for a longer time. In the studied suspensions, the viscosity maintained an acceptable concentration in the urine for at least 2 hr longer than that obtained from an aqueous dispersion.

Surface Properties of Membrane Systems: Interaction of Electrolyte and Lipid with Ca^{2+} Ionophores

GIUSEPPE COLACICCO *x and MUKUL K. BASU

Received May 22, 1978, from the *Albert Einstein College of Medicine, Bronx, NY 10461.* Accepted for publication October 29, 1979. *Present address: Bioelectrochemistry Laboratory, Columbia University, New York, NY 10032.

Abstract □ When spread from organic solvents onto electrolyte solutions, the Ca^{2+} ionophores A23187 (I) and X537A (II) formed films with relatively high surface pressures and surface potentials. Ionophore I had collapse pressures between 16 and 19 dynes/cm and nearly equal surface activity on distilled water and on 1000 mEq of either sodium chloride or calcium chloride. Film pressure did not reveal appreciable ion selectivity. However, the surface potential of I on calcium chloride solution was higher than that on sodium chloride, and the potential difference, $\Delta(\Delta V)$, of 40 mv was independent of the electrolyte concentration. In contrast, the ion selectivity of II was dependent on the electrolyte concentrations since the $\Delta(\Delta V)$ value between calcium chloride and sodium chloride was maximal (130 mv) on 1000 mEq and negligible on 500- and 2000-mEq salt solutions. The isotherms of phospholipid–ionophore films were markedly different from those of the individual components, although they revealed ionophore characteristics at low film pressures and phospholipid behavior at high film pressures. The magnitude of the surface potential indicated that dipalmitoyl phosphatidylcholine enhanced, whereas mitochondrial lipid and cardiolipin reduced, the preference of the two ionophores for Ca^{2+} over Na^+. Since the ion selectivity was manifested most at both high electrolyte and high lecithin concentrations, the ionophore probably prefers the low dielectric constant of neutral lipid membranes to complex with the selected cation.

acteristics of the ionophore molecule and could be related to two phenomena: (*a*) the ability of the ionophore to complex with the various ions, and (*b*) the modifications brought about in the architecture of the membrane when the ionophore picks up or delivers the ion or when the ionophore finally lodges in or crosses the membrane.

This paper describes the surface pressure and surface potential characteristics of films of ionophores I and II on various concentrations of sodium chloride and calcium chloride solutions. To evaluate the influence of membrane lipids on these parameters, films of mixtures of the ionophore with dipalmitoyl phosphatidylcholine, total mitochondrial lipids, and cardiolipin also were studied.

EXPERIMENTAL

The sodium salts of ionophores I and II were used[1]. Routine TLC (2) showed that the dipalmitoyl phosphatidylcholine and beef heart cardiolipin[2] were homogeneous, and they were not purified further. Rat liver mitochondria[3] were prepared according to published methods (7); the total lipid was extracted by shaking the aqueous mitochondrial suspension once with four volumes of chloroform–methanol (2:1) and then with four volumes of chloroform.

TLC was performed with precoated silica gel G plates[4], chloroform–methanol–water–concentrated ammonium hydroxide (70:30:2:4) as the solvent, and the appropriate lipid standards. The lipid pattern was typical of mitochondria, with phosphatidylcholine > phosphatidylethanolamine > cardiolipin > sphingomyelin. For all practical purposes, this lipid composition of mitochondria is independent of either the organ or the animal species (8).

The lipids for the film preparation were dissolved to give 1 mg/ml in chloroform–methanol (85:15), and the solutions were stored at −20° for no longer than 2 weeks. During the experiments, the lipid solutions were kept in ice. The organic solvents were of the highest spectroscopic grade. Water was distilled twice (9). The electrolyte solutions, prepared with freshly distilled water and reagent grade salts, were foamed to remove surface-active contaminants (10) and were stored for no longer than 3 days at room temperature.

The techniques for the determinations of surface pressure and surface potential were described previously (10), except that a circular constant area trough was used (11) instead of a rectangular trough. Measured volumes of the lipid or ionophore solution in organic solvent were applied onto a 20-cm^2 area, and the values of surface pressure and surface potentials were related to the quantity of the material applied per square centimeter or to the apparent molecular area of the ionophore and other lipid.

RESULTS AND DISCUSSION

The surface pressure and surface potential values are averages from three experiments, with deviations of ±0.2 dyne/cm and ±5 mv, respectively. The π and ΔV effects of the ionophores revealed characteristics that should be related to their molecular structures.

Theoretical Considerations—Since the two monocarboxylic acid ionophores, I and II, are complex molecules, the effects of the electrolyte on surface pressure and surface potential may not be predicted at once. Such a prediction, however, will contain information or suggestions about several possible phenomena: (*a*) interaction of the electrolyte cation with the ionized carboxylic group of the ionophore; (*b*) discrimination between Na^+ and Ca^{2+} in terms of surface pressure and/or surface potential; (*c*) conformational changes, which are known to occur during such interactions in bulk (1); (*d*) rigidity or flexibility of the ionophore molecule; (*e*) electrolyte penetration into the interface (12); and (*f*) changes in the interfacial structures of the water of hydration (13) and in the distribution of dipoles (13, 14).

Each of these effects is expected to contribute to both surface pressure and surface potential but, unfortunately, cannot be evaluated individually in the present state of the art. Nevertheless, determinations of surface pressure and surface potential of the Ca^{2+} ionophores can be used to establish empirical correlations between structure and function, correlations that are fundamental to future biological studies.

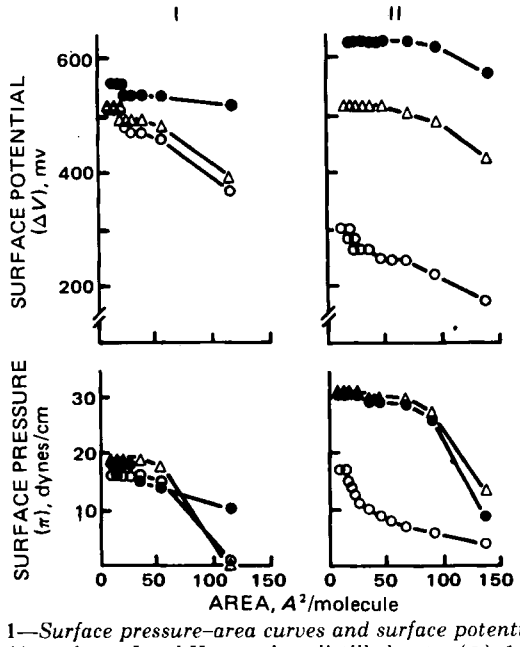

Figure 1—*Surface pressure–area curves and surface potential–area curves of ionophores I and II spread on distilled water* (○), *1 M NaCl* (△), *and 0.5 M* $CaCl_2$ (●) *at 25°.*

Effects of Electrolyte on Ionophore Surface Pressure–Area (π–*A*) and Surface Potential–Area (ΔV–*A*) Curves—Figures 1 and 2 describe experiments in which films of ionophores I and II were spread on distilled water and on aqueous solutions containing three concentrations of either sodium chloride or calcium chloride (150, 1000, and 2000 mEq). The film pressure, in dynes per centimeter, and the surface potential, in millivolts, are related to the apparent molecular area of each ionophore on water and on aqueous solutions of 1000 mEq of sodium chloride or calcium chloride in Fig. 1 and to the electrolyte concentration at the molecular area of 50 Å^2 for each ionophore in Fig. 2. The two ionophores were surface active with II more than I; according to their surface potentials, they discriminated differently between Na^+ and Ca^{2+}.

π–A *Curves*—Films of II were more expanded but had higher collapse pressures than those of I on the aqueous electrolytes; this difference could be ascribed to the greater flexibility of II, which requires constraints to build up pressure as compared to the more rigid I molecule, whose iso-

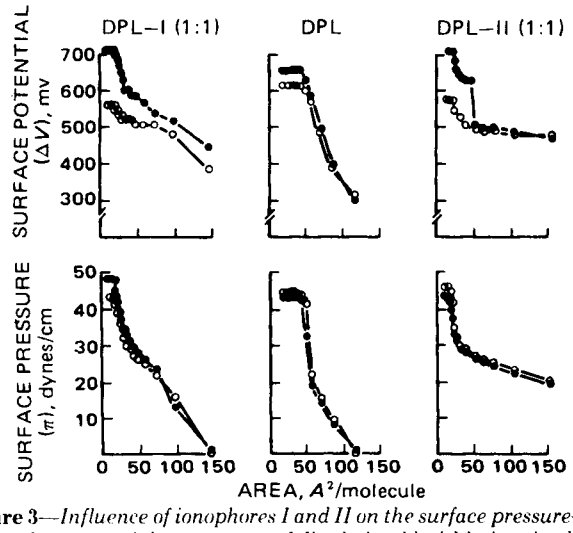

Figure 3—*Influence of ionophores I and II on the surface pressure–area and surface potential–area curves of dipalmitoyl lecithin in mixed films spread on 1.0 M NaCl (○) and 0.5 M $CaCl_2$ (●) at 25°. The apparent molecular areas are averages of the areas of lecithin and the ionophore.*

therm on distilled water did not differ much from that on the subphase containing various electrolyte concentrations. The slow rise of pressure with compression indicates that II must encounter difficulty in making a film on distilled water (Fig. 1); II was much more surface active than I on electrolyte solutions. The collapse pressures on 1000 mEq of sodium chloride or calcium chloride were 30 dynes/cm for II and 18 dynes/cm for I.

The virtual identity of the isotherms of II on solutions of 1000 mEq of sodium chloride or calcium chloride means that, at this electrolyte concentration, the ionophore cannot distinguish between Na^+ and Ca^{2+} on the basis of surface tension or surface pressure. Ionophore II did distinguish between the cations at lower concentration, where its isotherm on 150 mEq of calcium chloride (Fig. 2) was markedly more expanded (higher) than that on sodium chloride. At present, no explanation is available for this effect, which is the opposite of the film contraction expected from the interaction of Ca^{2+} with negatively charged lipids (15). The complexity of the ionophore molecule may be responsible for numerous deviations from the surface behavior of a straight-chain lipid.

The two ionophores were similar in that, on both electrolytes at all concentrations studied, they reached the different collapse or saturation pressures at an apparent molecular area of 50 Å², below which the π and ΔV values were quite stable. For reasons given earlier (6), interpretation of the apparent molecular area must be postponed until an exact determination is made of the effective number of ionophore molecules per square centimeter and their orientation in the film, parameters that are not accessible at present.

ΔV–A Curves—Unlike surface pressure, the surface potential revealed marked ion selectivities for both ionophores.

On distilled water, the surface potential of I was 200 mv higher than that of II. At all areas, I distinguished sodium chloride from water by 20 mv in favor of sodium chloride and sodium chloride from calcium chloride by 40 mv in favor of calcium chloride. Unlike I, II showed a marked dependence of π and ΔV on the electrolyte concentration (Fig. 2) and distinguished markedly well between Na^+ and Ca^{2+} at one electrolyte concentration (1000 mEq), although by a much greater difference (130 mv) as compared to 40 mv for I.

The π–A curves of II on 1000 mEq of sodium chloride and calcium chloride were nearly superimposable. The ΔV–A curve of II on sodium chloride was 300 mv higher than that on water; on calcium chloride, it was 130 mv higher than that on sodium chloride (Fig. 1). In contrast, the selectivity of I for Ca^{2+} was about the same (40 mv) at all electrolyte concentrations (Fig. 2).

These differences in surface behavior between the two ionophores are consistent with a rigid structure for I and a flexible structure for II. At present, it is not possible to relate these observations to the conformational changes that the ionophores undergo in bulk (1), primarily because of a lack of spectroscopic methods capable of viewing the interface directly *in situ*.

Lipid Influence on Ion Selectivity and Surface Behavior of the Ionophore—The foregoing data show that ionophores I and II are surface active and distinguish between Na^+ and Ca^{2+} in the absence of membrane lipids. Since the transport of Ca^{2+} by the ionophore across the membrane could imply some interaction of the ionophore with the membrane structures that negotiate Ca^{2+} with the ionophore, information about the membrane behavior of the ionophore may be attained by a study of the interaction of the electrolyte with films of ionophore and phospholipid mixtures.

Three mixtures were studied: dipalmitoyl phosphatidylcholine–ionophore, mitochondrial lipid–ionophore, and cardiolipin–ionophore. The lipid mixtures in chloroform–methanol (85:15) were spread on the aqueous subphase containing 1000 mEq of sodium chloride or calcium chloride. This electrolyte concentration was chosen for convenience, since the surface potential effects were largest; they were small at either lower or higher salt concentrations.

Dipalmitoyl Phosphatidylcholine—Figure 3 shows the π–A and ΔV–A curves of dipalmitoyl lecithin (DPL) and equal weight mixtures of it with I and II on 1000 mEq of sodium chloride or calcium chloride.

With this salt concentration, the dipalmitoyl lecithin films were slightly more expanded, and the ΔV values were appreciably higher than on more dilute solutions [*e.g.*, 100 mEq (12)]; dipalmitoyl lecithin did not significantly discriminate between Na^+ and Ca^{2+}. However, both ionophores influenced appreciably the π–A and ΔV–A curves of the phospholipid in the dipalmitoyl lecithin–ionophore film, in which dipalmitoyl lecithin seemed to enhance markedly the ion selectivity of the ionophore (Ca^{2+} over Na^+), especially in terms of surface potential.

The π–A and ΔV–A curves of the mixtures were quite different from those of individual components. The pressure–area curves of the mixed films had an ionophore character (expanded) at low pressure. At the average molecular area of 150 Å², the pressure was near zero for the dipalmitoyl lecithin–I system and near 20 dynes/cm for dipalmitoyl lecithin–II. This observation strengthens the suggestion that I is rigid whereas II is flexible and thus is more compressible than I.

Although the disappearance of the ionophore character from the mixed ionophore–lecithin film in terms of film pressure could suggest that, at high pressure, the ionophore may be squeezed out of the mixed film, which then resumes the lecithin character, this mechanism may not be valid because the surface potential increase at high pressure is that of a unique lecithin–ionophore mixture, far above the ΔV of lecithin alone. The mode of the ionophore–lecithin interaction thus remains to be investigated.

Whereas the dipalmitoyl lecithin–ionophore mixtures did not distinguish between Na^+ and Ca^{2+} by the surface pressure, they did distinguish between the cations markedly well by the surface potential, especially at high pressure where the $\Delta(\Delta V)$ difference between calcium chloride and sodium chloride reached ~150 mv for both ionophores as opposed to 40 mv for I and 130 mv for II in the absence of dipalmitoyl lecithin. The fact that the selectivity between Na^+ and Ca^{2+} was manifested at high film pressure and high electrolyte concentration is reminiscent of the Na^+–K^+ discrimination of valinomycin films, which required 700–1000 mEq of electrolyte and film pressures above 20 dynes/cm to show a dramatic effect of K^+ on the surface potential (5, 6, 16). Indeed, the presence of lipid brings about a low dielectric constant (favorable to ionic inter-

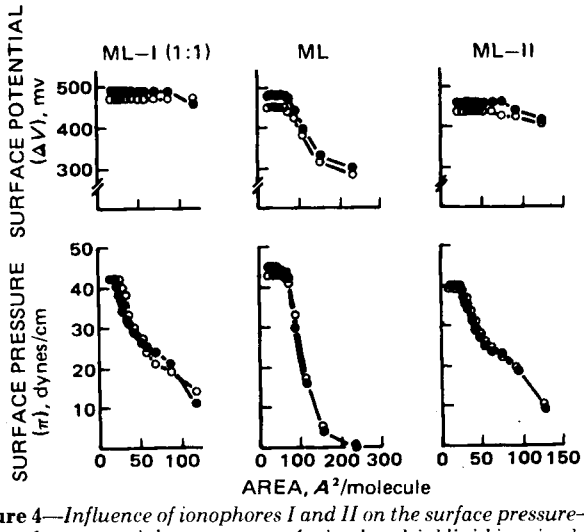

Figure 4—*Influence of ionophores I and II on the surface pressure–area and surface potential–area curves of mitochondrial lipid in mixed films spread on 1.0 M NaCl (○) and 0.5 M $CaCl_2$ (●) at 25°. The apparent molecular areas are calculated averages of the areas of ionophore and mitochondrial lipid.*

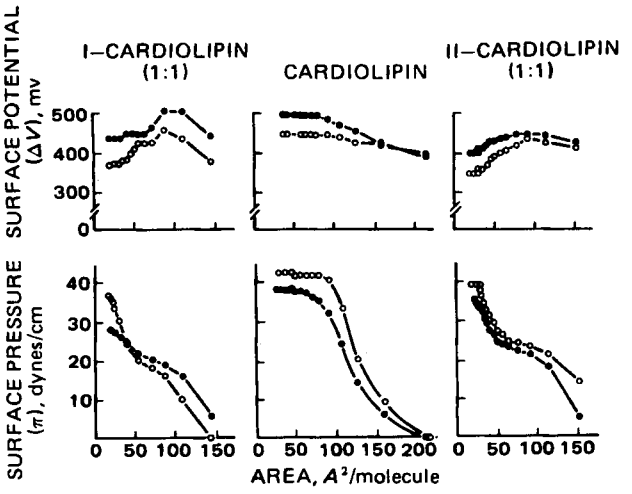

Figure 5—*Influence of ionophores I and II on the surface pressure–area and surface potential–area curves of cardiolipin on 1.0 M NaCl (○) and 0.5 M $CaCl_2$ (●) at 25°. The apparent molecular areas are averages of the areas of cardiolipin and the ionophore.*

actions) and high surface potentials (6, 13). The fact that this effect was not seen at higher electrolyte concentrations is interesting, has no explanation as yet, and clearly reflects a specificity that calls for optimal conditions of dose response in the interaction of Ca^{2+} with the ionophore.

Mitochondrial Lipid—The film was made by spreading the total lipid extract of rat liver mitochondria as a model of a membrane containing negatively charged groups, namely, the two phosphate groups of cardiolipin (diphosphatidylglycerol). Unlike dipalmitoyl lecithin, the mitochondrial lipid (ML) conferred little ion-discriminating ability to either ionophore (Fig. 4).

Although a high collapse pressure of the mitochondrial lipid was revealed in the isotherm of mixed films of the ionophore with this lipid, the surface potential of the mixture reflected an ionophore character in the sense that its ΔV–A curve was lifted to a constant saturation value that extended over the entire area range. However, the ΔV effect of the electrolyte in the two mixtures was not different from that of the mitochondrial lipid alone.

Cardiolipin—Since the major ionic component of mitochondrial lipid is cardiolipin, the behavior of the cardiolipin–ionophore mixed film was evaluated to see if the behavior of the mitochondrial lipid could be ascribed to cardiolipin. The results (Fig. 5) confirm that possibility.

More evident than with the total mitochondrial lipid was the contraction in the molecular area of cardiolipin in the presence of Ca^{2+} as compared to Na^+ (Fig. 5), a discrimination that is known for acidic phospholipids (15, 17) but was not so apparent and was modified partially with the mixed ionophore–cardiolipin films (Fig. 5). As with the mitochondrial lipid and with cardiolipin alone, the surface potential of the cardiolipin–ionophore mixed film showed a modest separation in ΔV between Na^+ and Ca^{2+}, with the value for Ca^{2+} higher as expected.

An unusual feature of the ionophore–cardiolipin mixed film was the maximum in surface potential, between pressures of 20 and 22 dynes/cm, above which, although the pressure continued to rise until saturation, the surface potential decreased appreciably on sodium chloride and on calcium chloride solutions. This unusual behavior is reminiscent of the ΔV–A curve of gangliosides (18). Since the film pressure continued to rise, one can argue that the film was not collapsing and that the fall in surface potential could be accounted for by reorganization of molecules and/or dipoles so as to produce a film with a higher dielectric constant, an excess of ∓-oriented ionic dipoles (including water), or both (6, 13, 19–21).

CONCLUSIONS

In the surface chemistry literature, there has been a misleading tendency to speculate or even make conclusions about the orientation of molecular groups and dipoles from surface potential data. That approach has been challenged; but for a variety of reasons that are given elsewhere (6, 12, 13, 19–22), quantitative models must be postponed until the molecular correlates of surface potentials are understood. Such models may be derived only after information is obtained about the detailed molecular topography of the films at the air–water interface; such experiments involving radiolabels and direct spectroscopy of the interface cannot be done in the present state of the art (12). Meanwhile, empirical comparisons and correlations are valuable.

The comparisons between Na^+ and Ca^{2+} were based on equivalent concentrations instead of uncomparable ionic strength (0.225 for calcium chloride and 0.150 for sodium chloride). This choice was made to avoid blurring of the data by electrostatic effects due to ion binding competition in such different equivalent concentrations. For similar reasons, in working with ionophore–phospholipid mixtures, the empirical π–A relationships were preferred to graphs of mean molecular area *versus* mole fraction.

Unlike prostaglandins (23) [carboxylic acids that produced films with very small surface pressures (0–9 dynes/cm) and surface potentials (−10 to +250 mv)], I and II were quite surface active and had fairly large surface potentials. Both the surface pressure and especially the surface potential values were influenced by certain electrolyte concentrations. As observed with acidic phospholipids (15, 17) and fatty acids (24) at pH 5.7, the ΔV values on calcium chloride were higher than those on sodium chloride, indicating preferential involvement or binding of Ca^{2+}. However, at certain low and high electrolyte concentrations, the two ionophores, especially II, could not distinguish between Na^+ and Ca^{2+}. Discrimination between Na^+ and Ca^{2+} in terms of surface potential was enhanced markedly when the ionophore was mixed with dipalmitoyl lecithin; it was diminished when the ionophore was mixed with acidic lipids, either mitochondrial lipids or cardiolipin, despite the fact that such lipids interacted with Ca^{2+} with a marked surface potential effect.

The monolayer experiments suggest that, in the presence of Ca^{2+}, both ionophores prefer the hydrophobic medium of membranes and are admitted more easily into membranes containing high doses of neutral or hydrophobic phospholipid. These concepts of surface science could be exploited in the interpretation of the behavior of ionophores in experiments that are aimed at differentiating between cell types on the basis of the ionophore's selectivity for Ca^{2+} and for the membrane lipid.

Digoxin Degradation in Acidic Dissolution Medium

TAKASHI SONOBE ˣ, SHUNJI HASUMI, TAKASHI YOSHINO, YOICHI KOBAYASHI, HIROITSU KAWATA, and TSUNEJI NAGAI *

Received January 8, 1979, from the *Institute of Research and Development, Yamanouchi Pharmaceutical Co., Ltd., 1-1-8 Azusawa, Itabashi-ku, Tokyo 174, Japan.* Accepted for publication October 31, 1979. *Present address: Hoshi Institute of Pharmaceutical Sciences, Hoshi College of Pharmacy, 2-4-41 Ebara, Shinagawa-ku, Tokyo 142, Japan.

Abstract □ The release of digoxin and its simultaneous conversion to digoxigenin bisdigitoxoside, digoxigenin monodigitoxoside, and digoxigenin in a USP dissolution test medium were followed by high-pressure liquid chromatography. Two products, Tablets A and B, were manufactured by solvent deposition and simple blending methods, respectively. Tablet A released digoxin faster than Tablet B in distilled water and in artificial intestinal juice, and no decomposition was observed. In the USP dissolution test medium, the rate of hydrolysis to digoxigenin bisdigitoxoside was almost equal to that of hydrolysis to digoxigenin monodigitoxoside, and a comparatively large formation rate of digoxigenin was observed. Concentrations of digoxin and its decomposition products were described by differential equations that included dissolution rates of digoxin (rapidly dissolving digoxin and digoxin crystals) and an apparent hydrolysis rate. In the earlier stage of dissolution, hydrolysis was rate determining; in the later stage, dissolution became the rate-determining step for overall digoxin degradation. To suppress digoxin hydrolysis in the USP dissolution test medium, a developmental formulation study was performed. The incorporation of magnesium oxide and magnesium hydroxide–aluminum hydroxide in the tablet formulations inhibited digoxin hydrolysis by 15.3 and 14.5%, respectively, after dissolution for 30 min without serious delay of drug release.

Keyphrases □ Digoxin—dissolution and degradation in acidic solution, high-pressure liquid chromatography, kinetic study □ Dissolution—digoxin tablets, biphasic dissolution □ Stability—digoxin in acidic solution, high-pressure liquid chromatography, kinetic study, incorporation of antacid □ Antacids—suppression of digoxin degradation

The bioavailability of digoxin preparations was reported to vary significantly among brands and batches (1–5). Many studies revealed the correlation between the dissolution rate and the bioavailability of digoxin, but little attempt was made to separate digoxin from its degraded glycosides (6–8). Digoxin reportedly was hydrolyzed in acidic media (9), and the therapeutic efficacy may have decreased as a result (10). Although the absorption kinetics of digoxin, digoxigenin bisdigitoxoside, and digoxigenin monodigitoxoside were in the same range, the blood concentrations of the latter two substances were five to six times lower than that of digoxin (11). The cardioactivity of digoxigenin was one-tenth of that of digoxin, but the other compounds possessed approximately the same activity (12).

It was of interest to study the dissolution and simultaneous hydrolysis of digoxin *in vitro* since they may be potential causes of the variation of bioavailability and clinical efficacy in different digoxin formulations. To investigate digoxin hydrolysis, a quantitative assay that distinguishes between digoxin and its decomposition products is required. All of the current assays (13–15) fail to determine digoxin and its decomposition products individually without additional separations, except for a high-performance liquid chromatographic method (16).

The purposes of the present investigation were to use high-pressure liquid chromatography (HPLC) to study the hydrolysis of digoxin released from tablets during dissolution and to establish a pharmaceutical method of preventing digoxin hydrolysis in an acidic medium.

EXPERIMENTAL

Materials—Digoxin, digoxigenin bisdigitoxoside, digoxigenin monodigitoxoside, and digoxigenin were used as received[1]. The following materials were USP grade: lactose, cornstarch, magnesium hydroxide–aluminum hydroxide, and magnesium oxide. Synthetic aluminum silicate was JP grade. The other reagents were reagent grade unless otherwise stated.

To prepare Tablet A, a 5% chloroform–ethanol solution (2:1 v/v) of digoxin was deposited on lactose–cornstarch (7:3 w/w) diluent and granulated with 10% cornstarch paste to make ~0.2% digoxin granules. The granules were compressed to tablets of 7 mm in diameter and 120 mg in weight by a single-punch tableting machine[2] (17).

To prepare Tablet B, digoxin crystals were blended with lactose–cornstarch (7:3 w/w) diluent to give a 10% digoxin powder. The powder was diluted repeatedly in the same manner to give a final digoxin content of ~0.2%. The resultant digoxin–diluent mixture was granulated and compressed to give tablets of the same size as Tablet A following the described procedure (17).

Tablets A and B each contained 0.25 mg of digoxin. A digoxin powder mixture also was prepared containing antacids to study the effect of antacids in suppressing digoxin hydrolysis in acidic media. This mixture was prepared by dissolving 0.25 g of digoxin crystals in 50 ml of ethanol–chloroform (1:2 v/v) solution and incorporating the resulting solution in 20 g of magnesium hydroxide–aluminum hydroxide, synthetic aluminum silicate, or magnesium oxide. After mixing, the solvents were evaporated by heating on a thermostated water bath at 40° for 4 hr. The powder mixture was blended with lactose–cornstarch (7:3 w/w) diluent and granulated with 10% cornstarch paste, and the mixture was dried and passed through a 32-mesh screen. The digoxin content of 120 mg of the powders was 0.25 mg.

Analyses of Digoxin and Glycosides—Spectrofluorometry was performed to determine the total amount of digoxin and glycosides. For the separate determination of digoxin and glycosides, an HPLC method was developed.

Spectrofluorometry—The digoxin concentration in solution was determined with a spectrofluorometer[3] following the assay described for the dissolution testing of digoxin tablets in USP XIX (13).

HPLC—The separation conditions developed by Castle (16) were modified for the present experiments. A high-pressure liquid chromatograph[4] was used. The eluent was monitored spectrophotometrically at 220 nm. The separation utilized a column[5] (4 mm × 15 cm) operating at 1.5 ml/min with 25% acetonitrile solution as the mobile phase.

The retention volumes for digoxin, digoxigenin bisdigitoxoside, digoxigenin monodigitoxoside, and digoxigenin were 12.1, 7.2, 4.5, and 3.8 ml, respectively. The practical detection limit for digoxin was 50 ng. The resolution between the closest peaks of digoxigenin and digoxigenin monodigitoxoside was maintained at >1.3.

For the quantitation of digoxin and glycosides, aqueous standard solutions were prepared by dissolving accurately weighed quantities of digoxin, digoxigenin bisdigitoxoside, digoxigenin monodigitoxoside, and digoxigenin and treating these solutions in the same manner as the sample solution. The amounts of the components were determined by comparing the peak heights with those of the standard solutions.

Dissolution Study—The dissolution tests for Tablets A and B were performed using a rotating-basket apparatus[6] described in USP XIX. Six tablets were used to determine the dissolution rate at 37° in 250 ml of distilled water, USP dissolution test medium (0.6% HCl), and artificial

intestinal juice[7] at a basket rotation speed of 100 rpm. At the specified time, 5 ml of the test medium was withdrawn and filtered immediately through a membrane filter[8] (pore size of 0.22 μm).

With the USP dissolution test medium, 1.5 ml of Sørensen borate buffer (0.2 *M*, pH 10.0) was added to prevent further digoxin hydrolysis. Five milliliters of the dissolution medium was added at each sampling time to maintain a constant volume. Sample solutions were analyzed by spectrofluorometry and HPLC after appropriate dilution with distilled water.

RESULTS AND DISCUSSION

Dissolution—The individual determination of digoxin, digoxigenin bisdigitoxoside, digoxigenin monodigitoxoside, and digoxigenin was accomplished satisfactorily by HPLC as shown in Fig. 1. The total amount of digoxin detected by the conventional spectrofluorometric method was consistent with the HPLC results.

Digoxin instability in gastric juice was confirmed by analysis of digoxin and its degraded materials and was suggested as a possible cause of decreased oral efficacy (10). Degradation steps or pathways of digoxin in acidic media have been considered (18). The glycoside bond in the monoglycoside was suggested as being more resistant to acid hydrolysis than the bisglycoside and digoxin (9). Digoxin decomposition is closely related to reduced cardiac action. The rate constant of digoxigenin appearance might be clinically significant because of the lowered pharmacological action.

Figure 2 shows the dissolution of digoxin from Tablets A and B in distilled water and in artificial intestinal juice. Tablet A released digoxin faster than did Tablet B; their $t_{1/2}$ values were 1 and >60 min, respectively, which suggested that Tablet B would not meet the USP XIX requirement. This difference in the dissolution rates resulted mainly from the production procedure, because the same lot of digoxin crystals was incorporated in both digoxin tablets. For Tablet A, digoxin was deposited on diluents after complete dissolution in ethanol–chloroform, which might have resulted in easier dissolution of digoxin crystals. This deposit might be the amorphous layer, the existence of which was demonstrated by ball milling the digoxin crystals (19). No digoxin decomposition was observed in distilled water and in artificial intestinal juice; earlier work showed that digoxin mainly undergoes degradation at acidic pH (9, 10).

The amount of digoxin that dissolved from Tablet A in the USP XIX dissolution medium increased remarkably in a short time. Digoxin release reached a peak in ~6 min, and this release was followed by a gradual decrease that was related to the increase of decomposed digoxin. The digoxigenin bisdigitoxoside concentration reached a plateau in 10 min, while the digoxigenin monodigitoxoside concentration increased linearly with the time. These findings suggest that the degradation rate of digoxin to digoxigenin bisdigitoxoside is almost equal to the degradation rate of digoxin to digoxigenin monodigitoxoside and that a comparatively high formation rate of digoxigenin exists. In a previous study (20) with a conventional solvent extraction method, 75% of the dissolved digoxin was degraded 60 min after the initiation of the dissolution test in the USP XIX dissolution test medium; that finding supports results obtained in this study.

After the disintegration of digoxin tablets, the digoxin dissolution is assumed to consist of two stages; the dissolution of digoxin into the medium from crystals and the simultaneous hydrolysis of digoxin by acid. It also is assumed that a freely soluble amorphous layer exists in crystals (21) and that the hydrolysis of digoxin at the surface of the digoxin solid is negligibly small compared to that in solution.

With these assumptions, the following differential equations are obtained for the description of the dissolution and degradation:

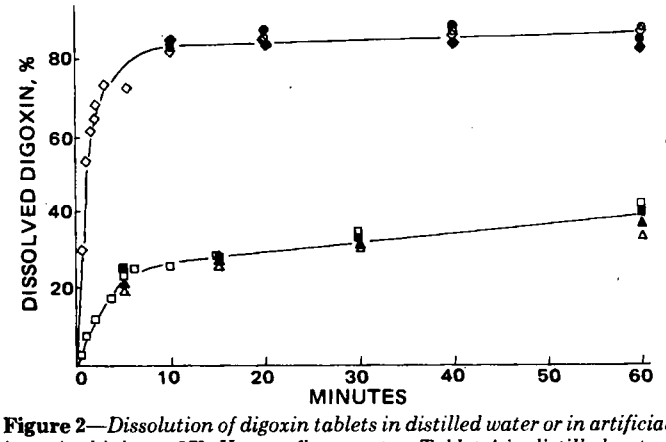

Figure 2—*Dissolution of digoxin tablets in distilled water or in artificial intestinal juice at 37°. Key: ♦, fluorometry, Tablet A in distilled water; ◇, HPLC, Tablet A in distilled water; ■, fluorometry, Tablet B in distilled water; □, HPLC, Tablet B in distilled water; ●, fluorometry, Tablet A in artificial intestinal juice; ○, HPLC, Tablet A in artificial intestinal juice; ▲, fluorometry, Tablet B in artificial intestinal juice; and △, HPLC, Tablet B in artificial intestinal juice.*

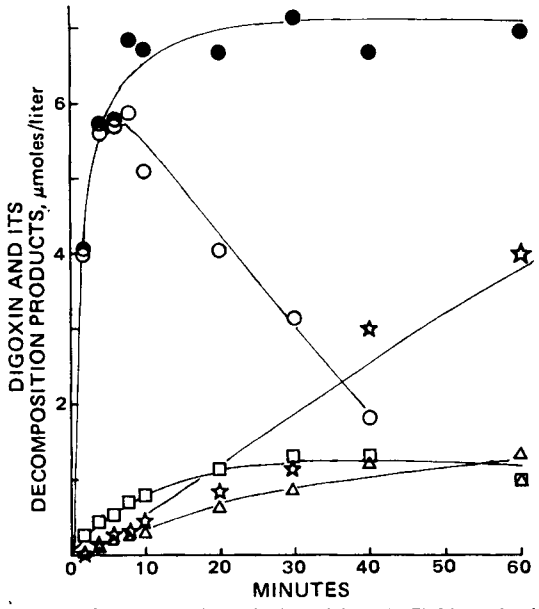

Figure 3—*Dissolution and degradation of digoxin Tablet A in the USP XIX dissolution test medium at 37°. Key: ●, total amount dissolved; ○, digoxin; ☆, digoxigenin; △, digoxigenin monodigitoxoside; and □, digoxigenin bisdigitoxoside.*

$$dA/dt = -K_{diss}A \quad \text{(Eq. 1)}$$

$$dB/dt = K_{diss}A - K_{degr}B \quad \text{(Eq. 2)}$$

$$dC/dt = K_{degr}B \quad \text{(Eq. 3)}$$

$$A + B + C = A_0 \quad \text{(Eq. 4)}$$

where $A = A_I + A_{II}$, $B = B_I + B_{II}$, $C = C_I + C_{II}$, and $A_0 = A_{0I} + A_{0II}$, in which A, B, C, and A_0 are the amounts of solid digoxin, digoxin in solution, digoxin degradation products (total amount of digoxigenin monodigitoxoside, digoxigenin bisdigitoxoside, and digoxigenin), and initial digoxin, respectively. The subscripts I and II denote the amorphous digoxin and digoxin crystals, respectively.

When $t = 0$, $A = A_0$ and $B = C = 0$. When t = infinity, $A = B = 0$ and $C = A_0$. Under these conditions, Eqs. 1–4 were integrated to give the following solutions:

$$A = A_0 \exp(-K_{diss}t) \quad \text{(Eq. 5)}$$

$$B = A_0\left(\frac{K_{diss}}{K_{degr} - K_{diss}}\right)[\exp(-K_{diss}t) - \exp(-K_{degr}t)] \quad \text{(Eq. 6)}$$

$$C = A_0\left[1 - \frac{K_{degr}\exp(-K_{diss}t) - K_{diss}\exp(-K_{degr}t)}{K_{degr} - K_{diss}}\right] \quad \text{(Eq. 7)}$$

For both solids I and II, the same solutions are given. Therefore, the residual digoxin dissolved in the solution could be described by the following equation:

$$B = A_{0I}\left(\frac{K_{dissI}}{K_{degr} - K_{dissI}}\right)[\exp(-K_{dissI}t) - \exp(-K_{degr}t)] + A_{0II}\left(\frac{K_{dissII}}{K_{degr} - K_{dissII}}\right)[\exp(-K_{dissII}t) - \exp(-K_{degr}t)] \quad \text{(Eq. 8)}$$

For Tablets A and B, the dissolution data were fitted to Eq. 8 by the least-squares method[9]. Figures 3 and 4 show the data points for the release of digoxin from Tablets A and B in the USP XIX dissolution test medium. Table I summarizes the rate constants calculated by the iterative least-squares method. The K_{degr} value is in good agreement with that determined in a hydrolysis study of digoxin in solution (20).

Tablet A should have essentially the same dissolution rate constants, K_{dissI} and K_{dissII}, as those of Tablet B. However, in this study, these kinetic constants were expressed as apparent constants which included

[9] Calculations were made by a digital computer, IBM S/370 model 158, with the NONLIN FORTRAN program developed by C. M. Metzler, G. L. Elfring, and A. J. McEwen, The Upjohn Co., Kalamazoo, Mich.

Table I—Values of K_{diss} and K_{degr} of Digoxin Obtained from Dissolution Tests of Tablet A and Tablet B

Parameter	Tablet A	Tablet B
K_{dissI}, min^{-1}	1.23	0.269
K_{dissII}, min^{-1}	0.00995	0.00429
K_{degr}, min^{-1}	0.0367 (0.0216)[a]	

[a] From Ref. 20.

effective surface area. Therefore, the differences of the diffusion rates indicate the existence of a more soluble layer and smaller digoxin crystals in Tablet A. The degradation rate constant was smaller than K_{dissI} but was larger than K_{dissII} in both Tablets A and B. This result indicates that degradation was rate determining in the earlier dissolution stage while dissolution became the rate-determining step in the later stage.

Suppression of Digoxin Hydrolysis—Digoxin is adsorbed by some antacids in aqueous solution (22). Moreover, when a large amount of an antacid is incorporated into a drug, the bioavailability of the drug may be reduced considerably (23). However, when specific antacids that have a large adsorption capability and dissolve comparatively quickly in acidic solution are selected, the stability of digoxin preparations can be enhanced without serious delay of drug release.

In this study, digoxin powders containing magnesium hydroxide–aluminum hydroxide, synthetic aluminum silicate, or magnesium oxide were placed in the dissolution apparatus in two positions, outside and inside the basket, to study the influence of granule dispersion on hydrolysis. The release of digoxin and hydrolyzed glycosides from digoxin powders in the USP XIX dissolution test medium was observed at different basket rotation speeds (Table II).

When the sample was placed inside the basket at a rotation speed of 50 rpm, magnesium oxide and magnesium hydroxide–aluminum hydroxide prevented the degradation of digoxin in the dissolution medium most, although the latter compound suppressed the release of digoxin. Aluminum silicate released digoxin more easily than did the other antacids but showed little antidegradation effect. When powders were placed outside the basket at a rotation speed of 100 rpm, synthetic aluminum silicate showed an inhibitory effect that probably was due to a reduced digoxin release rate because it released only 44.2% of the total amount of digoxin; magnesium hydroxide–aluminum hydroxide released 98.3% of the digoxin in 30 min. When samples were placed inside the basket at a rotation speed of 100 rpm, magnesium oxide and magnesium hydroxide–aluminum hydroxide released 100% of the digoxin in 30 min and still exerted a degradation inhibitory effect.

The dissolution rate was influenced considerably by the stirring conditions and the sample position in the dissolution apparatus. However, all samples showed reduced decomposition compared to that of the ref-

erence sample, which contained no antacid. Throughout the dissolution test, the dissolution medium pH was constant (1.3–1.4), and no significant influence of antiacidic agents on the medium pH was observed. This finding suggests that suppressed degradation of digoxin in the acidic medium by the incorporation of specific antacids is due to the antiacidic effect of those substances at the local dissolution site but is not due to an overall change in pH of the dissolution medium.

Adsorption of Lecithin by Cholesterol

ANNIE HOELGAARD *x and SVEN FRØKJAER ‡

Received September 17, 1979, from the **Department of Pharmaceutics, Royal Danish School of Pharmacy, 2 Universitetsparken, DK-2100 Copenhagen, Denmark*, and the ‡*NOVO Research Institute, Novo Allé, DK-2880 Bagsvaerd, Denmark.* Accepted for publication November 2, 1979.

Abstract □ Egg lecithin was adsorbed significantly by cholesterol monohydrate crystals. Adsorption data obtained at initial concentrations of <1.1 m*M* lecithin fitted the Langmuir equation. The calculated adsorption capacity suggested formation of a lecithin bilayer or a mixed bilayer of lecithin and cholesterol. The amount of lecithin adsorbed was highly dependent on the cholate concentration in the incubation medium. Minimal adsorption was observed at ~5 m*M* cholate. The presence of quaternary ammonium salts and dioctyl sodium sulfosuccinate caused desorption. The finding of an adsorptive layer supported the existence of an interfacial barrier that controls cholesterol dissolution.

Keyphrases □ Adsorption—formation of adsorptive lecithin layer on cholesterol, effect of detergents □ Lecithin—adsorption by cholesterol, effect of total bile acid concentration, lecithin concentration and type of bile acid □ Cholesterol—effect of lecithin adsorption on cholesterol dissolution, interfacial barrier formation

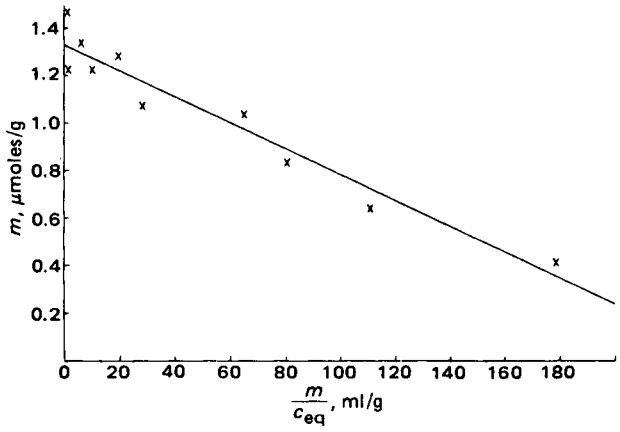

Figure 2—*Langmuir plot of lecithin adsorption in pH 7.4 tromethamine buffer with a constant cholate–lecithin molar ratio of 3.8.*

hydrate dissolution rate in artificial bile is ~20 times as slow as that predicted for diffusion-controlled dissolution.

The possibility arises that lecithin adsorbs onto the cholesterol surface and forms a condensed layer that restrains dissolution of cholesterol and thus acts as the interfacial barrier. The present study examined the *in vitro* adsorption of lecithin onto cholesterol and the effect of cholate concentration on binding.

EXPERIMENTAL

Materials—Commercial cholesterol[1] was ground in a mortar and stored in the dark in a desiccator saturated with water vapor. Differential scanning calorimetry[2] confirmed the hydrate nature of the crystals. The surface area of the cholesterol monohydrate powder was determined by an air permeability method (5).

Radioactive lecithin was prepared by mixing 10 mg of egg lecithin[3] in chloroform–methanol with 2 μCi of L-α-distearoyl[1-^{14}C]phosphatidylcholine[4] in benzene–ethanol. Before use, TLC confirmed the purity of the egg lecithin to be >99%, and the radiochemical purity of distearoylphosphatidylcholine was >95%.

The mixture was dried in an argon atmosphere and dissolved in 5 ml of pH 7.4, 0.1 *M* tromethamine buffer[5] containing 0.05 *M* NaCl and 4.6 m*M* sodium cholate[5]. The lecithin concentration was determined by measuring the phosphorus content by a method described previously (6).

Benzalkonium chloride Ph.Nord.63, lysolecithin[5], and dioctyl sodium sulfosuccinate[6] were used as received. Octadecyltrimethylammonium chloride[7] was dried *in vacuo*.

Adsorption Measurements—Cholesterol monohydrate, 0.50 g, was introduced into 2 ml of incubation medium in centrifuge tubes. The incubation medium was pH 7.4, 0.1 *M* tromethamine buffer containing 0.05 *M* NaCl with varying amounts of radioactive lecithin and sodium cholate. The tubes were filled with argon before closing. The powder was dispersed in the incubation medium by sonication in a bath-type instrument for 10 min.

After incubation in a circulating shaker at room temperature for 4 hr, the tubes were centrifugated. The supernate, 100 μl, was added to 5 ml of scintillation fluid[8], and the radioactivity was counted[9]. The amount of lecithin that was adsorbed was the difference between the initial and the equilibrium concentrations of the incubation medium. The effect of different substances on the adsorption of lecithin was measured by adding the substances at equilibrium, incubating for 4 hr, and remeasuring the radioactivity in the supernate.

RESULTS AND DISCUSSION

Adsorption at Constant Cholate–Lecithin Ratio—The adsorption of lecithin by cholesterol monohydrate from a medium with a cholate–lecithin molar ratio of 3.8 is shown in Figs. 1 and 2. The molar ratio of 3.8 is within the size range of physiological bile (4).

Figure 1 shows a plot of the amount of lecithin adsorbed per gram of cholesterol *versus* the equilibrium lecithin concentration. Since the isotherm becomes linear at low concentrations and shows a limiting value, the binding can be described by the Langmuir adsorption equation:

$$m = b\frac{Kc_{eq}}{1 + Kc_{eq}} \qquad \text{(Eq. 1)}$$

where m is the amount adsorbed, c_{eq} is the equilibrium concentration, and b and K are constants. By transformation of Eq. 1, the following expression is derived:

$$m = b - \frac{1}{K}\left(\frac{m}{c_{eq}}\right) \qquad \text{(Eq. 2)}$$

from which the constants can be determined. At sufficiently high concentrations, m approached the limiting value, b. Thus, b is a measure of the adsorbent capacity, and K is the adsorption intensity.

In Fig. 2, the results were plotted according to Eq. 2; the best straight line through the experimental data was calculated by the least-squares method. The values of b and K were determined from the intercept and the reciprocal of the regression line slope. The b value was 1.34 μmoles/g, and K was 1.8×10^5 liters/mole.

The effective area occupied by a lecithin molecule in a pure lecithin monolayer is 96 Å^2; but in mixtures with cholesterol (38 Å^2/molecule), the area occupied by a lecithin molecule is reduced, depending on the amount of cholesterol built into the layer (7). For example, when there are two or three lecithin molecules for one molecule of cholesterol, 1 m^2 is occupied by 1.67 or 1.76 μmoles of lecithin, respectively. A monolayer formed entirely of lecithin is occupied by 1.72 μmoles of lecithin/m^2.

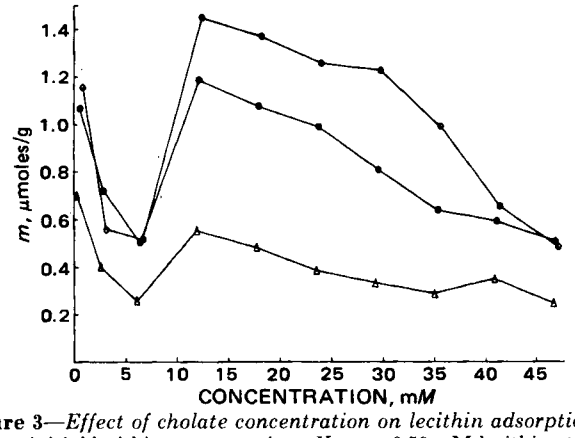

Figure 3—*Effect of cholate concentration on lecithin adsorption at various initial lecithin concentrations. Key:* ○, *0.50 mM lecithin;* ●, *0.38 mM lecithin; and* △, *0.18 mM lecithin.*

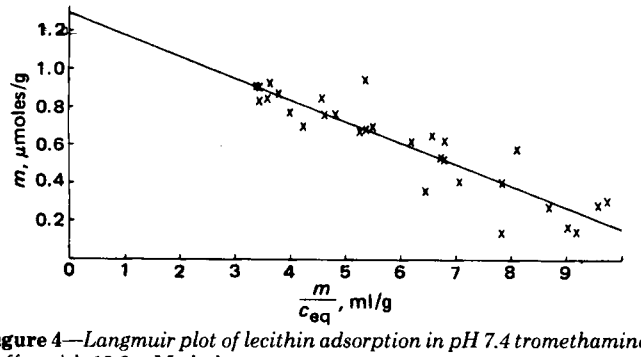

Figure 4—*Langmuir plot of lecithin adsorption in pH 7.4 tromethamine buffer with 12.2 mM cholate.*

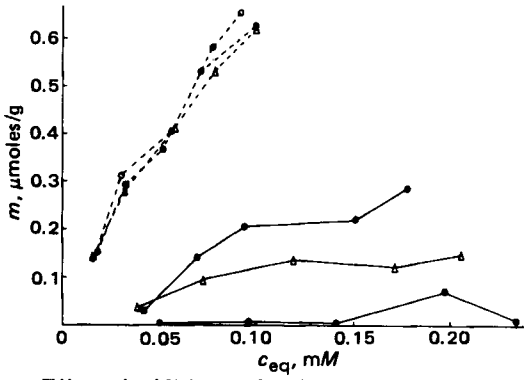

Figure 5—*Effect of additive on lecithin adsorption in pH 7.4 tromethamine buffer with 12.2 mM cholate. Key: - - -, no additive; ○, 1% octadecyltrimethylammonium chloride; △, 1% benzalkonium chloride; and ●, 1% dioctyl sodium sulfosuccinate.*

The surface area of the cholesterol powder was determined to be 0.4 m^2/g, which gives the experimental adsorptive capacity of 3.3 μmoles of lecithin/m^2 of cholesterol. Thus, the results are consistent with formation of a lecithin bilayer or a mixed bilayer.

A hydrophobic layer composed of lecithin or lecithin and cholesterol possibly could form the interfacial barrier for cholesterol dissolution in bile. A study conducted with liposomes showed that lecithin mixed with cholesterol forms condensed layers with reduced permeability (8).

Effect of Bile Salt Concentration—To investigate the effect of the bile salt concentration on adsorption, incubation was performed with cholate concentrations in the 0.05–50 m*M* range and at different initial lecithin concentrations. The results in Fig. 3 show that no simple correlation exists between cholate concentration and lecithin adsorption. The profiles showing a minimum at about 5 m*M* cholate, and decreased adsorption at concentrations greater than ~12 m*M* suggest that different mechanisms are involved.

A possible explanation of the minimum can be derived from the work of Shankland (9), who found that stable mixed micelles are formed only when the solution contains enough cholate to give the critical micelle concentration, which was 5 m*M* sodium cholate. This finding means that adsorption is highly dependent on how cholate molecules are associated in the solution. Since the detergent action of bile salts influences the structural integrity of liposomes (10), a similar effect on the adsorptive layer is expected at the higher cholate concentrations.

Adsorption experiments were carried out with a constant cholate concentration of 12.2 m*M*. The results are plotted in Fig. 4, and the constants of Eq. 2 were determined to be $b = 1.29$ μmoles/g and $K = 8.8 \times 10^3$ liters/mole. The result shows a low adsorption intensity but the same adsorption capacity as in the experiment with a constant cholate–lecithin molar ratio.

Desorption—Different substances were added to the incubation media to examine their effect on the adsorptive layer. Figure 5 shows the adsorption of lecithin from a 12.2 m*M* cholate solution measured before and after the addition of 1% octadecyltrimethylammonium chloride, benzalkonium chloride, or dioctyl sodium sulfosuccinate. These detergents caused desorption, especially dioctyl sodium sulfosuccinate, which prevented the formation of an adsorptive layer. Lysolecithin at 1% had no effect on adsorption.

If the adsorptive layer of lecithin is the interfacial barrier of dissolution, substances that cause desorption of lecithin may act as dissolution accelerators. Kwan *et al.* (11) found that amines and quaternary ammonium compounds were effective cholesterol dissolution accelerators.

The interfacial barrier is believed to be clinically important in gallstone dissolution (3). The observation of an adsorptive lecithin layer may contribute to the understanding of dissolution kinetics. The type of bile acid, the total bile acid concentration, and the lecithin concentration influence dissolution (12). These parameters also affect the formation of an adsorptive layer like the factors that increase the dissolution rate decrease adsorption. Preliminary experiments show that substitution of cholate with chenodeoxycholate leads to less lecithin adsorption onto cholesterol. The significance of the adsorptive layer in cholesterol dissolution as well as of the adsorption behavior under physiological conditions with various conjugated bile acids is not known.

By elucidating the type and structure of the rate-limiting barrier and the factors influencing it for dissolution, it may be possible to search for substances that reduce or destroy the barrier and thereby accelerate dissolution.

Molecular Structure Influencing Either a Sweet or Bitter Taste among Aldoximes

LEMONT B. KIER

Received July 5, 1979, from the *Department of Pharmaceutical Chemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication November 1, 1979.

Abstract □ A series of cyclohexylaldoximes was examined for their sweet or bitter taste using discriminant analysis. The structures of the molecules were described using molecular connectivity. A two-variable linear discriminant function and critical value were computed that correctly assigned 17 of the 20 molecules to their observed sweet or bitter taste categories. The same discriminant function can predict correctly the taste categories of seven of eight additional molecules.

Keyphrases □ Aldoximes—influence of molecular structure on sweet or bitter taste, discriminant analysis, molecular connectivity, taste category prediction □ Molecular connectivity indexes—aldoximes, influences of molecular structure on sweet or bitter taste □ Sweeteners, noncaloric—analysis of aldoximes for potential use as sweeteners, molecular connectivity indexes, discriminant analysis

A safe, stable, noncaloric sweetener continues to be an active research objective. The ban on cyclamate and the suspicion concerning the safe use of saccharin necessitate research for sweet-tasting molecules.

BACKGROUND

The prevailing hypothesis about the chemical structure governing sweet taste was proposed by Shallenberger and Acree (1) and extended by Kier (2). In essence, the hypothesis describes three structural features necessary, but not sufficient, for sweet taste. The first and second features are the presence of a potential hydrogen bond donor, designated AH, and the presence of a hydrogen bond acceptor, B (1). The optimum separation between A and B is about 3 Å. The third feature is a nonpolar region, X, capable of dispersion interaction at a receptor (2). It is a region of atoms located ~3.5 Å from A and ~5.5 Å from B.

One problem in the search for noncaloric sweeteners is the common occurrence of a bitter taste among a series of molecules under investigation. The bitter taste also can coexist with a sweet taste in the same molecule. A classic example is the perception of a bitter aftertaste with saccharin.

Some insight into structural influence on this taste dichotomy was revealed by Solms (3), who recorded that five D-amino acids are sweet while their L-forms are bitter. This finding implicates a stereochemical factor in the sweet and bitter response. Receptors for bitter and sweet taste have been shown to be activated by similar structural features so that closely related molecules impart either or both sensations (4).

The design of noncaloric sweeteners could be improved significantly if the structural characteristics influencing bitter and sweet taste could be discriminated. This knowledge would permit the design of molecules with an unambiguous taste.

A recent report (5) on a series of oximes presented an opportunity for such a discriminative structural analysis. In that study, 51 molecules were analyzed for taste potency and relative sweet–bitter contribution. The results from this oxime study (5) were used in these laboratories to analyze the structures by molecular connectivity, and a discrimination analysis was performed to find the best structural representation discriminating between these two tastes.

EXPERIMENTAL

Selection of Sweet- and Bitter-Tasting Molecules—Two taste characteristics that were defined previously (5) were considered in the present study to differentiate between sweet and bitter molecules. The first characteristic, taste potency compared to a 0.25 *M* sucrose solution, is a measure of taste intensity, regardless of whether the molecule is sweet or bitter. The other characteristic is the percentage of the taste identified as sweet and that identified as bitter.

For the present study, 10 molecules were selected from each taste category based on the largest percentage of sweet (or bitter) taste and the most potent taste response. All 20 molecules selected were aldoximes (Tables I and II).

Structural Analyses and Discrimination Analysis—The structural descriptions of the molecules in Tables I and II were made using molecular connectivity (6). Numerous studies on the structure–activity relationships of drug molecules have employed molecular connectivity to quantitate molecular structure effectively (6–9).

Discriminant analysis is an approach to differentiate between two or more classes of molecules. The procedure is a search for a linear combination of structural variables that describes a line, plane, or general surface that separates the molecule classes in the optimum manner. The value of y is related to the linear discriminant function by:

$$y = c_1x_1 + c_2x_2 + \ldots + c_nx_n \qquad \text{(Eq. 1)}$$

The function separates the categories with as little overlap as possible, thus providing discrimination between the categories. The coefficients, c_i, are determined so that the distance between the categories is maximized whereas the distance between members of the same category is minimized.

The analysis also produces the critical value, y^*, so that molecules with $y > y^*$ are assigned to one category and those with $y < y^*$ are assigned to the other category. The ratio of the between-category variance to the within-category variance is proportional to other statistical quantities such as D^2 (the Mahalanobis generalized distance), T^2 (defined by Hotelling), and the more standard F value (10).

The quality of the discriminant function may be assessed in three ways: comparison of the F value to tabulated values, determination of the

percentage of molecules correctly classified, and prediction of the classification of molecules not included in the original study.

RESULTS

The best linear discriminant function, using two molecular connectivity index variables, is:

$$y = 1.21^1\chi - 3.88^4\chi_p \quad \text{(Eq. 2)}$$

and the critical value is:

$$y^* = -3.27 \quad \text{(Eq. 3)}$$

When each y value is solved for the sweet (Table I) and bitter (Table II) molecules, values of $y > -3.27$ are assigned to the sweet category while

Table III—Taste Prediction from Discriminant Analysis R—CH=N—OH

Compound	R	Taste Potency Relative to Sucrose	Percent of Taste, Sweet/Bitter	$^1\chi$	$^4\chi_p$	$y - y^*$
I		90	50/15	4.432	1.884	1.32

IX		8	4/18	6.037	2.725	−0.01

values of $y < -3.27$ are assigned to the bitter category. Therefore, when $y - y^*$ is negative, the molecule is classified as bitter. The discriminant function is projected onto the $^1\chi$, $^4\chi_p$ plane for $y = y^*$ (Fig. 1) to illustrate the assignments to the two taste categories.

The discriminant function correctly assigns nine of the 10 sweet-tasting molecules (Table I) and eight of the 10 bitter-tasting molecules (Table II). The average percentage of correct assignment is 85%. The statistical significance can be stated as the T^2 value, which in this case is 5.9.

DISCUSSION

The linear discriminant function is an equation featuring two molecular connectivity indexes, $^1\chi$ and $^4\chi_p$. These indexes, weighted by the coefficients in the equation, describe two structural characteristics that influence whether a molecule is sweet or bitter.

The indexes convey structural information that is familiar to the medicinal chemist. The $^1\chi$ index describes the size of the molecule in terms of the number of bonds. Within the equation, the $^1\chi$ index indicates that the more bonds there are, the larger the y value will be. When $^1\chi$ is large enough, $y > y^*$ and the molecule is classified as sweet. The influence of size as expressed by $^1\chi$ is countered by the information conveyed by $^4\chi_p$. This index, as a negative term in the linear discriminant function, leads to lower y values when $^4\chi_p$ increases. The value of $^4\chi_p$ is influenced by the size of the molecule as well as by the substituents.

The indexes in the linear discriminant function indicate that the value of y is greater than that of y^* when the number of first-row atoms in the substituent of cyclohexylaldoxime is four or less. Thus, a *tert*-butyl group (*i.e.*, Compound IX, Table III) has a $y - y^*$ of virtually zero. Substituents with more than four first-row atoms, particularly if they are branched, give a y value less than y^* (Table II). The structural conclusions are that larger, more branched substituents on cyclohexylaldoximes increase the tendency for the molecule to be bitter. In contrast, smaller substituents, with four or fewer first-row atoms, influence sweet taste (Table I).

Another observation that can be made about the influence of structure on taste, based on the linear discriminant function, is that the two chi indexes are not of the valence class. This finding means that unsaturation or heteroatoms in the 20 molecules are not critical to the structures that influence the sweet or bitter taste. This conclusion is correct to the extent that 85% of the molecules are assigned correctly.

For the three incorrectly assigned molecules (III in Table I and IV and V in Table II), a molecular connectivity index of the valence type may be necessary for the correct assignment. However, the addition of a third molecular connectivity index in the discrimination analysis failed to improve the number of correctly assigned molecules in Tables I and II. The three incorrectly assigned molecules in Tables I and II have the lowest taste potencies among their respective taste classes. This observation suggests that high taste potency is important in the categorization of molecules as bitter or sweet tasting.

A test of the linear discriminant function and the molecular connectivity indexes that describe structures is the ability of the function and the associated critical value, y^*, to predict the taste categories of molecules not in the original study. For this test, nine additional molecules were selected from the study of Acton and Stone (5), based on their taste potencies and sweet–bitter taste ratios that favored one or the other category (Table III).

Calculation of the $^1\chi$ and $^4\chi_p$ indexes for each molecule and computation of $y - y^*$ for the linear discriminant function formed the basis of the taste category predictions shown in Table III. The first five molecules are reported to be sweet. The predictions for I–III and V are correct. The prediction for IV is ambiguous since $y = y^*$.

Compounds VI–IX are classified as bitter tasting. The solution of $y - y^*$ predicts VI, VIII, and IX to be bitter. Compound VII is predicted incorrectly.

Thus, seven of the predictions were correct, one was incorrect, and one was ambiguous. Without IV, the correct prediction for seven of eight compounds gave an accuracy of 87%, the same quality of classification as obtained with the assignments in Tables I and II combined.

The results of the study are encouraging in that molecular connectivity indexes appear to encode sufficient information about the structure influencing the taste category of cyclohexylaldoximes so that the discriminant analysis can assign correctly 17 of 20 molecules to the sweet or bitter taste category. Furthermore, the analysis based on these indexes can predict the taste category of additional molecules with the same accuracy. The study shows one approach to the possible separation of bitter taste from candidate molecules of interest as noncaloric sweeteners.

Biological Disposition of Sodium Dichloroacetate in Animals and Humans after Intravenous Administration

GEORGE LUKAS *x, KUNJBALA H. VYAS *, SHIRLEY D. BRINDLE *, ANNE R. Le SHER ‡, and WILLIAM E. WAGNER, Jr. ‡

Received April 27, 1979, from the *Research Department, Pharmaceuticals Division, Ciba-Geigy Corporation, *Ardsley, NY 10502, and ‡Summit, NJ 07901.* Accepted for publication October 5, 1979.

Abstract □ Sodium dichloroacetate, a potential antidote for lactic acidosis, was administered intravenously to rats, dogs, and four humans. In three rats, maximum plasma sodium dichloroacetate concentrations were 120–164 μg/ml after a 100-mg/kg dose and declined with half-lives of 2.1–4.4 hr. In two dogs, maximal concentrations of 447 and 508 μg/ml were attained after a 100-mg/kg dose. The subsequent decline was relatively slow with approximate half-lives of 17.1 and 24.6 hr. An intravenous infusion of 10 mg/kg was administered over 20 min to two human subjects. Two other subjects received 20 mg/kg. After the infusion, maximum plasma concentrations of 19.9 and 24.7 μg/ml were seen with the lower dose and 57.3 and 74.9 μg/ml were achieved with the higher dose. Thereafter, concentrations declined rapidly with half-lives of 20–36 min. The observed large interspecies differences in half-lives could be explained in terms of differences in the apparent volume of distribution and/or clearance.

Keyphrases □ Pharmacokinetics—sodium dichloroacetate, plasma concentration level-time curve, rats, dogs, humans □ Sodium dichloroacetate—pharmacokinetics, plasma concentration levels, rats, dogs, humans □ Clearance, intrinsic—plasma sodium dichloroacetate concentration, pharmacokinetics, rats, dogs, humans

Sodium dichloroacetate (I) has been reported to reduce normal or elevated blood lactate and pyruvate levels in animals by activating the pyruvate dehydrogenase enzyme complex (1–3). Oral administration of I to patients having nonketotic diabetes mellitus also led to an appreciable lowering of plasma lactate concentrations (4). The compound has been of possible interest as an intravenous antidote in patients suffering from lactic acidosis. This study was undertaken to provide information on the biological disposition of I in animals and humans since no data are available.

EXPERIMENTAL

Materials—Labeled[1] and unlabeled[2] sodium dichloroacetate were used. The material labeled in both carbon atom positions had a specific activity of 23.4 μCi/mg. Radiochemical purity, determined by TLC on silica gel plates in ethanol–chloroform–concentrated ammonium hydroxide–water (53:30:15:1.5), was >98%.

Animal Experiments—Each of three male Sprague–Dawley rats, 160–170 g, was given an intravenous injection of ^{14}C-I, diluted 1:20 with nonlabeled I, in a tail vein. The compound (100 mg/kg) was administered as a 10% aqueous solution. At specified times, animals were subjected to light ether anesthesia, and a 0.2–0.3-ml blood sample was collected in a heparinized centrifuge tube through a glass capillary by puncture of the suborbital sinus. Animals then were permitted to recover until the next sampling time.

Each of two male beagles, 9.0 and 10.5 kg, was given 100 mg of I/kg as a 20% aqueous solution intravenously in the cephalic vein. Animals were placed in individual metabolism cages. At specified times, blood was collected from a jugular vein without anesthesia.

Human Study—Four normal subjects, having given informed consent, participated after an overnight fast. Subjects 1 and 2, ages 42 and 38 years, respectively, each weighed ~70 kg. Subjects 3 and 4, ages 52 and 26 years, respectively, weighed 80 and 83 kg. In each case, the history, physical examination, ECG, and all laboratory tests were within normal limits.

Following the collection of the control urine sample and the drawing of a control blood specimen from Subjects 1 and 2, a 10-mg/kg dose of I dissolved in 100 ml of saline was infused over 20 min. Blood specimens were obtained from the contralateral antecubital vein at the time the infusion was completed. Specimens were drawn subsequently at 1 (40 min after termination of the infusion), 2, 3, 4, 6, 8, 10, 12, 24, 32, and 48 hr. All urine was collected for 96 hr with collection periods ending at 1, 2, 4, 8, 12, 24, 48, 72, and 96 hr.

Several weeks later, the procedure was repeated on Subjects 3 and 4, the sole change being that each received 20 mg/kg. All subjects were given a standard breakfast after the 4th hr. They remained under clinical observation for 8 hr.

Blood specimens were centrifuged as soon as they were collected. Plasma was separated and stored frozen until analysis. The urinary volume was measured and recorded. Aliquots of 20 ml from each urine sample were labeled and frozen for analysis.

