Table IV—Results of *K* Nearest Neighbor Analysis [a]

K	Percent Correct	
	Learning Set	Test Set[b]
1	87.0	66.7
3	89.1	55.6
4	89.1	55.6
5	89.1	55.6
6	87.0[c]	55.6[d]

[a] Classification was performed in the space of the standardized position variables *a*, *b*, *c*, *i*, and *j*. [b] Each observation in the test set was classified on the basis of observations in the learning set, omitting other test set compounds. [c] Learning set compounds misclassified (predicted group) were 21 (PROG), 24 (PROG), 25 (PROG), 27 (PROG), 39 (PROG), and 45 (PROG). [d] Test set compounds misclassified (predicted group) were III (ESTR), IV (PROG), VI (CORT), and VII (PROG).

Table V—Multicategory Linear Learning Machine Results: Final Weighting Vectors [a]

Variable	Group				
	ESTR	PROG	ANDR	CORT	CARD
a	0.357	0.646	0.469	−0.442	1.522
b	−1.250	0.747	1.392	−0.992	0.219
c	−0.828	0.373	0.719	−0.498	0.191
i	−0.643	0.194	0.113	0.010	0.209
j	0.527	0.283	−0.102	0.610	0.781
Constant	0.147	0.643	0.601	0.150	0.194

[a] Learning set results were 84.8% correct. Compounds misclassified (predicted group) were 13-15 (CORT), 16 (ANDR), and 19 (ANDR). Test set results were 66.7% correct. Compounds misclassified (predicted group) were IV (CORT), VI (CORT), and VIII (ANDR).

Table VI—Principal Component Models from a SIMCA Study

Group	Component[a]	Variable					Percent Correct in Group[b]
		a	*b*	*c*	*i*	*j*

[a] Cross-validation was performed to select the optimum number of components for each group, based on a partial *F* test that measures the significance of an added component, given the components already present. [b] Average learning set results were 84.8% correct. Compounds misclassified (predicted group) were 21 (PROG), 24 (PROG), 25 (PROG), 27 (PROG), 30 (PROG), 39 (PROG), and 45 (PROG). Average test set results were 66.7% correct. Compounds misclassified (predicted group) were IV (PROG), VI (CORT), and VII (PROG).

into the progestogen category. Examination of two- and three-dimensional scatter plots and Andrews curves of the progestogens revealed that this class of compounds showed wide within-group variation with respect to the position variables selected. To be classified successfully by a linear learning machine, the compounds must be linearly separable in the space of the descriptor variables, which perhaps is not the case here.

Statistical Isolinear Multicomponent Analysis—A more sophisticated method of pattern recognition than those mentioned previously was developed by Wold (14). The SIMCA method involves generating a separate principal components model for each class of observations. Components are generated iteratively, and the number of components retained for each class may vary. For each group, the model so obtained is solved by least-squares techniques to determine the relationships between the original variables and the derived principal components.

An observation can be classified, and goodness of fit can be determined, by calculating the principal component scores of the observation for each group and then determining the theoretical *x* values the observation should have if it were a member of the given group. The sum of squares of the differences between the calculated *x* values and the observed ones (*i.e.*, the residuals from the regression models) is a measure of how well

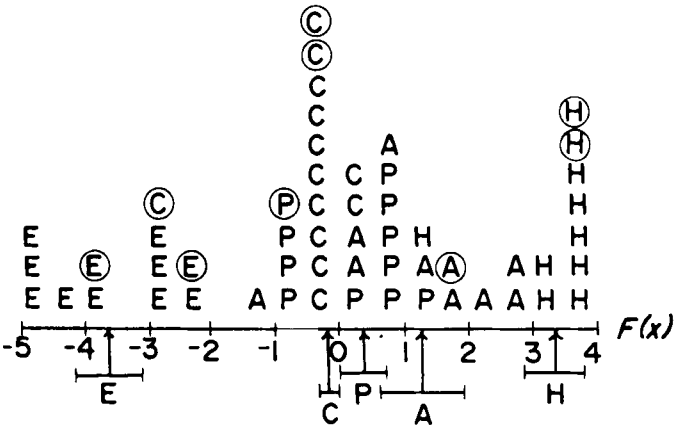

Figure 3—*Histogram of Andrews function values for the compounds in this study. Groups are estrogens (E), progestogens (P), androgens (A), corticosteroids (C), and cardiac steroids (H). Circled entries are test set compounds. Group means (±SD) are shown below the axis.*

the observation fits the model for a particular group. An observation can be placed into the group for which this deviation is smallest or, depending on some preset criteria, it may be placed into a new class instead of into any existing group.

Table VI summarizes the results of a SIMCA study of the data. The number of compounds misclassified by the SIMCA method for both the learning and test sets was the same as for the multiclass separator and the discriminant analysis techniques. However, the identities of the compounds misclassified were different. Those misclassified by the SIMCA method had more in common with the compounds misclassified by the *K* nearest neighbor analysis. This result may reflect a fundamental difference between the multiclass separator and discriminant analysis on the one hand and SIMCA and *K* nearest neighbor analysis on the other. The SIMCA and *K* nearest neighbor methods rely more on local properties of the data set (*i.e.*, the distribution of compounds in the immediate neighborhood of the compound being classified). By contrast, the discriminant function methods rely on a more global view of the data set, considering all groups at once or, in the case of the multiclass separator, comparing a given group with all other groups combined.

CONCLUSIONS

First-order molecular connectivity values contain information that can be used, with varying degrees of success, in the classification of molecular structures into their correct therapeutic categories using pattern recognition techniques. This has been demonstrated using a template-based method of variable assignment. Of course, any method of assigning position variables may be criticized on the basis of its subjectivity. An alternative method, involving whole-molecule molecular connectivity terms, is being studied, and encouraging results have been obtained[3].

For the compounds in this study, pattern recognition methods did not give better classification results than those obtained with the traditional discriminant analysis techniques. The latter methods, due to their statistical nature, have the advantage that stepwise procedures may be employed for variable selection. Such stepwise techniques are not used as commonly in most pattern recognition research.

The classification of observations *per se* is not usually considered a sufficient goal for research of the type reported here. The use of model-building methods of analysis, such as SIMCA, provides a basis for extending such investigations to include both qualitative and quantitative predictions (9). However, it is important that a variety of descriptor variables be studied to determine which variables are most suitable for particular purposes. Molecular connectivity indexes, because of their close relationship to molecular structure, have unique potential for classification problems.

Structural Information from Molecular Connectivity $^4\chi_{PC}$ Index

LEMONT B. KIER

Received June 5, 1978, from the *Department of Pharmaceutical Chemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication March 26, 1979.

Abstract □ The molecular connectivity $^4\chi_{PC}$ index was examined for its ability to describe uniquely molecules containing substituted benzene rings. The subgraphs comprising this index were shown to encode information about the number, placement, and type of ring substituents. Several examples illustrate the ability of the index to describe structure-influencing properties.

Keyphrases □ Molecular connectivity—description of molecules containing substituted benzene rings by $^4\chi_{PC}$ index □ Structure–activity relationships—molecules containing substituted benzene rings, interpretation of structure–activity relationship from molecular connectivity $^4\chi_{PC}$ index

Since the development of a new method of molecular structure quantitation called molecular connectivity, it has been utilized in numerous structure–activity relationship studies (1–7). The numerical indexes computed for each molecule are rich in information content; hence, constellations of indexes are of considerable value in describing structural features contributing to the numerical value of a physical property or biological activity. This study explored the information content of one important index, $^4\chi_{PC}$, and revealed how it plays a prominent role in several structure–activity relationship analyses.

THEORY

The molecular connectivity description of molecular structure gives rise to several numerical indexes of the general form $^m\chi_t$, where m is the order of the molecular fragment and t is the type. Indexes may be of the simple connectivity (unweighted adjacency) or valence level. The indexes are weighted counts of fragments within a molecule, conveying information about topological features such as molecular size, branching, cyclization, unsaturation, and heteroatom location and type.

One distinct advantage of a molecular connectivity analysis of structure in a structure–activity relationship study is that the indexes correlating with activity in a regression analysis can be interpreted directly in terms of structural fragments meaningful to the medicinal chemist (8–10). Depending on the study, various indexes will emerge from searches with one or more variables, each conveying various amounts of structural information.

It has become apparent in the studies conducted in these laboratories that certain patterns of index appearance are found in analyses of molecular structure using molecular connectivity. One noteworthy appearance is the $^4\chi_{PC}$ (or the $^4\chi^v_{PC}$) index in studies on the structures of molecules containing substituted benzene rings. This index frequently is important as a second or third variable in regression analyses on molecules in which the benzene rings possess different numbers, positions, and types of substituents.

This recurrence led to the belief that the $^4\chi_{PC}$ index carries a high degree of information content in these structural classes that is common to many drug molecules. The purpose of this report is to analyze and

reveal the information about benzene ring substitution encoded in the $^4\chi_{PC}$ index.

The $^4\chi_{PC}$ index describes the molecular fragment represented as Fragment A.

Fragment A

The index is calculated using the standard algorithm described previously (1, 7, 8). Each atom in the fragment is assigned a δ value based on the number of atoms bonded to it (adjacency) in the original molecule. A valence delta (δ^v) is assigned on the basis of adjacency or, in the case of heteroatoms or unsaturated carbons, use of the prescription $\delta^v = Z^v - h$, where Z^v is the number of valence electrons and h is the number of attached hydrogen atoms. The $^4\chi_{PC}$ (or $^4\chi_{PC}^v$) index then is computed as the sum of the reciprocal square roots of the products of delta values: $^4\chi_{PC} = \Sigma(\delta_i\delta_j\delta_k\delta_l)^{-1/2}$. The $^4\chi_{PC}^v$ index likewise is computed using δ^v values.

The index carries information about the number of benzene ring substituents, the substitution pattern, the length of the substituents up to three bond lengths, and the heteroatom type of substituent. Each category of information will be described, followed by examples of structure–activity relationship studies in which the $^4\chi_{PC}$ index is prominent.

RESULTS AND DISCUSSION

Number of Ring Substituents—The $^4\chi_{PC}$ index appears whenever a branch point in a chain or a ring substituent occurs in a molecular structure. Each ring substituent contributes at least two terms to this index. With substituents longer than one bond length, neglecting hydrogens, the number of terms per substituent is at least three.

Table I presents a number of substituted phenethylamines that were chosen to illustrate the information content of the $^4\chi_{PC}$ index. In the first 19 entries, the number of $^4\chi_{PC}$ terms and the $^4\chi_{PC}$ and $^4\chi_{PC}^v$ values for all possible methyl derivatives are reported. By plotting the number of

tert-Amylbenzene	4.15	4.08

[a] Molal solubility in water.

methyl substituents *versus* the $^4\chi_{PC}$ value in Fig. 1, it is obvious that the $^4\chi_{PC}$ values correlate closely with the number of methyl substituents. In other words, the $^4\chi_{PC}$ index carries significant information about the number of single-atom ring substituents (exclusive of hydrogen).

This information content is not unique to the $^4\chi_{PC}$ index. It also is encoded in the $^0\chi$, $^1\chi$, and $^3\chi_C$ indexes. However, the information about the number of substituents encoded in $^4\chi_{PC}$ establishes a base from which the greater utility of this index can be established in molecules containing benzene rings. The $^0\chi$, $^1\chi$, and $^3\chi_C$ indexes fail to perform as well as the $^4\chi_{PC}$ index in encoding additional structural information among substituted benzenes.

Orientation of Ring Substituents—The $^4\chi_{PC}$ index encodes information about the orientation of ring substituents. In general, the greater the adjacency or crowding of single-vertex substituents, the larger is the numerical value of the $^4\chi_{PC}$ index. This effect is illustrated in Fig. 2. In considering the six trisubstituted rings (V–X) in Table I, a plot of the number of adjacent pairs *versus* the $^4\chi_{PC}$ values shows an increase in value with an increased pairing of the substituents. The same effect is illustrated in Fig. 2 with the five tetrasubstituted rings (XI–XV) in Table I. Since there is no quantitative way of describing crowding, it is difficult to illustrate this effect in quantitative terms. In fact, the use of $^4\chi_{PC}$ may be a more meaningful way of quantifying crowding or adjacency of ring substituents.

Other indexes fail to discriminate among substitution isomers in every case. Molecule pairs III, IV; VI, VII; and XVII, XVIII have identical $^3\chi_C$ index values.

An examination of the $^4\chi_{PC}$ terms in these cases makes it apparent why it encodes this information. In Fig. 3, the skeletons of III and IV are shown. The $^3\chi_C$ fragments for each skeleton are identical with respect to the atomic δ values. As a result, the $^3\chi_C$ indexes for III and IV are equivalent.

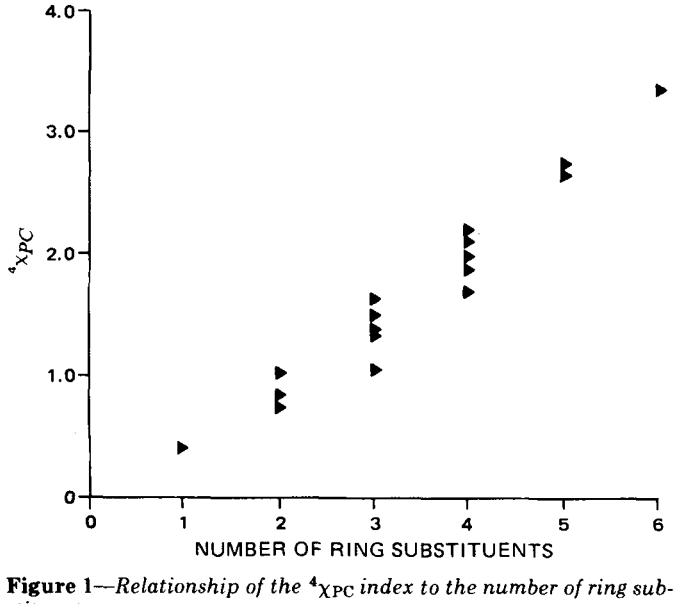

Figure 1—*Relationship of the $^4\chi_{PC}$ index to the number of ring substituents.*

Table III—Cytochrome P-450 Conversion by Substituted Phenols

Substituent	Observed pC^a	Calculated pC
None	1.07	1.02
3-Hydroxy	0.81	1.09

2-Chloro	1.60	1.36
3-Ethyl	1.82	1.83
4-Bromo	2.04	2.03
2-Iodo	2.09	2.23
2,4-Dichloro	2.11	1.89
2,4,6-Trichloro	2.21	2.33
2,3,4,6-Tetrachloro	2.65	2.59
Pentachloro	2.90	2.92

[a] From Ref. 12.

In contrast, III and IV give rise to differing sets of $^4\chi_{PC}$ fragments because $^4\chi_{PC}$ fragments *b* and *c* of III contain ring atoms that are positions of substitution. Compound IV does not have such fragments. Since a $^4\chi_{PC}$ fragment has a path-three feature, it is able to distinguish *ortho*-, *meta*-, and *para*-substitution patterns. Thus, in Fig. 3, the $^4\chi_{PC}$ index differentiates between the structures, thereby conveying information in numerical form.

Length of Ring Substituents—The effect on the numerical value of $^4\chi_{PC}$ is illustrated by two series of compounds, II, XX, and XXI and III, XXII, and XXIII. With the *ortho*-substitution series (II, XX, and XXI), lengthening the chain by one atom results in a consistent decrease in the $^4\chi_{PC}$ value. With the *meta*-substitution series (III, XXII, and XXIII), there is a decline in the $^4\chi_{PC}$ value beyond one bond length. Substituents with bond lengths of four or more are not distinguishable from those of three-bond length. On the other hand, a branched substituent such as an isopropyl group gives rise to additional $^4\chi_{PC}$ fragments and, hence, an increased numerical value of this index.

An interesting observation can be made about the $^4\chi_{PC}$ indexes and structures discussed in these two series. A ranking of these six compounds based on the extent of interaction between substituent groups is speculated as II, XX, XXI, XXIII, XXII, and III. This ranking closely parallels the decline in the value of their respective $^4\chi_{PC}$ indexes.

Heteroatom-Type Substituent—From Table I, it can be seen for XXIV–XXXVI that the $^4\chi_{PC}$ index is equivalent for all similarly substituted derivatives with the same number of bonds. Thus, XXIV, XXVII, and XXX have identical $^4\chi_{PC}$ indexes. The valence level index $^4\chi^v_{PC}$ must be employed to differentiate between substituents containing atoms of differing δ^v values; XXIV, XXVII, and XXX have different $^4\chi^v_{PC}$ indexes. The larger the δ^v for the heteroatom vertex in these molecules, the smaller is the numerical value of the $^4\chi^v_{PC}$ index.

The $^4\chi^v_{PC}$ index thus can add to the information encoded in the $^4\chi_{PC}$ index the presence of heteroatoms of various kinds in the substituent groups. In addition, the $^4\chi^v_{PC}$ index can distinguish between substituents

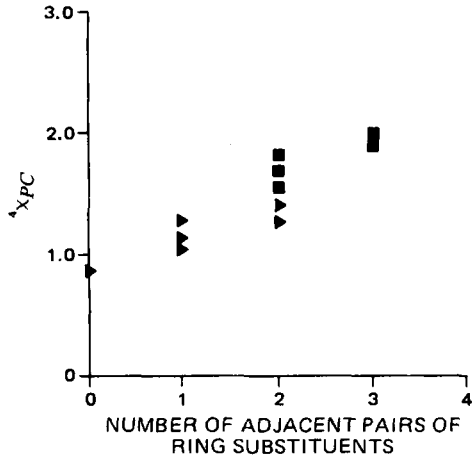

Figure 2—*Relationship of the $^4\chi_{PC}$ index to the number of adjacent pairs of ring substituents, showing the disubstituted (▲) and trisubstituted (●) phenalkylamines in Table I.*

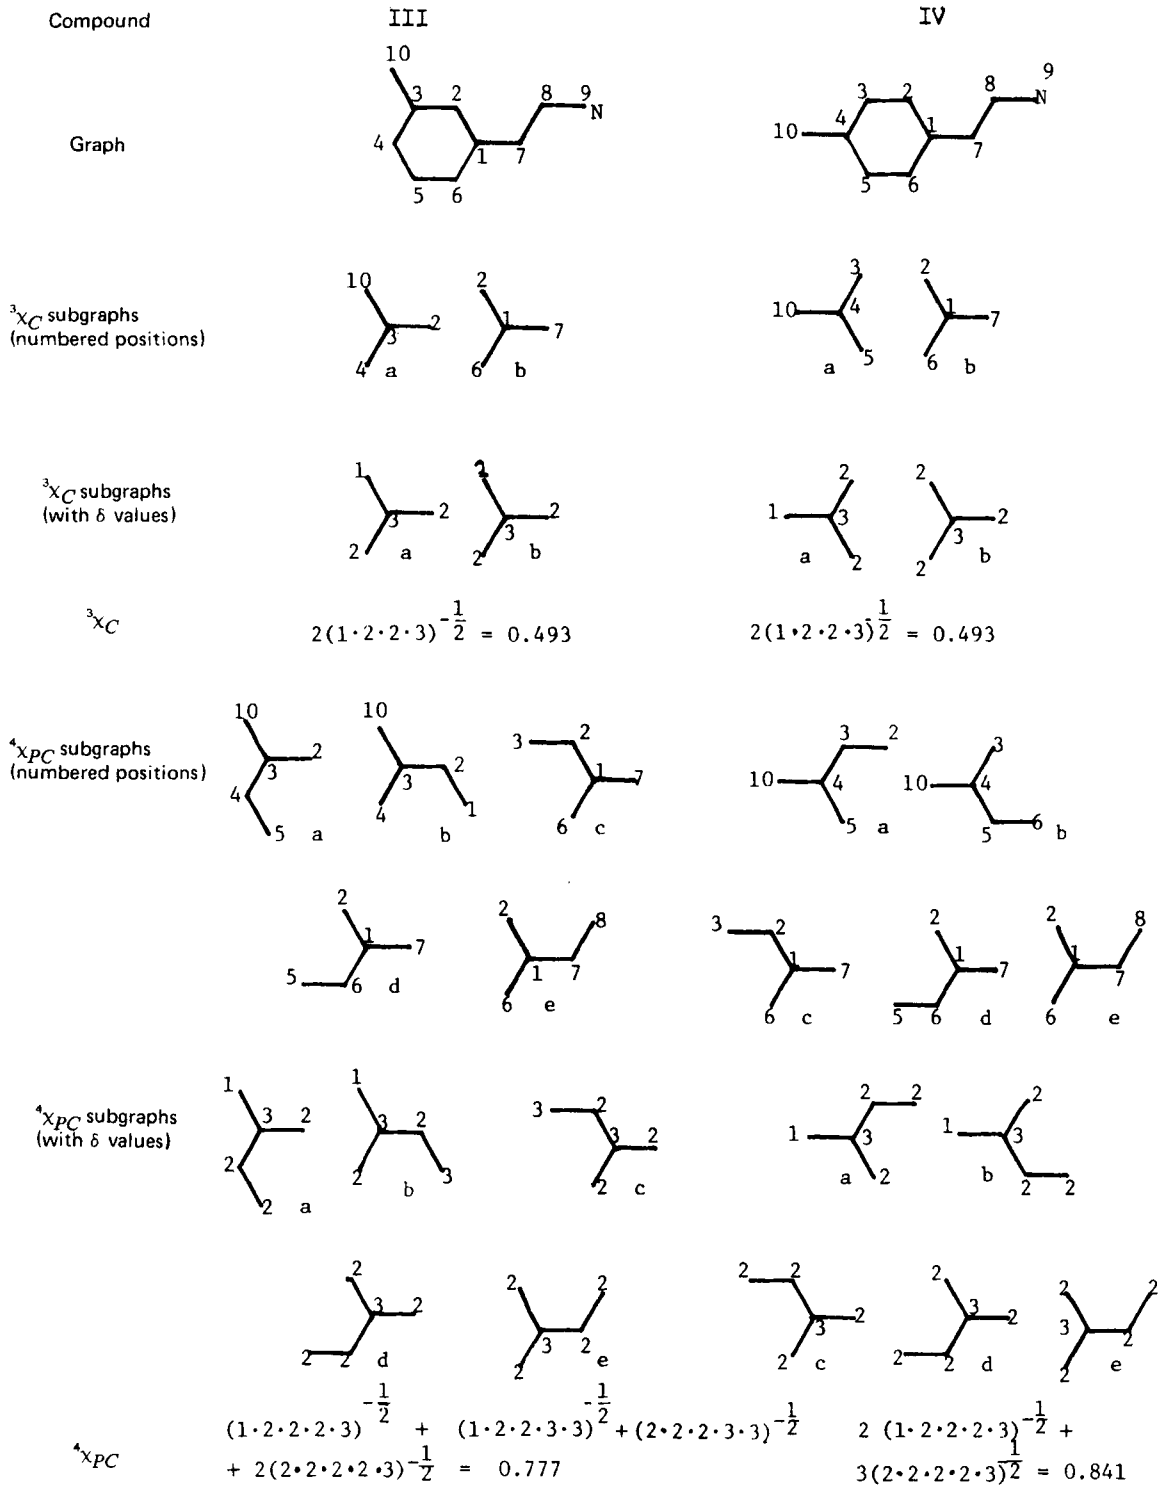

Figure 3—*Comparison of* $^3\chi_C$ *and* $^4\chi_{PC}$ *subgraphs for two molecules.*

containing the same heteroatoms but in different group positions (*e.g.*, XXXV and XXXVI).

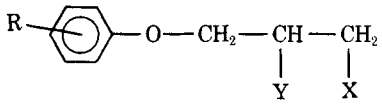
Examples of $^4\chi_{PC}$ Indexes in Structure–Activity Relationship Studies—*Propyl Phenyl Ethers*—The first reported use of $^4\chi_{PC}$ in a structure–activity relationship equation was a study on a series of substituted phenyl propyl ethers active against the fungus *Trichophyton mentagrophytes* (1). The same study later was employed in a detailed subgraph analysis (11).

These 28 molecules are related to log 1/*c* by:

$$\log(1/c) = 2.44\,{}^1\chi - 3.29\,{}^3\chi_P + 2.71\,{}^4\chi^v_{PC} - 1.31 \qquad \text{(Eq. 1)}$$

$$r = 0.957 \quad s = 0.149 \quad n = 28 \quad F = 87.4$$

The compounds in the study included mono-, di-, and tri-ring-substituted derivatives including methyl and chloro groups in varying numbers and ring positions.



X = H, OH Y = H, OH R = Cl, CH_3

The $^4\chi^v_{PC}$ index conveys the type of information described previously. The greater its magnitude, the greater is the calculated log 1/*c* value.

Table IV—Inhibition of *Aspergillus niger* by Substituted Benzyl Alcohols

Substituent	Observed log $1/c$[a]	Calculated log $1/c$
None	1.51	1.29
4-Chloro	2.07	1.93
2,4-Dichloro	3.07	2.61
3,4-Dichloro	3.07	2.66
2,4,5-Trichloro	3.32	3.34
3,4,5-Trichloro	3.63	3.35
2-Bromo	2.15	2.38
4-Bromo	2.27	2.32
4-Iodo	2.75	2.61
4-Methyl	1.79	1.83
2,4-Dimethyl	2.14	2.41
3,5-Dimethyl, 4-chloro	3.05	3.15
3,5-Dimethyl, 4-iodo	3.42	3.83
2-Nitro	2.49	2.13
4-Nitro	2.00	2.13
4-Cyano	1.67	1.83
2-Hydroxy	1.39	1.62
3-Hydroxy	1.39	1.54
4-Hydroxy	1.39	1.56

[a] From Ref. 13.

Thus, the $^4\chi^v_{PC}$ index indicates that multiple substitution of the ring, particularly in the *ortho*-position and in adjacent ring positions, enhances log $1/c$. Furthermore, the $^4\chi^v_{PC}$ index describes the favorable role of chlorine over methyl as the substituent.