Analysis of Unchanged I—Plasma and urine I concentrations were analyzed by a reported GLC method (5) as modified (6). Briefly, the method involved addition of trichloroacetic acid as an internal standard and 14% boron trifluoride in methanol as the derivatizing reagent. The resulting methyl esters of I and the internal standard were extracted with benzene and analyzed on a Chromosorb 101 column using an electron-capture detector.

Preliminary analyses of plasma samples obtained from human subjects indicated that many specimens contained very low I concentrations. Therefore, method sensitivity was improved from 300 ng/ml as reported previously (6) to 40–50 ng/ml by three minor modifications: (*a*) the volume of solvent used in the extraction was reduced from 2 to 0.5 ml; (*b*) between the extraction and centrifugation steps, the entire contents of the vial were transferred to a 5-ml centrifuge tube to facilitate aliquot removal; and (*c*) the volume of extract analyzed was changed from 2 to 3 μl. The linearity of standard curves obtained during analysis demonstrated that these changes had no effect on the accuracy and precision of the results.

Analysis of Total Radioactivity—A 10-μl aliquot of plasma or urine was dissolved in 15 ml of scintillation cocktail and counted[3]. External standardization was used to correct for quenching. The cocktail had the following composition: naphthalene, 400 g; 2,5-diphenyloxazole, 20 g; 2,2′-*p*-phenylenebis(4-methyl-5-phenyloxazole), 1.2 g; dioxane, 2920 ml; toluene, 540 ml; and methanol, 140 ml.

96 hr	16.6	ND	NS	NS	16.5	1

[a] Results are given in terms of both total radioactivity and GLC analysis. [b] NS = no sample. [c] ND = not detectable.

Distribution of I between Plasma and Erythrocytes—To 2 ml of heparinized fresh human blood obtained from three healthy volunteers was added 0.2 ml of an aqueous solution of ^{14}C-I to provide concentrations of 0.5, 5, and 50 μg/ml. The mixtures were incubated for 1 hr at 37° in a shaking water bath and cooled. Triplicate 0.1-ml aliquots were combusted in a sample oxidizer[4]. The resulting $^{14}CO_2$ was trapped and counted for the estimation of radioactivity in whole blood. The remaining blood samples were centrifuged, and radioactivity in triplicate 0.1-ml plasma aliquots was analyzed similarly by combustion and counting. In a separate experiment, the stability of I in whole blood for 1 hr at 37° was ascertained.

Stability of I in Frozen Plasma—To 1-ml aliquots of human plasma obtained from healthy volunteers was added 1 μg of I in 50 μl of water. The aliquots were sealed, stored at −20°, and analyzed in triplicate after periods ranging from 1 week to 6 months.

Pharmacokinetic Calculations—Pharmacokinetic parameters were calculated using standard procedures and assuming a one-compartment open model with constant-rate intravenous infusion (7). Half-lives were obtained with the least-squares method after logarithmic transformation of concentrations. Plasma clearance (8) was calculated as the ratio of the dose and the area under the concentration–time curve. The apparent volume of distribution was obtained as the ratio of clearance and the elimination rate constant, the latter value having been derived from the corresponding half-life estimate.

The importance of using blood clearance rather than plasma clearance in the calculation of intrinsic clearance was demonstrated previously (8, 9). Blood clearance was obtained from plasma clearance using a constant correction factor of 0.688. The value was obtained assuming a mean hematocrit of 0.45 and a mean distribution ratio of 4:1 between plasma and the cellular fraction of blood for I (see *Results*):

$$F = \frac{B(1 - H)}{P} \qquad \text{(Eq. 1)}$$

[4] Packard model 306.

where F is the correction factor, H is the hematocrit, and B and P represent concentrations in equal-volume aliquots of whole blood and plasma, respectively.

Intrinsic clearance was obtained from the blood clearance as described (9) by:

$$Cl_{in} = \frac{QCl_{bl}}{Q - Cl_{bl}} \qquad \text{(Eq. 2)}$$

where Cl_{in} and Cl_{bl} refer to the intrinsic and blood clearance, respectively, and Q indicates the hepatic blood flow rate. An approximate mean value of 1500 ml/min was used for the calculations in conformity with literature reports (9).

RESULTS

Reproducibility of GLC Method—Standard curves generated daily in conjunction with the analyses of human plasma samples are summarized in Table I. Each of the five curves represents five concentrations of I, usually in duplicate determinations, ranging from 0.05 to 10 μg/ml. Daily variations in the individual standard curves were acceptable, with the relative standard deviations ranging from 9.66 to 17.45% and giving an overall value of 12.66% over 5 days.

Animal Studies—Plasma levels in three rats after 100 mg/kg iv are summarized in Table II. Maximal concentrations of unchanged I ranged between 120 and 164 μg/ml. Subsequent declines of plasma concentrations occurred with half-lives of 2.1–4.4 hr. Total radioactive materials attained maximal concentrations of 166–209 μg/ml (expressed as unchanged I). Thus, at the peak concentration, unchanged I in plasma represented the bulk of total radioactivity. However, the subsequent decline of the total radioactivity concentrations was considerably less rapid, and apparent half-lives of 21–36 hr could be estimated, indicating extensive metabolism and slow elimination of metabolites.

Plasma levels of unchanged I in two dogs after 100 mg/kg iv are summarized in Table III. Maximum concentrations of 447 and 508 μg/ml were measured in the first plasma samples at 5 min. The subsequent decline was slow. Sampling in one animal was continued for 48 hr. In the other animal, sampling had to be discontinued after 24 hr because of collapsing veins and the formation of hematomas. Nevertheless, approximate half-lives of 17.1 and 24.6 hr could be estimated in the two animals.

Human Studies—No subjective or objective changes or signs of clinical activity were noted in any subject upon intravenous infusion of I.

Plasma concentrations of unchanged I are summarized in Table IV.

Table III—Plasma Sodium Dichloroacetate Levels (Micrograms per Milliliter) in Dogs following a 100-mg/kg iv Dose

[a] AUC = area under the plasma level-time curve, V_d = apparent volume of distribution, and Cl = clearance.

Table VI—Average Values (and Ranges) of Pharmacokinetic Parameters of Sodium Dichloroacetate in Humans, Rats, and Dogs [a]

Parameter	Humans 10 mg/kg	Humans 20 mg/kg	Rats, 100 mg/kg	Dogs, 100 mg/kg
$t_{1/2}$, hr	0.34 (0.33–0.36)	0.51 (0.41–0.61)	2.97 (2.1–4.4)	20.8 (17.1–24.6)
V_d, ml/kg	337 (308–366)	190 (186–195)	932 (701–1080)	256 (249–262)
Cl_{plasma}, ml/(min kg)	11.31 (10.86–11.76)	4.55 (3.53–5.58)	4.22 (1.84–5.94)	0.146 (0.123–0.168)
Cl_{in}, ml/(min kg)	69.7 (59.3–80.0)	10.7 (7.2–14.2)	6.9 (2.8–9.9)	0.21 (0.18–0.24)

[a] Values of 20, 67, and 40 ml/(min kg) were used in humans (9), rats (12), and dogs (13), respectively, for hepatic blood flow.

The highest concentrations were obtained immediately after the end of the infusion. Subjects 1 and 2, receiving 10 mg/kg, had maximum values of 19.9 and 24.7 μg/ml, respectively. Maximum concentrations of 57.3 and 74.9 μg/ml were seen in Subjects 3 and 4 after 20 mg/kg.

Concentrations of I declined rapidly following monoexponential kinetics. The values decreased to <0.04 μg/ml, the sensitivity of the method, at 4 hr after the lower dose and at 6 or 8 hr after the higher dose.

Urinary excretion of unchanged I became negligible after the first 8 hr; in all subjects, cumulative excretion amounted to considerably less than 1% of the dose.

The pharmacokinetic parameters are summarized in Table V. Half-lives in the four subjects ranged from 20 to 36 min. Values for the apparent volume of distribution were 15.5–25.3 liters. Plasma clearance ranged from 294 to 813 ml/min, and the corresponding values for blood clearance were 427–1180 ml/min. Hematocrit in the four subjects had a mean value of 0.45 (range of 0.43–0.49).

The following values were obtained for intrinsic clearance: Subjects 1 and 2, 4125 and 5530 ml/min; and Subjects 3 and 4, 1140 and 600 ml/min. Expressed on the basis of unit body weight, these values were 59.3, 80.0, 14.2, and 7.2 ml/(min kg), respectively.

The stability of I stored in frozen human plasma for 6 months was demonstrated in separate experiments.

In an *in vitro* study using fresh blood from three subjects, an average of 80% (range of 72–94%) of I present in whole blood was in the plasma. The distribution between plasma and the cellular fraction was independent of the concentration in the 0.5–50-μg/ml range.

DISCUSSION

After an intravenous infusion, I in human plasma declined monoexponentially over a 200–500-fold concentration range, corresponding to a range of 7–9 half-lives. These findings permitted a relatively simple pharmacokinetic analysis. Examination of the individual pharmacokinetic parameters (Table V) suggests some dose dependence because the apparent volume of distribution and the plasma clearance decreased with a doubling of the dose. Although this observation is necessarily limited by the size of the study, it suggests capacity-limited elimination.

Intrinsic clearance refers to the maximum capacity of an organ to remove the drug irreversibly by all pathways when blood flow to the organ is not rate limiting (10). The metabolism of I has not been explored in detail, but Demaugre *et al.* (11) demonstrated its hepatic biotransformation to oxalate. The present results show that the intrinsic clearance of I was considerably greater than, and the elimination presumably limited by, blood flow in subjects receiving 10 mg/kg. In subjects receiving 20 mg/kg, intrinsic clearance was considerably lower, lending support to the hypothesis of capacity-limited metabolism. Corresponding intrinsic values expressed on the basis of unit body weight indicated even more clearly the dose-dependent pharmacokinetics of I. A doubling of the dose led to an approximately sevenfold decrease in intrinsic clearance, yet the systemic (plasma or blood) clearance values decreased only by a factor of two or three. Thus, when the elimination rate is limited by hepatic blood flow, systemic clearance appears to reflect only partially any large changes occurring in intrinsic clearance.

Pharmacokinetic parameters also were estimated for rats and dogs. Average values and ranges of the animal and human data are summarized in Table VI for comparison. The large difference in the half-lives of I between humans and dogs may reflect the difference in clearance. In contrast, the observed difference in half-lives between humans and rats is consistent with the relatively high value of the apparent volume of distribution in the latter species.

In the present study, the I elimination rate in humans was dose dependent and limited by hepatic blood flow. The role of blood flow appeared to diminish with increasing dose. Elimination of high doses was not flow limited in rats and, particularly, in dogs since hepatic blood flow substantially exceeded intrinsic clearance[5]. The large differences seen show the difficulty in predicting the biological disposition and toxicity of therapeutic doses of a drug in humans from animals given large doses.

[5] The relative contributions of dose dependence and species difference were not determined. These factors could be assessed by additional studies wherein each subject or animal would receive both larger and smaller doses of I.

Analysis of Benzimidazoles in Body Fluids by High-Performance Liquid Chromatography

J. A. BOGAN ˣ **and S. MARRINER**

Received August 6, 1979, from the *Department of Veterinary Pharmacology, University of Glasgow, Bearsden Road, Bearsden, Glasgow, Scotland.* Accepted for publication November 2, 1979.

Abstract □ A simple assay for benzimidazole in plasma and GI fluids using high-performance liquid chromatography was developed. The benzimidazoles were extracted using ether and were chromatographed with methanol–ammonium carbonate mixtures as the eluting solvents. Benzimidazole was detectable in 4 ml of plasma or GI fluid to a limit of 20 ng/ml.

Keyphrases □ Benzimidazoles—analysis, high-performance liquid chromatography, GI fluids, plasma □ High-performance liquid chromatography—analysis, benzimidazoles, GI fluids, plasma □ Anthelmintics—benzimidazoles, high-performance liquid chromatographic analysis, GI fluids, plasma

The benzimidazole anthelmintics are characterized by low mammalian toxicity and a broad spectrum of activity against GI nematodes. Some members of the group also are active against lungworms, tapeworms, and liver flukes in humans, cattle, sheep, and other animals. This paper describes a simple assay for this important group of anthelmintics using high-performance liquid chromatography (HPLC).

BACKGROUND

The anthelmintic activity of the benzimidazole anthelmintics appears to be the result of the length of time over which the parasite is exposed to the drug rather than the peak concentration to which the parasite is exposed. Thus, administration of the drug in divided doses usually increases anthelmintic activity (1). The drugs exert their activity on the parasites by inhibiting glucose uptake (2) and/or by inhibiting the enzyme fumarate reductase (3). Differences between members of the group appear to be more a result of differing pharmacokinetics of the drugs in the host animal than of different inherent anthelmintic activity. However, there is a lack of data on the pharmacokinetics of these drugs, probably because of analytical problems.

Most published data on benzimidazole pharmacokinetics are from experiments using radiolabeled drug without distinguishing between the parent drug and the metabolites. A method was published for the analysis of fenbendazole using fluorescence spectrophotometry, but this method also fails to distinguish the parent drug from the metabolites (4). A radioimmunoassay for oxfendazole (5) was reported recently, but this complex method requires the raising of an antiserum, and some cross-reactivity with metabolites occurs.

This paper describes a sensitive HPLC method for the analysis of oxfendazole, fenbendazole, and albendazole, the most potent members of the group, in body fluids. The method can be adapted for the other five members of the group that are marketed in the United Kingdom.

EXPERIMENTAL

Materials—Analar reagents were used, and the HPLC solvents were distilled.

Extraction—The method is applicable to plasma, rumen fluid, abomasal fluid, and duodenal fluid.

To 4 ml of plasma or GI fluid in a 50-ml stoppered tube were added 4 ml of phosphate buffer (pH 7.4) and 20 ml of ether. The tube was shaken for 10 min on a rotary mixer. Then 16 ml of the ether layer was removed to a clean test tube, and 20 ml of ether was added to the first tube, which was shaken again for 10 min. Twenty milliliters of ether was removed and combined with the initial 16 ml of ether.

The ether was evaporated slowly on a dry bath at 60° under nitrogen to a volume of about 6 ml and then was transferred to a conical 10-ml glass tube. The 50-ml tube was washed with several milliliters of ether, and the washings were added to the conical tube. The ether then was evaporated to dryness, the walls of the conical tube were rinsed with ether, and the solution was evaporated again to dryness. The residue in the tube was redissolved in 50 μl of methanol with the aid of an ultrasonic bath. If higher concentrations were expected, larger volumes of methanol were used. Five microliters of this solution was used for HPLC analysis.

HPLC—The HPLC system consisted of a solvent delivery pump[1] and a variable-wavelength UV detector[2] with a 100 × 8-mm column[3] packed

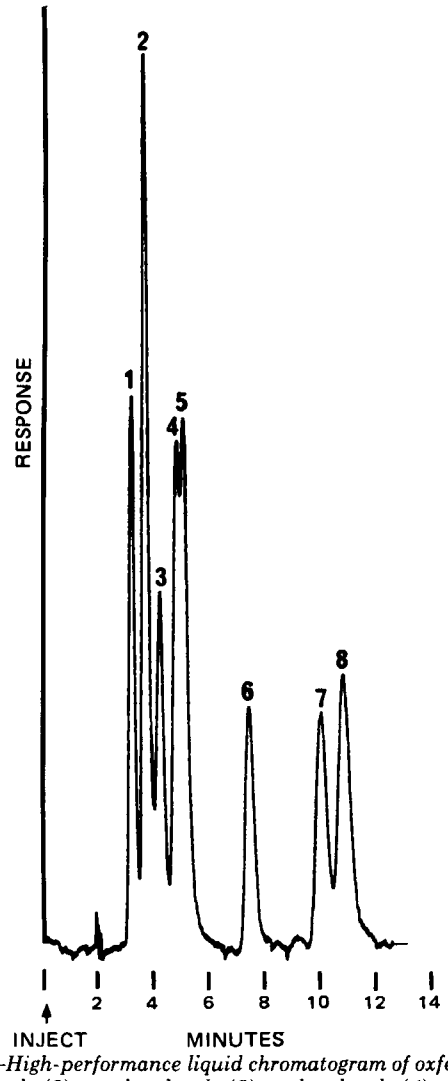

Figure 1—*High-performance liquid chromatogram of oxfendazole (1), thiabendazole (2), cambendazole (3), mebendazole (4), oxibendazole (5), albendazole (6), fenbendazole (7), and parbendazole (8) in methanol–ammonium carbonate (0.05 M) (65:35). Five microliters of a solution containing 10 μg/ml of each benzimidazole in methanol was used for injection.*

with ODS-Hypersil 10[4]. The solvent flow rate was 1.5 ml/min, and the detector wavelength was 292 nm.

The drug concentration in the samples was calculated with the aid of calibration curves prepared by adding known drug amounts (0.05–10 μg/ml) to blank plasma or GI fluids. The standard samples were run through the procedure, and the peak heights of drug in the sample were compared with the calibration curve prepared from the standard samples.

RESULTS AND DISCUSSION

The new broad-spectrum benzimidazoles have limited solubility in both water and organic solvents. While this feature enhances their action by slowing drug dissolution after oral dosage, it also produces difficulties in analysis because the concentrations found in plasma and in the GI contents are low and are present for long periods. The method described here is sensitive and practical for the evaluation of the pharmacokinetics of the benzimidazoles.

The retention times of the benzimidazoles varied considerably, and Fig. 1 shows a chromatogram of the eight benzimidazoles using a solvent mixture of methanol—ammonium carbonate (0.05 M) (65:35). For the analysis of individual benzimidazoles with longer retention times, retention times can be shortened by increasing the proportion of methanol in the solvent mixture. For example, parbendazole has a retention time of 3.6 min in 85:15 methanol–ammonium carbonate.

Recoveries were determined by measuring standard concentrations (0.2–5.0 μg/ml) of some benzimidazoles added to plasma, rumen fluid, and abomasal fluid (Table I). The method is sufficiently sensitive to measure plasma and GI fluid concentrations down to 0.02 μg/ml with 4 ml of sample or 0.01 μg/ml with 8 ml of sample.

The accuracy and precision of the method for oxfendazole were determined by adding known amounts of oxfendazole to 4 ml of abomasal fluid. Samples of each known concentration then were assayed in triplicate (Table II). It was determined that the recovery losses were due to the extraction procedure rather than to benzimidazole degradation.

Fenbendazole, oxfendazole, and albendazole, which are the most potent compounds of the benzimidazole series and have the broadest spectrum of activity, were administered at 10 mg/kg to three sheep with permanent ruminal and abomasal fistulae. Samples of plasma, ruminal fluid, and abomasal fluid were withdrawn at intervals for measurement of the benzimidazole concentration[5].

[4] Whatman Co., Clifton, N.J.

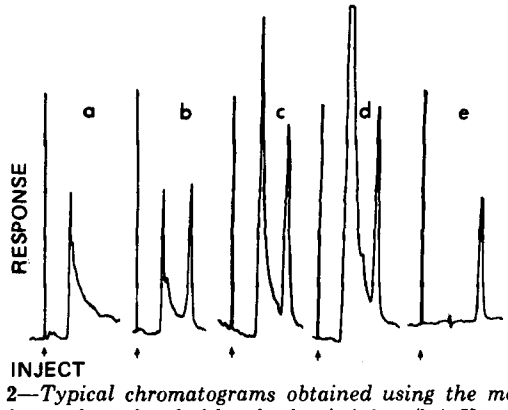

Figure 2—*Typical chromatograms obtained using the method on samples from a sheep dosed with oxfendazole (10 mg/kg). Key: a, plasma before oxfendazole administration; b, plasma at 12 hr after administration; c, abomasal fluid at 12 hr; d, ruminal fluid at 12 hr; and e, oxfendazole standard (10 μg/ml).*

Under the conditions described, no interfering substances were encountered in any fluid. The peaks encountered were symmetrical and, except at the lowest concentrations, were well defined. Typical chromatograms for oxfendazole are shown in Fig. 2.

The mean peak concentrations encountered in the three sheep for oxfendazole were 0.8, 0.4, and 4.6 μg/ml in plasma, ruminal fluid, and abomasal fluid, respectively. Oxfendazole was detectable for up to 11 days after administration. For fenbendazole, the mean peak concentrations were 0.13, 3.4, and 2.6 μg/ml, respectively, and it was detectable in all sheep 120 hr after administration. Fenbendazole was metabolized to oxfendazole (its equivalent sulfoxide metabolite), and the kinetics of the oxfendazole formed were similar to those of the administered oxfendazole.

Albendazole was not detectable in any plasma samples, although it could be detected in ruminal and abomasal fluids at maximum concentrations of 0.3 and 4.9 μg/ml, respectively. Albendazole was detectable in ruminal and abomasal fluids for at least 72 hr after administration. Metabolites (sulfoxide and sulfone) were found in high concentration in the plasma and abomasum after albendazole administration and were present for more than 48 hr. These metabolites did not interfere with the assay of the parent drug, but they also could be assayed by this method.

[5] A full description of the pharmacokinetics of these drugs in sheep will be the subject of a separate investigation.

Prostaglandin Prodrugs VI: Structure–Thermodynamic Activity and Structure–Aqueous Solubility Relationships

BRADLEY D. ANDERSON ˣ **and ROBERT A. CONRADI**

Received May 7, 1979, from *Pharmacy Research, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication November 6, 1979.

Abstract □ Solubilities in isooctane and water were determined for several C_1-phenolic esters of prostaglandin $F_{2\alpha}$ and prostaglandin E_2 and acetates having the same phenol moiety. Linear free energy relationships for solubility among the series were observed with slopes of ~1. These results suggest that the contributions of the phenyl substituent to the free energies of these processes are similar in the three series, even though the structure of the acyl moiety is varied. In addition, aqueous solubility was separated into two thermodynamic components, reflecting transfer from the solid phase to an inert solvent and transfer from the inert solvent to water, to evaluate the relative effects of various substituents on the escaping tendency of the drug from the solid phase and on solution interactions. It was found that polar, hydrogen-bonding functional groups in many cases do not bring about increased water solubility because of a corresponding increase in intermolecular interaction in the solid phase.

Keyphrases □ Prostaglandins—prodrugs, structure–thermodynamic activity and structure–aqueous solubility relationships □ Prodrugs—prostaglandins, structure–thermodynamic activity and structure–aqueous solubility relationships □ Solubility—prostaglandin prodrugs, solubility in isooctane and water

The physicochemical properties of a drug affect every aspect of drug design, from initial purification to optimization of drug concentration in the receptor region. Consequently, relationships between molecular structure and physical properties are extremely useful to the pharmaceutical or medicinal chemist. Predictive relationships are particularly important in prodrug design since the primary goal often is the improvement of pharmaceutical or pharmacodynamic properties of already active compounds through modifications of physical properties.

A variety of prostaglandin prodrugs have been synthesized in an attempt to improve the pharmaceutical or biological properties of the parent compounds (1–5). Among the problems encountered with prostaglandins are solid-state instability and their frequent existence as liquids, which pose difficulties in handling and formulation. In the E_2 series, some crystalline high-melting C_1-phenolic esters with improved solid-state stability were reported (1). A rough correlation was observed between the melting points of the esters and the parent phenols, suggesting that strong intermolecular interactions existing in the crystalline phenols may be retained upon ester formation. Similar melting-point correlations were observed for C_1-phenolic esters in the prostaglandin $F_{2\alpha}$ series[1].

This report describes an attempt to gain a more quantitative understanding of the effect of various prodrug moieties on aqueous solubility and on the thermodynamic activity of drugs in the pure crystalline solid as reflected by alkane solubility. Alkane and aqueous solubilities have been determined for several phenolic C_1-esters of prostaglandins of the E_2 and $F_{2\alpha}$ series and for acetates having the same phenolic moieties. Linear free energy relationships between series with slopes of ~1 have been observed in the alkane and aqueous solubilities, suggesting that the effect of a given substituent on the free energies of these processes is similar in all three series. Such relationships may be useful in the prediction of solubilities of other prostaglandin derivatives.

[1] W. Morozowich, The Upjohn Co., Kalamazoo, Mich., personal communication.

EXPERIMENTAL

The compounds examined in this study and their melting points are listed in Table I[2]. The syntheses of the prostaglandin E_2 esters were reported previously (1). The C_1-phenolic esters of prostaglandin $F_{2\alpha}$ and the corresponding acetates were prepared by a similar procedure[3].

Solubilities were determined by various methods, depending on the particular difficulties encountered with each compound. For pure, relatively soluble compounds, 10–50-mg samples were shaken in vials containing 10–25 ml of solvent at 25° for at least 24 hr. These solutions were filtered or centrifuged to remove undissolved solid; after the appropriate dilutions or concentrations, they were analyzed for dissolved drug.

Solution concentrations were determined spectrophotometrically[4] only if solubilities were quite high. Thus, the isooctane and water solubilities of acetates having solubilities greater than 2×10^{-5} *M* were determined by UV analysis, as were the isooctane solubilities of the biphenyl, naphthyl, and *p*-acetylphenyl esters of prostaglandin E_2. In the spectrophotometric analyses, solubilities were determined as a function of the amount of solid added to the vials. A constant apparent solubility suggested that impurities did not contribute significantly to the UV absorbance reading.

All other analyses were performed by high-pressure liquid chromatography[5] (HPLC) using a reversed-phase column[6] and acetonitrile–water solvent systems. Sample detection was at 254 nm.

In many cases, especially for compounds having low aqueous solubility but much higher solubility in isooctane, the method proposed by Higuchi *et al.* (6) was utilized. Solid samples, 10–50 mg, were shaken in vials at 25° in both isooctane and water for not less than 24 hr. When possible, the saturation solubility in both phases was determined as described previously. Because of the low water solubility in isooctane and vice versa (7), it was assumed that solubilities in water-saturated isooctane or in isooctane-saturated water were equal within experimental error to the solubilities in the pure solvents.

Water solubilities of extremely insoluble compounds or compounds that appeared to adsorb readily to glassware, filters, *etc.*, were determined by recycling the solvent through a cartridge containing a filter[7] and a 1–20-mg sample. The change in UV absorbance was monitored at 254 nm[8]. The solvent was pumped[9] through the filtration system at ~10–15 ml/min.

This system offered several advantages over conventional methods:

1. By monitoring absorbance with time, one can ascertain whether equilibrium is established within the system.
2. Withdrawal of filtered samples can be done easily and rapidly with a minimum temperature change.
3. Possible adsorption onto extraneous glassware or onto the filter no longer is a problem since all components become saturated with solute.

Equilibrium solubilities generally were approached within 1 day for

the major component, although impurities often leached out of the solid phase more slowly. Because impurities often contributed more to the UV absorbance than did the compound of interest, HPLC analysis of the saturated solution was necessary. All solubilities are reported in moles per liter.

RESULTS AND DISCUSSION

Molecular Structure–Aqueous Solubility Relationships—Aqueous solubilities of prostaglandin E_2 and $F_{2\alpha}$ derivatives and their corresponding acetates are listed in Table II. Plots of log solubility of the prostaglandin $F_{2\alpha}$ esters and the prostaglandin E_2 esters *versus* log solubility of the acetates are shown in Figs. 1 and 2. These quantities were obtained experimentally. Slopes of ~1 (Fig. 1: slope = 0.98, r = 0.9467; Fig. 2: slope = 1.03, r = 0.9468) are observed.

Since log solubility is proportional to the solution free energy, the plots in Figs. 1 and 2 are indicative of approximate linear free energy relationships for solubility; the effect of a substituent on the solution free energy in one series is linearly related to its effect in another series. Slopes of 1, as observed in the series of compounds examined, suggest that not only is there a proportionality in free energy but that the substituent effects on solubility are nearly the same for both prostaglandin series and the acetates. This effect was not known to be observed previously for polar crystalline materials. These observations should not be extrapolated to other series since the constancy in substituent group contributions probably depends on similar crystal lattice arrangements of molecules in all compounds examined.

The aqueous solubilities in Table II are listed from highest to lowest. There appears to be no correlation between the apparent polarity of the phenol moiety and aqueous solubility. This lack of correlation illustrates the inadequacy of simple maxims such as "like dissolves like" for predicting relative solubilities of solids in water. A more quantitative understanding of the relationship between molecular structure and aqueous solubility can be gained by separating aqueous solubility into two thermodynamic components.

Separation of Aqueous Solubility into Two Thermodynamic Components—As shown in Scheme I, the solution free energy of a drug in water can be expressed as a sum of the energies from the escape of the drug from the crystal into an inert solvent and the transfer of the drug from an inert solvent to water.

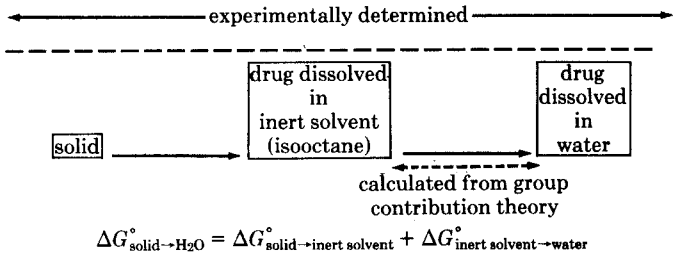
Component 1: Drug Escape from Crystal into Inert Solvent—The excaping tendency of a compound from its solid phase obviously is dependent on the strength of the intermolecular forces in the crystal. *A priori* attempts to predict the magnitude of these forces from molecular structural considerations still are largely undeveloped. Ideally, partial



Scheme I—Separation of aqueous solubility into two thermodynamic components

vapor pressures of the drug above the solid phase give relative escaping tendencies directly (8), but these quantities are not easily measured for most compounds. Consequently, it has been suggested (9, 10) that solubility in a relatively inert solvent such as an aliphatic hydrocarbon should be employed to compare escaping tendencies of drugs from the solid phase.

By choosing the infinitely dilute solution of the solute in an alkane solvent as the reference state and setting the thermodynamic activity of a hypothetical 1 *M* solution equal to 1, the thermodynamic activity of a drug in the solid phase may be defined as its alkane solubility (providing that the solubility is low). Differences in the free energies thus obtained reflect differences in such interactions as hydrogen bonding and Debye forces and the entropic content between the two states (10). Whereas specific interactions may be quite significant in the solid phase, solution interactions between the drug substance and alkane solvent are expected to be nonspecific and not highly sensitive to minor changes in molecular structure.

Alkane Solubilities—The alkane solubilities of acetates reported here were determined by direct measurement as described under *Experi-*

mental. Prostaglandin alkane solubilities were in many cases too low to measure experimentally. These values were estimated from their water solubilities and alkane–water partition coefficients estimated from group contribution theory (the method employed for calculating alkane–water partition coefficients of highly insoluble prostaglandin esters will be described).

Table III gives the alkane solubilities of the C_1-esters of prostaglandins E_2 and $F_{2\alpha}$ and the corresponding acetates. Plots of log alkane solubility in the prostaglandin series *versus* log alkane solubilities of the corresponding esters in the acetate series are shown in Figs. 3 and 4. The plots

are linear with slopes of ~1 (Fig. 3: slope = 0.89, r = 0.994; Fig. 4: slope = 0.96, r = 0.9967). The linear free energy correlations observed in the alkane solubilities are a direct consequence of the observed correlations in the aqueous solubilities since group contribution theory was employed in estimating the alkane–water partition coefficients used in calculating many of the alkane solubilities. Nevertheless, the exercise is useful because it enables one to separate structural effects on thermodynamic activity in the solid phase from structural effects on interactions in solution.

Some interesting observations can be made from Table III on the effect

	−0.85 (−0.71)	−0.05 (−0.20)
	−1.28 (−1.47)	−0.48 (−0.22)
	−2.2	−1.42
	−4.4	−3.6
	−5.2	−4.4
	−5.4	−4.6
	−5.4	−4.6
	−6.1	−5.3
	−6.8	−6.0

[a] Calculated values were obtained from:

log partition coefficient$_{\text{prostaglandin}}$  =

log partition coefficient$_{\text{prostaglandin}}$  + $(\pi_{alk})_X$

where $(\pi_{alk})_X$ values are listed in Table IV. [b] Experimental values are given in parentheses.

of molecular structure, particularly the incorporation of hydrogen-bonding substituents into the molecule, on the escaping tendency of drug from the solid phase. For example, a difference of over 3000-fold in the alkane solubility of *p*-acetylphenyl acetate compared to *p*-acetamidophenyl acetate shows the dramatic influence of a single hydrogen-bonding moiety on crystalline energy. This factor represents a difference of ~4.8 kcal in free energy, a difference that can be rationalized in terms of hydrogen-bonding differences in the crystals. Replacement of a terminal methyl group with a phenyl group (*p*-acetamidophenyl acetate *versus* *p*-benzamidophenyl acetate) has a small influence on alkane solubility, while addition of another acetamido substituent again lowers the solubility by the equivalent of 5.6 kcal in free energy.

Clustering of points is evident in Figs. 3 and 4. Points at high alkane solubilities represent compounds containing no hydrogen-bonding phenyl substituents, while addition of a single hydrogen-bonding group results in a second cluster of points 3–4 log units lower in solubility.

Component 2: Transfer of Drug from Inert Solvent to Water—Prediction of organic solvent–water partition coefficients from molecular structures is complicated by the present lack of understanding of solute–solvent interactions at the molecular level. Consequently, a semiempirical approach often is employed based on the group contribution concept (11).

Briefly, it is assumed that the free energy of the partitioning process

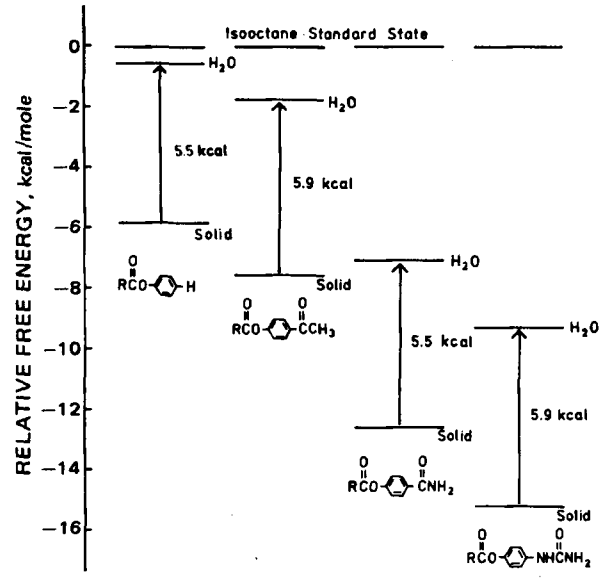

Figure 5—*Relative free energy diagram illustrating the effect of polar substituents on the thermodynamic activity of drug in the solid, on the free energy of transfer from alkane to water, and on aqueous solubility in which RCOO represents prostaglandin $F_{2\alpha}$.*

can be divided into independent contributions from the constituent groups in a molecule.

Alkane–Water Partitioning Behavior—Logs of the partition coefficients at 25° for acetates containing various substituted phenyl moieties are listed in Table IV. In most cases, these values were determined from solubility ratios, which are assumed to be reliable estimates of partition coefficients because isooctane and water are almost completely immiscible and because the solubilities usually were sufficiently low so that solute–solute interactions in solution were considered negligible.

Phenyl acetate was chosen as a reference compound for determining group contributions of various substituents to the free energy of transfer from water to isooctane. The standard free energy of transfer of a drug containing a substituent, X, from water to isooctane can be expressed as:

$$\Delta G^{\circ RX}_{H_2O\rightarrow alk} = -RT \ln PC_{RX} \qquad \text{(Eq. 1)}$$

where:

$$PC_{RX} = \frac{C_{alk}}{C_{H_2O}} \qquad \text{(Eq. 2)}$$

in which C is expressed in moles per liter.

The change in transfer free energy brought about by substitution is:

$$\Delta(\Delta G^{\circ}_{H_2O\rightarrow alk})_X = \Delta G^{\circ RX} - \Delta G^{\circ RH} = -RT \ln \frac{PC_{RX}}{PC_{RH}} \qquad \text{(Eq. 3)}$$

Values of $\Delta(\Delta G^{\circ}_{H_2O\rightarrow alk})_X$ for various substituents on the phenyl ring, derived from the acetate partition coefficients, also are listed in Table IV along with π_{alk} values that represent the quantity log PC_{RX}/PC_{RH}.

Partition coefficient data for the prostaglandin esters were generated from solubility ratios when possible or were estimated from group contributions. This calculation was done by adding the π_{alk} value for a phenyl substituent obtained from acetate partitioning data (Table IV) to the measured log of the partition coefficient of the unsubstituted phenyl ester of either prostaglandin E_2 or $F_{2\alpha}$ to obtain the log of the partition coefficient for the substituted phenyl prostaglandin ester. Calculated values of log partition coefficient for the substituted phenyl esters of prostaglandins $F_{2\alpha}$ and E_2 are shown in Table V (experimental values in parentheses).

Influence of Polar, Hydrogen-Bonding Substituents on Aqueous Solubility—Because of the large effect of polar groups on the partitioning behavior of a molecule, it occasionally is suggested that the introduction of polar groups into a molecule should increase aqueous solubility. The underlying assumption is that log solubility is inversely related to log partition coefficient, as has been shown for liquid solutes. However, the effect of polar groups capable of hydrogen bonding on the crystal lattice energies also must be considered for solids.

A diagram of relative free energy levels of solute in the solid phase, in

the aqueous solution standard state, and in the isooctane standard state (Fig. 5) illustrates the effect of polar groups in a series of prostaglandin $F_{2\alpha}$ esters. An alkane solution of drug at infinite dilution was chosen as the reference state according to the convention proposed previously (9, 10). Thus, the free energies of various derivatives in isooctane arbitrarily were set equal to zero so that relative energies in the solid phase and in water could be compared. Polar substituents dramatically lowered the energy level of a drug in the solid phase and in water relative to an alkane solution; but the free energy difference between solid and aqueous solution, which is reflected by aqueous solubility, remained similar upon addition of increasingly polar substituents.

The conclusion is that polar, hydrogen-bonding substituents may not result in increased aqueous solubility. Even though lipophilicity as measured by partition coefficients may be decreased drastically, the effect of polar groups on the thermodynamic activity of a drug in the solid may tend to offset the change in lipophilicity (Fig. 5). Both thermodynamic components of aqueous solubility must be considered in predicting aqueous solubility.

Preliminary Examination of Rabbit Conjunctival Mucins

VINCENT HON-LEUNG LEE * and JOSEPH R. ROBINSON ˣ

Received September 19, 1979, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication November 16, 1979. *Present address: School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

Abstract □ Conjunctival mucins from albino rabbits were fractionated using gel filtration and anion-exchange chromatography. Charge homogeneity of the various conjunctival mucin fractions was confirmed by polyacrylamide gel electrophoresis. The molecular weight characteristics of the isolated fractions varied with the analytical scheme employed. Two schemes yielded mucins with molecular weights of 10^4, 10^5, and 10^6. However, when anion-exchange chromatography was the first step in the fractionation scheme, the dominant mucin had a molecular weight of 1.7×10^5. In contrast, when gel filtration chromatography was the first step, the dominant mucin had a molecular weight of 5.7×10^4. It was postulated that during migration through the anion-exchange matrix, the low molecular weight conjunctival mucin underwent trimer formation. Comparison with the mucin fractions isolated from tear mucoid threads revealed that the scheme beginning with anion-exchange chromatography preserved the fractionation pattern seen in tear mucoid threads. This result implies that conjunctival mucins undergo an association prior to or after their entry into the tear film. The molecular event of interest in this process is self-association of the species with a molecular weight of 5.7×10^4, resulting in a trimer with a molecular weight of 1.7×10^5. This trimer appears to resist deaggregation on exposure to a medium of lesser ionic strength. Several explanations are offered for its formation as well as for its stability. The implication of multiple conjunctival (tear) mucins for tear film stability also is discussed.

Keyphrases □ Mucins—isolation from rabbit conjunctiva, fractionation by gel filtration and anion-exchange chromatography, determination of molecular weight, role in tear film stability □ Conjunctival mucins—isolation from rabbits, fractionation by gel filtration and anion-exchange chromatography, determination of molecular weight, role in tear film stability □ Ocular mucins—isolation from rabbit conjunctiva, fractionation by gel filtration and anion-exchange chromatography, determination of molecular weight, role in tear film stability

The strategic role assumed by conjunctival mucin in tear film stability has been recognized, but not understood, for many years. Alteration in either its chemical nature or quantity (probably both) has been implicated in keratoconjunctivitis sicca as well as other dry-eye syndromes (1–5), all of which are characterized by poor wetting of the corneal epithelium. It has been proposed that this fascinating substance derives its role from both the surface activity it is expected to exhibit at the air–tear and tear–corneal epithelium interfaces and the molecular events following its absorption at these two interfaces.

Principally because conjunctival mucins have never been isolated or identified, statements about their surface activity are based on experiments using bovine submaxillary mucin (6–9). In contrast, three tear mucins have been isolated (10), but the interrelationship between tear and conjunctival mucins is unknown. The tear mucins were shown to possess an amino acid and carbohydrate composition not shared by typical epithelial mucins (10, 11). Since the function it serves depends on its structure, considerable caution must be exercised in extrapolating the findings on surface activity of bovine submaxillary mucin to conjunctival and tear mucins. Successful isolation of conjunctival mucins, in reasonable quantity and purity, is important in understanding the mechanisms by which they confer stability to the tear film. This study is a first attempt in this direction; specifically, it concerns identifying conjunctival mucins present in a crude conjunctival extract.

The three tear mucins isolated by Iwata and Kabasawa (10) from tear mucoid threads on the conjunctival surface of albino rabbits possessed molecular weights of 4×10^5,

The strategic role assumed by conjunctival mucin in tear film stability has been recognized, but not understood, for many years. Alteration in either its chemical nature or quantity (probably both) has been implicated in keratoconjunctivitis sicca as well as other dry-eye syndromes (1–5), all of which are characterized by poor wetting of the corneal epithelium. It has been proposed that this fascinating substance derives its role from both the surface activity it is expected to exhibit at the air–tear and tear–corneal epithelium interfaces and the molecular events following its absorption at these two interfaces.

Principally because conjunctival mucins have never been isolated or identified, statements about their surface activity are based on experiments using bovine submaxillary mucin (6–9). In contrast, three tear mucins have been isolated (10), but the interrelationship between tear and conjunctival mucins is unknown. The tear mucins were shown to possess an amino acid and carbohydrate composition not shared by typical epithelial mucins (10, 11). Since the function it serves depends on its structure, considerable caution must be exercised in extrapolating the findings on surface activity of bovine submaxillary mucin to conjunctival and tear mucins. Successful isolation of conjunctival mucins, in reasonable quantity and purity, is important in understanding the mechanisms by which they confer stability to the tear film. This study is a first attempt in this direction; specifically, it concerns identifying conjunctival mucins present in a crude conjunctival extract.

The three tear mucins isolated by Iwata and Kabasawa (10) from tear mucoid threads on the conjunctival surface of albino rabbits possessed molecular weights of 4×10^5,

0022-3549/80/0400-0430$01.00/0

© 1980, American Pharmaceutical Association

5×10^4, and 1.4×10^4. Conspicuously absent was the mucin with a molecular weight of 10^6, a species commonly seen in epithelial mucins. However, this result probably is an artifact since the gel filtration medium employed, Sephadex G-150, does not fractionate proteins with molecular weights exceeding 4×10^5. Nevertheless, the isolation of multiple tear mucin fractions is intriguing because multiple fractions rarely have been isolated for simple proteins such as insulin and growth hormone. Moreover, since mucins in the precorneal area of the eye are derived from both the conjunctival (12) and lacrimal (13) glands and their composition varies with the source, it was of interest to see if the three tear mucin fractions were primarily of conjunctival origin. The results of the present study indicate that this is the case.

The three objectives of this study were: (*a*) to examine the type of mucins derived from the conjunctiva, as well as the interrelationship among them; (*b*) to learn how these mucins are related to those identified in the tear film; and (*c*) to gain further insight into tear film stability. The interrelationship between tear and conjunctival mucins will be reported later. The present paper concerns the interrelationship among conjunctival mucins and their probable roles in tear film stability.

EXPERIMENTAL

Materials—Male albino rabbits[1], 1.8–2.4 kg, were used.

The following chemicals and reagents were used as received: synthetic *N*-acetylneuraminic acid[2], 3,5-diaminobenzoic acid dihydrochloride[2], chromatographic gel[3], polyacrylamide gel[4], polyacrylamide gel basic buffer[5] (pH 8.9), protein assay kit[6], anion-exchange chromatographic gel[7], tracking dye solution[8] (acidic), trichloroacetic acid[9], Blue Dextran 2000[10], Sephadex G-25[10] (fine), rabbit albumin[11], γ-globulin[11], bovine submaxillary mucin[12] (type I), Coomassie brilliant blue G-250[12], and fumarase[13].

Analytical Methods—*Protein Assay*—In addition to its absorbance at 280 nm, A_{280}, the protein content of the column eluate was monitored using the protein assay kit. This assay is based on the differential color change of the dye in response to various protein concentrations (14). It was performed following the procedure outlined by the manufacturer (15).

Fluorometric Assay for Sialic Acid—A fluorometric assay (16) that can detect as little as 0.2 ng of sialic acid was adopted; the more widely used thiobarbituric acid assay (17) was found to underestimate sialic acid levels as a result of sialic acid degradation following its liberation from mucins (11).

The procedure was conducted as follows. To 10 μl of a sample containing sialic acid in a 1-ml ampul[14] was added 500 μl of 0.005 *M* 3,5-diaminobenzoic acid dihydrochloride in 0.125 *N* HCl. The ampul was sealed and placed in an oven at 100° for 16 hr. After cooling to room temperature, the contents of the ampul were transferred to a 5-ml volumetric flask and brought to volume with 0.05 *N* HCl. The fluorescence intensity was measured in a fluorescence spectrophotometer[15] with the excitation wavelength set at 425.8 nm and the emission wavelength at 507.5 nm. A standard curve was established daily using freshly prepared *N*-acetylneuraminic acid solutions.

Collection of Rabbit Conjunctivas—Rabbits were sacrificed with a rapid intravenous injection of pentobarbital sodium into a marginal ear vein. The corneal and conjunctival surfaces were washed thoroughly with 0.9% NaCl solution and blotted dry with tissue. A single incision was made at the upper nasal palpebral conjunctiva and was continued clockwise along the lid margin and terminated at the bulbar conjunctiva around the limbus. Each conjunctiva was rinsed carefully in saline, frozen, and stored frozen at −20° for a period not to exceed 3 months. Approximately 98 g of conjunctivas was collected from 150 rabbits.

Extraction of Conjunctival Mucins—The entire extraction was conducted in a cold room maintained at 4°. Approximately 90 g of conjunctivas was suspended in 450 ml of 0.01 *M* ammonium acetate buffer at pH 7.2 and homogenized in a blender for 10 min. The mixture was stirred constantly for 24 hr in the presence of toluene.

The homogenate was filtered through four layers of adsorbent cheesecloth, prerinsed in the buffer, and centrifuged at 15,000 rpm for 30 min at 4° in a centrifuge[16]. The supernate was filtered first through filter paper[17] and then through a 0.65-μm filter[18], both of which were placed in a buchner funnel connected to a water aspirator. The filtrate was lyophilized in a freeze-drying apparatus[19] at 65 μm Hg and −55° for 48 hr. The residue, denoted as conjunctival crude extract, was a yellowish powder and was stored in a desiccator placed in a freezer at −20°. Lyophilization was assumed to cause no changes in the mucin; this assumption was shown to be the case with bovine submaxillary mucin (18).

The conjunctival crude extract represented about 2.5% of the initial conjunctival weight.

Anion-Exchange Chromatography of Conjunctival Crude Extract—Approximately 70 mg of conjunctival crude extract was dissolved in 2.5 ml of 0.01 *M* ammonium acetate buffer at pH 7.2. Two milliliters of the resulting solution was layered onto an anion-exchange column (1.5 × 20 cm) that had been preequilibrated for 16 hr at 4° with the buffer. After the entire sample entered the gel, the column was washed with two bed volumes (100 ml) of the buffer at a constant flow rate of 58.5 ml/hr controlled by a peristaltic pump. The column then was eluted at the same flow rate with a linear gradient consisting of 200 ml each of 0.1 and 1 *M* NaCl, both dissolved in 0.01 *M* ammonium acetate at pH 7.2. Fractions of 1.5 ml were collected. The content of every third tube was measured for its absorbance at 280 nm and for sialic acid, protein, and sodium chloride concentrations.

Finally, the contents of several tubes were pooled, followed by desalting on a column (5 × 60 cm) of Sephadex G-25 (fine). The column was eluted with double-distilled water at a constant flow rate of 150 ml/hr. Fractions of 18.5 ml were collected. The proteins emerged with the void volume (~30% of total bed volume), while the salt emerged with ~80% of the total bed volume. Fractions containing protein were lyophilized at −55° and 65 μm Hg for 48 hr.

The lyophilizate was reconstituted with 0.01 *M* ammonium acetate buffer at pH 7.2. The behavior of the proteins contained therein was studied next on a chromatographic gel filtration column.

Gel Filtration of Conjunctival Crude Extract—Sample preparation and layering onto a column (1.5 × 60 cm) of chromatographic gel were essentially the same as described for anion-exchange chromatography. The column was eluted at a constant flow rate of 8.8 ml/hr with the buffer. Fractions of 1.5 ml were collected. The contents of appropriate tubes were examined at 280 nm for their protein and sialic acid content. Based on the results of these assays, certain tubes were selected for polyacrylamide gel electrophoresis. The contents of several tubes were pooled and lyophilized, and selected fractions were chromatographed further on an anion-exchange column (1.5 × 30 cm).

Molecular Weight Estimation—The molecular weight of various mucin fractions was estimated by calibrating a gel filtration column in the manner described previously (19–23). This procedure has been employed to estimate the molecular weight of tear mucins (10); consequently, a meaningful molecular weight comparison can be made between conjunctival and tear mucins.

A gel chromatography column (1.5 × 60 cm) was calibrated using the following proteins (or protein mixture): bovine submaxillary mucin (2.26 mg/ml) and rabbit γ-globulin (8.76 mg/ml), rabbit serum albumin (5.0 mg/ml), fumarase (5.0 mg/ml), and Blue Dextran 2000 (2.62 mg/ml). All solutions were prepared in 0.01 *M* ammonium acetate buffer at pH 7.2. To the Blue Dextran 2000 solution was added also 0.1 *M* NaCl. Two milliliters of sample was layered onto the column, which then was eluted

with 0.01 *M* ammonium acetate buffer at pH 7.2 at a flow rate of 8.8 ml/hr. Fractions of 1.5 ml were collected, and the absorbance of every third tube was measured at 280 nm.

The position of the peak maximum in the elution diagram, *i.e.*, absorbance *versus* tube number, was taken as the elution volume, V_e. The correlation between molecular weight and elution behavior was analyzed by plotting K_{av} *versus* log molecular weight. The regression equation for the plot is:

$$K_{av} = 1.497 - 0.228 \log \text{molecular weight} \qquad \text{(Eq. 1)}$$

($r = -0.995$, $r^2 = 0.989$), where K_{av} is the partition coefficient of the solute between the liquid phase and the gel phase.

Polyacrylamide Gel Electrophoresis—Polyacrylamide gel electrophoresis was performed at 4° using precast 4, 7.5, and 12% polyacrylamide gels and basic buffer at pH 8.9. The sample solution was mixed with tracking dye solution in a ratio of ~3:1. Thirty microliters of the resulting mixture was layered onto a gel using a microbiopet[6].

At the end of electrophoresis, each gel was carried through three steps leading to the visualization of protein bands:

1. The proteins were fixed onto the gel by immersing the gel for 90 min in a mixture of 12.5% trichloroacetic acid and 25% isopropanol.
2. The precipitated proteins were stained by immersing the gel for 6 hr in a Coomassie brilliant blue G-250 solution (the staining solution was 0.05% dye, 10% isopropanol, and 10% acetic acid).
3. The excess stain on the gel was removed in a diffusion destainer[20] filled with a mixture of 7% acetic acid and 25% ethanol.

The procedure outlined by Wardi and Michos (24) for staining glycoproteins on polyacrylamide gels was unsatisfactory for conjunctival mucins, probably due to the low sialic acid content of the glycoproteins. No further attempt was made to improve visualization of these glycoproteins on the gels.

RESULTS

Fractionation Procedure A—Scheme I summarizes the results obtained by chromatographing the crude conjunctival extract. The results were displayed as the ratio of area under each elution peak in a chromatogram (*AUC*) relative to an appropriately chosen reference peak; as the sialic acid content, in both amount and percent, corresponding to each peak; and, where appropriate, as the molecular weight corresponding to each peak as well as the number of protein bands yielded by each peak upon performing polyacrylamide gel electrophoresis.

Thus, anion-exchange chromatography on the crude extract yielded seven fractions, in close agreement with the seven bands observed in electrophoresis of the extract on a 12% polyacrylamide gel (Gel C in Fig. 1). The chromatogram displayed in Fig. 2 indicates that three peaks (A–C) emerged with the wash and that four peaks (D–G) emerged with the gradient. The major peaks were F and G, hereafter referred to as

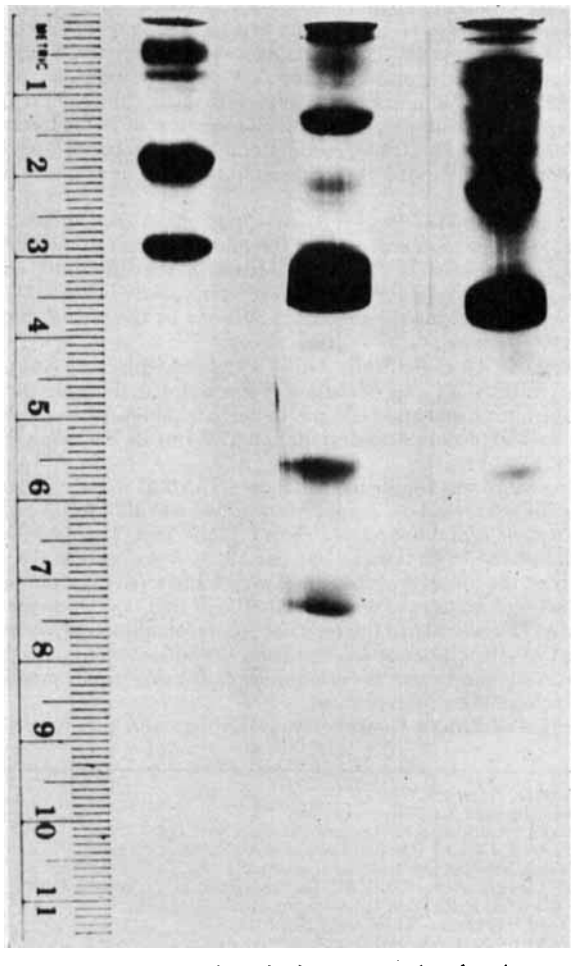

Figure 1—*Polyacrylamide gel electrophoresis of anion-exchange chromatography gradient Fractions 2 (G2) and 3 (G3) using 12% polyacrylamide gels. Key: Gel A, anion-exchange gel G2; Gel B, anion-exchange gel G3; and Gel C, conjunctival crude extract.*

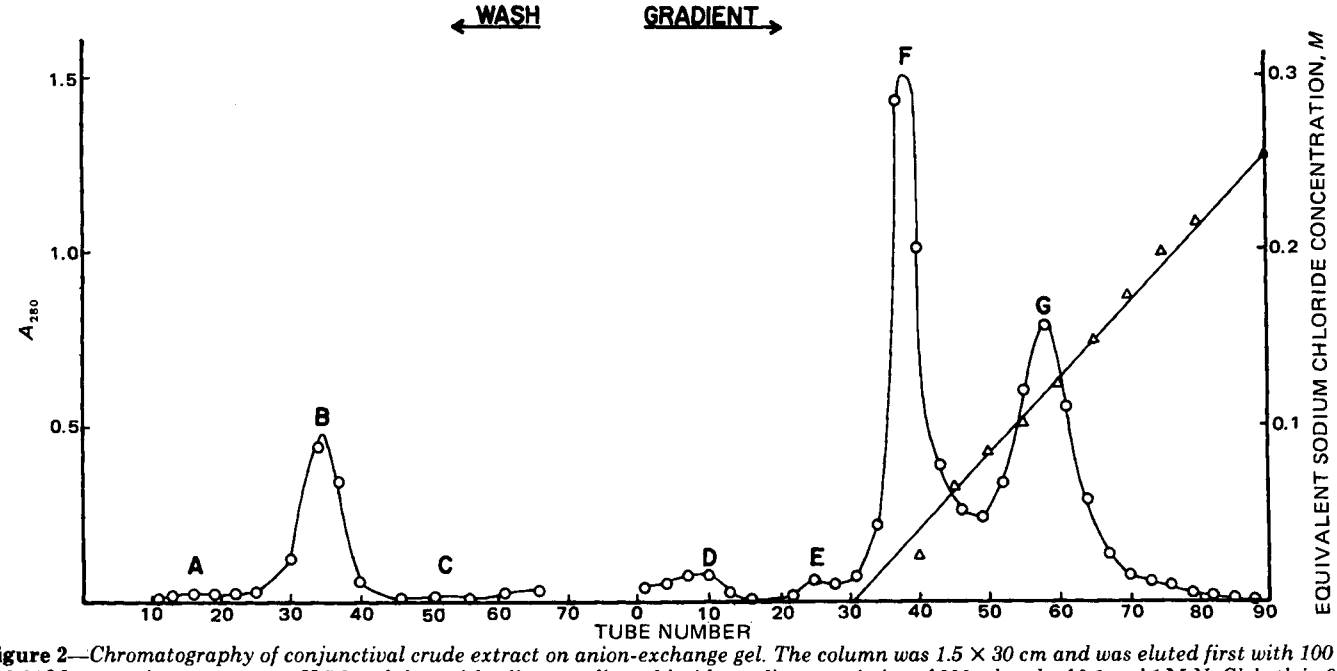

Figure 2—*Chromatography of conjunctival crude extract on anion-exchange gel. The column was 1.5 × 30 cm and was eluted first with 100 ml of 0.01* M *ammonium acetate at pH 7.2 and then with a linear sodium chloride gradient consisting of 200 ml each of 0.1 and 1* M *NaCl, both in 0.01* M *ammonium acetate at pH 7.2. The flow rate was 58.50 ml/hr. Fraction volumes were 1.5 ml.*

Fractions G2 and G3, respectively (Scheme I). Fraction G2 was eluted at 0.032 *M* NaCl, while Fraction G3 was eluted at 0.118 *M* NaCl. In contrast, under essentially the same chromatographic conditions, bovine submaxillary mucin eluted as a single peak at 0.146 *M* NaCl (Fig. 3).

The electrophoretic patterns due to Fractions G2 and G3 (Gels A and B) shown in Fig. 1 revealed that nearly all of the bands seen in the conjunctival crude extract (Gel C) represented these two fractions. At least three bands (0, 2, and 3 cm from the origin) due to Fractions G2 and G3 overlapped, reflecting, in part, the slight overlap between Fractions G2 and G3 as they were eluted from the anion-exchange column. Nevertheless, both fractions contained characteristic mucins. They were the two bands at 0.5 and 0.8 cm on Gel A, corresponding to Fraction G2, and the four bands at 1.3, 4, 5.5, and 7.4 cm on Gel B, corresponding to Fraction G3. The last three bands due to Fraction G3 were of higher charge density than the two bands due to Fraction G2. Together with the abundance of the band at 3 cm, this finding was consistent with the elution of Fraction G3 at a higher sodium chloride concentration. The major protein also was different for Fractions G2 and G3. In Fraction G2, the major protein migrated 1.8 cm into the gel; in Fraction G3, it migrated 3 cm into the gel.

The similarity in composition between Fractions G2 and G3 is apparent not only in their electrophoretic patterns (Fig. 4) but also in their chromatograms (Figs. 5 and 6). Moreover, according to Scheme I, both Fractions G2 and G3 contained mucins with molecular weights on the order of 10^5 and 10^6. The major fraction contained the lower molecular weight species; the area of the peak, B, containing it was approximately 15 times that of the peak containing the 10^6 species.

Two conclusions can be drawn from these observations. First, the elution of these two species, with a 10-fold difference in molecular weight, must be inversely related to their charge density since they eluted at the same sodium chloride concentration. Second, each species of a given molecular weight existed in two charge densities since it was eluted at sodium chloride concentrations differing by a factor of approximately four, *i.e.*, 0.032 and 0.118 *M*. These results indicate that four mucins, in suitable combinations of molecular weight and charge density, were present in Fractions G2 and G3.

In summary, Procedure A yielded mucins with molecular weights on the order of 10^4 (Fraction G2) and 10^5 and 10^6 (both from Fractions G2 and G3). Unlike other epithelial mucins, the major mucin was not the one with a molecular weight of 10^6. Rather, it was the one with a molecular weight of 10^5. This pattern is remarkedly consistent with that seen in tear mucins. The 10^5 and 10^6 species are heterogeneous with respect to charge.

Fractionation Procedure B—Scheme II summarizes the results obtained by chromatographing the conjunctival crude extract according to Procedure B.

As shown in Scheme II and Fig. 7, chromatography of the conjunctival crude extract on chromatographic gel yielded five peaks. Peak E did not contain proteins, as indicated by the protein assay. The molecular weight of the species contained in peak D was too low to be a protein. Therefore, proteins were detected only in peaks A, B, and C; this conclusion was confirmed by polyacrylamide gel electrophoresis (Fig. 8). Since all of the proteins reacted positively to the sialic acid assay, they were glycoproteins.

As with Procedure A, Procedure B did not yield the mucin with a molecular weight of ~10^6 as the major mucin. Unlike Procedure A, Procedure B yielded a major mucin with a molecular weight of ~10^4, not ~10^5. Clearly, the pattern seen in tear mucins was not preserved. The implication of this finding was elaborated upon previously. Briefly, trimer formation probably occurred as the mucin with a molecular weight of ~10^4 migrated through the anion-exchange matrix and a similar matrix may exist on the conjunctival surface.

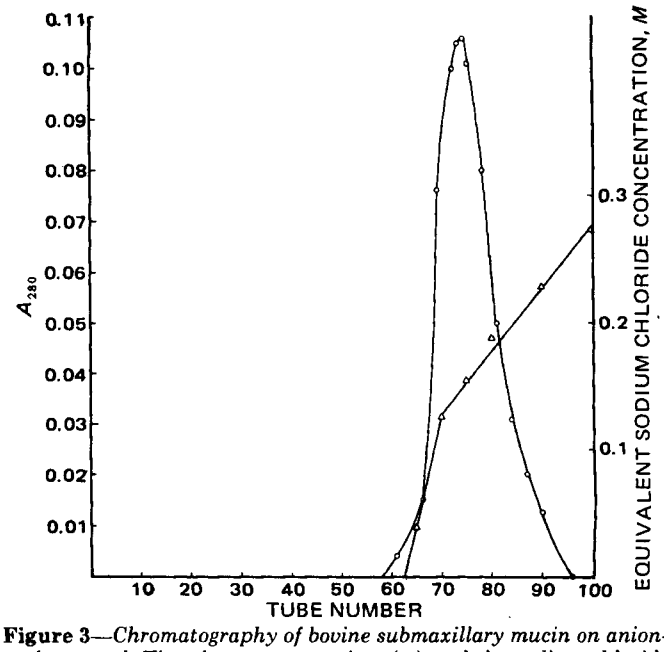

Figure 3—*Chromatography of bovine submaxillary mucin on anion-exchange gel. The plots represent* A_{280} (○) *and the sodium chloride concentration* (△). *The column was 1.5 × 30 cm and was eluted at 4° with a linear sodium chloride gradient at a flow rate of 58.5 ml/hr. Figure 4—*Comparison of electrophoretic patterns of anion-exchange gel-chromatographic gel Fraction G2, peak B (Gel A); anion-exchange gel-chromatographic gel Fraction G3, peak B (Gel B); and chromatographic gel peak C (Gel C) on 12% polyacrylamide gels.*

The fact that the species with molecular weights of $\sim 10^4$ and $\sim 10^5$ were heterogeneous with respect to charge is evident in the electrophoretic patterns (Fig. 8) and the anion-exchange chromatograms (Figs. 9 and 10). The absence of multiple bands in the gel (A) layered with the 10^6 species should be expected from its inability to enter the gel. In contrast, anion-exchange chromatography resolved this species into three fractions, which eluted at 0.1, 0.105, and 0.135 *M* NaCl (Fig. 9). Similarly, four fractions were resolved for the mucins with a molecular weight of $\sim 10^4$. They eluted at 0, 0.02, 0.1, and 0.154 *M* NaCl (Fig. 10).

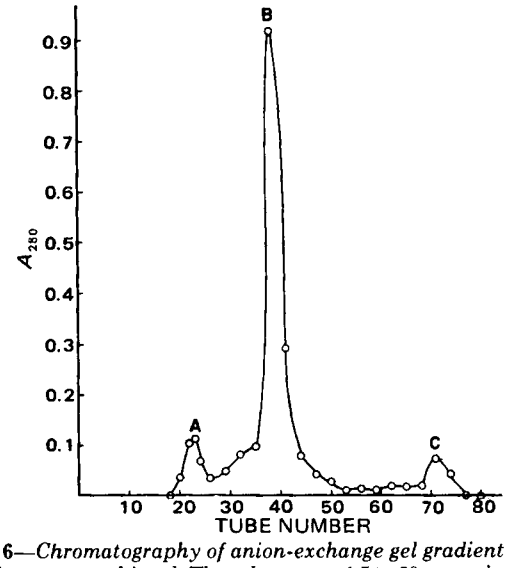

Figure 6—*Chromatography of anion-exchange gel gradient Fraction G3 on chromatographic gel. The column was 1.5 × 60 cm and was eluted with a flow rate of 8.8 ml/hr. Fraction volumes were 1.5 ml.*

DISCUSSION

This investigation showed that multiple conjunctival mucins exist, each differing in molecular weight and charge density. This finding is in accord with the isolation of multiple tear mucins in the precorneal area by Iwata and Kabasawa (10). There is evidence that the high molecular weight conjunctival mucins are aggregates of some monomer unit, and studies are underway to elucidate the mechanisms governing self-association and the factors contributing to stability of the resulting aggregates.

The remainder of this report will be devoted to an evaluation of the mucin extraction procedure, the conjunctival mucin fractionation schemes, postulated mechanisms of conjunctival mucin trimer formation, and the physiological significance of multiple conjunctival mucins in tear film stability.

Extraction of Mucin from Rabbit Conjunctivas—A caution exercised in this research was to isolate mucins from conjunctivas free from those in the precorneal area. To this end, each conjunctiva was rinsed with copious quantities of physiological saline following surgical removal from the eye. This rinsing should rid the surface of most of the adherent mucin and tear proteins since mucin was reported to be removed readily during increased tear secretion (25) and upon touching the conjunctival surface with a filter[18] (26, 27).

Another caution exercised in this research was to minimize denatur-

ation of conjunctival mucins during isolation. Gross fractionation of proteins from nonproteinaceous material by ammonium sulfate and ethanol precipitation is a step used in the fractionation schemes for many proteins (28). Such a treatment, while considered to be mild for most proteins, caused degradation of bovine and porcine submaxillary mucins (29–31). Because of this concern, the conjunctival crude extract was fractionated using chromatography as the first step.