Amphetamines—The $^4\chi^v_{PC}$ index emerged as one of three molecular connectivity indexes in a structure–activity relationship study of 23 ring-substituted amphetamines tested as hallucinogenic agents (8). The ring substituents were methoxy and methylenedioxy with a few alkyl groups and a bromo group.

The regression analysis presented the $^4\chi^v_{PC}$ index in reciprocal form:

$$\log MU = \frac{45.16}{^3\chi_P} + 1.29\,{}^6\chi_P - \frac{4.30}{^4\chi^v_{PC}} - 5.59 \qquad \text{(Eq. 2)}$$

$$r = 0.92 \quad s = 0.25 \quad n = 23 \quad F = 35$$

The $^4\chi^v_{PC}$ index describes the favorable role of substituent orientation, substituent length, and heteroatom presence.

Alkyl Benzenes—Molal solubility data are available for 13 alkylbenzenes (Table II). A two-index equation including the $^4\chi_{PC}$ index gives an excellent correlation with ln S:

$$\ln S = 0.782\,{}^0\chi^v - 0.344\,{}^4\chi_{PC} - 1.051 \qquad \text{(Eq. 3)}$$

$$r = 0.994 \quad s = 0.086 \quad n = 13 \quad F = 394$$

The calculated results in Table II reveal the role played by the $^4\chi_{PC}$ index, in concert with the $^0\chi^v$ index, in describing the various types and orientations of substituents on the benzene ring. The $^4\chi_{PC}$ index predicts the favorable influence of substituent branching on solubility. The influence on this physical property is revealed by the quality of the correlation with ln S.

Phenols—A series of heteroatom-substituted phenols are effective in the cytochrome P-450 conversion (12). These derivatives were subjected to molecular connectivity analysis (Table III). The 50% inhibitory concentration, pC, was found to be related to the two indexes by:

$$pC = 0.628\,{}^0\chi^v - 4.99\,{}^4\chi_{PC} - 1.81 \qquad \text{(Eq. 4)}$$

$$r = 0.971 \quad s = 0.161 \quad n = 13 \quad F = 82$$

The $^4\chi_{PC}$ index describes the number, orientation, and complexity of the substituents to the extent that it accounts for 94% of the variation in the data.

Benzyl Alcohols—A series of benzyl alcohol derivatives modified in the ring are known to inhibit *Aspergillus niger* (13). The molecular connectivity description reveals a correlation with $^1\chi^v$ and $^4\chi_{PC}$ accounting for 88% of the variance in the data:

Table V—Inhibition of *Mycobacterium tuberculosis* by Substituted Phenols

Substituent	Observed pC[a]	Calculated pC
None	0.95	1.02
4-Bromo	1.94	1.92
2-Methyl, 4-bromo	2.35	2.32
2-Ethyl, 4-bromo	2.70	2.70
2-Propyl, 4-bromo	3.18	3.10
2-Butyl, 4-bromo	3.76	3.49
2-Pentyl, 4-bromo	3.99	3.88
2-*sec*-Pentyl, 4-bromo	3.54	3.80
2-Hexyl, 4-bromo	4.26	4.27
2-Cyclohexyl, 4-bromo	3.75	3.88
2-Bromo	1.78	1.83
2-Bromo, 4-*tert*-pentyl	3.39	3.37
2-Bromo, 4-hexyl	4.11	4.20
2-Bromo, 4-propyl, 3,5-dimethyl	3.69	3.61

[a] From Ref. 14.

$$\log 1/c = 0.341\,{}^4\chi_{PC} + 0.979\,{}^1\chi^v - 1.404 \qquad \text{(Eq. 5)}$$

$$r = 0.940 \quad s = 0.268 \quad n = 19 \quad F = 61$$

The results (Table IV) reveal the role of $^4\chi_{PC}$ in describing the number and orientation of ring substituents.

Phenols—A series of alkyl bromophenols was reported as effective in inhibiting *Mycobacterium tuberculosis* (14). A molecular connectivity analysis reveals a high correlation with two variables, including the $^4\chi^v_{PC}$ index:

$$pC = 0.551\,{}^0\chi^v - 0.434\,{}^4\chi^v_{PC} - 1.052 \qquad \text{(Eq. 6)}$$

$$r = 0.992 \quad s = 0.134 \quad n = 14 \quad F = 357$$

The results in Table V show the role of the $^4\chi_{PC}$ index in describing structural information in the relationship.

Conclusion—Because of the structure of the molecular fragment described by $^4\chi_{PC}$, this index is ideally suited to quantifying structural features associated with ring substitution. The fragment may contain up to three consecutive phenyl ring bonds; as a consequence, *ortho-*, *meta-*, and *para*-substitution give rise to different terms, resulting in different $^4\chi_{PC}$ indexes in each case.

The structural information encoded in the $^4\chi_{PC}$ index should make it possible to interpret the structure–activity relationship from molecular connectivity descriptions when this index appears.

Synthesis of [8,9-$^2H_2$]Apomorphine and [1,3,8,9-$^2H_4$]Apomorphine for PMR, ^{13}C-NMR, and Mass Spectral Studies

WILLIAM H. SOINE *, JAMES E. HUDSON ‡, BEN A. SHOULDERS ‡, and ROBERT V. SMITH *x

Received March 23, 1979, from the **Drug Dynamics Institute, College of Pharmacy, and the* ‡*Department of Chemistry, University of Texas at Austin, Austin, TX 78712.* Accepted for publication June 6, 1979.

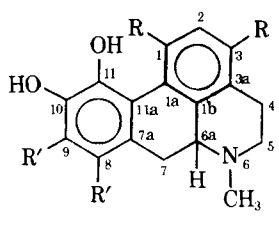
Abstract □ Methods are described for the preparation of [8,9-$^2H_2$]-apomorphine and [1,3,8,9-$^2H_4$]apomorphine based on reaction of apomorphine in trifluoroacetic acid-*d*. The mass spectral properties of these compounds and of the *O,O*-bis(heptafluorobutyrate) ester and the *O,O*-bis(trimethylsilyl) and *O,O*-bis(*tert*-butyldimethylsilyl) ethers of apomorphine, using electron impact and chemical ionization, are reported. [1,3,8,9-$^2H_4$]Apomorphine was used to elaborate the ^{13}C-NMR chemical shifts of the proton-bearing carbons of apomorphine.

Keyphrases □ Apomorphine—synthesis of deuterated analogs for PMR, ^{13}C-NMR, and mass spectral analyses □ Mass spectrometry—analysis, deuterated analogs of apomorphine □ NMR spectroscopy—analysis, deuterated analogs of apomorphine

There is a resurgence of interest in the aporphine alkaloid apomorphine (I) because of its utility in the treatment of Parkinson's disease (1–3), tardive dyskinesia (4), Huntington's chorea (5, 6), and schizophrenia (7). As part of ongoing studies of the mammalian metabolism of I (8–11), methods were desired for the preparation of its specifically deuterated analogs. The latter compounds were envisioned as being potentially useful in mass spectral assays of I and metabolites in biological fluids (12).

Early studies on the deuteration of I gave conflicting evidence on the site and extent of deuteration (13) or provided methodology requiring total synthesis of the aporphine skeleton (14). One report (13) suggested that deuterated analogs of I would not be suitable for use in a mass spectral assay due to proton scrambling during vaporization. Therefore, mass spectral studies were initiated with deuterated I to develop conditions suitable for use in biological assays.

During preliminary analysis, PMR analysis of I in trifluoroacetic acid-*d* showed facile exchange of the 8- and 9-protons with the deuterium ions from the solvent (15). The kinetics for the deuterium exchange of I were studied using PMR spectroscopy, and conditions were developed for the selective preparation of II and III using trifluoroacetic acid-*d*. The ester and silyl ether derivatives of I were used to study the electron-impact and chemical-ionization mass spectral characteristics of II and III for potential use as internal standards in qualitative and quantitative determinations of I. Finally, II was employed to analyze the ^{13}C-NMR spectrum of I.



I: R = R′ = H
II: R = R′ = D
III: R = H, R′ = D

RESULTS AND DISCUSSION

The deuteration of apomorphine (I) in trifluoroacetic acid-*d* was studied at various temperatures and in the presence of a transition metal catalyst (5% rhodium on aluminum oxide). Products with increasing deuterium substitution at the aromatic positions were isolated (Table I). PMR spectroscopy was used primarily to determine the sites of substitution, while the extent of incorporation was assessed through mass spectral and PMR analysis. When I was dissolved in trifluoroacetic acid-*d*, there was a collapse of the pair of doublets at δ 6.72 and 6.92 in the PMR spectrum, which is attributable to the exchange of the C-8 and C-9 protons, respectively. Careful analysis of this exchange in excess trifluoroacetic acid-*d* showed that it followed first-order kinetics (Fig. 1) and that C-8 H exchanged significantly faster ($t_{1/2}$ 69.4 min) than C-9 H ($t_{1/2}$ 115 min). This later observation may reflect differences in the resonance stabilization of cationic transition-state intermediates at C-8 and C-9 and correlates with previous work on the bromination of apomorphine dimethyl ether (16).

The protonated amine of apomorphine hydrochloride also underwent exchange in trifluoroacetic acid-*d* as expected. However, it was surprising that the exchange of the amine proton was more than one order of magnitude slower (k = 0.0325 hr^{-1}, r = 0.996, a = 87%, $t_{1/2}$ = 21.3 hr) than the exchange of the aromatic protons at C-8 and C-9.

In contrast to the C-8 and C-9 protons, the exchange of the C-1 and C-3 protons for deuterium in trifluoroacetic acid-*d* was relatively slow at room temperature. With PMR spectroscopy, it appeared that no more than a 15% exchange occurred at C-1 and C-3 in excess trifluoroacetic acid-*d*, even after 216 hr. Elevated temperatures were required to prepare a product significantly enriched in II, and no improvement in incorporation was observed with a rhodium catalyst (Table I). The exchange of the C-1 and C-3 protons for deuterium was observed through loss of the doublets at δ 8.15 and 7.11, respectively. These changes were accompanied by an expected collapse of the triplet observed for C-2 H at δ 7.31 into a singlet integrating for one proton.

The noted assignments parallel those made by Ginos *et al.* (13) for I and II in dimethyl sulfoxide-d_6. These investigators studied the deuteration of apomorphine in 85% D_3PO_4 (in deuterium oxide) and found that II was formed after heating at 95° for several hours or at 140° for 30 min. Convincing PMR evidence was provided for the purity and assign-

Table I—Deuteration of Apomorphine

Deuterated Analog of I	Percent Formation under Various Conditions[a]				
	A	B	C	D	E
d_0	—	—	—	1	—
d_1	10	11	4	6	1
d_2	83	85	19	22	7
d_3	7	2	41	35	32
d_4	—	2	30	29	44
d_5	—	—	6	6	16

I *tert*-butyldimethylsilyl ether[d]	EI	100–530	322	495 (4)	0.3	438 (15)

[a] Essentially identical results were obtained when methane or isobutane was used as the ionizing gas. All other chemical-ionization determinations were made with methane. [b] *O,O*-Bis(heptafluorobutyrate) ester. [c] *O,O*-Bis(trimethylsilyl) ether. [d] *O,O*-Bis(*tert*-butyldimethylsilyl) ether.

ment of deuterium atoms in II. However, mass spectral examination of this product proved to be somewhat anomalous; the mass spectrum indicated that ~55% of the aromatic protons had been exchanged for deuterium (d_0, 23; d_1, 0; d_2, 11; d_3, 19; d_4, 41; and d_5, 6), while the PMR spectrum indicated that 80% of the aromatic protons had been exchanged. The relatively high proportion of undeuterated product shown by the mass spectrum was attributed to the exchange between the proton from hydrogen chloride and the deuterium atoms on the aromatic rings (II was analyzed as its hydrochloride salt) during vaporization in the mass spectrometer. The PMR determinations of II and III performed during the present studies were in agreement (within ±4%) with the compositions estimated by mass spectral analysis (Table I).

The exchanges of the C-1 and C-3 protons in trifluoroacetic acid-*d* were facile compared to the exchange of C-2 H. Indeed, no exchange of C-2 H could be detected when I was treated with trifluoroacetic acid-*d* (Table I) or allowed to stand in trifluoroacetic acid-*d* for 9 days at 25°. The ease of exchange of C-1 and C-3 H relative to C-2 H probably results from the influence of the 11-hydroxyl group, which causes resonance stabilization of the developing positive charges at C-1 and C-3. In contrast, a resonance interaction of the 10-oxygen atom across both rings is prevented because of its *meta*-relationship to the A-ring. Furthermore, the 10-hydroxyl group of I may be protonated preferentially in trifluoroacetic acid, which could have important implications for selective *O*-acylations of I in this solvent (17).

Since II and III are proposed for use in biological disposition studies, indication of their stability (with respect to the deuterium–hydrogen exchange) in aqueous media was desired. To determine if the aromatic protons of I at C-8 and C-9 would exchange under mildly acidic conditions, ~60 μmoles of I·HCl was dissolved in 1 ml of 0.02 and 0.3 *M* ascorbic acid (to prevent oxidation of I) prepared in deuterium oxide (pH 2.92 and 2.28, respectively) and stored in screw-capped test tubes at room temperature for 14 days. No incorporation of deuterium was detected after this treatment following GLC–mass spectral analysis of the isolated product as its bis(trimethylsilyl) ether derivative.

The use of II and III as GLC–mass spectral internal standards in metabolic studies requires derivatization to improve volatility and prevent thermal decomposition. Furthermore, the production of suitable (high molecular weight) fragment or parent ions that retain the deuterium label is desired, and these ions should be formed in sufficient amounts (*i.e.*, they should represent a significant proportion of the total ionization current) to permit sensitive detection. Previous work with I (18, 19) indicated that the *O,O*-bis(trimethylsilyl) ether and the *O,O*-bis(heptafluorobutyrate) ester derivatives are readily formed quantitatively and may be applicable to GLC–mass spectral determinations. Compounds converted to *tert*-butyldimethylsilyl ethers frequently form intense ions at high *m/e* values due to loss of a *tert*-butyl radical (M − 57) using electron-impact (EI) conditions, and this derivative was evaluated as well. The electron-impact and chemical-ionization (CI) mass spectral characteristics of I–III and their derivatives are presented in Table II.

A common fragment ion observed in the electron-impact mass spectrum of aporphines is an $[M-1]^+$ species, which is due to loss of the 6a-proton. As indicated in Table II, I and its derivatives, except for apomorphine *O,O*-bis(*tert*-butyldimethylsilyl) ether, give rise to a

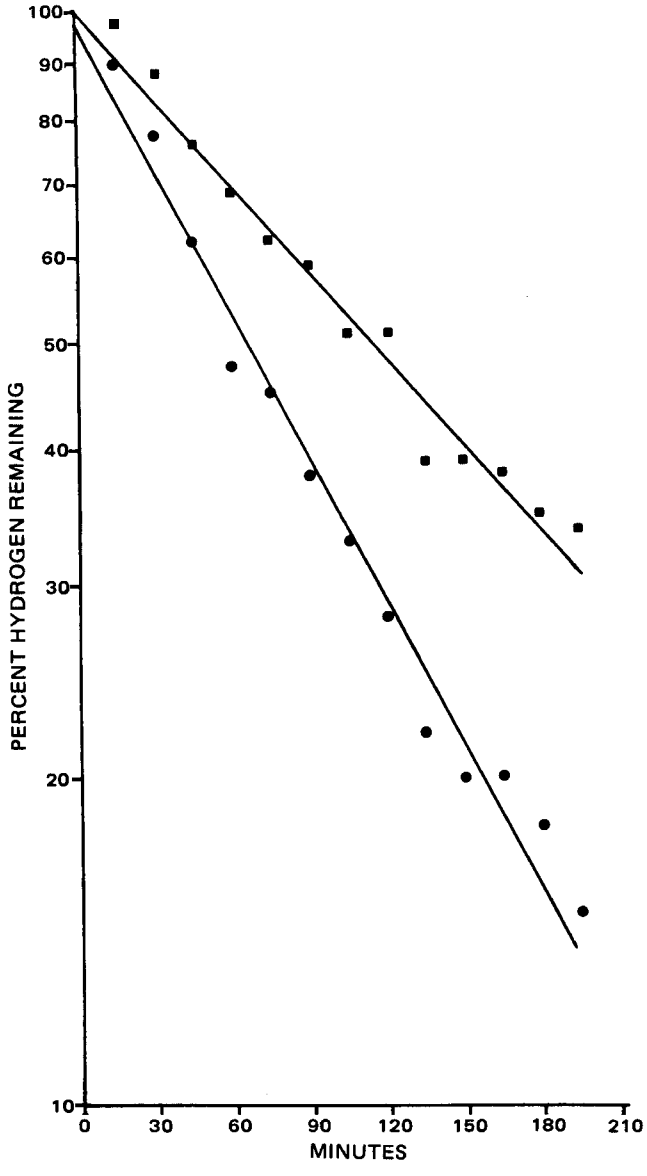

Figure 1—*Kinetics of exchange of C-8 H* (●) (k = *0.60 hr*$^{-1}$, r = *0.992*, a = *97.0%*, $t_{1/2}$ = *69.4 min*) *and C-9 H* (■) (k = *0.36 hr*$^{-1}$, r = *0.989*, a = *101.0%*, $t_{1/2}$ = *114.6 min*) *of apomorphine in trifluoroacetic acid-d at 25°.*

Table III—^{13}C-NMR Spectral Characteristics of Apomorphine in Trifluoroacetic Acid

Carbon	Chemical Shift, δ	Integrated Area[a]

[a] From broad-band decoupled spectrum. [b] Not sufficiently resolved from C-1b for accurate area measurement. [c] Peak height significantly less than that of quaternary carbons. [d] Not sufficiently resolved from C-2 for accurate area measurement. [e] Not sufficiently resolved from C-11a for accurate area measurement. [f] Not sufficiently resolved from C-8 for accurate area measurement. [g] Peak height significantly greater than aromatic carbons bearing hydrogens.

prominent $[M - 1]^+$ peak. The bis(heptafluorobutyrate) derivative of I under electron-impact conditions gave a moderate parent ion (*m/e* 659) in addition to extensive formation of the imine fragment (*m/e* 658). However, a drawback in using the heptafluorobutyrate derivative is the possibility of exchange of the deuterium atoms at C-8 and C-9 due to small quantities of heptafluorobutyric acid present during derivatization (19).

The electron-impact mass spectrum of the *O,O*-bis(trimethylsilyl) ether of I showed a parent ion that was 75% of the base peak and accounted for 3% of the total ion current. A strong fragment ion was observed at *m/e* 322 for apomorphine as its trimethylsilyl derivative, and corresponding ions at *m/e* 326 and 324 were noted for the same derivative of II and III, respectively. However, in all of these cases, the fragment-ion peaks represented <10% of the total ion currents.

When I was treated with excess *tert*-butyldimethylimidazole, it formed a diether derivative, as evidenced by a parent peak at *m/e* 495. The formation of this derivative was somewhat unexpected since there is significant steric crowding in the resulting derivatized catechol. As anticipated, the parent ion was rather weak in the electron-impact mass spectrum of I as its *tert*-butyldimethylsilyl ether derivative, but there was a fragment ion of moderate intensity at *m/e* 438 ($[M - 57]^+$), which probably arose due to the loss of a *tert*-butyl radical (20). This fragment ion was 15% of the base peak but accounted for only 1% of the total ionization current. A second fragment ion at *m/e* 322 served as the base peak but represented only 6% of the total ionization current. The intensity of these ions may have been enhanced by the use of lower ionization potentials; however, the use of the *tert*-butyldimethylsilyl derivative in GLC–mass spectral work is complicated by its GLC characteristics. Even on a short column (50 cm, 3% methylphenylsiloxane; see *Experimental*), this derivative has long retention times (*e.g.*, 44 min at 210° with a carrier flow rate of 20 ml/min).

Since none of the derivatives had the desired characteristics for quantitative GLC–mass spectral work employing electron-impact conditions, chemical-ionization mass spectrometry was evaluated. The chemical-ionization mode has two advantages over electron-impact spectra. First, it usually is more sensitive than the electron-impact mode. In a typical electron-impact spectrum, the base peak may account for only 20% or less of the total ion current, while many chemical-ionization spectra display base peaks representing as much as 70–80% of the total ion current. Apomorphine proved to be no exception. With the electron-impact mode, the base peak for I was at *m/e* 266 ($[M - 1]^+$) and was 22% of the total ion current; with chemical-ionization mass spectrometry (isobutane), the base peak at *m/e* 268 ($[M + 1]^+$) was 59% of the total ion current.

A second advantage to the chemical-ionization mode is that it often gives a strong pseudoparent ion ($[M + 1]^+$), which may, because of its high molecular weight, be less likely to suffer interference from other components of biological extracts. Apomorphine and its dideuterated analog, III, gave intense pseudoparent ions at *m/e* 268 and 270, respectively, which were the base peaks in both cases. Even when isobutane was used, M^+ and $[M - 1]^+$ ions at *m/e* 266 and 267, respectively, were observed in the chemical-ionization mass spectrum of I. These ions were in approximately the same relative proportion to one another as seen in the electron-impact mass spectrum of I. It has been observed, especially with tertiary amines using methane as the reactant gas, that the amine can undergo electron transfer with one of the reactant ions, giving an M^+ ion (21, 22). This transfer apparently occurs with I. A similar observation was made with glaucine, a related aporphine (23). This observation restricts the use of underivatized I for qualitative work because the noted phenomenon could lead to errors in quantitative determinations.

Of the three derivatives studied, the trimethylsilyl ethers were the most suitable for GLC–mass spectral work. With methane as the GLC carrier gas and the chemical-ionization reactant gas, the chemical-ionization mass spectrum of the trimethylsilyl ethers of I, II, and III showed base peaks at *m/e* 412, 416, and 414, respectively; the ions accounted for 25–32% of the total ion currents for these compounds. However, as was seen with underivatized I, the trimethylsilyl ethers underwent electron transfer with the reactant ions, giving appropriate M^+ and $[M - 1]^+$ ions (*m/e* 411 and 410 for I as its trimethylsilyl derivative) that were quite intense (59 and 29% of the base peak, respectively, for the trimethylsilyl derivative of I). In addition, there appeared to be significant hydrogen abstraction, most likely of the 6a-proton. This phenomenon is observed with tertiary amines in which the hydride loss is enhanced by referring the charge to an adjacent nitrogen atom (22, 24), and it makes the pseudoparent ions of the trimethylsilyl ethers of I–III less desirable for selective-ion monitoring. Fortunately, there are strong and clean fragment ions for the aporphines as their trimethylsilyl derivatives at *m/e* 396 (I), 400 (II), and 398 (III) which account for ~15% of the total ion current in each case. These ion fragments probably occur through the loss of methane from pseudoparent ions, probably from the trimethylsilyl groups. In conclusion, it appears that II and III can function as internal standards for I if chemical-ionization mass spectrometry is used and the noted fragment ions of their trimethylsilyl derivatives are monitored.

The availability of II presented an opportunity to elaborate chemical shifts of the proton-bearing carbons of I. By use of broad-band decoupling, off-resonance white noise decoupling, and selective-proton decoupling, the ^{13}C-NMR data listed in Table III were compiled.

The broad-band decoupling spectrum of I contained only 16 lines; however, the signal at δ 130.8 integrated for two carbons. The off-resonance white noise decoupling spectrum indicated that the signals at δ 144.8, 143.7, 133.5, 130.8, 128.9, 127.5, and 122.1 were nonprotonated carbons. Chemical shifts assigned to aliphatic carbons in I (Table III) were deduced from data reported previously for similar aporphines (25, 26). The ^{13}C-NMR spectrum of II had a single aryl CH signal at δ 129.2.

The use of selective-proton decoupling of the aromatic protons in trifluoroacetic acid presented some problems. Irradiation (0.3 w) at δ H 7.31 to enhance C-2 and δ H 7.11 to enhance C-3 caused enhancement of all of the protonated aromatic carbon signals. In contrast, irradiation at δ H 8.15 to enhance C-1 caused collapse of all of the protonated aromatic carbon signals represented by lines integrating for one carbon; this effect was especially noticeable for the signal at δ 129.7. However, during this experiment, the signal at δ 130.8 (which integrates for two carbons) still integrated for two carbons, indicating that the protonated carbon resonating at δ 130.8 is C-1. By default, the carbon signal at δ 129.7 corresponds to C-3.

Assignment of the carbon signals for C-8–C-11 are based on reported assignments in similar aporphines (25, 26). The carbon assignments for nuciferine and isocorydine suggest that C-11a (*ortho* to phenol) should be the farthest upfield while C-3a should be the farthest downfield of the signals possible for these nuclei. The remaining nonprotonated carbons are provided with proposed assignments (Table III) based on the chemical shifts suggested for analogous carbons in isocorydine (25).

An unusual observation was made with respect to carbon resonance intensities when trifluoroacetic acid was used as the solvent. All of the nonprotonated aromatic carbons possessed intensities greater than or equal to those of the protonated aromatic carbons (during broad-band decoupling); the opposite usually is true because of nuclear Overhauser enhancement. This observation may have general applicability in differentiating nonprotonated from protonated carbons and is under further investigation in these laboratories.

EXPERIMENTAL

Reagents—(*R*)-(−)-Apomorphine hydrochloride hemihydrate was used as purchased[1]. Trifluoroacetic acid-*d* was generated from trifluo-

[1] McFarland Smith Ltd., Edinburgh, Scotland.

roacetic anhydride[2] with deuterium oxide[3] (99.7 atom % D). All other solvents and reagents were analytical reagent grade.

Mass Spectral and GLC–Mass Spectral Studies—Mass spectra were determined in the electron-impact and chemical-ionization modes using an automated GLC–mass spectrometric[4] system consisting of a microprocessor-controlled gas chromatograph coupled (all glass jet separator) to a quadrapole mass spectrometer and data system. Mass spectra of I–III (free base and hydrochloride salts) were obtained by introduction of the sample on a solid probe programmed from 100 to 300° (30°/min). GLC–mass spectral determinations were implemented with a U-shaped glass column (50 cm × 2 mm i.d.) packed with 3% methyl phenyl siloxane on a specially treated silaceous support[5] (100–120 mesh).