In addition, since the slow process of denaturation would be delayed almost indefinitely if the temperature is low enough (32), all operations from tissue homogenization to chromatographic elution were conducted at 4° in a cold room. Similarly, to optimize stability of the glycoproteins on storage, the conjunctiva was frozen immediately following its removal at the temperature of a dry ice–acetone mixture. Thus, the ongoing glycoprotein synthesis is arrested and, depending on their quantities, such proteins may appear as mucin fractions when the crude extract is chromatographed. Similarly, unless they are membrane bound, the enzymes responsible for the biosynthesis (and, perhaps, degradation) of glycoproteins may be isolated. Neither possibility was vigorously investigated in this work.

An assumption made in this study was that little or none of the glycoproteins found in membranes (33) was isolated. Isolation of membrane glycoproteins often requires treatment of the cells with enzymes such as trypsin (34, 35) or chemicals such as lithium diiodosalicylate, phenol, aqueous pyridine, and sodium dodecylsulfate (36, 37). Since none of these agents was employed in the present study, the assumption seemed reasonable.

Influence of Fractionation Procedure on Conjunctival Mucin Trimer Formation—Two major findings emerged from fractionation of conjunctival mucins by Procedures A and B. First, both procedures yielded multiple mucin fractions. This finding agrees with the observation that mucins, unlike simple proteins, are polydisperse and microheterogeneous (38) and tend to yield several fractions during chromatographic separation. In general, the number of mucin fractions for a given mucin ranges from two to five; they differ primarily in their threonine, serine, sialic acid, and carbohydrate content as well as on their molecular weights (11). Conjunctival mucins with molecular weights on the order of 10^4, 10^5, and 10^6 were isolated in this work.

Second, the molecular weight of the dominant fraction was affected by the isolation procedure. When anion-exchange chromatography was the first step in fractionation, the dominant mucin possessed a molecular weight of 1.7×10^5. In contrast, when gel filtration was the first step, the dominant mucin possessed a lower molecular weight (5.7×10^4). The two fractions behaved similarly in polyacrylamide gel electrophoresis (Fig. 4). According to these electrophoretic patterns, the proteins concerned had the same charge density, suggesting that the mucin with a molecular weight of 5.7×10^4 underwent trimer formation when placed in an electrostatic field, which also was present at the positively charged surface of the anion-exchange gel. The trimer thus formed resisted deaggregation when it was exposed subsequently to the lesser charged media, Sephadex G-25 and the chromatographic gel. This finding indicates that simple electrostatic interaction was not the major stabilizing factor; short-range interactions such as hydrophobic bonding may play a more important role.

Conjunctival Mucin Trimer: Postulated Mechanisms of Its Formation and Stability—Self-association has been observed in over 300 proteins (39, 40) and is particularly prevalent in proteins with high molecular weights. According to Reithel (39), proteins with molecular weights exceeding 6.6×10^4 should be considered as aggregates. Consequently, it is reasonable to consider the conjunctival mucin with a molecular weight of 1.7×10^5 as an aggregate of a monomer with a molecular weight of 5.7×10^4, a value that is at the upper monomer molecular weight limit. The same probably is true of the conjunctival mucin with a molecular weight of 1.9×10^6. In proteins, dimers and tetramers are common; multimers with an odd number of monomers are rare. On this basis, the conjunctival mucin trimer may be an oddity.

Several glycoproteins exist in an associated form. They include canine tracheal mucin (41), several submaxillary mucins (41, 42), erythrocyte membrane glycoprotein (43, 44), and sucrase (invertase)–isomaltase, a membrane-bound glycoprotein complex located on the brush border of the small intestine (45–48). The majority of these glycoproteins resist deaggregation by urea, guanidine hydrochloride, and sodium dodecylsulfate, agents known to disrupt hydrogen and hydrophobic bonds. As indicated previously, the conjunctival mucin trimer appears to be stable to deaggregation in a medium of low ionic strength.

Figure 8—*Polyacrylamide gel electrophoresis on fractions obtained by chromatographing conjunctival crude extract on a chromatographic gel column (1.5 × 60 cm) using 12% polyacrylamide gels. Key: Gel A, peak A; Gel B, peak B; Gel C, peak C; Gel D, peak D; Gel E, peak E; and Gel F, conjunctival crude extract.*

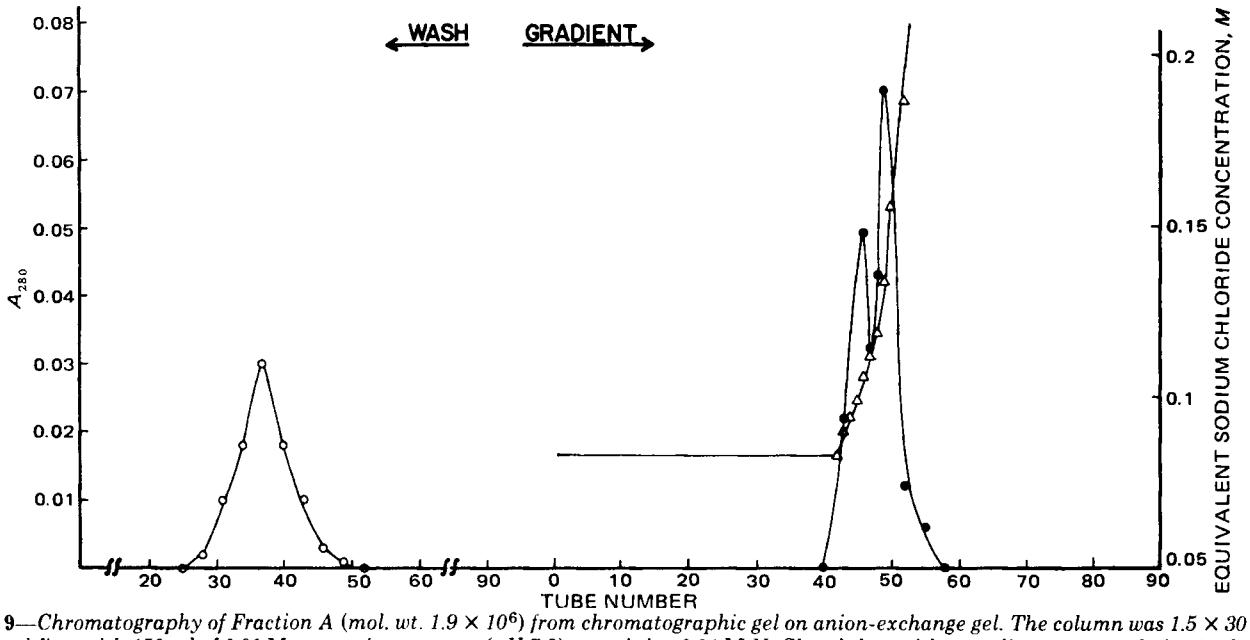

Figure 9—*Chromatography of Fraction A (mol. wt. 1.9 × 10^6) from chromatographic gel on anion-exchange gel. The column was 1.5 × 30 cm. It was eluted first with 150 ml of 0.01 M ammonium acetate (pH 7.2) containing 0.01 M NaCl and then with a gradient composed of 200 ml each of 0.1 and 1 M NaCl in the buffer. The flow rate was 62.4 ml/hr, and the fraction volumes were 1.6 ml.*

The mechanisms governing conjunctival mucin self-association, trimer formation in particular, have not been studied. However, two mechanisms can be postulated: the bulk mechanism and the surface mechanism. In the bulk mechanism, a monomer–trimer equilibrium already exists in the bulk. An ion-exchange gel promotes aggregation by preferentially adsorbing the trimers, thus effectively shifting the equilibrium in favor of the trimer.

At least three possibilities can be explored for the surface mechanism. A pH effect cannot be a possibility because the microenvironmental pH is higher than the bulk pH due to repulsion of hydrogen ions from the positively charged gel surface. The higher pH favors ionization of sialic, glutamic, and aspartic acids, and the attendant electrostatic repulsion among the molecules concerned hinders aggregation.

On the other hand, the ion-exchange gel may promote aggregation by providing the proper matrix to immobilize a glycoprotein molecule through electrostatic interaction between negative charges on the glycoprotein molecule and positive charges in the matrix.This interaction conceivably can initiate unfolding of the glycoprotein, thereby exposing its hydrophobic moieties and allowing hydrophobic interaction with another glycoprotein molecule to occur (Scheme III). Alternatively, as a glycoprotein binds to the ion-exchange gel, the Ca^{2+} ions known (49–51) to be associated with its sialic acid are displaced and become available for bridging the unbound sialic acids of two glycoprotein molecules (Scheme IV).

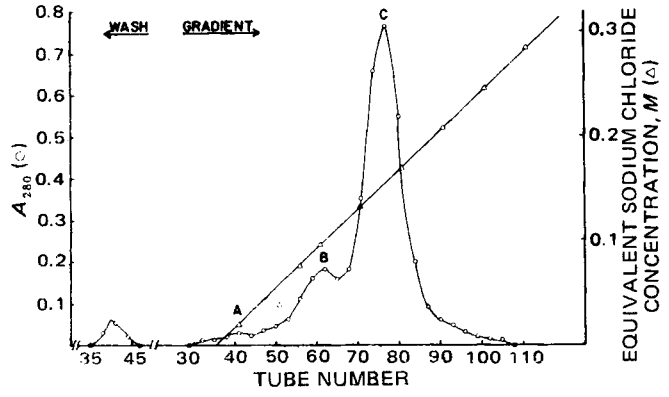

Figure 10—*Chromatography of Fraction C (mol. wt. 5.7 × 10^4) from chromatographic gel on anion-exchange gel. The column was 1.5 × 30 cm and was eluted with a 0.01 M ammonium acetate wash (100 ml) followed by a gradient composed of 200 ml each of 0.1 and 1 M NaCl in 0.01 M ammonium acetate buffer at pH 7.2. Fractions of 1.4 ml were collected. The flow rate was 56.0 ml/hr.*

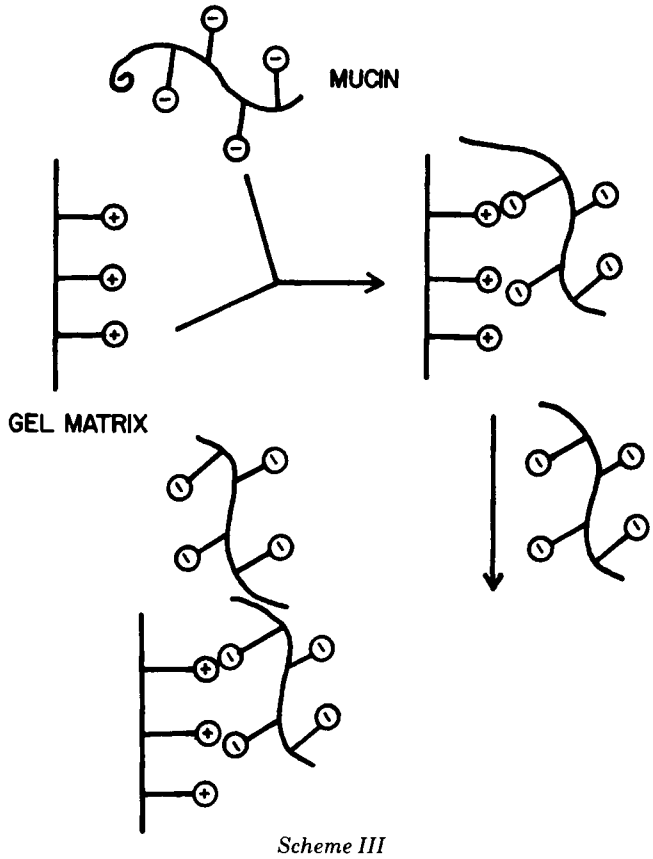
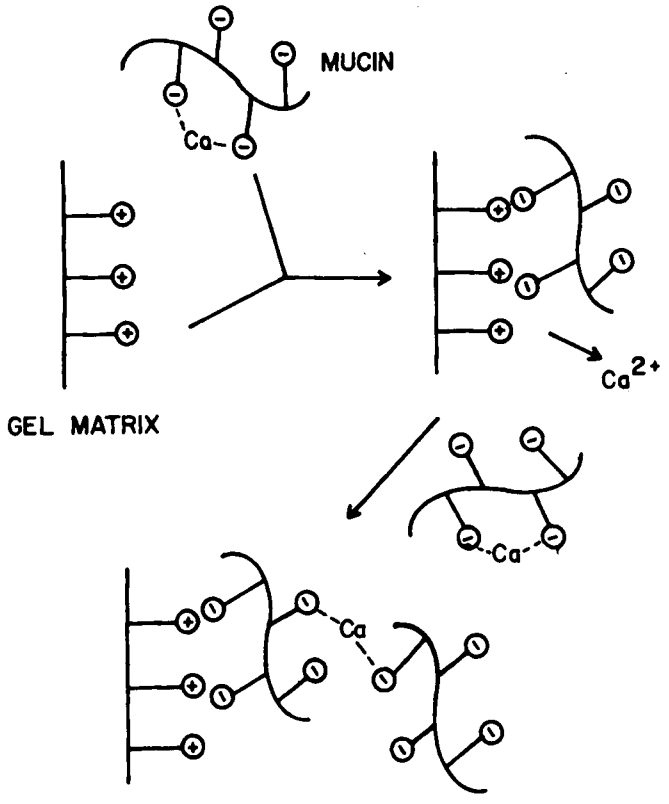
The third possibility centers on elution of bound glycoprotein from the ion-exchange gel. As the ionic strength of the eluting buffer increases, the thickness of the electrical double layer about a glycoprotein molecule decreases. This effect allows two or more glycoprotein molecules to approach each other, thus favoring aggregation (Scheme V). However, in light of the stability of the aggregate in a medium whose ionic strength is 10 times less, this mechanism appears unlikely.

Like the mechanisms governing its formation, the apparent stability of the resulting aggregate has not been studied. Hill *et al.* (52) studied the aggregation of ovine submaxillary mucins and its desialylated (asialomucin) and deglycosylated (apomucin) variants. They found that the



Scheme III



Scheme IV

apomucin did not aggregate whereas the asialomucin and parent mucin did, indicating that the carbohydrate portion of the molecule, with many hydrogen bonding sites, was necessary for aggregation.

Physiological Significance of Multiple Conjunctival Mucins in Tear Film Stability—A mucin layer adhering to the corneal surface has been considered an integral tear film component (53) since the tear film structure was proposed by Wolff (54) in 1946. The corneal epithelium is an intrinsically hydrophobic, low-energy surface, and a mucin layer at its surface generally is accepted as necessary to achieve complete wetting by tears. In fact, Mishima (55), as early as 1965, demonstrated that wiping the corneal surface rendered it unwettable by tears. This finding was confirmed subsequently by the *in vitro* experiments of Lemp *et al.* (8). Since then, the surface activity that mucin is expected to exhibit at the tear–corneal epithelium interface and, to a lesser extent, at the tear–lipid interface has captured the attention of researchers. To date, the mystery surrounding the driving force for tear film stability remains far from solved.

The principal reasons underlying this dilemma are the lack of information about the chemical nature of conjunctival mucins and the precise mechanisms by which they exercise their roles. Understanding the mechanisms by which each conjunctival mucin exercises its roles requires knowledge of factors contributing to thin film stability (or rupture).

Several factors contribute to rupture of thin liquid films (56). They include dissolution of the film liquid into the adjoining bulk phase, *e.g.*, evaporation, drainage of interlamellar liquid, gravitational convection, and marginal regeneration at the film borders. Although these factors originally were proposed for films that are at most 0.1 μm thick, they should also hold for a tear film that is 10 times thicker. Of course, some factors such as evaporation and drainage may predispose the tear film to rupture more readily than others.

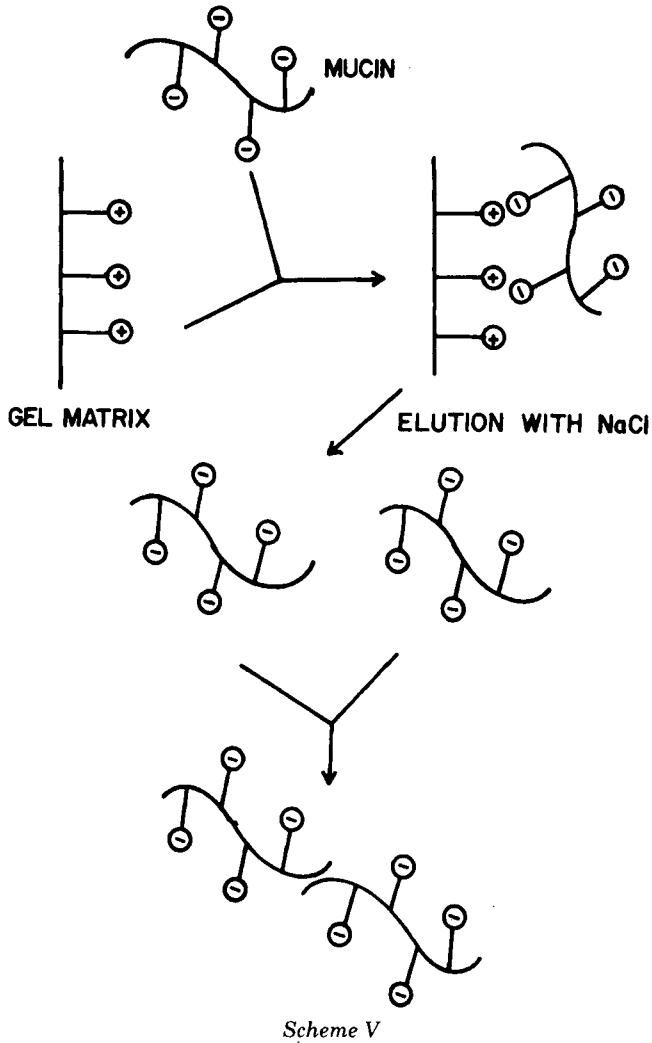
Thus, conjunctival mucin can stabilize the tear film in several ways. For instance, it may interact with the meibomian lipids, resulting in a mixed film that is surface rheologically stable. This film, when coupled with another surface rheologically stable layer at the corneal epithelial surface, can resist drainage. Drainage also can be reduced by increased bulk viscosity due to mucin. On the other hand, the evaporation tendency of the tear may be diminished due to the mixed mucin–lipid film and the diffusional barrier secondary to hydration of mucin in the bulk. Additionally, the shape and net charge of the mucin molecule can affect tear film stability through their influence on the surface activity, hydration, and surface and bulk viscosity of the mucin. It is clear that the surface activity of the mucin is just one of the many elements contributing to tear film stability.

It is useful to speculate about the functions performed by each conjunctival mucin. There are at least three conjunctival mucins with molecular weights of 1.9×10^6, 1.7×10^5, and 5.7×10^4. It is reasonable to expect each conjunctival mucin to possess a characteristic shape, degree of hydration, solubility, and surface activity, although each mucin has not been studied with regard to each property. Thus, the mucin with a molecular weight of 5.7×10^4, being a monomer and like other epithelial mucins, may have clearly delineated hydrophobic and hydrophilic regions and, therefore, may be well suited to adsorb at the superficial meibomian lipid layer as well as at the corneal epithelial surface.

The trimer, with its hydrophobic regions being buried by the prominent oligosaccharide mantle, may be the most soluble mucin despite its molecular weight. This characteristic helps to retain water of hydration, thus establishing a diffusional barrier to tear evaporation and eventually stabilizing the tear film. The trimer may be the least surface-active mucin and may interact minimally with either the air–tear or tear–cornea interface.

As the molecular weight exceeds 1.7×10^5, aqueous solubility diminishes, meaning that the mucin with a molecular weight of 1.9×10^6 prefers the interface to the bulk. Due to its molecular inflexibility compared to the mucin monomer, it is unlikely to be the species forming the monolayer at the corneal surface. However, it may exercise an important role in multilayer formation because less of it is necessary to achieve extensive surface coverage. Multilayer formation by the high molecular weight mucin at the corneal surface is roughly equivalent to viscoelastic film formation at the surface. This result not only allows lubrication of the surface but also hinders drainage of the liquid film.

This discussion implies that tear film stability hinges on an intricate balance among various conjunctival mucins. Therefore, a strategy to control dry-eye syndromes must involve selection of a polymer that behaves similarly to conjunctival mucins, *i.e.*, one that has the ability to self-associate to yield various fractions in the proper proportion and with the proper degree of hydration and affinity for interfaces. Selection of



Scheme V

the proper polymer alone may not be sufficient; it may be necessary to fabricate it into a unit possessing anion-exchange properties.

SUMMARY

Several mucins have been isolated from the albino rabbit conjunctiva. The preponderance of each mucin depends on whether gel filtration or anion-exchange chromatography is the first step in fractionation. As reported previously, the conjunctival mucins bear a closer resemblance to the tear mucins in their molecular weights when anion-exchange chromatography is the first step. The discrepancy centers on the anion-exchange fraction with a molecular weight of 1.7×10^5 and the gel filtration fraction with a molecular weight of 5.7×10^4. It is postulated that self-association (trimer formation) induced by the microenvironment of the ion-exchange gel occurs. It is postulated also that the same sequence of events exists during transit of conjunctival mucin from the goblet cell to the precorneal area of the eye. The resulting scenario is one in which the mucin with a molecular weight of 1.7×10^5 is a major tear mucin component.

The physiological advantage of having multiple rather than single fractions in the precorneal area has yet to be elucidated. Nevertheless, it seems reasonable to expect each mucin to perform a specific role in tear film stability. An evaluation of each conjunctival mucin with regard to its amino acid and carbohydrate composition, hydration, shape, and structure is desirable. Factors conferring stability to the mucin possessing a molecular weight of 1.7×10^5, a trimer of the one with a molecular weight of 5.7×10^4, should be identified. Studies are underway in these laboratories to investigate trimer formation and stability.

Measurement of Film-Coating Adhesiveness

RAYMOND M. FUNG * **and EUGENE L. PARROTT** ˣ

Received June 11, 1979, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication November 9, 1979. *Present address: Hong Kong.

Abstract □ A modified balance was used to measure the adhesive force between the film coating and the tablet surface of 10 commercial film-coated tablets. The adhesiveness or force required to remove the film coating from a unit area of tablet surface ranged from 1.06 to 4.67 × 10^4 Nm^{-2}. Measurement of at least eight film coatings from the sides of four tablets was calculated to be required to obtain a result with 95% confidence. The method also was useful in studying the influence of solvents and humidity on bonding of the film coating to the tablet.

Keyphrases □ Adhesiveness—commercial film-coated tablets, measurement of force between film coating and tablet surface, effect of solvents and humidity on bonding of film to tablet surface □ Tablets—commercial film-coated preparations, measurement of adhesion of film coating to tablet surface, effect of solvents and humidity on bonding of film to tablet surface □ Film-coated tablets—measurement of adhesion of film coating to tablet surface, effect of solvents and humidity on bonding of film to tablet surface

Although film coating has been used in pharmacy for over 25 years, limited research has been conducted on the measurement of the adhesive force between the film coat and the tablet surface. The first method suggested for studying the adhesion of a film coating to a film-coated tablet was a peel test in which a section of the film coating was peeled from the tablet by a tensile tester (1, 2). To overcome the deficiencies of the peel test, an instrument was designed for removing the film normal to the interface between the film coating and the tablet surface (3, 4). Examination of the tablet and the film after removal showed that a rupture occurred at the boundary between the film surface and the tablet surface (5).

In the last 15 years, there has been an emphasis on quality assurance, increased testing, and stringent specifications for pharmaceuticals. Although coated tablets are evaluated in terms of exposure to moisture and chipping of the coating during handling, no test is used to express quantitatively the adhesiveness of a coating to a tablet. A method for measuring the adhesiveness would be useful in developmental work to evaluate tablet excipients (6), solvents (1), polymeric coating materials, humidity effects, formulations, and processes; it also would be useful in quality control to ensure uniformity of application.

This report demonstrates the feasibility of measuring the force required to remove a film coating from a film-coated tablet and explores the range of adhesiveness that has been acceptable on marketed film-coated tablets. The usefulness of the adhesive force measurement in determining solvent and humidity effects on adhesiveness also is demonstrated.

EXPERIMENTAL

Instrumentation—An analytical balance[1] was modified by replacing the left pan and pan support with a metal ring attached by a nylon cord. The coated tablet was attached to the metal ring by a hook with a 35-mm shaft, which was soldered at a right angle to an 18-mm circular stainless steel plate. A backing cut from a rubber stopper was carved on one side to fit any curvature of the tablet and was attached by double-sided adhesive tape[2] to the circular plate. Preliminary work showed that a backing was required to ensure even compressive force over the entire surface of the tablet when the adhesive tape was applied to the coated tablet. Another piece of double-sided adhesive tape was applied to the second surface of the backing.

The coated tablet was positioned carefully and pressed firmly onto the adhesive tape attaching it to the assembly (Fig. 1). The assembly holding the coated tablet was hooked onto the metal ring and nylon cord attached to the left arm, and the balance was balanced by counterweights. The tablet then was clamped on its edge into a fixed position during the measurement using two sets of screws attached to a heavy metal base. The weight applied to the right pan was increased until the film coating separated from the tablet.

In preparation for measurement, the coating on the edge of the tablet was removed with a razor blade to ensure that the force was used to remove only the film coating from the upper tablet surface and to eliminate any coating effect at the tablet edge.

The dimensions of each tablet and the film-coating thickness were measured by a micrometer[3]. For round, flat tablets, the surface area is πr^2. When the same relationship is used to estimate the surface area of tablets prepared with standard concave punches, an error of ~5% is introduced (4).

Humidity—Relative humidities (RH) of 0, 20, 45, 70, and 90% were obtained using various concentrations of sulfuric acid and water (7). Tablets of each commercial product were placed in aluminum cups and were kept at each of the five humidities for 2 weeks at room temperature. The adhesive force was measured immediately after removal from the humidity chamber.

Preparation of Film-Coated Tablets—Tablets with a hardness of 8 ± 1 kg were prepared in batches of 20,000 using a standard concave 11.11-mm punch and die set in a single-punch tablet machine[4]. Each tablet contained 10 mg of FD&C Red No. 3, 380 mg of dicalcium phosphate[5], 20 mg of cornstarch, 85 mg of microcrystalline cellulose[6], and 5 mg of magnesium stearate.

Approximately 2000 tablets were coated in a 20-cm coating pan that was rotating at 25 rpm. With the organic solvent systems, six applications of 25, 20, 15, 12, 8, and 5 ml of coating solution were applied, with drying between each application. The aqueous solution was applied in eight applications of 4 ml each. The coating solution contained 4.9% (w/v) hydroxypropylcellulose[7], 1.0% (w/v) propylene glycol 4000, and the solvent system to 100 ml. The solvent systems were methylene chloride–methanol (9:1), 95% ethanol, acetone–water (9:1), chloroform, and distilled water.

RESULTS AND DISCUSSION

Ten commercial film-coated tablets of various shapes and sizes were selected (Table I). With the modified balance, the intact film coating was pulled from these tablets without tearing or rending. Close examination showed that only traces of the substrate were pulled from the tablet surface with the film coating and that a rupture occurred at the interface between the film coating and the tablet as reported previously (5). The integrity of a removed film coating was not affected by the lettering indentations on the surfaces of Products D–G and J.

Adhesive force is the force required to pull a film coating from the tablet surface. Adhesiveness may be defined as the force required to remove the film coating from a unit area of the tablet surface.

The adhesive force was measured on both sides of 10 tablets of each product. For all tablets except Product J, there was no significant difference in the adhesive force measured on either tablet surface (Table I). Thus, there was no disturbance of the film coating on the opposite surface of the tablet when the adhesion of one side was measured (3).

Product J was a double-layered tablet with a white side and a colored side. Because the substrate was different on the two sides, the adhesive force would not necessarily be the same on each surface.

Since there was no difference in adhesive force on either side of the film-coated tablet, the adhesiveness was calculated using the average adhesive force of 20 film coatings. For the 10 products studied, adhesiveness ranged from 1.06 to 4.67 × 10^4 Nm^{-2}.

There presently is no standard for the adhesiveness of film coating. Because the adhesiveness of a coating reflects the bonding between the film coating and the substrate and the physical stability of the film-coated tablet, its evaluation is important in film-coating development and in product evaluation. Although the data were collected from commercial film-coated products of different formulations that probably were coated by more than a single process, they provide a range of values that describes the variation in coating adhesiveness of products that already were marketed and were regarded as acceptable from the viewpoint of processing, resistance to the environment, and handling.

In any test, the number of determinations must be decided to provide a statistically valid sample. To calculate the sample size, n, a tolerance interval containing a certain proportion, p, of the population must be developed. When both the population mean and the standard deviation are known, $\mu \pm k\sigma$ may be used as a tolerance level, where μ is the population mean, σ is the population standard deviation, and k is a constant.

When both the population mean and the standard deviation are unknown, the tolerance limits, which will include on the average a proportion, p, of the normal universe, are:

$$\bar{x} \pm t_{1-\alpha,n-1}\sqrt{\frac{n+1}{n}}S \qquad \text{(Eq. 1)}$$

where $\bar{x}$ is the mean of a sample of n observations, S is the sample standard deviation, and $t_{1-\alpha,n-1}$ is a Student t value for $n-1$ degrees of freedom that is exceeded in absolute value by the probability, α.

By equating the tolerance intervals, the minimum number of observations, n, needed to provide a significant result is obtained with:

$$K_{s,p} = t_{1-\alpha,n-1}\sqrt{\frac{n+1}{n}} \leq \frac{k\sigma}{S_{max}} \qquad \text{(Eq. 2)}$$

To determine the number of film-coated tablets needed, the adhesive force values of both sides of the tablet were averaged and the standard deviations were calculated (Table I). The estimated population mean of 313.6 ± 107.2 g was taken as the mean of the nine product means (Product J was excluded). A tolerance level of 313.6 ± 214.4 g was selected at which k equals 2.

The standard deviation, S_{max}, of Product D that had the highest value among the film-coated tablets was used. Thus:

$$K_{s,p} = t_{1-\alpha,n-1}\sqrt{\frac{n+1}{n}} \leq \frac{2 \times 107.2}{49.6} = 4.323 \qquad \text{(Eq. 3)}$$

The value of $K_{s,p}$, which relates sample size, n, and tolerance intervals, is obtained from the statistical table (8). For a 95% confidence limit, the minimum n that gives a $K_{s,p}$ value of ≤4.323 is 4. Thus, at least four film-coated tablets are required; the adhesive force is measured on their eight film coatings to give a statistically significant result with 95% confidence.

Influence of Humidity—The influence of humidity on the film-coating adhesiveness is shown in Table II. With Products E and F, there

Table II—Adhesiveness of Film-Coated Tablets at Various Relative Humidities

Product	Adhesiveness × 10^{-4}, Nm^{-2}: 0%	20%	45%	70%	90%
A	1.36	2.08	1.90	1.30	1.96

F	1.38	1.52	1.71	1.66	2.30

[a] Spongy and deformed.

Table III—Adhesiveness of Hydroxypropylcellulose Coatings Applied from Various Solvent Systems

Solvent System	Adhesive Force[a]: g	Adhesive Force[a]: N	Area, cm^2	Adhesiveness × 10^{-4}, Nm^{-2}
Methylene chloride–methanol (9:1)	295.0	2.89	0.97	2.98
Ethanol, 95%	237.0	2.32	0.97	2.39
Acetone–water (9:1)	199.5	1.96	0.97	2.02
Chloroform	142.5	1.40	0.97	1.44
Water	70.5	0.69	0.97	0.71

[a] Average obtained from 10 film-coated tablets.

[7] Klucel, Hercules, Wilmington, Del.

was a linear relationship with a slight increase in adhesiveness as the relative humidity was increased.

With Products A and C, the maximum value of adhesiveness occurred at ~30% RH. With Product A, a minimum value of adhesiveness was reached at 70% RH, and then the adhesiveness increased with a further increase in humidity. With Product C at >50% RH, the tablet and the coating became spongy and deformed so that measurements could not be made.

Since the coating material, solvent, coating process, and substrate were unknown, speculation on these differences serves no useful purpose; however, the results confirm the applicability of this method to the detection of changes occurring in a film-coated product.

Influence of Solvent—The solvent from which a film coating is applied may affect the adhesion of the film to the substrate (2). When hydroxypropylcellulose was applied from the five solvent systems shown in Table III, there was a twofold difference ($1.44–2.98 \times 10^4$ Nm^{-2}) in adhesiveness among the organic solvents. When hydroxypropylcellulose was applied from aqueous solution, the adhesiveness (0.71×10^4 Nm^{-2}) was one-fourth to one-half as great as that from the organic solvents.

Applications—The method may be used to evaluate the stability of a film-coated tablet to moisture and its physical stability during shipment. The method also may be used in product development to express quantitatively the bonding between the film coating and the tablet surface and to compare the effect of various solvents on the bonding.

Role of α- and β-Adrenergic Activation in Ventricular Fibrillation Death of Corticoid-Pretreated Rats

MARK GREEN ˣ, GIANCARLO GUIDERI, and DAVID LEHR

Received March 5, 1979, from the *Department of Pharmacology, New York Medical College, Valhalla, NY 10595.* Accepted for publication November 8, 1979.

Abstract □ Death in ventricular fibrillation was induced consistently in desoxycorticosterone acetate-pretreated rats by the β-adrenergic agonist isoproterenol but not by norepinephrine or epinephrine, both of which possess α- as well as β-adrenergic activity. Aminophylline, which enhances β-adrenergic activity, and phenoxybenzamine, an α-receptor blocking agent, were used to study the roles of α- and β-adrenergic stimulation in the production of ventricular fibrillation. With the addition of aminophylline, both norepinephrine and epinephrine produced death in ventricular fibrillation, and the existing cardiotoxicity of isoproterenol was potentiated. Similarly, in the presence of phenoxybenzamine, doses of norepinephrine and epinephrine that had been well tolerated became lethal. Interventions that favor β-adrenergic preponderance, either by enhancing β-effects or by blocking protective α-adrenergic activation, apparently increase the arrhythmogenic propensity of norepinephrine and epinephrine in steroid-pretreated rats. The similarity of some forms of stress to the experimental protocol of chronic steroid treatment followed by acute catecholamine exposure is discussed.

Keyphrases □ Ventricular fibrillation—role of α- and β-adrenergic activity, desoxycorticosterone acetate-pretreated rats □ Arrhythmias—catecholamine induced, effect of steroid pretreatment □ Aminophylline—effect on catecholamine-induced arrhythmias, steroid-pretreated rats □ Phenoxybenzamine—effect on catecholamine-induced arrhythmias, steroid-pretreated rats

Earlier studies in this laboratory showed that, following pretreatment of the albino rat with the steroid desoxycorticosterone acetate and saline as the drinking fluid, the administration of isoproterenol elicited severe cardiac arrhythmias at dose levels that otherwise are well tolerated (1, 2). The enhanced cardiotoxicity was reflected in a shift of the isoproterenol LD_{50} from 680 mg/kg (3) in untreated rats to 14.5 μg/kg in desoxycorticosterone acetate–saline-pretreated rats (4), a nearly 47,000-fold potentiation. The deaths produced by this drug–drug interaction usually occurred within 60 min and consistently were due to ventricular fibrillation, while the mortality observed in untreated rats developed over 24 hr and usually was attributable to acute heart failure, lung edema, and shock. Recent studies showed that prednisone, administered either subcutaneously or orally, also can sensitize the myocardium to the arrhythmogenic effect of isoproterenol (4). It has been suggested that this type of drug interaction may expose patients such as asthmatics, taking steroids and isoproterenol simultaneously, to potentially life-threatening cardiac arrhythmias (5).

The mechanism underlying this phenomenon is not well understood. Alterations in the myocardial electrolyte content may be a factor in the increased myocardial vulnerability to isoproterenol. Electrolyte changes such as those seen with this treatment (6) have been well documented as increasing the propensity of the heart to arrhythmias and ventricular fibrillation (7).

The ability of steroids to affect protein synthesis also might be important in the sensitization process. In preliminary studies, agents that inhibit protein synthesis blocked the steroid-induced myocardial sensitization to isoproterenol (8).

The present investigation was undertaken to determine: (*a*) whether norepinephrine and epinephrine, which are both α- and β-adrenergic agonists, exhibit enhanced arrhythmogenic activity following steroid pretreatment comparable to that observed with isoproterenol; and (*b*) whether aminophylline, an agent administered frequently

was a linear relationship with a slight increase in adhesiveness as the relative humidity was increased.

With Products A and C, the maximum value of adhesiveness occurred at ~30% RH. With Product A, a minimum value of adhesiveness was reached at 70% RH, and then the adhesiveness increased with a further increase in humidity. With Product C at >50% RH, the tablet and the coating became spongy and deformed so that measurements could not be made.

Since the coating material, solvent, coating process, and substrate were unknown, speculation on these differences serves no useful purpose; however, the results confirm the applicability of this method to the detection of changes occurring in a film-coated product.

Influence of Solvent—The solvent from which a film coating is applied may affect the adhesion of the film to the substrate (2). to asthmatics alone or with steroids and catecholamines, affects the existing interaction between corticoids and adrenergic agonists.

EXPERIMENTAL

Male albino rats, 250–300 g, were pretreated with desoxycorticosterone acetate (I) and saline as the drinking fluid. Pellets of the steroid were implanted subcutaneously and provided a constant source of I over the entire 21-day pretreatment period. The methodology for the manufacture and implantation of these pellets was described previously (4). Except where noted, all animals received steroid pretreatment.

All drug solutions were prepared in normal saline immediately prior to injection, except for phenoxybenzamine, which was suspended in a 10% acacia solution. All drugs were administered subcutaneously. Aminophylline, 75 mg/kg, was administered to rats 10 min prior to the catecholamines; chlorisondamine, 10 mg/kg, and phenoxybenzamine, 4 mg/kg, were given 30 min before the catecholamines.

Animals were observed for 90 min following catecholamine administration, and mortality rates were noted. ECG's were monitored from selected animals in each group to observe arrhythmias and to verify that mortality was due to ventricular fibrillation. The ECG was obtained by taping gold-plated disk electrodes to each limb of the rat, which otherwise was unrestrained.

The data obtained are reported as mortality rates. This selection was made because mortality rates reflect both the relative toxicities of the various agents and their relative arrhythmogenic activity since early death was attributable consistently to ventricular fibrillation.

A χ-square analysis was used to determine significant differences between treatment groups. Linear regression was used to determine the best-fit lines through data points on the graphs and to calculate LD_{50} values.

RESULTS

Effect of Norepinephrine and Epinephrine—Several doses of norepinephrine and epinephrine were administered to I–saline-pretreated rats (Table I). Within the dose ranges used, there was no mortality. The ECG's recorded from some rats did not show any of the tachyarrhythmias usually seen with isoproterenol in I–saline-pretreated rats. The largest dose of epinephrine did elicit bradyarrhythmias, which often are seen with the substantial elevations of blood pressure produced by this dose of epinephrine. However, these bradyarrhythmias are unlike the arrhythmias produced by isoproterenol.

[a] $p < 0.001$ compared to the group with aminophylline.

Cardiotoxicity of Aminophylline—The administration of aminophylline, 75 mg/kg, to I–saline-pretreated rats resulted in a 77% incidence of mortality (Table II). Animals in Group II were handled 10 min after aminophylline administration and showed a 67% incidence of mortality. Group III animals were given an injection of normal saline (0.1 ml/100 g) 10 min after aminophylline administration, resulting in a mortality rate of 82%.

Although a direct effect of aminophylline on the heart could not be ruled out, past experience showed that β-adrenergic stimulation was necessary to produce these deaths in ventricular fibrillation. To determine whether reflex release of endogenous catecholamines in response to the stress of handling, the injections, or simply the laboratory environment was the cause of these deaths, the ganglionic blocking agent chlorisondamine, 10 mg/kg, was used. Animals in Group IV received this agent 30 min prior to aminophylline admininstration (Table II). Ganglionic blockage was expected to prevent reflex release of catecholamines and to help determine whether the observed toxic effect was attributable to a direct action of aminophylline on the heart.

Following chlorisondamine administration, the combination of aminophylline followed by a saline injection produced only a 7% mortality rate, a highly significant decrease from the 82% seen without chlorisondamine. This result was compatible with the assumption that stress-induced reflex release of catecholamines, and not a direct effect of aminophylline, was responsible for the observed high death rate.

The importance of steroid pretreatment to this response is illustrated by the data for Group V (Table II). These animals were given aminophylline, 75 mg/kg, followed by a saline injection, but they did not receive I–saline pretreatment. Their mortality rate was significantly different ($p < 0.001$) from that of Group III, which had received steroid pretreatment in addition to the aminophylline and saline injections.

Toxicity of Catecholamines following Aminophylline—In this study and all following studies, chlorisondamine was used routinely together with aminophylline to block endogenous catecholamine release in order to evaluate the effect of aminophylline on administered catecholamines.

Table III shows the effect of aminophylline on norepinephrine and epinephrine toxicity. Unlike the initial study in which administration of the two agonists produced no fatality, dose-dependent increases in the mortality rate were observed with both catecholamines. Data for isoproterenol have been included to show its relative potency. The calculated LD_{50} values show that isoproterenol was nearly seven times more potent than epinephrine, which, in turn, was about four times more active than norepinephrine. The role of aminophylline in eliciting this cardiotoxicity is seen when comparing the effect of equal catecholamine doses in its presence and absence. Table III shows that in the presence of aminophylline, chlorisondamine, and I–saline, norepinephrine, 300 μg/kg, and epinephrine, 100 μg/kg, produced mortality rates of 90 and 87%, respectively. Without aminophylline, neither drug produced any mortality at equal dose levels.

Unlike norepinephrine and epinephrine, isoproterenol produced ventricular fibrillation deaths without aminophylline, but its effect with aminophylline was enhanced greatly (Fig. 1). The isoproterenol used in this study was the racemic hydrochloride salt, not the l-isomer of the

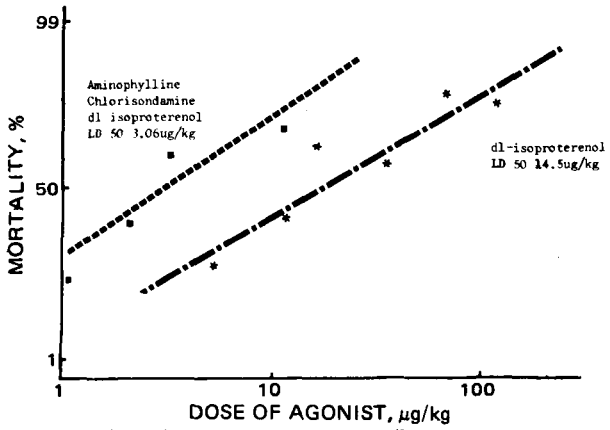

Figure 1—*Effect of aminophylline (75 mg/kg) on isoproterenol cardiotoxicity in desoxycorticosterone acetate-saline-pretreated rats after ganglionic blockage with chlorisondamine (10 mg/kg).*

bitartrate used in all other studies. The curve on the right represents isoproterenol toxicity following I–saline pretreatment alone. The addition of aminophylline (and chlorisondamine to prevent release of endogenous catecholamines) produced a marked shift to the left, decreasing the LD_{50} value from 14.5 to 3.06 μg/kg, a nearly fivefold potentiation (95% confidence limits of the potentiation were 2.48–9.4 times).

Effect of α-Blockage on Catecholamine Toxicity—While isoproterenol alone could produce ventricular fibrillation deaths in I–saline-pretreated rats, norepinephrine and epinephrine did so only in the presence of aminophylline. Phenoxybenzamine, an α-adrenergic blocking agent, was used to determine whether the potent α-agonist properties of norepinephrine and epinephrine were protecting the animals from fibrillation deaths (Fig. 2). Norepinephrine, 300 μg/kg, produced no deaths in I–saline-pretreated rats; but with the addition of the α-blocker, a 40% mortality rate was produced. Similarly, 100 μg of epinephrine/kg was nontoxic in steroid-pretreated rats; but in combination with phenoxybenzamine, it produced a 70% mortality rate.

Phenoxybenzamine itself did not show any acute toxicity in I–saline-pretreated rats. Ten animals injected with the drug followed by a saline injection did not exhibit any signs of the lethal interaction. Blockage of the α-adrenergic component of norepinephrine and epinephrine apparently allows the unopposed β-adrenergic activity to produce fibrillation deaths in these animals in a manner similar to that of the pure β-agonist isoproterenol.

Effect of Norepinephrine on Isoproterenol Cardiotoxicity—The interaction between α- and β-adrenergic stimulation was examined from a different perspective. In this study, a dose of *l*-isoproterenol, which produced a 75% mortality rate, was administered 10 min after 300 μg of norepinephrine/kg. As shown in Fig. 2, this dose of norepinephrine produced fibrillation deaths only if its α-adrenergic activity was blocked. Since the α-agonist component of norepinephrine prevented this catecholamine from inducing fibrillation deaths, it was expected that it also might attenuate the response of the pure β-agonist isoproterenol. This

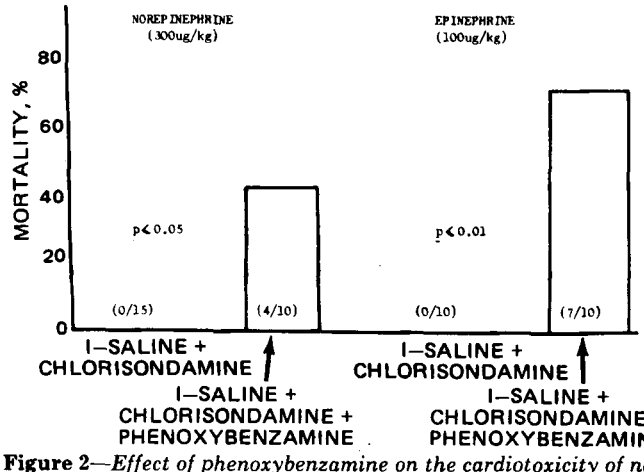

Figure 2—*Effect of phenoxybenzamine on the cardiotoxicity of norepinephrine and epinephrine in desoxycorticosterone acetate–saline-pretreated rats.*

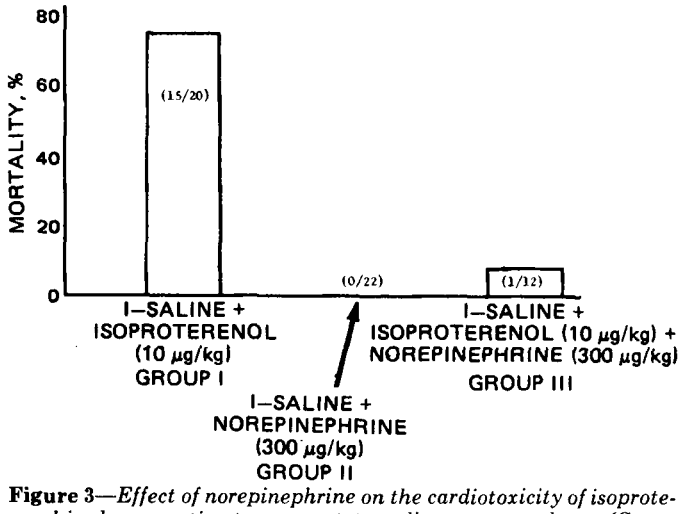

Figure 3—*Effect of norepinephrine on the cardiotoxicity of isoproterenol in desoxycorticosterone acetate–saline-pretreated rats (Group I* versus *Group III,* $p < 0.01$).

effect did, in fact, occur (Fig. 3). The addition of norepinephrine reduced the mortality rate attributable to isoproterenol alone from 75 to 8%.

DISCUSSION

Injections of norepinephrine and epinephrine can produce lethal cardiac arrhythmias in steroid-pretreated rats when combined with either aminophylline or the α-blocking agent phenoxybenzamine. The cardiotoxicity of isoproterenol, already established following steroid pretreatment alone, is enhanced greatly by aminophylline. Comparison of the LD_{50} value of isoproterenol in untreated rats to that of I–saline-pretreated rats also given aminophylline shows a decrease from 680 mg/kg to 3.06 μg/kg, a >200,000-fold increase in toxicity. The effect of aminophylline is so great that even the amounts of norepinephrine and epinephrine released endogenously as a stress response become lethal in its presence.

The ability of both phenoxybenzamine and aminophylline to increase the cardiotoxicity of adrenergic agonists may relate to the importance of β-adrenergic stimulation in this phenomenon. Norepinephrine and epinephrine contain potent α-adrenergic agonist activity in addition to their β-properties. Phenoxybenzamine and aminophylline each can upset, in a different way, the relative balance between α- and β-tone in favor of β-activity. The protective effect of α-stimulation may be due to its ability to raise the fibrillation threshold (9, 10). This effect would decrease the vulnerability of the heart to fibrillation induced by β-stimulation, reducing both the morbidity and mortality of the drug interaction.

Phenoxybenzamine may upset the α–β-balance by removing the α-component by receptor blockage. Aminophylline may produce its effect through its synergistic activity with β-adrenergic stimulation. This result might be accomplished through the adenylate cyclase system. β-Activity has been closely related to this system (11), and aminophylline, a potent phosphodiesterase inhibitor (12, 13), would prevent the degradation of formed adenosine-3′,5′-monophosphate (cyclic AMP) and enhance the activity of agents, such as β-agonists, whose actions depend on the elaboration of cyclic AMP. By either blocking α-receptors or enhancing β-stimulation, the net effect is to promote a β-preponderance, resulting in ventricular fibrillation.

The demonstrated beneficial effect of norepinephrine on isoproterenol cardiotoxicity is consistent with this theory. In this situation, potent α-adrenergic stimulation was added to an environment that was unbalanced favorably for β-adrenergic activity. By reestablishing a balance between α- and β-activity, the appearance of lethal arrhythmias was suppressed. The β-adrenergic component of norepinephrine may have played a small role in the diminution of the effect of isoproterenol. It is a weaker β-agonist than isoproterenol and, therefore, can act as a partial antagonist at certain dosage combinations with isoproterenol. However, this effect alone could not produce the observed decrease in mortality, from 75 to 8%. Hence, the potent α-activity of norepinephrine must have played the major role in decreasing the cardiotoxic response to isoproterenol.

The finding that endogenously released catecholamines can trigger ventricular fibrillation in steroid-pretreated rats fits well with current theories concerning the pathology of stress. Balazs *et al.* (14) found that

both cold and isolation stress increased the heart's sensitivity to isoproterenol and speculated that steroid hormones released by stress may have sensitized the myocardium to the β-agonist. Raab (15) also suggested that stress-induced discharge of adrenal corticoids may enhance the cardiotoxicity of endogenously released catecholamines. In discussing unexpected sudden death during sleep, he implicated a combination of 17-hydroxycorticosteroids, which reach peak levels during sleep, and dream-induced catecholamine discharges as being contributory to a fatal cardiotoxic interaction (16). The prolonged administration of steroids followed by exposure to catecholamines, as seen in the present study, may mimic the hormonal milieu produced by chronic stress, resulting in the similarity of toxic sequelae.

The applicability of these experimental findings to the clinical setting has to be determined. However, the data point out the potential danger of chronic steroid treatment. In such instances, there might be increased risk not only from administered catecholamines but also from agents that potentiate the effects of endogenous catecholamines, such as aminophylline and possibly monoamine oxidase inhibitors, and from agents that produce catecholamine discharge, such as tyramine, an ingredient of many foods.

Application of High-Pressure Liquid Chromatography and Thermal Energy Analyzer to Analysis of Trinitroglycerin and Its Metabolites in Blood

RONALD J. SPANGGORD ˣ and RODNEY G. KECK

Received August 29, 1979, from the *Life Sciences Division, SRI International, Menlo Park, CA 94025.* Accepted for publication November 20, 1979.

Abstract □ A highly selective and sensitive analytical procedure for the determination of trinitroglycerin and four metabolites in whole blood was developed. Trinitroglycerin and its metabolites were extracted from whole blood with ethyl acetate and analyzed by high-pressure liquid chromatography using the thermal energy analyzer detector. Linearity of response was observed over the 1–1000-ng range. The applicability of this method to the analysis of whole blood from dogs orally dosed with trinitroglycerin is described.

Keyphrases □ Trinitroglycerin—high-pressure liquid chromatographic analysis of parent drug and metabolites in whole blood □ High-pressure liquid chromatography—analysis of trinitroglycerin and metabolites in whole blood □ Thermal energy analyzer—analysis of trinitroglycerin and metabolites in whole blood

The analysis of trinitroglycerin in blood has been performed primarily by electron-capture GLC (1–3). Although this method possesses high sensitivity and some selectivity for trinitroglycerin, it requires extensive cleanup procedures and solvent purification. Furthermore, it does not adequately account for the primary metabolites of trinitroglycerin, the isomeric mono- and dinitroglyceryl esters. A recent report (4) described the detection of ethylene glycol dinitrate esters in water by use of the thermal energy analyzer. It was thought that the analyzer detection system also may be applicable to the analysis of trinitroglycerin in complex matrixes such as whole blood.

This report describes the development of a high-pressure liquid chromatographic (HPLC) method to determine trinitroglycerin as well as the primary isomeric dinitro- and mononitroglyceryl metabolites in whole blood. The application of this methodology to the blood of dogs orally dosed with trinitroglycerin is described.

EXPERIMENTAL

Reagents—Acetone[1] and ethyl acetate[1] were glass distilled. Trinitroglycerin[2] was used as a powder (10% trinitroglycerin in lactose). *N*-Nitrosodipropylamine[3] was supplied as a standard solution in isooctane. All other chemicals and solvents were standard reagent grade and were used without further purification. Authentic samples of 1,3- and 1,2-dinitroglycerols and 1- and 2-mononitroglycerols were obtained[4].

Apparatus—The chromatographic system consisted of a liquid

both cold and isolation stress increased the heart's sensitivity to isoproterenol and speculated that steroid hormones released by stress may have sensitized the myocardium to the β-agonist. Raab (15) also suggested that stress-induced discharge of adrenal corticoids may enhance the cardiotoxicity of endogenously released catecholamines. In discussing unexpected sudden death during sleep, he implicated a combination of 17-hydroxycorticosteroids, which reach peak levels during sleep, and dream-induced catecholamine discharges as being contributory to a fatal cardiotoxic interaction (16). The prolonged administration of steroids followed by exposure to catecholamines, as seen in the present study, may mimic the hormonal milieu produced by chronic stress, resulting in the similarity of toxic sequelae.

The applicability of these experimental findings to the clinical setting has to be determined. However, the data point out the potential danger of chronic steroid treatment. In such instances, there might be increased risk not only from administered catecholamines but also from agents that potentiate the effects of endogenous catecholamines, such as aminophylline and possibly monoamine oxidase inhibitors, and from agents that produce catecholamine discharge, such as tyramine, an ingredient of many foods.

Application of High-Pressure Liquid Chromatography and Thermal Energy Analyzer to Analysis of Trinitroglycerin and Its Metabolites in Blood

RONALD J. SPANGGORD ˣ and RODNEY G. KECK

Received August 29, 1979, from the *Life Sciences Division, SRI International, Menlo Park, CA 94025.* Accepted for publication November 20, 1979.

Abstract □ A highly selective and sensitive analytical procedure for the determination of trinitroglycerin and four metabolites in whole blood was developed. Trinitroglycerin and its metabolites were extracted from whole blood with ethyl acetate and analyzed by high-pressure liquid chromatography using the thermal energy analyzer detector. Linearity of response was observed over the 1–1000-ng range. The applicability of this method to the analysis of whole blood from dogs orally dosed with trinitroglycerin is described.

Keyphrases □ Trinitroglycerin—high-pressure liquid chromatographic analysis of parent drug and metabolites in whole blood □ High-pressure liquid chromatography—analysis of trinitroglycerin and metabolites in whole blood □ Thermal energy analyzer—analysis of trinitroglycerin and metabolites in whole blood

The analysis of trinitroglycerin in blood has been performed primarily by electron-capture GLC (1–3). Although this method possesses high sensitivity and some selectivity for trinitroglycerin, it requires extensive cleanup procedures and solvent purification. Furthermore, it does not adequately account for the primary metabolites of trinitroglycerin, the isomeric mono- and dinitroglyceryl esters. A recent report (4) described the detection of ethylene glycol dinitrate esters in water by use of the thermal energy analyzer. It was thought that the analyzer detection system also may be applicable to the analysis of trinitroglycerin in complex matrixes such as whole blood.

This report describes the development of a high-pressure liquid chromatographic (HPLC) method to determine trinitroglycerin as well as the primary isomeric dinitro- and mononitroglyceryl metabolites in whole blood. The application of this methodology to the blood of dogs orally dosed with trinitroglycerin is described.

EXPERIMENTAL

Reagents—Acetone[1] and ethyl acetate[1] were glass distilled. Trinitroglycerin[2] was used as a powder (10% trinitroglycerin in lactose). *N*-Nitrosodipropylamine[3] was supplied as a standard solution in isooctane. All other chemicals and solvents were standard reagent grade and were used without further purification. Authentic samples of 1,3- and 1,2-dinitroglycerols and 1- and 2-mononitroglycerols were obtained[4].

Apparatus—The chromatographic system consisted of a liquid

chromatograph[5] with gradient elution capability. A 250 × 4.6-mm Lichrosorb Si-60[6] (5-μm) column was used. The solvent system was isooctane–ethyl acetate–acetone, 54:6:40 (v/v) for 10 min isocratically and programmed to 9:1:90 (v/v) over 5 min at a flow rate of 1.4 ml/min. The detection of trinitroglycerin was accomplished with a thermal energy analyzer[7] using the following parameters: furnace temperature, 450°; argon flow rate, 15 ml/min; and oxygen flow rate, 5 ml/min.

Extraction—Whole blood, 2 ml, was combined with 100 μl of 1 *M* $AgNO_3$. The silver nitrate was added to inhibit trinitroglycerin degradation before extraction (3). Extraction was achieved by rapid injection of ethyl acetate (2 ml, then 5 × 1 ml) into the whole blood solution. The organic layers were drawn off after each injection, combined, dried, and filtered through a short column of anhydrous sodium sulfate. The dried extract was concentrated to 500 μl using a gentle nitrogen stream. Then 500 μl of isooctane was added, and the solution was concentrated to 500 μl.

Dosing—A female beagle[8] dog (13.5 kg) was fasted overnight, with free access to water, and dosed by gavage over 10 min with 6.7 g of lactose containing 10% trinitroglycerin (670 mg) incorporated into canned dog food. At various times thereafter, blood (2 ml) was drawn from the cephalic vein into a heparin-containing syringe and then was placed in a vial containing silver nitrate.

Quantitation—Quantitation of the samples was achieved by the internal standard method; the internal standard was *N*-nitrosodipropylamine. A known amount of the internal standard was added to the sample before extraction. Peak areas were determined with the aid of an integrator–recorder[9].

RESULTS AND DISCUSSION

HPLC was applied previously to the analysis of trinitroglycerin and the primary hydrolysis products, 1,3- and 1,2-dinitroglycerols, in wastewaters from trinitroglycerin production (5). The sensitivity and specificity of this technique were improved greatly when it was coupled to the thermal energy analyzer detector.

Figure 1 shows a normal-phase HPLC profile of an ethyl acetate extract of trinitroglycerin spiked in whole blood, an unspiked ethyl acetate extract of whole blood, and an ethyl acetate solvent control concentrate using the thermal energy analyzer detector. The relatively interference-free baseline of the spiked and unspiked whole blood extracts

demonstrates the selectivity of the thermal energy analyzer detector for trinitroglycerin in the presence of numerous coextractants. Ethyl acetate was chosen as the extraction solvent because of its ability to extract the more polar mono- and dinitroglyceryl metabolites from whole blood; these metabolites also are responsive to the thermal energy analyzer detector. This selectivity for organonitrates permits the quantitative analysis of the 1,2- and 1,3-dinitroglyceryl and 1- and 2-mononitroglyceryl esters (Fig. 2), which could only be qualitatively estimated by previous GLC methods (2, 3). Linear gradient programming allows for the analysis of trinitroglycerin and its four nitro-containing metabolites in 17 min. This programming also flushes the column to remove nonresponsive polar materials and it prolongs column life.

Internal as well as external standard quantitation methods can be applied to the quantitative analysis of trinitroglycerin using the thermal energy analyzer. With *N*-nitrosodipropylamine as an internal standard, the relative responses of trinitroglycerin and its metabolites to this standard, along with the lower limits of detection for each compound, appear in Table I. For trinitroglycerin, a linear response was obtained over the 1–1000-ng range with a correlation coefficient of 0.99.

Ethyl acetate proved to be an efficient extraction solvent for trinitroglycerin and its metabolites in whole blood. Since ethyl acetate readily emulsifies with whole blood upon shaking, rapid injection of the ethyl acetate into the blood from a syringe and removal of the separated phases by syringe provided adequate extraction efficiency with little emulsion problem. Due to the partitioning of this solvent in whole blood, repeated injections were performed for quantitative removal. The precision of the HPLC–thermal energy analyzer method is shown in Table II, which gives recovery values for spiked blood samples.

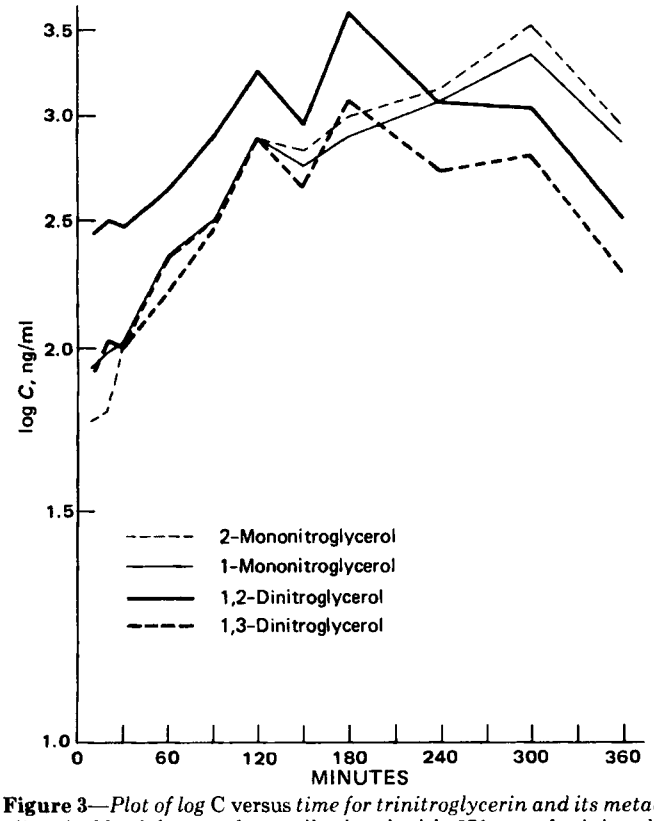

Figure 3—*Plot of log* C versus *time for trinitroglycerin and its metabolites in blood from a dog orally dosed with 670 mg of trinitroglycerin.*

The sensitivity of this method for whole blood was 0.5 ng (25% scale deflection) with the thermal energy analyzer detector at an attenuation of 8. The sensitivity of previously reported GLC methods using electron-capture detection was 0.5–0.1 ng in serum only after extensive cleanup and sample preparation (2, 3). The present method has the advantage of minimal sample preparation and is useful in situations where large samples of serum are not readily available (such as rat and mouse studies); it should be applicable to the study of therapeutic doses of trinitroglycerin in humans.

To test the applicability of the method, a beagle dog was dosed orally (force fed) with trinitroglycerin (49.6 mg/kg). Blood samples were removed at various times and analyzed over 6 hr. The quantitative distribution of trinitroglycerin and its metabolites appears in Table III. As reported previously (3, 6), trinitroglycerin is metabolized rapidly; no trinitroglycerin (<0.5 ng/ml) was detected 20 min after administration. However, the 1,2- and 1,3-dinitroglyceryl and the 1- and 2-mononitroglyceryl metabolites increased to high levels in a parallel fashion and started to decline 5 hr after administration. This finding is consistent with results reported by Hodgson and Lee (7), who found maximum carbon-14 activity in blood 4 hr after oral administration of [^{14}C]trinitroglycerin to rats. A plot of log *C versus* time appears in Fig. 3.

The relative distribution of metabolites in the blood observed in this study paralleled that found by DiCarlo *et al.* (8) in the urine of rats orally dosed with [^{14}C]trinitroglycerin, indicating similar disposition routes of trinitroglycerin for the two species. In both cases, the deesterification appeared to be stepwise.

The data show that there was a slight preference to deesterify at the primary carbon atom. In the early stages of metabolism, the 1,2-dinitroglycerol concentration was three times that of the 1,3-dinitroglycerol isomer. This ratio fell to <2.0 (the expected value if deesterification occurred equally at primary and secondary carbons) at 6 hr. At the same time, the ratio of 2-mononitroglycerol to 1-mononitroglycerol increased from an initial value of 0.68 to 1.5 over 5 hr. Since the source of 2-mononitroglycerol is 1,2-dinitroglycerol (assuming a stepwise process) and the source of 1-mononitroglycerol is both the 1,2- and 1,3-dinitroglycerols, the ratio increase of 2-mononitroglycerol to 1-mononitroglycerol indicates that the 2-position is less reactive to deesterification than is the 1-position.

The present study demonstrates the utility of the thermal energy analyzer detector in the analysis of organonitrates in blood. The application of this method to tissues and other complex matrixes should be useful in pharmacological studies.

Use of Mannitol to Obviate Propranolol-Induced Myocardial Depression in Ischemic Canine Heart

GEORGE KYRIAKIDIS and MICHAEL BARLETTA ˣ

Received December 18, 1978, from the *Department of Pharmaceutical Sciences, College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY 11439.* Accepted for publication November 16, 1979.

Abstract □ To obviate the myocardial depressant action of propranolol, the use of this drug in combination with a positive inotropic agent, mannitol, was studied in the ischemic heart of the dog. Mannitol (25%) administered prior to propranolol augmented myocardial contractility, as shown by an upward shift of the relationship between the pressure change with time and the mean left atrial pressure. Subsequent administration of propranolol did not offset the positive inotropic response to mannitol whereas it markedly reduced the heart rate from a control ischemic value of 127.8 ± 3.4 to 109 ± 4.0 beats/min. The myocardial oxygen requirement, as determined by the tension–time index per minute, decreased 26.3 ± 1.2% below the control ischemic value. These findings suggest that hypertonic mannitol augments contractility in the ischemic failing heart while sustaining the desirable negative chronotropic action of propranolol. This procedure may potentiate the beneficial effects of propranolol on the myocardial oxygen balance and serve as an effective therapeutic modality in the control of acute irreversible ischemia.

Keyphrases □ Propranolol—β-adrenergic blocking activity, effect on myocardial contractility, oxygen requirement, and heart rate, combined action of propranolol and hypertonic mannitol, hemodynamic changes in dogs □ β-Adrenergic blocking activity—effects of propranolol on ischemic failing heart, effects of hypertonic mannitol, dogs □ Myocardial depressants—propranolol, effects of hypertonic mannitol, β-adrenergic blocking activity, dogs

Propranolol, a β-adrenergic blocking agent, was introduced for clinical use in 1968. The value of this drug in the control of reversible ischemia (angina) has been established and reviewed extensively (1). Reversible myocardial ischemia suggests that there is a temporary imbalance between the myocardial oxygen supply and demand and the inability of the coronary vessels to provide adequate oxygenated blood. If the oxygen supply cannot be improved, the only way to establish the myocardial oxygen balance is to reduce the oxygen demands of the heart. Propranolol achieves this goal by reducing the heart rate and cardiac contractility.