Helium (20 ml/min) was the carrier gas in all electron-impact studies; methane was the carrier gas (20 ml/min) in most chemical-ionization work. GLC–mass spectral analyses were carried out with a column temperature of 180–220°. The mass spectrometer was operated with an electron energy of 70 ev, an emission current of 350 μamp, an ion source temperature of 220°, and a scan rate of 30 scans/min from *m/e* 50 or 100 to 700. The final spectrum of each compound was an averaged sum of 10 or more spectra with the average background subtracted.

Trimethylsilyl derivatives were prepared by dissolving ~1 mg of I, II, or III in 100 μl of *N,O*-bis(trimethylsilyl)acetamide and heating at 65° for 30 min. The *tert*-butyldimethylsilyl derivative of I was prepared by reaction of ~1 mg of I·HCl with 200 μl of *tert*-butyldimethylsilylimidazole reagent[6] at 65° for 1 hr. Apomorphine *O,O*-bis(heptafluorobutyrate) was formed by a method reported previously (18).

NMR Studies—PMR and kinetic studies were performed with a 100-MHz[7] instrument, and chemical shifts are reported relative to tetramethylsilane. The rates of deuterium exchange were determined through analyses of integrated areas for C-8 and C-9 H relative to C-2 H in apomorphine hydrochloride. When I·HCl was reacted for 9 days at 25° in trifluoroacetic acid-*d* (containing 2 mg of dithionite/ml to prevent oxidation of I), the integrated area for C-2 H relative to the aliphatic protons remained constant within experimental error.

^{13}C-NMR spectra were obtained with a 90-MHz Fourier transform system[8], and chemical shifts are reported relative to tetramethylsilane. Solutions containing 200 mg of I·HCl/ml of trifluoroacetic acid and 75 mg of II·HCl/ml of trifluoroacetic acid-*d* were analyzed with an external deuterium oxide capillary for locking. For selective-proton decoupling experiments, approximate proton chemical shifts relative to carbon resonances were determined from analysis of acetone-d_6 solutions of I·HCl. The sample for ^{13}C-NMR analysis then was irradiated at the appropriate chemical shift with the source set at 0.3 w.

[1,3,8,9-$^2H_4$]Apomorphine (II)—(*R*)-(−)-Apomorphine hydrochloride hemihydrate (400 mg, 1.2 mmoles) was dissolved in trifluoroacetic acid-*d* (5 ml, 67.3 mmoles) in a silylated 16 × 100-mm polytef-lined screw-capped culture tube and placed in a pipe bomb at 140° for 96 hr. The trifluoroacetic acid-*d* was removed under a nitrogen stream, leaving a pale-brown oil. The oil was treated with a saturated solution of sodium bicarbonate, and the mixture was extracted with ether (4 × 5 ml). The ether was removed under reduced pressure, and the residue was redissolved in dry ether (15 ml). The hydrochloride salt, obtained by bubbling hydrogen chloride through the ether solution, was filtered and dried under vacuum to give 88 mg (44% of theoretical yield) of pale-green powder. Recrystallization from methanol–acetone gave off-white to pale-green crystals.

Purity was >99% as determined by UV spectrophotometry using spectral comparisons and absorbance values at 273 nm from authentic I·HCl [λ_{max} (water) 273 nm, ϵ = 17,300]. The GLC retention time of II as its heptafluorobutyrate derivative was identical to that obtained from similarly derivatized I. The parent peak of II as the free base was at *m/e* 271 ($C_{17}H_{13}D_4NO_2$) with a base peak at *m/e* 270 ($C_{17}H_{12}D_4NO_2$) and a retro-Diels–Alder peak at *m/e* 228 ($C_{15}H_8D_4O_2$). PMR analysis (trifluoroacetic acid-*d*) showed a signal at δ 7.42 (s, C-2 H) and residual signals at δ 8.24 and 7.20 from I-d_3 (Table I).

[8,9-$^2H_2$]Apomorphine (III)—(*R*)-(−)-Apomorphine hydrochloride hemihydrate (200 mg, 0.66 mmole) was dissolved in trifluoroacetic acid-*d* (5 ml, 67.3 mmoles) and kept in the dark at room temperature for 72 hr. The workup was the same as that described for II and gave 140 mg (70% of theoretical yield) of III·HCl as an off-white to pale-green powder. Purity was >99% as determined by UV spectrophotometry, and the GLC retention time of the heptafluorobutyrate derivative of III was identical to that of the corresponding derivative of I. The parent peak of III as the free base was at *m/e* 269 ($C_{17}H_{15}D_2NO_2$), the base peak was at *m/e* 268 ($C_{17}H_{14}D_2NO_2$), and the retro-Diels–Alder peak was at *m/e* 226 ($C_{15}H_{10}D_2O_2$); PMR (trifluoroacetic acid-*d*): δ 8.24 (d, 1H, *J* = 8.0, C-1 H), 7.42 (t, 1H, *J* = 8.0, C-2 H), 7.20 (d, 1H, *J* = 8.0, C-3 H), 6.96 (s, C-9 H, due to the presence of a trace amount of C-8 $^2H_1$), and 6.83 (s, C-8 H, due to the presence of a trace amount of C-9 $^2H_1$) (Table I).

Use of Rhodium Catalyst—Reactions were performed as indicated except that 50 mg of 5% rhodium on aluminum oxide[9] was added and the reaction mixtures were agitated for the times indicated. Workup procedures were identical to those outlined.

Antitumor Agents XXXVI: Structural Elucidation of Sesquiterpene Lactones Microhelenins-A, B, and C, Microlenin Acetate, and Plenolin from *Helenium microcephalum*

YASUHIRO IMAKURA *, KUO-HSIUNG LEE *x, DONALD SIMS *, RONG-YANG WU *, IRIS H. HALL *, HIROSHI FURUKAWA ‡, MASATAKA ITOIGAWA ‡, and KAZUE YONAHA ‡

Received December 26, 1978, from the **Department of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514*, and the ‡*Faculty of Pharmacy, Meijo University, Tempaku, Nagoya, Japan.* Accepted for publication April 6, 1979.

Abstract □ The antitumor sesquiterpene lactones microhelenins-A, B, and C, microlenin acetate, and plenolin were isolated from *Helenium microcephalum*. The structures and stereochemistry of these lactones were determined by physical methods as well as by chemical transformations and correlations. Microlenin acetate appears to be the first novel dimeric sesquiterpene lactone demonstrated to have significant antileukemic activity.

Keyphrases □ Antitumor agents—microhelenins, microlenin acetate, and plenolin, isolation from *Helenium microcephalum*, determination of structure and stereochemistry □ Microhelenins—isolation from *Helenium microcephalum*, determination of structure and stereochemistry □ Sesquiterpene lactones—microhelenins, microlenin acetate, and plenolin, isolation from *Helenium microcephalum*, determination of structure and stereochemistry

Search for an ample supply of helenalin for investigation into the relationship between the structure of sesquiterpene lactones and their cytotoxic antitumor activity led to the use of the plant *Helenium microcephalum*[1] (1). Preexamination of the whole plant extract revealed that the removal of helenalin left a mother liquor, which retained significant inhibitory activity against Walker 256 carcinosarcoma in rats and P-388 lymphocytic leukemia in mice. Further work with the chloroform extract resulted in the isolation[2] and structural determination of the new antitumor agents microhelenins-A (I) (2), B (VI) (3), C (VIII) (3), and D (mexicanin-E, XIV) (3) and microlenin[3] (4, 5), which were described in preliminary reports.

The purpose of this paper is to describe fully the isolation and structural elucidation of microhelenins-A, B, and C, the new dimeric antileukemic agent microlenin acetate[3] (X), and the companion pseudoguaianolide plenolin (VII) (7).

RESULTS AND DISCUSSION

The final chloroform extract of the whole plant of *H. microcephalum* was chromatographed on silica gel using chloroform and chloroform–ethyl acetate (9:1) as the eluents. The initial chloroform eluate afforded a gum of several components. Further silica gel column chromatography and preparative TLC of this mixture led to the isolation of microhelenins-A, B, C, and D. Subsequent elution with chloroform–ethyl acetate (9:1) gave plenolin and microlenin as well as helenalin. Microlenin acetate was isolated from the mother liquor after the removal of helenalin.

Microhelenin-A (I)—Microhelenin-A (I), $C_{15}H_{18}O_4$ (high-resolution mass spectral and elemental analyses), mp 140–141°, $[\alpha]_D^{24}$ +89.0°, showed the partial structure A, with the lactone ring closed at C-7 and C-8 and the methylene group of CH_2OCH attached at C-5 on the basis of IR and NMR (Table I) evidence as reported previously (2).

The circular dichroism and optical rotatory dispersion data of microhelenin-A are listed in Table II together with data for 2,3-dihydrohelenalin (II) (8), whose absolute configuration has been established. Similarities in the sign and magnitude of ketone Cotton effects indicated that I possessed the same *trans*-fused cyclopentanone ring system (C-1α, C-5β-CH_2O) as II. Determination of the *cis*-stereochemistry of the γ-lactone ring in I was based on the generalization that *cis*-fused lactones closed toward C-8, exhibiting a positive lactone Cotton effect, as exemplified by II (9, 10). In addition, Samek's rule (11) ($J_{7,13}$ *trans*-lactone $\geq 3 \geq J_{7,13}$ *cis*-lactone), which generally has been applicable to guaianolides, also indicated that I contains a *cis*-fused lactone since $J_{7,13e}$ = 2.5–3.0 and $J_{7,13f}$ = 2.0–3.0[4]. This evidence led to postulation of possible conformations of the seven-membered ring of I (C and D).

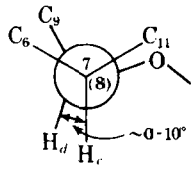
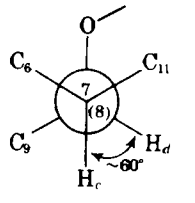
D: chair



E: boat



F: half-chair

[1] The constituents of *H. microcephalum* were examined previously and reported to contain helenalin in good yield (1).

[2] Helenalin also was isolated from this chloroform extract.

[3] Microhelenins-A, B, C, and D and microlenin showed significant (T/C ≥ 125%) inhibitory activity against Walker 256 carcinosarcoma in rats at T/C = 148, 138, 159, 144, and 172% at 2.5 mg/kg, respectively. Microlenin and microlenin acetate demonstrated significant (T/C ≥ 120%) inhibitory activity against P-388 lymphocytic leukemia in mice at T/C = 167 and 147% at 12.5 mg/kg, respectively, according to a literature method (6). Plenolin showed T/C = 138% at 25 mg/kg in the P-388 screen.

[4] The coupling constants of $J_{7,13}$ were changed by the conditions of the NMR instrument (XL-100), as shown in the data.

Microlenin acetate appears to be the first novel dimeric sesquiterpene lactone demonstrated to have significant antileukemic activity.

Keyphrases □ Antitumor agents—microhelenins, microlenin acetate, and plenolin, isolation from *Helenium microcephalum*, determination of structure and stereochemistry □ Microhelenins—isolation from *Helenium microcephalum*, determination of structure and stereochemistry □ Sesquiterpene lactones—microhelenins, microlenin acetate, and plenolin, isolation from *Helenium microcephalum*, determination of structure and stereochemistry

Search for an ample supply of helenalin for investigation into the relationship between the structure of sesquiterpene lactones and their cytotoxic antitumor activity led to the use of the plant *Helenium microcephalum*[1] (1). Preexamination of the whole plant extract revealed that the removal of helenalin left a mother liquor, which retained significant inhibitory activity against Walker 256 carcinosarcoma in rats and P-388 lymphocytic leukemia in mice. Further work with the chloroform extract resulted in the isolation[2] and structural determination of the new antitumor agents microhelenins-A (I) (2), B (VI) (3), C (VIII) (3), and D (mexicanin-E, XIV) (3) and microlenin[3] (4, 5), which were described in preliminary reports.

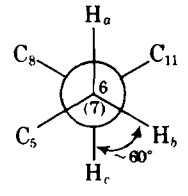
The purpose of this paper is to describe fully the isolation and structural elucidation of microhelenins-A, B, and C, the new dimeric antileukemic agent microlenin acetate[3] (X), and the companion pseudoguaianolide plenolin (VII) (7).

RESULTS AND DISCUSSION

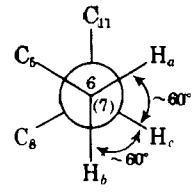
The final chloroform extract of the whole plant of *H. microcephalum* was chromatographed on silica gel using chloroform and chloroform–ethyl acetate (9:1) as the eluents. The initial chloroform eluate afforded a gum of several components. Further silica gel column chromatography and preparative TLC of this mixture led to the isolation of microhelenins-A, B, C, and D. Subsequent elution with chloroform–ethyl acetate (9:1) gave plenolin and microlenin as well as helenalin. Microlenin acetate was isolated from the mother liquor after the removal of helenalin.

Microhelenin-A (I)—Microhelenin-A (I), $C_{15}H_{18}O_4$ (high-resolution mass spectral and elemental analyses), mp 140–141°, $[\alpha]_D^{24}$ +89.0°, showed the partial structure A, with the lactone ring closed at C-7 and C-8 and the methylene group of CH_2OCH attached at C-5 on the basis of IR and NMR (Table I) evidence as reported previously (2).

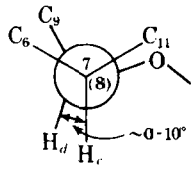
The circular dichroism and optical rotatory dispersion data of microhelenin-A are listed in Table II together with data for 2,3-dihydrohelenalin (II) (8), whose absolute configuration has been established. Similarities in the sign and magnitude of ketone Cotton effects indicated that I possessed the same *trans*-fused cyclopentanone ring system (C-1α, C-5β-CH_2O) as II. Determination of the *cis*-stereochemistry of the γ-lactone ring in I was based on the generalization that *cis*-fused lactones closed toward C-8, exhibiting a positive lactone Cotton effect, as exemplified by II (9, 10). In addition, Samek's rule (11) ($J_{7,13}$ *trans*-lactone $\geq 3 \geq J_{7,13}$ *cis*-lactone), which generally has been applicable to guaianolides, also indicated that I contains a *cis*-fused lactone since $J_{7,13e}$ = 2.5–3.0 and $J_{7,13f}$ = 2.0–3.0[4]. This evidence led to postulation of possible conformations of the seven-membered ring of I (C and D).



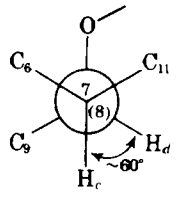
C: boat and half-chair



D: chair



E: boat



F: half-chair

[1] The constituents of *H. microcephalum* were examined previously and reported to contain helenalin in good yield (1).

[2] Helenalin also was isolated from this chloroform extract.

[3] Microhelenins-A, B, C, and D and microlenin showed significant (T/C ≥ 125%) inhibitory activity against Walker 256 carcinosarcoma in rats at T/C = 148, 138, 159, 144, and 172% at 2.5 mg/kg, respectively. Microlenin and microlenin acetate demonstrated significant (T/C ≥ 120%) inhibitory activity against P-388 lymphocytic leukemia in mice at T/C = 167 and 147% at 12.5 mg/kg, respectively, according to a literature method (6). Plenolin showed T/C = 138% at 25 mg/kg in the P-388 screen.

[4] The coupling constants of $J_{7,13}$ were changed by the conditions of the NMR instrument (XL-100), as shown in the data.

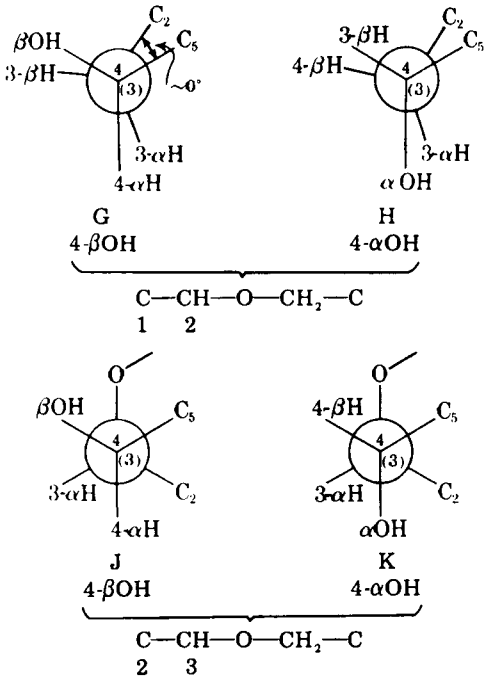
Table I—Decoupling Experiment Data for IX*b* in PMR Spectrum[a]

Changed Signal Position	Irradiation Position: C-11 CH_3 (δ 1.47)	H-7 (δ 2.74)	H-11 (δ 2.74)	H-8 (δ 4.71)	H-6 (δ 5.38)
C-11 CH_3			d, J = 7.5 ↓ s		
H-7			br dd, J = 6.0 and 10.0 ↓ d, $J_{7,8}$ = 6.0	br dd, J = 6.0 and 10.0 ↓ d, $J_{7,11}$ = 10.0	br dd, J = 6.0 and 10.0 ↓ sharp dd, and J = 6.0 and 10.0
H-11	dq, J = 7.5 and 11.0 ↓ d, $J_{7,11}$ = 10.0	dq, J = 7.5 and 11.0 ↓ d, $J_{11,13}$ = 7.5			
H-8		br t ↓ m			
H-6		br s, $W_{1/2}$ = 2.5 ↓ sharp s			

[a] Values are expressed in parts per million. Multiplicities are indicated by the usual symbols: d, doublet; m, multiplet whose center is given; br s, broad singlet; br t, broad triplet; dd, doublet of doublets; and dq, doublet of quartets. The values are in Hertz. Measurements were recorded with a 100-MHz instrument and were taken in deuterochloroform.



The conformation of the seven-membered ring was determined by a series of INDOR[5] experiments. The magnitude of $J_{6,7}$ determined the relative configuration at C-6 (H_a) and C-7 (H_c); hence, if the configuration of H_c were established as α, then the configurations for H_a and H_b at C-6 would be known accordingly. When the quartet lines of H_a (δ 1.67) were monitored, they gave the INDOR signals arising from H_b at $\delta \sim$ 2.30–2.50 (2). The J values observed between H_a and H_c (J = 13.0 Hz) clearly indicated a diaxial relationship between H_a and H_c, and the value between H_b and H_c (J = 3.0 Hz) indicated a dihedral angle of ~60°, as illustrated in C. Consequently, the conformation of I was assigned the boat or half-chair form.

In addition, the coupling constant ($J_{7,8}$ = 9.0 Hz) between H_c and H_d indicated an eclipsed relationship between H_c and H_d, as illustrated in E, and not a dihedral angle of ~60°, as illustrated in the half-chair form F. Thus, the boat form shown in B was the preferred conformation of the seven-membered ring of I. The linkage position of the remaining methine proton in CH_2OCH was determined as follows. The physical data of I suggested that the methine proton in CH_2OCH could be placed only at C-2 or C-3; in this case, the possible configuration relationships between C-3 and C-4 could be shown as G, H, J, and K (Structure B).

[5] Internal Nuclear Double Resonance.

Treatment of I with sodium borohydride afforded a monohydroxy 11,13-dihydro derivative (III*a*) in which the methylene group of CH_2OCH was linked at C-5 on the basis of spectral evidence (2).

The protons at C-2 and C-4 appeared as a multiplet at δ 4.0. However, the NMR spectrum of III*a* measured in deuterated chloroform–benzene (1:1) showed the presence of H-2 as a multiplet at δ 3.77 and of H-4 as a doublet of doublets of doublets at δ 3.49 (J = 2.0, 4.0, and 10.0 Hz), which indicated that the methine proton of CH_2OCH was placed at C-2, as illustrated in G.

The configuration of the methyl group at C-10 was assigned on the basis of NMR data. If the C-10 methyl group were in the β-axial configuration, the C-2 β-oxygen group would be expected to deshield the C-10 β-methyl group (δ 1.34), as was shown for bipinantin (IV) (12). On the other hand, a C-2 α-hydroxyl group, as found in ivoxathin (V) (13), would be expected to have little or no effect on it (δ 1.11). In addition, a positive Nuclear Overhauser Effect (NOE) between a C-10 β-methyl group and the 5β-axial proton (H_h) should be observed.

The C-10 methyl group of I was observed as a doublet at δ 1.17 and showed no NOE in the NMR spectrum. Therefore, the C-10 methyl group was assigned to an α-configuration and thus gave the complete Structure B for microhelenin-A. The high-resolution mass spectral data of I shown in Scheme I supported this structural assignment.

Microhelenins-B (VI) and C (VIII)—Microhelenin-B (VI), $C_{20}H_{28}O_5$ (high-resolution mass spectrum), mp 111–113°, $[\alpha]_D^{28}$ −84.91°, was recrystallized as colorless needles from chloroform. The IR (tetrachloromethane) and NMR spectra (Table III) showed the presence of an α,β-unsaturated cyclopentenone and an α-methyl-γ-lactone, as found in plenolin (VII) (7) as described previously (3).

The remaining two oxygen atoms of the empirical formula were assigned as part of a five-carbon saturated ester side chain (IR bands at 1741, 1230, and 1190 cm^{-1}), as evidenced by the facile loss of a $C_5H_{10}O_2$ fragment and the appearance of a $C_5H_9O^+$ ion as the base peak in the mass spectrum (Scheme II). The nature of this ester side chain was revealed by the NMR spectrum, which had the same characteristic peaks of a 2-methylbutanoate, as found in tetrahydrobrevilin-A (IX*a*) (14). Based on the physical data, Structure VI was postulated for microhelenin-B. The attachment of the 2-methylbutanoyl side chain at C-6 (δ 5.50, br s, $W_{1/2}$ = 3.0 Hz, H at C-6) and the closing of the lactone ring at C-8 (δ 4.80, br t-like, J = 6.0 Hz, H at C-8) were based on comparable substitution patterns found in other pseudoguaianolides. The high-resolution mass spectral data supported the structural assignment (Scheme II).

Microhelenin-C (VIII), $C_{20}H_{26}O_5$ (high-resolution mass spectrum), $[\alpha]_D^{23}$ −85.0°, was isolated in small quantity as a gum by silica gel column chromatography and preparative TLC. The IR (tetrachloromethane) and NMR spectra (Table III) indicated the presence of an α-methyl-γ-lactone ring, an α,β-unsaturated cyclopentenone of the type found in VI and VII, and a tiglate[6] ester moiety as reported previously (3). In addition,

[6] In general, the βH and βCH_3 protons in methyl tiglate were observed at δ 6.73 and 1.73, respectively, and the protons in methyl tiglate were observed at δ 5.98 and 1.97, respectively (15). The NMR spectrum of VIII indicated the presence of a tiglate ester group, as shown in Table III.

the PMR spectrum showed the presence of two methyl signals [δ 1.05 (s, 5-CH_3) and 1.25 (d, J = 6.0 Hz, 10-CH_3)]. In accordance with these deductions, the high-resolution mass spectrum exhibited diagnostically important peaks at m/e 346.1782 ($C_{20}H_{26}O_5$, M^+), 246.1252 ($M^+ - C_5H_8O_2$, base peak), 123.0808 ($C_8H_{11}O^+$), and 83.0494 ($C_5H_7O^+$). Consequently, the structure of microhelenin-C was formulated as VIII, and the stereochemistry was established by direct comparison (TLC and superimposable IR, NMR, and mass spectra) with the synthetic plenolin tiglate prepared from plenolin (VII) and tigloyl chloride in pyridine-benzene.

Catalytic hydrogenation of VI and VIII with 10% palladium-on-carbon in ethanol yielded the same amorphous compound (IX*b*). The IR, PMR, and mass spectra reflected changes resulting from saturation of a cyclopentenone chromophore and a tigloyl side chain. In addition, the PMR spectrum (Table III) was strikingly similar to that of tetrahydrobrevilin-A (IX*a*), which differed only in the stereochemistry of the methyl group at C-11. Thus, the conformations of the seven-membered ring and the configurations of 11-CH_3 could be described as shown in L–N.

The complete assignments of protons for C-6, C-7, C-8, and C-11 of IX*b* were achieved by extensive decoupling experiments (Table I). If the usual assumption is made that the C-7–C-11 bond is equatorial and β as in all sesquiterpene lactones of documented stereochemistry, then the observed large value of $J_{7,11}$ requires that H-11 be *cis* to H-7 and α and the small value of $J_{6,7}$ requires that H-6 be *cis* to H-7 and β. Thus, the lactone ring must be *cis*-fused and the seven-membered ring must be in the chair conformation, as shown in L. In addition, the stereochemistry of tetrahydromicrohelenins-B and C was confirmed to be identical to the

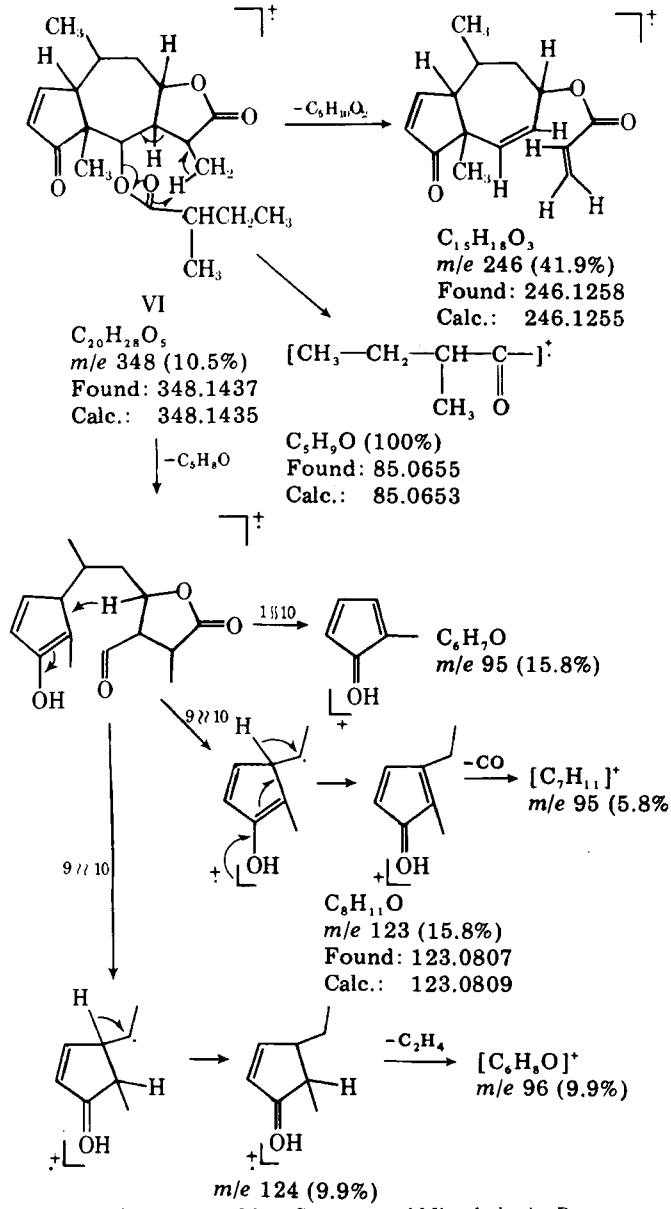
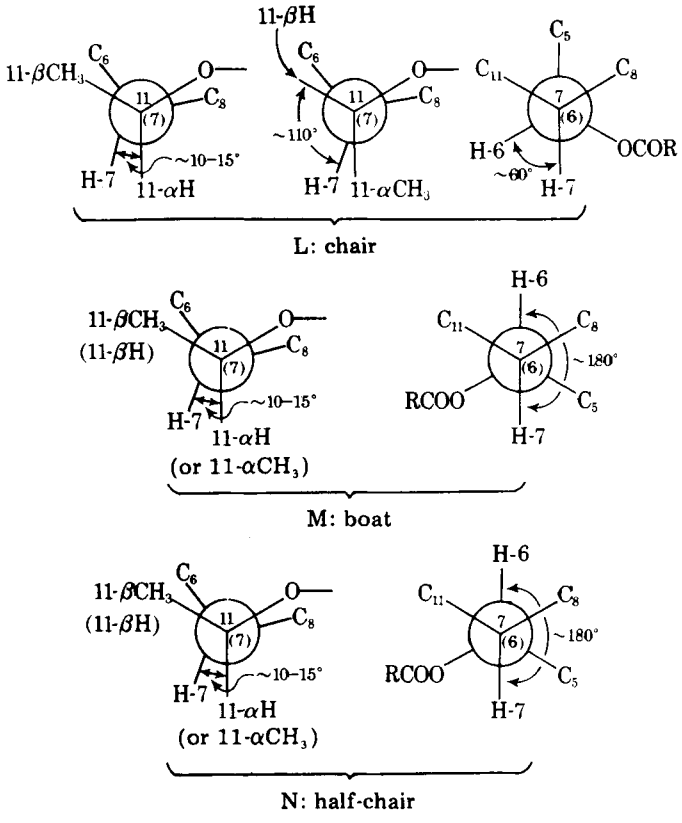
hydrogenation product prepared from plenolin tiglate by direct comparison of TLC results and IR and NMR spectra. Thus, the stereochemistry of tetrahydromicrohelenins-B and C was established as IX*b*. The foregoing evidence led to the establishment of the structures of microhelenins-B and C as VI and VIII, respectively.

Microlenin Acetate (X)—Microlenin acetate (X), $C_{31}H_{36}O_8$, *m/e* 536 (M^+), mp 289–291° dec., was isolated from the mother liquor after the removal of helenalin and recrystallized as colorless needles from chloroform–ether. In the PMR spectrum of X, the presence of one acetyl singlet (δ 1.97), one methyl singlet (δ 0.94), and two methyl doublets [δ 1.18 and 1.23 (d, 3H each, J = 7.0 Hz)] coupled with the characteristic signals corresponding to one cyclopentenone [δ 7.67 (dd, J = 2.0 and 6.0 Hz) and 6.06 (dd, J = 3.0 and 6.0 Hz)] and one α-methylene-γ-lactone moiety [δ 6.28 (d, J = 3.0 Hz) and 5.52 (d, J = 3.0 Hz)] suggested an acetylated dimeric sesquiterpene lactone possessing a cyclopentenone and an α-methylene-γ-lactone for the structure of X. Final identification of X with an acetate of microlenin (XI), prepared by acetylation of XI with acetic anhydride–pyridine, was established by direct comparison (IR, NMR, and mass spectra).



Scheme II—Mass Spectrum of Microhelenin-B



Plenolin (VII)—Plenolin (VII), $C_{15}H_{20}O_4$, *m/e* 264 (M^+), mp 222–224°, was isolated from the chloroform–ethyl acetate (9:1) eluate and recrystallized as colorless needles from chloroform. The IR and NMR

[a] Values are in parts per million. Multiplicities are indicated by the usual symbols: d, doublet; m, multiplet whose center is given; and br, slightly broadened singlet. Unmarked signals are singlets. Figures in parentheses are coupling constants in Hertz. Measurements were recorded with a 100-MHz instrument and were taken in deuterochloroform. [b] Measured at 60 MHz (in deuterochloroform). [c] Obscured signal.

spectra of this compound were identical with those of synthetic dihydrohelenalin prepared by catalytic hydrogenation of helenalin. To confirm further the structure of VII, its identity with natural plenolin, isolated from Florida *Helenium autumnale* (15), was established by direct comparison (TLC and superimposable IR, NMR, and mass spectra).

EXPERIMENTAL[7]

Isolation of Microhelenins-A (I), B (VI), C (VIII), and D (XIV), Microlenin Acetate (X), and Plenolin (VII) from *H. microcephalum*.—The *H. microcephalum* (Compositae) used was from a collection made in June 1972 in Burleson County, Tex[8]. The ground, air-dried, whole plant material (7 kg) was extracted exhaustively with chloroform and worked up in the usual manner (16), affording 181 g of a dark-brown gum. The gum (146 g) was chromatographed on silica gel (10 × 70 cm) with chloroform, chloroform–ethyl acetate (9:1), and acetone. Fractions of 250 ml were collected (Fractions a, b, and c) and examined by TLC.

The first chloroform eluate (fractions 7–15 = Fraction a) gave a gummy solid (10 g) upon evaporation of the solvent. The subsequent chloroform eluate (fractions 16–25 = Fraction b) yielded a gum which, upon chromatography on silica gel [200 g, eluted with benzene–chloroform (1:1) and collected at 75 ml/fraction], gave 0.2 g of microhelenin-A upon recrystallization of fractions 13–32 with ether. Recrystallization with ether–tetrachloromethane of the mother liquor after the removal of microhelenin-A afforded 0.2 g of microhelenin-D. The chloroform–ethyl acetate (9:1) eluate (fractions 50 and 51 = Fraction c) yielded helenalin (XII) and plenolin (VII, 80 mg) in addition to a gummy solid (1 g), which was recrystallized from chloroform–ether to give 400 mg of microlenin (XI) as colorless needles. Microlenin acetate (X, 28 mg) was isolated from the mother liquor after the removal of helenalin.

The first chloroform eluate (Fraction a, 10 g) was rechromatographed on silica gel (200 g) with benzene–acetone (25:1) (collected at 20 ml/fraction). Fractions 50–60, after evaporation of the solvent, left a semisolid residue (318 mg). This residue was purified by preparative TLC [benzene–chloroform–acetone (4:4:1), UV detection] to yield a mixture of microhelenins-B and C (205 mg) as indicated by NMR and mass spectra. Further purification of this mixture was achieved by a second preparative TLC procedure [silica gel impregnated with silver nitrate, chloroform–ethyl acetate (3:1), developed twice and detected with UV light] to give 109 mg of microhelenin-B (VI) and 50 mg of microhelenin-C (VIII). Fractions 81–180 gave microhelenin-D (mexicanin-E) (1.8 g) after recrystallization from ether–tetrachloromethane. Fractions 190–250 yielded microhelenin-A (30 mg) upon recrystallization from chloroform.

Microhelenin-A (I)—The analytical data for I were: mp 140–141°, $[\alpha]_D^{24}$ +89.0° (*c*, 1.00 in methanol), C, 68.47; H, 6.88 ($C_{15}H_{18}O_4$ requires C, 68.68; H, 6.92); IR (tetrachloromethane): no hydroxyl group, 1772, 1665 (α-methylene-γ-lactone), and 1758 (cyclopentanone) cm^{-1}; mass spectrum: *m/e* (%) 262.293 (M^+, 100) (calc. 262.294), 220 [M^+ − 42 (CH_2=CO), 98], 178 [M^+ − (42 + CH_3CH=CH_2), 47], 136 [M^+ − (42 + 84), 17], 94 ($C_5H_5O_2^+$, 34), and 84 ($C_5H_8O^+$, 11). The PMR data (100 MHz, deuterochloroform) are shown in Table III.

Microhelenin-B (VI)—The analytical data for VI were: mp 111–113°, $[\alpha]_D^{28}$ −84.91° (*c*, 1.75 in methanol); IR (tetrachloromethane): 1782 (γ-lactone), 1741 (ester), 1726, and 1586 (cyclopentenone) cm^{-1}; mass spectrum: *m/e* (%) 348.1937 (M^+, 6.9) ($C_{20}H_{28}O_5$ requires 348.1935), 246.1258 (M^+ − $C_5H_{10}O_2$, 41.9) ($C_{15}H_{18}O_3$ requires 246.1255), 123.0807 ($C_8H_{11}O^+$, 15.8) ($C_8H_{11}O$ requires 123.0809), and 85.0655 [$CH_3CH_2CH(CH_3)C$=$O)^+$, 100] (C_5H_9O requires 85.0653). The PMR data (60 MHz, deuterochloroform) are shown in Table III.

Microhelenin-C (VIII)—The analytical data for VIII (a gum) were: $[\alpha]_D^{23}$ −85.0° (*c*, 1.30 in methanol); IR (tetrachloromethane): 1782 (α-methyl-γ-lactone), 1725, 1583 (cyclopentenone), 1725, 1651, 1260, and 1182 (tigloyl ester) cm^{-1}; mass spectrum: *m/e* (%) 346.1782 (M^+, 11.8) ($C_{20}H_{26}O_5$ requires 346.1779), 246.1252 (M^+ − $C_5H_8O_2$, 100) ($C_{15}H_{18}O_3$ requires 246.1255), and 83.0494 [$CH_3CH_2CH(CH_3)C$=O^+, 98.1] (C_5H_7O requires 83.0496). The PMR data (60 Hz, deuterochloroform) are shown in Table III.

Sodium Borohydride Reduction of Microhelenin-A (I)—To a solution of I (40 mg) in methanol (2 ml) was added sodium borohydride (20 mg). The total mixture was kept stirring at room temperature for 25 min, treated with acetone (5 ml) and methanol (3 ml), stirred further for 10 min, and worked up in the usual manner. The reaction product was purified by preparative TLC [benzene–methanol (20:2), detection with iodine] to give a monohydroxy dihydro derivative (III*a*) (15 mg), mp 138–140° (chloroform); IR (chloroform): 3590 (OH) and 1762 (γ-lactone) cm^{-1}; mass spectrum: *m/e* (%) 266.1518 (M^+, 9.8) ($C_{15}H_{22}O_4$ requires 266.1518) and 248 (M^+ − H_2O, 4.5); PMR (100 MHz, deuterochloroform): δ 1.07 (d, 3H, *J* = 7.0 Hz, 10-CH_3), 1.18 (d, 3H, *J* = 7.5 Hz, 11-CH_3), 2.84 (dq, 1H, *J* = 7.5 and 10.0 Hz, H-11), 3.50 (dd, 1H, *J* = 2.0 and 8.0 Hz, C-5 CH_2O), 4.18 (d, 1H, *J* = 8.0 Hz, 1H, C-5 CH_2O), 4.0 (m, 2H, H-2 and H-4), and 4.78 (m, 1H, H-8); PMR (100 MHz, deuterated chloroform and benzene, deuterated water treatment): δ 0.81 and 0.99 (d, 3H each, *J* = 7.0 Hz, 10-CH_3 and 11-CH_3), 3.23 (dd, 1H, *J* = 2.0 and 8.0 Hz, C-5 CH_2O), 3.49 (ddd, 1H, *J* = 2.0, 4.0, and 10.0 Hz, H-4), 3.77 (m, 1H, H-2), 3.98 (d, 1H, *J* = 8.0 Hz, C-5 CH_2O), and 4.29 (m, 1H, H-8).

Acetylation of III*a*—Acetylation of III*a* (7 mg) with acetic anhydride (0.5 ml) and pyridine (0.5 ml) at room temperature for 20 hr followed by the usual workup yielded a product (5 mg). This product was purified

[7] Melting points were determined on a Thomas-Hoover melting-point apparatus and are uncorrected. Specific rotations were on a Perkin-Elmer model 141 polarimeter (1 = 1 dm). IR spectra were recorded with a Perkin-Elmer model 257 grating IR spectrometer. The PMR spectrum was determined with either a Jeolco C60 HL or a Varian XL-100 NMR spectrometer (tetramethylsilane as the internal standard). Mass spectra were determined on an AEI MS-902 instrument at 70 ev using a direct-inlet system. Optical rotatory dispersion and circular dichroism spectra were measured on a Cary model 60 spectrometer. Silica gel was used for column chromatography (Mallinckrodt CC-7, 200–325 mesh) and for TLC (Merck silica gel G). Detection of components was made by spraying with 1% cerium sulfate–10% sulfuric acid solution followed by heating. Elemental analyses were performed by Atlantic Microlab, Atlanta, Ga.

[8] Dr. John J. Sperry, Texas A & M University, collected and identified the plant material. A voucher specimen (J. J. Sperry, No. 4020) is available for inspection at the Herbarium, Department of Botany, University of North Carolina at Chapel Hill.

with preparative TLC [chloroform–methanol (40:1), detection with iodine] to give an acetylated derivative (III*b*, 3.5 mg) of III*a*. The analytical data for III*b* were: mp 135–138° (chloroform); mass spectrum: *m/e* (%) 308.1620 (M^+, 100) ($C_{17}H_{24}O_5$ requires 308.1624) and 248 (M^+ – CH_3COOH, 33); PMR (100 MHz, deuterochloroform): δ 2.14 (s, 3H, C-4 $OCOCH_3$), 4.09 (m, 1H, H-2), 4.7, and 5.1 (m, 2H, H-4 and H-8).

Catalytic Hydrogenation of Microhelenin-C (VIII)—A solution of VIII (50 mg) in ethanol (8 ml) was shaken with hydrogen at room temperature (22°) and atmospheric pressure in the presence of 10% palladium-on-charcoal (50 mg). The reaction mixture was filtered after the initial rapid absorption slowed. Removal of ethanol *in vacuo* resulted in a gum (49 mg), which was purified by preparative TLC [benzene–chloroform–acetone (4:4:1), detection with iodine] to give an amorphous compound (IX*b*, 36 mg) from acetone; IR (tetrachloromethane): 1782 (α-methyl-γ-lactone), 1749, and 1740 (sh) (ester and cyclopentanone) cm^{-1}; mass spectrum: *m/e* (%) 350.2091 (M^+, 7.0) ($C_{20}H_{20}O_5$ requires 350.2093), 248 [M^+ – $CH_3CH_2CH(CH_3)COOH$, 58.3], 85 $[CH_3CH_2CH_2C{=}O)^+$, 58.3] and 57 ($CH_3CH_2C^+HCH_3$, 100); PMR (100 MHz, deuterochloroform): δ 0.84 (s, 3H, 5-CH_3), 1.06 (d, 6H, J = 7.0 Hz, 10-CH_3 and 2′-CH_3), 1.47 (d, 3H, J = 7.5 Hz, 11-CH_3), 2.74 (dd, 1H, J = 6.0 and 10.0 Hz, H-7), 3.03 (dq, 1H, J = 7.5 and 10.0 Hz, H-11), 4.71 (br t-like, 1H, J = 6.0 Hz, H-8), and 5.38 (br s, 1H, H-6). The methyl triplet of the side chain was submerged in the methyl and methylene envelope.

Catalytic Hydrogenation of Microhelenin-B (VI)—The hydrogenation of VI was repeated under the described conditions. The product was identical to IX*b* according to TLC (three solvent systems), IR (tetrachloromethane), and PMR spectra (deuterochloroform).

Synthesis of Microhelenin-C (VIII) from Plenolin and Tigloyl Chloride—A solution of plenolin (120 mg) in dry benzene (2 ml) and dry pyridine (1 ml) was treated with tigloyl chloride (0.2 ml). The solution was heated under reflux for 3 hr. Evaporation to dryness under reduced pressure left a solid residue, which was suspended in 5% sodium bicarbonate, extracted with ether, and worked up in the usual manner. The product obtained from the ether extract was purified by silica gel (40 g, eluted with chloroform) column chromatography to give plenolin tiglate (54 mg) as a gum. This gum was identified as VIII by direct comparison with the material isolated previously from this plant; IR (tetrachloromethane): 1781 (α-methyl-γ-lactone), 1725, 1583 (cyclopentenone), 1725, 1651, 1262, and 1182 (tigloyl ester) cm^{-1}; PMR (60 MHz, deuterochloroform): δ 1.05 (s, 3H, 5-CH_3), 1.23 (d, 3H, J = 6.0 Hz, 10-CH_3), 1.51 (d, 3H, J = 6.0 Hz, 11-CH_3), 1.70 (br s, 3H, 2′-CH_3), 1.71 (br d, 3H, J = 6.5 Hz, 3′-CH_3), 4.75 (m, 1H, H-8), 5.47 (s-like, 1H, $W_{1/2}$ = 3.0 Hz, H-6), 6.04 (dd, 1H, J = 3.0 and 6.0 Hz, H-3), 6.65 (m, 1H, H-3′), and 7.70 (dd, 1H, J = 2.0 and 6.0 Hz, H-2).

Catalytic Hydrogenation of Plenolin Tiglate—A solution of the plenolin tiglate (45 mg) in ethanol (8 ml) was hydrogenated with 10% palladium-on-charcoal until hydrogen absorption ceased and then was treated as described. The product was purified by preparative TLC [benzene–chloroform–acetone (4:4:1), detection with iodine] to give an amorphous compound (30 mg) from acetone. The compound was identical with IX*b*, which was obtained previously by hydrogenation of VI and VIII. The IR spectra were superimposable, and the TLC behavior was identical; PMR (60 MHz, deuterochloroform): δ 0.83 (s, 3H, 5-CH_3), 1.05 (d, 3H, J = 6.75 Hz, 10-CH_3), and 1.46 (d, 1H, J = 6.75 Hz, H-10).

Microlenin Acetate (X)—The analytical data for X were: mp 289–291° dec., $[\alpha]_D^{20}$ +47.9° (*c*, 1.90 in methanol); IR (chloroform): no hydroxyl group, 1757 (γ-lactone), 1741, 1662 (α-methylene-γ-lactone), 1715, and 1580 (cyclopentenone) cm^{-1}; NMR (100 MHz, deuterochloroform): δ 0.94 (s, 3H, 5-CH_3), 1.18 and 1.23 (d, 3H each, J = 7.0 Hz, 10-CH_3 and 10′-CH_3), 1.97 (s, 3H, C-6 $OCOCH_3$), 2.48 (d, 1H, J = 8.0 Hz, H-7), 3.29 (m, 1H, H-7′), 4.71 (m, 1H, H-8′), 4.95 (m, 1H, H-8), 5.52 and 6.28 (d, 1H each, J = 3.0 Hz, H-13′), 5.62 (s, 1H, H-6), 6.06 (dd, 1H, J = 3.0 and 6.0 Hz, H-3), and 7.67 (dd, 1H, J = 2.0 and 6.0 Hz, H-2). The IR and NMR spectra of X were identical to those of microlenin acetate prepared from acetylation of microlenin (XI) with acetic anhydride in pyridine (5).

Plenolin (VII)—The analytical data for VII were: mp 222–224°; IR (chloroform): 3450 (hydroxyl), 1752 (γ-lactone), and 1690 (cyclopentenone) cm^{-1}; NMR (100 MHz, deuterochloroform): δ 0.96 (s, 3H, 5-CH_3), 1.21 (d, 3H, J = 7.0 Hz, 10-CH_3), 1.35 (d, 3H, J = 7.0 Hz, 11-CH_3), 4.40 (d, 1H, J = 4.0 Hz, H-6), 4.80 (m, 1H, H-8), 6.05 (dd, 1H, J = 3.0 and 6.0 Hz, H-3), and 7.70 (dd, 1H, J = 2.0 and 6.0 Hz, H-2); mass spectrum: *m/e* 264 (M^+).

Catalytic Hydrogenation of Helenalin (XII)—A solution of XII (60 mg) in ethyl acetate (25 ml) was hydrogenated with hydrogen at room temperature and atmospheric pressure in the presence of 5% palladium-on-carbon (25 mg). After the reaction mixture was filtered and the solvent was removed *in vacuo*, the residue was purified by column chromatography [silica gel, chloroform–ethyl acetate (9:1)] and preparative TLC [chloroform–ethyl acetate (1:1)] to give rise to the dihydro (23 mg, mp 222–224°) and the tetrahydro (XIII, 25 mg, mp 175–176°) derivatives.

The IR and NMR spectra of the dihydro derivative were identical to those of plenolin (VII) (7). The spectral data of the tetrahydro derivative were in accord with the structure of 2,3,11,13-tetrahydrohelenalin (XIII) (8, 17); mass spectrum: *m/e* 266 (M^+); IR (chloroform): 3580 (hydroxyl), 1750 (γ-lactone), and 1720 (cyclopentenone) cm^{-1}; NMR (deuterochloroform): δ 0.80 (s, 3H, 5-CH_3), 1.04 (d, 3H, J = 7.0 Hz, 10-CH_3), 1.36 (d, 3H, J = 7.0 Hz, 11-CH_3), 4.30 (br s, 1H, H-6), 4.75 (t-like, 1H, J = 6.0 Hz, H-8), and 2.95 (m, 2H, H-3).

Antitumor Agents XXXVIII: Isolation and Structural Elucidation of Novel Germacranolides and Triterpenes from *Elephantopus mollis*

KUO-HSIUNG LEE *x, TOSHIRO IBUKA *, HIROSHI FURUKAWA *, MUTSUO KOZUKA *, RONG-YANG WU *, IRIS H. HALL *, and HUAN-CHANG HUANG ‡

Received April 4, 1979, from the **Department of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514,* and the ‡*School of Pharmacy, Kaohsiung Medical College, Kaohsiung, Taiwan, Republic of China.* Accepted for publication July 27, 1979.

Abstract □ The ethanolic extract of *Elephantopus mollis* yielded three novel cytotoxic antitumor germacranolides, molephantin, molephantinin, and phantomolin. The extract also yielded three inactive known triterpenes, β-amyrin acetate, lupeol acetate, and epifriedelanol, as well as stigmasterol. The structure and stereochemistry of the cytotoxic antitumor agents molephantin, molephantinin, and phantomolin were determined on the basis of chemical transformations and spectral evidence. Preliminary *in vivo* tumor assays indicated that molephantinin and phantomolin were potent inhibitors of Ehrlich ascites carcinoma and Walker 256 carcinosarcoma. Molephantinin also showed significant antileukemic activity in the P-388 lymphocytic leukemia screen.

Keyphrases □ *Elephantopus mollis*—isolation and structural determination of molephantin, molephantinin, and phantomolin □ Antineoplastic agents, potential—molephantin, molephantinin, and phantomolin, isolation from *Elephantopus mollis*, structural determination □ Molephantin—isolation from *Elephantopus mollis* and structural determination □ Molephantinin—isolation from *Elephantopus mollis* and structural determination □ Phantomolin—isolation from *Elephantopus mollis* and structural determination

During a continuing search of Formosan plants for agents with potential antitumor activity (1), the alcoholic extract of *Elephantopus mollis*[1] (Compositae) showed significant reproducible inhibitory activity in both *in vitro* (KB cell culture) and *in vivo* (Walker 256 carcinosarcoma) screens[2]. Preliminary reports described the structural determination of three novel cytotoxic antitumor germacranolides, molephantin (I) (4), molephantinin (II) (5), and phantomolin (III) (6). The present report fully describes the isolation and structural elucidation of these novel antitumor sesquiterpene lactones as well as the companion triterpenes β-amyrin acetate (IV), lupeol acetate (V), epifriedelanol (VI), and stigmasterol (VII).

RESULTS AND DISCUSSION

The active alcoholic extract of the whole plant (winter growth) was concentrated and partitioned between water and chloroform. Guided by the assay in KB cells (Scheme I and Table I), the active principles were concentrated in the chloroform extract (Fraction C). Partitioning of this extract between 33% aqueous methanol and hexane concentrated the activity in the aqueous methanolic layer (Fraction D). The aqueous methanolic layer was concentrated and extracted further with chloroform. Chromatography of the active chloroform extract (Fraction G) over silica gel isolated the active principles, molephantin (I), molephantinin (II), and phantomolin (III). Compounds I and III were isolated at 0.025 and 0.023%, respectively, as the major components in this winter collection. In a spring collection of the same plant, I was isolated at ~0.020% as the major cytotoxic principle.