The role of β-adrenergic blockade in the treatment of irreversible myocardial ischemia (acute myocardial infarction) has been controversial. β-Adrenergic blockade has been demonstrated to reduce the area of myocardial ischemia in the dog heart following experimental occlusion of the anterior descending coronary artery (2, 3). Studies in humans also have provided evidence that propranolol may reduce the area of ischemia, as evidenced by a reversal of the S-T segment elevation during acute myocardial infarction (4). Similar results were obtained using the cardioselective β-blocking drug practolol (5).

Nevertheless, most reports have implied that β-adrenergic blockade is contraindicated in acute myocardial infarction because it decreases myocardial contractility and may aggravate or precipitate heart failure (6–8). Accordingly, the present study was undertaken to determine whether administration of a nonadrenergic positive inotropic agent, such as hypertonic mannitol (9–11), in conjunction with propranolol may prevent myocardial depression. A second objective was to evaluate the combined effects of mannitol and propranolol in myocardial oxygen requirements during generalized left ventricular ischemia in the intact canine heart. To date, the combined administration of hypertonic mannitol to obviate propranolol-induced myocardial depression in the intact dog has not been investigated. The results of these experiments could have important therapeutic implications.

EXPERIMENTAL

Healthy male and female mongrel dogs, 16–21 kg, were anesthetized by intravenous administration of chloralose (60 mg/kg). The trachea was intubated, and ventilation was instituted with a respiratory pump. The heart was exposed through a left thoracotomy at the fifth intercostal space by pericardiotomy, and the left main coronary artery was dissected free from the adjacent connective tissue.

Left ventricular pressure was recorded with a transducer attached to a polyethylene catheter, which was introduced into the left ventricle through the apex. Mean systemic arterial and left atrial pressures were measured through polyethylene cannulas inserted *via* the carotid artery and left atrial appendage, respectively, and connected to transducers. The maximal rate of left ventricular pressure development was obtained with an R–C differentiator, the amplitude of which was a linear function of 70 Hz. All variables were recorded on a polygraph.

After all parameters had stabilized following the surgical procedures, the mean left atrial and mean systemic pressures, changes in the left ventricular pressure, and heart rates were obtained. Control coronary occlusions were performed to determine the effects of ischemia alone. Generalized left ventricular ischemia was produced by gradual closure of a coarse cotton snare surrounding the left main coronary artery. The magnitude of ischemia was monitored by assessing the left ventricular myocardial contractility, which was evaluated by relating the change in the left ventricular pressure to the mean left atrial pressure. The latter parameter is an approximation of the left ventricular end diastolic pressure (12), and it was selected to avoid the artifacts generated by undamped catheters. Alterations in contractility produced by various interventions were used to assess their effects on the severity of myocardial ischemia. It was assumed that changes in the myocardial oxygen requirements mediated by the infused drugs affected the magnitude of ischemia and, thereby, myocardial contractility.

Alterations in myocardial oxygen requirements were evaluated using the tension–time index, which was obtained by multiplying the mean aortic systolic pressure by the duration of the systole (13). Mean systolic arterial pressure was estimated by:

$$\text{mean systolic pressure} = a - (a - b/3) \qquad \text{(Eq. 1)}$$

where a represents the peak systolic pressure and b is the aortic valve closure pressure (14).

Twelve dogs were divided into two equal study groups. In the first group, the effects of propranolol (0.5 mg/kg iv) in the ischemic failing heart were studied. After the onset of ischemia in the second group, the dogs were treated with hypertonic mannitol (25 g/100 ml) infused through the cannulated femoral vein at 3.82 ml/min by an infusion pump, and the responses to mannitol alone were recorded. Following recovery, the effects of mannitol plus propranolol (0.5 mg/kg) were assessed.

Serum osmolality was checked before, during, and after mannitol infusion and was consistent with the expected level (17 mOsm above the control value). Each experimental animal was used as its own control before any intervention was made in each experiment. The control state was considered to be the ischemic stage before treatment. The magnitude of ischemia was monitored by the decline in myocardial contractility. The standard t test, as described by Snedecor and Cochran (15), was used for group comparisons; the t test for paired comparison was used as presented

[a] Each value is expressed as the mean ± *SEM* of 12 experiments.

by Hill (16). All results are expressed with their standard error of the mean.

RESULTS

Ischemia—After partial occlusion of the left main coronary artery, myocardial contractility showed a rapid and pronounced decline (Fig. 1). As shown in Fig. 2, concurrent with the rise in the mean left atrial pressure (122.8 ± 3.3%), the left ventricular pressure fell (14.5 ± 1.9%); the heart rate increased from 106.5 ± 2.5 to 125 ± 3 beats/min whereas the mean systemic arterial pressure exhibited a moderate fall (6.8 ± 1.1%). The data are summarized in Table I. Table II shows the effect of generalized left ventricular ischemia on the tension-time index.

Propranolol—The hemodynamic changes following propranolol administration during generalized left ventricular ischemia are illustrated in Fig. 3. The mean left atrial pressure rose from an average control level of 8.9 ± 1.6 to 14.7 ± 2.3 mm Hg whereas the change in the left ventricular pressure decreased by 21 ± 2.5%, indicating a decline in cardiac contractility (Table III). Figure 4 depicts the myocardial depressant effect of propranolol in the ischemic failing heart. Although the heart rate fell substantially (17.9 ± 1.4%), the myocardial oxygen requirements did not decrease significantly, as evidenced by the tension-time index per minute. Propranolol evidently raised the tension-time index per beat by lengthening the systolic ejection time, as a result of which the tension-time index per minute failed to decrease (Fig. 5).

Mannitol—As shown in Fig. 4, infusion of hypertonic mannitol enhanced myocardial contractility in the ischemic heart; the mean left atrial pressure fell from the control ischemia value of 15.3 ± 2.1 to 6.7 ± 1 mm Hg whereas the change in the left ventricular pressure increased by 18.1 ± 1% (Table III). No significant changes in the heart rate and the mean systemic arterial pressure were noted. Although the heart rate remained essentially unaltered, the tension-time index per minute fell substantially (Fig. 5). By decreasing the systolic ejection time (12 ± 0.4%) (Table III), mannitol lowered the tension-time index per beat, thereby reducing the tension-time index per minute (Table IV).

Mannitol plus Propranolol—Administration of propranolol subsequent to mannitol infusion produced a progressive rise in the change in the left ventricular pressure (18.7 ± 0.7% above the control ischemia level) accompanied by a fall in the mean left atrial pressure (41 ± 4.5% below the control ischemia value), indicating a rise in myocardial contractility (Fig. 4). The heart rate fell from an average control ischemia value of 127.8 ± 3.4 to 109 ± 4 beats/min whereas the mean systemic arterial pressure remained essentially unaltered (Table III). The results clearly show that hypertonic mannitol may prevent the myocardial depressant action of propranolol (Fig. 4) but not its negative chronotropic effect (Fig. 3).

Direct comparison of the effects of mannitol and of mannitol plus propranolol in myocardial oxygen requirements were made in the same animals (Fig. 5). Propranolol administration subsequent to mannitol infusion greatly decreased the tension-time index per minute (26.7 ± 1.2% below the control ischemic value); this decrease was much greater than that achieved when mannitol was administered alone (9.7 ± 1.2%).

DISCUSSION

The present investigation demonstrates the ability of hypertonic mannitol to prevent the myocardial depressant action of propranolol in the ischemic failing canine heart without increasing the myocardial oxygen requirements. These results are in accord with reported observations (9) that infusion of hypertonic mannitol markedly improved ventricular function in the failing heart–lung preparation following occlusion of the left anterior descending coronary artery. The fact that the increased myocardial contractility was not accompanied by ECG S-T segment elevation suggested that the positive inotropic effects of mannitol are not oxygen wasting (9).

The effect of hypertonic mannitol on myocardial contractility is indicated by the rate of rise of the left ventricular pressure, an index of vigor of the left ventricular contraction. The change in the left ventricular pressure is determined mainly by the ventricular end diastolic volume and myocardial contractility (17). The decrease in the left ventricular pressure changes and the rise of the mean left atrial pressure manifested after the induction of ischemia indicate a depression of cardiac contractility (Fig. 1). As shown in Fig. 3, the rise in the left ventricular pressure changes that occurred concurrently with a fall in the mean left atrial pressure after mannitol infusion clearly shows the cardiotonic effects of mannitol in the ischemic failing heart.

The possible mechanisms by which hypertonic mannitol exerts its positive inotropic effects in the ischemic tissue are not known at present. It has been postulated that its osmotic action may decrease cellular edema

and thereby enhance blood flow, which, in turn, may improve organ function (18). Ames *et al.* (19) stressed that edematous cells may impede blood flow within an organ and thus may impair nutritional circulation in the tissues. Summers and Jamison (20) used the silicone rubber technique to visualize the patency of the renal vasculature during ischemia to demonstrate, in the rat kidney, that cellular edema during transient ischemia may obstruct small vessels and thus intensify tissue damage. Apparently, the lumen of minute vessels, although narrowed by compression from the surrounding edematous cells, permitted the passage of the silicone rubber particles but not of the erythrocytes. Intravascular injection of hypertonic mannitol reestablished a normal vascular pattern, reduced tissue injury, and improved renal function (20). Osmotic shrinkage of the swollen cells presumably reduced the extravascular pressure exerted on the vascular bed, thus enhancing the blood flow.

Although hypertonic mannitol augmented collateral as well as total coronary blood flow in experimentally induced ischemia (9), the increase observed in myocardial contractility may not be totally dependent on changes in myocardial perfusion. It was demonstrated recently that hypertonic mannitol also exerts a positive inotropic effect in the isolated cat papillary muscle (11). The developed tension and the rate of tension rise were significantly greater when the papillary muscles were treated with mannitol regardless of whether mannitol was introduced before or later in the hypoxic period (11).

It has been postulated that a decrease in the intracellular volume produced by the osmotic action of hypertonic mannitol may increase the degree of activation of the myocardial contractile elements. This increased contractile activity may be a result of an increased calcium con-

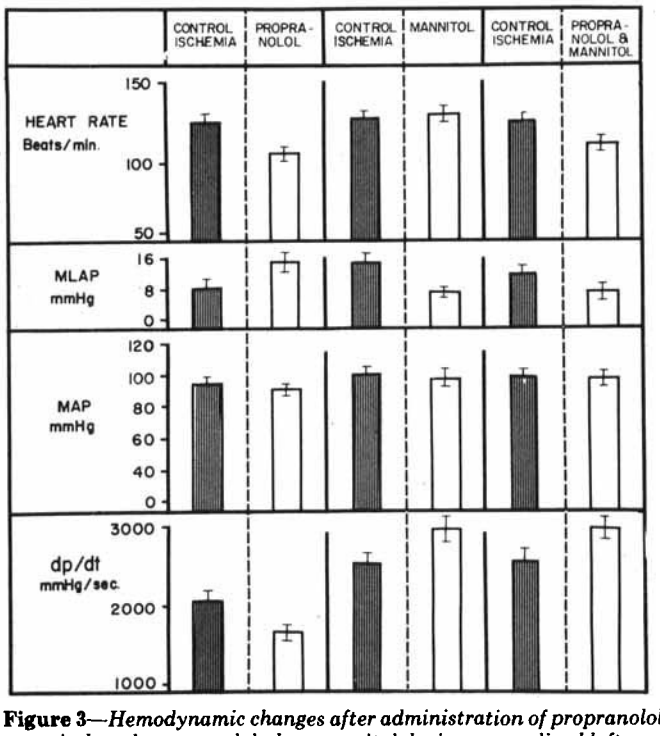

Figure 3—*Hemodynamic changes after administration of propranolol, mannitol, and propranolol plus mannitol during generalized left ventricular ischemia. centration in a superficial area of the muscle fiber (21). In contrast, Apstein *et al.* (22) were unable to observe any increase in contractility in the isolated hypoxic tissue by mannitol. However, this discrepancy may be explained by the fact that Apstein *et al.* used smaller concentrations of mannitol than those used by the other investigator.

The present study shows that hypertonic mannitol enhances myocardial contractility in the ischemic failing heart without raising myocardial oxygen demands. Although the mean arterial oxygen levels were not measured directly in this investigation, the changes in the tension–time index reflected alterations in the myocardial oxygen requirements (13). These observations were consistent with the findings of Sarnoff *et al.* (23), who showed that norepinephrine may exert a positive inotropic effect in the ischemic failing heart without augmenting mean arterial oxygen levels; the inotropic action of norepinephrine was associated with a marked decrease in the left ventricular end diastolic volume (23). This effect, according to the Laplace principle, tends to lower myocardial tension and offsets the rise in the mean arterial oxygen levels produced by increased contractility. A similar effect also was demonstrated in the pharmacologically depressed dog after ouabain administration (24).

Although the decrease in ventricular tension may prevent a rise in the mean arterial oxygen levels associated with augmentation of myocardial contractility, the present results suggest that the systolic ejection time also may be an important factor. Figure 4 and Tables III and IV show that mannitol augmented myocardial contractility whereas the heart rate and the mean systemic arterial pressure were not altered significantly. As contractility rose and the systolic ejection time decreased, the tension–time index per beat fell. The fact that the tension–time index per minute was lowered significantly, although neither the heart rate nor the mean systolic pressure was decreased, indicates that augmentation of myocardial contractility may diminish myocardial oxygen requirements in the failing heart by decreasing the systolic ejection time.

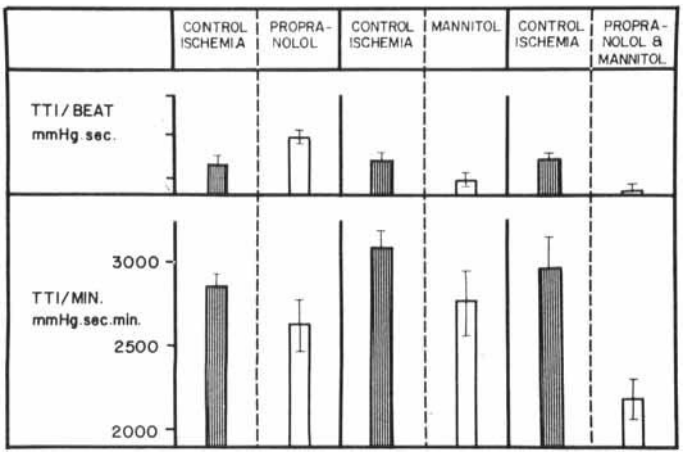

Figure 5—*Effect of propranolol, mannitol, and propranolol plus mannitol on the tension–time index during generalized ventricular ischemia. The* y *axis shows the tension–time index per beat (TTI/beat); the* x *axis shows the tension–time index per minute (TTI/min).*

In contrast, propranolol, through reduced contractility (Fig. 4) and a lowered heart rate (Table III), produced no significant decrease in myocardial oxygen requirements. Figure 5 demonstrates the effects of propranolol on the tension–time index; the tension–time index per minute was not altered significantly whereas the tension–time index per beat exhibited a pronounced increase. The results show that propranolol raised the myocardial oxygen demands by increasing the systolic ejection time (Table III), thereby offsetting the oxygen-sparing effect of its negative chronotropic action. This observation suggests that the principal benefit of β-adrenergic blocking drugs such as propranolol lies in their ability to lower the heart rate rather than to reduce myocardial contractility. Consistent with this view are the findings of Balcon (25), who showed that propranolol could not reduce the pain threshold in patients in whom angina was produced by electrical pacing of the heart. Evidently, the failure of the drug to exert its negative chronotropic activity prevented its beneficial effect. The most pronounced decreases in myocardial oxygen requirements were noted in this study when the myocardial depressant action of propranolol was prevented by administration of hypertonic mannitol (Fig. 5).

Furthermore, when the mean systolic pressure was multiplied by the heart rate, there was a significant drop in the tension–time index per minute after the combined administration of mannitol with propranolol (Fig. 5). The fall in this product was much greater than that achieved by mannitol or propranolol alone. This result was due largely to the fact that propranolol lowered the heart rate whereas the systolic ejection times and the mean systolic pressures, as compared to mannitol, were not very different.

The findings of the present investigation suggest that augmentation of contractility in the ischemic failing heart by a positive nonadrenergic agent may potentiate the beneficial effects of propranolol on the myocardial oxygen balance and prevent cardiac depression. Mannitol is an inotropic agent with highly desirable properties since it does not produce any unwanted hemodynamic or ECG changes. Finally, the ability of mannitol to augment myocardial perfusion (9) may be of great physiological importance. Although further studies are required, augmentation of myocardial contractility and the reduction in heart rate brought about by the combined action of mannitol and propranolol may prove to be an effective therapeutic modality in the control of acute irreversible ischemia.

Synthesis and Cyclization of Dialkylmalonuric Esters

JAMES A. BERES ˣ, MAX G. VARNER, and CARMEN BRIA

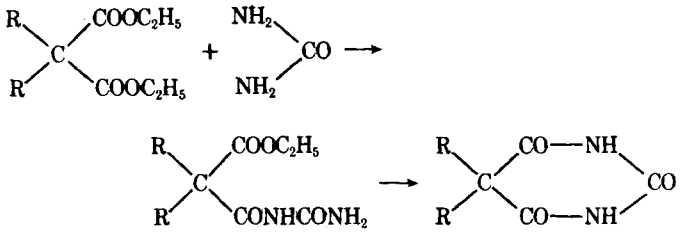
Received September 10, 1979, from the *Department of Chemistry, Shippensburg State College, Shippensburg, PA 17257.* Accepted for publication November 26, 1979.

Abstract □ A novel method for the synthesis of methyl dialkylmalonuric esters was developed using the base-catalyzed ring opening of an isopropylidene malonic ester with urea as the key step. The rates of cyclization of these malonuric esters to the corresponding barbituric acids then were studied at buffer concentrations ranging from 0.01 to 1.00 *M*. The reaction was shown to be general base catalyzed, and the reaction rate was found to be subject to a deuterium isotope effect, $k_{H_2O}/k_{D_2O} = 1.3$. The thermodynamic activation parameters also were determined. A three-step mechanism for the conversion of malonuric esters to barbituric acids was proposed; it involved a rapid cyclization step, followed by proton removal by a general base catalyst and a rate-determining collapse of the resulting tetrahedral intermediate aided by a general acid.

Keyphrases □ Dialkylmalonuric esters—synthesis, cyclization to barbituric acids □ Barbituric acids—mechanism for formation by cyclization of malonuric acids □ Activation parameters—cyclization of dialkylmalonuric esters to barbituric acids

Numerous barbituric acids have been synthesized over the past 75 years, but the mechanism of the reaction has not been defined. Barbituric acids usually are prepared by reacting a malonic ester with urea in the presence of a basic catalyst. The mechanism proposed some years ago (1) involved the formation of an intermediate malonuric ester (I), followed by rapid ring closure to the barbituric acid product (Scheme I).

The fact that malonuric esters undergo facile cyclization in basic media was suggested in 1907 (2), and later these esters were shown to cyclize rapidly in weakly basic solution (1). In a continuing effort to elucidate the mechanism of the reaction between malonic esters and urea, the present study focuses on the cyclization step.



I

Scheme I

BACKGROUND

Although no kinetic studies on the cyclization of malonuric esters have been reported, hydrolysis of barbituric acids in alkaline solution has been investigated. Such hydrolyses produce various products, including the malonuric acid. A complete scheme for the alkaline decomposition of barbiturates was given by Aspelund (3), and a kinetic study on the hydrolysis rate of barbituric acid derivatives was reported by Garrett *et al.* (4). The latter report stated that malonuric acids are capable of hydrolysis to the barbituric acids at pH 7–10, and the enthalpy (ΔH^*) and entropy (ΔS^*) of activation were determined for the hydrolysis of numerous barbituric acids.

One facet of the present investigation involved determination of the mechanism of base catalysis in the cyclization of esters of diethylmalonuric acid. The classical experiment for distinguishing general base catalysis from specific base catalysis involves determining the reaction rate in a series of buffers of constant pH but with varying concentrations of total buffer species at constant ionic strength (5). General base catalysis, which requires catalysis by all bases present, is demonstrated if the reaction rate depends on the total absolute buffer concentration. Specific base catalysis is independent of the absolute buffer concentration.

UV spectrophotometry was employed to monitor the cyclization reaction of the malonuric esters. A pH 10 buffer system was chosen since at that pH the barbituric acid product exists as the monoanionic species (99+%), which absorbs strongly at 240 nm (6), facilitating easy assessment of its formation rate.

This method also was used to measure the reaction rates in deuterium oxide since a comparison of rates in heavy *versus* light water can be valuable in mechanism elucidation. Jencks (7) reported that because of zero-point energy differences and different stretching frequencies, rate constants for OH and OD bond cleavage can be 10-fold larger for hydrogen than for deuterium.

Determination of the thermodynamic activation parameters also was undertaken. The entropy and enthalpy of activation were obtained from plots of $\log k/T$ *versus* $1/T$ (8).

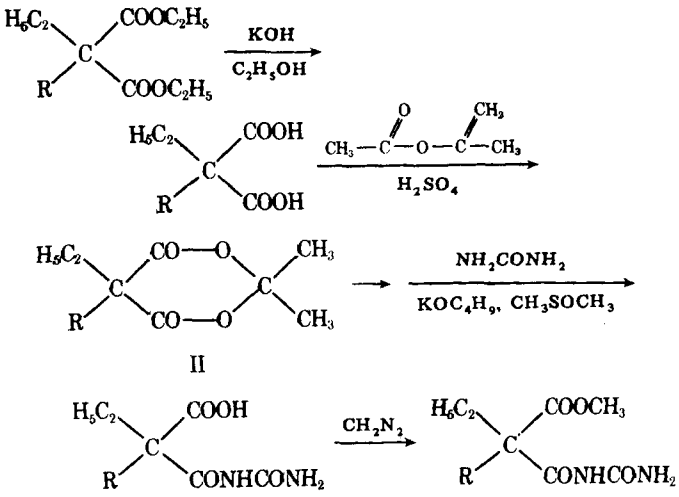
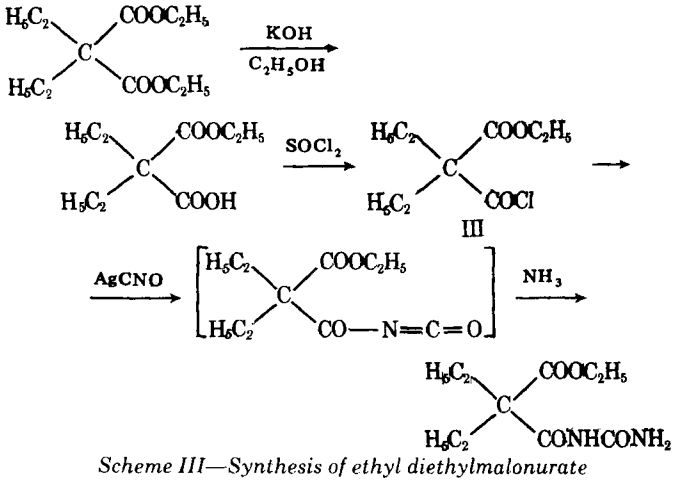


Scheme II—Synthesis of methyl esters of dialkylmalonuric acids



Scheme III—Synthesis of ethyl diethylmalonurate

EXPERIMENTAL

Synthesis of Reactants—The methyl esters of diethylmalonuric acid and ethylisoamylmalonuric acid were prepared by the sequence shown in Scheme II. This reaction represents a novel procedure for the preparation of various methyl dialkylmalonuric esters from the readily available malonic esters. The isopropylidene malonate (II), prepared by a modified method of Davidson and Bernhard (9), serves as a convenient intermediate for the base-catalyzed conversion to the malonuric acid. This reaction presumably occurs *via* a nucleophilic attack of urea on the carbonyl group of II with simultaneous ring opening and elimination of acetone.

The ethyl ester of diethylmalonuric acid was prepared by the sequence shown in Scheme III. Preparation of the intermediate diethylmalonyl chloride monoethyl ester (III) was accomplished using standard procedures, and its conversion into the malonuric ester was reported previously (1). In this instance, the acyl isocyanate was not isolated but was treated immediately upon generation with aqueous ammonia to give a mixture of the desired ethyl ester of diethylmalonuric acid and a substantial amount of the ethyl ester of diethylmalonamic acid, which was separated by fractional crystallization from ligroin.

Reagents—Ethanolamine was redistilled. Concentrated hydrochloric acid was refluxed until a constant vapor temperature of 107° was obtained, and then it was standardized as 6.36 *M* against tris(hydroxymethyl)aminomethane. Reagent grade potassium chloride, sodium bicarbonate, and sodium carbonate were used without further purification. The deuterium oxide, 99.8% pure, was used as received. Sodium deuteriocarbonate was prepared by dissolving 0.5 g of sodium bicarbonate in 10 ml of deuterium oxide and evaporating the solution to dryness (10).

Syntheses[1]—*Diethylmalonic Acid*—Diethyl diethylmalonate, 79.5 ml (0.37 mole), was added dropwise to a refluxing solution of 123 g (2.20 moles) of potassium hydroxide in 500 ml of ethanol. After the mixture was heated for 3–4 hr, a white solid began to separate. Then the mixture was cooled, and the precipitate was filtered off and washed once with cold ethanol.

The solid was purified by dissolving it in water, acidifying the solution, and collecting the crystalline free acid by filtration. The yield was 39.4 g (67%) of colorless crystals, mp 122–127° [lit. (11) mp 125°]; IR (KBr): 3440 (OH), 1700 (C=O), 1410, and 915 cm^{-1}.

Isopropylidene Diethylmalonate (II)—Sulfuric acid (0.5 ml) was added cautiously to a mixture of 10.0 g (62.5 mmoles) of diethylmalonic acid and 7.6 ml (70 mmoles) of isopropenyl acetate. Then a second equivalent (70 mmoles) of isopropenyl acetate was added, and the mixture was heated briefly to 40°. It then was stirred for 4–5 hr at room temperature. After removal of the volatiles at reduced pressure, the residue was dissolved in ether, washed with sodium bicarbonate and water, and dried over magnesium sulfate.

Removal of the ether left an orange oil. This oil was vacuum distilled to yield 2.9 g (23%) of a colorless liquid, bp 97–100° (0.3 mm), which crystallized on standing to a colorless solid, mp 35–37.5°; IR (KBr): 1785 and 1755 (C=O) cm^{-1}; NMR (acetone-d_6): δ 1.93 (q, 4H, CH_2), 1.66 [s, 6H, $C(CH_3)_2$], and 0.87 (t, 6H, CH_3).

Anal.—Calc. for $C_{10}H_{16}O_4$: C, 60.04; H, 8.06; saponification equivalent 200. Found: C, 60.16; H, 7.90; saponification equivalent 201.

Methyl Diethylmalonurate—A solution of isopropylidene diethylmalonate (2.00 g, 10 mmoles) and urea (0.90 g, 15 mmoles) in 20 ml of dry dimethyl sulfoxide was added slowly, with stirring, to a solution of 2.24 g (20 mmoles) of potassium *tert*-butoxide in 20 ml of dimethyl sulfoxide. Stirring was continued at room temperature for 4 hr. Then the mixture was poured into 100 ml of ice water and extracted once with 50 ml of ether.

The aqueous layer was acidified with hydrochloric acid and extracted three times with 50 ml of ether. These extracts were dried over magnesium sulfate, and the solvent was removed under vacuum, depositing a crystalline residue. This residue was recrystallized from water, yielding 0.47 g (25%) of diethylmalonuric acid as colorless platelets, mp 158–161° [lit. (12) mp 162°]; IR (KBr): 1710, 1650, and 1250 cm^{-1}.

An ethereal solution containing a three- to fivefold excess of diazomethane (generated from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide[2]) at 0° was added, with stirring, to an ether solution of 0.26 g (1.3 mmoles) of diethylmalonuric acid at 0°. The mixture was stirred for 1 hr at room temperature, and the ether then was evaporated under a nitrogen stream to yield an oil that solidified on cooling. The solid was recrystallized from ligroin to give 116 mg (42% yield) of colorless needles, mp 112–114.5°; IR (KBr): 3420, 1725, 1700, and 1585 cm^{-1}; NMR ($CDCl_3$): δ 3.70 (s, 3H, OCH_3), 1.90 (q, 4H, CH_2), and 0.78 (t, 6H, CH_3).

Anal.—Calc. for $C_9H_{16}N_2O_4$: C, 49.99; H, 7.46. Found: C, 50.04; H, 7.46.

Methyl Ethylisoamylmalonurate—Methyl ethylisoamylmalonurate was prepared from diethyl ethylisoamylmalonate by the same route as for methyl diethylmalonurate. It was obtained as colorless crystals from ligroin, mp 74–76° [lit. (13) mp 74–75°]; IR (KBr): 3410, 1740, 1715, 1690, and 1570 cm^{-1}; NMR ($CDCl_3$): δ 3.70 (s, 3H, OCH_3), 1.85 (m, CH_2), and 0.80 [d, 6H, $CH(CH_3)_2$].

General Buffer Preparation[3]—Buffers for the kinetic studies were prepared with ethanolamine in carbon dioxide-free distilled water and were adjusted to pH 10.0 with constant boiling hydrochloric acid. Potassium chloride was added when necessary to maintain the ionic strength. The buffers were prepared on a cold plate at the experimental temperature at concentrations of 0.011, 0.110, and 1.100 *M* with respect to ethanolamine so that, upon dilution with the malonuric ester solutions, the final concentrations for the kinetic studies were 0.010, 0.100, and 1.000 *M*, respectively.

For the deuterium oxide study, the buffers were prepared from sodium carbonate and sodium deuteriocarbonate to give a final concentration of 0.18 *M* total buffer at pH 10.0 and 15°.

General Spectrophotometric Method[4]—Malonuric ester solutions were prepared with either carbon dioxide-free distilled water or degassed deuterium oxide at 10^{-3} *M* and were used on the same day. The malonuric

[1] Melting points were determined with a Fisher Mel-Temp apparatus and are uncorrected. IR spectra were recorded on a Perkin-Elmer model 457 grating spectrophotometer, and NMR spectra were recorded on a Hitachi Perkin-Elmer R-20B spectrometer. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn.

[2] Diazald, Aldrich Chemical Co.

[3] All pH measurements were made with a Corning model 10 pH meter equipped with a glass electrode and a potassium chloride reference electrode. The meter was standardized with buffer solutions at the experimental temperature before use.

[4] UV spectral data were obtained on a Beckman DK-2A recording spectrophotometer.

Table I—First-Order Rate Constants for the Cyclization of Diethylmalonuric Esters

Medium	k, min^{-1} [a] Methyl Diethylmalonurate	Ethyl Diethylmalonurate
0.01 *M* Buffer[b,c]	0.61	0.28
0.10 *M* Buffer[b,c]	0.79	0.38
1.00 *M* Buffer[b,c]	1.07	0.51
Water[c,d]	0.93	0.43
Deuterium oxide[c,e]	0.70	0.33

[a] The k values represent an average of at least six determinations. [b] Ethanolamine–hydrochloric acid buffer; the ionic strength was maintained at 0.51 *M* with potassium chloride. [c] Reaction temperature of 15.0 ± 0.1°. [d] Buffered with sodium carbonate–sodium bicarbonate at 0.18 *M*. [e] Buffered with sodium carbonate–sodium deuteriocarbonate at 0.18 *M*.

ester solution, the appropriate buffer, and the cell compartment of the spectrophotometer were preequilibrated at the experimental temperature (±0.1°). The reactions were initiated by injecting 0.3 ml of the malonuric ester solution from a calibrated syringe into the spectrophotometer cell already containing 2.7 ml of buffer. The solution was agitated and placed quickly into the spectrophotometer cell compartment. Absorbance at 240 nm was recorded as a function of time compared to the pure buffer solution reference.

Data for the calculation of the rate constants were obtained directly from the absorbance plots and were treated by the Guggenheim method (14).

RESULTS

The cyclization of the dialkylmalonuric esters was studied in aqueous ethanolamine–hydrochloric acid buffers at pH 10.0 over total buffer concentrations ranging from 0.01 to 1.00 *M*. The rate constants for the methyl and ethyl esters of diethylmalonuric acid are given in Table I. The rates varied with total absolute buffer concentration, consistent with a mechanism involving general base catalysis. Since the reaction is an ester aminolysis, the mechanism proposed by Bunnett and Davis (15) implicating general base catalysis in the reaction of butylamine with ethyl formate might be expected to apply. In addition, general base catalysis in the aminolysis of phenyl acetate was observed (10), and susceptibility to general base catalysis appears to be a general characteristic of ester aminolysis reactions (15).

The thermodynamic activation parameters are shown in Table II for the same two esters and the methyl ester of ethylisoamylmalonuric acid. The values of the thermodynamic parameters indicate that the variation in overall cyclization rates was due largely to the ΔS^* term. The ΔH^* values were all close (<5% difference) and actually in reverse order to the measured rates. The methyl ester, which reacted fastest, had the highest ΔH^* value. However, the ΔS^* values were significantly different and closely paralleled the observed rates. In fact, a plot of ΔS^* *versus* k for the three esters was linear. Combining the ΔH^* and ΔS^* terms produced an overall ΔG^* that paralleled the observed rate differences.

The cyclization rates in water and deuterium oxide containing sodium carbonate–bicarbonate buffers also are shown in Table I. Both esters showed a rate decrease in deuterium oxide of approximately the same magnitude, $k_{H_2O}/k_{D_2O} = 1.3$.

DISCUSSION

A probable mechanism for the cyclization of malonuric esters, based on the general mechanism for ester aminolysis given by Bunnett and

Table II—First-Order Rate Constants and Activation Parameters for the Cyclization of Dialkylmalonuric Esters

Compound	k, min^{-1} [a,b] 10°	15°	20°	Activation Parameters ΔH^*, kcal/mole	ΔS^*, cal/K° mole	ΔG^*, kcal/mole
Methyl diethylmalonurate	0.59	1.06	1.91	18.8	−3.2	19.7

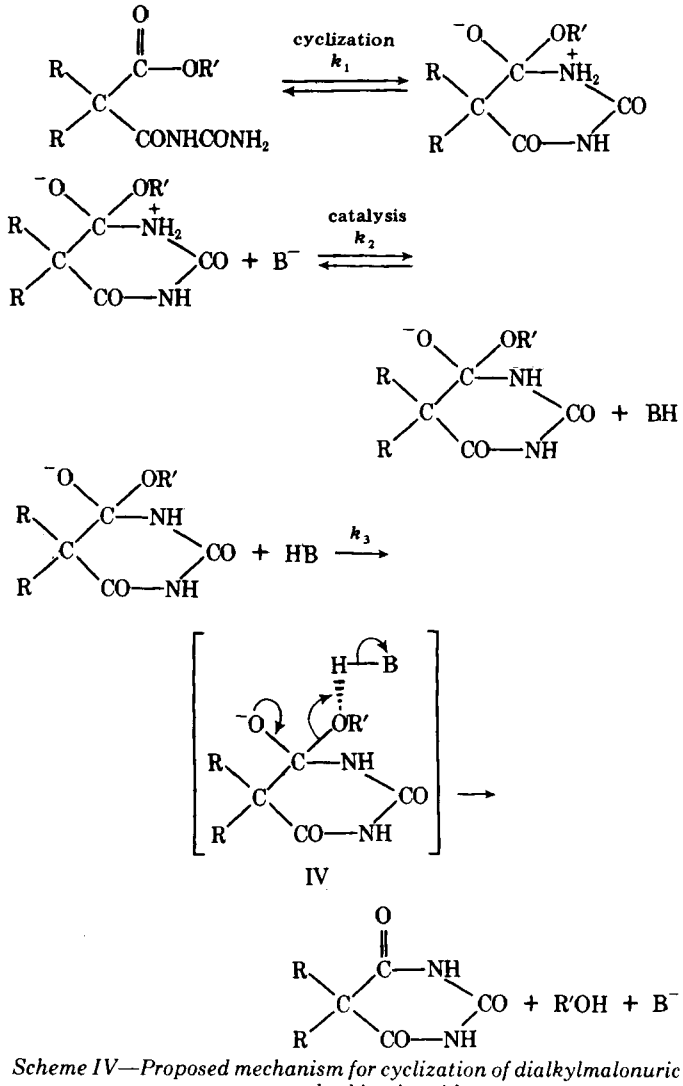
[a] The k values represent an average of at least six determinations. [b] The buffer concentration was 1.00 *M*, and the ionic strength was 0.59 *M*.

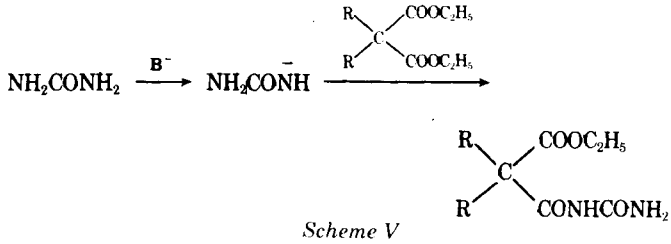


Scheme IV—Proposed mechanism for cyclization of dialkylmalonuric esters to barbituric acids

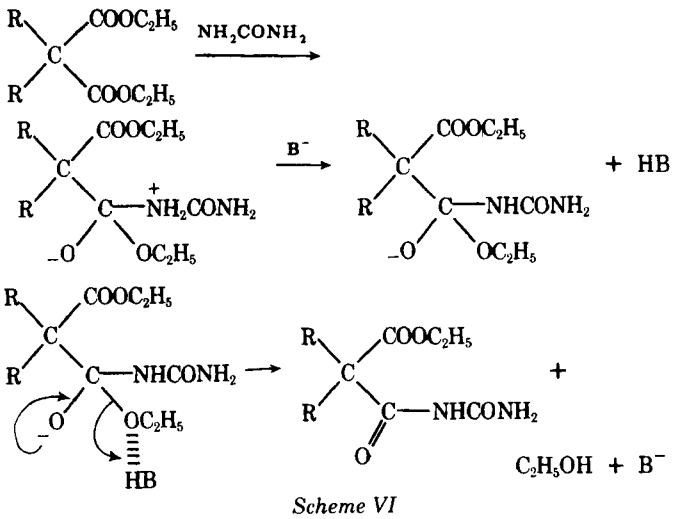
Davis (15), is shown in Scheme IV. Several kinetic pathways are possible, depending on which step is rate determining. If the cyclization step is slow (k_2 and $k_3 > k_1$), the reaction is subject to specific base catalysis since the strongest base in the medium, OH^-, should eliminate catalysis by the weaker bases once the cyclization occurs. However, if catalysis is rate limiting ($k_1 > k_2$ and k_3), then general base catalysis is observed since all basic species present should catalyze these steps at individual measurable rates.

Since the reaction rate of both the methyl and ethyl esters has been shown experimentally to decrease by a factor of 1.8 as the total buffer concentration is varied 100-fold, the reaction must be subject to general base catalysis, and the rate-determining step is either the catalytic step, k_2, or the collapse of the tetrahedral intermediate aided by the general acid (HB), k_3. The measured deuterium isotope effect, $k_H/k_D = 1.3$, tends to implicate k_3 as the limiting step. Even though the observed isotope effects are small compared to normal d^2 isotope effects, k_H/k_D values in the range of 1.1–1.5 have been reported for the general base-catalyzed reaction of phenyl acetate with glycine and ammonia (10).

The observations that substitution of an isoamyl group for an ethyl group in the acyl portion of the malonuric ester caused a rate decrease



Scheme V



Scheme VI

by a factor of 1.3 and, more importantly, that substitution of the ethyl ester for the methyl ester decreased the rate by a factor of 2.1 also are consistent with a rate-limiting collapse of the tetrahedral intermediate. This dependence on the bulkiness of both the acyl substituents and the leaving alkoxy groups can be attributed to steric hindrance from formation of the hydrogen-bonded intermediate (IV). It also seems reasonable that the identity of the alkoxy group should play the greater role since it is closer to the reaction site. On the other hand, the identity of these groups should have little effect on the proton removal in the catalytic step (k_2).

In view of these findings, it also seems reasonable that the mechanism proposed for the formation of the malonuric ester from urea and the malonic ester needs to be revised (1). Rather than the base functioning to form urea anions, which subsequently attack the malonic ester (Scheme V), the base probably functions in proton removal from the dipolar tetrahedral intermediate that results from the initial attack of neutral urea on the malonic ester (Scheme VI).

Distribution of Tetracycline in Red Blood Cells

H. W. JUN ˣ and B. H. LEE

Received July 6, 1979, from the *Department of Pharmacy, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication October 15, 1979.

Abstract □ The distribution of tetracycline into human red blood cells was studied *in vitro* at 37°. The drug was taken up rapidly by the cells, and its distribution equilibrium was reached after ~10 min of incubation. The steady-state distribution ratio of the drug between the red cells and extracellular fluid of 0.9% NaCl solution was 2.84, while the distribution ratio between the cells and the plasma solution was 0.9. The reduced cellular uptake in plasma was due to binding of the drug to plasma components. Calcium ions in plasma appeared to reduce tetracycline uptake by the red cells. The red cell distribution of tetracycline in dogs was in close agreement with the *in vitro* data using the washed human red cells. A dog suffering from severe hypoalbuminemia showed greater uptake of the drug by the erythrocytes, while a normal healthy dog exhibited the red cell–plasma distribution ratio of 0.98. The release rate of tetracycline from the preloaded cells into normal saline solution indicated that the release was directly proportional to the cellular concentration of the drug; the first-order release rate was ~1.38 hr^{-1}.

Keyphrases □ Tetracycline—distribution in red blood cells □ Antibacterials—tetracycline, distribution in red blood cells □ Drug distribution—tetracycline, uptake by red blood cells

One important function of red blood cells is to store hemoglobin, which carries and supplies oxygen to various tissues in the body. Drugs can enter red blood cells and bind to the intracellular constituents (1–3). For many drugs, however, erythrocyte uptake means that less drug is available at the site of pharmacological action.

Plasma and serum concentrations have been monitored commonly to study the pharmacokinetics of drugs in the body, with the assumption that drug levels in the plasma and serum are linearly related to drug concentrations in whole blood. Although several drugs such as chlorthalidone (4) and salicylate (5) were shown to accumulate significantly in the red cells, several reports (6–8) indicated that extensive plasma protein binding lowers the red cell uptake of the drug by reducing the free plasma drug concentration. In patients suffering from hypoalbuminemia, the basic pharmacokinetic parameters of the drug thus can be different from those obtained in normal patients (9, 10).

This study was an attempt to elucidate the *in vitro* and *in vivo* distribution characteristics of tetracycline into red blood cells and to measure the effects of the normal plasma components on the red cell uptake of this drug.

EXPERIMENTAL

Materials and Equipment—Tetracycline hydrochloride[1], pentobarbital sodium[2], trichloroacetic acid[3], calcium chloride[3], and human serum albumin[2] were used as received. A rotating apparatus[4] with multiple sample holders was immersed in a water bath, which was kept at 37 ± 1° by a controlled-temperature circulating pump[5]. Fluorescence measurements were made using a spectrophotofluorometer[6] equipped with a 150-w xenon lamp and a R-447 photomultiplier tube.

Preparation of Red Cell Suspensions for *In Vitro* Distribution Studies—Human blood, obtained from either healthy young volunteers or a local blood bank[7], was centrifuged at 1200×*g* for 8 min. The packed red cells were obtained after removing the plasma water and buffy layer containing leukocytes. The cells then were washed three times with isotonic buffer solution (pH 7.4). After the final washing, the cells were suspended in either 0.9% NaCl solution or human plasma solution containing varying amounts of tetracycline (5, 10, 20, 30, and 50 μg/ml). These concentrations are slightly higher than normal clinical concentrations of the drug in patients (11).

Distribution of Tetracycline into Cells—The distribution of tetracycline into the red cells was measured by assaying the drug both in the extracellular fluid and in the cells after incubating the samples consisting of 5 ml of washed cells and 5 ml of 0.9% NaCl solution or human plasma containing 20 μg of tetracycline/ml in a rotating water bath (40 rpm) at 37 ± 1°. Following the incubation for different time intervals (3, 5, 10, 15, 20, and 30 min), the cells were separated by centrifugation at 1200×*g* for 8 min for the assay of the drug in the cells and in the medium.

Effect of pH on Cellular Uptake of Tetracycline—Five milliliters of red cells was suspended in 5 ml of phosphate buffer solution (pH 6.7, 7.4, or 8.0) containing 20 μg of tetracycline/ml. After incubation for 15 min in a rotating water bath at 37 ± 1°, the cells were separated by centrifugation. The concentration ratio of tetracycline between the medium and red cells was determined for each pH solution.

Drug Release Rate from Red Cells—The release rate of tetracycline from the preloaded cells into 0.9% NaCl solution was measured by assaying the drug in the extracellular fluid after incubation of the samples in a rotating water bath at 37 ± 1°. Initially, 5 ml of washed red cells, preequilibrated with 5 ml of tetracycline solution (20 μg/ml) in 0.9% NaCl solution for 15 min, was mixed with 5 ml of 0.9% NaCl solution; this mixture was subjected to incubation in a rotating water bath at 37 ± 1° for 10 min. After centrifugation at 1200×*g* for 8 min, the tetracycline concentration in the extracellular medium was measured. The remaining cells then were reequilibrated with an equal volume of fresh 0.9% NaCl solution for 10 min, followed by centrifugation and assay of the drug in the extracellular fluid. The procedure was repeated five times.

Effect of Plasma Albumin and Calcium Ion on Red Cell Uptake of Tetracycline—The cellular uptake of tetracycline was measured in the solutions containing plasma albumin (4%) and/or calcium chloride (2.5×10^{-5} *M*). The results then were compared with the distribution of tetracycline between the red cells and 0.9% NaCl solution.

Red Cell Uptake of Tetracycline in Dogs—*In vivo* distribution of tetracycline between the plasma and red cells was determined in a healthy beagle dog (Dog A) and in another beagle dog (Dog B) suffering from hypoalbuminemic conditions. The red cell counts for Dogs A and B were 5.59×10^6 and 5.48×10^6/ml, respectively. The normal ranges of the average red cell counts and albumin levels in dogs are 5.26×10^6–6.57×10^6/ml and 3.1–4.0%, respectively. The dogs received a bolus intravenous injection of 10 mg of tetracycline/kg, and the blood samples taken at different time intervals were assayed for the drug both in the cells and in the plasma.

Assay of Tetracycline in Cells and Extracellular Fluids—A spectrophotofluorometric method (12) was used. This method measures

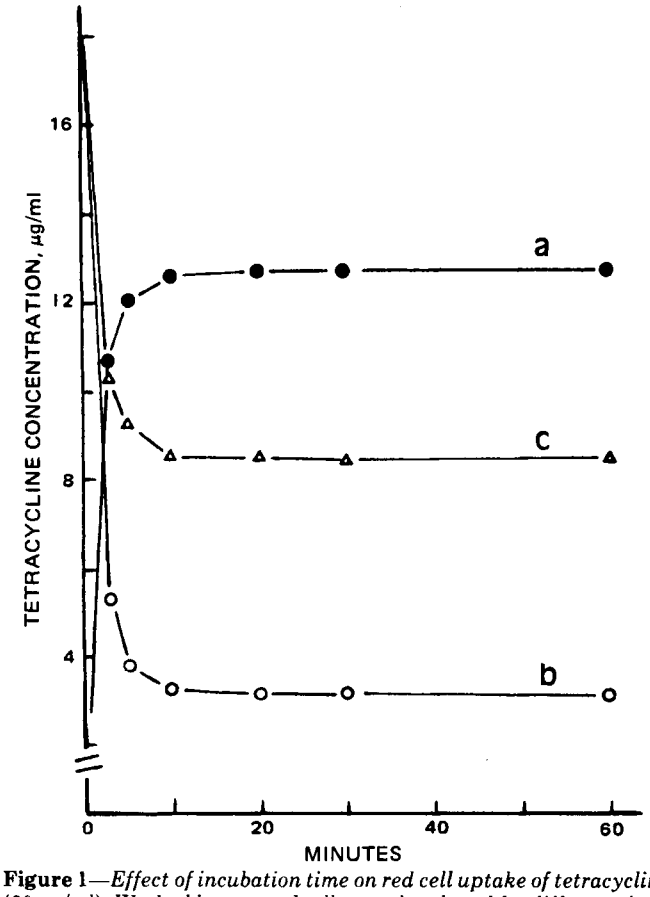

Figure 1—*Effect of incubation time on red cell uptake of tetracycline (20 μg/ml). Washed human red cells were incubated for different times in 0.9% NaCl solution (a, drug in red cells; and b, drug in extracellular fluid) and in human plasma (c, drug in extracellular fluid).*

the fluorescence intensity of the tetracycline–pentobarbital–calcium complex at 525 nm when it is activated at 390 nm.

RESULTS AND DISCUSSION

Figure 1 shows the distribution profile of tetracycline into the red cells as a function of time during the incubation of the washed cells in an equal volume of 0.9% NaCl solution containing 20 μg of tetracycline/ml. During the first 10 min of incubation, the drug was taken up rapidly by the cells, and the steady-state distribution ratio between the red cells and extracellular fluid was ~2.84. The large distribution into the cells probably was due to the significant binding of tetracycline to the intracellular components. However, when tetracycline was subjected to equilibration between the human plasma and erythrocytes, the distribution ratio between the red cells and plasma was 0.9 ± 0.12 (Fig. 1, curve c).

Since plasma contains various proteins and also divalent cations that form lipid-insoluble complexes with tetracycline (13), studies were done to identify the plasma components responsible for the lowered cellular uptake of the drug in the plasma as compared with that in 0.9% NaCl solution. Figure 2 compares the distribution ratios of tetracycline between the red cells and 0.9% NaCl solution (bar A) in the presence of various additives. When both calcium (2.5×10^{-5} *M*) and serum albumin (4%) were added to 0.9% NaCl solution, the steady-state distribution ratio of

Medium	5.14	5.24	5.27
Red cell-medium ratio	2.88	2.81	2.81

[a] Initial extracellular concentration was 20 μg/ml. [b] Average of three experiments.

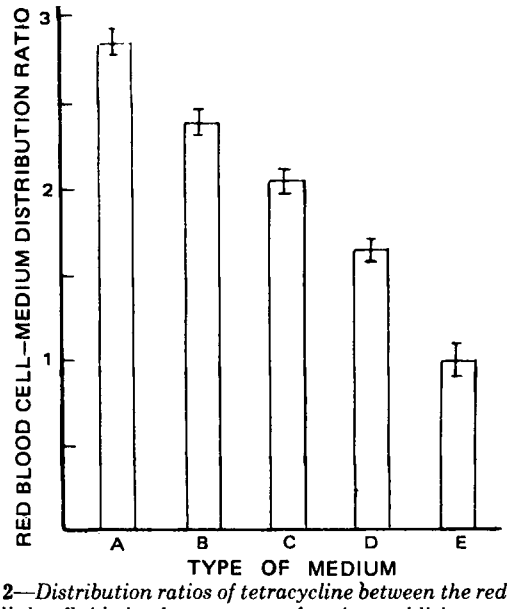

Figure 2—*Distribution ratios of tetracycline between the red cells and extracellular fluids in the presence of various additives at 37°. The extracellular fluids were 0.9% NaCl solution containing 20 μg of tetracycline/ml (A); 20 μg of tetracycline/ml and 2.5×10^{-5} M $CaCl_2$ (B); 20 μg of tetracycline/ml and 4% albumin (C); and 20 μg of tetracycline/ml, 2.5×10^{-5} M $CaCl_2$, and 4% albumin (D); and human plasma containing 20 μg of tetracycline/ml (E). The vertical bars* (I) *represent the standard error of the mean.*

tetracycline between the cells and medium was significantly lower (bar D) than that in the solution containing calcium (bar B) or albumin (bar C) alone. However, the cellular uptake of tetracycline in human plasma (bar E) was still lower than that in 0.9% NaCl solution containing calcium and albumin (bar D).

These results indicate that the components other than calcium and albumin in the plasma also were responsible for the lowered drug partitioning into the cells. Globulins in the plasma possibly may provide additional binding sites to tetracycline. Nevertheless, the distribution of tetracycline into the red cells observed in this study was somewhat similar to the rate of uptake of tetracycline by *Escherichia coli* cells. Franklin and Higginson (14) found that tetracycline rapidly entered the bacterial cells, and its distribution equilibrium between the cells and extracellular medium was reached within 10 min of incubation.

Figure 3 illustrates the effect of tetracycline concentration on the red cell uptake in 0.9% NaCl solution. The steady-state distribution ratio between the cells and extracellular fluid generally was the same among the different total tetracycline concentrations studied. When the concentration of tetracycline was increased from 5 to 50 μg/ml, the distribution of the drug into the cells also was increased while the steady-state distribution ratio between the red cell and the medium was maintained

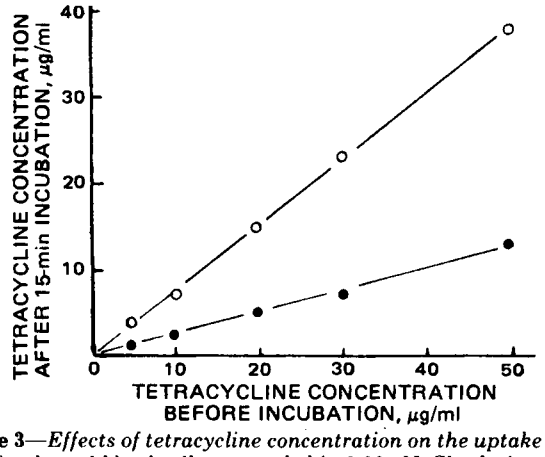

Figure 3—*Effects of tetracycline concentration on the uptake of tetracycline by red blood cells suspended in 0.9% NaCl solution at 37°. Key:* O, *red blood cells; and* ●, *0.9% NaCl solution.*

Table II—Distribution of Tetracycline into Red Blood Cells in Two Dogs

	Dog A	Dog B[a]

Red cell–plasma ratio	0.98	1.97	1.74

[a] The data were obtained 2 weeks apart.

at 2.84. This finding probably was due to the fact that a large amount of tetracycline could partition into the cellular components of the red cells.

Table I shows the effect of pH on the distribution of tetracycline into the red cells. Between pH 6.7 and 8.0, the steady-state distribution ratio of the drug remained nearly the same. Since tetracycline undergoes extensive ionization in this pH range, the transport of this drug across cellular membranes probably was mediated by facilitated diffusion as suggested previously (15).

Figure 4 shows the steady-state concentrations of tetracycline in the red cells and the medium after each successive 10-min equilibration with 0.9% NaCl solution. The rate of drug release apparently was an exponential function of the drug concentration in the cells, and the concentration-dependent release rate was $\sim 1.38\ hr^{-1}$. The large release rate constant of the drug from the red cells as compared to its relatively slow

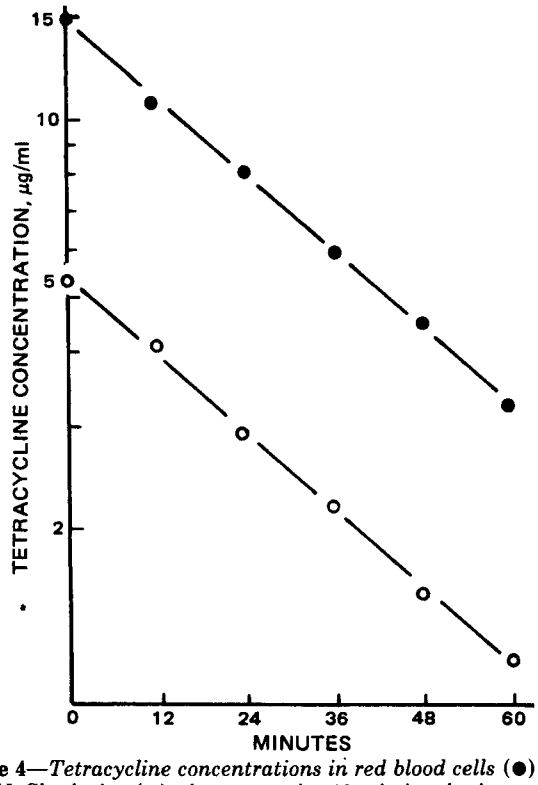

Figure 4—*Tetracycline concentrations in red blood cells (●) and in 0.9% NaCl solution (○) after successive 10-min incubations.*

elimination rate constant ($0.07\ hr^{-1}$) in humans (11) indicates that elimination of tetracycline from the body usually was not affected by the red cell uptake of the drug. Tetracycline will be released quickly from the erythrocytes as the drug in the blood disappears from the body by elimination.

It is generally recognized that the pharmacokinetic behavior of the drug in the normal healthy population may differ from that in patients suffering from chronic illness. Several investigators (9, 10, 16) showed that hypoalbuminemic patients tend to suffer more often than normal patients from adverse drug reactions. Table II compares the distribution of tetracycline in the blood of a dog suffering from severe hypoalbuminemia (1.68%) to that of a normal healthy dog. Dog A, with a normal albumin level (2.98%), had a cell–plasma distribution ratio of 0.98; Dog B, which suffered from hypoalbuminemia, showed a distribution ratio of 1.8, which was nearly two times higher than that in Dog A. These findings are in close agreement with the results obtained from the *in vitro* experiments using the human plasma and the solutions containing different additives.

In summary, tetracycline rapidly enters red blood cells, forming a steady-state distribution equilibrium with the extracellular fluid within 10 min of incubation. The steady-state distribution ratio of the drug between the red cells and extracellular fluid of 0.9% NaCl solution was 2.84, while the distribution ratio between the cells and the plasma solution was 0.9. The low cellular uptake in the plasma was due to binding of the drug to the plasma components. A dog suffering from severe hypoalbuminemia exhibited much greater red cell uptake of tetracycline. The large release rate of the drug from the cells found in this study indicates that the elimination rate of tetracycline from the body is not influenced by the cellular uptake of the drug.

Induced Resistance in *Staphylococcus aureus* for Assay of Antibiotic Mixtures in Pharmaceutical Preparations

DORA BALANDRANO ˣ **and RAMÓN VALLE**

Received February 5, 1979, from the *Department of Quality Control Assurance, S.A. Pharmaceutical Division, Syntex, Apdo. 10-821, México 10, D.F.* Accepted for publication October 15, 1979.

Abstract □ A new microbiological method was developed for the assay of neomycin and spiramycin. These antibiotics usually cannot be quantitated individually when they are combined in a pharmaceutical preparation since both act on the same test organism. By inducing resistance to each antibiotic in *Staphylococcus aureus*, two new strains were obtained. Quantitation can be accomplished easily with these strains.

Keyphrases □ Neomycin—microbiological determination with spiramycin □ Spiramycin—microbiological determination with neomycin □ *Staphylococcus aureus*—microbiological determination of antibiotic mixtures, induced resistance to neomycin and spiramycin

The combination of two or more antibiotics in a pharmaceutical preparation is used widely in the therapy of several infections to permit reduction of the dose of a potentially toxic drug, to prevent the development of bacterial resistance, and to develop a synergistic effect. The last of these uses probably is the most important.

However, these mixtures frequently create problems in the quantitation of their components by microbiological procedures. Arret *et al.* (see Ref. 1) prepared tables with which approximate results may be obtained. Similar tables should be prepared in each laboratory for every antibiotic combination.

BACKGROUND

Arret *et al.* demonstrated that if the test organism used for the assay of one antibiotic (A) is not affected by a second antibiotic (B), no problem results. However, if the test organism is affected by both antibiotics, erroneous high or low values are obtained. Therefore, more specific methods must be developed to eliminate the effect of B. Such methods could involve: (*a*) inactivation of B, (*b*) use of a different test organism that is sensitive to A and relatively resistant to B, (*c*) separation of the antibiotics by differential solubility techniques, and (*d*) compensation for the presence of B by its addition to every solution of A used for the standard response curve.

Grove and Randall (2) presented numerous applications of these possibilities. For instance, they discussed the use of specific enzymes or chemical inactivators to eliminate certain antibiotics from action and the extraction of one antibiotic with a solvent in which the other is not soluble. However, the preferred technique is to choose as the test organism a microorganism that is very sensitive to one antibiotic and is not sensitive to the other antibiotic.

An organism can be made resistant to an antibiotic by forcing its growth in media containing increasing amounts of the antibiotic until the desired resistance is attained. This organism then can be used as a test organism. This paper describes a microbiological method to quantitate two antibiotics mixed in a pharmaceutical dosage form.

EXPERIMENTAL

Materials—The equipment used was that required by the USP XIX (3) cylinder-plate assay, and the assay plates were prepared (3) using antibiotic medium No. 11 for the base layer and No. 1 for the inoculum layer. Sample and standard solutions were diluted in phosphate buffer solution No. 3 (pH 8).

Neomycin sulfate USP was used as the standard. The test organisms were *Staphylococcus aureus* (ATCC 6538P) and *Bacillus subtilis* (ATCC 6633).

Table I—Precision and Accuracy of the Determination of Neomycin and Spiramycin

Antibiotic	Precision at 95% Confidence Interval, % ± *SD*	Accuracy at 95% Confidence Interval, % ± *SD*
Neomycin	105 ± 2.8	98.6 ± 2.0
Spiramycin	95.4 ± 3.07	102 ± 1.6

Table II—Results for Neomycin and Spiramycin in Stability Samples

Sample	Neomycin, %	Spiramycin, %
6 months at room temperature	107, 106	105, 100
	100, 107	105, 100
	93, 104	107, 105
	107, 116	102, 106
6 months at 37°	97, 94	71, 69
	94, 93	78, 78
	97, 98	76, 74
	93, 93	69, 70
6 months at 45°	89, 87	66, 60

	92, 88	64, 66

Resistance to Spiramycin[1]—The test organism was inoculated successively in a series of tubes of medium No. 1 containing increasing amounts of the antibiotic. From 1 unit of spiramycin base/ml in the first tube, the concentration was increased until a strain was obtained that was able to grow in a medium containing 20 units of spiramycin base/ml. Assays by the cylinder-plate method were made to confirm that the microorganism was resistant to this spiramycin concentration.

Resistance to Neomycin—By following steps similar to those used for spiramycin, *S. aureus* was inoculated successively in tubes of medium No. 1 containing increasing amounts of the antibiotic, from 1 to 10 μg of neomycin base/ml of culture medium. Assays by the cylinder-plate method also were made to confirm the resistance of the strain obtained.

With this technique, two new strains were obtained. One strain was resistant to 20 IU of spiramycin base/ml of medium (for the determination of neomycin), and the other strain was resistant to 10 μg of neomycin base/ml of medium (for the determination of spiramycin).

Method—Analyses were performed as described in the USP under the cylinder-plate method (3). The basic steps of this method are: (*a*) inhibition of growth by different dilutions of the antibiotic placed in cylinders on agar plates inoculated with the test organism, (*b*) measurement of the zones of inhibition, and (*c*) quantitative estimation by interpolation of the values obtained in a standard curve.

Statistical Evaluation—To determine the precision of the method, repeated assays were carried out in a homogeneous sample of a topical solution for cattle containing, in 100 ml, 2.0 mg of neomycin base (as the sulfate), 2.0 mg of spiramycin base (as the adipate), and 2.5 mg of flumethasone with polyethylene glycol-water as the vehicle.

For accuracy, a placebo of the dosage form was dosed with known amounts of the antibiotics (5, 8, and 10 mg of neomycin base/g and 5, 8, and 10 IU of spiramycin/g), and recovery assays were done after homogenization. The results are given in Table I.

[1] The spiramycin was obtained from the World Health Organization.

© 1980, American Pharmaceutical Association

The specificity of the method was determined with dosage form samples maintained for 6 months at room temperature, 37°, and 45°. The results are given in Table II.

RESULTS AND DISCUSSION

A microbiological method for the determination of neomycin and spiramycin mixed in pharmaceutical preparations was developed. The initial plan was to develop a *Staphylococcus* strain that was resistant to spiramycin for the determination of neomycin and to develop a *Bacillus* strain that was resistant to neomycin for the determination of spiramycin.

Resistance to spiramycin in *S. aureus* was obtained easily. However, since the *B. subtilis* inoculum was a spore suspension, a strain resistant to neomycin was not obtained. Therefore, since *S. aureus* also is recommended for the evaluation of spiramycin (4), this microorganism was chosen for both antibiotics.

This method may be used as a quality control procedure for samples of production batches as well as in stability studies since substances produced by degradation products of excipients or other active ingredients do not interfere. The assay may be carried out without special preparation of the sample. This technique may be used in the assay of mixtures of other antibiotics by inducing resistance in the proper microorganisms.

Determination of Dextro- and Levomethorphan Mixtures Using Chiral Lanthanide NMR Shift Reagents

IRVING W. WAINER ˣ, MARC A. TISCHLER, and ERIC B. SHEININ

Received August 20, 1979, from the *Division of Drug Chemistry, Food and Drug Administration, Washington, DC 20204.* Accepted for publication October 29, 1979.

Abstract □ Europium and praseodymium chiral NMR shift reagents were used to differentiate between dextro- and levomethorphan. The enantiomeric shift differences ($\Delta\Delta\delta$) demonstrated by the singlet associated with the methoxy protons were large enough to identify the *levo*- and *dextro*-isomers and to allow for the determination of as little as 10% of one enantiomer in the presence of the other in a prepared mixture. The analytical method is rapid and can analyze samples as small as 1 mg.

Keyphrases □ Dextromethorphan—NMR determination with levomethorphan □ Levomethorphan—NMR determination with dextromethorphan □ Enantiomers—NMR determination of dextromethorphan and levomethorphan mixtures, chiral lanthanide shift reagents □ NMR spectroscopy—determination of dextro- and levomethorphan mixtures, chiral lanthanide shift reagents □ Analgesics, narcotic—levomethorphan, NMR identification with dextromethorphan □ Antitussives, nonnarcotic—dextromethorphan, NMR identification with levomethorphan

The determination of the enantiomeric purity of a substance is an important aspect of the regulatory process. This determination is especially important in cases such as methorphan where the *levo*- and racemic forms of the drug are regulated narcotics while the *dextro*-isomer is a widely used nonnarcotic antitussive.

BACKGROUND

Specific rotation (1) is the standard method used to distinguish dextromethorphan from levomethorphan. This method is simple and accurate if there is an adequate amount of sample and if one can be reasonably certain that there are no interfering compounds. The hanging microdrop technique (2), which has a sensitivity of 0.2 μg, also is used. However, these approaches cannot serve as identification tests and they cannot accurately detect one enantiomer in the presence of the other.

Chiral lanthanide nuclear magnetic shift reagents may be utilized in the development of rapid, sensitive, and accurate assays of enantiomeric purity. Shaath and Soine (3) recently demonstrated the utility of this approach in the determination of the enantiomeric purity of isoquinoline alkaloids. By using a europium chiral shift reagent, they differentiated rapidly between the components of five enantiomeric pairs and accurately detected an enantiomeric mixture of 95:5.

This paper reports the application of the chiral lanthanide shift reagents to the identification of the methorphan enantiomers and the determination of one isomer in the presence of the other.

EXPERIMENTAL

Instrumentation—A 60-MHz NMR spectrometer[1] equipped with a Fourier transform system[2] was used for all spectra.

Reagents and Chemicals—Deuterated chloroform was used as purchased[3].

Dextro- and levomethorphan were supplied as their hydrobromide salts[4], and the free bases were prepared according to the NF procedure (1). Stock solutions (0.16 *M*) of the free bases were prepared by dissolving 220 mg of the respective enantiomer in 5.00 ml of deuterated chloroform. Enantiomeric mixtures were prepared from the two stock solutions.