Compound I, mp 212–213°, $C_{19}H_{22}O_6$ (mass spectrum and elemental analysis), contained an α-methylene-γ-lactone, as evidenced by the characteristic NMR signals (Table II) for the methylene protons [δ 6.36 (d, J = 2.5, H_a-13) and 5.83 (d, J = 2.0, H_b-13)] and the IR bands [1773 (γ-lactone) and 1650 (C=C) cm^{-1}]. The UV spectrum of I showed, in addition to the α-methylene-γ-lactone at 210 nm (ε 30,960), a dienone system at 242 nm (ε 18,210, shoulder). The presence of an α,β-unsaturated ester group in I was indicated by IR absorption at 1713 and 1650 (C=C) cm^{-1} and was supported by the base peak at *m/e* 69 [CH_2=$C(CH_3)CO^+$] in the mass spectrum. The NMR spectrum of I suggested a methacrylate pattern for the acid portion of the ester since it showed two multiplets at δ 6.15 and 5.68 (2H, H-19) and one vinyl methyl multiplet at δ 1.96 (H-18)[3], which are typical signals for the methacrylate group (8, 9). Thus, I is an α-methylene-γ-lactone sesqui-

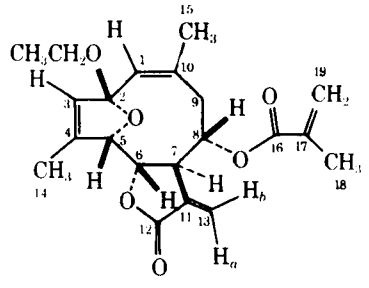
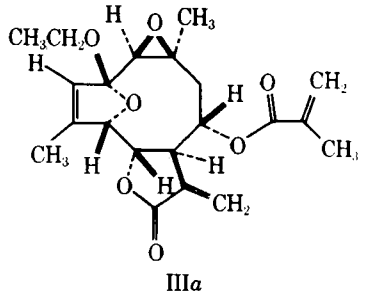
[a] KB refers to human carcinoma of the nasopharynx. Cytotoxicity was assayed according to a literature method (3). A compound is active if the average ED_{50} is ≤4 μg/ml for the pure compound. [b] n = number of animals per group. These *in vivo* data were reported previously (7).

terpene lactone that possesses an additional dienone system and a methacrylate ester.

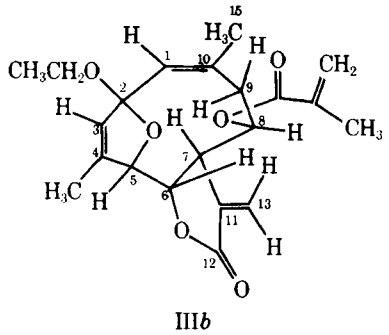
Compound I also possesses a secondary hydroxyl group. It showed an IR absorption band at 3420 cm^{-1} and a M − 18 (water) peak at *m/e* 328.1305[4] in the mass spectrum. The C*H*OH proton (*i.e.*, H-5) was seen as a one-proton singlet at δ 5.46 and was displaced to δ 6.57 in the NMR spectrum of molephantin acetate [I*a*, mp 169°, *m/e* 388.1522 (M^+) for $C_{21}H_{24}O_7$], obtained by acetylation of I with acetic anhydride in pyridine. Since the lactonic proton at C-6 was seen as a doublet (J = 3.5 Hz each) at δ 4.26 in I and 4.35 in I*a*, it indicated that there was almost no coupling between H-5 and H-6 (*i.e.*, the dihedral angle between H-5 and H-6 is ~90°) and that C-4 should be tetrasubstituted, *i.e.*, a vinyl methyl or a carbonyl group was attached at C-4 in I or I*a*.



III



III*a*



III*b*

The assignment of protons at C-7, C-8, C-9, and C-1, as well as the three vinyl methyl groups at C-17, C-10, and C-4, was made possible by spin-decoupling experiments of I*a*. Thus, irradiation at the frequency of H-7 (multiplet) at δ 3.42 collapsed the two doublets of H_a-13 and H_b-13 at δ 6.35 and 5.79 to two singlets, the doublet of H-6 ($J_{5,6}$ = 0 and $J_{6,7}$ = 3.5 Hz) at δ 4.35 to a singlet, and the doublet of triplets of H-8 ($J_{7,8}$ = 10.5 Hz, $J_{8,d}$ = 4.0 Hz, and $J_{8,c}$ = 0) to a pair of doublets ($J_{8,d}$ = 4.0 Hz and $J_{c,d}$ = 11.0 Hz). Conversely, irradiation of H-8 sharpened the multiplet of H-7 as well as converted the doublet ($J_{c,d}$ = 11.0 Hz) of H_c-9 at 2.58 and the doublet of doublets ($J_{c,d}$ = 11.0 Hz and $J_{8,d}$ = 4.0 Hz) of H_d-9 at 2.79 to a pair of doublets ($J_{c,d}$ = 11.0 Hz), thereby suggesting a tetrasubstitution at C-10.

Since most sesquiterpene lactones, especially the germacranolides, contain methyl groups at C-4 and C-10, the two vinyl methyl groups at δ 1.98 (d, J = 1.5 Hz) and 1.80 (d, J < 1.0 Hz) were assigned to these C-4 and C-10 positions, respectively. Consequently, the last oxygen function was placed at C-2, the last position available, as the dienone carbonyl group. This assignment was confirmed by the fact that H-1 and H-3 appeared as a low-field singlet and multiplet at δ 6.37 and 6.05, respectively. Irradiation of the C-4 methyl group at δ 1.98 collapsed the H-3 multiplet to a singlet. Irradiation of the C-17 methyl group at δ 1.94 changed the two one-proton multiplets of H-19 at δ 6.14 and 5.67 to two doublets (J = 1.8 Hz each), confirming the presence of the methylacrylate ester side chain. The remaining narrowly split three-proton doublet at δ 1.79 then was assigned to the vinyl methyl group at C-10.

The foregoing evidence led to the formulation of Structure I for molephantin, exclusive of the complete stereochemistry. A consideration of the relationship between the J value and the dihedral angle (10) with the aid of a Dreiding model established the stereochemical relationships among protons at C-5, C-6, C-7, C-8, and C-9, as shown in I*f*. These assignments were based on the assumption of a β-oriented H-6, followed by the dihedral angles shown between H-5 and H-6, H-6 and H-7, H-7 and H-8, and H-8 and H-9 deduced from their corresponding J values, *i.e.*, $\phi_{5,6} \simeq 90°$ ($J_{5,6}$ = 0), $\phi_{6,7} \simeq 120°$ ($J_{6,7}$ = 3.5 Hz), $\phi_{7,8} \simeq 140°$ ($J_{7,8}$ = 10.5 Hz), $\phi_{8,d} \simeq 50°$ ($J_{8,d}$ = 4.0 Hz), and $\phi_{8,c} \simeq 90°$ ($J_{8,c}$ = 0).

The establishment of these relationships was possible only when the C-10 methyl group was forced to lie close above the π-electron cloud of the C-3–C-4 double bond. This arrangement was supported by the NMR spectra of I and I*a*, in which the C-10 methyl group (δ 1.79 in I and 1.80 in I*a*) was shifted upfield by 0.23 to 0.18 ppm by the C-3–C-4 double bond compared to the C-4 methyl group (δ 2.02 in I and 1.98 in I*a*). A similar upfield shift of H-6 in I and I*a* (δ 4.26 in I and 4.35 in I*a*) further confirmed that H-6 was located close above the C-1–C-10 double bond. When C_5-OH was oxidized to the corresponding ketone [*i.e.*, dehydromolephantin (I*b*), $C_{19}H_{20}O_6$, mp 132–133°, λ_{max} 211 nm (ε 29,070)] by Jones

[4] The calculated *m/e* value for $C_{19}H_{20}O_5$ was 328.1311, which further confirmed the composition of $C_{19}H_{22}O_6$ for I.

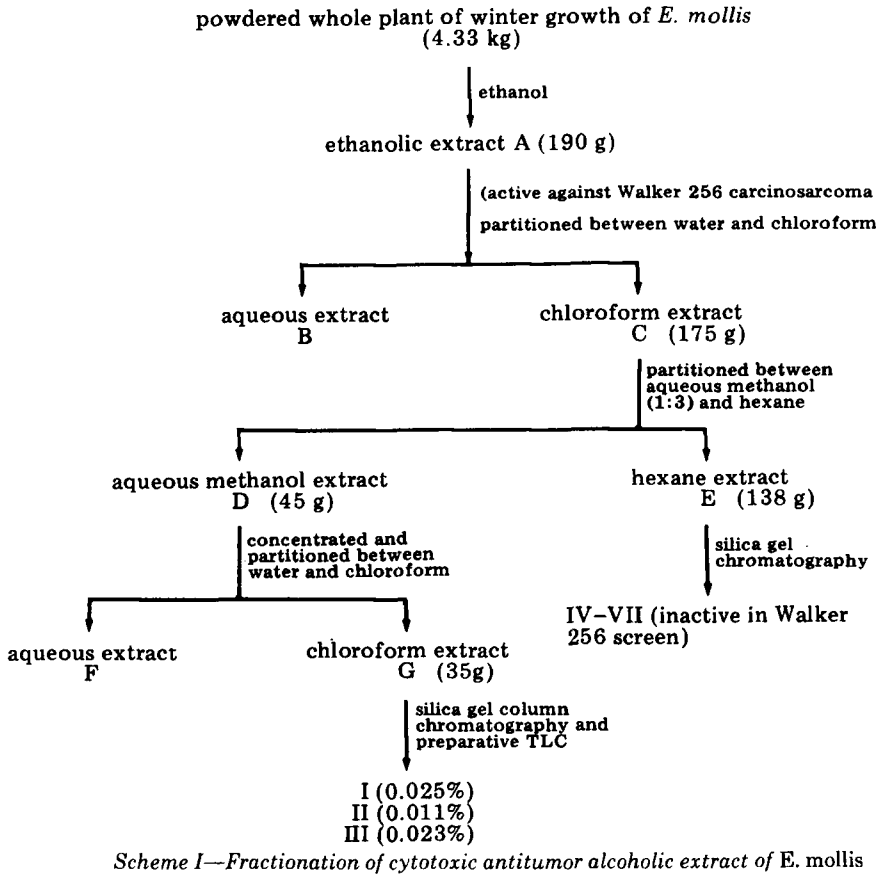
[a] Run in deuterochloroform at 100 MHz. Values are in parts per million. Multiplicities are indicated by the usual symbols: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet whose center is given; and br, slightly broadened singlet. Figures in parentheses are coupling constants in Hertz. [b] Run in deuterochloroform at 60 MHz. [c] Overlapped signals. [d] Signals disappeared upon addition of deuterium oxide.



Scheme I—Fractionation of cytotoxic antitumor alcoholic extract of E. mollis

reagent, H-6 (δ 4.73 in I*b*) was shifted downfield by 0.38 to 0.47 ppm compared to the ones found in I and I*a*. This shift, coupled with the significant downfield shift of the C-10 methyl group (δ 1.92) in I*b*, suggested that a conformational change had occurred in I*b*.

An examination of the conformation of the 10-membered ring of I*b* based on the dihedral angles derived from the *J* values of H-6 to H-9 in I*b* (Table II) as illustrated in A–C led to the conclusion that Ig was the preferred conformation of dehydromolephantin, in which the C-10 methyl group was in an α-axial configuration and now was deshielded by the C-3–C-4 double bond. The H-1 (δ 5.98) was in a β-axial position and was shielded by the β-oriented C-5 carbonyl group by 0.24–0.39 ppm compared to those found in I (δ 6.22) and I*a* (δ 6.37). The C-1–C-10 double bond was in proximity to the β-oriented C-5 carbonyl group, and this arrangement gave rise to the intramolecular cyclization products when I*b* was treated with sulfuric acid in acetone. These products, which were formed *via* a mechanism shown in Scheme II, were characterized as two guaianolides, Ic and I*d*.

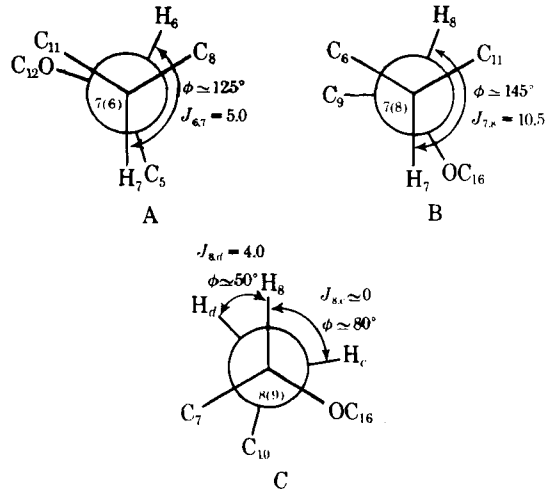
Compound Ic, $C_{19}H_{22}O_7$, mp 168–170°, showed IR (mineral oil) bands at 1750, 1640 (α-methylene-γ-lactone), and 1715 and 1700 (two α,β-unsaturated carbonyl groups) cm^{-1}. The presence of two hydroxyl groups was revealed by IR bands at 3440 and 3320 cm^{-1}, the disappearance of two signals at δ 3.90 (1H) and 2.90 (s, 1H) in the NMR spectrum on the addition of deuterated water, and by an ion of *m/e* 344.1265[5] (M − 18) in the mass spectrum. The NMR spectrum of Ic disclosed the presence of three methyl groups. The three-proton doublet (J = 2.0 Hz) at δ 2.31 was assigned to the cyclopentenone β-methyl group at C-4. The multiplet at δ 1.98 was attributable to the methacrylate methyl group at C-17 as seen in I, I*a*, and I*b*. The methyl singlet in the higher field at δ 1.40 was assigned to the methyl group attached to the carbon bearing a hydroxyl group at C-10. The lactonic proton at C-6 appeared as a doublet with a larger coupling constant compared to that found in I, I*a*, and I*b* and indicated the presence of a second hydroxyl group at C-5 in a guaianolide structure. Assignment of other protons (Table II) was achieved by extensive decoupling experiments. For example, the multiplets at δ 6.22 and 5.74 were assigned to the protons at C-19 since, upon irradiation of the C-17 methyl group at δ 1.98, both changed to two doublets (J = 1.5 Hz each). Irradiation of the C-4 methyl group at δ 2.31 collapsed the multiplet of H-3 at δ 6.09 to a singlet.

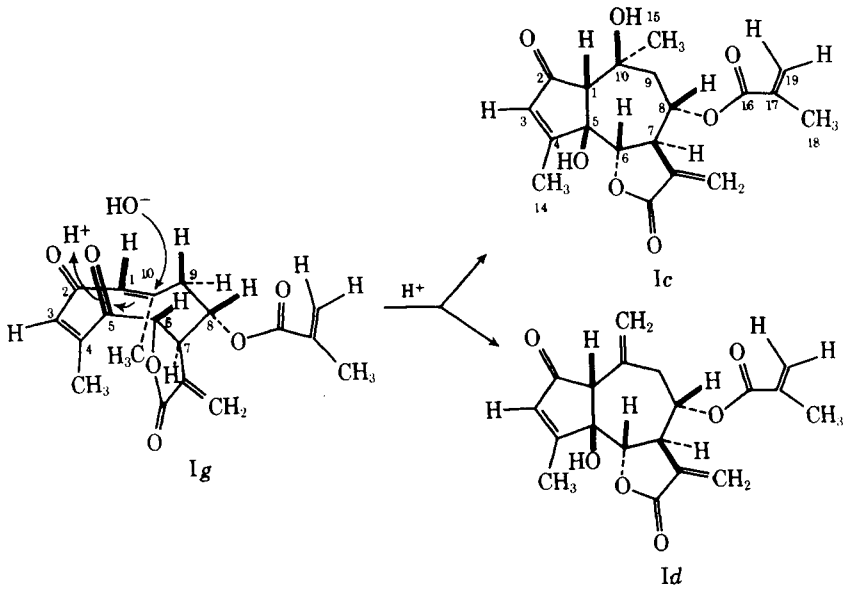
[5] The calculated *m/e* value for $C_{19}H_{20}O_6$ was 344.1260.

Compound I*d*, mp 188–189°, had a composition of $C_{19}H_{20}O_6$ and showed IR (chloroform) bands at 3400, 1770, 1713 (double strength), 1650, and 1625 cm^{-1}. The NMR spectrum of I*d* indicated the absence of the C-10 methyl group as seen in Ic and the presence of one additional terminal methylene group at C-10 at δ 5.21 compared to Ic, suggesting that I*d* was the dehydrated form of Ic. Further assignment of protons (Table II) that supported I*d* as the structure for this product also was achieved by extensive NMR decoupling experiments.

The assignment of a β-hydroxyl and an α-methyl group at C-10 in Ic as well as the β-oriented proton at C-1 and the β-oriented hydroxyl group at C-5 in both Ic and I*d* was based on the mechanism involved in the intramolecular cyclization of I*b* to Ic and I*d*, in which the hydroxyl ion could only make a nucleophilic attack at C-10 of a *trans*-C-1–C-10 double bond from the sterically less hindered β-side since the C-5 carbonyl group was β-oriented. Thus, it gave rise to a β-hydrogen and a β-hydroxyl group at C-1 and C-5, respectively.

This evidence led to the establishment of I*b* for dehydromolephantin, I*a* for molephantin acetate, and I for molephantin. Further unequivocal proof of the structure, stereochemistry, and absolute configuration of I





Scheme II

for molephantin was achieved by a single-crystal X-ray analysis of molephantin *p*-bromobenzenesulfonate (Ie, $C_{25}H_{25}BrO_8S$, mp 165–167°) (4).

Molephantinin (II), mp 223–225°, had a composition of $C_{20}H_{24}O_6$ and showed IR, NMR, and mass spectra similar to those of molephantin (I), except for the difference in the acid portion of the ester side chain. The ester moiety in II was identified as a tigloyl group instead of a methacrylate as in I. This assignment was based on the characteristic NMR signals shown in II for the tigloyl group as the broad vinyl multiplets at δ 6.92 (1H, H-19) and the vinyl methyl multiplets at δ 1.83 (6H, H-18 and H-20) (11, 12), as well as a base peak in the mass spectrum at *m/e* 83 due to the cleavage of a tiglic acid ester (13).

Molephantinin yielded an acetate [IIa, mp 131°, $C_{22}H_{26}O_7$ (*m/e* 402.1670, M^+)] upon acetylation with acetic anhydride in pyridine and a dehydro derivative (IIb, mp 136°, $C_{20}H_{22}O_6$) upon oxidation with Jones reagent. The IR, NMR (Table II), and mass spectral data, especially the data obtained from the extensive NMR decoupling experiments[6], of molephantinin, molephantinin acetate, and dehydromolephantinin were in accordance with the assigned structures of II, IIa, and IIb, respectively. The circular dichroism curve of II showed a strong positive Cotton effect at 244 nm, indicating that molephantinin possessed the same stereochemistry and absolute configuration as molephantin. Accordingly, molephantinin acetate and dehydromolephantinin carried exactly the same stereochemistries as those of molephantin acetate (Ia) and dehydromolephantin (Ib), as depicted in IIa and IIb.

Phantomolin (III) was isolated as a colorless oil and had a composition of $C_{21}H_{26}O_6$ on the basis of high-resolution mass spectrometry (M^+ at *m/e* 374.1880). It was an α-methylene-γ-lactone compound [IR (chloroform) bands at 1770 and 1664 cm^{-1}] and contained a methacrylate ester (1719 and 1640 cm^{-1}) side chain. The NMR spectrum (Table II) confirmed these assignments, showing the α-methylene group of the γ-lactone at δ 6.33 (d, J = 3.0 Hz) and 5.80 (d, J = 3.0 Hz) and the methacryl methyl group at C-17 as a multiplet at δ 1.99 and the two protons at C-19 as multiplets at δ 6.17 and 5.72. The assignment of the one-proton signals at δ 5.25 ($J_{5,6}$ = 4.0 Hz) for H-5, 4.65 (dd, $J_{5,6}$ = 4.0 and $J_{6,7}$ = 6.0 Hz) for H-6, 3.14 (m) for H-7, and 5.24 (m) for H-8 was based on decoupling experiments. Thus, irradiation at the frequency of H-7 at δ 3.14 collapsed two doublets for H-13 to two singlets, changed the doublet of doublets at δ 4.65 to a doublet with J = 4.0 Hz, and sharpened the multiplet at δ 5.24 for H-8. Conversely, irradiation at H-6 sharpened the H-7 and H-8 multiplets.

Irradiation at δ 5.25 (H-5) converted H-6 to a doublet with $J_{6,7}$ = 6.0 Hz. The one-proton broad singlet at δ 5.51 was assigned to H-1 since, upon irradiation of the C-10 methyl group (δ 1.79, d, J = 1.5 Hz), it gave rise to a sharp singlet. The remaining low-field one-proton multiplet at δ 5.67 then was assigned to H-3, which coupled with the C-4 methyl group (δ 1.73, m). The characteristic two-proton quartet (J = 7.0 Hz) at δ 3.48 and the three-proton triplet (J = 7.0 Hz) at δ 1.20 were assigned to an *O*-ethyl group[7]. The location of this group at C-2 rather than C-9 was suggested by the fact that no known germacranolide contained oxygenation at C-9. This assignment also was substantiated by a one-proton multiplet at δ 5.24 for H-8, indicating two protons at C-9. Thus, the last oxygen was placed between C-2 and C-5 as an ether linkage, as shown in III.

Consideration of the cooccurrence of phantomolin (III), molephantin (I), and molephantinin (II) suggested the similar *trans*-axial arrangement among protons at C-6, C-7, and C-8. If the configuration of H-6 was β-oriented, as was likely, then H-7 was α and H-8 was β. The coupling constants of $J_{6,7}$ = 6.0 Hz and $J_{5,6}$ = 4.0 Hz were suggestive of the approximate dihedral angles of 38 and 128° for H-6 and H-7 and 51 and 122° for H-5 and H-6. A Dreiding model indicated the feasibility of only one conformation, *i.e.*, with H-5 as β-oriented, CH_3CH_2O as β-oriented and a C-10 vinyl methyl group *cis* to H-1, as shown in IIIb in which the dihedral angles were ~128° for H-6 and H-7 and ~50° for H-5 and H-6.

Further proof of the structure and relative stereochemistry of III was achieved by an X-ray analysis (6) of a *cis*-1,10-epoxide of phantomolin (IIIa), prepared from epoxidation of III with *m*-chloroperbenzoic acid in chloroform.

Fractionation of the inactive hexane extract (Scheme I) led to the isolation of four colorless crystalline substances, IV (mp 239–241°, $C_{32}H_{52}O_2$), V (mp 218°, $C_{32}H_{52}O_2$), VI (mp 285°, $C_{30}H_{50}O$), and VII (mp 170°, $C_{29}H_{48}O_2$), which were identified as triterpenes β-amyrin acetate, lupeol acetate, epifriedelanol, and stigmasterol, respectively (15, 16).

The *in vitro* cytotoxic molephantin, molephantinin, and phantomolin were tested for *in vivo* antitumor activity against four tumor lines (7). As shown in Table I, molephantinin and phantomolin were potent inhibitors of Walker 256 ascites carcinosarcoma in Sprague–Dawley rats at 2.5 mg/kg/day and of Ehrlich ascites tumor in CF_1 male mice at 33.3 mg/kg/day. Molephantinin also showed significant (T/C ≥ 125%) antileukemic activity in the P-388 lymphocytic leukemia screen at T/C = 146% (DBA/2 mice at 25 mg/kg/day). Further studies on the structure–activity relationships and mechanism of action among compounds related to molephantinin and phantomolin are in progress (17).

EXPERIMENTAL[8]

Isolation of Molephantin (I), Molephantinin (II), and Phanto-

[6] Data on NMR decoupling experiments of molephantinin acetate were reported previously (5).

[7] The presence of an ethyl ether is novel and appears to represent the first example in naturally occurring germacranolides and the second instance of the sesquiterpene lactone lactal hymenolide (14).

[8] Unless otherwise specified, melting points were determined on a Thomas-Hoover melting-point apparatus and are uncorrected. Specific rotations were taken on a Perkin-Elmer model 141 polarimeter (1 = 1 dm). IR spectra were recorded with a Perkin-Elmer 257 grating IR spectrometer in chloroform. NMR spectra were determined in deuterochloroform with a Varian XL-100 NMR spectrometer (tetramethylsilane as the internal standard). Mass spectra were determined on an A.E.I. MS-902 instrument at 70 ev using a direct-inlet system. Circular dichroism was measured on a Cary model 60 spectrometer. Silica gel was used for column chromatography (Mallinckrodt CC-7, 200–325 mesh), TLC (Merck silica gel G), and preparative TLC (Merck silica gel GF 254, 2000 μm). Elemental analyses were performed by Atlantic Microlab, Atlanta, Ga.

molin (III) from *E. mollis*—The *E. mollis* (Compositae) used was from a collection made in January 1973 in Chia-Sen, Kaohsiung, Taiwan[9]. The ground, air-dried, whole plant material (4.33 kg) was extracted exhaustively with ethanol. Guided by the bioassay in KB cells (Scheme I and Table I), the final active chloroform extract (35 g, Fraction G) was chromatographed on silica gel[10] (100 mesh, 7 × 32-cm column) with chloroform, chloroform–acetone (1:1), and acetone as the eluting solvents. Fractions of 1 liter each were collected and examined by TLC.

Fractions 1–4 gave traces of residue upon solvent evaporation. Fractions 5–10 yielded 1.44 g of colorless needles, which later proved to be a 1:1 mixture of I and II after a careful NMR analysis, although they showed only a single spot with different solvent systems. Rechromatography of the mother liquor (9 g) after the isolation of the mixture on a silica gel column (3 × 50 cm) in chloroform (1.5 liters) afforded 270 mg of the same mixture as crystalline solids. A final separation of this mixture was achieved by column chromatography on silica gel (4 × 60-cm column) and elution with chloroform to yield 550 mg (0.011%) of pure II from the first 450 ml of the chloroform eluate and 1.26 g (0.025%) of pure I from the second 600 ml of the chloroform eluate. The mother liquors (5 g), after the isolation of pure I and II, were combined and rechromatographed on silica gel (70–230 mesh, 4 × 70-cm column). The chloroform eluates, which showed a new spot different from I and II on TLC, were combined and chromatographed again on silica gel (70–230 mesh, 2.6 × 60-cm column). Evaporation of the solvent resulting from elution with benzene–chloroform (3:2) yielded pure III (1.035 g, 0.023%).

Isolation of I–III from spring growth of the same plant (collected on March 19, 1972 at the same site) using the described procedure gave rise to different yields, *i.e.*, 0.0199% of I, 0.0086% of II, and 0.015% of III.

Molephantin (*I*)—Molephantin was recrystallized from chloroform–ethyl acetate, mp 212–213°; mass spectrum: *m/e* 346 (M^+), 328.1305 (M − 18) ($C_{19}H_{20}O_5$ requires 328.1311), and 69 [base peak, $CH_2{=}C(CH_3)CO^+$]. Table II shows the NMR data.

Anal.—Calc. for $C_{19}H_{22}O_6$: C, 65.88; H, 6.40. Found: C, 66.48; H, 6.67.

Molephantin Acetate (*Ia*)—Molephantin (10 mg) was acetylated with acetic anhydride (0.2 ml) and pyridine (0.2 ml) for 15 hr at room temperature to yield 10 mg of Ia after usual workup and one recrystallization from ether, mp 169°; IR: 1770, 1745, 1720, 1650, and 1620 cm^{-1}; mass spectrum: *m/e* 388.1522 (M^+, $C_{21}H_{24}O_7$ requires 388.1527), 346 [M − 42 ($COCH_3$)], 328 [M − 60 (CH_3COOH)], 319 [M − 69 [$COC(CH_3){=}CH_2$]], 302 [M − 86 [$HOOCC(CH_3){=}CH_2$]], 277 (M − 42 − 69), 260 (M − 42 − 86), 242 (M − 60 − 86), and 69. The NMR data are shown in Table II.

Anal.—Calc. for $C_{21}H_{24}O_7$: C, 64.93; H, 6.23. Found: C, 64.84; H, 6.38.

Dehydromolephantin (*Ib*)—A solution of molephantin (300 mg) in acetone (5 ml) was cooled to 5–10° with stirring and treated with 20 drops of Jones' reagent. After 5 min, methanol (5 ml) was added and the solution was extracted with ether. The ethereal extract was washed with water, dried (anhydrous sodium sulfate), and evaporated *in vacuo* to afford Ib (145 mg) as colorless prisms after one recrystallization from acetone–ether (1:2), mp 132–133°; IR (mineral oil): 1770, 1720, 1705, 1660, and 1640 cm^{-1}; mass spectrum: *m/e* 344.1256 (M^+, $C_{19}H_{20}O_6$ requires 344.1260). The NMR data are shown in Table II.

Treatment of Dehydromolephantin with Sulfuric Acid: Compounds Ic and Id—A mixture of dehydromolephantin (70 mg) in 0.5% sulfuric acid–acetone (5 ml) was stirred for 30 min at room temperature. The mixture was evaporated *in vacuo*, extracted with chloroform, and dried (anhydrous sodium sulfate). The dried chloroform extract was evaporated to furnish a residue showing two spots on TLC. Separation of this residue was achieved by preparative TLC [chloroform–acetone (10:1)] to yield Ic (14 mg) as colorless prisms (from ether) and Id (40 mg) as colorless needles (from ether).

For Ic, the analytical data were: mp 168–170°; IR (chloroform): 3530, 3410, 1772, 1712, 1692, and 1629 cm^{-1}; mass spectrum: *m/e* 362 (M^+) and 344.1265 (M − 18) ($C_{19}H_{20}O_6$ requires 344.1260). The NMR data are given in Table II.

For Id, the analytical data were: mp 188–189°; IR: 3400, 1770, 1713 (double strength), 1650, and 1625 cm^{-1}; mass spectrum: *m/e* 344.1256 (M^+, $C_{19}H_{20}O_6$ requires 344.1260). The NMR data are given in Table II.

Molephantin p-*Bromobenzenesulfonate* (*Ie*)—A solution of molephantin (25 mg) in dry pyridine (0.5 ml) was added with *p*-bromobenzenesulfonyl chloride (35 mg), and the reaction mixture was allowed to stand at 5°. After 12 hr, the mixture was diluted with water and extracted with chloroform, dried, and evaporated to give a product. Recrystallization from isopropanol–ether (1:1) afforded colorless needles, mp 165–167°.

Molephantinin (*II*)—The analytical data for II were: mp 223–225° (ethanol); IR: 3420, 1775, 1713, 1650, and 1615 cm^{-1}; mass spectrum: *m/e* 360 (M^+), 342.1462 (M − 18) ($C_{20}H_{24}O_6$ requires 342.1467), and 83 [base peak, $CH_3CH{=}C(CH_3)C{=}O^+$]. The NMR data are shown in Table II.

Molephantinin Acetate (*IIa*)—Acetylation of molephantinin (10 mg) with acetic anhydride in pyridine in the usual way gave IIa as colorless prisms in quantitative yield, mp 131° (ether); IR: 1775, 1745, 1713, 1655, and 1615 cm^{-1}; mass spectrum: *m/e* 402.1670 (M^+) ($C_{22}H_{26}O_7$ requires 402.1679), 360 [M − 42 ($COCH_3$)], 342 [M − 60 (CH_3COOH)], and 83 [base peak, $CH_3CH{=}C(CH_3)CO^+$]. The NMR data are shown in Table II.

Dehydromolephantinin (*IIb*)—Molephantinin (26 mg) in acetone (2 ml) was oxidized with Jones' reagent (0.3 ml) in the manner described for Ib. The product was purified by preparative TLC [developed with chloroform–acetone (5:1)] and recrystallized from ether to give IIb (24 mg) as colorless pillars, mp 136°; IR: 1776, 1710, 1660, and 1620 cm^{-1}; mass spectrum: *m/e* 400 (M^+). The NMR data are shown in Table II.

Anal.—Calc. for $C_{20}H_{22}O_6$: C, 67.02; Found: C, 67.25: H, 6.23.

Phantomolin (*III*)—Phantomolin was isolated as a colorless oil; IR: 1770, 1725, 1719, 1664, and 1640 cm^{-1}; mass spectrum: *m/e* 374 (M^+). The NMR data are shown in Table II.

Anal.—Calc. for $C_{21}H_{26}O_6$: C, 67.36; H, 7.00. Found: C, 67.40; H, 6.98.

Phantomolin cis-*1,10-Epoxide* (*IIIa*)—A solution of phantomolin (15 mg) in chloroform (1 ml) was treated with a solution of *m*-chloroperbenzoic acid (20 mg) in chloroform (1 ml), and the mixture was allowed to stand at room temperature for 48 hr. The chloroform was evaporated under reduced pressure, and the residue was dissolved in ether. The ether solution was washed with 1% sodium bicarbonate and water, dried, and evaporated *in vacuo* to yield a product. This product, upon preparative TLC separation, yielded IIIa as colorless needles (6 mg) after one recrystallization from ether-hexane (3:1), mp 172°; IR: 1775, 1725, 1672, 1660, and 1643 cm^{-1}; mass spectrum: *m/e* 390 (M^+). The NMR data are shown in Table II.

Anal.—Calc. for $C_{21}H_{26}O_7$: C, 64,60; H, 6.71. Found: C, 64.31; H, 6.68.

Isolation and Characterization of β-Amyrin Acetate (IV), Lupeol Acetate (V), Epifriedelanol (VI), and Stigmasterol (VII)—The nonpolar *n*-hexane extract (~80 g) was chromatographed on a silica gel column[10] (silicic acid, 100 mesh, 10 × 100 cm) with *n*-hexane and then *n*-hexane–chloroform (9:1) as the eluents.

The first eluate from *n*-hexane was evaporated to dryness. Recrystallization of the residue from *n*-hexane afforded 400 mg of IV as colorless needles, mp 239–241°, $[\alpha]_D^{20}$ +74° (*c*, 1.0 in chloroform). The IR spectrum of IV was identical to that of an authentic sample of β-amyrin acetate[11] (15).

Anal.—Calc. for $C_{32}H_{52}O_2$: C, 81.99; H, 11.18. Found: C, 81.99; H, 11.33.

The second eluate from *n*-hexane was evaporated to dryness. Recrystallization of the residue from *n*-hexane–ether (1:1) afforded V (10 mg) as colorless needles, mp 218°, $[\alpha]_D^{20}$ +40.1° (*c*, 1.0 in chloroform). The IR spectrum (in potassium bromide) of V was identical to that of an authentic sample of lupeol acetate[11].

Anal.—Calc. for $C_{32}H_{52}O_2$: C, 81.99; H, 11.18. Found: C, 81.89; H, 11.00.

The first eluate from *n*-hexane–chloroform (9:1) was evaporated to dryness. Recrystallization of the residue from chloroform gave VI (20 mg) as colorless prisms, mp 285°, $[\alpha]_D^{20}$ +21° (*c*, 1.0 in chloroform). The IR spectrum of VI was superimposable with that of an authentic sample of epifriedelanol[11] (16).

Anal.—Calc. for $C_{30}H_{52}O$: C, 84.04; H, 12.33. Found: C, 84.24; H, 12.43.

The second eluate from *n*-hexane–chloroform (9:1) was evaporated to dryness. Recrystallization of the residue from acetone yielded VII (400 mg) as colorless silky needles, mp 170°, $[\alpha]_D^{20}$ −50.0° (*c*, 1.0 in chloroform); mass spectrum: *m/e* 412 (M^+). A mixed melting point of VII with authentic stigmasterol (16) showed no depression, and the IR spectra were identical.

Anal.—Calc. for $C_{29}H_{48}O_2$: C, 84.40; H, 11.72. Found: C, 84.23; H, 11.79.

Convenient Synthesis of (*S*)-(+)-Apomorphine from (*R*)-(−)-Apomorphine

PATRICK J. DAVIS *, SELIM SEYHAN *, WILLIAM SOINE ‡§, and ROBERT V. SMITH ‡x

Received May 7, 1979, from the **Division of Pharmaceutical Chemistry and the* ‡*Drug Dynamics Institute, College of Pharmacy, University of Texas at Austin, Austin, TX 78712.* Accepted for publication June 1, 1979. §Present address: Department of Medicinal Chemistry, School of Pharmacy, Virginia Commonwealth University, Richmond, VA 23298.

Abstract □ A method was devised for preparing (*S*)-(+)-apomorphine from (*R*)-(−)-apomorphine. Dehydrogenation of the dimethyl ether of (*R*)-(−)-apomorphine with 10% palladium-on-carbon followed by reduction with sodium cyanoborohydride under acidic conditions resulted in quantitative racemization to give (*R,S*)-apomorphine dimethyl ether, which then was resolved with (−)-tartaric acid. Ether cleavage of (*S*)-(+)-apomorphine dimethyl ether (−)-tartrate with hydriodic acid in acetic anhydride yielded (*S*)-(+)-apomorphine, which was isolated as the hydrochloride salt in 99% enantiomeric excess.

Keyphrases □ Apomorphine—synthesis of (*S*)-(+)-stereoisomer from (*R*)-(−)-stereoisomer □ Dopaminergic agonists—apomorphine, synthesis of (*S*)-(+)-stereoisomer from (*R*)-(−)-stereoisomer □ Stereoisomers—apomorphine, synthesis of (*S*)-(+)-stereoisomer from (*R*)-(−)-stereoisomer

Current interest in apomorphine (I) stems from its activity as a dopaminergic agonist and its consequential antiparkinsonism activity (1–3). Clinical utility has been demonstrated for I alone and in combination with other agents such as levodopa (4). Further studies are aimed at preparing suitable prodrug derivatives to overcome the drawbacks to its use (5). In addition to parkinsonism, recent studies indicated potential new uses for I in ameliorating the symptoms of Huntington's chorea (6), tardive dyskinesia (7), Gilles de la Tourette's syndrome (8), and schizophrenia (9, 10).

BACKGROUND

Most work to date involved the use of (−)-apomorphine (*R*-configuration), synthesized commercially by the acid-catalyzed rearrangement of (−)-morphine (11). Investigations into the pharmacological properties of (*S*)-(+)-apomorphine (II) have been limited to *in vivo* assays including dog emesis, a caudate brain-lesioned mouse preparation (12, 13), and evaluation of the racemate in comparison to (*R*)-(−)-I in these assays as well as on overt behavior in the monkey (13, 14). Previous reports utilized a *de novo* synthesis of (*R,S*)-I *via* Pschorr cyclization followed by resolution of the racemate (12, 15).

Molecular pharmacologists have extended the knowledge of dopaminergic mechanisms by the examination of several receptor assays, culminating in the postulation of several distinct dopamine receptors (16). Along with other criteria, these receptors are distinguished from one another by the differential action of dopaminergic agonists and antagonists, including (*R*)-(−)-I. Thus, apparently difficult to rationalize effects, such as the improvement of schizophrenic symptoms with exceedingly low doses of I, possibly can be understood on the basis of presynaptic dopamine receptors modulating dopaminergic transmission and, consequently, postsynaptic dopaminergic activity (9).

Because of the renewed interest in apomorphine pharmacology and the known differential receptor activity of stereoisomeric pharmacological agents (17), a reexamination of the two antipodes of I was desired. Also, a more direct method was sought for the synthesis of II from the commercially available (*R*)-(−)-antipode rather than the *de novo* synthesis. The synthesis of II reported here is patterned after an earlier procedure for racemization of the related aporphine alkaloid glaucine (18).

EXPERIMENTAL

hydride[4] were used without further purification. All other solvents and reagents were analytical reagent grade or better.

Spectral Studies—PMR spectra were obtained on a 60-MHz[5] or a 100-MHz[6] spectrometer, and chemical shifts are reported relative to tetramethylsilane. Optical rotations were analyzed on a spectropolarimeter[7]. Melting points were taken on a digital melting-point analyzer[8] and are corrected. Mass spectra were obtained on a medium-resolution mass spectrometer[9] by direct-probe insertion.

TLC was performed on 0.25-mm silica gel plates[10] that were developed with benzene–methanol (4:1). Plates were visualized under short (254 nm) and long (280 nm) wavelength UV light. GLC of apomorphine was conducted as its *O,O*-heptafluorobutyryl derivative as described previously (19). Apomorphine dimethyl ether also was analyzed using this GLC procedure.

Synthesis of (*R*)-(−)-Apomorphine Dimethyl Ether (III)—(*R*)-(−)-Apomorphine hydrochloride was converted to III by the method of Neumeyer *et al.* (13) using ethereal diazomethane. The free base was crystallized from *n*-hexane[11] to yield pale-yellow needles, mp 75–77° [lit. (20) mp 77.5–79°], $[\alpha]_D^{22}$ −142° (*c*, 1.59 in absolute ethanol) [lit. (21) $[\alpha]_D^{22}$ −148° (*c*, 1.64 in absolute ethanol)]; PMR (100 MHz, $CDCl_3$): δ 2.54 (s, 3H, *N*-CH_3), 2.15–3.30 (m, 7H, aliphatic), 3.71 (s, 3H, C_{11}-OCH_3), 3.88 (s, 3H, C_{10}-OCH_3), 6.84 (m, 2H, H-8 and H-9), 7.07 (m, 1H, H-2), 7.25 (m, 1H, H-3), and 8.25 (dd, 1H, H-1), identical in all respects to the reported spectrum (15); mass spectrum: *m/e* (%) 295 (68) (M^+), 294 (100), 281 (20), 264 (18), and 252 (18).

Synthesis of 6a,7-Dehydroapomorphine Dimethyl Ether (IV)—Compound III (2 g, 6.8 mmoles) was refluxed with 2 g of 10% palladium-on-carbon in 100 ml of acetonitrile under a dry nitrogen atmosphere according to the method of Cava *et al.* (22). TLC analysis indicated complete conversion in 8 hr (R_f of III = 0.50, R_f of IV = 0.85). The catalyst was removed by filtration through sintered glass and was washed repeatedly with acetonitrile. The filtrate was taken to dryness *in vacuo* to give a dark-green oil (1.9 g). This product gave a single spot on TLC and was used without further purification; PMR (60 MHz, $CDCl_3$): δ 3.09 (s, 3H, *N*-CH_3), 3.35 (s, 4H, CH_2CH_2), 3.94 (s, 3H, C_{11}-OCH_3), 4.00 (s, 3H, C_{10}-OCH_3), 6.68 (s, 1H, H-7), 7.0–7.6 (m, 4H, aromatic), and 9.65 (dd, 1H, H-1); mass spectrum: *m/e* (%) 293 (100) (M^+), 278 (80), 263 (12), 250 (25), and 235 (50).

Synthesis of (*S*)-(+)-Apomorphine Dimethyl Ether (V)—Compound IV (1.9 g, 6.5 mmoles) was dissolved in 250 ml of absolute ethanol with heat. The solution and the reaction mixture to follow were purged continuously with dry nitrogen and constant stirring. Sodium cyanoborohydride (2.0 g, 32 mmoles) was added, and the reaction was initiated and maintained at an apparent pH of 5.0 by periodic additions of ethanolic hydrochloric acid. After 18 hr, an additional 2 g of sodium cyanoborohydride was added and the reaction was allowed to continue for 2 hr, at which time TLC analysis indicated a complete conversion to (*R,S*)-apomorphine dimethyl ether. The reaction mixture was taken to dryness *in vacuo*, and the residue was solubilized in 150 ml of water, alkalinized with potassium carbonate, and extracted with ethyl acetate (3 × 200 ml). The organic layer was washed with 50 ml of water, dried with anhydrous sodium sulfate, and taken to dryness *in vacuo* to give a gold oil (1.85 g), $[\alpha]_D^{22}$ −9.2° (*c*, 1.5 in absolute ethanol, indicating 97% racemization). The PMR and mass spectra were identical to those given for III.

The racemate (1.85 g) was dissolved in 10 ml of absolute ethanol and filtered. A filtered solution of 1.2 g (−)-tartaric acid (8.0 mmoles) in 17 ml of absolute ethanol was added, and the cloudy solution was heated to clarification. The white granular crystals that separated (1.15 g) were washed with ethyl acetate and recrystallized repeatedly from absolute ethanol to yield 0.635 g of (*S*)-(+)-apomorphine dimethyl ether (−)-tartrate, $[\alpha]_D^{22}$ +62.1° (*c*, 2.06 in water) [lit. (12) $[\alpha]_D^{22}$ +64.0° (*c*, 1 in water)], mp 189–191° dec. [lit. (12) mp 179–184° dec.]. Authentic (*R*)-(−)-apomorphine dimethyl ether (+)-tartrate prepared from pure (*R*)-(−)-IV (prepared as described) gave $[\alpha]_D^{22}$ −60.0° (*c*, 1 in water) [lit. (12) $[\alpha]_D^{22}$ −59.6° (*c*, 1 in water)], mp 186–187° [lit. (12) mp 177–183°].

***S*-(+)-Apomorphine (II) Hydrochloride**—The free base V was generated from 300 mg of the (−)-tartrate salt prepared by extraction from 10 ml of saturated sodium bicarbonate solution with ethyl acetate (3 × 25 ml). The organic layer was washed once with 10 ml of water, dried *in vacuo*, and dried further by azeotroping twice with 10 ml of benzene. The ether functions were cleaved using hydriodic acid–acetic anhydride according to the method of Neumeyer *et al.* (15) as modified by Saari *et al.* (12). The reaction was monitored by TLC and was complete in 30 min. The reaction was adjusted carefully to pH 7–8 with saturated sodium bicarbonate containing 20 mg of dithionite as an antioxidant and exhaustively extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate and taken to dryness *in vacuo*.

The product was dissolved in ether and filtered, and hydrogen chloride was passed through to yield the hydrochloride salt as a white powder. This powder was collected by filtration and dried *in vacuo* at 65° for 18 hr to give 104 mg (50%) of II·HCl, $[\alpha]_D^{22}$ 47.4° (*c*, 1.13 in 0.02 *N* HCl) [(*R*)-(−)-apomorphine hydrochloride gave $[\alpha]_D^{22}$ −48.7°; lit. (23) $[\alpha]_D^{22}$ −49–−51°], indicating 99% enantiomeric excess. UV comparison to (*R*)-(−)-apomorphine indicated 98.8% purity (λ_{max} 275 nm, ε 17,300), mp 249–260° dec. [lit. (12) mp 258–268° dec.]; mass spectrum: *m/e* (%) 267 (78) (M^+), 266 (100), 250 (22), 224 (34), and 221 (23), identical to the spectrum of (*R*)-(−)-apomorphine hydrochloride. GLC analysis indicated cochromatography with authentic (*R*)-(−)-apomorphine [as the heptafluorobutyryl derivative (19)] and >99% purity.

RESULTS AND DISCUSSION

Interest in racemizing and resolving aporphines continues because naturally occurring aporphines and aporphines generated from natural products [*e.g.*, (−)-apomorphine from (−)-morphine (11)] usually exist as single antipodes. A recent study (24) allowed for the racemization and resolution of the catatonic aporphine (+)-bulbocapnine by a route similar to that described in this study (Scheme I).

This reported preparation of (*S*)-(+)-apomorphine represents a facile conversion of the readily available (*R*)-(−)-antipode rather than a *de novo* synthesis of the aporphine skeleton by Pschorr cyclization (12, 15). Due to the instability of the catechol, a protecting group was necessary for subsequent reactions; the dimethyl ether was chosen because of its ease of preparation and subsequent removal (12, 15).

The racemization of III was accomplished in the manner used previously for the preparation of racemic glaucine, which involved oxidation to the dehydroaporphine followed by nonstereospecific reduction (18). While the first step was accomplished earlier by oxidation with iodine and sodium acetate (25) or with mild permanganate oxidation (26), the method described recently (22) of refluxing the aporphine in acetonitrile with 10% palladium-on-carbon proved to be a clean and facile route to IV. The dehydroaporphine corresponding to III exhibited a characteristic PMR spectrum consisting of a relatively deshielded *N*-methyl substituent (δ 3.09 *versus* 2.54 in III) as well as the signal for the H-1 proton (δ 9.65 *versus* 8.25 in III) (26). In addition, the four H-4 and H-5 protons of IV resonated as a broad singlet (δ 3.35) and the H-7 proton resonated as a singlet at δ 6.68. The same characteristics were observed in 6a,7-dehydroglaucine (18) and *O,O*-diacetyl-6a,7-dehydroapomorphine (27).

The dehydroaporphine IV is reduced easily using sodium cyanoborohydride at acidic pH, probably due to an increased development of 6,6a-quaternary imine character under acidic conditions. Other reduction methods such as dissolving metal (28) and catalytic reduction with Adam's catalyst in acetic acid have been used. Some investigators reported a sluggish reaction in the latter case (28). The sodium cyanoborohydride procedure provided a facile and nearly quantitative racemization of IV with inexpensive reagents. The method of Kametani *et al.* (29) also has been used for similar reactions, but this method requires longer reaction times, an apparatus for hydrogenation at atmospheric pressure, and, in most cases, a weight of the expensive Adam's catalyst equal to the weight of the alkaloid.

Resolution of the racemate of apomorphine dimethyl ether was accomplished in a manner similar to that of Saari *et al.* (12). In the present study, however, oiling was encountered repeatedly using ethanol–ethyl acetate as recommended by these investigators (12). Recrystallization from ethanol ultimately was more satisfactory. Repeated recrystallization gave V as the (−)-tartrate salt in 99% enantiomeric excess. The protecting groups were removed by hydriodic acid in acetic anhydride (12, 15). In alternative experiments, TLC and GLC evidence indicated smooth cleavage using boron tribromide in methylene dichloride using a literature method (30) (*i.e.*, when the solvent was not freed of ethanol prior to use).

The (*S*)-(+)-apomorphine hydrochloride isolated through the reactions indicated in Scheme I was in >99% enantiomeric excess and was >98% pure by UV spectroscopy when compared to authentic I. Considerable variability of the optical rotation was observed with high dilutions of the salt (from −74° at *c* 0.16 to −49° at *c* 1.03 or above in 0.02 *N* HCl). Thus, a minimum *c* value of 1.0 was necessary for obtaining accurate optical rotation data. This phenomenon may be attributable to the salt–free base equilibrium, which favors the latter at high dilution. Indeed, when samples were run in 0.2 *N* HCl, lower values were obtained (−63–−47° for the concentration range).

The (*S*)-(+)-compound prepared was submitted for preliminary *in vitro* pharmacological evaluation. In the presynaptic dopaminergic receptor assay of Steinsland and Heible (31), the agent exhibits 1% of the activity of (*R*)-(−)-I, as expected based on its optical purity and its expected inactivity as a dopaminergic agonist (12). However, preliminary results in the receptor assay of Seeman *et al.* (32) show an unexpected affinity similar to that of I. Complete pharmacological evaluation of II will be the subject of a subsequent report from these laboratories.

Topographical Model of the Renal Vascular Dopamine Receptor

PAUL W. ERHARDT

Received April 27, 1979, from the *Department of Pharmaceutical Research, Arnar-Stone Laboratories, McGaw Park, IL 60085.* Accepted for publication December 6, 1979.

Abstract □ Based on review and examination of recent additions to dopaminergic structure–activity relationships, a topographical model of the renal vascular dopamine receptor is presented. The implications of this model for the design of new dopaminergic drug candidates are discussed briefly.

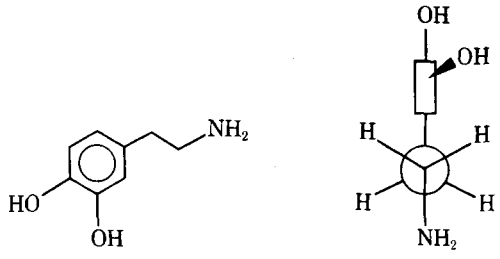
Keyphrases □ Dopamine—topographical model of renal vascular receptor □ Drug–receptor interactions—topographical model of renal vascular dopamine receptor □ Structure–activity relationships—dopaminergic drugs

Several reports (1–4) suggested that the preferred conformation for dopamine, when it is interacting with its biological receptor sites, resembles the fully extended *trans*-form (I). In this conformation, the catechol ring and amine function are in an antiperiplanar arrangement. Cannon and coworkers (5–7) suggested that a biologically significant conformer has the *m*-hydroxy group rotated toward the amine, as depicted in I. This arrangement has been designated as the α-rotamer, and the antiperiplanar conformation having the *m*-hydroxy group rotated away from the amine function has been designated as the β-rotamer (5). Both a dihedral angle approximating 180° (8, 9) and near coplanarity (5, 7) of the catechol ring and ethylamine system have been implicated as important structural features for dopaminergic activity.