The europium and praseodymium chiral shift reagents were used as purchased[5]. Stock solutions (0.2 *M* in deuterated chloroform) were prepared in a dry box under a nitrogen atmosphere before the start of each series of experiments. Each solution was stored in a sealed vial equipped with a septum and sampled using a microliter syringe.

Procedure—The appropriate methorphan solution (0.4 ml) was placed in an NMR tube equipped with a rubber septum. The shift reagent then was added sequentially in 20-μl increments. An NMR spectrum with 64 additive pulses was run after each addition, and the peak chemical shifts were computer recorded.

The peak height ratios associated with the various molar ratios of levo- and dextromethorphan were measured after the addition of 300 μl of the europium shift reagent or 260 μl of the praseodymium shift reagent.

RESULTS AND DISCUSSION

The effect of the europium shift reagent on the NMR spectrum of an equimolar mixture of dextro- and levomethorphan is shown in Fig. 1. The

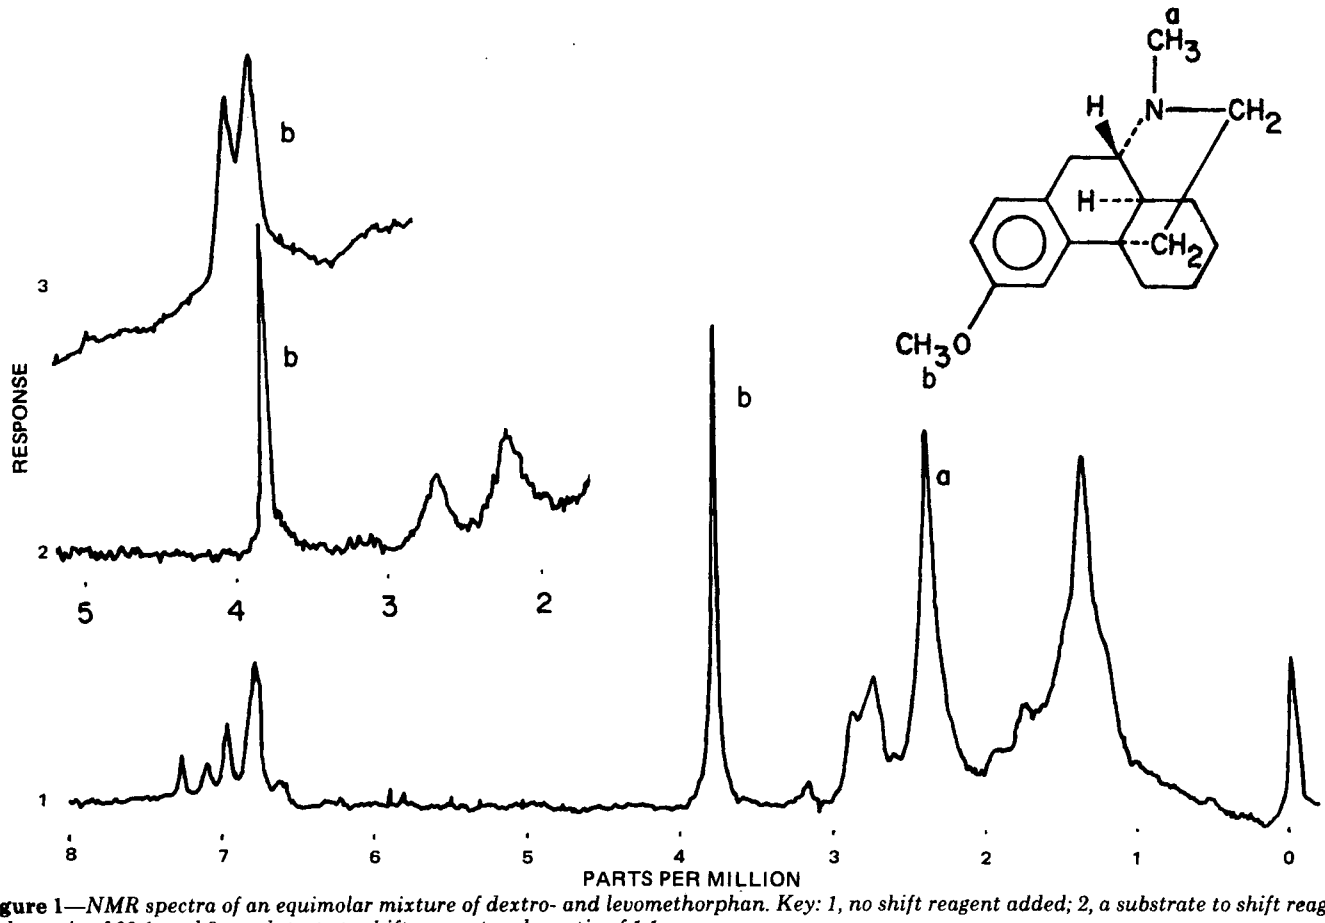

Figure 1—*NMR spectra of an equimolar mixture of dextro- and levomethorphan. Key: 1, no shift reagent added; 2, a substrate to shift reagent molar ratio of 80:1; and 3, a substrate to shift reagent molar ratio of 1:1.*

singlet associated with the N-methyl protons at 2.9 ppm broadened and disappeared at a substrate to reagent molar ratio of 80:1. This result suggests that the nitrogen atom is the site of pseudocontact or dipolar interaction between the methorphan and the shift reagent.

The induced shifts ($\Delta\delta$) and the enantiomeric shift differences ($\Delta\Delta\delta$) for the singlet due to the methoxy protons are shown in Figs. 2 and 3, respectively. The europium shift reagent had little effect on the spectra up to a substrate to shift reagent molar ratio of 8:3. Continued addition of the shift reagent shifted the signal associated with the *dextro*-isomer downfield while the signal associated with the *levo*-isomer remained relatively constant. The maximum resolution of the signals occurred at a substrate to reagent molar ratio of ~1:1. Beyond this point, peak broadening tended to collapse the peaks. The signal from the *dextro*-isomer was the one most affected by this broadening, with the result that the peak height associated with dextromethorphan was 85% of the corresponding peak height for levomethorphan at a 50:50 ratio of the two isomers.

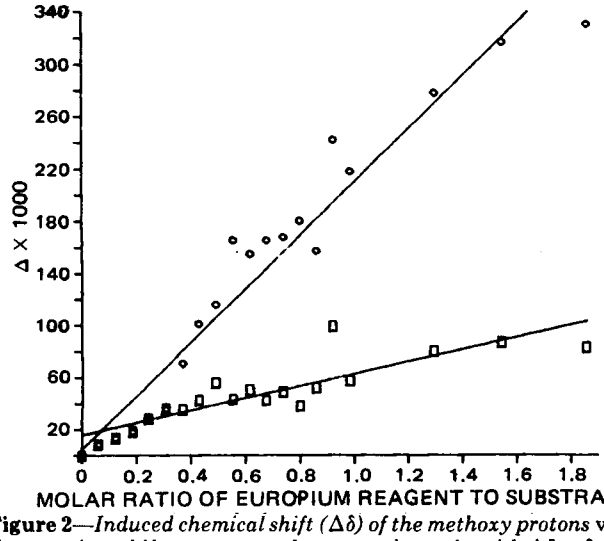

Figure 2—*Induced chemical shift ($\Delta\delta$) of the methoxy protons* versus *the europium shift reagent to substrate molar ratio, with $\Delta\delta = \delta t - \delta_0$, where δ_0 is the chemical shift of the initial signal and δt is the chemical shift of the signal after the addition of the shift reagent. Key:* ○, *dextromethorphan; and* □, *levomethorphan.*

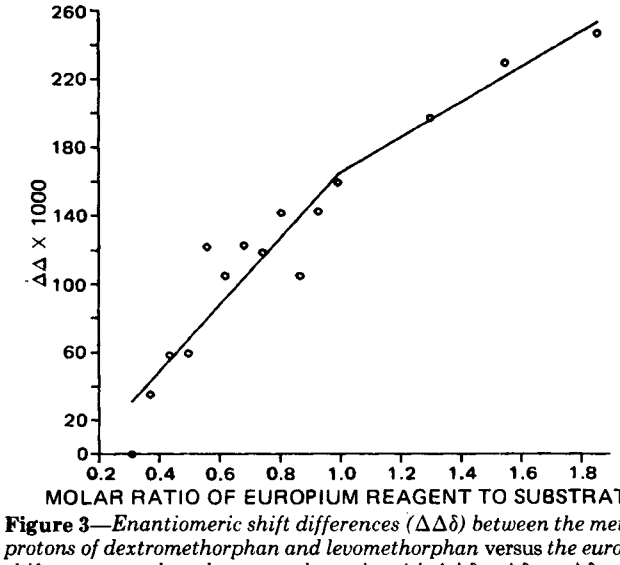

Figure 3—*Enantiomeric shift differences ($\Delta\Delta\delta$) between the methoxy protons of dextromethorphan and levomethorphan* versus *the europium shift reagent to the substrate molar ratio, with $\Delta\Delta\delta = \Delta\delta_D - \Delta\delta_L$, where $\Delta\delta_D$ is the induced chemical shift for the methoxy protons of dextromethorphan and $\Delta\delta_L$ is the induced chemical shift for the methoxy protons of levomethorphan.*

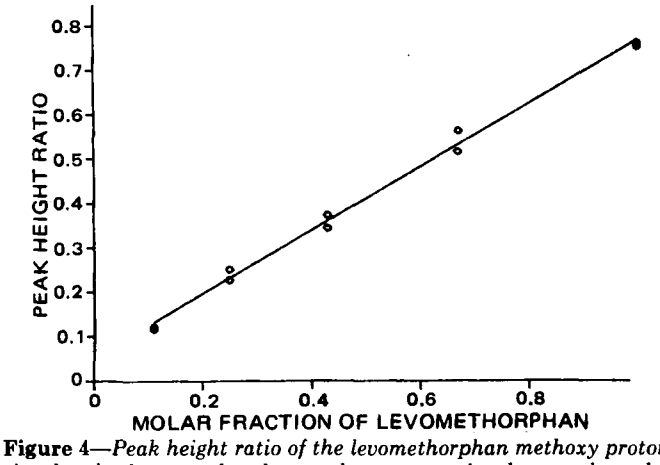

Figure 4—*Peak height ratio of the levomethorphan methoxy proton signal to the dextromethorphan methoxy proton signal* versus *the molar fraction of levomethorphan in dextromethorphan.*

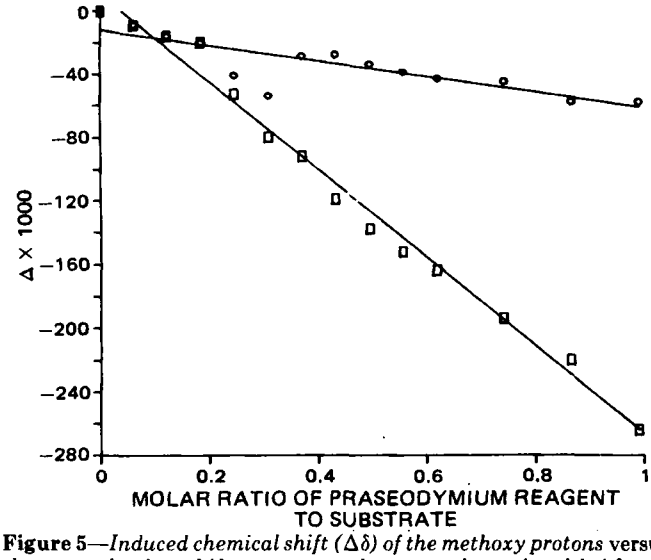

Figure 5—*Induced chemical shift ($\Delta\delta$) of the methoxy protons* versus *the praseodymium shift reagent to substrate molar ratio, with $\Delta\delta = \delta t - \delta_0$, where δ_0 is the chemical shift of the initial signal and δt is the chemical shift of the signal after the addition of the shift reagent. Key:* O, *levomethorphan; and* □, *dextromethorphan.*

The peak height ratios that correspond to prepared solutions of various molar ratios of the two enantiomers are shown in Fig. 4. The peak heights were determined by direct measurement to an adjusted baseline. The peak heights of shoulders were determined by dropping a vertical line to intersect the tangent of the slope of the larger peak. In this manner, as little as 10% of the *levo*-isomer could be estimated in the presence of the *dextro*-isomer. At this level, the signal associated with the *levo*-isomer appeared as a shoulder of the signal associated with the *dextro*-isomer, with a peak height of ~1:10.

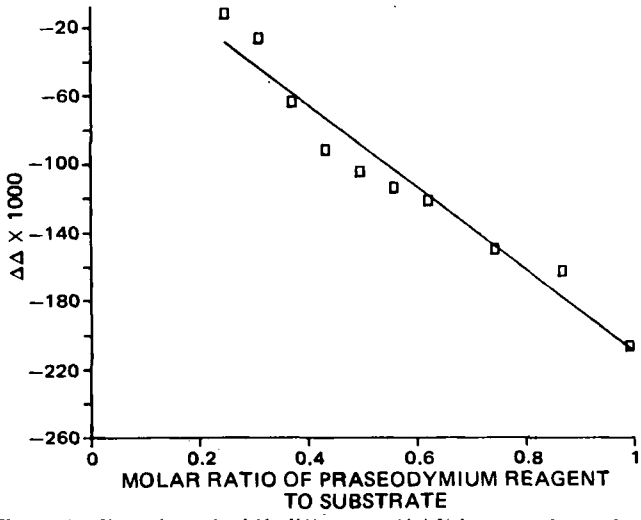

Figure 6—*Enantiomeric shift differences ($\Delta\Delta\delta$) between the methoxy protons of dextromethorphan and levomethorphan* versus *the praseodymium shift reagent to substrate molar ratio, with $\Delta\Delta\delta = \Delta\delta_D - \Delta\delta_L$, where $\Delta\delta_D$ is the induced chemical shift for the methoxy protons of dextromethorphan and $\Delta\delta_L$ is the induced chemical shift for the methoxy protons of levomethorphan.*

The induced shifts ($\Delta\delta$) and the enantiomeric shift differences ($\Delta\Delta\delta$) of the methoxy protons after the addition of the praseodymium reagent are shown in Figs. 5 and 6, respectively. The effects of this reagent on the spectra of the *dextro*- and *levo*-isomers were similar to those observed with the europium reagent, except that the signal associated with dextromethorphan was shifted upfield. The maximum resolution between the two methoxy signals occurred at a substrate to reagent molar ratio of 10:8. The peak height ratios associated with the various molar ratios of the two enantiomers also were similar to those determined with the europium shift reagent. However, the peak broadening associated with the praseodymium reagent was greater than that observed with the europium reagent, making the praseodymium reagent less sensitive as an analytical probe for the detection of one isomer in the presence of the other.

In conclusion, the chiral lanthanide shift reagents can be used to identify the enantiomers of methorphan. This method rapidly and accurately differentiates between dextromethorphan and levomethorphan, with detection and estimation of as little as 10% of one isomer in the presence of the other.

Potent Inhibition of Oxidative Phosphorylation by Marine Natural Products

DANA D. JAMIESON ˣ, PAUL J. de ROME, and KENNETH M. TAYLOR

Received June 29, 1979, from the *Roche Research Institute of Marine Pharmacology, Dee Why, New South Wales, 2099 Australia.* Accepted for publication October 22, 1979.

Abstract □ Many lipid-soluble extracts from various marine organisms have a nonspecific depressant effect on smooth muscle contractions. Novel compounds isolated from such lipid-soluble extracts were tested for their effects on the respiration of rat liver mitochondria and produced potent stimulation or inhibition of oxygen uptake by the mitochondria.

Keyphrases □ Oxidative phosphorylation—effect of marine natural products on mitochondrial respiration □ Adenosine diphosphate—stimulating and inhibitory effects on mitochondrial respiration by compounds from marine organisms, oxidative phosphorylation □ Depressants, smooth muscle—novel marine compounds □ Respiration, mitochondrial—effect of marine natural products

Der Marderosian (1) observed that marine organisms offered enormous potential for the development of new and different pharmaceuticals, and he cited examples of the pharmacological activities from marine sources known at that time. In addition, Der Marderosian stressed the difficulties in handling the crude extracts for biological screening and the problems inherent in the extraction and characterization of the compounds responsible for the biological activity. While research of marine natural products in pharmacology and microbiology has continued since that time, there has been little biochemical experimentation, and marine natural products have not been tested yet in the field of energy metabolism.

During routine screening of compounds isolated from marine organisms in these laboratories, it was observed that many compounds obtained from organic solvent extraction depressed the contractile activity of mammalian smooth muscle preparations. The most sensitive tissue to the inhibitory action was the isolated guinea pig ileum. The inhibition was nonspecific in that the contractions produced by acetylcholine, histamine, nicotine, and 5-hydroxytryptamine were affected equally. One possible mode of action of the compounds was inhibition of energy metabolism. Therefore, in the present experiments, the compounds were tested for their effects on oxygen uptake by isolated rat liver mitochondria.

EXPERIMENTAL

Mitochondria were prepared by homogenizing rat liver in 20 volumes of solution (pH 7.0) containing 225 m*M* mannitol, 75 m*M* sucrose, and 0.5 m*M* ethylenediaminetetraacetic acid using a polytef pestle and a glass tube. From the supernate obtained after centrifugation at 500×*g* for 5 min, the mitochondria were precipitated by centrifugation at 9000×*g* for 5 min. The mitochondrial pellet was washed twice by resuspension in the described solution, followed by centrifugation at 9000×*g* for 5 min. The washed mitochondrial pellet was resuspended in 2 ml of the preparation medium.

Mitochondrial respiratory activity was measured in a medium containing 225 m*M* mannitol, 75 m*M* sucrose, 20 m*M* tromethamine hydrochloride, and 10 m*M* monobasic potassium phosphate adjusted to pH 7.4. The reaction vessel was a 4-ml glass cell, and oxygen uptake was measured with a polytef-covered oxygen electrode connected to a pO_2 module and a pen recorder. The temperature was 23.5°. Additions to the mitochondrial suspension (2.5–3 mg of protein) were made with microsyringes through a rubber seal in the sidearm of the reaction vessel in a manner essentially the same as that described by Estabrook (2).

Because the compounds tested had low water solubility, they were dissolved in dimethyl sulfoxide to suitable dilutions such that 1–10 μl of solution was added to the reaction vessel. Control experiments showed that <50 μl of dimethyl sulfoxide had no effect on the oxygen uptake of the rat liver mitochondria. Protein determinations were carried out according to Lowry *et al.* (3). Results are expressed as micromoles of oxygen consumed per minute per milligram of protein.

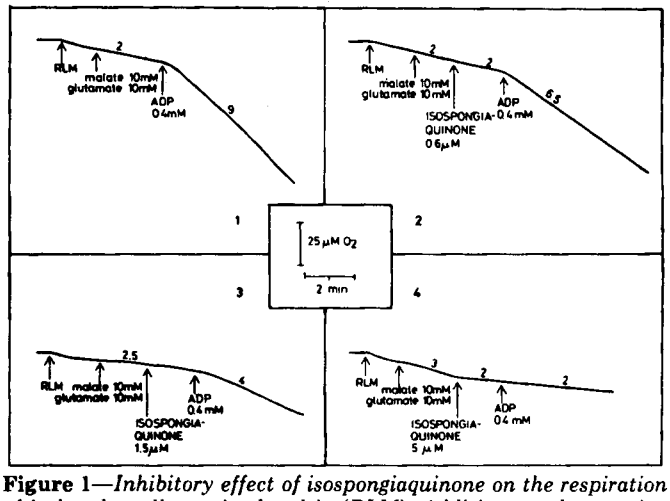

Figure 1—*Inhibitory effect of isospongiaquinone on the respiration of isolated rat liver mitochondria (RLM). Additions to the reaction vessel are as indicated, and numerals on the trace indicate micromoles of oxygen consumed per liter per minute per milligram of mitochondrial protein.*

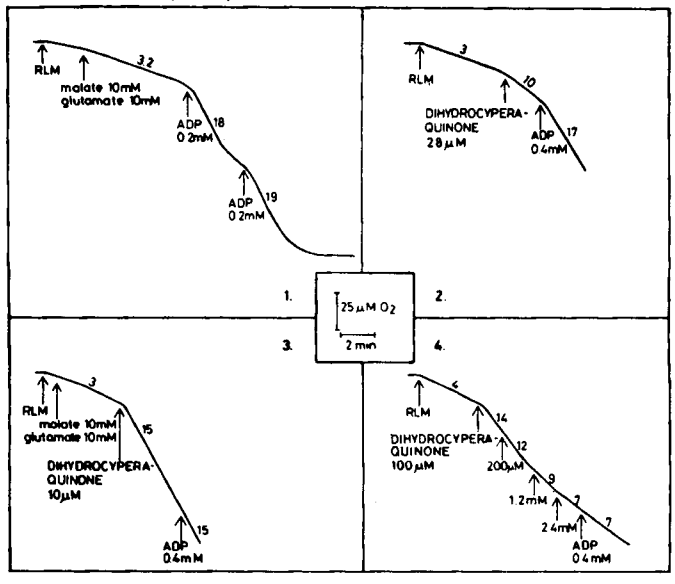

Figure 2—*Effect of dihydrocyperaquinone in stimulating the respiration of rat liver mitochondria (RLM). In Panel 4, increasing concentrations of dihydrocyperaquinone above 100 μM gradually decreased the initially stimulated respiration.*

After a steady State 4 respiration (4) was established with substrates of 10 mM malate and 10 mM glutamate, the test compound was added to the reaction vessel; adenosine diphosphate was added ~5 min later. Thus, the effects on both State 4 (resting, adenosine diphosphate-limited) and State 3 (active, adenosine diphosphate-stimulated) respiration were assessed in each trial. Each compound was tested at three or more concentrations on three batches of mitochondria to estimate an accurate concentration for doubling of State 4 respiration (*i.e.*, uncoupling action) or inhibition of the adenosine diphosphate-stimulated respiration to one-half of its control value.

RESULTS AND DISCUSSION

The chemical isolation and structural determinations of the compounds isolated from marine organisms in these laboratories have been reported, and the references are given in Table I. The structures of the tested compounds, the organisms from which the compounds were extracted, and the mean compound concentration required to produce doubling of oxygen uptake in mitochondria in State 4 (uncoupling effect) or 50% inhibition of oxygen uptake in State 3 respiration are summarized in Table I. The estimated effective potencies for each compound were very similar in the different mitochondrial batches.

Several compounds were very potent in either stimulating or inhibiting respiration. The most potent compounds were two closely related substances, isospongiaquinone and dihydroisospongiaquinone, extracted from a sponge of the family Spongiidae (5). Both compounds produced ~50% inhibition of State 3 respiration at 1 μM; at 5 μM, considerable depression of State 4 respiration also was seen. The effect of isospongiaquinone is illustrated in Fig. 1.

The most potent stimulant of State 4 respiration was dihydrocyperaquinone (6), which approximately doubled State 4 respiration at 4 μM. As the dihydrocyperaquinone concentration was increased, State 3 respiration gradually decreased, as is usual with compounds that uncouple oxidative phosphorylation. However, concentrations of 1 mM were needed to produce 50% inhibition of the State 3 respiration (Fig. 2).

Several other compounds showed mixed effects. The halogenated compounds costatol (7), heterocladol (13), and acetoxyfimbrolide (15) all showed mixed stimulation of State 4 and inhibition of State 3 respiration such that, while State 4 respiration could be approximately doubled at the concentrations shown in Table I, there was little or no further stimulation of respiration by adenosine diphosphate. As the concentration of these compounds was increased further, decreased stimulation of State 4 respiration was observed. However, such mixed effects on mitochondrial respiration were not always apparent with halogenated compounds. Filiformin and the pentabromopyrone from *Ptilonia australasica* (11) produced only inhibition with no uncoupling action.

While the precise site of action of these novel marine compounds in the respiratory chain is unknown, their nonselective inhibitory effects on smooth muscle preparations may be explained largely by the inhibition of electron transport or the uncoupling of oxidative phosphorylation (18, 19). In addition, compounds that uncouple oxidative phosphorylation affect the permeability of many excitable cells (20). Other enzyme systems also may be inhibited by these compounds because it was shown recently that several halogenated compounds isolated from red algae and from the sea hare *Aplysia dactylomela* prolonged pentobarbital-induced sleeping times and blood pentobarbital levels in mice, probably by inhibiting pentobarbital metabolism (21, 22).

Inhibition of *In Vitro* Cytochrome P-450-Catalyzed Reactions by Substituted Pyridines

JERRY L. BORN ˣ and WILLIAM M. HADLEY

Received August 29, 1979, from the *College of Pharmacy, University of New Mexico, Albuquerque, NM 87131.* Accepted for publication October 25, 1979.

Abstract □ A series of substituted pyridines was investigated as inhibitors of cytochrome P-450-catalyzed reactions. The relative potencies for the *in vitro* inhibition of aminopyrine demethylation and aniline hydroxylation are reported for a series of 2-, 3-, and 4-substituted pyridines.

Keyphrases □ Oxidation—cytochrome P-450, inhibition of *in vitro* metabolism of aniline and aminopyrine, effect of substituted pyridines on inhibition □ Aniline—hydroxylase activity, effect of substituted pyridines on *in vitro* aniline metabolism, cytochrome P-450 oxidation reactions □ Aminopyrine—demethylation activity, effect of substituted pyridines on *in vitro* aminopyrine metabolism, cytochrome P-450 oxidation reactions

Cytochrome P-450 is the terminal oxygenase responsible for the metabolism of many drugs and xenobiotics. Numerous pyridine-containing compounds such as metyrapone and ellipticine are known to inhibit cytochrome P-450-catalyzed reactions (1,2). It has been suggested that potent inhibitors of cytochrome P-450-catalyzed oxidations may be useful therapeutically in the prevention of chemical-induced cancer (2). Another potential use of cytochrome P-450 inhibitors is to increase the half-lives for drugs, thus increasing their therapeutic effectiveness.

The nonselective nature of the known inhibitors of cytochrome P-450-mediated reactions limits their therapeutic application. For example, metyrapone is used to inhibits steroid 11-β-hydroxylase, but it also is a potent inhibitor of many other cytochrome P-450 transformations (1, 3).

To develop leads in designing potent substrate-selective inhibitors of hepatic cytochrome P-450-catalyzed reactions, the ability of some simple pyridine compounds to inhibit the metabolism of aniline and aminopyrine was investigated.

EXPERIMENTAL

Male Sprague–Dawley rats were sacrificed by cervical dislocation, and their livers were excised and placed in ice-cold isotonic 1.15% KCl–tromethamine [tris(hydroxymethyl)aminomethane] buffer (0.1 *M*, pH 7.4). The following steps were performed at 0–4°. The liver was pressed through a tissue press, and the mince was weighed and homogenized[1] in three volumes of ice-cold isotonic potassium chloride–tromethamine buffer.

The homogenate was centrifuged for 20 min at 9000×*g* in an ultracentrifuge[2] using a No. 30 rotor. The supernate was withdrawn and centrifuged at 78,000×*g* for 60 min. Then the supernate was decanted, and the pellet was resuspended in tromethamine buffer so that 1 ml of buffer contained microsomes from 250 mg of liver. The protein content was determined using the method of Lowry *et al.* (4).

Aniline hydroxylase activity was determined by the analysis for *p*-hydroxyaniline. Metabolic reactions were run in 25-ml erlenmeyer flasks. The 5-ml reaction volume contained microsomal protein (10 mg), glucose-6-phosphate (30 μM), nicotinamide adenine dinucleotide phosphate (4 μM), magnesium chloride (50 μM), glucose-6-phosphate dehydrogenase (2 units), inhibitor in tromethamine buffer (pH 7.4), and substrate (1.09 μM) in buffer (pH 7.4). The reaction components, except the substrate, were preincubated for 5 min at 37° in a metabolic incubator under oxygen (flow rate >1000 ml/min) at 100 oscillations/min. Substrate then was added, and the reaction was incubated for 30 min. The production of *p*-hydroxyaniline was analyzed as described by Netter and Seidel (5).

Aminopyrine demethylation was determined by the analysis of formaldehyde. The 5-ml reaction volume contained the same cofactors used for aniline hydroxylation. The aminopyrine concentration was 8 m*M*. Formaldehyde was analyzed by the method of McMahon and Easton (6).

All samples were run in duplicate, and each experiment was repeated. The I_{50} values were calculated from three inhibitor concentrations.

All compounds were prepared by literature methods, and their physical constants corresponded to the literature values (7–9).

RESULTS AND DISCUSSION

The inhibition of aniline and aminopyrine metabolism by the substituted pyridines is shown in Table I. Inhibition of aniline metabolism was highly dependent on the position of substitution on pyridine. The 4-substituted pyridines were the most potent inhibitors of aniline metabolism, and the 3-substituted pyridines were more potent inhibitors than the 2-substituted pyridines. The presence of a hydroxyl group in the inhibitors lowered their ability to inhibit aniline metabolism. The decreased lipid solubility of the hydroxyl-substituted pyridines may be involved in their lower inhibitory activity.

Table I—Inhibition of *In Vitro* Metabolism of Aniline and Aminopyrine by Substituted Pyridines

Inhibitor	I_{50} of Aniline[a], M	I_{50} of Aminopyrine[b], M	$\frac{I_{50} \text{ of Aminopyrine}^c}{I_{50} \text{ of Aniline}}$
4-(*n*-Pentoxy)pyridine (I)	4.9×10^{-6}	1.1×10^{-4}	22.4
1-(4-Pyridyl)pentane (II)	5.3×10^{-6}	1.0×10^{-4}	18.9
1-(4-Pyridyl)pentanol (III)	1.1×10^{-5}	1.3×10^{-4}	11.8
1-(3-Pyridyl)pentane (IV)	9.6×10^{-5}	1.0×10^{-4}	10.4
1-(3-Pyridyl)pentanol (V)	1.6×10^{-4}	1.35×10^{-4}	0.8
1-(2-Pyridyl)pentane (VI)	3.6×10^{-4}	1.8×10^{-4}	0.5
1-(2-Pyridyl)pentanol (VII)	1.35×10^{-3}	2.7×10^{-4}	0.2

[a] Aniline concentration = 1.09 μM. [b] Aminopyrine concentration = 8 mM. [c] A ratio of >1 indicates that the compound is a more potent inhibitor of aniline hydroxylation than of aminopyrine demethylation.

Aminopyrine demethylation showed much less sensitivity to inhibition by the 4-substituted pyridines than did aniline hydroxylation. In each case, the pyridine compounds that contained an alcohol functional group were less potent inhibitors than the corresponding alkylpyridines. The magnitude of this effect was significantly less than that observed for inhibition of aniline metabolism. The most potent inhibitors of aminopyrine demethylation, 1-(4-pyridyl)pentane (II) and 1-(3-pyridyl)pentane (IV), were only 2.7 times as active as the least potent compound, 1-(2-pyridyl)pentanol (VII). A similar comparison of the most potent inhibitor of aniline hydroxylation, 4-(*n*-pentoxy)pyridine (I), and VII reveals a 275-fold difference in potency.

The most selective inhibitors of this series were the 4-substituted pyridines. Compound I was 22 times more potent an inhibitor of aniline hydroxylation than it was an inhibitor of aminopyrine demethylation. The differential in potency of inhibitors for the two substrates suggests that appropriate molecular modifications on pyridine compounds may produce substrate-selective inhibitors of cytochrome P-450 reactions.

Solid Dispersion of Morphine–Tristearin with Reduced Presystemic Inactivation in Rats

KEY S. CHANG and CHARLES I. JAROWSKI ˣ

Received June 15, 1979, from the *Department of Allied Health and Industrial Sciences, College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY 11439.* Accepted for publication October 24, 1979.

Abstract □ Solid dispersions of morphine in tristearin, β-sitosterol, and cholesterol were prepared by evaporation of their ethanol solutions. Weight ratios of morphine–lipid of 1:1, 1:3, and 1:4.5 were prepared. Dissolution studies of the solid dispersions and morphine were conducted in a simulated GI medium at 37°. The release rates of morphine from the tristearin dispersions were the slowest. The 1:1 morphine–tristearin dispersion was administered orally to rats. Free and total morphine levels in rat urine were determined by spectrofluorometric and enzymatic immunoassay procedures, respectively. The morphine–tristearin dispersion yielded a higher percentage of free morphine after 24 and 48 hr as compared with morphine and its sulfate.

Keyphrases □ Morphine–tristearin—solid dispersion, reduced presystemic inactivation, rats □ Analgesics—morphine, solid dispersion containing tristearin, reduced presystemic inactivation, rats □ Dissolution—morphine–tristearin solid dispersion, *in vitro*

Orally administered morphine produces a poorer analgesic response as compared with the parenteral route (1). In addition, the LD_{50} of orally administered morphine in rats was 905 ± 144 mg/kg, whereas it was 237 ± 6 mg/kg with the intravenous dose.

In the past, the major organ responsible for first-pass metabolism has been assumed to be the liver. Incubation of morphine with liver tissue was shown to result in inactivation (2). Although the drug-metabolizing capacity of the gut mucosa has been known for many years (3), the involvement of the intestinal wall in the biotransformation of opiates has been observed only recently (4). By using tritium-labeled morphine in rats, approximately two-thirds of the overall first-pass effect (82%) of morphine was estimated to be due to extraction and/or metabolism in the intestine and the remaining one-third occurs in the liver (5).

It was of interest to determine if solid dispersions of morphine in lipids might reduce the extent of first-pass inactivation after oral administration. It was demonstrated previously (6) that orally administered progesterone gave higher blood levels when the hormone was solvent deposited on lactose as a solid solution with cholesterol or its acetate ester. Patel and Jarowski (7) reported that urinary excretion of unmetabolized salicylate was increased when

Solid Dispersion of Morphine–Tristearin with Reduced Presystemic Inactivation in Rats

KEY S. CHANG and CHARLES I. JAROWSKI ˣ

Received June 15, 1979, from the *Department of Allied Health and Industrial Sciences, College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY 11439.* Accepted for publication October 24, 1979.

Abstract □ Solid dispersions of morphine in tristearin, β-sitosterol, and cholesterol were prepared by evaporation of their ethanol solutions. Weight ratios of morphine–lipid of 1:1, 1:3, and 1:4.5 were prepared. Dissolution studies of the solid dispersions and morphine were conducted in a simulated GI medium at 37°. The release rates of morphine from the tristearin dispersions were the slowest. The 1:1 morphine–tristearin dispersion was administered orally to rats. Free and total morphine levels in rat urine were determined by spectrofluorometric and enzymatic immunoassay procedures, respectively. The morphine–tristearin dispersion yielded a higher percentage of free morphine after 24 and 48 hr as compared with morphine and its sulfate.

Keyphrases □ Morphine–tristearin—solid dispersion, reduced presystemic inactivation, rats □ Analgesics—morphine, solid dispersion containing tristearin, reduced presystemic inactivation, rats □ Dissolution—morphine–tristearin solid dispersion, *in vitro*

Orally administered morphine produces a poorer analgesic response as compared with the parenteral route (1). In addition, the LD_{50} of orally administered morphine in rats was 905 ± 144 mg/kg, whereas it was 237 ± 6 mg/kg with the intravenous dose.

In the past, the major organ responsible for first-pass metabolism has been assumed to be the liver. Incubation of morphine with liver tissue was shown to result in inactivation (2). Although the drug-metabolizing capacity of the gut mucosa has been known for many years (3), the involvement of the intestinal wall in the biotransformation of opiates has been observed only recently (4). By using tritium-labeled morphine in rats, approximately two-thirds of the overall first-pass effect (82%) of morphine was estimated to be due to extraction and/or metabolism in the intestine and the remaining one-third occurs in the liver (5).

It was of interest to determine if solid dispersions of morphine in lipids might reduce the extent of first-pass inactivation after oral administration. It was demonstrated previously (6) that orally administered progesterone gave higher blood levels when the hormone was solvent deposited on lactose as a solid solution with cholesterol or its acetate ester. Patel and Jarowski (7) reported that urinary excretion of unmetabolized salicylate was increased when

salicylic acid was given to humans as a solid solution in cholesteryl *n*-decylate.

This investigation concerned the *in vitro* dissolution rate of morphine (I) from solid dispersions containing cholesterol (II), β-sitosterol (III), or tristearin (IV). Based on the *in vitro* data, a candidate was selected for an *in vivo* study in rats. Measurement of the urinary excretion and its biologically inactive glucuronide showed whether first-pass inactivation was reduced.

EXPERIMENTAL

Materials—The following materials were obtained commercially: morphine[1], morphine sulfate pentahydrate[1], cholesterol[2], β-sitosterol[3], tristearin[4], absolute ethanol[5] (ACS), chloroform[5] (ACS), isopropanol[5] (ACS), hydrochloric acid[5] (ACS), sodium hydroxide[5] (ACS), citric acid monohydrate[6] (laboratory grade), potassium chloride[5] (ACS), monobasic potassium phosphate[5] (ACS), boric acid[5] (ACS), dibasic anhydrous sodium phosphate[5] (ACS), ammonium hydroxide[5] (ACS), opiate antibody reagent[7] (Reagent A), opiate enzyme immunoassay reagent[7] (Reagent B), bacterial suspension[7], buffer[7], and laboratory chow[8].

Equipment—The following equipment was used: a differential scanning calorimeter with a recorder[9], a turret spectrofluorometer with a Servo recorder[10], a dissolution basket stirrer[11], a grating spectrophotometer with digital display[12], a microsample spectrophotometer with thermal control[13], a gyrotory incubator shaker[14], a zeromatic pH meter[12], a polytherm water bath with thermal control[15], U.S. standard sieve No. 60[16], a Swinny adaptor[17] (13 mm), a filter disk[17] (13 mm, 0.45 μm), a medium porosity sintered-glass filter[18] (ASTM 10–15 M), and polycarbonate metabolism units[19].

Preparation of Morphine–Lipid Solid Dispersions—Powdered morphine base (1 g) was blended with powdered lipid (cholesterol, β-sitosterol, or tristearin) in drug–lipid ratios of 1:1, 1:3, and 1:4.5. The blend was dissolved in sufficient absolute ethanol (~300 ml). The solutions were magnetically stirred while the solvent was evaporated in a gentle stream of air. The residue was dried to constant weight at 37°, passed through a 60-mesh sieve, and manually bottle blended. Portions of the blended material were assayed for morphine. Only those samples assaying 100 ± 5% were used in the dissolution study.

Differential Scanning Calorimetry—Thermal analyses were performed on the 1:1 ratio of morphine–tristearin, morphine, and tristearin using a differential scanning calorimeter. Aluminum pans and lids were used for all samples. Studies were conducted from 20 to 300° with nitrogen as the effluent gas (20 ml/min). Temperature calibrations were made using indium (156.6°) and tin (231.9°) as standards with scanning speeds of 10°/10 mm/min (morphine–tristearin and morphine) and 10°/5 mm/min (tristearin). The transition temperature was determined by extrapolating a linear portion of the leading edge of the endothermic peak to the baseline.

Spectrophotometric Absorption and Calibration Curves for Morphine in Selected Solvent Systems—Absorption spectral curves for morphine base (100 μg/ml) in four solvent systems were drawn. The absorption maxima were 288 nm for ethanol and 286 nm for distilled water and simulated gastric and intestinal fluids. The morphine concentration in these solvent systems obeyed Beer's law. Incorporation of the three lipids did not alter the absorbance values for morphine.

Dissolution Studies—The dissolution procedure was described previously (8). It was established that 144 mg of morphine forms a saturated solution in 500 ml of distilled water at 37°. Consequently, sink conditions were maintained since only 30 mg of morphine equivalent was used in the dissolution studies in simulated gastric fluid (without pepsin) and simulated intestinal fluid (without pancreatin). A basket speed of 50 rpm was used for all samples.

Morphine stability in simulated gastric fluid was excellent for 72 hr at 37° (absorbance increase of 0.42%). However, in simulated intestinal fluid, a similar absorbance increase was seen after 2 hr; after 24 hr, the absorbance increase was 3.74%. Five-milliliter aliquots were withdrawn at 15, 30, 60, 90, 120, and 150 min by a pipet adapted with a sintered-glass filter (medium porosity). The dissolution medium volume (500 ml) was maintained by replacement of 5-ml aliquots of preheated simulated GI fluids.

The dissolution data are shown in Table I. Each data point represents the average of two readings. Concentrations were corrected by taking into account the amount of morphine discarded in prior 5-ml aliquots.

Morphine Bioavailability in Rats—Eight male Sprague–Dawley rats, 350–450 g, were allowed free access to water and laboratory food. An aqueous vehicle was used for the oral intubation of morphine, morphine sulfate, and morphine–tristearin (1:1). The aqueous vehicle contained methylcellulose 4000 (0.4%), benzyl alcohol (0.9%), polysorbate 80 (0.5%), and sodium chloride (0.9%). Each rat was placed in individual metabolism cages, and each animal served as its own control.

The dosing volume employed for the solution (morphine sulfate) or the suspensions (morphine or morphine–tristearin) was 3.5–4.5 ml/kg. The morphine equivalent administered was 15 mg/kg. Blank urine was collected for 24 hr after oral administration of the placebo vehicle. After oral administration of one morphine candidate, 24-hr urine samples were collected over 4 days. All samples were frozen immediately.

Aliquots of each 24-hr urinary collection were proportionally pooled and filtered through a 0.45-μm filter disk. Proportional pooling was necessary to provide adequate urine volumes for the assays. The filtered urine was diluted 1:10 with distilled water and assayed for free and total morphine. Weekly intervals were maintained between experiments.

Total Morphine Assay in Rat Urine (9)—The proportionally pooled

Table II—Percent of Free and Total Morphine Recovered from the Urine of Rats Given 15 mg of Morphine Equivalent/kg Orally

Drug	Percent Recovered in 24 hr		Percent Recovered in 48 hr		Percent Recovered in 72 hr	
	Free	Total	Free	Total	Free	Total
Morphine sulfate	23.80	40.46	39.66	61.71	—	71.07
Morphine	21.31	25.57	30.90	35.43	—	38.84
Morphine–tristearin (1:1)	32.45	36.35	45.82	51.63	—	55.44

urine from the eight rats that had been diluted with distilled water was treated with 1 *N* HCl or NaOH if the pH was outside the 5.5–8 range. Fifty microliters of the diluted urine sample was added to 250 μl of buffer. Fifty microliters of the morphine antibody (Reagent A) was added followed by 50 μl of the enzyme-labeled morphine (Reagent B).

The reaction mixture (1.1 ml) was aspirated into a spectrophotometer, which automatically activated the enzymatic immunoassay printer. After a 10-sec delay for thermal equilibration, the initial absorbance was printed. After an additional 40 sec, a second absorbance was measured and recorded, followed by a printing of the differences between these values. The amount of morphine in the urine sample was determined by reference to a standard curve. The data points in the standard curve were determined by applying the identical assay on pooled blank urines spiked with known quantities of morphine. The results are summarized in Table II.

Free Morphine Assay in Rat Urine (10)—Two milliliters of the diluted urine sample was transferred to a 15-ml borosilicate glass-stoppered centrifuge tube. The pH of the solution was adjusted between 9 and 10 with 3.7 *N* NH_4OH. Four milliliters of chloroform–isopropanol (3:1 v/v) was added, and the mixture was shaken manually for 60 sec. The organic layer was evaporated to dryness on a water bath at 85° under a stream of air, and the residue was dried in an oven at 100° for 10 min. Concentrated sulfuric acid (0.1 ml) was added to the residue and mixed. One milliliter of distilled water was added, followed by 1 ml of concentrated ammonium hydroxide. After thorough shaking, the samples were autoclaved for 15 min at 120° at 15–18 psi.

The solution was transferred to a 7 × 150-mm round, borosilicate glass cell, and its fluorescence was determined in an automated turret spectrofluorometer using a No. 4-77 filter in combination with a 410-nm interference filter. This filter combination provided an excitation wavelength maximum at 392 nm with an emission wavelength maximum at 425 nm.

The spectrofluorometer was equipped with an 85-w high-intensity mercury vapor lamp, quartz lenses, and 0.2-mm slits. Sample readings were recorded in 20 sec. The emission monochromator drum dial was set at 410 nm, and all samples were scanned to 510 nm.

The recorded curve was cut out and weighed. Its concentration then could be determined from a standard curve prepared by plotting concentration *versus* curve weight. The standard solutions were prepared by diluting a stock solution of morphine in pooled, blank rat urine (100 μg/ml) with distilled water. These solutions were assayed spectrofluorometrically as described, and the recorded curves were cut out and weighed.

RESULTS

The thermograms for morphine and morphine–tristearin revealed that the melting point of morphine base was not significantly lowered in the presence of an equal weight of tristearin. A similarity in the transition temperature of morphine–tristearin indicated the presence of crystalline morphine base in the solid dispersion. The slope ratios of the endothermic peaks for morphine and morphine–tristearin were coincident. This result indicates that essentially no morphine decomposition occurred during the preparation of the solid dispersion (11). The thermograms showed no evidence for the existence of polymorphic forms.

On the basis of the dissolution data in Table I, the solid dispersion of morphine–tristearin (1:1) was selected for the *in vivo* study in rats. Only 37% of the morphine in this solid dispersion had dissolved in 150 min, whereas 53.9% of morphine base alone had dissolved in 15 min. The more dilute dispersions (1:3 and 1:4.5) were not considered in the interest of using as little tristearin as possible.

Dissolution studies in simulated gastric fluid were conducted with a larger morphine equivalent (250 mg) since the 30-mg equivalent dissolved too rapidly. As expected, the dissolution of morphine base was essentially complete in 15 min. Solid dispersions of morphine in cholesterol or β-sitosterol were ineffective in altering the morphine dissolution rate.

The *in vivo* results in Table II indicate that a reduction in first-pass inactivation was achieved by the administration of morphine base or its 1:1 solid dispersion in tristearin. Thus, at the end of 24 hr, 58.8% of the total morphine recovered was unmetabolized when morphine sulfate was administered orally. After the base was administered, 83.3% of the total morphine recovered was unmetabolized. Oral administration of the 1:1 solid dispersion yielded 89.3% of unmetabolized morphine. The recovery data after 72 hr reveal that the rank order in free morphine collected was solid dispersion > morphine sulfate > morphine base. Oral administration of morphine sulfate yielded the largest values for total morphine at the three time intervals studied. On the other hand, the percentage of free morphine was highest at all time intervals after oral administration of the 1:1 solid dispersion.

Oguri *et al.* (12) reported that after 30 mg of morphine equivalent/kg was administered subcutaneously to rats, free urinary morphine recovered during 24 hr amounted to 19.5% of the dose; total morphine conjugate recovered during this time was 3.5% of the dose. The higher percentage of free morphine recovered by this administration route is not surprising since intestinal wall enzymatic inactivation is significantly bypassed. The reduced total recovery was attributed to biliary excretion of morphine and its conjugates by the rat.

Cochin *et al.* (13) reported that urinary free morphine recovered during 24 hr after an oral dose of morphine sulfate (30 mg/kg) was given to dogs ranged from 10 to 15%; morphine conjugates recovered during this period ranged from 60 to 70%. Yeh *et al.* (14) administered morphine hydrochloride subcutaneously to cats (morphine equivalent of 20 mg/kg). During the first 48 hr after dosing, urinary recovery of free morphine amounted to 19.2 ± 1.5%; morphine conjugates recovered during this period amounted to 48.4 ± 2.4% of the dose.

The following explanation is proposed for the interesting results obtained with the 1:1 morphine–tristearin dispersion. Release of morphine from the lipid dispersion occurs more efficiently beyond the pylorus where contact is made with the fat-emulsifying bile secretions. Inhibition of the intestinal wall enzymes by the emulsified lipid component permits a portion of the simultaneously released morphine molecules to evade inactivation partially. Two-thirds of the total morphine inactivation in rats occurs in the gut wall and one-third occurs in the liver (5).

The lesser recovery of total morphine from the morphine–tristearin solid dispersion as compared with morphine sulfate was not unexpected in view of the slow dissolution rate of the former substance in simulated GI media. The superior oral absorption efficiency of morphine from the solid dispersion as compared with morphine base may be the result of smaller drug particle size in the solid dispersion. The facile *in vivo* absorption of a neutral lipid molecule such as tristearin may expose finely divided morphine base molecules for rapid dissolution and absorption.

The reduction in first-pass inactivation should stimulate further research on the use of lipid dispersions with drugs enzymatically inactivated after oral administration.

Identification of Degradation Products in a Phenylbutazone Tablet Formulation

F. MATSUI ˣ, D. L. ROBERTSON, M. A. POIRIER, and E. G. LOVERING

Received April 27, 1979, from the *Drug Research Laboratories, Health Protection Branch, Tunney's Pasture, Ottawa, Ontario, Canada, K1A 0L2.* Accepted for publication October 24, 1979.

Abstract □ Two previously reported but unidentified phenylbutazone degradation products were isolated from a tablet that was stored at 60° for 203 days. The compounds, α-(*N*-phenylcarbamoyl)-*N*-caproylhydrazobenzene and α-hydroxy-α-(*N*-phenylcarbamoyl)-*N*-caproylhydrazobenzene, were isolated by chromatography, identified by mass and NMR spectrometry, and synthesized by the reaction of aniline with phenylbutazone or its hydroxy analog, respectively.

Keyphrases □ Phenylbutazone—tablets, identification of degradation products □ Anti-inflammatory agents—phenylbutazone, tablets, identification of degradation products □ Degradation products—phenylbutazone, tablets, identification

In a recent study on the stability of phenylbutazone formulations under stress conditions (1), one formulation (G) was found to contain one or more compounds previously unidentified in degradation of the drug. These compounds are α-(*N*-phenylcarbamoyl)-*N*-caproylhydrazobenzene (I) and α-hydroxy-α-(*N*-phenylcarbamoyl)-*N*-caproylhydrazobenzene (II). This paper describes the isolation, identification, and synthesis of I and II.

EXPERIMENTAL

Materials—Tablets of Formulation G (1) were obtained directly from the manufacturer. Phenylbutazone[1] (*III*), cyclohexane[2], chloroform[2], methanol[2], ethyl acetate[2], and acetic acid[3] were used as received. Phenyl phthalate[4] was recrystallized from acetone[2]–water, and 1,2-diphenyl-4-*n*-butyl-4-hydroxypyrazolidine-3,5-dione (IV) was prepared by the method described previously (1, 2). TLC plates[5] precoated with silica gel G-60 F-254, 60–200-mesh silica gel[6], diatomaceous earth[7], and nylon tubing[8] were used.

Equipment—The gas chromatograph[9] was equipped with a flame-ionization detector and a U-shaped glass column packed with 5% OV-7 on Gas Chrom Q[7] (100–120 mesh). NMR spectra were obtained on a 90-MHz instrument[10]; chemical shifts are reported in parts per million from tetramethylsilane, the internal standard. All spectra were recorded in deuterated chloroform[11] ($CDCl_3$). Mass spectra[12] were recorded at an ionizing potential of 70 ev, and the samples were introduced *via* the direct probe at 120 and 130°. Accurate mass measurements were made by the peak matching technique.

TLC Solvent System A (3) consisted of cyclohexane–chloroform–methanol–acetic acid (60:30:5:5), and Solvent System B was chloroform–ethyl acetate (80:20). Filter paper-lined TLC tanks were equilibrated with the solvent system for 30 min prior to use. Spots were visualized by UV light at 254 nm and by spraying with a solution of 0.5% potassium dichromate in 20% (v/v) H_2SO_4.

Isolation of Degradation Products from Formulation G—Five tablets (equivalent to 500 mg of phenylbutazone), which had been stored for 203 days at 60°, were finely powdered, wetted with ethyl acetate, and triturated with 2 g of diatomaceous earth until the mixture was uniform. The triturate was placed at the top of a nylon column containing 200 g of 60–200-mesh silica gel, which had been deactivated with 30 ml of water and dry packed into a 0.03 × 1-m nylon column. A 500-ml solution of Solvent System A was added until the solvent front reached the bottom of the column. The tube was incised into 5-cm sections, and the location of each compound on the column was established by removing small portions of the silica gel from the different incised sections of the nylon tube, extracting these portions with ethyl acetate, and spotting aliquots directly onto a TLC plate.

The spots were visualized with the potassium dichromate spray, and the spots containing the components of interest immediately developed a bright-purple color. The sections of interest then were cut; the degradation products were extracted from the silica gel with ethyl acetate, concentrated under nitrogen, and rechromatographed on a TLC plate using Solvent System A to remove residual phenylbutazone. The R_f values of I, II, and III in this system were 0.37, 0.37, and 0.43, respectively.

The band containing the mixture of I and II was visualized by spraying the edges of the TLC plate with dichromate spray. The band was scraped off and extracted with ethyl acetate, and the eluate was reduced to a small volume under nitrogen. Resolution of I and II was effected by TLC using Solvent System B. Isolation was carried out by elution with ethyl acetate and evaporation under nitrogen. The R_f values of I, II, and III using Solvent System B were 0.56, 0.50, and 0.58, respectively.

Syntheses—*Compound I*—A solution of 308 mg (1 mmole) of III and 180 mg of aniline (100% excess) in 15 ml of chloroform was heated under nitrogen at 45° for 48 hr in a culture tube. Compound I was separated from unreacted phenylbutazone by TLC (System A), and the spot was scraped from the plate and eluted with ethyl acetate. Traces of II were removed by subsequent TLC using Solvent System B. Crystallization from ethanol–water (90:10) gave pure I, mp 197–199°; NMR ($CDCl_3$): δ 8.9 (s, NH), 8.5 (s, CONH), 7.4–6.8 (m, 15H, aromatic), 4.2 (t, CH), 2.0, 1.5, and 0.87 (*n*-butyl) ppm; mass spectrum (70 ev, 120°): *m/e* 401 (M^+ 5.3%), 307 (7.1), 218 (12.5), 184 (48.1), 148 (13.1), 120 (18.1), 93 (100), and 77 (72.3). The GLC[13] retention time was 11.0 min or 0.92 relative to the internal standard, phenyl phthalate.

Compound II—Compound II was prepared from 1,2-diphenyl-4-*n*-butyl-4-hydroxypyrazoline-3,5-dione (IV) by the procedure described for the synthesis of I. Compound II also can be obtained from III by carrying out the reaction under an oxygen atmosphere. After purification by TLC, crystallization from ethanol–water (90:10) yielded II, mp

Identification of Degradation Products in a Phenylbutazone Tablet Formulation

F. MATSUI ˣ, D. L. ROBERTSON, M. A. POIRIER, and E. G. LOVERING

Received April 27, 1979, from the *Drug Research Laboratories, Health Protection Branch, Tunney's Pasture, Ottawa, Ontario, Canada, K1A 0L2.* Accepted for publication October 24, 1979.

Abstract □ Two previously reported but unidentified phenylbutazone degradation products were isolated from a tablet that was stored at 60° for 203 days. The compounds, α-(*N*-phenylcarbamoyl)-*N*-caproylhydrazobenzene and α-hydroxy-α-(*N*-phenylcarbamoyl)-*N*-caproylhydrazobenzene, were isolated by chromatography, identified by mass and NMR spectrometry, and synthesized by the reaction of aniline with phenylbutazone or its hydroxy analog, respectively.

Keyphrases □ Phenylbutazone—tablets, identification of degradation products □ Anti-inflammatory agents—phenylbutazone, tablets, identification of degradation products □ Degradation products—phenylbutazone, tablets, identification

In a recent study on the stability of phenylbutazone formulations under stress conditions (1), one formulation (G) was found to contain one or more compounds previously unidentified in degradation of the drug. These compounds are α-(*N*-phenylcarbamoyl)-*N*-caproylhydrazobenzene (I) and α-hydroxy-α-(*N*-phenylcarbamoyl)-*N*-caproylhydrazobenzene (II). This paper describes the isolation, identification, and synthesis of I and II.

EXPERIMENTAL

Materials—Tablets of Formulation G (1) were obtained directly from the manufacturer. Phenylbutazone[1] (*III*), cyclohexane[2], chloroform[2], methanol[2], ethyl acetate[2], and acetic acid[3] were used as received. Phenyl phthalate[4] was recrystallized from acetone[2]–water, and 1,2-diphenyl-4-*n*-butyl-4-hydroxypyrazolidine-3,5-dione (IV) was prepared by the method described previously (1, 2). TLC plates[5] precoated with silica gel G-60 F-254, 60–200-mesh silica gel[6], diatomaceous earth[7], and nylon tubing[8] were used.

Equipment—The gas chromatograph[9] was equipped with a flame-ionization detector and a U-shaped glass column packed with 5% OV-7 on Gas Chrom Q[7] (100–120 mesh). NMR spectra were obtained on a 90-MHz instrument[10]; chemical shifts are reported in parts per million from tetramethylsilane, the internal standard. All spectra were recorded in deuterated chloroform[11] ($CDCl_3$). Mass spectra[12] were recorded at an ionizing potential of 70 ev, and the samples were introduced *via* the direct probe at 120 and 130°. Accurate mass measurements were made by the peak matching technique.

TLC Solvent System A (3) consisted of cyclohexane–chloroform–methanol–acetic acid (60:30:5:5), and Solvent System B was chloroform–ethyl acetate (80:20). Filter paper-lined TLC tanks were equilibrated with the solvent system for 30 min prior to use. Spots were visualized by UV light at 254 nm and by spraying with a solution of 0.5% potassium dichromate in 20% (v/v) H_2SO_4.

Isolation of Degradation Products from Formulation G—Five tablets (equivalent to 500 mg of phenylbutazone), which had been stored for 203 days at 60°, were finely powdered, wetted with ethyl acetate, and triturated with 2 g of diatomaceous earth until the mixture was uniform. The triturate was placed at the top of a nylon column containing 200 g of 60–200-mesh silica gel, which had been deactivated with 30 ml of water and dry packed into a 0.03 × 1-m nylon column. A 500-ml solution of Solvent System A was added until the solvent front reached the bottom of the column. The tube was incised into 5-cm sections, and the location of each compound on the column was established by removing small portions of the silica gel from the different incised sections of the nylon tube, extracting these portions with ethyl acetate, and spotting aliquots directly onto a TLC plate.

The spots were visualized with the potassium dichromate spray, and the spots containing the components of interest immediately developed a bright-purple color. The sections of interest then were cut; the degradation products were extracted from the silica gel with ethyl acetate, concentrated under nitrogen, and rechromatographed on a TLC plate using Solvent System A to remove residual phenylbutazone. The R_f values of I, II, and III in this system were 0.37, 0.37, and 0.43, respectively.

The band containing the mixture of I and II was visualized by spraying the edges of the TLC plate with dichromate spray. The band was scraped off and extracted with ethyl acetate, and the eluate was reduced to a small volume under nitrogen. Resolution of I and II was effected by TLC using Solvent System B. Isolation was carried out by elution with ethyl acetate and evaporation under nitrogen. The R_f values of I, II, and III using Solvent System B were 0.56, 0.50, and 0.58, respectively.

Syntheses—*Compound I*—A solution of 308 mg (1 mmole) of III and 180 mg of aniline (100% excess) in 15 ml of chloroform was heated under nitrogen at 45° for 48 hr in a culture tube. Compound I was separated from unreacted phenylbutazone by TLC (System A), and the spot was scraped from the plate and eluted with ethyl acetate. Traces of II were removed by subsequent TLC using Solvent System B. Crystallization from ethanol–water (90:10) gave pure I, mp 197–199°; NMR ($CDCl_3$): δ 8.9 (s, NH), 8.5 (s, CONH), 7.4–6.8 (m, 15H, aromatic), 4.2 (t, CH), 2.0, 1.5, and 0.87 (*n*-butyl) ppm; mass spectrum (70 ev, 120°): *m/e* 401 (M^+ 5.3%), 307 (7.1), 218 (12.5), 184 (48.1), 148 (13.1), 120 (18.1), 93 (100), and 77 (72.3). The GLC[13] retention time was 11.0 min or 0.92 relative to the internal standard, phenyl phthalate.

Compound II—Compound II was prepared from 1,2-diphenyl-4-*n*-butyl-4-hydroxypyrazoline-3,5-dione (IV) by the procedure described for the synthesis of I. Compound II also can be obtained from III by carrying out the reaction under an oxygen atmosphere. After purification by TLC, crystallization from ethanol–water (90:10) yielded II, mp

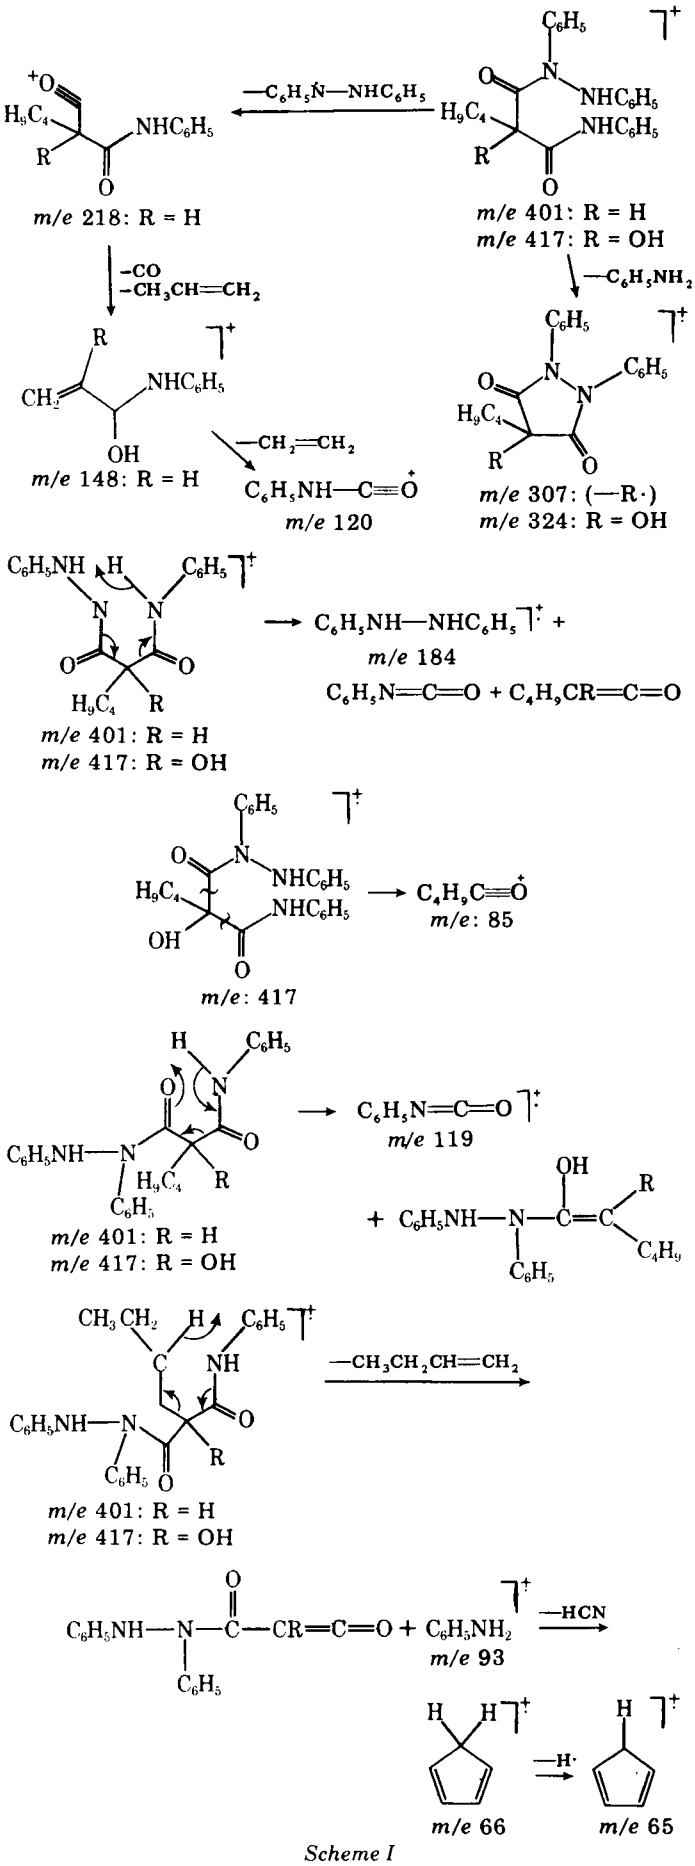
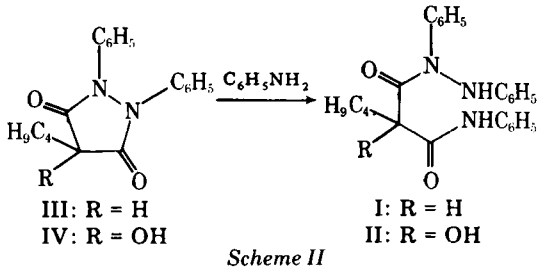


Scheme I



Scheme II

175–176°; NMR ($CDCl_3$): δ 9.4 (s, NH), 9.0 (s, CONH), 7.5–7.2 (m, 15H, aromatic), 5.4 (broad, OH), 2.0, 1.2, and 0.70 (*n*-butyl) ppm; mass spectrum (70 ev, 130°): *m/e* 417 (M^+ 10.3%), 324 (11.5), 207 (12.7), 184 (100), 164 (16.5), 119 (13.4), 93 (89.5), 85 (28.3), 81 (14.2), and 77 (77.3). The GLC[13] retention time was 11.0 min or 0.92 relative to the internal standard, phenyl phthalate.

RESULTS AND DISCUSSION

The mass spectra of I and II contained major peaks at *m/e* 401 (5.3%) and 417 (10.3), respectively, corresponding to their molecular ions. The possible fragmentation patterns of I and II are presented in Scheme I. The mass spectra of I and II differ from those of their respective precursors, III and IV (2, 5), in that they exhibit major losses of aniline at *m/e* 93 (100 and 90%, respectively), indicating the presence of open-ring compounds. The loss of aniline seems to occur with ring closure in the mass spectrometer, giving ions at *m/e* 307 (7.1%) and 324 (11.5). Most fragments in the mass spectrum can be rationalized by McLafferty rearrangements (5, 6).

The most common ions in the mass spectra of pyrazolidinediones are the series of peaks at 183, 184, and 185, which are characteristic of hydrazobenzene fragments. The ion at *m/e* 184 may originate from the molecular ions of I or II by a McLafferty rearrangement with a loss of phenyl isocyanate. A characteristic fragment in pyrazolidinediones is the loss of phenyl isocyanate as a neutral molecule or as an ion at *m/e* 119 (5.1% for I and 13.4% for II). The formation of the fragment at *m/e* 184 in the mass spectra of I and II is rationalized by a proton transfer from the anilide portion (2). The formation of the ion at *m/e* 85 in II, attributable to (C_4H_9–C≡O$^+$), indicates the presence of the hydroxyl group at carbon 4.

The NMR spectra of I and II in deuterochloroform showed two singlets due to NH protons at δ 8.9 and 8.5 and 9.4 and 9.0 ppm, respectively. One of these NH signals corresponds to an amide function. This assignment is supported by the chemical shifts and by the fact that one singlet disappears slowly when deuterated water is added, while the other disappears immediately. The chemical shifts of the methine proton in I (4.2 ppm, triplet, J = 8.0 Hz, HCCH) and 5.4 ppm for the hydroxylic proton in II are in agreement with the chemical shifts of the equivalent proton in the free α-carboxy compounds reported previously (7). Integration of the aromatic protons revealed the presence of three aromatic rings. The complexity of the aromatic pattern in the spectra of I and II, as compared to that of III, suggests that the plane of symmetry was destroyed, an observation that supports the proposed structure of I and II.