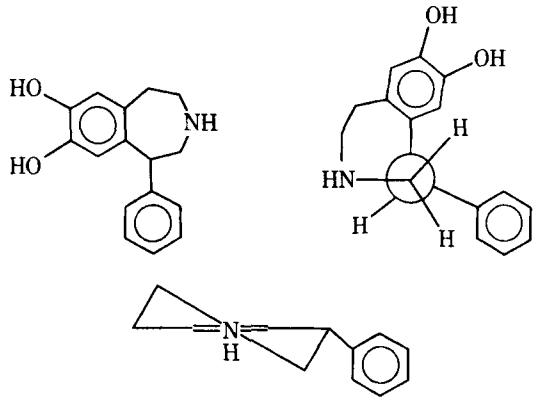
BACKGROUND

The benzazepine derivative II recently was reported to possess significant renal dopaminergic-mediated vasodilator properties[1] (10). In this molecule, the catechol and amine functions can exist only in *gauche* and eclipsed conformations, while the phenyl ring and amine system can assume a nearly antiperiplanar arrangement. Although there are examples of nonoxygenated 2-aminotetralins that show central dopaminergic activity (11, 12), there is no precedent for such systems having renal dopaminergic activity where an intact catechol function appears to be a requisite structural feature for agonist action. Therefore, the pharmacological profile for II seems to contradict the hypothesis that an antiperiplanar arrangement of the key pharmacophoric groups is important in determining dopaminergic activity. Alternatively, as shown in its side view, there is a partially eclipsed conformation for II in which the amine function lies within the plane established by the catechol ring.

Examination of various dopamine agonists reveals that aryl–amine coplanarity or very near coplanarity is a feature common to all of the agents, whereas the dihedral angle varies considerably. Even certain 2-



I



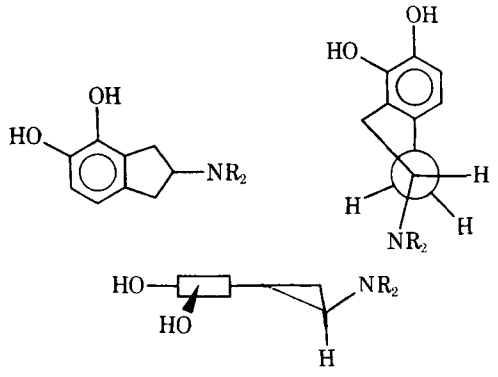
II

indanamine derivatives (III), previously regarded as an enigma (3, 5), possess aryl ring–amine coplanarity when assuming an envelope conformation (13).

In addition to coplanarity, structure–activity relationships indicate that specific nitrogen to hydroxyl group distances are optimal for interaction with certain dopaminergic receptor populations (5, 9, 14). Because of the noted differences in dopamine receptors (15–19), it is important to specify which receptor population is under consideration when addressing this structural parameter. Table I indicates the nitrogen to *p*-hydroxy and nitrogen to *m*-hydroxy distances and the renal dopaminergic activity for several dopamine analogs. In active compounds, the *m*- and *p*-hydroxy groups reside ~7–8 Å away from the amine function. Apomorphine, which has a somewhat shorter nitrogen to *m*-hydroxy group distance, is an exception. However, its pharmacological profile also is somewhat different; apomorphine is best classified as a weak, partial agonist in the renal dopaminergic system (16). Furthermore, its activity may be partially derived from additional binding contributions from its molecular portions outside of its apparent dopaminergic pharmacophore (17).

More interesting is the inactivity observed for isoapomorphine, which satisfies both coplanarity and amine–hydroxy group distance criteria. Two receptor models were proposed to account for this finding. Grol and Rollema (21) suggested that a receptor boundary is present which hampers interaction with molecules bearing bulky groups on the side of the molecule opposite the *m*-hydroxy group. Goldberg *et al.* (16, 17) also attributed isoapomorphine inactivity to a steric parameter and further emphasized an improper orientation of its amine free electron pair for preferred interaction with a stereospecific amine recognition site on the receptor.

Recent experiments in these laboratories provided additional insight into dopaminergic structure–activity relationships. The synthesis (24,



III

[1] Comparison between intravenous injection of II and injection of II directly into the renal artery (10) indicates that II itself is an active drug and not dependent on aromatic hydroxylation or any other metabolic process for its activation.

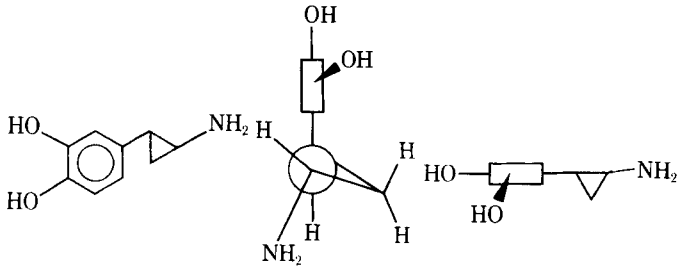
Table I—Amine-to-Hydroxy Group Distances [a] for Selected Dopamine Analogs [b]

Compound	Distance, Å		Renal Dopaminergic Activity
	Nitrogen to *p*-Hydroxy	Nitrogen to *m*-Hydroxy[c]	
Apomorphine	7.8	6.5	Partial agonist (16)
Isoapomorphine	7.8	7.3	Inactive (16, 17)
Tetrahydroisoquinolines[d]	6.0	6.4	Inactive (14)
II	7.0	7.0	Active (10)
Dopamine, antiperiplanar, β-rotamer	7.8	7.3	Active[e]
Dopamine, partially eclipsed[f]	7.0	7.0	Active [g]
2-Amino-6,7-dihydroxytetralin[h]	7.8	7.3	Active (14)
2-Amino-5,6-dihydroxytetralin[h]	7.8	6.5	Inactive (14)
IV	7.7	7.4	Inactive (23)

[a] Determinations agree with various literature values within ±0.1 Å (3–5, 20, 21). [b] All compounds can possess aryl ring–amine coplanarity or near coplanarity. [c] Analogous to the *meta*- and *para*-positions of dopamine. [d] 6,7-Dihydroxytetrahydroisoquinoline and *N*-methyl-6,7-dihydroxytetrahydroisoquinoline. Although the preferred conformations for these systems are such that the amine function resides above or below the plane of the aromatic ring (22), coplanarity of these groups is not thermodynamically precluded, especially when considering that drug–receptor associations may produce a net energetically favored situation. [e] The β-rotamer is thought (14) to be optimal for interaction with renal dopaminergic receptors. [f] Conformation superimposed on that depicted for II. [g] By analogy to II. [h] Determined with the nitrogen in a pseudo-equatorial orientation, as is thought to be the active conformer (6, 9).



IV

25) and pharmacological activity (23, 25, 26) of *E*- and *Z*-2-(3,4-dihydroxyphenyl)cyclopropylamines, two semirigid analogs of dopamine, were reported. Since the *E*-isomer (IV) is similar to conformer I in terms of aryl–amine coplanarity, its inactivity as a renal dopaminergic agonist or antagonist was surprising. However, the additional steric bulk resulting from incorporation of the methylene unit forming the cyclopropyl system resembles that present in α-methyldopamine, which also is inactive as a renal dopaminergic agonist (27). In α-methyldopamine and in IV, the bond between the β-carbon and the aryl ring is free to rotate such that both the α- and β-rotameric conformers are accessible. Furthermore, this rotation should proceed with minimal thermodynamic constraint; conformational considerations, therefore, seem an unlikely explanation for the inactivity of these compounds.

Alternatively, if one observes IV from the side as shown, it is apparent that the methylene unit protrudes perpendicularly out from the plane established by the aryl ring and amine function. This protrusion results in a molecular thickness of ~2 Å midway between the aromatic ring and the amine moiety. If a steric boundary were localized in a corresponding location above the receptor, then this protrusion would be expected to preclude effective receptor binding. The fact that this boundary must be localized specifically in this region is apparent from the activity observed for compounds such as apomorphine, 2-amino-6,7-dihydroxytetralin, and II, whose somewhat smaller but similar bulk in this region is directed toward the α- and β-carbons. Interestingly, Sheppard and Burghardt (28), employing Newman projections, also referred to a steric parameter localized specifically in the "9 o'clock position" to explain certain structure–activity relationships observed for aryl-substituted analogs derivatized in the 2-position.

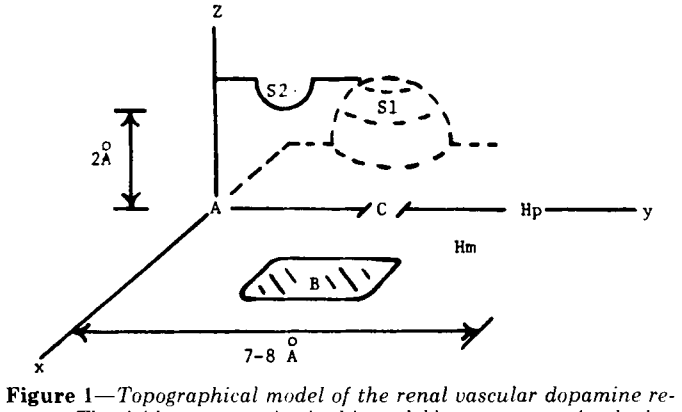


Figure 1—*Topographical model of the renal vascular dopamine receptor. The rigid representation in this model is not meant to imply that a more dynamic relationship, such as mutual molding, is not operative during drug–receptor interaction.*

THEORETICAL

Combining the structural parameters discussed affords a three-dimensional map (29) of the renal dopamine receptor that contains the following topographical features (Fig. 1):

1. A single plane containing amine (A) and catechol (Hm, Hp, and C) recognition sites.
2. A distance between the amine recognition site and *p*- (Hp) and *m*- (Hm) hydroxy group recognition sites of ~7–8 Å.
3. A steric parameter (S1) located to one side of the principal pharmacophoric recognition site. Depending on the α- or β-rotameric relationship, this parameter could limit the bulk on the side opposite to the *m*-hydroxy group of molecules attempting to align with the receptor properly (21). An additional hydrophobic binding region (B) located on the same side as the analogous *m*-hydroxy group also may be present in the plane established by A, C, Hp, and Hm (17).
4. A second steric parameter (S2) located ~2 Å above the plane of the receptor and localized specifically along the analogous α- and β-carbon chain region.

DISCUSSION

Although conceptual in nature, topographical mapping of receptors can be useful in the design of new drug entities. In this regard, the receptor model described here implies that new renal dopaminergic structural candidates should possess overall planarity and a somewhat narrow molecular thickness, especially in the analogous α- and β-carbon region. Concern about an appropriate dihedral angle or even about a classical two-carbon bridge between the amine and aromatic functions is not necessary as long as key nitrogen-to-catechol hydroxyl group distances are maintained. Furthermore, significant steric bulk opposite the position analogous to the dopamine *m*-hydroxy group should be avoided, while incorporation of hydrophobic character on the same side as the analogous *m*-hydroxy group could be beneficial for receptor binding.

Thalifaurine and Dehydrodiscretine, New Quaternary Protoberberines from *Thalictrum fauriei*

CHUNG-HSIUNG CHEN ˣ, TZER-MING CHEN, and CHRISTINE LEE

Received March 26, 1979, from the *School of Pharmacy, National Taiwan University, Taipei, Taiwan, Republic of China.* Accepted for publication May 4, 1979.

Abstract □ Two new quaternary protoberberines, thalifaurine and dehydrodiscretine, were isolated from the ethanolic extract of *Thalictrum fauriei* Hayata. Based on spectral analysis and correlation with compounds of known structure, thalifaurine was shown to be 3-hydroxy-2-methoxy-10,11-methylenedioxyberbinium chloride and dehydrodiscretine was established as 3-hydroxy-2,10,11-trimethoxyberbinium chloride. The structural assignment was confirmed by synthesis of both compounds. Magnoflorine also was isolated and identified.

Keyphrases □ Thalifaurine—new quaternary protoberberine isolated from *Thalictrum fauriei*, structural determination □ Dehydrodiscretine—new quaternary protoberberine isolated from *Thalictrum fauriei*, structural determination □ Protoberberines, quaternary—thalifaurine and dehydrodiscretine, isolation from *Thalictrum fauriei*, structural determination □ *Thalictrum fauriei*—isolation of thalifaurine and dehydrodiscretine and their structural determination

Thalictrum fauriei Hayata (Ranunculaceae) is a perennial herb that is distributed widely over the mountainous area of Taiwan, especially in wet places (1). In view of an increasing interest in the biological activity of some Thalictrum alkaloids (2), a study was initiated on the alkaloidal constituents of *T. fauriei*.

Previous reports from this laboratory described the isolation and characterization of three known aporphines, (+)-oconovine (Ia) (3), (+)-isocorydine (Ib) (3), and (+)-corydine[1] (Ic), from the tertiary base fraction. Continuing investigation of the quaternary base fraction has provided two new protoberberinium salts, thalifaurine (IIa) and dehydrodiscretine (IIb), in addition to the known aporphine magnoflorine (III). The isolation and structural characterization of these quaternary salts are described in this report.

[1] C.-H. Chen, T.-M. Chen, and C. Lee, unpublished data.

RESULTS AND DISCUSSION

The ethanolic extract of the whole plant material of *T. fauriei* was processed by the usual acid–base treatment and solvent partitioning to separate the quaternary alkaloid fraction from the tertiary base fraction. The quaternary salt was precipitated with Mayer reagent and then was exchanged by an anionic resin into the chloride form. Extensive fractionation of this chloride salt on silica gel columns yielded three crystalline compounds, designated as alkaloids Q-3, Q-4, and Q-6 according to their increasing polarity on TLC plates.

Alkaloid Q-4—Alkaloid Q-4 was isolated as the chloride salt, mp 258–260°, and was optically inactive. The UV spectrum appeared as a complicated pattern with absorption maxima at 241, 263, 291, and 341 nm and shoulders at 310 and 380 nm. This pattern was characteristic of quaternary protoberberine salts, and the shoulder at 310 nm suggested a 2,3,10,11-substituted pseudoprotoberberinium pattern (4). Bathochromic shifts in the presence of bases and the broad IR absorption bands at 3510 and 3326 cm^{-1} indicated the phenolic nature of Q-4. The NMR spectrum of Q-4 revealed one methoxy group at δ 4.02, one methylenedioxy group at δ 6.33, two triplets of two protons each at δ 3.17 and 4.74 (J = 6 Hz), and six aromatic protons at δ 6.87 (s, 1H), 7.51 (s, 2H), 7.64 (s, 1H), 8.59 (s, 1H), and 9.25 (s, 1H) ppm.

Simanek *et al.* (5) made a detailed analysis of the chemical shifts for each aromatic proton on various protoberberinium and pseudoprotoberberinium salts. The data for pseudopalmatinium (IIe) and pseudoepiberberinium (IIf) salts were taken from their report and compared with those of Q-4 (Table I); the data for Q-4 were consistent with the 2,3,10,11-substitution pattern. In the chemical-ionization mass spectrum of Q-4 with isobutane as the reagent gas, the molecular ion M^+ appeared at m/e 322 and base ion c appeared at m/e 320; both were highly abundant, which reflected the unusual stability of the parent ion under the chemical-ionization mode. Ion a at m/e 323 and ion b at m/e 337 represented the result from thermal disproportionation of the parent ion (M^+), a fact proven for berberine derivatives by Habermehl *et al.* (6). Ions d (m/e 177), e (m/e 178), and f (m/e 176) suggested the presence of hydroxy and methoxy groups on ring A. Ion g (m/e 148) served to locate the methylenedioxy group on ring D.

Two structures were compatible with the evidence: 3-hydroxy-2-methoxy-10,11-methylenedioxyberbinium chloride (IIa) and 2-hydroxy-3-methoxy-10,11-methylenedioxyberbinium chloride (IIc).

Thalifaurine and Dehydrodiscretine, New Quaternary Protoberberines from *Thalictrum fauriei*

CHUNG-HSIUNG CHEN ˣ, TZER-MING CHEN, and CHRISTINE LEE

Received March 26, 1979, from the *School of Pharmacy, National Taiwan University, Taipei, Taiwan, Republic of China.* Accepted for publication May 4, 1979.

Abstract □ Two new quaternary protoberberines, thalifaurine and dehydrodiscretine, were isolated from the ethanolic extract of *Thalictrum fauriei* Hayata. Based on spectral analysis and correlation with compounds of known structure, thalifaurine was shown to be 3-hydroxy-2-methoxy-10,11-methylenedioxyberbinium chloride and dehydrodiscretine was established as 3-hydroxy-2,10,11-trimethoxyberbinium chloride. The structural assignment was confirmed by synthesis of both compounds. Magnoflorine also was isolated and identified.

Keyphrases □ Thalifaurine—new quaternary protoberberine isolated from *Thalictrum fauriei*, structural determination □ Dehydrodiscretine—new quaternary protoberberine isolated from *Thalictrum fauriei*, structural determination □ Protoberberines, quaternary—thalifaurine and dehydrodiscretine, isolation from *Thalictrum fauriei*, structural determination □ *Thalictrum fauriei*—isolation of thalifaurine and dehydrodiscretine and their structural determination

Thalictrum fauriei Hayata (Ranunculaceae) is a perennial herb that is distributed widely over the mountainous area of Taiwan, especially in wet places (1). In view of an increasing interest in the biological activity of some Thalictrum alkaloids (2), a study was initiated on the alkaloidal constituents of *T. fauriei*.

Previous reports from this laboratory described the isolation and characterization of three known aporphines, (+)-oconovine (Ia) (3), (+)-isocorydine (Ib) (3), and (+)-corydine[1] (Ic), from the tertiary base fraction. Continuing investigation of the quaternary base fraction has provided two new protoberberinium salts, thalifaurine (IIa) and dehydrodiscretine (IIb), in addition to the known aporphine magnoflorine (III). The isolation and structural characterization of these quaternary salts are described in this report.

RESULTS AND DISCUSSION

The ethanolic extract of the whole plant material of *T. fauriei* was processed by the usual acid–base treatment and solvent partitioning to separate the quaternary alkaloid fraction from the tertiary base fraction. The quaternary salt was precipitated with Mayer reagent and then was exchanged by an anionic resin into the chloride form. Extensive fractionation of this chloride salt on silica gel columns yielded three crystalline compounds, designated as alkaloids Q-3, Q-4, and Q-6 according to their increasing polarity on TLC plates.

Alkaloid Q-4—Alkaloid Q-4 was isolated as the chloride salt, mp 258–260°, and was optically inactive. The UV spectrum appeared as a complicated pattern with absorption maxima at 241, 263, 291, and 341 nm and shoulders at 310 and 380 nm. This pattern was characteristic of quaternary protoberberine salts, and the shoulder at 310 nm suggested a 2,3,10,11-substituted pseudoprotoberberinium pattern (4). Bathochromic shifts in the presence of bases and the broad IR absorption bands at 3510 and 3326 cm^{-1} indicated the phenolic nature of Q-4. The NMR spectrum of Q-4 revealed one methoxy group at δ 4.02, one methylenedioxy group at δ 6.33, two triplets of two protons each at δ 3.17 and 4.74 (J = 6 Hz), and six aromatic protons at δ 6.87 (s, 1H), 7.51 (s, 2H), 7.64 (s, 1H), 8.59 (s, 1H), and 9.25 (s, 1H) ppm.

Simanek *et al.* (5) made a detailed analysis of the chemical shifts for each aromatic proton on various protoberberinium and pseudoprotoberberinium salts. The data for pseudopalmatinium (IIe) and pseudoepiberberinium (IIf) salts were taken from their report and compared with those of Q-4 (Table I); the data for Q-4 were consistent with the 2,3,10,11-substitution pattern. In the chemical-ionization mass spectrum of Q-4 with isobutane as the reagent gas, the molecular ion M^+ appeared at m/e 322 and base ion c appeared at m/e 320; both were highly abundant, which reflected the unusual stability of the parent ion under the chemical-ionization mode. Ion a at m/e 323 and ion b at m/e 337 represented the result from thermal disproportionation of the parent ion (M^+), a fact proven for berberine derivatives by Habermehl *et al.* (6). Ions d (m/e 177), e (m/e 178), and f (m/e 176) suggested the presence of hydroxy and methoxy groups on ring A. Ion g (m/e 148) served to locate the methylenedioxy group on ring D.

Two structures were compatible with the evidence: 3-hydroxy-2-methoxy-10,11-methylenedioxyberbinium chloride (IIa) and 2-hydroxy-3-methoxy-10,11-methylenedioxyberbinium chloride (IIc).

Structure IIc is dehydropseudocheilanthifoline, a naturally occurring compound isolated from *Isopyrum thalictroides* (7). An authentic sample of IIc was different from Q-4 in all respects. Thus, Structure IIa was assigned tentatively to Q-4.

On reduction with sodium borohydride, Q-4 yielded a tetrahydroprotoberberine, Q-4-H, mp 142–144°. High-resolution mass spectral analysis of the molecular ion at *m/e* 325 agreed with a composition of $C_{19}H_{19}NO_4$. The UV absorption maxima at 230 and 290 nm were consistent with the expected chromophore, and a bathochromic shift on base treatment coupled with the IR bands at 3571 cm^{-1} suggested a phenolic function. The NMR spectrum showed one methoxy group at δ 3.85, one methylenedioxy group at δ 5.86, and four aromatic protons at δ 6.56 (s, 2H), 6.65 (s, 1H), and 6.82 (s, 1H) ppm. The electron-impact mass spectrum revealed the collapse of ring C to give base peak k (*m/e* 148) from ring D and ions i (*m/e* 178) and j (*m/e* 176) from rings A and B.

These data were identical to those of an authentic sample of 3-hydroxy-2-methoxy-10,11-methylenedioxyberbine (IVa), a by-product obtained from Suguna and Pai (8) in their synthesis of tetrahydrogroenlandicine. By a standard procedure, 6-hydroxy-7-methoxy-1-(3′,4′-methylenedioxybenzyl)-1,2,3,4-tetrahydroisoquinoline (Va) was synthesized and condensed with formaldehyde to give IVa, which also was found to be identical to Q-4-H. Further oxidation of IVa with mer-

Major fragments from electron-impact mass spectra of Q-4-H (IV*a*) ($R_1 = R_2 = OCH_2O$) and Q-3-H (IV*b*) ($R_1 = R_2 = OCH_3$).

curic acetate provided 3-hydroxy-2-methoxy-10,11-methylenedioxyberbinium chloride (II*a*), which was identical in every respect to Q-4. The structure of Q-4 therefore was firmly established as II*a*, and, since it was a new protoberberine from nature, it was named thalifaurine.

Alkaloid Q-3—Alkaloid Q-3 was isolated in a minute amount as the chloride salt, mp 230–234°, and was optically inactive. The UV spectrum was similar to that of Q-4, showing maximum absorptions at 243, 264.5, 289, 310 (sh), 341, and 379 (sh) nm. A bathochromic shift on base treatment and the IR absorption at 3400 cm^{-1} suggested its phenolic nature. The NMR spectrum showed three methoxy groups at δ 4.07, 4.01, and 3.89 ppm and one triplet of two protons at δ 3.05 ppm (J = 6 Hz), with a similar triplet obscured by the solvent peak. In the aromatic region, six protons were observed at δ 9.07 (s, 1H), 8.27 (s, 1H), 7.43 (s, 2H), 7.33 (s, 1H), and 6.53 (s, 1H) ppm. A comparison in this region with Q-4, II*e*, and II*f* (Table I) suggested that Q-3 is another 2,3,10,11-substituted pseudoprotoberberinium salt.

Examination of its chemical-ionization mass spectrum revealed the molecular ion M^+ (*m/e* 338) and the ions from thermal disproportionation of M^+, a (*m/e* 339) and b (*m/e* 353), all of which supported the skeleton of the parent ion, although they were in significantly lower abundance than similar ions from Q-4. Ions d (*m/e* 177), e (*m/e* 178), and h (*m/e* 164) were in agreement with the presence of three methoxy groups and located the phenolic function on ring A as well.

Two alternative structures were compatible with these data: 3-hydroxy-2,10,11-trimethoxyberbinium chloride (II*b*) and 2-hydroxy-3,10,11-trimethoxyberbinium chloride (II*d*). Structure II*d* is pseudocolumbamine, an alkaloid isolated from *I. thalictroides* (7). An authentic sample of II*d* was entirely different from Q-3, which required the assignment of Structure II*b* to Q-3.

Further evidence came from the reduction of Q-3 with sodium borohydride, giving a tetrahydroprotoberberine, Q-3-H, mp 180–182°. The molecular ion at *m/e* 341 was analyzed for $C_{20}H_{23}NO_4$ by high-resolution mass spectrometry. In agreement with the expected chromophore, the UV spectrum showed maximum absorption at 225 (sh) and 286.5 nm. A bathochromic shift was observed in the presence of base, which corroborated the IR phenolic absorption bands at 3570 and 3440 cm^{-1}. The NMR spectrum revealed three methoxy groups at δ 3.86 (s, 6H), and 3.89 (s, 3H) ppm and four aromatic protons at δ 6.58 (s, 1H), 6.66 (s, 2H), and 6.72 (s, 1H) ppm. The major mode of fragmentation in the electron-impact mass spectrum was the cyclic collapse of ring C, yielding base peak l (*m/e* 164) from ring D and ions i (*m/e* 178) and j (*m/e* 176) from rings A and B.