Compounds I and II may have formed in Formulation G by the reaction of aniline with III and IV, respectively (Scheme II). The source of the aniline required for the formation of these compounds is not known. It may originate from the degradation of III by an unusual excipient-induced mechanism. The presence of II in the tablets can be rationalized in terms of air oxidation of I at carbon 4 (2). On the basis of previous results (1), the ring opening of the lactam-type compounds by aniline seems to be more probable than hydrolysis of III and IV to α-carboxy-*N*-caproylhydrazobenzene and α-carboxy-α-hydroxy-*N*-caproylhydrazobenzene, respectively (2, 7), followed by combination with aniline. Antacid formulations would be expected to show degradation *via* hydrolysis, and the presence of relatively high concentrations of carboxy compounds in antacid formulations subjected to 60° storage for 18 months is in accord with this expectation. These antacid formulations showed only traces of the previously unidentified I and II, thus giving indirect evidence for the ring-opening reaction with aniline.

Stability-Indicating Colorimetric Assay for Indicine *N*-Oxide Using TLC

JOSEPH B. D'SILVA and ROBERT E. NOTARI ˣ

Received May 18, 1979, from the *College of Pharmacy, Ohio State University, Columbus, OH 43210.* Accepted for publication October 31, 1979.

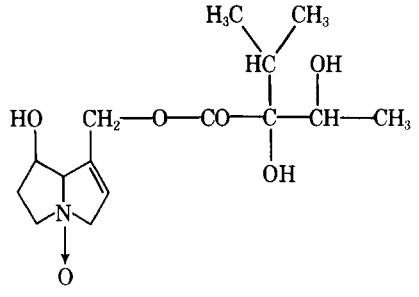
Abstract □ Aliquots of aqueous solutions in which indicine *N*-oxide may be degraded were mixed with 0.5 *M* formic acid (1:3) to adjust the pH to ~2–4 to quench the reaction and to ensure adequate TLC resolution. Silica-coated aluminum sheets were used to isolate indicine *N*-oxide by cutting the appropriate region from the chromatogram. By a modification of a known procedure, the silica gel then was treated with an acetic anhydride–diglyme mixture, and the mixture was heated to convert the drug to a pyrrole, which was then coupled with 4-dimethylaminobenzaldehyde to produce a color. The absorbance of the resulting solution was determined at 566 nm, and the apparent molar absorptivity, ϵ, based on the final indicine *N*-oxide concentration was 6.13×10^4. The recovery was ~92%, and the assays were readily reproducible with a coefficient of variation of 4.4%.

Keyphrases □ Indicine *N*-oxide—stability-indicating colorimetric assay using TLC □ Alkaloids—indicine *N*-oxide, stability-indicating colorimetric assay using TLC □ Antineoplastic agents, potential—indicine *N*-oxide, stability-indicating colorimetric assay using TLC

Indicine *N*-oxide[1] (I), an unsaturated pyrrolizidine alkaloid found in *Heliotropium indicum* Linn (Boraginaceae) (1), is undergoing clinical testing as an anticancer agent (2). While stability data have not been reported, alkaline ester hydrolysis is predicted from degradation studies of related alkaloids.

BACKGROUND

Approximate half-lives for the decomposition of 12 pyrrolizidines were estimated in 0.5 *N* aqueous or hydroalcoholic sodium hydroxide at room temperature (3). The relatively facile hydrolysis of esters of trachelanthic and viridifloric acids was attributed to their potential for β-hydroxyl participation, presumably *via* hydrogen bonding (3). This potential for intramolecular catalysis is present in I, which also is a trachelanthic acid ester (of retronecine *N*-oxide). The products obtained from the hydrolysis of indicine in 2 *N* NaOH at 100° for 2 hr were shown to be retronecine and a diastereoisomer of trachelanthic acid (4). It is not known whether the presence of the *N*-oxide in I gives rise to additional degradation pathways. Kugelman *et al.* (1) found that the properties of I extracted from *H. indicum* Linn (Boraginaceae) did not agree with those of synthesized I. Although these differences were ascribed to solvation problems, they also might reflect chemical instability.



I

Two assays for I in biological samples have been reported (2, 5). An electron-capture GLC assay after formation of the pentafluoropropionic anhydride derivative of indicine was applied to the analysis of mixtures of indicine and I in plasma and urine (2). Prior to analysis, indicine was extracted selectively with chloroform; the I remaining in the raffinate then was reduced to indicine. A GLC–mass spectrometric method using selective-ion monitoring recently achieved nanogram sensitivity through formation of the trimethylsilyl derivative of I (5). Although the method is selective for I, the equipment required is sophisticated and expensive.

This study was undertaken to develop a simple, specific assay for I in the presence of its degradation products. A colorimetric assay for unsaturated pyrrolizidine alkaloids using modified Ehrlich reagent (6) was adapted to assay I under aqueous conditions, in which it was shown to be unstable. TLC on aluminum sheets was employed to isolate I from buffers and reaction products. After the appropriate region was cut and scraped, the silica gel mixture was treated to convert the pyrrolizidine structure to a pyrrole. The pyrrole then was coupled with 4-dimethylaminobenzaldehyde to produce a color which was measured spectrophotometrically.

EXPERIMENTAL

Materials and Chemicals—The TLC aluminum sheets were precoated with 0.2 mm of silica gel 60 F-254[2]. Ether[3], absolute ethanol[4], ammonium hydroxide solution[5], acetic anhydride[6], and acetone[3] were analytical reagent grade. The diglyme[7] was kept free of peroxides (6). Modified Ehrlich reagent was prepared by dissolving 2% (w/v) 4-dimethylaminobenzaldehyde[8] in an ethanolic solution containing 14% (w/v) boron trifluoride, which was incorporated as its etherate complex (6, 7).

pH Adjustment—The assay results, obtained from absorbance values, were consistent provided that the sample to be spotted had a pH of 2–4.5. At pH < 2, erratic absorbance values were obtained. The pH was maintained at <4.5 since I degraded in alkali but not in acid. One part of 0.5 *M* formic acid was effective in controlling the pH when it was mixed with three parts of simulated reaction solutions of pH 2–13. Indicine *N*-oxide solutions treated in this manner were stable for several weeks under refrigeration.

Optimum Conditions—The amount of acetic anhydride used in the conversion of I to the pyrrole was varied from 0.1 to 0.4 ml. The best results were obtained with 0.2 ml. The optimum heating time for this step was 3.5 min. An optimum heating period of 4.5 min was observed for the color-producing step using modified Ehrlich reagent.

Assay of I in Aqueous Solutions or Reaction Mixtures—An aliquot of ~0.01 *M* I solution or reaction mixture at pH 2–13 was mixed with

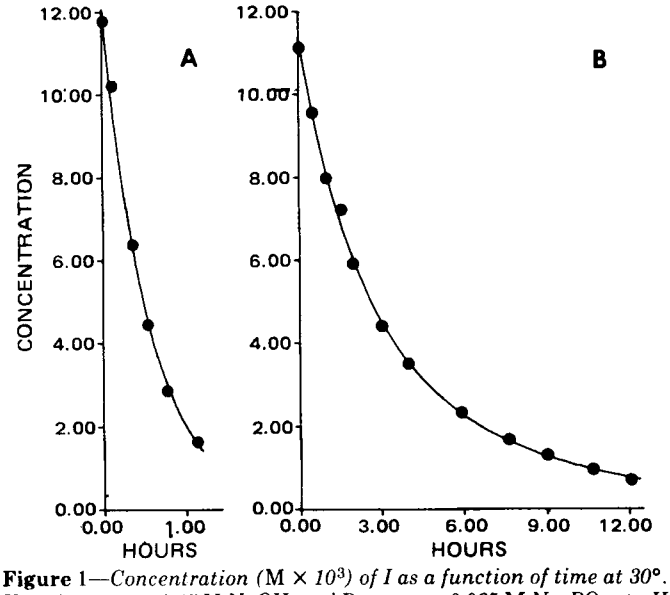

Figure 1—*Concentration (M × 10³) of I as a function of time at 30°. Key: A, aqueous 0.15 N NaOH; and B, aqueous 0.065 M Na_3PO_4 at pH 12.18.*

one-third of its volume of 0.5 *M* formic acid to adjust the pH to 2–4. An 8-μl sample was spotted on a TLC sheet, and the spot was air dried. Eight microliters of a reference solution consisting of I (~8×10^{-3} *M*) also was spotted on the same sheet. The sheet was developed (12 cm) with ether–ethanol–ammonium hydroxide solution–water (5:4:1:1) and air dried.

The entire channel containing the reference spot was cut out, sprayed with sulfuric acid–ether (1:4), and heated in an oven to locate I, which appeared at $R_f \sim 0.42$. The area in the sample channel corresponding to the I reference spot was scraped into a glass-stoppered test tube (12 × 1.5 cm). One milliliter of diglyme, followed by 0.2 ml of acetic anhydride, was added; the mixture was agitated thoroughly and heated in a boiling water bath for 3.5 min, during which it was agitated thoroughly at the end of 1 and 2 min. The tube was cooled to room temperature using a water bath (10–15°), and 1 ml of modified Ehrlich reagent was added.

The mixture then was agitated thoroughly and heated in a water bath at 57.5° for 4.5 min, during which it was agitated at the end of 100 and 200 sec. The tube was cooled, and 2 ml of acetone was added with thorough agitation followed by centrifugation at 3400 rpm for 1.5 min. The clear supernate was swirled carefully around the sides of the tube to wash down any silica gel particles. The tube was centrifuged a second time for 3.5 min, and the absorbance of the clear supernate was determined immediately at 566 nm against a similarly prepared blank.

The concentration of I in the initial solution may be calculated from:

$$[\mathrm{I}] = \frac{(A_{566})(R)}{\epsilon} \qquad \text{(Eq. 1)}$$

where A_{566} is the measured absorbance at 566 nm (λ_{max}), ϵ is the apparent molar absorptivity in the final solution (6.13×10^4), and R is the ratio of the final volume of the assayed solution to the sample volume spotted on the TLC sheet.

Beer's Law Plots—Aliquots of 2, 4, 6, 8, and 10 μl of a solution of I (8×10^{-3} *M*) in 0.125 *M* formic acid were chromatographed and assayed as described. A Beer's law plot was constructed using the absorbance data and the I concentration in the final assay solution.

Indicine *N*-oxide (8×10^{-3} *M*) was dissolved in a 3:1 mixture of phosphate buffer (pH 11.93, [Na_3PO_4] = 0.0328 *M*) and 0.5 *M* formic acid. Aliquots were chromatographed and used to prepare a Beer's law plot as described.

Percent Recovery—Aliquots of 2, 4, 6, 8, and 10 μl of an aqueous solution of I (8×10^{-3} *M*) were placed in glass-stoppered test tubes (12 × 1.5 cm) and dried under a dry nitrogen stream since water interferes with the assay (6). The residues were assayed without TLC separation. A Beer's law plot of absorbance at 566 nm *versus* the I concentration in the final assay solution was constructed.

RESULTS AND DISCUSSION

Beer's Law Plots—The apparent molar absorptivity, ϵ, from the Beer's law plot prepared by chromatographic assays of solutions of I in 0.125 *M* formic acid was 6.13×10^4 ($r^2 = 0.9996$). The molar absorptivity from the Beer's law plot prepared by assaying the I solution in the phosphate buffer–formic acid mixture was 6.37×10^4 ($r^2 = 0.9996$), which is within 4% of that obtained for I in 0.125 *M* formic acid alone. The Beer's law plots passed through the origin, and all experimental points were on the regression lines.

Assay reproducibility was assessed by estimating ϵ 18 times, each using two known concentrations of I in solutions simulating a variety of reaction conditions ($\bar{\epsilon} = 6.18 \times 10^4$, $s = 0.27 \times 10^4$).

TLC Assay Recovery of I—The percent recovery of I following chromatographic separation was evaluated relative to solutions that were not chromatographed by comparing their Beer's law plots. The ϵ value without chromatographic separation was 6.69×10^4 ($r^2 = 0.9990$). Therefore, the percent recovery of I in the TLC assay was 91.6% as calculated from:

$$\%\ \text{recovery} = \frac{(100)(6.13 \times 10^4)}{(6.69 \times 10^4)} \qquad \text{(Eq. 2)}$$

Application to Kinetics of I Degradation—Preliminary studies indicated that I was unstable in alkali. The assay successfully measured the decreasing concentration of I as a function of time under a wide variety of aqueous alkaline conditions. Figure 1 shows two examples that illustrate the stability-indicating efficacy of this assay. Detailed studies on the kinetics and mechanisms of I degradation are in progress.

Abstract □ A series of pyrrolo[2,3-*d*]pyrimidine-2,4-diones and intermediates was tested for anticonvulsant activity in mice. Eleven of the 15 compounds possessed anticonvulsant activity against pentylenetetrazol-induced convulsions. One compound afforded more anticonvulsant protection against pentylenetetrazol than did trimethadione (67 and 50%, respectively). A suspension of this compound was found to be as effective as a solution in producing anticonvulsant activity. The results suggest that the nitrile analogs were more potent compared to the carbamyl analog due to higher lipid solubility.

Keyphrases □ Pyrrolo[2,3-*d*]pyrimidine-2,4-diones and intermediates—anticonvulsant activity, structure–activity relationships □ Anticonvulsant activity—pyrrolo[2,3-*d*]pyrimidine-2,4-diones and intermediates, structure–activity relationships □ Structure–activity relationships—pyrrolo[2,3-*d*]pyrimidine-2,4-diones and intermediates, anticonvulsant activity

Many clinically useful anticonvulsants such as the hydantoins (1), succinimides (2), oxazolidinediones (3), and barbiturates (4) incorporate a cyclic imide structure. A series of substituted pyrrolopyrimidinediones synthesized in this laboratory (5) also contain a cyclic imide structure and, therefore, were postulated to possess possible anticonvulsant activity. Preliminary information from this laboratory confirmed the hypothesis and demonstrated that several of the pyrrolopyrimidinediones possessed anticonvulsant activity against pentylenetetrazol-induced seizures in mice.

In addition, some clinically useful anticonvulsants such as the propanediol carbamates (6) and acetylureas (7) contain a linear carbamate or urea function. Since intermediates in the synthesis of pyrrolopyrimidinediones contained carbamate functions, these compounds also were predicted to possess anticonvulsant activity.

Johnson *et al.* (8) reported the synthesis of a series of 2-aminopyrrole analogs of lidocaine that possessed cardiovascular depressant properties devoid of central nervous system (CNS) motor stimulation (9,10). Since one compound appeared to possess CNS depressant properties, it also was predicted to possess anticonvulsant activity.

The purpose of this study was to examine the anticonvulsant activity and structure–activity relationship for selected pyrrolo[2,3-*d*]pyrimidine-2,4-diones and related intermediates.

EXPERIMENTAL[1]

The synthesis of the compounds (I*b*, Ic, IIc–II*i*, III*a*, and III*b*) (Table I) used in this study was reported previously (5). The intermediates (I*a*, II*a*, and II*b*) were synthesized by the following procedure.

Chemistry—*2-(2-Chlorocarbethoxyamido)-3-cyano-4-methyl-5-benzylpyrrole* (*Ia*)—A solution of 2-amino-3-cyano-4-methyl-5-benzylpyrrole (16.5 g, 0.078 mole) (11) in acetone (100 ml) and pyridine (6.8 g, 0.086 mole) was stirred in an ice bath with the dropwise addition of 2-chloroethyl chloroformate (12.3 g, 0.086 mole). After the addition was complete, the bath was removed, and the solution was stirred at room temperature for 30 min. The solution was diluted with ice water (400 ml), and the precipitate was collected and air dried. The crude carbamate was recrystallized from 300 ml of methanol–water (2:1) to yield beige crystals (22.2 g, 89.5%). Recrystallization from methanol yielded beige crystals that were homogeneous on TLC with ethyl acetate (R_f 0.55), mp 110–111°; IR (KBr): 3560, 3300, 2200, 1715, 1630, 1240, and 1020 cm^{-1}.

Anal.—Calc. for $C_{16}H_{16}ClN_3O_2$: C, 60.47; H, 5.08; Cl, 11.16; N, 13.22. Found: C, 60.58; H, 5.13; Cl, 11.05; N, 13.25.

2-(2-Chlorocarbethoxyamido) -3- carbamyl-4-methyl-5-benzylpyrrole (*IIa*)—The carbamate (I*a*) (20.0 g, 0.063 mole) was added to 85% phosphoric acid (300 ml) that was preheated to 110°. The resulting solution was stirred for 7 min at 110–130° and then was poured over ice (1000 g). Potassium hydroxide (100 g) dissolved in water was added, and the precipitate was collected, washed with water, and air dried. The crude product (14.0 g, 66.3% yield) was recrystallized from 95% ethanol (500 ml), followed by recrystallization from methanol to yield pale-pink crystals that were homogeneous on TLC with ethyl acetate (R_f 0.45), mp 172–173°; IR (KBr): 3500, 3420, 3340, 3300, 1715, 1640, 1600, 1580, 1560, 1390, and 1210 cm^{-1}.

Anal.—Calc. for $C_{16}H_{18}ClN_3O_3$: C, 57.23; H, 5.40; Cl, 10.56; N, 12.51. Found: C, 57.30; H, 5.44; Cl, 10.55; N, 12.51.

2-(2,2,2-Trichlorocarbethoxyamido) -3- carbamyl-4,5-dimethylpyrrole (*IIb*)—A solution of 2-(2,2,2-trichlorocarbethoxyamido)-3-cyano-4,5-dimethylpyrrole (23.4 g, 0.0753 mole) in concentrated sulfuric acid (50 ml) was stirred at 100° for 6 min and then was poured slowly into 800 g of ice water (1:1). The precipitate was collected, washed with water, and air dried. The product was recrystallized from methanol (800 ml) to yield pale-pink crystals (18.0 g, 72.7% yield) that were homogeneous on TLC with ethyl acetate (R_f 0.60), mp > 300°; IR (KBr): 3525, 3360, 3280, 1730, 1650, 1590, 1570, 1560, 1400, 1200, 810, 750, and 720 cm^{-1}.

Anal.—Calc. for $C_{10}H_{12}Cl_3N_3O_3$: C, 36.55; H, 3.68; N, 12.79. Found: C, 36.46; H, 3.72; N, 12.85.

Pharmacology—*Animal Preparation*—Male HA/ICR mice[2], 15–30 g, were used. Compounds tested for anticonvulsant activity were prepared as 3% suspensions containing polysorbate 80[3] (0.5%) and acacia (0.5%) in water and were injected intraperitoneally. Solutions for intravenous administration (6%) were prepared by dissolving the compound in 30% propylene glycol and adjusting the pH to 8.0 with sodium hydroxide. Intravenous injections were administered *via* the tail vein using a 27-gauge needle and a mouse holder.

Maximal Electroshock Seizure Test—Mice were administered 50 mamp of alternating current[4] (60 Hz) for 200 msec through corneal electrodes (12). Several drops of 0.9% NaCl were instilled in each eye prior to application of the electrodes. Abolition of the tonic hindlimb extensor component of the seizure was defined as anticonvulsant activity.

Phenytoin[5] was used as the reference anticonvulsant for maximal electroshock. Three-hour pretreatment with phenytoin (10 mg/kg sc) produced 100% protection against maximal electroshock seizures in mice (12). The procedure was modified by using a 45-min pretreatment with a dose of 30 mg/kg ip (suspension) to produce 100% protection.

Pentylenetetrazol Seizure Test—Pentylenetetrazol[6] was administered subcutaneously at a dose of 85 mg/kg (ED_{97}) to elicit a clonic seizure lasting at least 5 sec (12). Trimethadione[7] was used as the reference

[1] IR spectra were determined on a Beckman AccuLab 4 spectrophotometer using the potassium bromide technique. Melting points were obtained using a Thomas-Hoover capillary apparatus and are uncorrected. TLC was performed using Eastman chromatogram sheets, type 6060 (silica gel), and the sheets were developed in an iodine chamber. Carbon, hydrogen, chlorine, and nitrogen values were obtained from Atlantic Microlab, Atlanta, Ga.

Phenytoin (30 mg/kg)				—	0

[a] Male mice were injected with 30 mg/kg ip (suspension) of test compound and evaluated for maximal electroshock protection. All compounds were injected 45 min before administration of 50 mamp of alternating current for 200 msec. None of the compounds exhibited any protection against maximal electroshock-induced convulsions. Phenytoin, 30 mg/kg ip, provided 100% protection (n = 6). [b] Male mice were injected with 400 mg/kg ip of test compounds (suspension) 45 min before 85 mg of pentylenetetrazol/kg sc. Percent protection equals the percentage of animals protected against seizures induced by 85 mg of pentylenetetrazol/kg (ED_{97}) (n = 6). [c] Previously trained male mice received 400 mg/kg ip of test compounds (suspension) 45 min before placement on the rotorod for 90 sec. Rotorod toxicity is defined as the percentage of animals that did not remain on the rod for at least 90 sec (n = 6). [d] 2-Diethylaminoacetamido-3-carbamyl-4-methyl-5-benzylpyrrole hydrochloride (8, 9). [e] Control mice received 3.84 ml of suspension vehicle/kg (0.5% polysorbate 80 and 0.5% acacia in water).

Table II—Effect of Injection Route and Solubilization of I*b* on Anticonvulsant Activity

Convulsive Method[a]	Dose of I*b* and Route	Preparation[b]	Protection[c], %	Rotorod Toxicity[d], %
Electroshock	Control[e], ip	Solution	0	—
	30 mg/kg ip or iv	Solution	0	0
	30 mg/kg ip	Suspension	0	0
Pentylenetetrazol	Control, ip	Solution	0	—
	50 mg/kg ip or iv	Solution	0	0
	400 mg/kg ip	Solution	83	83
	400 mg/kg ip	Suspension	67	83

[a] Male mice were injected with 30 mg of I*b*/kg ip (suspension) and evaluated for maximal electroshock protection. Compound I*b* was injected 45 min before administration of 50 mamp of alternating current for 200 msec. Male mice were injected with I*b* 45 min before 85 mg of pentylenetetrazol/kg sc (ED_{97}) (n = 6). [b] Solution of I*b* was prepared in 30% propylene glycol. Suspension of I*b* was prepared as described in *Experimental* (n = 6). [c] Percent protection equals the percentage of animals protected against seizures induced by 85 mg of pentylenetetrazol/kg (ED_{99}) or electroshock (n = 6). [d] Rotorod toxicity is defined as the percentage of animals that did not remain on the rod for at least 90 sec (n = 6). [e] Control = 3.84 ml/kg of 30% propylene glycol (1.2 g/kg of propylene glycol).

pentylenetetrazol antagonist. At a pretreatment time of 45 min, 400 mg/kg of trimethadione suspension given intraperitoneally protected 50% of the animals against pentylenetetrazol-induced convulsion.

Test compounds were administered intravenously or intraperitoneally at a dose of 50 or 400 mg/kg 45 min before injection of pentylenetetrazol. Anticonvulsant activity was recorded if clonic spasms were not observed within 30 min after the pentylenetetrazol administration. The data were reported as the percentage of animals protected against seizures induced by 85 mg of pentylenetetrazol/kg given subcutaneously.

Rotorod Test—Previously trained mice were placed on a 2.54-cm diameter rubber-coated plastic rod (rotorod) rotating at 6 rpm before and 45 min after administration of the test compound. Rotorod toxicity was defined as the percentage of animals that did not remain on the rod for at least 90 sec.

RESULTS AND DISCUSSION

A test compound dose of 400 mg/kg was chosen for comparison with the anticonvulsant ED_{50} dose (400 mg/kg) of trimethadione (Table I). Suspensions of the test compounds were administered intraperitoneally due to solubility problems. At a dose of 400 mg/kg ip, 11 of the 15 test compounds protected against pentylenetetrazol-induced seizures (Table I). Compound I*b* was more active than trimethadione (67 *versus* 50% protection, respectively). Compounds II*e* and I*a* were slightly less active than trimethadione (33 *versus* 50% protection, respectively). Compounds I*c*, II*a*, II*c*, II*f*, II*h*, III*a*, III*b*, and IV exhibited slight anticonvulsant activity (17%).

Phenytoin at a dose of 30 mg/kg ip afforded 100% protection against maximal electroshock seizures. Since the test compounds were insoluble,

suspensions of the compounds including phenytoin were prepared. None of the test compounds exhibited any protection against maximal electroshock seizures at 40 mg/kg ip (suspension, footnote *a*, Table I). Compounds II*e* and I*b* produced definite signs of neurological toxicity (33 and 83%, respectively) as measured on the rotorod at 400 mg/kg (Table I). No CNS toxicity was observed with any other test compound.

The anticonvulsant evaluation indicated that compounds possessing a nitrile group at the 3-position (I*a*–I*c*) were more potent compared to compounds possessing a carbamyl group at that position (II*a*–II*i*). Introduction of the more polar carbamyl group (13) in II*a*–II*i* resulted in decreased lipid solubility compared to I*a*–I*c*, which contain the nitrile group. Decreased lipid solubility probably retards the passage of these compounds into the CNS.

The effect of the administration route and solubilization method on the most potent compound (I*b*) was examined further (Table II). Suspensions of I*b* were administered intraperitoneally due to solubility limitations. Suspensions then were compared to the anticonvulsant effects produced by propylene glycol solutions of I*b* when it was administered intraperitoneally or intravenously.

In the electroshock studies, 30 mg of I*b*/kg was chosen since phenytoin produced 100% protection against maximal electroshock seizures when it was administered as an intraperitoneal suspension. Variation in neither the injection route (intraperitoneal *versus* intravenous) nor the means of solubilization (suspension *versus* solution) was effective in producing anticonvulsant activity.

Compound I*b*, 75 mg/kg, was lethal following intravenous administration. Gross observation of the animals following this dose indicated that death was probably due to cardiovascular toxicity. Therefore, 50 mg/kg iv was selected as the maximum allowable dose for comparative purposes. Unfortunately, at 50 mg of I*b*/kg, variation in the administration route (intravenous *versus* intraperitoneal) was ineffective in producing protection against pentylenetetrazol-induced seizures.

Since 400 mg of I*b*/kg ip (suspension) afforded 67% protection in the pentylenetetrazol seizure test, 400 mg/kg ip of I*b* then was administered as a solution in propylene glycol for comparison (Table II). The completely dissolved solution of I*b* appeared to be slightly more effective than the intraperitoneally injected suspension of I*b* (83 *versus* 67% protection, respectively). However, the extent of rotorod toxicity appeared equivalent (83%). Therefore, complete solubilization of I*b* was concluded to be unnecessary for anticonvulsant activity.

Drugs that are useful in petit mal seizures are effective in elevating the threshold of electroshock- and drug-induced convulsions (14). Drugs used for grand mal epilepsy do not significantly affect the threshold of electrically induced seizures. None of the test compounds exhibited anticonvulsant activity against maximal electroshock but did block pentylenetetrazol-induced seizures. The active pyrrolopyrimidinediones and intermediates probably exert their activity through an elevation of the convulsive threshold, similar to trimethadione (14).

High-Pressure Liquid Chromatographic Analysis of Pramoxine Hydrochloride in High Lipoid Aerosol Foam Dosage Form

R. WEINBERGER ˣ, B. MANN, and J. POSLUSZNY

Received July 10, 1979, from *Reed & Carnrick Research Institute, Kenilworth, NJ 07033.* Accepted for publication November 1, 1979.

Abstract □ A rapid and quantitative method for the determination of pramoxine hydrochloride by high-pressure liquid chromatography is presented. The drug is extracted as the salt from a preparation with a high lipoid composition by partitioning it to the aqueous phase of an ether–methanol–water–acetic acid system. The extract is chromatographed on an octadecylsilane bonded packing with a methanol–water–acetic acid–methanesulfonic acid mobile phase. The time required for each separation is ~6 min. Analytical recoveries of 100.4 ± 1.5% were obtained.

Keyphrases □ Pramoxine hydrochloride—analysis, high-pressure liquid chromatography, high lipoid aerosol foam dosage form □ High-pressure liquid chromatography—analysis, pramoxine hydrochloride, high lipoid aerosol foam dosage form □ Anesthetics, topical—pramoxine hydrochloride, high-pressure liquid chromatographic analysis, high lipoid aerosol foam dosage form

Pramoxine hydrochloride, a widely used topical anesthetic, can present analytical difficulties due to its surfactant behavior. Its hydrophilic and lipophilic properties result in substantial matrix effects from common pharmaceutical excipients, particularly when the drug is incorporated into a high lipoid content base.

The conventional analytical method described in NF XIV (1) is based on nonspecific, nonaqueous titrimetry and spectrophotometric determinations. TLC[1] was used for qualitative analysis. Mario and Meehan (2) used the drug as an internal standard for a GLC assay of cough–cold preparations. Analysis of the high lipoid composition by GLC in this laboratory resulted in lengthy sample preparation and 30-min separations.

This study was undertaken to develop a rapid and reliable method for the determination of pramoxine hydrochloride in high lipoid preparations. The method was re-

High-Pressure Liquid Chromatographic Analysis of Pramoxine Hydrochloride in High Lipoid Aerosol Foam Dosage Form

R. WEINBERGER ˣ, B. MANN, and J. POSLUSZNY

Received July 10, 1979, from *Reed & Carnrick Research Institute, Kenilworth, NJ 07033.* Accepted for publication November 1, 1979.

Abstract □ A rapid and quantitative method for the determination of pramoxine hydrochloride by high-pressure liquid chromatography is presented. The drug is extracted as the salt from a preparation with a high lipoid composition by partitioning it to the aqueous phase of an ether–methanol–water–acetic acid system. The extract is chromatographed on an octadecylsilane bonded packing with a methanol–water–acetic acid–methanesulfonic acid mobile phase. The time required for each separation is ~6 min. Analytical recoveries of 100.4 ± 1.5% were obtained.

Keyphrases □ Pramoxine hydrochloride—analysis, high-pressure liquid chromatography, high lipoid aerosol foam dosage form □ High-pressure liquid chromatography—analysis, pramoxine hydrochloride, high lipoid aerosol foam dosage form □ Anesthetics, topical—pramoxine hydrochloride, high-pressure liquid chromatographic analysis, high lipoid aerosol foam dosage form

Pramoxine hydrochloride, a widely used topical anesthetic, can present analytical difficulties due to its surfactant behavior. Its hydrophilic and lipophilic properties result in substantial matrix effects from common pharmaceutical excipients, particularly when the drug is incorporated into a high lipoid content base.

The conventional analytical method described in NF XIV (1) is based on nonspecific, nonaqueous titrimetry and spectrophotometric determinations. TLC[1] was used for qualitative analysis. Mario and Meehan (2) used the drug as an internal standard for a GLC assay of cough–cold preparations. Analysis of the high lipoid composition by GLC in this laboratory resulted in lengthy sample preparation and 30-min separations.

This study was undertaken to develop a rapid and reliable method for the determination of pramoxine hydrochloride in high lipoid preparations. The method was re-

[a] Single-can assays; theoretical amount = 220 mg/can.

quired to handle relatively large samples to accommodate a total contents assay for the aerosol dosage form. A practical requirement was that the technique not utilize large quantities of solvents or reagents.

EXPERIMENTAL[2]

Reagents and Chemicals—A commercial pramoxine hydrochloride sample[3] was used as the reference standard. Absolute methanol[4], ether[4], acetic acid[4], and deionized water were used for the extraction. The mobile phase contained 50% methanol[5], 48.9% deionized water, 1% acetic acid[4], and 0.1% methanesulfonic acid[6]. After mixing, the mobile phase was filtered through a 0.45-μm filter[7]. The solution was prepared fresh daily and was degassed prior to use.

Standard Solutions for Calibration Curves—Standard solutions of pramoxine hydrochloride (0.8, 0.9, and 1.0 mg/ml) were prepared in 50% methanol. The three standards were analyzed, and the results were subjected to regression analysis.

Sample Preparation—The contents of each aerosol unit were dispensed into a 500-ml separator. After expulsion of the foam, the unit was opened and the remainder of the contents was transferred to the separator with 100 ml of ether–methanol (5:1). The sample was extracted twice with 100- and 75-ml aliquots of 20% acetic acid, respectively. The aqueous extracts then were combined in a 250-ml volumetric flask and brought to volume with water.

Chromatographic Conditions—Octadecyltrichlorosilane was permanently bonded to 10-μm porous silica particles and packed into a 25-cm × 4-mm i.d. stainless steel column[8]. The mobile phase was pumped through the column at 2 ml/min at room temperature until a stable baseline was obtained. The variable-wavelength detector was set at 286 nm. A range of 0.1 aufs was used.

Replicate 15-μl injections were made using an autosampler[9]. The output of the spectrophotometer was monitored with a 10-mv strip-chart recorder[10]. Peak height measurements, determined electronically[11], were used for all calculations.

RESULTS AND DISCUSSION

The pharmaceutical aerosol foam dosage form presents a unique problem; it is difficult to analyze a portion of the aerosol content with precision because of the solubility of the propellant in the foam base. To circumvent this feature, the contents of an entire aerosol unit may be assayed, with the results reported in milligrams per can. The technique fits in well with the commercial production of pharmaceutical aerosols.

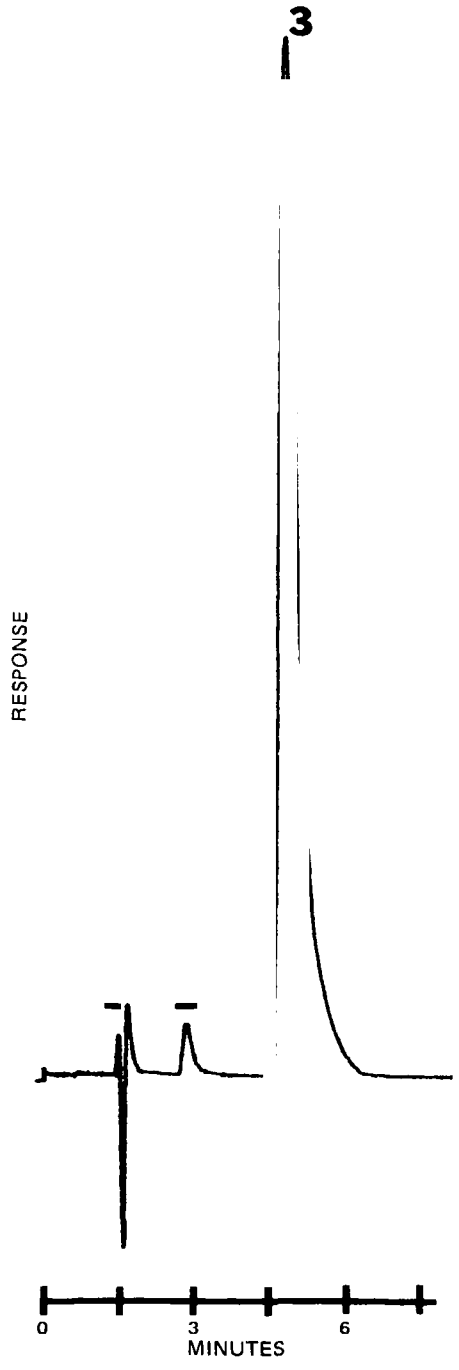

Figure 1—*Chromatogram of high lipoid extract obtained under the assay conditions. Key: 1 and 2, methylparaben; and 3, pramoxine hydrochloride.*

Information concerning potency, net content, and uniformity can be discerned simultaneously from the analytical data.

In this context, it became necessary to analyze 20–25-g high lipoid samples containing pramoxine hydrochloride, and several approaches were followed. Direct extraction with chloroform yielded substantial chromatographic interference. Dissolution of the sample required almost 1 liter of methanol–tetrahydrofuran (50:50).

The described extraction procedure required only 100 ml of ether–methanol and 175 ml of 20% acetic acid. The method had the advantage of partitioning the drug directly into the aqueous phase, which allowed determination by reversed-phase liquid chromatography without further manipulation.

To determine the accuracy and precision of the method, aerosol units were prepared quantitatively at three levels of potency, and these units were assayed. The average recovery at the 100% potency level was 100.4 ± 1.5 (*SD*)% (Table I). Recoveries at other potency levels were compa-

rable. Analysis of the commercial preparation[12] gave results (Table II) that were consistent with the potency and the amount of the aerosol concentrate contained in each unit. Typical correlation coefficients for the standard curve were usually ≥0.999. Therefore, with the accuracy of the system established, the external standardization was considered satisfactory. A placebo preparation gave no interference.

The amount and concentration of the acetic acid solution were critical to the success of the extraction. If less than the prescribed amounts were used, difficulties with emulsification and incomplete recoveries resulted. A stronger acid such as hydrochloric acid could have been used at lower concentrations; but since the system was to be automated, a milder acid was preferred to preserve the instruments.

Prior to introduction into the high-pressure liquid chromatograph, good chromatographic practice generally requires filtering the analytical solutions through a fractional micrometer filter. This practice caused a 1–2% increase in recovery above that expected in the analytically prepared samples. Because of this feature, filtering samples is not recommended. The speed and accuracy of the method make occasional chromatograph filter and frit changes worthwhile.

A typical chromatogram of the high lipoid extract is shown in Fig. 1. The only excipient carried through the extraction and appearing on the chromatogram was methylparaben ($k' = 1$). Pramoxine hydrochloride ($k' = 2.2$) eluted in ~6 min.

The described method has general applicability to most pharmaceutical dosage forms containing pramoxine hydrochloride. In many cases, the drug can be extracted directly with the mobile phase or the entire composition can be dissolved. The high lipoid aerosol foam dosage form analysis was described because of the restrictions imposed on the analytical method.

Antileukemic Activity of 2-Bis(2-methylthio)vinyl-1-methylquinolinium Iodides

WILLIAM O. FOYE ˣ and JOEL M. KAUFFMAN

Received September 13, 1979, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy, Boston, MA 02115.* Accepted for publication November 16, 1979.

Abstract □ Reaction of 1-methylquinolinium-2-dithioacetic acid zwitterions with excess methyl iodide in dimethylformamide gave the corresponding bis(2-methylthio)vinyl derivatives. These compounds were more soluble in both aqueous and organic media than the dithioacetic acid zwitterions but showed comparable antileukemic activity in mice. Reaction with morpholine converted a bis(2-methylthio)vinyl derivative almost quantitatively to the 2-mono(methylthio)-2-morpholino derivative. Leukemia cell culture studies of the 6-methyl derivative showed no effect on cell cycle processes.

Keyphrases □ Antileukemic activity—2-bis(2-methylthio)vinyl-1-methylquinolinium iodides, comparative testing in cell culture and mice □ 2-Bis(2-methylthio)vinyl-1-methylquinolinium iodides—NMR analysis and synthesis of bis(methylthio)vinyl derivatives, comparative testing for antileukemic activity in cell culture and mice □ NMR spectroscopy—analysis, synthesized bis(methylthio)vinyl derivatives

1,6-Dimethylquinolinium-2-dithioacetic acid zwitterion (III*b*) was found to have appreciable activity against P-388 lymphocytic leukemia in mice (1) and against CD_8F_1 mammary tumor in mice[1]. Other 6-substituted 1-methylquinolinium-2-dithioacetic acid zwitterions showed comparable antileukemic activity in mice (2), regardless of the electron-donating or electron-releasing ability of the 6-substituent. Since these zwitterions were amorphous and poorly soluble in both aqueous and organic media, more soluble derivatives were desired having potential chemical reactivity similar to that of the dithioacetic acid function. Accordingly, the bis(methylthio)vinyl derivatives were prepared (Scheme I), and their antileukemic activities were determined. These derivatives are crystalline and more soluble in both water and organic solvents.

[1] Screening results were obtained from the Division of Cancer Treatment, National Cancer Institute, National Institutes of Health.

DISCUSSION

Chemistry—Gompper *et al.* (3) reported the formation of the 2-bis(2-methylthio)vinyl compound (V*a*) by reaction of iodomethane with the dithioacetic acid zwitterion (III*a*). No reaction temperature or yield was stated. Mizuyama *et al.* (4) also reported the formation of a mono(methylthio) compound from the corresponding 1,2-dihydroquinoline analog and iodomethane, but no physical constants or experimental data were given. The procedure of Rosenhauer (5), in which the intermediate zwitterion (III*a*) was not isolated but was treated with excess iodomethane, was employed accordingly. The 6-unsubstituted bis(methylthio)vinyl compound and the corresponding 6-bromo derivative were reported previously (2).

Dilute sodium hydroxide generally sufficed for removal of the 2-methyl proton prior to condensation with carbon disulfide, but sodium hydride in 2-propanol was required for the 6-methoxy derivative. To obtain the bis(methylthio)vinyl derivatives, the methiodides (I) were treated with aqueous base, and the methylene derivatives (II) were extracted into toluene. The toluene solutions were treated with carbon disulfide, and the precipitated zwitterions (III) were taken up in dimethylformamide and were allowed to react with excess iodomethane. The 6-bromo and 6-unsubstituted analogs (3) were prepared by suspending the zwitterions (III) in dimethylformamide and adding iodomethane.

In the preparation of the methiodides (I), use of colored quinaldines gave impure methiodides, which could not be purified by recrystallization. Therefore, freshly distilled quinaldine was used. The methiodides were prepared with excess iodomethane without solvent. The quinaldines were prepared as described previously (2). The prepared bis(methylthio)vinyl compounds gave NMR spectra that agreed with the proposed structure (V). The *N*-methyl protons appeared at δ 4.4 ppm, and the aromatic protons appeared at δ 7.5–9.4 ppm. The 2-methyl protons of the methiodides at δ 3.1 ppm were absent in the bis(methylthio)vinyl derivatives; a methine proton appeared as a singlet at δ 6.6–6.8 ppm. The *S*-methyl protons were found as separate peaks at δ 2.5 and 2.7 ppm. The 6-methyl protons of V*b* appeared at δ 2.6 ppm, and the 6-methoxy protons (V*c*) were found at δ 4.0 ppm.

With the possible exception of the 6-bromo analog, none of the bis(methylthio)vinyl compounds was obtained in yields over 50%. The recrystallization liquors of the 6-methyl derivative were examined, and only one definable material was found, the original 1,2,6-trimethylqui-

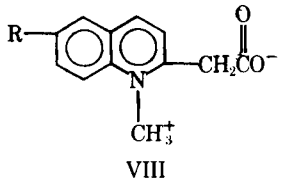
d: R = Br

Scheme I

nolinium iodide. It is unlikely that this compound was unreacted starting material since it would not be soluble in the toluene extraction of the methylene base (II*b*). Instead, abstraction of one of the methylene protons of the mono(methylthio) derivative (IV*b*) by the intermediate zwitterion (III*b*) may have taken place to form a free dithioacetic acid (III*b*-HI), which lost carbon disulfide to give I*b*. The mono(methylthio) derivative then reacted with a second mole of iodomethane to give the bis(methylthio) compound (V*b*). The ease of abstraction of a methylene proton from quinolinium-2-acetate esters has been recorded (6).

An attempt was made to hydrolyze the 6-unsubstituted zwitterion (III*a*) with 3 *N* HCl. Hydrogen sulfide was evolved slowly at 25–35°, and the reaction still was incomplete after 10 days. Refluxing produced elemental sulfur. Evaporation of the resulting neutralized solution gave no organic products. A possible hydrolysis product, 1-methylquinolinium-2-acetate (VIII), was not found in the literature, and the ready decarboxylation of quinoline-2-acetic acids has been noted (7). Thus, with the synthesis of the quinoliniumdithioacetic acid zwitterions, it was possible to prepare stable sulfur analogs of acids that are not stable in the oxygen series. In addition, a recent attempt to prepare quinoline-2-acetic acid by carbonation of quinaldinyl lithium gave no identifiable acid (8).

As an indication of the reactivity of the bis(methylthio)vinyl compounds with amines, the 6-methyl derivative (III*b*) was reacted with morpholine in dimethylformamide at 35°. A 91% yield of the mono(methylthio)morpholino compound (VI*b*) was obtained over 5 days, with evolution of methanethiol. The 6-bromo analog (VI*d*) gave a comparable conversion to the mono(methylthio)morpholine derivative in a comparable period. Although these conditions were not physiological, the temperature was comparable; the mixture remained nearly neutral throughout the reaction. Evidently, the bis(methylthio)vinyl compounds may react readily with cellular amines.



VIII

The NMR spectrum of VI*b* showed the remaining *S*-methyl protons as a singlet at δ 2.51 ppm. This finding allows the assignment of the *S*-methyl protons in the bis(methylthio) derivatives since the morpholine is assumed to be *trans* to the quinoline ring. The eight morpholine protons appeared as a broad singlet at δ 3.71 ppm. This observation can be explained by the existence of a partial positive charge on the morpholino nitrogen. The *N*-methyl peak at δ 4.09 ppm was shifted upfield from 4.41 ppm in the starting material, indicating decreased positive charge on the quinoline nitrogen. The vinyl proton, at δ 5.59 ppm, was shielded drastically compared with its position at δ 6.76 ppm in the bis(methylthio) compound. These facts, as well as the green color of the compound, indicate the contribution of resonance form VII to the structure and reinforce the assumption of the *trans* morpholine configuration.

Antileukemia Test Results—Antileukemia testing[2] of the bis(methylthio) compounds was performed in mice. The NCI protocol (9) and P-388 lymphocytic leukemia were used. Details regarding the dose and survival times of the treated animals are listed in Table I. No weight loss was found at the highest dose used, except with the 6-bromo derivative, which gave T/C (test/control) values of −0.3, −1.2, and −2.7 at 6.25, 12.5, and 25.0 mg/kg, respectively.

All tested compounds showed positive activity (a T/C × 100 ratio of 125 or better). Similar testing of the corresponding dithioacetic acid zwitterions (2) showed that the 6-unsubstituted derivative gave slightly less activity than the 6-substituted compounds. With the bis(methyl-

[2] Results were reported through the courtesy of Dr. Ralph G. Child, Lederle Laboratories; the 6-bromo derivative was tested at the National Cancer Institute (NCI).

thio)vinyl derivatives, the 6-unsubstituted compound was slightly more active than the 6-substituted derivatives, but the differences in both cases were small. Apparently, a 6-substituent is not required for antileukemic activity of the bis(methylthio)vinyl compounds.

Leukemic cell culture studies also were performed using the 6-methyl derivative[3]. Human leukemic lymphoblasts in culture were incubated with 10^{-4}, 10^{-5}, 10^{-6}, and 10^{-7} *M* test compound for 24 hr. Then the cells were harvested, stained with propidium iodide, and analyzed by flow cytometry. The flow cytometry data showed no accumulation of cells in any particular phase of the cell cycle at any drug concentration used. This negative result *in vitro* may indicate that a metabolic conversion of the bis(methylthio)vinyl compounds as well as their dithioacetic acid precursors, possibly to the reactive methylene intermediates (II), may be necessary for antileukemic activity.

EXPERIMENTAL[4]

2-Bis(2-methylthio)vinyl-1,6-dimethylquinolinium Iodide—A suspension of 22.44 g (0.075 mole) of 1,2,6-trimethylquinolinium iodide (1) and 100 ml of water was covered with 450 ml of toluene and stirred while 22 g of 50% NaOH solution was added quickly. Stirring was continued for 1 hr, and the toluene layer was decanted, dried with potassium carbonate for 5 min, decanted, and treated with 6.77 ml (0.1125 mole) of carbon disulfide. The mixture was swirled, capped, and allowed to stand overnight at 25°. The precipitated zwitterion was filtered, washed with toluene, suspended in 75 ml of dimethylformamide, and treated with 14.0 ml (0.225 mole) of iodomethane.

The mixture was kept overnight at 25°, and the yellow-green powder was filtered, washed with 50 ml of acetone, and dried at 80° (30 torr) for 4 hr. Recrystallization from water, with cooling only to 25°, gave 8.3 g (27% yield) of bronze needles, mp 205–207° dec.; NMR: δ 2.50 (s, 3H, SCH_3), 2.60 (s, 3H, 6-CH_3), 2.70 (s, 3H, SCH_3), 4.41 (s, 3H, NCH_3), 6.76 (s, 1H, vinyl), and 7.95–9.00 (m, 5H, aromatic) ppm.

Anal.—Calc. for $C_{15}H_{18}INS_2$: C, 44.66; H, 4.50; N, 3.47; S, 15.90. Found: C, 44.60; H, 4.46; N, 3.39; S, 16.10.

6-Methoxy-1-methyl-2-bis(2-methylthio)vinylquinolinium Iodide—Sodium hydride (2.1 g, 0.05 mole) (57% dispersion in oil)[5] was allowed to react with 150 ml of 2-propanol at 27–37°, and the flask then was packed in ice. 1,2-Dimethyl-6-methoxyquinolinium iodide (2) (15.76 g, 0.05 mole) was added below 10°, with stirring for 15 min after the addition. Carbon disulfide (11.7 g, 0.15 mole) was added dropwise over 60 min, and stirring was maintained for another 60 min. The resulting red zwitterion was filtered and washed with ether. The solid was suspended quickly in 50 ml of dimethylformamide and treated with iodomethane (21.29 g, 0.15 mole).

The mixture was kept overnight at 30°, diluted with 100 ml of ether, allowed to stand at 25° for 3 hr, and filtered. The crude product was washed with ether, dried at 20° (1 torr) for 16 hr, and recrystallized from water (cooling only to 20°) to give 2.12 g (10% yield) of brown needles, mp 222–225° dec.; NMR: δ 2.40 (s, 3H, SCH_3), 2.60 (s, 3H, SCH_3), 3.90 (s, 3H, OCH_3), 4.35 (s, 3H, NCH_3), 6.63 (s, 1H, vinyl), and 7.6–9.1 (m, 5H, aromatic) ppm.

Anal.—Calc. for $C_{15}H_{18}INOS_2$: C, 42.96; H, 4.33; N, 3.34. Found: C, 43.04; H, 4.26; N, 3.29.

Isolation of 1,2,6-Trimethylquinolinium Iodide in Preparation of 2-Bis(2-methylthio)vinyl-1,6-dimethylquinolinium Iodide—The aqueous mother liquor from which V*b* was crystallized deposited no solid on prolonged cooling at 1°. The liquid, 700 ml, was treated with 0.5 g of activated charcoal[6] at 20°, and water was removed with a rotary evaporator until a solid appeared. The yield was 0.3 g, mp 240–244° dec. Further evaporation and three recrystallizations from 95% ethanol gave 1.9 g, mp 252–252.5° dec.; mixed with a sample of I*b*, the melting point was 248–250° dec. The NMR spectrum was identical to that of I*b*.

1,6-Dimethyl-2-[2-methylthio -2- (1-morpholino)vinyl]quinolinium Iodide—A flask was charged with 7.26 g (0.018 mole) of 2-bis(2-methylthio)vinyl-1,6-dimethylquinolinium iodide, 80 ml of dimethylformamide, and 1.74 g (0.020 mole) of morpholine (redistilled after drying with a 3-Å molecular sieve). A drying tube containing 20 g of indicating calcium sulfate[7] was attached, and the reaction was stirred magnetically at 35° for 5.5 days. The reaction could be followed by the progression of brown coloration on the calcium sulfate and the detection of the odor of methanethiol. Toluene, 80 ml, was added, and the mixture was stored at 25° for 4 hr.

Following filtration, the filtrate was diluted with 350 ml of toluene and kept at −20° to give a first crop of 6.78 g (85% yield), mp 198–199° dec. A second crop was obtained by heating the filtrate to 90°, diluting with 250 ml of toluene, and cooling to −20°; 0.44 g was obtained (6% yield), mp 197–199° dec.; NMR: δ 2.51 (s, 3H, SCH_3), 2.57 (s, 3H, 6-CH_3), 3.71 (s, br, 8H, morpholine), 4.09 (s, 3H, NCH_3), 5.59 (s, 1H, vinyl), and 7.65–8.20 (m, 5H, aromatic) ppm.

Anal.—Calc. for $C_{18}H_{23}IN_2OS$: C, 48.87; H, 5.24; N, 6.33. Found: C, 48.77; H, 5.04; N, 5.93.

Hepatic Extraction of Endogenous Inhibitors of Plasma Protein Binding

Keyphrases □ Drug binding—plasma protein, hepatic extraction of endogenous inhibitors □ Pharmacokinetics—plasma protein binding, hepatic extraction of endogenous inhibitors □ Plasma protein binding—hepatic extraction of endogenous inhibitors

To the Editor:

Determination of the systemic intrinsic clearance of free (unbound) drug requires measurement of the drug's free fraction in blood, plasma, or serum. For drugs whose total clearance from the blood is much lower than the blood flow through the eliminating organ(s), the intrinsic clearance of the free drug is equal to the total clearance divided by the free fraction (1, 2). The use of free fraction values obtained in the usual manner (*i.e.*, by *in vitro* determinations of protein binding in plasma from peripheral venous blood) for intrinsic clearance calculations is based on the assumption that drug protein binding does not change as the blood passes through the liver or another drug-eliminating organ.

The free fraction value of many drugs in blood or plasma is reasonably constant over a wide drug concentration range. Consequently, it will not be affected by modest drug concentration changes during a single pass of blood through the liver. If, however, protein binding of the drug is affected by endogenous or exogenous (other drugs) inhibitors of binding, then the organ extraction ratio of these inhibitors must be considered. The potential consequences of hepatic extraction of binding inhibitors on the pharmacokinetics and pharmacological activity of a restrictively cleared drug can be appreciated by considering the following limiting cases.

If the extraction ratio [(concentration in inflowing blood − concentration in outflowing blood)/concentration in inflowing blood] of inhibitors of protein binding is close to zero (*i.e.*, there is very little extraction), then the inhibitors will cause an increase in the free fraction, a decrease in the steady-state total concentration, and *no change* in the steady-state free concentration of drug in peripheral blood or plasma (3). Since the pharmacological activity of a drug is usually a function of its free concentration (4), the intensity of pharmacological activity at steady state should not be affected by poorly extracted inhibitors of binding unless they have pharmacological effects of their own.

Conversely, if an inhibitor of protein binding is very rapidly and completely extracted from blood by the liver during a single pass (extraction ratio is near unity and the time for extraction of inhibitor from blood is much shorter than the transit time of that blood through the liver), then the inhibitor will have little or no effect on the steady-state concentration of total (free plus bound) drug, but it will cause the free fraction and the steady-state concentration of free drug in extrahepatic blood or plasma to be *increased*. This result would come about for two reasons:

1. Protein binding of the drug in blood is normal (rather than reduced) during most of the residence time of any one small portion of blood in the liver.
2. Protein binding of the drug leaving the liver is soon reduced as that blood mixes with inhibitor-containing blood in the vena cava, causing the free fraction and concentration of free drug to rise again.

Drug binding inhibitors with hepatic extraction ratios near unity may be cleared quite rapidly from the body. However, their concentration in blood can be quite stable if they are continuously formed endogenously, are continuously administered (other drugs or dietary components), or have a large apparent volume of distribution. Such inhibitors can be expected to increase the pharmacological activity of drugs that they displace by increasing the steady-state free concentration of these drug in extrahepatic blood. Since the steady-state concentration of total drug may be almost unchanged, the increased pharmacological activity may be unanticipated.

It is relatively easy to determine the hepatic extraction characteristics of drugs that act as displacers of other drugs from plasma protein binding sites; such a determination can be done by measuring the hepatic clearance of the displacer drugs. However, this approach is not possible (at least at this time) in the case of endogenous inhibitors associated with certain changes in the pathophysiological status of humans and animals. The hepatic extraction characteristics of binding inhibitors associated with pregnancy (5) and renal failure (6) are presently being investigated directly. To describe the method used for this investigation and to demonstrate in principle that certain endogenous inhibitors are indeed subject to considerable hepatic extraction, data on heparin-induced inhibitors of protein binding will be reported here. Hepatic Extraction of Endogenous Inhibitors of Plasma Protein Binding

Keyphrases □ Drug binding—plasma protein, hepatic extraction of endogenous inhibitors □ Pharmacokinetics—plasma protein binding, hepatic extraction of endogenous inhibitors □ Plasma protein binding—hepatic extraction of endogenous inhibitors

To the Editor:

Determination of the systemic intrinsic clearance of free (unbound) drug requires measurement of the drug's free fraction in blood, plasma, or serum. For drugs whose total clearance from the blood is much lower than the blood flow through the eliminating organ(s), the intrinsic clearance of the free drug is equal to the total clearance divided by the free fraction (1, 2). The use of free fraction values obtained in the usual manner (*i.e.*, by *in vitro* determinations of protein binding in plasma from peripheral venous blood) for intrinsic clearance calculations is based on the assumption that drug protein binding does not change as the blood passes through the liver or another drug-eliminating organ.

The free fraction value of many drugs in blood or plasma is reasonably constant over a wide drug concentration range. Consequently, it will not be affected by modest drug concentration changes during a single pass of blood through the liver. If, however, protein binding of the drug is affected by endogenous or exogenous (other drugs) inhibitors of binding, then the organ extraction ratio of these inhibitors must be considered. The potential consequences of hepatic extraction of binding inhibitors on the pharmacokinetics and pharmacological activity of a restrictively cleared drug can be appreciated by considering the following limiting cases.

If the extraction ratio [(concentration in inflowing blood − concentration in outflowing blood)/concentration in inflowing blood] of inhibitors of protein binding is close to zero (*i.e.*, there is very little extraction), then the inhibitors will cause an increase in the free fraction, a decrease in the steady-state total concentration, and *no change* in the steady-state free concentration of drug in peripheral blood or plasma (3). Since the pharmacological activity of a drug is usually a function of its free concentration (4), the intensity of pharmacological activity at steady state should not be affected by poorly extracted inhibitors of binding unless they have pharmacological effects of their own.

Conversely, if an inhibitor of protein binding is very rapidly and completely extracted from blood by the liver during a single pass (extraction ratio is near unity and the time for extraction of inhibitor from blood is much shorter than the transit time of that blood through the liver), then the inhibitor will have little or no effect on the steady-state concentration of total (free plus bound) drug, but it will cause the free fraction and the steady-state concentration of free drug in extrahepatic blood or plasma to be *increased*. This result would come about for two reasons:

1. Protein binding of the drug in blood is normal (rather than reduced) during most of the residence time of any one small portion of blood in the liver.
2. Protein binding of the drug leaving the liver is soon reduced as that blood mixes with inhibitor-containing blood in the vena cava, causing the free fraction and concentration of free drug to rise again.

Drug binding inhibitors with hepatic extraction ratios near unity may be cleared quite rapidly from the body. However, their concentration in blood can be quite stable if they are continuously formed endogenously, are continuously administered (other drugs or dietary components), or have a large apparent volume of distribution. Such inhibitors can be expected to increase the pharmacological activity of drugs that they displace by increasing the steady-state free concentration of these drug in extrahepatic blood. Since the steady-state concentration of total drug may be almost unchanged, the increased pharmacological activity may be unanticipated.

It is relatively easy to determine the hepatic extraction characteristics of drugs that act as displacers of other drugs from plasma protein binding sites; such a determination can be done by measuring the hepatic clearance of the displacer drugs. However, this approach is not possible (at least at this time) in the case of endogenous inhibitors associated with certain changes in the pathophysiological status of humans and animals. The hepatic extraction characteristics of binding inhibitors associated with pregnancy (5) and renal failure (6) are presently being investigated directly. To describe the method used for this investigation and to demonstrate in principle that certain endogenous inhibitors are indeed subject to considerable hepatic extraction, data on heparin-induced inhibitors of protein binding will be reported here. Since the composi-

tion of these endogenously produced inhibitors is not established definitively, their activity in plasma was determined indirectly by measuring their effect on the protein binding of a suitable marker substance, bilirubin.

Intravenous injection of heparin causes a decrease in the plasma protein binding of bilirubin and certain drugs, apparently due to increased concentrations of fatty acids (7–9). In this study, male adult Sprague–Dawley rats had a cannula inserted in the femoral vein under ether anesthesia. A blood sample (~0.7 ml) was then collected. Immediately thereafter, the rats received an intravenous injection of heparin (500 units/kg) or an equal volume of normal saline solution. The liver was then exposed through a midline abdominal incision, a cannula was inserted in the hepatic vein of the left lobe (10), and the hepatic vein was clamped near its junction with the vena cava immediately before the hepatic vein blood sample was taken. These procedures were completed within 1–3 min.

Blood samples (0.7 ml) were obtained simultaneously from the femoral and hepatic veins from 3 to 5 min after heparin injection. Plasma was separated, bilirubin was added to yield a final concentration of ~10 mg/100 ml, and the free fraction of this substance was determined by a peroxidase-catalyzed reaction rate method (3, 11). Blood samples obtained before heparin or saline injection were treated in the same manner.

In the control (saline injection) experiments, the plasma bilirubin free fraction values (mean $\times 10^4 \pm SD$, $n = 6$) were 3.06 ± 0.63 before injection, 3.75 ± 1.05 in plasma from the femoral vein after injection, and 3.98 ± 0.87 in plasma from the hepatic vein after injection. The ratio of the bilirubin free fraction values, hepatic vein plasma: femoral vein plasma, was 1.08 ± 0.10 (mean ± SD, $n = 6$). Thus, perfusion through the liver had no apparent effect on the bilirubin binding characteristics of plasma in control animals.

Heparin injection caused a rapid and pronounced increase in the plasma free fraction of bilirubin as reported previously (7). Moreover, there was a pronounced difference between the protein binding of bilirubin in femoral vein and hepatic vein plasma. The ratio of the bilirubin free fraction values, hepatic vein plasma:femoral vein plasma, was 0.647 ± 0.192 (mean ± SD, $n = 11$).

The results of this investigation demonstrate that certain endogenous inhibitors of plasma protein binding are extracted quite efficiently by the liver. The plasma protein binding of drugs affected by these inhibitors is not the same in plasma obtained from a peripheral vein and in plasma obtained immediately after passage through the liver. Therefore, estimations of the intrinsic clearance of free drug in the presence of inhibitors of protein binding of that drug are incorrect if these inhibitors have large hepatic (or other eliminating organ) extraction ratios.

High-Pressure Liquid Chromatography of Triamcinolone Acetonide: Effect of Different Octadecylsilane Columns on Mobility

Keyphrases □ Triamcinolone acetonide—high-pressure liquid chromatographic analysis, effects of various octadecylsilane columns on mobility □ High-pressure liquid chromatography—analysis, triamcinolone acetonide, effects of various octadecylsilane columns on mobility □ Anti-inflammatory agents—triamcinolone acetonide, high-pressure liquid chromatographic analysis, effects of various octadecylsilane columns on mobility

To the Editor:

Triamcinolone acetonide[1], a topical anti-inflammatory agent, was assayed by high-pressure liquid chromatography (1) with fluoxymesterone as the internal standard. A reversed-phase octadecylsilane column was used with a mobile phase of acetonitrile–water (30:70) at a flow rate of 2 ml/min. Detection was at 254 nm.

With a column[2] packed with particles 10% covered by octadecylsilane, fluoxymesterone eluted in 10 min and triamcinolone acetonide eluted in 12 min. With a column[3] covered with 5% octadecylsilane, and under otherwise identical chromatographic conditions, fluoxymesterone eluted in 8 min and triamcinolone acetonide eluted in 6 min. The elution patterns were reversed, as also was shown by separate injections of the individual steroids and linearity studies using various concentrations of both steroids.

Both columns are ostensibly the same L-1 type (2). This reversal may be due to the difference in coverage of the particles by octadecylsilane[4] if no other proprietary differences are assumed. The former column separates primarily on the basis of partition, and the latter separates primarily by a combination of partition and adsorption. [The order of elution using the first column can be reversed by using a mobile phase of methanol–water (60:40) instead of acetonitrile–water (30:70).] Both columns gave similar values for triamcinolone acetonide.

This striking difference between similarly designated columns may represent the possible extremes in retention. Columns should be tested for suitability prior to use for the official method (1). Alternatively, either the internal standard can be omitted (3) if a precision loop injector[5] is used or the mobile phase composition may be altered to change the elution order of the steroids.

Effect of Plasma Protein Binding on Renal Clearance of Drugs

Keyphrases □ Plasma protein binding—effect on renal clearance of drugs □ Drug clearance, renal—effect of plasma protein binding □ Renal clearance—effect of plasma protein binding

To the Editor:

The theoretical concepts of the relationships between plasma or serum protein binding and hepatic metabolic clearance of drugs are now reasonably well defined (1–3 and references cited therein). On the other hand, corresponding theory and experimental data concerning the effect of plasma protein binding on the renal excretion of drugs are quite limited (4–13). The purpose of this communication is to propose certain relationships between plasma protein binding and renal clearance of drugs that may be useful for the design and interpretation of experimental studies.

The renal excretion of drugs usually involves three processes: glomerular filtration, renal tubular secretion, and partial reabsorption from the renal tubular lumen. Glomerular filtration is a passive process and may be assumed to be a function of the free (unbound) concentration of drug in plasma (11) if the glomeruli are intact. Renal tubular secretion is a specialized process; it is saturable in principle but appears to be linear for most drugs under the usual clinical or experimental conditions. The rate of renal tubular secretion may be proportional to the concentration of free or total (free and bound) drug in plasma; it may or may not be affected by blood flow. Renal tubular reabsorption of most drugs involves passive diffusion of nonionized molecules from the renal tubular lumen. Therefore, the rate of reabsorption is proportional to the concentration gradient of diffusible (usually free and nonionized) drug across the renal tubular boundary. Consequently, reabsorption may be affected by the urine flow rate and by the urine pH if the drug is a weak acid or base. The concentration of diffusible drug on the tissue side of the renal tubule is likely to be negligible compared to that in the lumen of the tubule, except in some cases of pronounced diuresis or urine pH alteration. Drug in the urine exists in unbound form unless there is serious nephropathy with marked proteinuria[1]. Thus, if the glomerular excretion rate is proportional to and the renal tubular secretion rate is a function of the concentration of *free* drug in plasma:

$$\text{renal excretion rate} = k_g fC + \frac{Qfk_sC}{Q + fk_s} - F\left(k_g fC + \frac{Qfk_sC}{Q + fk_s}\right) \quad \text{(Eq. 1)}$$

where k_g is the glomerular filtration clearance and k_s is the intrinsic renal tubular secretion clearance (both clearances are referenced to the free drug concentration in plasma), Q is the flow rate of plasma perfusing the renal tubular secretion sites, f is the free fraction of drug in plasma (which is assumed to be independent of concentration in the usual therapeutic or experimental concentration range), C is the concentration of total drug in plasma, and F is a (possibly urine flow rate- and urine pH-dependent) dimensionless constant equal to the fraction of filtered and secreted drug that is reabsorbed.

Implied in the equation is the assumption that F for filtered and secreted drug is the same; this assumption is reasonable if secretion takes place in the proximal region of the tubules and reabsorption occurs mainly from the distal region of the renal tubules. If the concentration ratio, erythrocytes:plasma, of the drug is substantial and reequilibration of the drug between erythrocytes and plasma is very rapid, C may be designated as the concentration of drug in whole blood and k_g, k_s, Q, and f have to be defined accordingly. However, this approach may be complicated if, as was suggested (9), a proportion of the erythrocytes is separated off by "plasma skimming" and shunted into the renal veins without contacting the renal tubules.

The second term on the right side of Eq. 1 is analogous to, and derived in a similar manner as, the hepatic metabolic clearance equation (2). If $Q \gg fk_s$, that term reduces to fk_sC and Eq. 1 reduces to:

$$\text{renal excretion rate} = k_g fC + k_s fC - F(k_g fC + k_s fC) \quad \text{(Eq. 2)}$$

Since renal clearance equals excretion rate/C, division of both sides of Eq. 2 by C and rearrangement yield:

$$\text{renal clearance} = f[k_g + k_s - F(k_g + k_s)] \quad \text{(Eq. 3)}$$

Therefore, a plot of renal clearance *versus* f should be linear and intersect the origin. This situation appears to be the case with salicylic acid in rats, according to preliminary results obtained in this laboratory[2]. If tubular reabsorption is prevented (which can be done with certain weak acids or bases by changing the urine pH), $F = 0$ and the slope of a plot of renal clearance *versus* f increases to $(k_g + k_s)$. The value of $(k_g + k_s)$ should not exceed the renal blood flow unless the compound is formed entirely or in part in the kidneys.

[1] Another rare exception is the case in which a drug or endogenous substance and a complexing or chelating agent are excreted concurrently, separately and as the complex. Each of these species will exhibit distinct renal pharmacokinetic characteristics.

This striking difference between similarly designated columns may represent the possible extremes in retention. Columns should be tested for suitability prior to use for the official method (1). Alternatively, either the internal standard can be omitted (3) if a precision loop injector[5] is used or the mobile phase composition may be altered to change the elution order of the steroids.

Effect of Plasma Protein Binding on Renal Clearance of Drugs

Keyphrases □ Plasma protein binding—effect on renal clearance of drugs □ Drug clearance, renal—effect of plasma protein binding □ Renal clearance—effect of plasma protein binding

To the Editor:

The theoretical concepts of the relationships between plasma or serum protein binding and hepatic metabolic clearance of drugs are now reasonably well defined (1–3 and references cited therein). On the other hand, corresponding theory and experimental data concerning the effect of plasma protein binding on the renal excretion of drugs are quite limited (4–13). The purpose of this communication is to propose certain relationships between plasma protein binding and renal clearance of drugs that may be useful for the design and interpretation of experimental studies.

The renal excretion of drugs usually involves three processes: glomerular filtration, renal tubular secretion, and partial reabsorption from the renal tubular lumen. Glomerular filtration is a passive process and may be assumed to be a function of the free (unbound) concentration of drug in plasma (11) if the glomeruli are intact. Renal tubular secretion is a specialized process; it is saturable in principle but appears to be linear for most drugs under the usual clinical or experimental conditions. The rate of renal tubular secretion may be proportional to the concentration of free or total (free and bound) drug in plasma; it may or may not be affected by blood flow. Renal tubular reabsorption of most drugs involves passive diffusion of nonionized molecules from the renal tubular lumen. Therefore, the rate of reabsorption is proportional to the concentration gradient of diffusible (usually free and nonionized) drug across the renal tubular boundary. Consequently, reabsorption may be affected by the urine flow rate and by the urine pH if the drug is a weak acid or base. The concentration of diffusible drug on the tissue side of the renal tubule is likely to be negligible compared to that in the lumen of the tubule, except in some cases of pronounced diuresis or urine pH alteration. Drug in the urine exists in unbound form unless there is serious nephropathy with marked proteinuria[1]. Thus, if the glomerular excretion rate is proportional to and the renal tubular secretion rate is a function of the concentration of *free* drug in plasma:

$$\text{renal excretion rate} = k_g fC + \frac{Qfk_sC}{Q + fk_s} - F\left(k_g fC + \frac{Qfk_sC}{Q + fk_s}\right) \quad \text{(Eq. 1)}$$

where k_g is the glomerular filtration clearance and k_s is the intrinsic renal tubular secretion clearance (both clearances are referenced to the free drug concentration in plasma), Q is the flow rate of plasma perfusing the renal tubular secretion sites, f is the free fraction of drug in plasma (which is assumed to be independent of concentration in the usual therapeutic or experimental concentration range), C is the concentration of total drug in plasma, and F is a (possibly urine flow rate- and urine pH-dependent) dimensionless constant equal to the fraction of filtered and secreted drug that is reabsorbed.

Implied in the equation is the assumption that F for filtered and secreted drug is the same; this assumption is reasonable if secretion takes place in the proximal region of the tubules and reabsorption occurs mainly from the distal region of the renal tubules. If the concentration ratio, erythrocytes:plasma, of the drug is substantial and reequilibration of the drug between erythrocytes and plasma is very rapid, C may be designated as the concentration of drug in whole blood and k_g, k_s, Q, and f have to be defined accordingly. However, this approach may be complicated if, as was suggested (9), a proportion of the erythrocytes is separated off by "plasma skimming" and shunted into the renal veins without contacting the renal tubules.

The second term on the right side of Eq. 1 is analogous to, and derived in a similar manner as, the hepatic metabolic clearance equation (2). If $Q \gg fk_s$, that term reduces to fk_sC and Eq. 1 reduces to:

$$\text{renal excretion rate} = k_g fC + k_s fC - F(k_g fC + k_s fC) \quad \text{(Eq. 2)}$$

Since renal clearance equals excretion rate/C, division of both sides of Eq. 2 by C and rearrangement yield:

$$\text{renal clearance} = f[k_g + k_s - F(k_g + k_s)] \quad \text{(Eq. 3)}$$

Therefore, a plot of renal clearance *versus* f should be linear and intersect the origin. This situation appears to be the case with salicylic acid in rats, according to preliminary results obtained in this laboratory[2]. If tubular reabsorption is prevented (which can be done with certain weak acids or bases by changing the urine pH), $F = 0$ and the slope of a plot of renal clearance *versus* f increases to $(k_g + k_s)$. The value of $(k_g + k_s)$ should not exceed the renal blood flow unless the compound is formed entirely or in part in the kidneys.

[1] Another rare exception is the case in which a drug or endogenous substance and a complexing or chelating agent are excreted concurrently, separately and as the complex. Each of these species will exhibit distinct renal pharmacokinetic characteristics.

If tubular secretion is blocked ($k_s = 0$) and k_g is assumed to equal the glomerular filtration rate (GFR), Eq. 3 becomes:

$$F = 1 - (\text{renal clearance}/f\ \text{GFR}) \quad \text{(Eq. 4)}$$

A similar form of that equation was developed by Arita *et al.* (14); the inverse of the term in parentheses is the excretion ratio as defined by Fisher *et al.* (15). With F determined by means of Eq. 4, k_s can be calculated by a rearranged form of Eq. 3:

$$k_s = \frac{\text{renal clearance}}{f(1 - F)} - \text{GFR} \quad \text{(Eq. 5)}$$

It is reasonable to assume that k_g, being referenced to free drug and characterizing a physical rather than enzymatic or carrier process, is equal to the glomerular filtration rate, a constant that can be determined from the renal clearance of inulin or creatinine.

If the rate of renal tubular secretion is proportional to the concentration of *total* drug in plasma and if the previously stated assumptions apply:

$$\text{renal excretion rate} = k_g fC + k_s^* C - F(k_g fC + k_s^* C) \quad \text{(Eq. 6)}$$

where k_s^* is the renal secretion clearance referenced to the total drug concentration in plasma. Division of both sides of the equation by C and rearrangement yield:

$$\text{renal clearance} = fk_g(1 - F) + k_s^*(1 - F) \quad \text{(Eq. 7)}$$

In this case, a plot of renal clearance *versus* f should be linear and have a positive intercept. Such a relationship was observed recently by Yacobi and Levy (7) with respect to the renal clearance of sulfisoxazole in rats.

Dividing the slope of a plot of renal clearance *versus* f according to Eq. 7 by its intercept gives:

$$\frac{\text{slope}}{\text{intercept}} = \frac{k_g(1 - F)}{k_s^*(1 - F)} = \frac{k_g}{k_s^*} \quad \text{(Eq. 8)}$$

Consequently, inhibition of renal tubular secretion (for example, by administration of probenecid in the case of certain acidic drugs) should cause an increase of the slope:intercept ratio if the renal tubular secretion rate is proportional to the total drug concentration in plasma.

Inhibition or absence of renal tubular reabsorption ($F = 0$) reduces Eq. 7 to:

$$\text{renal clearance} = fk_g + k_s^* \quad \text{(Eq. 9)}$$

and, therefore, results in increased slope and intercept values but has no effect on the slope:intercept ratio. The slope should not exceed the glomerular filtration rate of a completely filtered substance such as inulin or creatinine, and k_s^* should not exceed the renal blood flow minus k_g unless the excreted substance is entirely or partly formed in the kidneys.

Equation 8 may be useful for estimating k_s^*, again with the assumption that k_g = GFR. Then, k_s^* = GFR (intercept/slope). Thus, it may be possible to estimate k_s^* under physiological conditions, *i.e.*, without changing the urine pH to prevent renal tubular reabsorption or administering a drug that blocks renal tubular secretion. Since the intercept of a plot of renal clearance *versus* f according to Eq. 7 is equal to $k_s^*(1 - F)$, F can be estimated if k_s^* is known.

Proportionality between the renal tubular secretion rate and the total rather than the free drug concentration in plasma may be a consequence of blood flow rate-limited secretion (12). Under these conditions, the sum of k_g and k_s^* may be equal to the renal blood flow or it may be less than that if part of the blood perfusing the kidneys bypasses the sites of renal secretion for a particular drug (12, 16). Thus, Eq. 6 may be a limiting case of Eq. 1 when $fk_s \gg Q$. Then the second term on the right side of Eq. 1 reduces to QC, and k_s^* in Eqs. 6–9 becomes Q.

REVIEWS

Autonomic Pharmacology: Experimental and Clinical Aspects. By MICHAEL D. DAY. Churchill Livingstone, 19 West 44th St., New York, NY 10036. 1979. 255 pp. 14 × 21 cm. Price $15.00 (soft cover).

This excellent small book, in the words of the author, "is intended primarily for undergraduate students of medical sciences." Students of medicine, pharmacy, dentistry, nursing, and other health sciences also should be included. Written for British students, this book contains many drug names that are not familiar to American students. This is due mainly to the fact that the FDA considers some of these drugs neither safe nor effective, even though they have been used in England for many years. The fact that drugs available on this side of the Atlantic are not identified may be a slight handicap. However, by describing these foreign drugs, this book gives the American student a better and more complete view of autonomic drug development.

There are three chapters covering the anatomy, physiology, and chemistry of the autonomic motor system and neurohumoral transmission. Ten chapters cover adrenergic and cholinergic agonists and blocking agents. For each drug class, one or two prototype compounds are described in detail. Other drugs of the same category then are briefly compared clinically to the prototype. The historical aspects of autonomic physiology and pharmacology are well covered. As far as the drugs that are included and the mechanism of actions described are concerned, this work is up to date. The only thing missing is some mention of radioligand studies of receptors. This book is recommended for all biomedical students.

The Anticancer Drugs. By WILLIAM B. PRATT and RAYMOND W. RUDDON. Oxford University Press, 200 Madison Ave., New York, NY 10016. 1979. 323 pp. 15 × 23 cm. Price $18.95 hard cover or $12.95 soft cover.

The stated purpose of this text is to offer "a full, but concise description of anticancer drugs, both old and new." The authors have achieved their objective with respect to describing currently used agents for human neoplastic diseases. There is excellent integration of the proposed mechanism of action of the agent, its uses against specific tumor types, and toxicity of the agent in humans.

The first chapter is a cursory review of the incidence of cancer in the United States and the world, biochemical and genetic characteristics of malignant cells, and role of drugs in cancer therapy.

Historical milestones in the development of the major chemical categories of antineoplastic agents are dealt with in the second chapter.

The third chapter discusses Gompertizian cell growth of tumors, the cell cycle, fraction of cells in mitosis, development of drug-resistant states, and determinant factors of the host involved in drug response.

Chapter 4 reviews, as general concepts, the responsiveness of tumors to chemotherapy drugs, the choice of drugs for specific types of tumors, combination chemotherapy, adjuvant therapy, and toxicity of antineoplastics.

Individual alkylating agents, antimetabolites, antibiotics, hormones, plant alkaloids, enzymes, and miscellaneous drugs are delineated in Chapters 5–9. The chemical structure, mechanism of action, administration routes, absorption, bioactivation, metabolism, distribution, excretion, causes of resistant states, and toxicity are given.

The last chapter briefly describes how new drugs are established as antineoplastic agents in animal models. Thirteen new drugs are discussed that are currently in human clinical trials, potent in animal screens, or unique in structure as an approach to drug design. This chapter also includes a treatment of biological markers of neoplastic cells, *e.g.*, antigens or enzymes, which is more appropriately included in an earlier chapter.

There are several weaknesses of the book as a general text in academic instruction. There is no discussion of structure–activity relationships or the reasons some agents are restricted from use in this country. Only a limited conceptual discussion of immunotherapy agents and their uses in neoplastic therapy and the use of chemotherapy prior to and post-surgery and/or radiation is presented. Neither percentages of response in the clinic to a specific agent for a given tumor type nor the percentage of relapses from therapy is delineated in the text. Furthermore, no differentiation is made between singular and combination therapy in the discussion of the uses of an agent.

The primary emphasis of this book is on the mechanisms of action as seen from the viewpoint of both biochemistry and molecular biology. Few texts have achieved such a complete description of all major agents.

Index of Antibiotics from Actinomycetes, Vol. 11. Edited by HAMAO UMEZAWA. University Park Press, 233 E. Redwood St., Baltimore, MD 21202. 1979. 1466 pp. 18 × 23 cm. Price $97.50.

This update of a 1966 index lists the antibiotics produced by Actinomycetes reported mainly between 1966 and 1976. Chapter I lists generic names, common names, trivial names, and selected trade names, including those from the previous volume, in alphabetical order followed by those antibiotics designated by letter and numerical arrangement. The group to which the antibiotic belongs and its synonyms are given along with a page reference to an entry in the previous or present volume.

Chapter II gives data on the antibiotics. A typical compound entry includes the antibiotic group, synonyms and similar compounds, molecular weight and formula, structure, isolation, physical properties such as melting point and solubility, elemental analysis, UV characteristics, IR spectrum, activity, LD_{50} value, and literature references.

Analytical Profiles of Drug Substances, Vol. 8. Edited by KLAUS FLOREY. Academic, 111 Fifth Ave., New York, NY 10003. 1979. 558 pp. 15.5 × 23.5 cm.

This ongoing series is concerned with reporting supplemental information on drug substances that are listed in the official compendia but for which the compendia do not provide detailed physical or chemical data, methods of synthesis, or pathways of physical or biological degradation and metabolism.

Volume 8 contains individual monographs for the following drugs: aspirin, bromocriptine methanesulphonate, calcitrol, chlortetracycline hydrochloride, dobutamine hydrochloride, erythromycin, gramicidin, griseofulvin, halcinonide, hydralazine hydrochloride, calcium leucovorin, methimazole, nalidixic acid, neomycin, pseudoephedrine hydrochloride, triprolidine hydrochloride, and sodium valproate and valproic acid. The monographs contain some or all of the general headings such as introductory information (*e.g.*, history, appearance, and odor), physicochemical properties (*e.g.*, elemental analysis, spectra, crystal properties, solubility, and partition coefficients), synthesis, stability and degradation, biopharmaceutics (*e.g.*, pharmacokinetics and metabolism), toxicology, analytical methods, and literature references. Most of the monographs seem to have surveyed the drug literature through 1977 or 1978. The spectra and other analytical curves in the book have been reproduced in a clear and uncluttered fashion.

The entire series should be available in libraries of drug firms, FDA laboratories, toxicology laboratories, and schools of medicine and pharmacy. The volumes are not organized for use as textbooks in courses such

The third chapter discusses Gompertizian cell growth of tumors, the cell cycle, fraction of cells in mitosis, development of drug-resistant states, and determinant factors of the host involved in drug response.

Chapter 4 reviews, as general concepts, the responsiveness of tumors to chemotherapy drugs, the choice of drugs for specific types of tumors, combination chemotherapy, adjuvant therapy, and toxicity of antineoplastics.

Individual alkylating agents, antimetabolites, antibiotics, hormones, plant alkaloids, enzymes, and miscellaneous drugs are delineated in Chapters 5–9. The chemical structure, mechanism of action, administration routes, absorption, bioactivation, metabolism, distribution, excretion, causes of resistant states, and toxicity are given.

The last chapter briefly describes how new drugs are established as antineoplastic agents in animal models. Thirteen new drugs are discussed that are currently in human clinical trials, potent in animal screens, or unique in structure as an approach to drug design. This chapter also includes a treatment of biological markers of neoplastic cells, *e.g.*, antigens or enzymes, which is more appropriately included in an earlier chapter.

There are several weaknesses of the book as a general text in academic instruction. There is no discussion of structure–activity relationships or the reasons some agents are restricted from use in this country. Only a limited conceptual discussion of immunotherapy agents and their uses in neoplastic therapy and the use of chemotherapy prior to and post-surgery and/or radiation is presented. Neither percentages of response in the clinic to a specific agent for a given tumor type nor the percentage of relapses from therapy is delineated in the text. Furthermore, no differentiation is made between singular and combination therapy in the discussion of the uses of an agent.

The primary emphasis of this book is on the mechanisms of action as seen from the viewpoint of both biochemistry and molecular biology. Few texts have achieved such a complete description of all major agents.

Index of Antibiotics from Actinomycetes, Vol. 11. Edited by HAMAO UMEZAWA. University Park Press, 233 E. Redwood St., Baltimore, MD 21202. 1979. 1466 pp. 18 × 23 cm. Price $97.50.

This update of a 1966 index lists the antibiotics produced by Actinomycetes reported mainly between 1966 and 1976. Chapter I lists generic names, common names, trivial names, and selected trade names, including those from the previous volume, in alphabetical order followed by those antibiotics designated by letter and numerical arrangement. The group to which the antibiotic belongs and its synonyms are given along with a page reference to an entry in the previous or present volume.

Chapter II gives data on the antibiotics. A typical compound entry includes the antibiotic group, synonyms and similar compounds, molecular weight and formula, structure, isolation, physical properties such as melting point and solubility, elemental analysis, UV characteristics, IR spectrum, activity, LD_{50} value, and literature references.

Analytical Profiles of Drug Substances, Vol. 8. Edited by KLAUS FLOREY. Academic, 111 Fifth Ave., New York, NY 10003. 1979. 558 pp. 15.5 × 23.5 cm.

This ongoing series is concerned with reporting supplemental information on drug substances that are listed in the official compendia but for which the compendia do not provide detailed physical or chemical data, methods of synthesis, or pathways of physical or biological degradation and metabolism.

Volume 8 contains individual monographs for the following drugs: aspirin, bromocriptine methanesulphonate, calcitrol, chlortetracycline hydrochloride, dobutamine hydrochloride, erythromycin, gramicidin, griseofulvin, halcinonide, hydralazine hydrochloride, calcium leucovorin, methimazole, nalidixic acid, neomycin, pseudoephedrine hydrochloride, triprolidine hydrochloride, and sodium valproate and valproic acid. The monographs contain some or all of the general headings such as introductory information (*e.g.*, history, appearance, and odor), physicochemical properties (*e.g.*, elemental analysis, spectra, crystal properties, solubility, and partition coefficients), synthesis, stability and degradation, biopharmaceutics (*e.g.*, pharmacokinetics and metabolism), toxicology, analytical methods, and literature references. Most of the monographs seem to have surveyed the drug literature through 1977 or 1978. The spectra and other analytical curves in the book have been reproduced in a clear and uncluttered fashion.

The entire series should be available in libraries of drug firms, FDA laboratories, toxicology laboratories, and schools of medicine and pharmacy. The volumes are not organized for use as textbooks in courses such

REVIEWS

Autonomic Pharmacology: Experimental and Clinical Aspects. By MICHAEL D. DAY. Churchill Livingstone, 19 West 44th St., New York, NY 10036. 1979. 255 pp. 14 × 21 cm. Price $15.00 (soft cover).

This excellent small book, in the words of the author, "is intended primarily for undergraduate students of medical sciences." Students of medicine, pharmacy, dentistry, nursing, and other health sciences also should be included. Written for British students, this book contains many drug names that are not familiar to American students. This is due mainly to the fact that the FDA considers some of these drugs neither safe nor effective, even though they have been used in England for many years. The fact that drugs available on this side of the Atlantic are not identified may be a slight handicap. However, by describing these foreign drugs, this book gives the American student a better and more complete view of autonomic drug development.

There are three chapters covering the anatomy, physiology, and chemistry of the autonomic motor system and neurohumoral transmission. Ten chapters cover adrenergic and cholinergic agonists and blocking agents. For each drug class, one or two prototype compounds are described in detail. Other drugs of the same category then are briefly compared clinically to the prototype. The historical aspects of autonomic physiology and pharmacology are well covered. As far as the drugs that are included and the mechanism of actions described are concerned, this work is up to date. The only thing missing is some mention of radioligand studies of receptors. This book is recommended for all biomedical students.

The Anticancer Drugs. By WILLIAM B. PRATT and RAYMOND W. RUDDON. Oxford University Press, 200 Madison Ave., New York, NY 10016. 1979. 323 pp. 15 × 23 cm. Price $18.95 hard cover or $12.95 soft cover.

The stated purpose of this text is to offer "a full, but concise description of anticancer drugs, both old and new." The authors have achieved their objective with respect to describing currently used agents for human neoplastic diseases. There is excellent integration of the proposed mechanism of action of the agent, its uses against specific tumor types, and toxicity of the agent in humans.

The first chapter is a cursory review of the incidence of cancer in the United States and the world, biochemical and genetic characteristics of malignant cells, and role of drugs in cancer therapy.

Historical milestones in the development of the major chemical categories of antineoplastic agents are dealt with in the second chapter.

The third chapter discusses Gompertizian cell growth of tumors, the cell cycle, fraction of cells in mitosis, development of drug-resistant states, and determinant factors of the host involved in drug response.

Chapter 4 reviews, as general concepts, the responsiveness of tumors to chemotherapy drugs, the choice of drugs for specific types of tumors, combination chemotherapy, adjuvant therapy, and toxicity of antineoplastics.

Individual alkylating agents, antimetabolites, antibiotics, hormones, plant alkaloids, enzymes, and miscellaneous drugs are delineated in Chapters 5–9. Handbook of U.S. Colorants for Foods, Drugs, and Cosmetics. By DANIEL M. MARMION. Wiley-Interscience, One Wiley Drive, Somerset, NJ 08873. 1979. 350 pp. 13.5 × 21 cm.

The purpose of this book is to give a general survey of the colorants used in the United States in foods, drugs, and cosmetics. The author divided his book into three approximately equal parts. The first one offers a concise, well-written summary of the regulations related to coloring agents. It deals with the permanent and temporary listing of the colorants and sums up their properties, specifications, permitted uses, and limitations.

The second part of the book is a useful survey of the qualitative and quantitative analytical procedures applied for the colorants and their impurities. The author describes a wide range of techniques such as column, paper, and thin-layer chromatography, thermal analytical methods [differential thermal analysis (DTA) and differential scanning calorimetry (DSC)], spectrophotometry, IR spectrometry, and NMR spectroscopy. Model spectra and thermograms help the reader to understand the interpretation of the plotted data. The selected examples are presented in simple, clear language with good diagrams where needed, and they can be followed easily by chemists or technicians with appropriate training in analytical laboratory techniques. A reasonably up-to-date bibliography in each chapter assists those who desire more theoretical background or technical details.

The last section of the book basically is an extended biography, with ample comments by the author, on the analysis of colorant mixtures and commercial products such as beverages, cosmetics, drugs, and meat. These chapters, of course, were not intended to cover every possible product or application; nevertheless, the selection is a good starting point for the analyst who has to solve problems in the analysis of color additives.

In summary, this book is a first in this area. While the scope is restricted to color additives used in the United States, the book also may help professionals in other countries who are manufacturing, controlling, or using colorants.

CRC Handbook Series in Clinical Laboratory Science, Section B: Toxicology, Vol. 1. Edited by DAVID SELIGSON and IRVING SUNSHINE. CRC Press, 2255 Palm Beach Lakes Blvd., West Palm Beach, FL 33409. 1978. 414 pp. 19 × 26 cm. Price $54.95 ($62.95 outside the United States).

The preface states that "in the last few years, there has been a flood of scientific articles dealing with use and misuse of chemical agents. From this surfeit has come a plethora of data which need to be at the fingertips of many scientists." This volume is an attempt to fill that need.

The book consists of five chapters. The first and major chapter encompasses slightly over 300 pages or 75% of the book. This chapter is a detailed presentation of the chromatographic separation of drugs and chemicals. It is divided into several subsections including a basic introduction to chromatography, a presentation of GC, a presentation of TLC, and a final section on high-pressure liquid chromatography (HPLC). These sections include extensive tables on the methodology to be employed to separate hundreds of chemicals of interest to the analytical toxicologist. These tables include listings of numerous solvent systems, which are frequently indexed according to their R_f values. The section on HPLC is the least extensive of the sections on chromatography but is still a valuable introduction to the technology.

The second major chapter is on the immunoassay of drugs and includes a brief description of the development of radioimmunoassay. This chapter lists 70 drugs that can be quantitated by this technique and includes over 400 references.

The third chapter has microcrystalline tests for approximately 250 drugs and chemicals with references and explanations for each particular test.

The fourth chapter is a tabulation of solubilities of numerous antibiotics arranged in two tables. One table gives the solubility of 76 antibiotics in 24 solvents at 28°. The second table includes 53 additional antibiotics and their solubilities at 21° in 24 solvents.

The last chapter is a tabulation of approximately 600 chemicals arranged in ascending order of their melting points.

In summary, as stated in the preface, this book is a compilation of a large number of tables dealing with the separation and identification of toxic chemicals. The one drawback is that it takes a fair amount of time to become familiar with its organization since the tables frequently are extremely long. However, this book should be valuable to individuals involved with identifying chemicals in biological systems.

Sustained and Controlled Release Drug Delivery Systems, Vol. 6. Edited by JOSEPH R. ROBINSON. Dekker, 270 Madison Ave., New York, NY 10016. 1978. 773 pp. 15 × 23 cm. Price $59.75.

The book starts with a standard overview of controlled-release delivery systems, but the inclusion of the role of disease states and of circadian rhythm makes the chapter stimulating. Chapter 2 also gives standard material with a brief discussion of liposomes. Reference 200 in this chapter is cited incorrectly. Salicylate, not aspirin, has a biological half-life of 6 hr. Chapters 3 and 4 discuss physical methods of obtaining a sustained-release drug delivery system.

Chapter 5, as written, seems totally irrelevant to the rest of the book and should have been omitted. Chapters 6 and 7 give interesting accounts of the prodrug and biomedical engineering approach. Chapters 8 and 9 give the classical pharmacokinetic picture of sustained-release systems.

In general, the book provides a current and comprehensive picture of the sustained-release product area and is recommended to anyone interested in understanding the principles, technologies, and applications of controlled-release drug delivery systems.

A reasonably up-to-date bibliography in each chapter assists those who desire more theoretical background or technical details.

The last section of the book basically is an extended biography, with ample comments by the author, on the analysis of colorant mixtures and commercial products such as beverages, cosmetics, drugs, and meat. These chapters, of course, were not intended to cover every possible product or application; nevertheless, the selection is a good starting point for the analyst who has to solve problems in the analysis of color additives.

In summary, this book is a first in this area. While the scope is restricted to color additives used in the United States, the book also may help professionals in other countries who are manufacturing, controlling, or using colorants.

CRC Handbook Series in Clinical Laboratory Science, Section B: Toxicology, Vol. 1. Edited by DAVID SELIGSON and IRVING SUNSHINE. CRC Press, 2255 Palm Beach Lakes Blvd., West Palm Beach, FL 33409. 1978. 414 pp. 19 × 26 cm. Price $54.95 ($62.95 outside the United States).

The preface states that "in the last few years, there has been a flood of scientific articles dealing with use and misuse of chemical agents. From this surfeit has come a plethora of data which need to be at the fingertips of many scientists." This volume is an attempt to fill that need.

The book consists of five chapters. The first and major chapter encompasses slightly over 300 pages or 75% of the book. This chapter is a detailed presentation of the chromatographic separation of drugs and chemicals. It is divided into several subsections including a basic introduction to chromatography, a presentation of GC, a presentation of TLC, and a final section on high-pressure liquid chromatography (HPLC). These sections include extensive tables on the methodology to be employed to separate hundreds of chemicals of interest to the analytical toxicologist. These tables include listings of numerous solvent systems, which are frequently indexed according to their R_f values. The section on HPLC is the least extensive of the sections on chromatography but is still a valuable introduction to the technology.

The second major chapter is on the immunoassay of drugs and includes a brief description of the development of radioimmunoassay. This chapter lists 70 drugs that can be quantitated by this technique and includes over 400 references.

The third chapter has microcrystalline tests for approximately 250 drugs and chemicals with references and explanations for each particular test.

The fourth chapter is a tabulation of solubilities of numerous antibiotics arranged in two tables. One table gives the solubility of 76 antibiotics in 24 solvents at 28°. The second table includes 53 additional antibiotics and their solubilities at 21° in 24 solvents.

The last chapter is a tabulation of approximately 600 chemicals arranged in ascending order of their melting points.

In summary, as stated in the preface, this book is a compilation of a large number of tables dealing with the separation and identification of toxic chemicals. The one drawback is that it takes a fair amount of time to become familiar with its organization since the tables frequently are extremely long. However, this book should be valuable to individuals involved with identifying chemicals in biological systems.

Sustained and Controlled Release Drug Delivery Systems, Vol. 6. Edited by JOSEPH R. ROBINSON. Dekker, 270 Madison Ave., New York, NY 10016. 1978. 773 pp. 15 × 23 cm. Price $59.75.

The book starts with a standard overview of controlled-release delivery systems, but the inclusion of the role of disease states and of circadian rhythm makes the chapter stimulating. Chapter 2 also gives standard material with a brief discussion of liposomes. Reference 200 in this chapter is cited incorrectly. Salicylate, not aspirin, has a biological half-life of 6 hr. Chapters 3 and 4 discuss physical methods of obtaining a sustained-release drug delivery system.

Chapter 5, as written, seems totally irrelevant to the rest of the book and should have been omitted. Chapters 6 and 7 give interesting accounts of the prodrug and biomedical engineering approach. Chapters 8 and 9 give the classical pharmacokinetic picture of sustained-release systems.

In general, the book provides a current and comprehensive picture of the sustained-release product area and is recommended to anyone interested in understanding the principles, technologies, and applications of controlled-release drug delivery systems.

Microcapsule Processing and Technology. By ASAJI KONDO. Edited and revised by J. WADE VAN VALKENBURG. Dekker, 270 Madison Ave., New York, NY 10016. 1979. 182 pp. Price $22.50.

This hard-bound book represents an edited English revision of the original text published in Japanese by Asaji Kondo in 1970. The first four chapters provide an in-depth discussion into the history, general principles, and applications of microencapsulation. The remaining 14 chapters examine various methods of preparing microcapsules. In all cases, the author attempted to simplify each system, with detailed explanations of the various procedures employed to manufacture microcapsules. Schematic diagrams, tables, and scanning electron micrographs are scattered liberally throughout the text and adequately illustrate the concepts under discussion. The bulk of the book is devoted to explana-

as drug analysis or pharmaceutics, although the information contained in each volume can be used as reference material.

The volumes are highly recommended to any scientist who is actively involved in drug research and development.

Handbook of U.S. Colorants for Foods, Drugs, and Cosmetics. By DANIEL M. MARMION. Wiley-Interscience, One Wiley Drive, Somerset, NJ 08873. 1979. 350 pp. 13.5 × 21 cm.

The purpose of this book is to give a general survey of the colorants used in the United States in foods, drugs, and cosmetics. The author divided his book into three approximately equal parts. The first one offers a concise, well-written summary of the regulations related to coloring agents. It deals with the permanent and temporary listing of the colorants and sums up their properties, specifications, permitted uses, and limitations.

The second part of the book is a useful survey of the qualitative and quantitative analytical procedures applied for the colorants and their impurities. The author describes a wide range of techniques such as column, paper, and thin-layer chromatography, thermal analytical methods [differential thermal analysis (DTA) and differential scanning calorimetry (DSC)], spectrophotometry, IR spectrometry, and NMR spectroscopy. Model spectra and thermograms help the reader to understand the interpretation of the plotted data. The selected examples are presented in simple, clear language with good diagrams where needed, and they can be followed easily by chemists or technicians with appropriate training in analytical laboratory techniques. A reasonably up-to-date bibliography in each chapter assists those who desire more theoretical background or technical details.

The last section of the book basically is an extended biography, with ample comments by the author, on the analysis of colorant mixtures and commercial products such as beverages, cosmetics, drugs, and meat. These chapters, of course, were not intended to cover every possible product or application; nevertheless, the selection is a good starting point for the analyst who has to solve problems in the analysis of color additives.

Microcapsule Processing and Technology. By ASAJI KONDO. Edited and revised by J. WADE VAN VALKENBURG. Dekker, 270 Madison Ave., New York, NY 10016. 1979. 182 pp. Price $22.50.

This hard-bound book represents an edited English revision of the original text published in Japanese by Asaji Kondo in 1970. The first four chapters provide an in-depth discussion into the history, general principles, and applications of microencapsulation. The remaining 14 chapters examine various methods of preparing microcapsules. In all cases, the author attempted to simplify each system, with detailed explanations of the various procedures employed to manufacture microcapsules. Schematic diagrams, tables, and scanning electron micrographs are scattered liberally throughout the text and adequately illustrate the concepts under discussion. The bulk of the book is devoted to explana-

tions of process applications for the manufacture of paper, adhesives, plasticizers, copying materials, pigments, perfumes, and many other substances including drugs.

My biggest criticism of the book is that the original text by Asaji Kondo is 10 years old. As a result, the English version by J. Wade Van Valkenburg contains reference material published prior to 1970. However, microencapsulation is a highly patented field and several patents discussed in the book will expire in the 1980's. Therefore, the text could prove to be of great assistance to scientists working in this field.

Catecholamines: Basic and Clinical Frontiers, Vols. I and II. Edited by E. USDIN, I. J. KOPIN, and J. BARCHAS. Pergamon Press, Maxwell House, Fairview Park, Elmsford, NY 10523. 1979. Vol I: 1003 pp. Vol. II: 946 pp. 17 × 25 cm. Price $200.00 per volume.

The material in both volumes represents the phenomenal growth of research in catecholamines. Although the impact of catecholamine research in medicine has been universal, this international symposium represents research carried out mainly in the United States, France, Sweden, Britain, and Germany. The opening chapter presents a coherent, concise, and important summary by the internationally respected scientist–teacher, Arvid Carlsson, concerning the impact of catecholamine research on medical science and practices.

Compared to the previous symposium, a meaningful morphology appears on many pages. Dopamine occupies the central theme with which other endogenous substances such as enkephalins, substance P, and γ-aminobutyric acid (GABA) are intertwined. Drug-induced side effects and their influence on neurochemistry receive only limited attention. The value of genetics in relation to psychotropic illness with or without coherent neurochemical markers is included. One occasionally sees a marked overlap between the material published in these symposia and that published elsewhere. In the present era of rapid scientific communication, publishing the same material repeatedly should be discouraged. Catecholamine receptors occupy a large section in Vol. I.

The cost of both volumes may produce mental and neurochemical disturbances in the poor scientist who may want to buy them, so only departmental and institutional purchases are recommended.

Introduction to Powder Surface Area. By S. LOWELL. Wiley, 605 Third Ave., New York, NY 10016. 1979. 199 pp. 15 × 23 cm. Price $17.95.

The subject of micromeritics should be important to pharmaceutical scientists. The features of a powder, *e.g.*, particle size, shape, and area, can greatly influence product development and processing as well as the properties of the finished product. However, the articles published about powders often present complicated dissolution equations derived for idealized situations. Thus, the important term for powder surface area in many pharmaceutical papers is calculated from assumed particle distributions for regularly shaped, isotropic particles. The assumption of no pores, no surface irregularities, and no interparticle forces leading to aggregation is far from reality. It should be of interest in pharmacy to characterize powders in regard to actual surface area and then to seek valid relationships between area and powder behaviors. This book may provide the proper introduction into this field for many pharmaceutical scientists.

Lowell treats powder surface area and pore-size distribution mostly as a subject of gas adsorption. However, mercury porosimetry is discussed. The book is relatively small (199 pages) and is divided into two parts. The author discusses the theoretical bases for surface area measurements in the first part. The topics discussed in these first 11 chapters also may be found in books on surface chemistry or particle-size measurement, but Lowell's presentation is clear and generally easy to follow. For example, in Chapter 5, he carefully leads the reader through the Brunauer, Emmett, and Teller theory using 25 equations.

The second section, the experimental section, should be quite helpful to those entering the field of surface area measurement. The basic techniques are described, but the narratives on vacuum volumetric methods (Chapter 13) and particularly on dynamic flow methods (Chapter 14) are somewhat less clear than the discussions in the first part of the book. Quick comparisons on various points (gas mixtures, calibration, speed, *etc.*) of the three important gas adsorption techniques (*i.e.*, vacuum volumetric, continuous flow, and gravimetric methods) are given in Chapter 17.

One frustrating feature of this book is the large number of typographical and content errors. These errors reduce reader confidence in the text. Many of these are immediately recognizable as errors but some are not. Thus, while trying to understand the vacuum volumetric method in Chapter 13, we depend on Eqs. 13.3–13.8 to help, not hinder, us. Here, a simple sign error can lead to considerable confusion.

The real advantage of this book may be psychological. The author has separated the topic from the generally larger subject of particle-size measurement. By limiting the topic, he has made it possible for us to become more immediately interested in surface area measurement and, perhaps, more willing to use such measurements.

Thus, this book should be worthwhile for self-study or as a basic reference and should be recommended to pharmaceutical scientists. Nevertheless, it is only an introduction. The implication given on the dust cover that meaningful measurements of powder surface areas will immediately result from study of this book is probably too optimistic.

PR IN THE PHARMACEUTICAL SCIENCES

"Better Living Through Chemistry!"

For those readers who are in the same age bracket as this writer, there is no need to identify the slogan quoted above, or to tell when it was in wide, popular use. For our younger readers, however, we should explain that this was a theme that ran through the extensive advertising of the DuPont Chemical Company during and immediately following World War II.

Having developed artificial fibers, and nylon in particular, from a virtual nothing into a huge segment of American industrial production during the decade of the 1940's, the DuPont firm could truly boast of the wonderous changes that chemistry, nylon, and DuPont had worked for the citizens of this country in the span of a few short years.

But chemistry was responsible for more than just women's sheer stockings and Air Force pilots' parachutes. It also was the vehicle that brought us vitamins, miracle drugs, artificial rubber tires, sudsy detergents, and countless other consumer products that literally transformed the average person's daily life-style more dramatically than mankind had previously experienced in time periods covering hundreds or even thousands of years.

Consequently, to have grown up as a teenager during those fabulous late forties was to feel and share the excitement of breathtaking new discoveries and to marvel at the almost daily new products and conveniences.

And, at that time, to be able to tell friends, colleagues, and relatives that you were embarking on the study of science and chemistry was to feel the pride and to sense the adulation experienced more recently by moon-walking astronauts or Super Bowl quarterbacks.

But as time went on, the public began to hear about insecticide buildup in birds and fish, about waterways being fouled with nonbiodegradable detergents, about the cancer risk of certain food additives, about growth hormone residues in food animals, about the risk of nuclear power plant accidents, and about dozens of other problems associated with those wonderful products of the chemical age—and all of a sudden it wasn't too popular to be identified as a chemist or scientist.

Pharmacy and pharmacists shared to a great extent in these swings of public favor. After all, pharmacy and pharmacists most directly deal with the drugs, the vitamins, the hormones, the pharmaceutical excipients, the flavors, the artificial sweeteners, and so on that first appeared so attractive but later were looked upon with misgivings and fear. And aside from chemists *per se*, among the professions, pharmacists probably take more chemistry courses in their formal education than any other professionals with the possible exception of chemical engineers.

And naturally, within the community of pharmacy, pharmaceutical scientists probably felt the brunt of this fall from public popularity more severely than any other group. But, on the other hand, no group is more aware than pharmaceutical scientists of the many good things that science, chemistry, and more specifically the pharmaceutical sciences have done to contribute to better health and longer lives.

Consequently, it may be timely for some down-to-earth, grass-roots public relations in which we take the opportunity to talk at meetings of consumer groups, fraternal organizations, ladies' clubs, boy scouts, community associations, better business bureaus, or whatever and to provide a balanced picture of the benefits and risks of drugs as well as the special stories about timed-release preparations, about novel drug delivery systems, and about the development of prodrugs.

The key to success in such public relations efforts is that such presentations must be credible. The hazards of potent drugs, the unknown problems associated with all new products, and the difficulty of achieving zero defects in product quality must also be recognized in an honest and forthright manner.

Certainly, the "pill for every ill" approach is harmful and dangerous to society; as such, we must do what we can to reject such thinking. However, for the public to espouse an attitude of therapeutic nihilism would be at least equally unfortunate for society.

Pharmaceutical scientists have the information, background, and opportunity to influence public opinion to see that neither of these extremes is allowed to prevail. And, in speaking out with such a message, pharmaceutical scientists will enhance their own image in the area of public esteem.

PR IN THE PHARMACEUTICAL SCIENCES

"Better Living Through Chemistry!"

For those readers who are in the same age bracket as this writer, there is no need to identify the slogan quoted above, or to tell when it was in wide, popular use. For our younger readers, however, we should explain that this was a theme that ran through the extensive advertising of the DuPont Chemical Company during and immediately following World War II.

Having developed artificial fibers, and nylon in particular, from a virtual nothing into a huge segment of American industrial production during the decade of the 1940's, the DuPont firm could truly boast of the wonderous changes that chemistry, nylon, and DuPont had worked for the citizens of this country in the span of a few short years.

But chemistry was responsible for more than just women's sheer stockings and Air Force pilots' parachutes. It also was the vehicle that brought us vitamins, miracle drugs, artificial rubber tires, sudsy detergents, and countless other consumer products that literally transformed the average person's daily life-style more dramatically than mankind had previously experienced in time periods covering hundreds or even thousands of years.

Consequently, to have grown up as a teenager during those fabulous late forties was to feel and share the excitement of breathtaking new discoveries and to marvel at the almost daily new products and conveniences.

And, at that time, to be able to tell friends, colleagues, and relatives that you were embarking on the study of science and chemistry was to feel the pride and to sense the adulation experienced more recently by moon-walking astronauts or Super Bowl quarterbacks.

But as time went on, the public began to hear about insecticide buildup in birds and fish, about waterways being fouled with nonbiodegradable detergents, about the cancer risk of certain food additives, about growth hormone residues in food animals, about the risk of nuclear power plant accidents, and about dozens of other problems associated with those wonderful products of the chemical age—and all of a sudden it wasn't too popular to be identified as a chemist or scientist.

Pharmacy and pharmacists shared to a great extent in these swings of public favor. After all, pharmacy and pharmacists most directly deal with the drugs, the vitamins, the hormones, the pharmaceutical excipients, the flavors, the artificial sweeteners, and so on that first appeared so attractive but later were looked upon with misgivings and fear. And aside from chemists *per se*, among the professions, pharmacists probably take more chemistry courses in their formal education than any other professionals with the possible exception of chemical engineers.

And naturally, within the community of pharmacy, pharmaceutical scientists probably felt the brunt of this fall from public popularity more severely than any other group. But, on the other hand, no group is more aware than pharmaceutical scientists of the many good things that science, chemistry, and more specifically the pharmaceutical sciences have done to contribute to better health and longer lives.

Consequently, it may be timely for some down-to-earth, grass-roots public relations in which we take the opportunity to talk at meetings of consumer groups, fraternal organizations, ladies' clubs, boy scouts, community associations, better business bureaus, or whatever and to provide a balanced picture of the benefits and risks of drugs as well as the special stories about timed-release preparations, about novel drug delivery systems, and about the development of prodrugs.

The key to success in such public relations efforts is that such presentations must be credible. The hazards of potent drugs, the unknown problems associated with all new products, and the difficulty of achieving zero defects in product quality must also be recognized in an honest and forthright manner.

Certainly, the "pill for every ill" approach is harmful and dangerous to society; as such, we must do what we can to reject such thinking. However, for the public to espouse an attitude of therapeutic nihilism would be at least equally unfortunate for society.

Pharmaceutical scientists have the information, background, and opportunity to influence public opinion to see that neither of these extremes is allowed to prevail. And, in speaking out with such a message, pharmaceutical scientists will enhance their own image in the area of public esteem.

Extended Hildebrand Solubility Approach: Solubility of Theophylline in Polar Binary Solvents

A. MARTIN ˣ, J. NEWBURGER, and A. ADJEI

Received September 6, 1979, from the *Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712.* Accepted for publication November 21, 1979.

Abstract □ A quantitative approach is presented for predicting solubilities of crystalline compounds in binary solvent systems. The solubility of theophylline in mixed solvents consisting of dioxane and water was determined at 25 ± 0.1°. The solubilities across this range of polar solvents were back-calculated using a technique involving an interaction energy term, W. This parameter is regressed against a polynomial expression in δ_1, the solubility parameter for the mixed solvents. Except for the end-points, solubilities were predicted within <12% and with considerably better accuracy in most cases. The new approach modifies the well-known Hildebrand solubility equation to make it applicable to polar systems. Although the method may be used with solutes in pure solvents, its greatest application appears to be the prediction of drug solubility in binary solvent mixtures.

Keyphrases □ Theophylline—solubility in polar binary solvents □ Solvent systems—solubility of theophylline in polar binary solvents

Solubility data on drugs and pharmaceutical adjuncts in mixed solvents have wide application in the drug sciences. Knowledge of interactive forces between solutes and solvents are of considerable theoretical and practical interest throughout the physical and biological sciences.

BACKGROUND

The term regular solution was introduced by Hildebrand (1) to describe solutions showing random molecular distribution and orientation as found in ideal solutions. There is no entropy change, but heat is absorbed when the components of a regular solution are mixed. Although these solutions are not ideal, they yield curves of log solubility *versus* $1/T$ that are quite regular. Other kinds of solutions, those that involve solvation or association, produce irregular solubility curves. Modifications of the Hildebrand approach for irregular solutions have been reported in the field of solution technology by various investigators (2–8).

The Hildebrand–Scatchard equation for the solubility of solids in a regular solution may be written as (9–13):

$$-\log X_2 = \frac{\Delta S_m^f}{R}\log\frac{T_m}{T} + \frac{V_2\phi_1^2}{2.303RT}(\delta_1 - \delta_2)^2 \qquad \text{(Eq. 1)}$$

where X_2 is the mole fraction solubility of the solute or drug (represented by subscript 2); ΔS_m^f is the entropy of fusion of the crystalline drug at its melting point, T_m, on the Kelvin scale; T is the temperature in degrees Kelvin at which the solubility is determined; R is the molar gas constant; V_2 is the molar volume of the drug; ϕ_1 is the volume fraction of the solvent (represented by subscript 1); δ_2 is the solubility parameter of the solute; and δ_1 is the solubility parameter of the solvent or mixed solvent. Solubility parameters also are referred to as delta values. The first right-hand term of Eq. 1 frequently is written as $(\Delta H_m^f/2.303RT)(1/T - 1/T_m)$, but the ΔS_m^f term of Eq. 1 is more correct, as will be discussed later.

The solubility parameter or delta value of the solvent, δ_1, is obtained as suggested by Hildebrand and Scott (10) using the relationship:

$$\delta_1 = \left(\frac{\Delta E_1^v}{V_1}\right)^{1/2} = \left(\frac{\Delta H_1^v - RT}{V_1}\right)^{1/2} \qquad \text{(Eq. 2)}$$

where ΔE_1^v is the molar energy of vaporization, ΔH_1^v is the heat of vaporization, and V_1 is the molar volume of the solvent. The square of δ_1, or $\Delta E_1^v/V_1$, is called the cohesive energy density of the solvent. Other methods for obtaining δ_1 were given by Hildebrand and Scott (10).

The solubility parameter of a solid compound is difficult to obtain, and few values are recorded in the literature. The δ^2 value for iodine is ~14.1 (10), and the value for naphthalene, phenanthrene, and anthrancene is ~9.8. Several investigators (12, 14) estimated the solubility parameters of benzoic acid and some *p*-hydroxybenzoic acid esters from the peak values obtained from a plot of mole fraction solubility *versus* delta values of solvents. The parameter for benzoic acid also was determined from the solubility data in hexane and was found to be 11.5. The solubility parameters for barbiturates have been determined (15, 16). Yalkowsky *et al.* (17) obtained the solubility parameters for *p*-aminobenzoate esters from their solubility in hexane. For example, the value for the ethyl ester was 12.05. James *et al.* (18) reported solubility parameters for some testosterone esters and related compounds.

The first term on the right side of Eq. 1, the ideal solubility term, is for the dissociation of the crystal lattice of a solid compound, rendering it in the liquid form. In the presence of solvents that form nearly ideal solutions, the second right-hand quantity, the regular solution term, is nearly zero and may be omitted.

The regular solution term, involving solubility parameters, is an activity coefficient, log α_v, used to represent nonideality due to the interaction of solute and solvent molecules in a regular solution where only nonpolar and weak polar forces exist:

$$\log \alpha_v = A(\delta_1 - \delta_2)^2 \qquad \text{(Eq. 3)}$$

where A represents $V_2\phi_1^2/2.303RT$ and the subscript v stands for van der Waals forces.

Following the suggestion by Crowley *et al.* (8), Hansen (5, 6) introduced a three-dimensional system of solubility parameters. The energy of va-

0022-3549/80/0500-0487$01.00/0
© 1980, American Pharmaceutical Association

porization in Eq. 2 was assumed to be an additive quantity composed of three energies representing London dispersion forces (ΔE_d^v), polar forces (ΔE_p^v), and hydrogen bonding (ΔE_h^v) in the solvent. Dividing each term by the molar volume of the solvent (V_1), the total cohesive energy density was obtained:

$$\frac{\Delta E^v}{V_1} = \frac{\Delta E_d^v}{V_1} + \frac{\Delta E_p^v}{V_1} + \frac{\Delta E_h^v}{V_1} \qquad \text{(Eq. 4)}$$

or, in terms of delta values:

$$\delta^2 = \delta_d^2 + \delta_p^2 + \delta_h^2 \qquad \text{(Eq. 5)}$$

where δ^2 is the total cohesive energy density for the liquid. Values for δ_d were determined by reference to a corresponding hydrocarbon called a homomorph, and δ_p and δ_h were estimated by empirical methods. Hoy *et al.* (19) developed extensive tables of three-dimensional delta values, which differ somewhat from the values of Hansen (5, 6). Hansen noted that there is yet no theoretical basis for the new three-dimensional solubility parameters, and he used them empirically to interpret the solubility of polymers and other solutes employed in industry and commerce.

Weimer and Prausnitz (20) calculated polar and nonpolar solubility parameters using the homomorph concept, and Blanks and Prausnitz (7) applied these values to the study of polymer solubility in polar solvents. These investigators did not consider hydrogen bonding systems.

The method presented here[1] allows calculation of the solubility of polar and nonpolar solutes in solvents ranging from nonpolar (hexane) to aprotic polar (*e.g.*, *N,N*-dimethylformamide) and highly polar protic solvents such as alcohols, acids, and water. Although formulated specifically in terms of the solubility of a nonelectrolytic solid in liquid solution, the technique should apply as well to liquid–liquid and other equilibrium systems.

Equation 1 ordinarily provides a poor prediction for the solubility of a drug or other crystalline compound in a polar solvent. These solutions are quite irregular, often involving self-association or solvation. The logarithm of the activity coefficient, calculated using Eq. 3, accounts for the nonideality of solutions resulting from the interaction of solute and solvent molecules of the physical or van der Waals type. Several investigators, including Hildebrand, have cautioned that expressions in the form of Eq. 3 are not good representations of nonideality in solutions of polymers and various polar and semipolar compounds in polar and hydrogen bonding solvents. For irregular solutions, a total activity coefficient, α_2, must be written consisting of the term (Eq. 3) representing physical or van der Waals forces and an additional term, $\log \alpha_R$, representing residual, presumably stronger, forces:

$$\log \alpha_2 = \log \alpha_v + \log \alpha_R \qquad \text{(Eq. 6)}$$

The total activity coefficient may be written as:

$$\log \alpha_2 = A(\delta_1^2 + \delta_2^2 - 2W) \qquad \text{(Eq. 7)}$$

where W is the interaction energy between the solute and solvent in an irregular solution.

Employing Eqs. 3, 6, and 7, one obtains for the residual term:

$$\log \alpha_R = 2A(\delta_1\delta_2 - W) \qquad \text{(Eq. 8)}$$

The logarithm of the total activity coefficient may be written for irregular solutions as:

$$\log \alpha_2 = A(\delta_1 - \delta_2)^2 + 2A(\delta_1\delta_2 - W) \qquad \text{(Eq. 9)}$$

and the modified Hildebrand solubility equation becomes:

$$-\log X_2 = \frac{\Delta S_m^f}{R} \log \frac{T_m}{T} + A(\delta_1^2 + \delta_2^2 - 2W) \qquad \text{(Eq. 10)}$$

EXPERIMENTAL

Materials—Anhydrous theophylline[2] and *p*-dioxane[3] were obtained commercially.

Solubility Determination—The solubility of theophylline ($\delta^2 = 14.0$) was determined in mixed solvents consisting of dioxane ($\delta_{1_a} = 10.01$) and water ($\delta_{1_b} = 23.45$). Glass-distilled deionized water was used to prepare mixtures with dioxane in concentrations of 0–100% by volume of dioxane. About 10 ml of the mixture was introduced into screw-capped vials containing excess theophylline. The vials were agitated for 96 hr in a shaker bath maintained at 25 ± 0.1°. Preliminary studies showed that this period was sufficient to ensure saturation at 25°.

After equilibrium was attained, vials were removed for analysis. The solutions were filtered, and aliquots were placed in volumetric flasks and brought to the final volume with the solvent mixture in which the drug was originally dissolved. The solutions were analyzed in a spectrophotometer[4] at 273.4 nm. Three samples were withdrawn from four separate vials and measured at each mixed solvent concentration. The standard error for the analysis of individual samples was $<\pm 0.7$ μg/ml.

The densities of the solvent mixtures and the filtrates of the saturated solutions of theophylline were determined in triplicate at 25 ± 0.1° using a pycnometer.

Heat of Fusion—The heat of fusion of crystalline theophylline was determined experimentally in a differential scanning calorimeter[5,6]. Thermograms were run at 100 psi to retard sublimation, and the heat of fusion was determined from the area under the curve, using indium metal as a standard. The equation employed in calculating the heats of fusion from differential scanning calorimetry is:

$$\Delta H_m^f = \Delta H_m^f \text{ (standard)} \times \text{standard weight} \times \text{sample peak area} \times \frac{\text{instrument range for sample} \times \text{sample mol. wt.}}{\text{instrument range for standard} \times \text{sample weight} \times \text{standard mol. wt.} \times \text{standard peak area}} \qquad \text{(Eq. 11)}$$

To obtain the ideal solubility, X_2^i, Hildebrand *et al.* (22) showed that entropy of fusion, ΔS_m^f, can replace heat of fusion to take into account the molar heat capacity change, ΔC_p, in going from a solid to a liquid solute. The equation for calculating the ideal solubility employing ΔS_m^f is (22):

$$\log X_2^i \cong \frac{\Delta S_m^f}{R} \log \frac{T}{T_m} \qquad \text{(Eq. 12)}$$

The entropy of fusion is obtained by plotting $\log X_2$ *versus* $\log T$ under ideal solution conditions. With solubility data, X_2, at three or four temperatures, a linear plot with a slope proportional to ΔS_m^f is obtained. However, the ΔH_m^f and T_m values may be determined more conveniently using a differential scanning calorimeter (23). Once these values are obtained, ΔS_m^f is calculated from:

$$\Delta S_m^f = \frac{\Delta H_m^f}{T_m} \qquad \text{(Eq. 13)}$$

Solubility Parameter of Mixed Solvents—The solubility parameter, δ_1, for a mixture of two solvents, a and b, is calculated (24, 25) using the expression:

$$\delta_1 = \frac{\phi_a\delta_a + \phi_b\delta_b}{\phi_a + \phi_b} \qquad \text{(Eq. 14)}$$

where:

$$\phi_1 = \phi_a + \phi_b \qquad \text{(Eq. 15)}$$

in which ϕ_1 is the total volume fraction of the two solvents and δ_1, the solubility parameter of solvents a and b, is averaged in terms of volume fractions.

Volume Fraction and Mean Molar Volume in Mixed Solvents—The total volume fraction, ϕ_1, of the solvent mixture is calculated using the expression:

$$\phi_1 = \frac{(1 - X_2)V_1}{(1 - X_2)V_1 + X_2V_2} \qquad \text{(Eq. 16)}$$

where X_2 is the mole fraction solubility of the drug in the mixed solvent and V_1 is the mean molar volume of the binary solvent. For each mixed solvent composed of solvents a and b in various proportions:

$$V_1 = \frac{X_aM_a + (1 - X_a)M_b}{\rho_1} \qquad \text{(Eq. 17)}$$

where X_i and M_i are the mole fraction and molecular weight of the par-

[a] Mole fraction solubilities are obtained at best to five figures following the decimal point. Two additional positions have been retained to provide four to six significant figures and thus facilitate comparison with calculated solubility values and to compute percentage differences.

ticular solvent in the mixture, respectively, and ρ_1 is the density of the solvent mixture at the experimental temperature.

Molar Volume and Solubility Parameter for Solute—The molar volume of theophylline taken as a supercooled liquid at 25° is calculated using the group contribution approach of Fedors (26). The solubility parameter, δ_2, for theophylline is obtained at the peak solubility where the δ_1 value of the solvent should equal δ_2 as required by Eq. 1. This principle was discussed previously (12). The δ_2 value of theophylline also may be calculated by the Fedors method (26).

Calculations of Ideal Solubility, Activity Coefficients, and W—The method begins with a calculation of the ideal solubility, X_2^i, of theophylline, employing the first right-hand term of Eq. 1 or 10. The logarithmic ideal solubility, together with the logarithm of the experimentally determined solubility, yields the logarithm of the solute activity coefficient:

$$\log X_2^i - \log X_2 = \log \alpha_2 \qquad \text{(Eq. 18)}$$

Log α_v is obtained from the application of Eq. 3, and log α_R is obtained from Eq. 6 or 8. Values for W, the solute–solvent interaction energy, are calculated with Eq. 7.

RESULTS AND DISCUSSION

The experimentally determined solubilities of theophylline at 25° in dioxane–water mixtures are found in Table I together with the composition and densities of the solutions. The densities of solutions are included in reporting solubility data to allow conversion from mole fractions to molar concentrations, to assist in obtaining partial molar volumes, and to permit the calculation of other quantities. The calculated log α_2, log α_v, log α_R, and W values also are found in Table I.

By employing the procedure described under *Experimental* to yield ideal solubility, a ΔH_m^f value of 7097 cal/mole[7] and T_m value of 547.7°K were obtained. Then ΔS_m^f was calculated using Eq. 13 to yield a value of 12.96 cal/mole/degree and a mole fraction ideal solubility for theophylline of 0.01896 (log X_2^i = −1.7222). The molar volume of theophylline is 124.

The experimental solubilities, expressed as mole fractions, are plotted in Fig. 1 against the solubility parameter, δ_1, of the various mixed solvents. Also shown in Fig. 1 is the ideal solubility level (horizontal line at a mole fraction of 0.01896). The regular solution line of Fig. 1 is a curve expressing solubilities of theophylline, with the assumption that the mixtures follow regular solution theory. The solubility of theophylline (δ_2 = 14.0) in pure dioxane (δ_1 = 10.01), in pure water (δ_1 = 23.45), and in the binary solutions composed of these two solvents did not approach the level of ideality, namely X_2 = 0.019, and did not coincide with regular solution behavior except where the experimental curve, by chance, crossed the regular solution line.

[7] L. T. Grady and W. H. Yalkowsky (personal communications) obtained values of ΔH_m^f varying between 5940 and 7225 cal/mole.

The original Hildebrand equation for regular solution behavior cannot be used to represent solubility in these polar solvents. However, Eq. 10, which involves the interaction term, W, does reproduce exactly the solubility of theophylline in dioxane, water, and the mixed solvent systems. Figure 1 shows that the peak solubility, although lower than ideal, occurred at a δ_1 value of ~14.0, which was taken as the δ_2 value of theophylline. The Fedors method (26) of calculating δ values from molecular group and fragment constants gives essentially the same value (14.1).

When solubility was plotted as moles per liter instead of as mole fraction concentration, a slightly different shape than the curve of Fig. 1 was obtained. Peaks and valleys were not obtained in the curve of theophylline in dioxane–water mixture as reported by Paruta *et al.* (27). However, two small plateaus were found. These plateaus possibly were overlooked because the solubility measurements were not spaced as closely in the solvent composition as in the results of Paruta *et al.* Ongoing work in this laboratory with caffeine in dioxane–water has reproduced the two-peak maximum reported by Paruta *et al.* (27).

[a] Back-calculated by Eq. 19. [b] Back-calculated by Eq. 21.

Figure 2 shows the three activity coefficients, log α_v, log α_R, and log α_2, which represent the van der Waals interactions between the solute and solvent, the residual term that accounts for stronger interactions, and the total solute activity coefficient, respectively. As expressed by Eq. 6, log α_2 is the sum of log α_v and log α_R. As noted in Fig. 2, log α_v is plotted using a positive vertical axis (left side), while log α_R is plotted with reference to a negative (right) axis. The positive and negative values almost balance each other so that their composite values, represented by log α_2, yield only a moderately bowed curve across the range of δ_1 values (horizontal axis). This result demonstrates that the nonregularity in mixed solvents is not large and, when contrasted to individual solvents, provides a greater possibility of predicting solubilities by back-calculation as described.

The usefulness of a theoretical approach is the ability to calculate solubilities of a drug in mixed or pure solvents, using only fundamental physicochemical properties of the solute and solvent. Unfortunately, W is not a property that is readily and accurately back-calculated by independent means. The method could be useful for predicting solubilities, however, if a procedure were found for estimating W in this range of mixed solvents. Then, with Eq. 10, the solubility of theophylline could be estimated in pure dioxane, pure water, and mixed dioxane–water solvents for which the δ_1 values were known.

When W values, obtained from Eq. 7, are plotted against δ_1, a curved line results, as shown in Fig. 3 for theophylline in dioxane–water. This curve suggests that W should be regressed against a polynomial in δ_1 for as many solutions for which accurate experimental solubilities are available. With the data of Table I, the following third-degree (cubic) equation was obtained:

$$W = 42.121367 + 9.424012\delta_1 - 0.005242\delta_1^2 + 0.008163\delta_1^3 \quad \text{(Eq. 19)}$$

The W values calculated by the cubic expression (Eq. 19) are shown in Table II and are comparable to the original W values (Table I) calculated by Eq. 7. The W values obtained from the cubic polynomial are substituted into Eq. 10 to predict the solubility of theophylline in mixed solvents. The back-calculated solubilities are recorded in Table II.

The solid line, passing through the experimental points in Fig. 1, was obtained by this procedure. The solubilities are faithfully reproduced for solvent mixtures of high δ_1 values. At the peak of the curve, the experimental points fall below the solubility predicted by the theoretical line, but the error is not great (<~12%). Solubilities represented by the points to the left of the peak values are reproduced less well than to the right of the peak. The solubilities of theophylline in pure dioxane and in pure water are predicted within an error of <40% by this method. Solubilities in these pure solvents are quite small, and this percentage error is not excessive.

The drug solubility obtained by this method is expressed in mole fraction concentration. It can be converted to molal concentration or to grams of solute per gram of solvent. Since the various solution densities are known (Table I), solubility also may be expressed in molarity or in

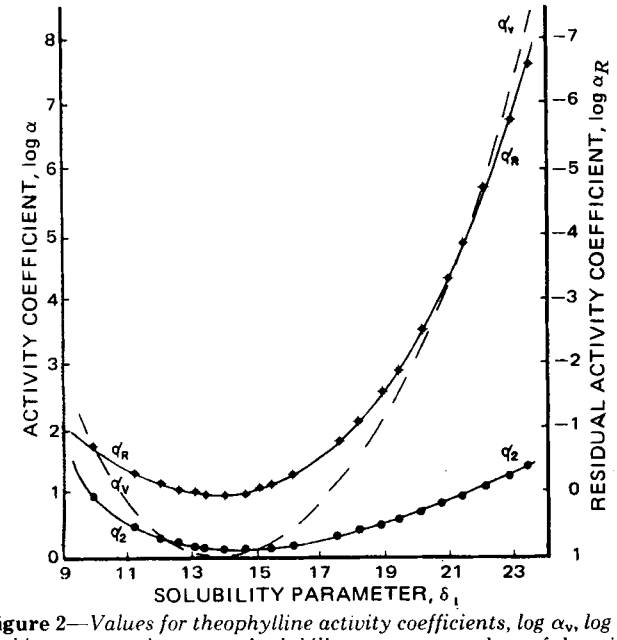

Figure 2—*Values for theophylline activity coefficients, log α_v, log α_R, and log α_2, over the range of solubility parameter values of the mixed dioxane–water solvent system. Log α_v and log α_2 are plotted with reference to the vertical axis on the left side of the figure; log α_R is plotted with reference to the right side.*

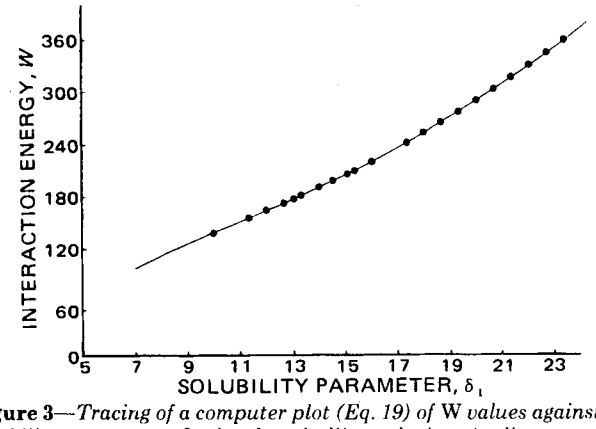

Figure 3—*Tracing of a computer plot (Eq. 19) of W values against the solubility parameter, δ_1, for theophylline solutions in dioxane–water mixtures. Points represent W values calculated from experimental solubility data using Eq. 7.*

grams of solute per liter or per milliliter of solution.

The interaction value, W, may be bypassed and log α_2/A may be back-calculated directly. The removal of W occurs by observing from Eq. 7 that:

$$2W = \delta_1^2 + \delta_2^2 - \log \alpha_2/A \qquad \text{(Eq. 20)}$$

Substituting Eq. 20 for W in Eq. 19 yields:

$$\log \alpha_2/A = 111.757266 - 18.848024\delta_1 + 1.010484\delta_1^2 - 0.016327\delta_1^3 \qquad \text{(Eq. 21)}$$

Equations 19 and 21 are analogous and yield identical results except for rounding-off errors. The back-calculated log α_2 values are found in Table II and may be compared with the original values obtained from experimental solubilities found in Table I.

This method for adapting the Hildebrand approach to polar systems has advantages and drawbacks, and certain precautions should be taken in its use. The best δ_1 values should be used for pure solvents and should be accurate to two decimal points where possible. Bagley *et al.* (28) and Nisbet (29) discussed methods for obtaining accurate solvent delta values.

Solute delta values, δ_2, and molar volumes, V_2, for solids ordinarily are not recorded in the literature and are difficult to determine. An interesting result of the new approach is that solubility predictions do not depend on the choice of δ or V of the solute. Whatever values for these quantities were used originally to obtain the W values will, of course, remain unchanged in the back-calculation and will not affect the accuracy of solubility predictions. However, the investigator must make every effort to obtain reasonable values for δ_2 and V_2 and to employ the same values each time a solubility analysis is conducted for a particular solute. The best possible δ_2 and V_2 values must be estimated and used uniformly from one laboratory to another if consistent and reproducible data are to be recorded in the literature.

CONCLUSION

The present technique is an extension of the Hildebrand method for expressing the solubility of solids in liquid solvents. It should also find use in related equilibria studies. The new method extends the Hildebrand approach from regular solutions, where van der Waals forces predominate, to irregular systems involving stronger solute–solvent interactions such as hydrogen bonding and other acid–base interactions.

The method is not a new physical theory but rather is a technique partly based on polynomial regression for back-calculating solubilities of drugs and other solutes in polar and nonpolar liquids. In a previous report (21) and in cases to be treated later, the procedure may be used to reproduce solubilities of drugs in a range of pure solvents, most satisfactorily in a particular class of solvents; however, it appears to be considerably more successful in predicting solubilities in mixed solvent systems.

Dissolution Studies of Povidone–Sulfathiazole Coacervated Systems

A. A. BADAWI ˣ and A. A. EL-SAYED

Received February 22, 1979, from the *Department of Pharmaceutics, Faculty of Pharmacy, Cairo University, Cairo, Egypt.* Accepted for publication November 20, 1979.

Abstract □ Sulfathiazole and povidone were coacervated by many methods, indicating complexation of the two compounds. The coacervated complex had a higher solubility and dissolution rate than did sulfathiazole. It resisted the action of dilute acids and alkalies, suggesting a helical structure with sulfathiazole situated between two povidone chains and a hydrogen bond linking the amino groups of the sulfathiazole to the oxygen of povidone. Upon addition of precipitants for sulfathiazole, the povidone portion attempted to compensate and to solubilize the whole complex; hence, partial precipitation or coacervation occurred. A model is given to describe the dissolution profile of the different coacervate systems prepared.

Keyphrases □ Povidone—coacervation with sulfathiazole, dissolution of coacervated system □ Sulfathiazole—coacervation with povidone, dissolution of coacervated system □ Coacervation—povidone and sulfathiazole, dissolution of coacervated system

The interaction of povidone with drugs is of theoretical and practical importance since it may influence their availability, efficacy, and transport (1).

Povidone reduced the dissolution rate of salicylic acid. This reduction was attributed to increased viscosity or to complex formation (2). When incorporated into compressed disks of ephedrine hydrochloride, potassium chloride, and sodium chloride, the polymer reduced their dissolution rates (3, 4).

However, several investigators described increases in solubility of various compounds by povidone (5, 6). A solid dispersion of reserpine, a poorly water-soluble drug, with the polymer enhanced its *in vitro* dissolution and absorption (7). A povidone–digitoxin coprecipitate exhibited enhanced dissolution and absorption, as indicated by a decrease in the LD_{50} value (8). Increased dissolution of hydroflumethiazide (9), hydrochlorothiazide (10), and ellipticine (11) was achieved by incorporation of the polymer into similar products.

Simonelli *et al.* (12, 13) described the preparation of a high energy form of sulfathiazole when it is dissolved in an alcoholic solution of povidone and evaporated to dryness or when an aqueous solution of its sodium salt and povidone is acidified. There was no explanation for the precipitation of the polymer along with the sulfathiazole, although the polymer by itself is not affected by acids. The nature of this high energy form and the mechanism of its formation were not given. Only the possible formation of a complex was reviewed.

The present study attempted to explain the coprecipitation from another viewpoint. The study was based on the facts that povidone is a linear polymer and that, when its complex with sulfathiazole is treated with acids that precipitate sulfathiazole, the whole molecule coils to form a coacervate. When dried, the coacervate droplets give colloidal particles of sulfathiazole complexed with the polymer, and a higher dissolution rate results.

In this study, sulfathiazole and povidone were mixed to form solutions. Different precipitants for sulfathiazole or for the polymer then were added separately. The products were examined microscopically to follow the development of the coacervate droplets and their transformation to solid colloidal particles.

EXPERIMENTAL

Interaction of Sulfathiazole and Povidone—*Method 1*—Sulfathiazole[1] and povidone[2] (mol. wt. 25,000), 5 g each, were dissolved in 25 ml of alcohol, which was evaporated on a water bath. When the volume was reduced to ~5 ml, a sample was taken and examined microscopically. Evaporation was continued, and a dried alcohol coacervate was obtained.

Method 2—Five grams of each of the two materials was dissolved by heating in 15 ml of alcohol. Water was added dropwise, the colloidal dispersion formed, and this precipitate coacervate was examined.

Method 3—Sulfathiazole, 5 g, was placed in a beaker, and 8 *N* NaOH was added until dissolution was complete. Povidone, 5 g, was added and dissolved by stirring. An equivalent quantity of 8 *N* HCl was added dropwise with continuous stirring to give the pH coacervate.

Method 4—Sulfathiazole, 5 g, was dissolved using an equivalent amount of 8 *N* NaOH. Povidone, 5 g, was added and dissolved by stirring. Resorcinol[1] solution, 20%, was added dropwise, and the colloidal dispersion obtained was investigated microscopically. This dispersion is referred to as the resorcinol coacervate.

Each process was repeated using different ratios of sulfathiazole and povidone. Each ratio will be described by its percent content of povidone.

Microencapsulation of Sulfathiazole—Sulfathiazole powder, 3 or 10 g, was suspended in 50 ml of 2% povidone solution. Resorcinol solution, 20%, was added dropwise with continuous stirring until complete phase separation was obtained. The microcapsules were filtered and air dried. The product was used without sieving because it was free flowing and very fine.

Separation of pH Coacervate into Its Components—Sulfathiazole, 7 g, was dissolved in 50 ml of water containing an equivalent quantity of sodium hydroxide. Povidone, 3 g, was added and dissolved by stirring. Hydrochloric acid, 5 *N*, was added dropwise with continuous stirring. When the povidone was consumed, the sticky mass that formed was withdrawn. The rest of the equivalent volume of the acid was added, and the fine particles that precipitated were filtered and dried.

Dissolution Study—Weighed quantities of each prepared sample were compressed into tablets using a single-stroke compression tablet machine[3] with a 1-cm die. The tablets were compressed to an average hardness of 5–6 kg. Each tablet was fixed to the top of a test tube with melted wax and placed at a constant level into a 600-ml beaker containing 400 ml of water as the dissolution medium.

Hydrodynamic equilibrium was established with a constant stirrer placed at a fixed distance from the tablet surface. At each time interval, a 0.5-ml aliquot was withdrawn, diluted suitably, and assayed spectrophotometrically at 283 nm.

Solubility Study—Weighed excesses of sulfathiazole and of each sample of the coacervated systems were placed in 25-ml ampuls containing 10 ml of water. The ampuls were sealed and placed on a rotating shaft (42 rpm) immersed in a water bath at 25 ± 1°. Duplicate samples were withdrawn, filtered, and assayed spectrophotometrically at 283 nm.

RESULTS AND DISCUSSION

Figure 1 shows the coacervate formed in all cases. These coacervates

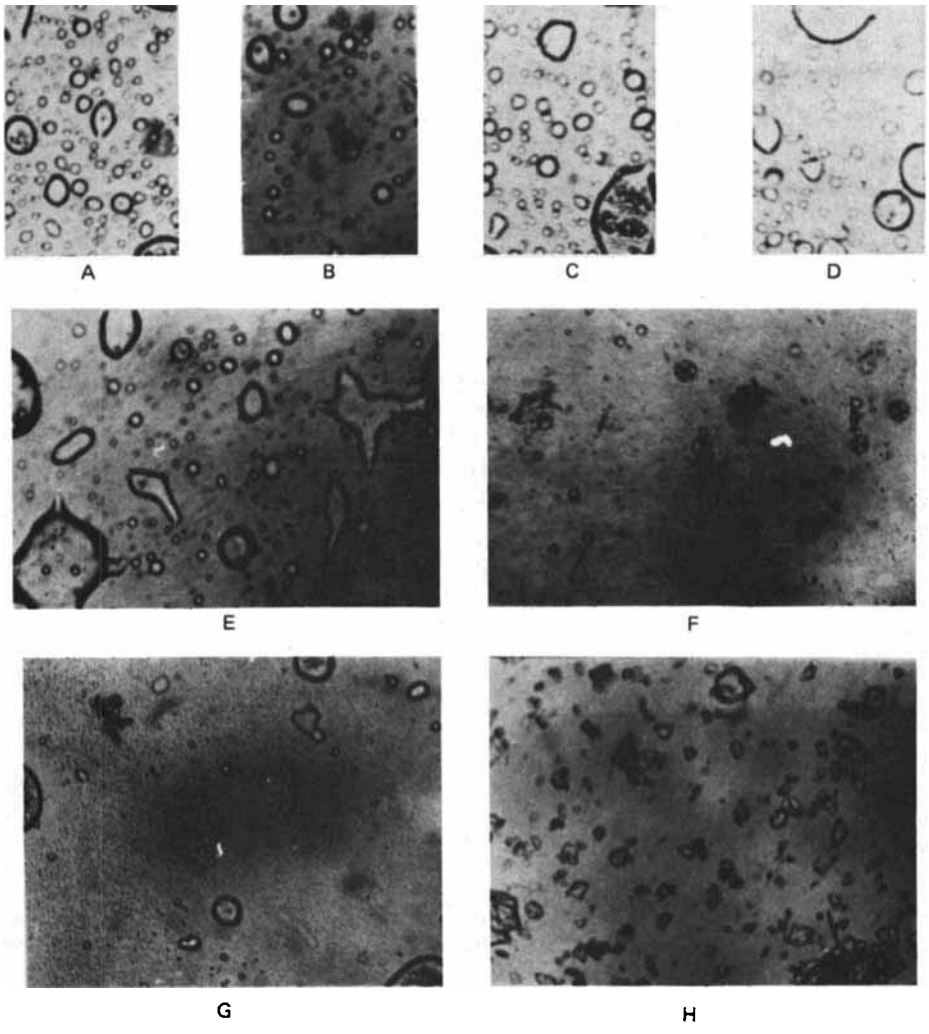

Figure 1—*Photographs (×40) of sulfathiazole–povidone coacervated systems. Key: A, alcohol coacervate; B, pH coacervate; C, precipitate coacervated; D, resorcinol coacervate; E, coalesced coacervate; F, dried coacervate; G, dried coacervate treated with water; and H, sulfathiazole precipitated with pH change.*

exhibited brownian motion. Upon continuous stirring, they coalesced into larger drops, which dried to give very fine particles. These particles were distributed in water to give spherical colloidal particles in the submicron range, which rapidly went into solution.

Coacervation can be considered as an intermediate state between true solution and complete precipitation, or it can be described as partial precipitation. When a solution of the sodium salt of sulfathiazole is treated with hydrochloric acid or when its hydrochloride salt solution is treated with sodium hydroxide, precipitation of amorphous or crystalline sulfathiazole normally occurs. On the other hand, povidone is not affected by acids or alkalis.

The coacervate formed when sulfathiazole and povidone both are present can be explained only by the interaction of povidone and sulfathiazole to form a complex with intermediate properties. Povidone retains its linear polymeric structure, which may be coacervated. Sulfathiazole still is affected by its precipitants. The povidone portion counteracts the precipitation of sulfathiazole and tries to solubilize the whole complex. The molecule thus is coiled around itself, thereby reducing its surface area that holds minimal water and reducing the total free energy of the coacervated system.

On the same basis, povidone is very soluble in both water and alcohol and does not precipitate if its solution in one solvent is treated with the other solvent. Sulfathiazole alone in its alcoholic solution precipitates as amorphous particles or as crystals when it is mixed with water. Again, the coacervate formed when the alcoholic solution of the two materials was mixed with water indicated the formation of a complex that was coacervated by the nonsolvent addition phase separation method. On the other hand, when the aqueous solution of sulfathiazole sodium and povidone was treated with resorcinol solution, which is a coacervating agent for povidone, a coacervate containing sulfathiazole was formed.

When sulfathiazole was suspended in the povidone solution and resorcinol solution was added, the coacervated povidone droplets microencapsulated the sulfathiazole particles, which, upon drying, were free flowing. The dissolution of the microcapsules was exactly the same as that of pure sulfathiazole when the coat to core ratio was 1:10 and slightly higher when the ratio was 1:3 (Fig. 2). This result indicated that the povidone did not interact with sulfathiazole when it was in the insoluble form and that the coacervated povidone microencapsulated the drug to form a protective layer. It rapidly went into solution to give sulfathiazole since the coacervation of povidone by resorcinol is reversible and since solvation of povidone occurs once the equilibrium is disturbed.

During the preparation of the pH coacervate, it was clear that the

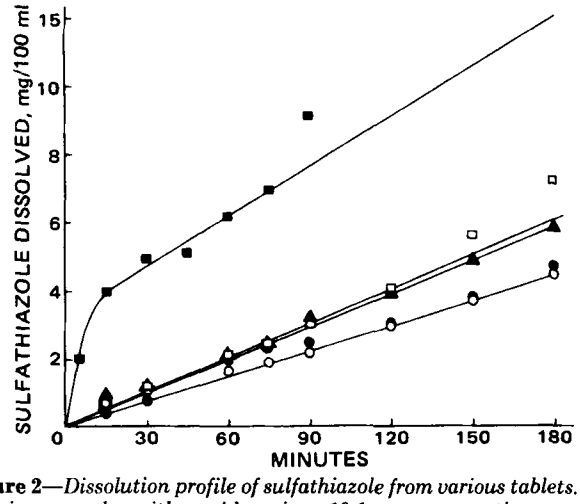

Figure 2—*Dissolution profile of sulfathiazole from various tablets. Key: ●, microcapsules with povidone in a 10:1 core-coat ratio; ▲, microcapsules of povidone in a 3:1 core-coat ratio; ■, alcohol coacervate with 20% povidone; ○, amorphous sulfathiazole; and □, physical mixture containing 20% povidone.*

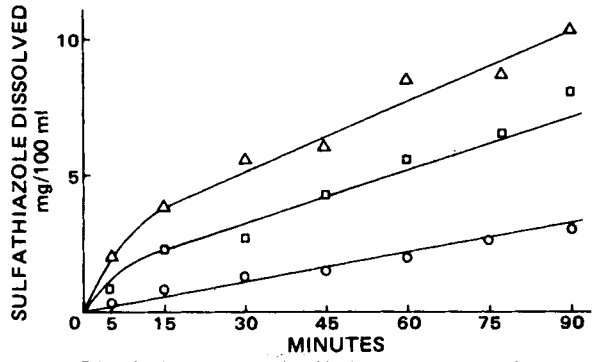

Figure 3—*Dissolution profile of sulfathiazole from a pH coacervate containing 40% povidone made with different volumes of equilibrium liquid. Key: ○, 100 ml; □, 50 ml; and △, 25 ml.*

volume of the equilibrium liquid greatly affected the product (Fig. 3). The large volume caused dissolution of the coacervated complex. Therefore, for preparation of samples for dissolution studies, 12 ml of liquid was used. However, to observe the process sequence, a volume of 50 ml was more suitable. Upon addition of hydrochloric acid by drops, coacervate droplets were formed; they coalesced into a sticky mass upon stirring. When the povidone was consumed, subsequent addition of acid caused the fine precipitated sulfathiazole particles to become enmeshed within the sticky mass. At a low povidone ratio, the sticky mass was small and the fine particles were large. With successive increases in the povidone ratio, the amount of fine particles precipitated was smaller; a homogeneous mass was obtained at 65%.

Figure 4 shows the release profile of sulfathiazole from the two components of the 30% povidone system. The fine particles gave almost the same profile as did sulfathiazole alone, and the sticky mass had a much higher dissolution rate. The mixture of the two compounds had a high initial rate and a slower terminal rate. On this basis, the release profile of sulfathiazole from its alcohol coacervates or its pH coacervates (Figs. 5–8) composed of different weight fractions of povidone could be explained easily.

This profile greatly resembled that of Simonelli *et al.* (12, 13), whose model was divided into five stages. For up to 25% povidone, amorphous

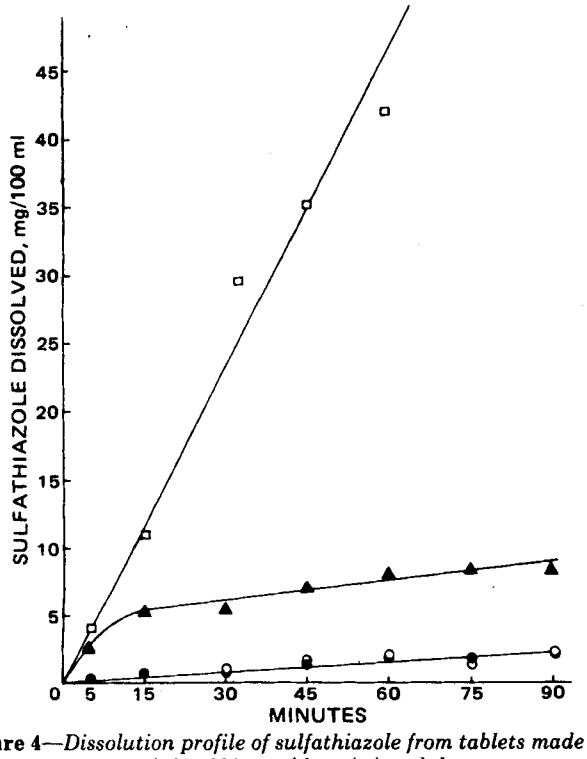

Figure 4—*Dissolution profile of sulfathiazole from tablets made of a pH coacervate containing 30% povidone (▲) and the same proportion separated into a fine powder (○) and a sticky mass (□). The dissolution profile of sulfathiazole is shown for comparison (●).*

or unbound sulfathiazole was dissolved to leave an outer layer of crystalline Form I. From 25 to 50% povidone, amorphous sulfathiazole initially formed the outer layer, but a secondary layer of crystalline Form I eventually was formed in front of the previous amorphous layer. From

50 to 77% povidone, the thickness of the amorphous sulfathiazole layer allowed the povidone to carry the sulfathiazole into solution. As the povidone weight fraction was increased from 78 to 80%, the thickness of the amorphous layer continued to decrease until it became zero. At this point, the sulfathiazole and povidone boundaries receded at the same rate, and the tablet retained the integrity of the original composition throughout the experiment. Above 80% povidone, the povidone boundary was in front and the sulfathiazole boundary moved behind.

In the present work, the dissolution medium was large enough to guard against the precipitation of crystalline Form I. However, the same stages

recognized in the dissolution profile (Fig. 9) can be explained by the formation of a highly soluble coacervated complex of sulfathiazole and povidone. At a low povidone content, the coacervated systems contained a lower percentage of the complex and a larger amount of free sulfathiazole. The complex rapidly went into solution, leaving behind the sulfathiazole, which was amorphous in the case of the pH coacervate and was Form I in the case of the alcohol coacervate. Table I shows good agreement between the percent content of the complex within the coacervate and its initial dissolution rate. Also, the solubility of the coacervates tested showed direct dependency on the ratio of the complex.

Increasing the ratio of povidone, *i.e.*, increasing the ratio of the complex, resulted in approachment of the initial and terminal rates. Above 60% povidone, the coacervates gave a line function whose slope increased with increasing povidone content.

From these findings, it was postulated that, in the presence of its excess, sulfathiazole interacted with povidone in the ratio of one molecule of sulfathiazole to four units of povidone; this ratio corresponded to 63.5% povidone. Above this ratio, a greater number of units of povidone participated in the interaction and many complexes were formed; the more polymer that was included, the more soluble was the coacervate. This region was described by Simonelli *et al.* (12) as the carrier region, and this description held well in the present model in which the povidone carried the complexed sulfathiazole to the dissolution medium.

Above 75% povidone, the alcohol coacervates showed a decrease in their dissolution rates, indicating that saturation of the povidone chain oc-

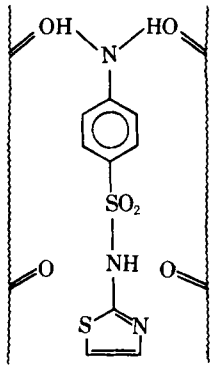
curred at 77.7%, corresponding to eight units of povidone to each molecule of sulfathiazole. The tablet in this region was formed of two entities, the complex and excess povidone, which hindered the dissolution of the complex or its dissolution. With the pH coacervate, such a decline was not noticed. This finding was explained on the basis that the excess povidone was not precipitated with the coacervated complex.

With the resorcinol coacervate system (Fig. 10), a sudden and pronounced increase in the dissolution rate was noticed. A plateau was reached at 40% povidone, and then a linear decline occurred up to 100% povidone. This observation can be explained by the fact that, in the presence of a large excess of sulfathiazole, resorcinol coacervates a complex made of povidone with an equivalent amount of sulfathiazole, leaving its excess in solution as the sodium salt. With an increased povidone concentration, the amount of complexed sulfathiazole increases until the concentration of the two materials are equivalent; this effect yields a product with the maximal dissolution rate. With excess povidone, a mixture of the coacervated complex and coacervated povidone forms, and the access of sulfathiazole to the dissolution medium is hindered. Hence, the decline in the dissolution rate is observed.

Figure 11 shows that 0.05 *N* HCl gave slightly higher dissolution rates of pure sulfathiazole and of the alcohol coacervate containing 30 and 40% povidone. Sodium hydroxide at the same strength had a much higher effect, which was more pronounced in plain sulfathiazole than with the two coacervates. The coacervate with 30% povidone dissolved more rapidly than that with 40% povidone.

Both 60% alcohol and the pH coacervate (Fig. 12) greatly resisted the action of sodium hydroxide and hydrochloric acid. Both reagents had nearly the same dissolution rate, which was slightly higher than that of water. This result may suggest that sulfathiazole is linked by hydrogen bonds through its amino group to the oxygen of the povidone:



The polymer still retains its linearity; upon addition of any precipitant to sulfathiazole, the whole molecule is coiled and coacervated.

Quantitative Structure–Activity Relationships in Drug Metabolism and Disposition: Pharmacokinetics of *N*-Substituted Amphetamines in Humans

BERNARD TESTA ˣ and BJARNE SALVESEN *

Received August 20, 1979, from the *School of Pharmacy, University of Lausanne, CH-1005 Lausanne, Switzerland.* Accepted for publication November 26, 1979. *Institute of Pharmacy, University of Oslo, Blindern, Oslo 3, Norway.

Abstract □ Pharmacokinetic data of 15 *N*-alkyl-substituted amphetamines in humans have been the object of a retrospective quantitative structure–activity relationship study. The urinary excretion of amphetamines was shown to decrease with increasing lipophilicity; the correlation equations revealed that, for identical lipophilicities, tertiary amines are excreted faster than secondary amines, which are excreted faster than primary amines. The apparent *n*-heptane–pH 7.4 buffer partition coefficient correlates better with urinary excretion than does the true *n*-octanol–water partition coefficient, probably because it includes a pKa term that accounts for the fraction of the drug present in the tubules as nonionic species. The *N*-dealkylation rate increases with increasing lipophilicity of the substrates (enhanced enzyme affinity) but decreases with increasing bulk of the *N*-substituent that is split off (steric hindrance of initial C_α-hydroxylation).

Quantitative structure–activity relationships have many pharmacological and toxicological applications. The correlation equations obtained in such studies often provide valuable steps in the rational design of improved drugs (1).

Suitable results of drug metabolism studies also can provide a valuable biological input to quantitative structure–activity relationship studies. While the results thus obtained could help in designing drugs with improved metabolic profiles, previous investigations (2–5) concentrated entirely on interpreting the correlation equations in terms of reaction mechanisms and of the structural factors influencing the biological response.

One prerequisite of any quantitative structure–activity relationship investigation is the need for quantitative and reliable biological data. This fact may help to explain why applications of quantitative structure–activity relationships to drug metabolism and disposition have been based almost exclusively on results from *in vitro* studies (*e.g.*, protein binding, drug–enzyme interactions, and parameters of *in vitro* biotransformation). In contrast, few, if any, *in vivo* studies have led to successful quantitative structure–activity relationship interpretations.

The present report describes the application of quantitative structure–activity relationship methodology to the results of a pharmacokinetic study of *N*-alkyl-substituted amphetamine derivatives in humans (6). The thoroughness of the work of the previous investigators, the quantitative nature of results, the number (15) of molecules investigated, and the large spread in the biological responses made this study an attractive candidate for a quantitative interpretation in terms of molecular properties. Furthermore, the previous investigators measured the apparent

partition coefficient of their compounds and established graphical correlations for limited subsets of observations.

EXPERIMENTAL

Table I lists the 15 molecules investigated. Two parameters are used as a measure of lipophilicity: (*a*) the apparent *n*-heptane–water partition coefficient measured at pH 7.4 (6), and (*b*) the sum of the hydrophobic fragmental constants of the two nitrogen substituents (hydrogen and/or alkyl) (7). The latter parameter represents the incremental contributions of molecular fragments to the true *n*-octanol–water partition coefficient (8).

The degree of substitution on the nitrogen atom (primary, secondary, or tertiary) is taken into account by the structural descriptor NH, *i.e.*, the number of hydrogen atoms on the nitrogen. Two parameters specifically consider the *N*-alkyl substituent that is cleaved from the molecule: the volume of the substituent, calculated according to Bondi (9), and the number of hydrogen atoms on the α-carbon.

Donike *et al.* (6) determined three biological responses that are valuable parameters in this study. They are: (*a*) the cumulative urinary excretion of unchanged drug expressed as the percent of the administered dose [percent excreted unchanged (PEU)]; (*b*) the rate constant of urinary excretion, EXC, in hours^{-1}; and (*c*) the rate constant of the first *N*-dealkylation step, DEA, in hours^{-1}.

Three subjects were used in the study of Donike *et al.* (6). Subjects 1 and 2 were kept under acidic urinary control by ingestion of ammonium chloride (urinary pH values were 5.0–5.2 and 4.9–5.1, respectively). The urinary pH of Subject 3 was not controlled and was comparatively higher (5.4–5.7). The individual values of log PEU, log EXC, and log DEA for Subjects 1–3 are reported in Tables II–IV. These data provided the input for the dependent variables in the present calculations.

The multiple linear regression analyses were performed on a computer[1] using the SPSS program (10) with a stepwise method. The program calculates the regression coefficients of all independent variables and their standard deviation (given in parentheses) and the constant term (intercept). The statistics performed include the squared multiple correlation coefficient, r^2, the standard deviation of the equation, *s*, and the *F* test. Testing the null hypotheses for each regression coefficient individually is done by the Student *t* test; these values are not reported here, but all variables included in Eqs. 1–28 are significant at the probability level of 0.05 or better.

Table V gives the correlation matrixes for 15 observations (Eqs. 1–19) and for 17 observations (Eqs. 20–28).

RESULTS AND DISCUSSION

Cumulative Urinary Excretion of Unchanged Drugs—The significant correlation equations derived for log PEU are shown in Table VI, revealing that this biological response depends heavily on the lipophilicity of the molecules as assessed by the apparent *n*-heptane–water partition coefficient (Eqs. 1, 5, and 9). These equations indicate that the total excretion of unchanged drug increases with decreasing log P_H; *i.e.*, high hydrophilicity favors fast excretion and limited biotransformation. This linear correlation can be improved by the inclusion of a squared term to yield parabolic equations (Eqs. 2 and 6). The optimal log P_H value thus determined is that of amphetamine for Subject 1, while the value for Subject 2 is that of a hypothetical derivative somewhat more hydrophilic than amphetamine.

However, Eqs. 2 and 6 are not truly meaningful from a physical point of view. It is reasonable to expect that hypothetical derivatives that are

[a] The italicized numbers are the correlation matrix for 17 observations (Eqs. 20–28).

markedly more hydrophilic than amphetamine will simply be excreted totally unchanged (log PEU = 2.0); in this region, a plot of log P_H *versus* log PEU should be a horizontal line, and the true nature of the mathematical relationship can be envisioned as a bilinear function. However, testing of this hypothesis is not feasible due to a lack of suitable observations. In any case, extrapolation of Eqs. 2 and 6 to hypothetical compounds that are more hydrophilic than amphetamine is misleading.

For Subject 3, the inclusion of a squared term is not significant, indicating that the lack of urinary pH control alters not only the magnitude of excretion but apparently also the nature of the mathematical relationship between elimination and lipophilicity.

Equations 3 and 7 explore another aspect of the structure–activity relationships: total excretion of unchanged drug increases with the number of *N*-substituents once the lipophilicity of the molecules is accounted for by the log P_H term. The correlation between log PEU and NH alone is positive (Table V), but Eqs. 3 and 7 indicate that, for identical lipophilicities, tertiary amines are excreted faster and are less metabolized than are secondary amines. However, such a relationship holds only in the case of urinary pH control, with the inclusion of the NH parameter being nonsignificant for Subject 3.

Replacement of log P_H by $f_{RR'}$, a measure of the *n*-octanol–water partition coefficient of the nonprotonated bases, to yield Eqs. 4, 8, and 10 results in less favorable statistics, as evidenced by smaller r^2 values, and considerably larger standard deviations. Also, the inclusion of any other variable in Eqs. 4, 8, and 10 is nonsignificant.

The better correlations displayed by log P_H as compared to $f_{RR'}$ probably is due to the fact the log P_H includes a pKa term, thus accounting for the fraction of drug present in the tubules as nonionic species. This fraction is no less important than the lipophilicity of the neutral form in influencing the urinary excretion of amphetamines.

The best equations for log PEU_i are Eqs. 2, 6, and 9. A comparison of experimental and calculated log PEU_i values is given in Table II.

Rate Constant of Urinary Excretion—The significant correlation equations obtained for log EXC are given in Table VII. As with the previous examples, this biological response is mainly dependent on lipophilicity. Equations 11, 14, and 17 show that the rate of excretion increases with decreasing log P_H, confirming that high hydrophilicity favors fast excretion, presumably due to minimal tubular reabsorption. The relationship is linear, with the parabolic equations being nonsignificant.

In contrast, the inclusion of the NH parameter markedly improves the statistics (Eqs. 12, 15, and 18). These equations confirm the conclusions obtained previously in that, for identical lipophilicities and when pKa is accounted for, tertiary amines undergo faster excretion than do secondary amines, which are excreted faster than primary amines. This structural influence has never been characterized, and no convincing physicochemical or biochemical explanation can be offered at present. Steric hindrance in the reabsorption process is a mere possibility.

Replacing log P_H with $f_{RR'}$ yields Eqs. 13, 16, and 19 in which the constant term is eliminated. The equations are less satisfactory than Eqs. 11, 14, and 17 due to larger standard deviations for reasons outlined earlier.

The best equations for log EXC_i are Eqs. 12, 15, and 18. Table III compares experimental and calculated log EXC_i values.

Rate Constant of First *N*-Dealkylation—For this biological response, 17 observations are available and consist of 14 compounds, three

of which bear two different N-substituents. From Table V, it is clear that log DEA is markedly dependent on lipophilicity, with log P_H and $f_{RR'}$ each accounting for ~50–60% of the variance (~30% for Subject 3). Equations based on log P_H or $f_{RR'}$ alone thus are below acceptable levels of significance and are not reported. The inclusion of quadratic terms or of NH did not improve the correlation.

Good levels of significance were obtained by including a second parameter that served as a descriptor of the N-substituent removed by dealkylation. This approach results in Eqs. 20–28 (Table VIII). Equations 20, 21, 23, 24, 26, and 27 indicate that the rate of the first dealkylation increases with increasing lipophilicity of the molecules (as assessed by log P_H or $f_{RR'}$) and with decreasing volume of the substituent that is split off. There is an apparent contradiction between these two trends, allowing an interesting insight into the molecular factors controlling N-dealkylation. The equations may mean that a high lipophilicity favors affinity to cytochrome P-450 and, hence, a fast reaction (2). On the other hand, the bulkier the substituent to be split off, the less favorable appears the initial C_α-hydroxylation ultimately leading to N-dealkylation.

Such an interpretation is strengthened by Eqs. 22, 25, and 28, which show that the rate of dealkylation increases with the number of hydrogen atoms on the α-carbon. In other words, increasing the steric bulk on the α-carbon being hydroxylated decreases the rate of N-dealkylation, suggesting that, in terms of the reaction mechanism, the C_α-hydroxylation by oxene transfer is the rate-limiting step in the overall N-dealkylation reaction.

Table VIII shows that the utility of the three sets of independent variables (log P_H and V_R, $f_{RR'}$ and V_R, and $f_{RR'}$ and $C_\alpha H$) varies from one subject to another. The set of log P_H and V_R yields the best correlations for Subjects 1 and 3 but not for Subject 2. This situation outlines the interest in quantitative structure–activity relationship studies of having a variety of parameters and descriptors available. The fourth possible set of variables, log P_H and $C_\alpha H$, does not yield significant equations, despite the orthogonality of the two variables (Table V).

Experimental log DEA_i values are compared in Table IV with the values calculated from the best equations in Table VIII.

CONCLUSION

The present study indicates that careful pharmacokinetic studies can yield biological data suitable for quantitative structure–activity relationship treatment and that following pharmacokinetic calculations with quantitative structure–activity relationship calculations can lead to new insights into, and a better understanding of, drug metabolism and disposition. This study also shows that the excretion of amphetamines decreases with increasing lipophilicity of the molecules and that, given the same lipophilicity, tertiary amines are excreted faster than secondary amines, which are excreted faster than primary amines. Also, the correlation equations indicate that the rate of N-dealkylation increases with increasing lipophilicity of the substrates (enhanced enzyme affinity) but decreases with increasing bulk of the N-substituent that is split off (steric hindrance of C_α-hydroxylation).

The quantitative nature of the correlations obtained will allow interesting comparisons with other series of drugs when data become available.

Interactions of Cephalosporins and Penicillins with Nonpolar Octadecylsilyl Stationary Phase

FRANCISCO SALTO ˣ, JULIO G. PRIETO, and MARY TERESA ALEMANY

Received June 18, 1979, from the *Departamento Interfacultativo de Bioquimica, Cátedra de Química, Facultad de Veterinaria, Leon, Spain.* Accepted for publication November 26, 1979.

Abstract □ The capacity factors of several penicillins and cephalosporins, as well as those of 7-aminocephalosporanic acid, 6-aminopenicillanic acid, and 7-aminodeacetoxycephalosporanic acid, were determined at pH 2.5–7.5 with different methanol concentrations in the mobile phase. The influence of ionic strength on activity factors also was studied. Some theoretical equations providing a quantitative description of the influence of the mobile phase pH on the retention of penicillins and cephalosporins by an octadecylsilyl stationary phase were established. The analysis of experimental data by a nonlinear least-squares fit to theoretically deduced equations permitted determination of the capacity factors of anionic, cationic, zwitterion, and undissociated forms of the substances studied.

Keyphrases □ Cephalosporins—interactions with a nonpolar octadecylsilyl stationary phase □ Penicillins—interactions with a nonpolar octadecylsilyl stationary phase □ Capacity factors—cephalosporins and penicillins, interactions with a nonpolar octadecylsilyl stationary phase □ Antibiotics—cephalosporins and penicillins, interactions with a nonpolar octadecylsilyl stationary phase, capacity factors

Penicillins and cephalosporins constitute a large family of antibiotics of generalized use and similar structure. All of these compounds have at least one carboxylic group, and some possess one or more amino groups. Therefore, depending on the medium, they can be in undissociated, anionic, cationic, or zwitterion form.

There have been several studies of nonpolar stationary phases for the separation of certain cephalosporins and penicillins (1–4). However, a more systematic study of the influence of the ionization of penicillins and cephalosporins on interactions with nonpolar octadecylsilyl stationary phases was desired to elucidate the factors in the chro-

of which bear two different N-substituents. From Table V, it is clear that log DEA is markedly dependent on lipophilicity, with log P_H and $f_{RR'}$ each accounting for ~50–60% of the variance (~30% for Subject 3). Equations based on log P_H or $f_{RR'}$ alone thus are below acceptable levels of significance and are not reported. The inclusion of quadratic terms or of NH did not improve the correlation.

Good levels of significance were obtained by including a second parameter that served as a descriptor of the N-substituent removed by dealkylation. This approach results in Eqs. 20–28 (Table VIII). Equations 20, 21, 23, 24, 26, and 27 indicate that the rate of the first dealkylation increases with increasing lipophilicity of the molecules (as assessed by log P_H or $f_{RR'}$) and with decreasing volume of the substituent that is split off. There is an apparent contradiction between these two trends, allowing an interesting insight into the molecular factors controlling N-dealkylation. The equations may mean that a high lipophilicity favors affinity to cytochrome P-450 and, hence, a fast reaction (2). On the other hand, the bulkier the substituent to be split off, the less favorable appears the initial C_α-hydroxylation ultimately leading to N-dealkylation.

Such an interpretation is strengthened by Eqs. 22, 25, and 28, which show that the rate of dealkylation increases with the number of hydrogen atoms on the α-carbon. In other words, increasing the steric bulk on the α-carbon being hydroxylated decreases the rate of N-dealkylation, suggesting that, in terms of the reaction mechanism, the C_α-hydroxylation by oxene transfer is the rate-limiting step in the overall N-dealkylation reaction.

Table VIII shows that the utility of the three sets of independent variables (log P_H and V_R, $f_{RR'}$ and V_R, and $f_{RR'}$ and $C_\alpha H$) varies from one subject to another. The set of log P_H and V_R yields the best correlations for Subjects 1 and 3 but not for Subject 2. This situation outlines the interest in quantitative structure–activity relationship studies of having a variety of parameters and descriptors available. The fourth possible set of variables, log P_H and $C_\alpha H$, does not yield significant equations, despite the orthogonality of the two variables (Table V).

Experimental log DEA_i values are compared in Table IV with the values calculated from the best equations in Table VIII.

CONCLUSION

The present study indicates that careful pharmacokinetic studies can yield biological data suitable for quantitative structure–activity relationship treatment and that following pharmacokinetic calculations with quantitative structure–activity relationship calculations can lead to new insights into, and a better understanding of, drug metabolism and disposition. This study also shows that the excretion of amphetamines decreases with increasing lipophilicity of the molecules and that, given the same lipophilicity, tertiary amines are excreted faster than secondary amines, which are excreted faster than primary amines. Also, the correlation equations indicate that the rate of N-dealkylation increases with increasing lipophilicity of the substrates (enhanced enzyme affinity) but decreases with increasing bulk of the N-substituent that is split off (steric hindrance of C_α-hydroxylation).

The quantitative nature of the correlations obtained will allow interesting comparisons with other series of drugs when data become available.

matographic process and to determine the conditions necessary for optimum separation. It also may help to define the hydrophobic properties of the various penicillins and cephalosporins and their possible relationships to pharmacological characteristics.

EXPERIMENTAL

Materials—The penicillins, cephalosporins, 7-aminocephalosporanic acid, 6-aminopenicillanic acid, and 7-aminodeacetoxycephalosporanic acid were used as supplied[1]. The chemicals were of the highest commercial grade available and were used without further purification.

Phosphate buffer solutions were used at a concentration of 0.05 *M*; sodium sulfate was used to obtain the desired ionic strength in each case. The mixtures of methanol and the buffer solution are expressed in volume percent.

Chromatographic Conditions—A 2.5 × 600-mm steel column, fitted with suitable adaptors and a 10-μm filter, was packed using a dry-packing technique with 30–70-μm silica with bonded octadecylsilane[2]. After packing, the column was conditioned with 200 ml of dimethylformamide at 40° followed immediately by 300 ml of methanol. The liquid chromatograph was fitted with a pump[3], a 20-μl sample valve injector[4], a 250-nm UV detector[5], and a strip-chart recorder[6].

[3] Constametrick II, Laboratory Data Control.
[4] Model 7120, Rheodyne.
[5] UV III monitor, Laboratory Data Control.
[6] Model XER, Sargent-Welch Scientific Co., Skokie, Ill.

The solutions of the chromatographed substances were prepared in the mobile phase at a concentration of 0.5 mg/ml, except for the penicillins, which were dissolved at a concentration of 3 mg/ml. In each case, 20 μl of a sample solution was injected. The flow rate was 1 ml/min, and the sensitivity of the UV detector was set between 0.004 and 0.128 aufs according to the coefficient of extinction of the analyzed product.

The capacity factors, k', were calculated using $k' = (V_R - V_0)/V_0$, where V_R is the elution volume of the chromatographic peak and V_0 is the column void volume, determined as the elution volume of a nonretained peak.

Determination of pKa—The literature does not contain pKa values of the drugs determined under appropriate conditions of the mobile phase. Therefore, the apparent pKa values were determined by a potentiometric method (5) for the ionic strength and methanol content of each mobile phase at room temperature.

Analysis of Experimental Data—The numerical analysis of the experimental data was carried out on a calculator[7] specially programmed for a nonlinear least-squares fit.

RESULTS AND DISCUSSION

The structures of the studied substances are given in Table I. The apparent pKa values, determined at room temperature at an ionic strength of 0.15 and at different methanol concentrations, are given in Table II.

Influence of pH—Due to the low stability of the penicillins, cephalosporins, and the stationary phase in strongly acidic or alkaline media, the studies were conducted within the pH 2.5–7.7 range.

XIV	—	—	—	4.21	—	—	—	—

Figure 1 shows the capacity coefficients for I, V, VI, and X at room temperature at different pH values and with a mobile phase of 0.05 *M* phosphate buffer at an ionic strength of 0.15. An octadecylsilyl stationary phase was used.

The capacity factors for II–IV, VI–IX, and XI at the various pH values are shown in Fig. 2. The mobile phase was a 10:90 mixture of methanol and the corresponding 0.05 *M* phosphate buffer at an ionic strength of 0.05. Figure 3 shows the capacity factors of the same substances as well as XII at different pH values when a mobile phase of 20 volumes of methanol and 80 volumes of 0.05 *M* phosphate buffer and an ionic strength of 0.15 was used. Figure 4 shows the capacity factors of the described penicillins and cephalosporins along with those of XII and XIV for different pH values with a mobile phase that was a 30:70 mixture of methanol and 0.05 *M* phosphate buffer at an ionic strength of 0.15. All tests were carried out at room temperature.

The physicochemical interactions between the solutes and the nonpolar stationary phase may be interpreted in accordance with the solvophobic theory (6); therefore, the influence of the solute ionization on chromatographic retention may be justified.

Depending on the pH of the medium, I, V, X, and penicillins and cephalosporins with amino and carboxyl groups may be found in solution in cationic ($^+H_3NPCOOH$), anionic (H_2NPCOO^-), or dipolar ($^+H_3NPCOO^-$) form. The dissociation equilibria are:

$$^+H_3NPCOOH \rightleftharpoons {}^+H_3NPCOO^- + H^+$$

Scheme I

$$K_{a_1} = \frac{[^+H_3NPCOO^-][H^+]}{[^+H_3NPCOOH]} \qquad \text{(Eq. 1)}$$

$$^+H_3NPCOO^- \rightleftharpoons H_2NPCOO^- + H^+$$

Scheme II

$$K_{a_2} = \frac{[H_2NPCOO^-][H^+]}{[^+H_3NPCOO^-]} \qquad \text{(Eq. 2)}$$

The chromatographic process may be considered as a reversible association of the solute, in any of its forms, with the ligand, L, formed by the octadecyl radical joined covalently to the surface of the silica. The process essentially is governed by solvophobic interactions, and no ionic or hydrogen bond is formed between the solute and the stationary phase. The equilibria governing these processes and their respective constants are:

$$^+H_3NPCOO^- + L \rightleftharpoons L^+H_3NPCOO^-$$

Scheme III

$$K_{L^+HP} = \frac{[L^+H_3NPCOO^-]}{[^+H_3NPCOO^-][L]} \qquad \text{(Eq. 3)}$$

$$H_2NPCOO^- + L \rightleftharpoons LH_2NPCOO^-$$

Scheme IV

$$K_{LP^-} = \frac{[LH_2NPCOO^-]}{[H_2NPCOO^-][L]} \qquad \text{(Eq. 4)}$$

$$^+H_3NPCOOH + L \rightleftharpoons L^+H_3NPCOOH$$

Scheme V

$$K_{L^+HP} = \frac{[L^+H_3NPCOOH]}{[^+H_3NPCOOH][L]} \qquad \text{(Eq. 5)}$$

The retention of a solute is expressed by the capacity factor, k', defined as the coefficient of distribution of the solute between the mobile and stationary phases. In a column where the relationship between the volume of the stationary phase and that of the mobile phase is constant and equal to ϕ, the distribution ratio is given by:

$$k' = \phi \frac{[L^+H_3NPCOOH] + [LH_2NPCOO^-] + [L^+H_3NPCOO^-]}{[^+H_3NPCOOH] + [H_2NPCOO^-] + [^+H_3NPCOO^-]} \qquad \text{(Eq. 6)}$$

The numerator of Eq. 6 is the sum of the concentrations of each solute form bound to the stationary phase; the denominator is the sum of the concentrations of each solute form in the mobile phase.

By substituting into Eq. 6 the values of the concentrations of each form found in Eqs. 1–4 and defining the capacity factor of the dipolar form, k'_0, as $k'_0 = \phi[L]K_{L^+HP^-}$, the capacity factor of the anionic form, k'_{-1}, as $k'_{-1} = \phi[L]K_{LP^-}$, and the capacity factor of the cationic form, k'_{+1}, as $k'_{+1} = \phi[L]K_{L^+HP}$, Eq. 6 finally may be transformed into:

$$k' = \frac{k'_0 + k'_{-1}\frac{K_{a_2}}{[H^+]} + k'_{+1}\frac{[H^+]}{K_{a_1}}}{1 + \frac{K_{a_2}}{[H^+]} + \frac{[H^+]}{K_{a_1}}} \qquad \text{(Eq. 7)}$$

Therefore, Eq. 7 should explain the influence of pH on the capacity factors of the amphoteric penicillins and cephalosporins as well as those of I, V, and X.

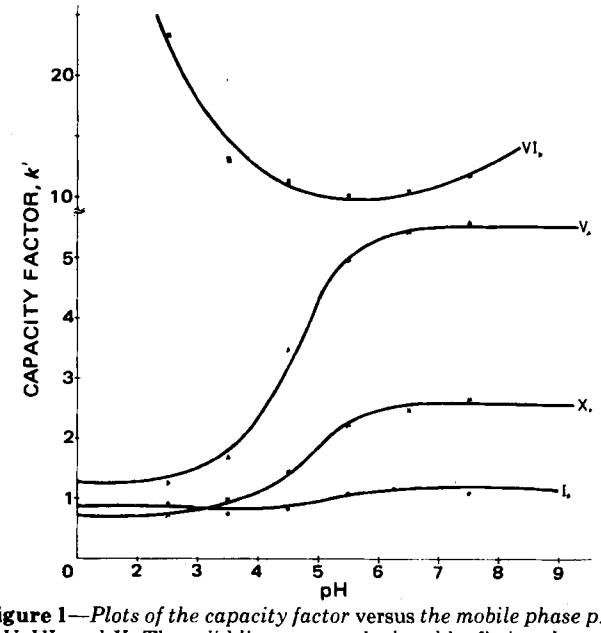

Figure 1—*Plots of the capacity factor* versus *the mobile phase pH for I, V, VI, and X. The solid lines were calculated by fitting the experimental data to Eq. 7.*

Each dissociated and undissociated form of penicillins and cephalosporins with only one ionizable group can interact with the stationary phase, giving rise to equilibria similar to those discussed previously.

By proceeding in the same way as for amphoteric penicillins and cephalosporins, the following is obtained:

$$k' = \frac{k'_0 + k'_{-1}\dfrac{K_a}{[H^+]}}{1 + \dfrac{K_a}{[H^+]}} \qquad \text{(Eq. 8)}$$

where k'_0 and k'_{-1} represent the capacity factors of the undissociated and anionic forms of the penicillins and cephalosporins, respectively.

The continuous lines in Figs. 1–4 were obtained by a nonlinear least-squares fit of the experimental data to Eq. 7 for I, V, and X as well as for the amphoteric penicillins and cephalosporins (III, IV, VIII, and XI). For penicillins and cephalosporins having only one carboxyl group (II, VII, IX, and XII–XIV), the lines were obtained with Eq. 8. The analysis of the experimental data by a nonlinear least-squares fit to Eq. 7 permitted calculation of the capacity factors for the zwitterion (k'_0), anionic (k'_{-1}), and cationic (k'_{+1}) forms of I, V, X, and amphoteric penicillins and cephalosporins (Table III). Similarly, a nonlinear least-squares fit to Eq. 8 was used to calculate the capacity factors of the undissociated (k'_0) and dissociated (k'_{-1}) forms of penicillins and cephalosporins with only one carboxyl group (Table III).

The acylation of the amino group of I, V, and X gave cephalosporins and penicillins that were retained more by the octadecylsilyl column. In general, cephalosporins were retained less than were penicillins.

For the nucleus of penicillins and cephalosporins, the hightest k' values were for V and the lowest ones were for I; X had intermediate values (Fig. 1). The greater retention of V may be attributed to its greater hydrophobicity due to the introduction of the acetoxy group in position 3.

For I, V, X, and the amphoteric penicillins and cephalosporins, the capacity factors of the anionic forms (k'_{-1}) (Table III) had the highest values, possibly due to the protective effect of the water molecules (7), which form hydrogen bonds with the protonated amino groups; this protection is smaller in the anionic forms, thus favoring hydrophobic interactions with the stationary phase. For I, V, and X, the capacity factors of the zwitterion form (k'_0) were similar to, but somewhat higher than, those of the cationic form (k'_{+1}). On the other hand, for amphoteric penicillins and cephalosporins, the capacity factors of the zwitterion form

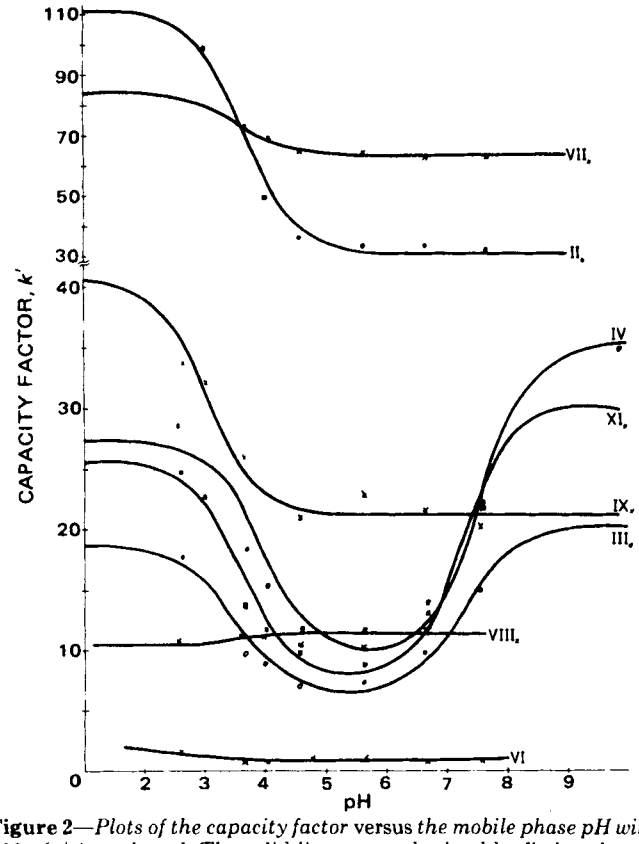

Figure 2—*Plots of the capacity factor* versus *the mobile phase pH with 10% (v/v) methanol. The solid lines were obtained by fitting the experimental data for III, IV, and XI to Eq. 7 and for II and VII–IX to Eq. 8.*

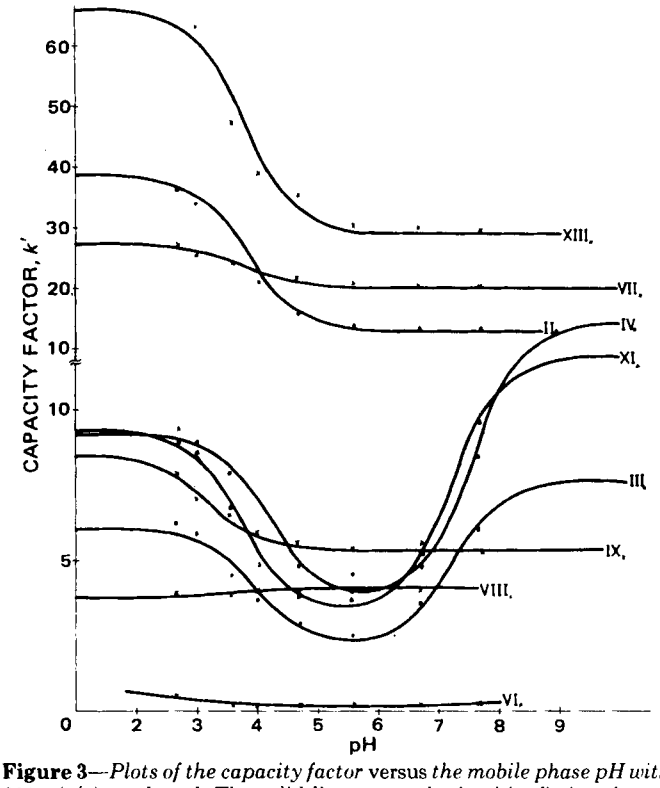

Figure 3—*Plots of the capacity factor* versus *the mobile phase pH with 20% (v/v) methanol. The solid lines were obtained by fitting the experimental data for II, IV, and XI to Eq. 7 and for II, VII–IX, and XII to Eq. 8.*

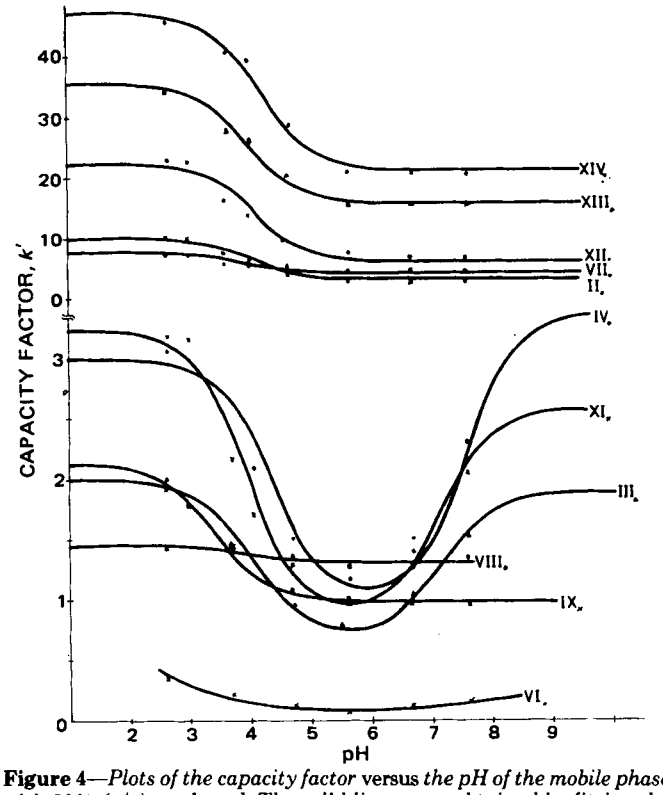

Figure 4—*Plots of the capacity factor* versus *the pH of the mobile phase with 30% (v/v) methanol. The solid lines were obtained by fitting the experimental data for III, IV, and XI to Eq. 7 and for II, VII–IX, and XII–XIV to Eq. 8.*

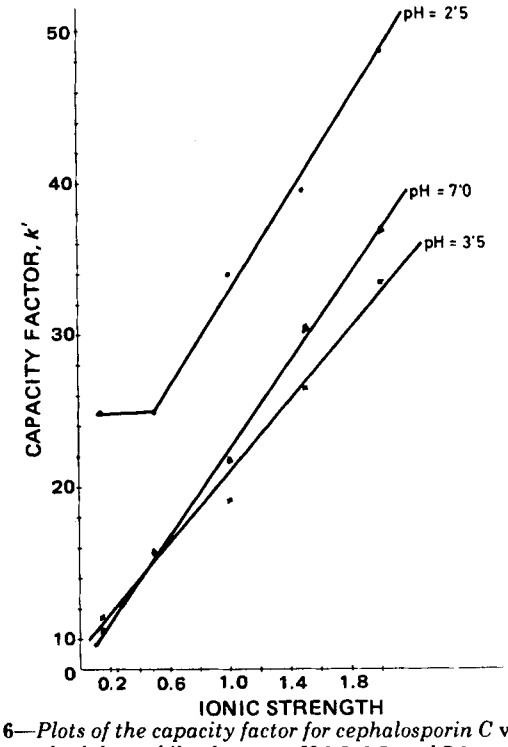

Figure 6—*Plots of the capacity factor for cephalosporin C* versus *the ionic strength of the mobile phase at pH 2.5, 3.5, and 7.0.*

(k'_0) were systematically lower than those of the other two (k'_{+1} and k'_{-1}). Therefore, in amphoteric cephalosporins and penicillins, the dipolar form interacts the least with the octadecylsilyl stationary phase, probably because although the form has no charge, there are a positive charge and a negative charge, which make the hydrophobic interaction with the stationary phase difficult.

In penicillins and cephalosporins with only one carboxyl group, as expected, the capacity factor of the undissociated acid form with no charge (k'_0) was greater than that of the negatively charged dissociated form (k'_{-1}).

Among cephalosporins, the influence of the nature of the lateral chain is remarkable. Of the cephalosporins studied, cephalothin had the highest capacity factor and cephalosporin C had the lowest.

Cephalothin (VII) was more retained by the nonpolar stationary phase than was cephaloridine (VIII). This result probably was a consequence of the substitution in position 3 of the cephalothin thiazine ring of a charged pyridino group by the acetoxy group, thus increasing the polarity and consequently decreasing cephaloridine retention.

For deacetoxycephalosporins, the capacity factor values decreased in the order 7-phenylacetamidoacetoxycephalosporin > cephradine >

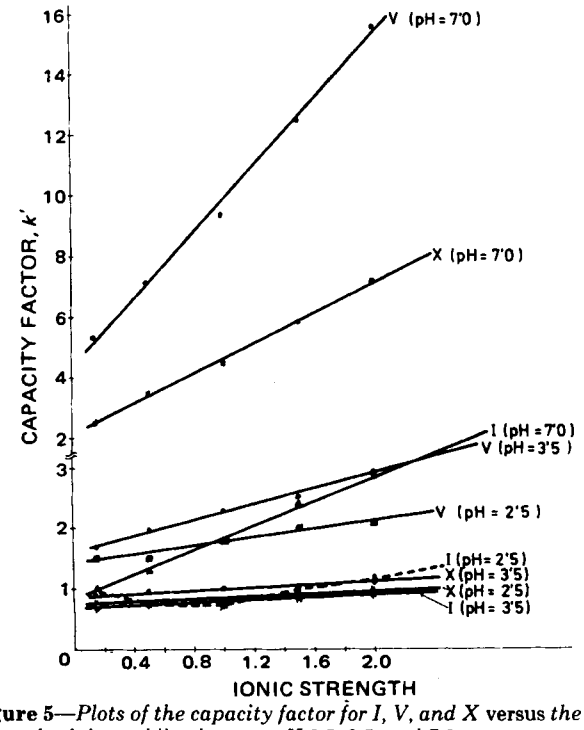

Figure 5—*Plots of the capacity factor for I, V, and X* versus *the ionic strength of the mobile phase at pH 2.5, 3.5, and 7.0.*

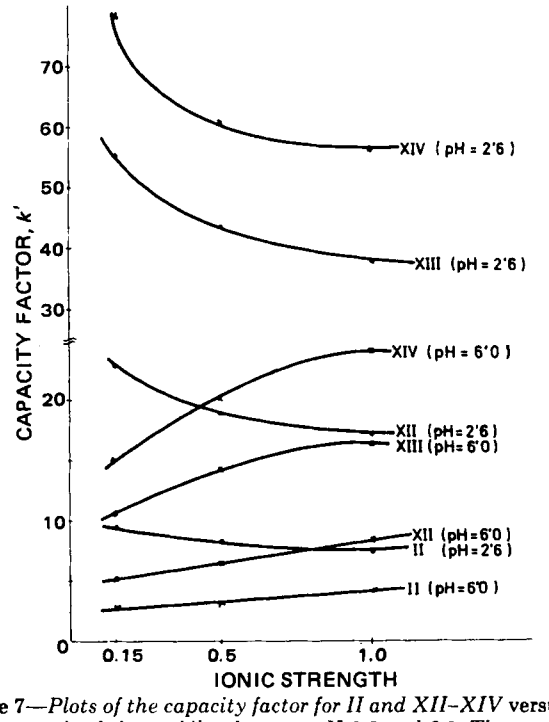

Figure 7—*Plots of the capacity factor for II and XII–XIV* versus *the ionic strength of the mobile phase at pH 2.6 and 6.0. The methanol content in the mobile phase was 20% (v/v).*

cephalexin. The introduction of an amino group in the lateral chain evidently reduced considerably the hydrophobicity of the molecule and, therefore, its retention by the octadecylsilyl column. In penicillins, capacity factors decreased in the order XIV > XIII > XII > XI.

Influence of Methanol Content in Mobile Phase—As expected, the retention of cephalosporins and penicillins by the nonpolar octadecylsilyl stationary phase decreased as the methanol concentration of the mobile phase increased. For the various penicillins and cephalosporins studied, the representation of $\log k'_0$, $\log k'_{-1}$, or $\log k'_{+1}$ *versus* the methanol concentration in the mobile phase, expressed in volume percent, shows a reasonable linear relationship with similar slopes.

Yamana *et al.* (8) used $\log k'$ as a lipophilic index for certain cephalosporins and penicillins, considering it to be analogous to the R_m index determined for cephalosporins and penicillins by means of reversed-phase TLC and comparable to $\log P$, the logarithm of the distribution ratio, determined in *n*-octanol–water systems, which is generally accepted as a lipophilic index. Similarly, $\log k'_0$, $\log k'_{-1}$, and $\log k'_{+1}$ could represent the lipophilic character of each form of penicillins and cephalosporins.

Influence of Salt Concentration—The effect of ionic strength on the capacity factor for I, V, and X was studied (Fig. 5). The mobile phases used were 0.05 *M* phosphate buffers at pH 2.5, 3.5, and 7.0; the ionic strength was varied from 0.51 to 2.0 for each pH value. The influence of the ionic strength on capacity factors at pH 2.5 and 3.5, where I, V, and X are in cationic or zwitterion forms, was very small. At pH 7.0, where these substances are in anionic form, this influence was important, especially for V; it decreased in the order V > X > I.

According to Horvath *et al.* (6), the increase in k' with ionic strength can be attributed to an increase in water surface tension when the salt concentration increases. On the contrary, the ionic form of cephalosporin C does not affect the influence of ionic strength on capacity factors. The k'/μ plots are straight lines of similar slope for each pH value studied, except at pH 2.5 and a very low ionic strength (Fig. 6).

The influence of ionic strength on the retention of II and XII–XIV also was studied at pH 2.6 and 6.0 (Fig. 7). The mobile phase was a mixture of 0.05 *M* phosphate buffer and methanol (2:1 v/v). Plotting k'/μ resulted in lines with negative slopes at the lowest acid pH, where the penicillins are in cationic or undissociated form. At pH 6, where the penicillins and the cephalosporins are in anionic form, the slopes of the k'/μ lines are positive.

It must be emphasized that the ionic strength of the mobile phase has a greater influence on the capacity factors of charged forms than on those of uncharged ones, and it is in the opposite direction. In fact, an increase of the ionic strength increases the retention of the charged forms while decreasing the retention of the uncharged acid forms.

CONCLUSION

The effect of cephalosporin and penicillin ionization on the chromatographic retention by nonpolar stationary phases can be interpreted in terms of hydrophobic interactions between the solute and the hydrocarbon function bound to the support surface. This quantitative study permitted determination of the capacity factors of each molecular form (k'_0, k'_{-1}, and k'_{+1}) of the investigated drugs.

The results given in this work will aid in the separation and analysis of some of the investigated substances.

The logarithms of the capacity factors of each molecular form, being independent of pH, probably will represent more adequately the lipophilic or hydrophobic characteristic of a compound having ionizable groups.

Abstract □ A series of 1-(4-biphenylyl)pentyl hydrogen 3-alkylglutarates and 3-hydroxy-3-alkylglutarates was synthesized and assayed for inhibition of rat liver β-hydroxy-β-methylglutaryl-CoA reductase. Limited solubility of the monoesters in the enzyme assay system prevented the determination of the I_{50} values. However, the limited data indicated no significant changes in the activity of the analogs when they were assayed at identical concentrations.

Keyphrases □ Hypocholesterolemic agents—inhibition of β-hydroxy-β-methylglutaryl-CoA reductase, monoesters of substituted glutaric acids, rat liver microsomes □ Microsomes, rat liver—inhibition of cholesterol biosynthesis, monoesters of substituted glutaric acids □ Enzyme inhibition—effect of monoesters of glutaric acids on cholesterol biosynthesis, rat liver microsomes

An approach to the design of cholesterol biosynthesis inhibitors as potential hypocholesterolemic agents was discussed previously (1, 2). The rationale for the inhibition of the enzyme β-hydroxy-β-methylglutaryl-CoA reductase was presented (1). Structure–activity relationships indicated that maximum activity was observed when R_1 = biphenylyl, R_2 = *n*-butyl, and n = 1–4 in a series of arylalkyl hydrogen alkanedioates (I). In addition, the incorporation of a β-hydroxy-β-methyl moiety into the acid portion of the glutarate analog provided II, which was seven times more active than the glutarate analog of I.

This paper describes the synthesis and assay of a series of 1-(4-biphenylyl)-*n*-pentyl hydrogen 3-alkylglutarates (III) and 3-hydroxy-3-alkylglutarates (IV). The 3-alkyl series (III) was designed specifically to determine if there was a hydrophobic binding site on the enzyme where the 3-alkyl group of the glutaric acid moiety could bind. The

cephalexin. The introduction of an amino group in the lateral chain evidently reduced considerably the hydrophobicity of the molecule and, therefore, its retention by the octadecylsilyl column. In penicillins, capacity factors decreased in the order XIV > XIII > XII > XI.

Influence of Methanol Content in Mobile Phase—As expected, the retention of cephalosporins and penicillins by the nonpolar octadecylsilyl stationary phase decreased as the methanol concentration of the mobile phase increased. For the various penicillins and cephalosporins studied, the representation of $\log k'_0$, $\log k'_{-1}$, or $\log k'_{+1}$ *versus* the methanol concentration in the mobile phase, expressed in volume percent, shows a reasonable linear relationship with similar slopes.

Yamana *et al.* (8) used $\log k'$ as a lipophilic index for certain cephalosporins and penicillins, considering it to be analogous to the R_m index determined for cephalosporins and penicillins by means of reversed-phase TLC and comparable to $\log P$, the logarithm of the distribution ratio, determined in *n*-octanol–water systems, which is generally accepted as a lipophilic index. Similarly, $\log k'_0$, $\log k'_{-1}$, and $\log k'_{+1}$ could represent the lipophilic character of each form of penicillins and cephalosporins.