These spectral data were in good agreement with those of discretine (IV*b*) isolated from *Xylopia discreta* (9). Following literature procedures (10, 11), IV*b* was synthesized by condensing 6-hydroxy-7-methoxy-1-(3′,4′-dimethoxybenzyl)-1,2,3,4-tetrahydroisoquinoline (V*b*) with formaldehyde. This synthetic sample of (±)-discretine (IV*b*) was identical with Q-3-H in all respects. In addition, oxidation of IV*b* with mercuric acetate produced a compound, II*b*, that was identical to Q-3. Therefore, the structure of Q-3 was proven to be 3-hydroxy-2,10,11-trimethoxyberbinium chloride (II*b*). Since it is a dehydro form of discretine, it was named dehydrodiscretine.

Alkaloid Q-6—The major alkaloid in the quaternary base fraction was Q-6, isolated as the iodide salt, mp 250–252°. The spectral properties of this compound were identical to those of an authentic sample of magnoflorine (III) iodide.

EXPERIMENTAL[2]

Plant Material—The whole plant of *T. fauriei* Hayata[3] was collected during spring 1976 from the mountains near Wulai, Taipei County, Taiwan. The whole plant material was dried in an oven at 45° and milled to a fine powder.

Extraction and Initial Fractionation—Powdered plant material (3.29 kg) was extracted with 95% ethanol by percolation at room temperature until a negative test for alkaloids in the extract was shown with Valser reagent. The percolate was concentrated *in vacuo* to give 350 g of a greenish-brown semisolid residue. This residue was triturated with 3% citric acid and filtered. The process was continued until the filtrate showed a negative Valser test.

The combined acidic solution (3.5 liters) was extracted with ethyl acetate (4 liters) to remove the acidic and neutral fractions. The citric acid solution was adjusted to pH 9–10 with concentrated ammonium hydroxide and then extracted successively with ether (2 liters) and chloroform (3 liters), which removed the tertiary base fraction. The aqueous solution was adjusted to pH 4.4 with saturated citric acid solution, and Mayer reagent was added to precipitate the quaternary alkaloids.

After standing overnight in a refrigerator, the precipitate was filtered and washed with ether. The residue (106 g) then was dissolved in methanol–acetone–water (3:1:1), and the insoluble material was filtered off. The filtrate was stirred with an anion-exchange resin[4] for 3 days. After removal of the resin by filtration, the filtrate was evaporated under reduced pressure to give a semisolid residue (27.5 g) of the quaternary alkaloids as the chloride salts. Part of this residue (6.6 g) was chromatographed on a silica gel[5] (313 g) column and eluted with methanol in chloroform, with the methanol concentration increasing stepwise (1, 3, 7.5, 15, 30, 50, and 100%). Each 100 ml of eluate was collected and analyzed by TLC.

Isolation and Identification of Thalifaurine (II*a*, Q-4)—The residue (260 mg) from column fractions 50–52, eluted with 30% methanol in chloroform, was crystallized from methanol and recrystallized from the same solvent, yielding Q-4 as fine yellow needles (50 mg), mp 258–260°, $[\alpha]_D^{25}$ 0° (*c*, 0.2 in methanol); IR (KBr): ν_{max} 3510 (m), 3326 (m, OH), 1640 (m, C=N), 1613 (m), and 933 (w, OCH_2O) cm^{-1}; UV (methanol): λ_{max} (log ϵ) 241 (4.31), 263 (4.28), 291 (4.66), 310 (sh, 4.40), 341 (4.23), and 380 (sh, 3.83) nm; UV (methanol–0.1 *N* NaOH): λ_{max} (log ϵ) 252.5 (4.45), 311 (4.32), and 380 (4.44) nm; NMR (CD_3OD): 3.17, 4.74 (2 t, J = 6 Hz, CH_2CH_2), 4.02 (s, OCH_3), 6.33 (s, OCH_2O), 7.51 (s, 2H, aromatic), and 6.87, 7.64, 8.59, and 9.25 (4 s, 1H each, aromatic); electron-impact mass spectrum: *m/e* (%) 337 ($M^+ + O - H$, 6.2), 336 (8.6), 335 (10.2), 334 (8.5), 323 (19.4), 322 (M^+, 31.4), 321 (71.4), 320 (97.5), 319 (69.9), 318 (91.0), 307 (10.5), 306 (19.3), 305 (10.1), 278 (7.2), 277 (6.4), 261 (6.3), 260 (5.5), 202 (6.0), 177 (1.8), 176 (2.7), 160 (7.0), 159 (7.7), 130 (9.4), 52 (32.4), and 50 (100); chemical-ionization mass spectrum (isobutane as reagent gas):

[2] Melting points were taken with a Thomas-Hoover apparatus and are uncorrected. UV spectra were determined with a Hitachi model 200-20 spectrophotometer. IR spectra were taken with a Perkin-Elmer model 577 spectrophotometer in potassium bromide pellets. NMR spectra were recorded in suitable solvents, with tetramethylsilane as the internal standard, on a Varian A-60A or Bruker HX-90E spectrometer; chemical shifts are reported as δ (parts per million) values.

Optical rotations were measured on a Perkin-Elmer model 241 polarimeter. Mass spectra were obtained using a DuPont 21-491 double-focusing spectrometer *via* a direct-inlet probe, and the chemical-ionization mass spectra employed isobutane as the reactant gas. High-resolution mass spectra were determined on an A.E.I. MS-902 instrument using a direct-inlet system. Elemental analyses were performed by the Laboratory of Microanalysis, Chung-Shan Institute of Science and Technology, Chung-Li, Taiwan.

[3] A specimen of this plant was authenticated by Mr. Muh-Tsuen Kao, Department of Botany, National Taiwan University, and a voucher specimen was deposited in the School of Pharmacy of that University.

[4] IRA-410, chloride form.

[5] E. Merck No. 7734.

m/e (%): 378 (M^+ + 56, 4.0), 376 (2.9), 364 (M^+ + 42, 10.5), 362 (14.9), 337 (M^+ + O − H, 11.8), 336 (16.7), 335 (8.5), 324 (12.7), 323 (40.3), 322 (M^+, 93.8), 321 (90.6), 320 (100), 319 (65.9), 318 (16.3), 178 (1.8), 177 (1.8), 176 (2.7), and 148 (4.0). IR, UV, NMR, and mass spectral comparisons showed that this compound was identical to a synthetic sample of 3-hydroxy-2-methoxy-10,11-methylenedioxyberbinium chloride (II*a*), and a mixed melting-point determination showed no depression.

Reduction of II*a* to Q-4-H (IV*a*)—A solution of Q-4 (61 mg) in methanol (18 ml) was cooled on an ice bath and treated portionwise with sodium borohydride (122 mg). The mixture was stirred at room temperature for 24 hr and then evaporated under reduced pressure to remove methanol. The residue was treated with 6% NH_4OH (30 ml) and extracted with chloroform (4 × 30 ml). The combined chloroform extracts were washed with water (50 ml), dried (anhydrous potassium carbonate), and evaporated to give a syrup.

Crystallization from chloroform–methanol provided Q-4-H (30 mg) as pale-yellow plates, mp 142–144°; IR (KBr): ν_{max} 3571 (m, OH), 2930 (w), 2894 (w), 2853 (w), 2813 (w, *trans*-quinolizidine bands), 1505 (s), 1477 (s), and 930 (m, OCH_2O) cm^{-1}; UV (methanol): λ_{max} (log ϵ) 230 (sh, 4.00) and 290 (3.94) nm; UV (methanol–0.1 *N* NaOH): λ_{max} (log ϵ) 240 (sh, 4.01) and 296 (4.04) nm; NMR (CD_3OD): δ 2.49–3.97 (m, 9H, aliphatic), 3.85 (s, OCH_3), 5.86 (s, OCH_2O), 6.56 (s, 2H, aromatic), and 6.65 and 6.82 (2 s, 1H each, aromatic); electron-impact mass spectrum: *m/e* (%) 326 (13.6), 325 (M^+, 62.5), 324 (24.9), 310 (4.4), 178 (1.2), 177 (5.8), 176 (29.2), 150 (14.7), 149 (27.4), 148 (100), 147 (21.8), and 146 (4.6). The high-resolution mass measurement of *m/e* 325 (M^+) showed a value of 325.1315 for $C_{19}H_{19}NO_4$ (calc. 325.1312). The IR, UV, NMR, and mass spectra and a mixed melting-point determination showed that this compound was identical to an authentic sample of 3-hydroxy-2-methoxy-10,11-methylenedioxyberbine (IV*a*).

Synthesis of IV*a*—A mixture of 6-hydroxy-7-methoxy-1-(3′,4′-methylenedioxybenzyl)-1,2,3,4-tetrahydroisoquinoline (V*a*) (125 mg as the hydrochloride salt) and formaldehyde (4 ml) in acetic acid (4 ml) was refluxed for 3 hr. The reaction mixture was evaporated, and the resulting residue was made alkaline with 10% NH_4OH (30 ml). The aqueous solution was extracted with chloroform (4 × 30 ml), and the combined extracts were washed with water (50 ml), dried (anhydrous sodium sulfate), and evaporated to leave a residue (110 mg). The residue was purified further on a silica gel (7 g) column with the eluent (acetone in benzene) increasing from 1 to 20%.

Each 30-ml eluate was collected and analyzed by TLC. The residue from column fractions 18–61 was crystallized from chloroform–methanol to yield IV*a* (40 mg), mp 145–146°. The spectral properties of this compound were identical in every respect to those of an authentic sample synthesized by another route (8), mixed mp 144–145°. It also was identical to Q-4-H in terms of the IR, UV, NMR, and mass spectra and the mixed melting point (144–145°).

Anal.—Calc. for $C_{19}H_{19}NO_4$: C, 70.14; H, 5.89; N, 4.30. Found: C, 70.02; H, 5.95; N, 4.22.

Synthesis of II*a*—A solution of IV*a* (30 mg) in 25% acetic acid (30 ml) was treated with a saturated solution of mercuric acetate in acetic acid (1.5 ml), and the resulting mixture was refluxed on a water bath for 1 hr. The reaction mixture was evaporated, and the residue was dissolved in anhydrous ethanol (30 ml). A stream of hydrogen sulfide gas was introduced into the solution to precipitate the mercuric ion as the sulfide salt. The precipitate was removed by centrifugation and filtration over a layer of filter aid. The residue was washed with ethanol (3 × 40 ml) and filtered.

The combined ethanolic filtrates were evaporated to leave a residue. This residue was dissolved in warm concentrated hydrochloric acid (10 drops) and set aside to crystallize. The crude crystals were collected and recrystallized from methanol to yield fine yellow needles (15 mg) of II*a*, mp 259–261°. Compound II*a* was identical to Q-4 in terms of their IR, UV, NMR, and mass spectra. The mixed melting point was 258–260°.

Anal.—Calc. for $C_{19}H_{16}ClNO_4 \cdot H_2O$: C, 60.73; H, 4.83; Cl, 9.43; N, 3.73. Found: C, 60.15; H, 4.67; Cl, 9.45; N, 3.84.

Isolation and Identification of Dehydrodiscretine (II*b*, Q-3)—The residue from column fractions 46–49, eluted with 30% methanol in chloroform, was combined (125 mg) and rechromatographed on a small silica gel (15 g) column. Elution was performed by using methanol in chloroform (increasing from 5 to 20%) and collecting each 15-ml fraction. Additional Q-4 (15 mg) was isolated from fractions 34–43. The residue from fractions 46–53 was dissolved in a minimum amount of methanol and set aside in a refrigerator for 3 days.

The fine reddish-brown needles of Q-3 (10 mg) were filtered, mp 230–234°, $[\alpha]_D^{25}$ 0° (*c*, 0.15 in methanol); IR (KBr): ν_{max} 3400 (m, OH), 1633 (m), 1614 (m), 1517 (s), 1500 (s), 1430 (s), 1358 (s), 1290 (s), 1220 (s), 1128 (m), 1008 (m), and 880 (m) cm^{-1}; UV (methanol): λ_{max} (log ϵ) 243 (4.24), 264.5 (4.21), 289 (4.48), 310 (sh, 4.36), 341 (4.19), and 379 (sh, 3.82) nm; UV (methanol–0.1 *N* NaOH): λ_{max} (log ϵ) 254 (4.42), 310 (4.24), and 378 (4.37) nm; NMR (CD_3OD): δ 3.89, 4.01, and 4.07 (3 s, OCH_3 each), 3.05 (t, J = 6 Hz, CH_2), 7.43 (s, 2H, aromatic), and 6.53, 7.33, 8.27, and 9.07 (4 s, 1H each, aromatic); chemical-ionization mass spectrum (isobutane as reagent gas): *m/e* (%) 353 (M^+ + O − H, 2.0), 339 (0.3), 338 (M^+, 0.3), 208 (1.0), 206 (0.7), 178 (1.7), 177 (1.1), 169 (3.0), 167 (7.5), 165 (1.2), 164 (3.0), 163 (1.4), 152 (3.6), 150 (14.5), 149 (14.3), 141 (14.8), 137 (8.3), 128 (5.5), 127 (100), 126 (19.9), 105 (8.2), 103 (3.2), 95 (4.2), 91 (3.2), 85 (5.3), 76 (6.6), 75 (34.6), 74 (87.8), and 73 (5.1). This compound was shown to be 3-hydroxy-2,10,11-trimethoxyberbinium chloride (II*b*) by direct comparison with a synthetic sample.

Reduction of II*b* to Discretine (IV*b*)—A solution of Q-3 (8 mg) in methanol (5 ml) was reduced with sodium borohydride (20 mg) following a procedure similar to that described for the reduction of Q-4. The reduced product was crystallized from methanol as colorless needles (3 mg) and was designated as Q-3-H. Additional Q-3-H was obtained from reduction of the mother liquid of Q-3, which also was admixed with Q-4. The reduced mixture of Q-3-H and Q-4-H was separated on a preparative TLC plate of silica gel[5] (1 mm) and eluted with acetone–benzene (1:3). The zone corresponding to Q-3-H (R_f 0.31) was scraped and extracted with methanol–chloroform (1:9). The extract was evaporated, and the residue was crystallized from methanol to provide 9 mg of Q-3-H.

The combined material of Q-3-H was recrystallized from methanol, mp 180–182°; IR (KBr): ν_{max} 3570 (m), 3440 (m, OH), 2940 (m), 2840 (w), 1615 (m), 1520 (s), 1448 (m), 1350 (m), 1260 (s), 1140 (m), and 1030 (m) cm^{-1}; UV (methanol): λ_{max} (log ϵ) 225 (sh, 4.18) and 286.5 (3.87) nm; UV (methanol–0.1 *N* NaOH): λ_{max} (log ϵ) 245 (4.08), 290.5 (3.96), and 300 (sh, 3.83) nm; NMR ($CDCl_3$): δ 2.50–3.80 (m, 9H, aliphatic), 3.86 (s, 2 OCH_3), 3.89 (s, OCH_3), 6.66 (s, 2H, aromatic), and 6.58 and 6.72 (2s, 1H each, aromatic); electron-impact mass spectrum: *m/e* (%) 342 (1.9), 341 (M^+, 7.8), 340 (3.4), 339 (3.0), 338 (4.3), 283 (5.3), 181 (3.5), 180 (2.4), 178 (2.8), 177 (3.6), 176 (12.0), 166 (11.9), 165 (38.1), 164 (100), 151 (3.0), 150 (4.7), 135 (4.1), and 133 (4.1). The high-resolution mass measurement of *m/e* 341 (M^+) showed a mass for $C_{20}H_{23}NO_4$ of 341.1624 (calc. 341.1626). This compound was identical to a synthetic sample of IV*b* in terms of their IR, UV, NMR, and mass spectra and a mixed melting-point determination.

Synthesis of II*b* from IV*b*—(±)-Discretine was synthesized according to the method of Kametani *et al.* (10, 11) by condensation of 6-hydroxy-7-methoxy-1-(3′,4′-dimethoxybenzyl)-1,2,3,4-tetrahydroisoquinoline (V*b*) with formaldehyde or by debenzylation of *O*-benzyldiscretine. The pure product of IV*b* was crystallized from acetone–ether as white plates, mp 183–184° [lit. (10) mp 182–184°]. Direct comparison of their IR, UV, NMR, and mass spectra showed that this compound was identical to Q-3-H; a mixed melting point of 182–184° was observed.

A solution of IV*b* (300 mg) in acetic acid (12 ml) was added to a warm solution of mercuric acetate (2.1 g) in acetic acid (14 ml). The resulting mixture was refluxed on a water bath for 7 hr. Following a workup similar to that described for the synthesis of II*a*, a yellow residue was obtained. This residue was dissolved in concentrated hydrochloric acid (5 ml). The crude crystal was collected and recrystallized from methanol to yield II*b* as fine reddish-yellow needles (284 mg), mp 232–234°. This compound was identical to Q-3 in terms of their IR, NMR, and UV spectra, and a mixed melting point of 230–233° was obtained.

Anal.—Calc. for $C_{20}H_{20}ClNO_4 \cdot H_2O$: C, 61.30; H, 5.66; Cl, 9.05; N, 3.57. Found: C, 60.95; H, 5.68; Cl, 8.84; N, 3.64.

Isolation and Identification of Magnoflorine (III) Iodide (Q-6)—The crude brown residue (1.76 g) from column fractions 65–118, eluted with 75% methanol in chloroform, was dissolved in methanol. To this solution was added an excess of saturated methanolic potassium iodide solution. The solution was kept at room temperature for 2 days, and the resulting white precipitate was removed by filtration. The precipitate was crystallized twice from methanol to yield Q-6 (85 mg) as white crystals, mp 250–252°. This compound was identified as magnoflorine (III) iodide on the basis of its TLC behavior and IR, UV, circular dichroism, NMR, and mass spectral data, which were identical to those obtained for an authentic sample of magnoflorine iodide. In addition, there was no depression in the mixed melting-point determination with an authentic sample of magnoflorine iodide.

Acetylcarnitine and Cholinergic Receptors

K. W. REED, W. J. MURRAY ˣ, and E. B. ROCHE

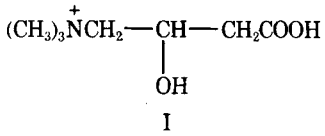
Received April 2, 1979, from the *Department of Biomedicinal Chemistry, College of Pharmacy, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication April 28, 1980.

Abstract □ Acetylcarnitine, a naturally occurring compound found in high concentration in heart and skeletal muscle of vertebrates, bears structural resemblance to acetylcholine, and studies have shown that it has slight cholinergic properties. Acetylcarnitine was subjected to conformational analysis by extended Hückel theory (EHT) and complete neglect of differential overlap (CNDO/2) molecular orbital methods. The preferred conformations were examined with respect to their similarity to the Kier and Chothia–Pauling models of cholinergic receptor patterns. The preferred conformations of both isomers did not fit the receptor pattern described by Kier's model, although energy barriers to rotation are low enough to permit accommodation. The Chothia–Pauling model predicts activity for the *S*-isomer only. These studies partially explain the low cholinergic activity found for acetylcarnitine and the higher activity of (*S*)-acetylcarnitine compared to the *R*-isomer.

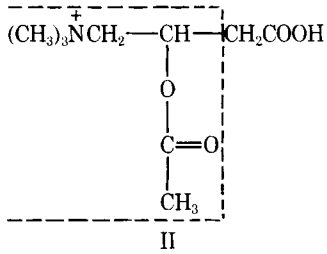
Keyphrases □ Acetylcarnitine—conformational analysis, comparison to cholinergic receptor patterns □ Cholinergic activity—acetylcarnitine, conformational analysis, comparison to cholinergic receptor patterns □ Structure–activity relationships—acetylcarnitine, conformational analysis, comparison to cholinergic receptor patterns

L-(−)-Carnitine [(*R*)-carnitine, I] is a naturally occurring substance found in high concentrations in plants, microorganisms, and animals. The muscles of vertebrates and invertebrates have especially high levels. Its principal physiological function is to transport free fatty acids into the mitochondria prior to their oxidation *via* the β-oxidation cycle (1).

(*R*)-Acetylcarnitine (II), a derivative of carnitine, also is found in high concentrations in the tissues of vertebrates. Enveloped within the structure of acetylcarnitine is the structure of the parasympathetic neurotransmitter acetylcholine (indicated by the dashed lines in II). The close structural similarity of acetylcarnitine to acetylcholine has



I



II

prompted investigations into its pharmacological properties as either a cholinomimetic or an anticholinergic compound (2–11).

BACKGROUND

It was reported that high doses of acetylcarnitine exerted a cholinergic effect on the heart which was blocked by atropine (2). Strack and Försterling reported that carnitine had little biological activity (3). However, Dallemagne *et al.* (4) found that carnitine and acetylcarnitine depolarized motor end plates. They reported that (*R,S*)-carnitine was 1/1000 as potent as acetylcholine on frog rectus abdominis muscle and that (*R*)-acetylcarnitine was 10–25% as potent as acetylcholine (4).

In contrast, Blum *et al.* (5) found (*R*)-carnitine to have 1/10,000 and (*S*)-carnitine to have 1/4000 the activity of acetylcholine on rectus abdominis muscle. They also reported that (*R*)- and (*S*)-acetylcarnitine were 1/700 as potent as acetylcholine in lowering arterial blood pressure in dogs (5). They concluded that acetylcarnitine acts at the cholinergic site rather than by blocking acetylcholinesterase. Two other groups found that synthetic (*R,S*)-acetylcarnitine possessed only weak to no nicotinic activity (6, 7).

Hosein and Proulx (8) claimed to have isolated a cholinergic active fraction of brain synaptosomes and identified this fraction as containing the coenzyme A ester derivatives of γ-butyrobetaine, crotonbetaine, carnitine, and acetylcarnitine. Six groups of investigators were unable to verify Hosein's isolation and identification of the active cholinergic substance of the brain, and the substance isolated by Hosein *et al.* apparently was acetylcholine itself (7). Falchetto *et al.* (9) reported that cortical neurons excited by acetylcholine also are excited by carnitine and acetylcarnitine. Carnitine was found to be more potent than acetylcarnitine.

Fritz (10) injected (*R,S*)-acetylcarnitine intracisternally into rat brains and evoked pronounced motor activity, which was not observed with

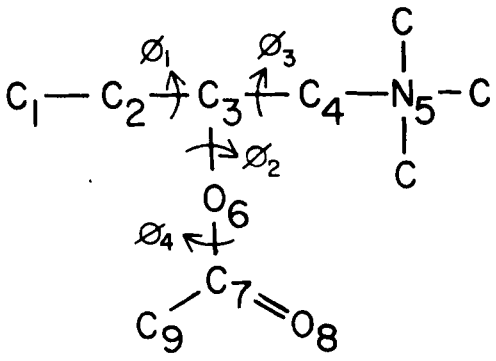

Figure 1—*Torsional angles for acetylcarnitine. Key:* ϕ_1, C_1-C_2-C_3-O_6; ϕ_2, C_2-C_3-O_6-C_7; ϕ_3, C_2-C_3-C_4-N_5; *and* ϕ_4, C_3-O_6-C_7-O_8.

(*R,S*)-carnitine. (*R,S*)-Acetylcarnitine injected intraventricularly caused phonation, pupillary dilatation, and markedly increased motor activity. Walker *et al.* (11) reported carnitine and acetylcarnitine to be less than 1/5000 as active as acetylcholine on excitatory neurons from *Helix aspera*.

Overall, the evidence shows that (*R*)- and (*S*)-acetylcarnitines possess low cholinergic activity. Since atropine is reported to block the cholinergic action of acetylcarnitine, its activity may be primarily at muscarinic receptors (5).

Many models of muscarinic and nicotinic receptors have been proposed based on the activity of potent cholinergic compounds. Therefore, it is of interest to examine the preferred conformations of (*R*)- and (*S*)-acetylcarnitines and to compare their fit to these proposed models. If the models are useful in predicting a pattern for an active cholinergic compound, then low activity compounds should not be expected to fit the pattern.

EXPERIMENTAL

To determine the preferred conformations, two quantum chemical methods were used: the extended Hückel theory (EHT)[1] (12) and complete neglect of differential overlap (CNDO/2)[2] (13). Although EHT usually exaggerates the energy barriers to rotation, it does correctly predict preferred rotational conformers. The CNDO/2 method relies less on empirical parameters than does EHT and uses a self-consistent field technique to estimate electronic interactions (13). Compared to EHT, CNDO/2 gives more realistic estimations of electronic parameters such as electron populations and charge densities and also gives reasonable estimations of energy barriers to rotation. The CNDO/2 method was used to verify the EHT calculations for preferred conformations and allowed the determination of the effect of electrostatic interactions between the quaternary ammonium group and the carboxylate anion.

The conformational problem concerns the steric and electronic effects of the C_1-carboxylate anion and the N_5-quaternary ammonium cation and the effect of the acetyl group in determining the rotational and conformational properties of the carnitine molecule. The numbering scheme and dihedral angles considered are given in Fig. 1. A torsional angle, ϕ (A–B–C–D), between the bonded atoms A–B–C–D represents the angle between planes ABC and BCD.

Viewed from the direction of A, positive rotations of ϕ are clockwise and negative rotations are counterclockwise, with the BCD plane rotating with respect to the ABC plane. The value $\phi = 0°$ corresponds to the *cis*-planar arrangement of bonds AB and CD.

The problem is analogous to that encountered by Kier (14) with cholinergic agents. To simplify calculations for acetylcholine, Kier segmented the molecule into two parts to determine the preferred conformation of each segment, which is dependent only on the nearest neighboring groups. This approach is used in the present study with both acetylcarnitine isomers.

Acetylcarnitine is segmented to include four torsional angles: ϕ_1 (C_1-C_2-C_3-O_6), ϕ_2 (C_2-C_3-O_6-C_7), ϕ_3 (C_2-C_3-C_4-N_5), and ϕ_4 (C_3-O_6-C_7-O_8)

[1] The EHT calculations were carried out with QCPE Program 64.
[2] The CNDO/2 calculations were carried out with QCPE Program 91.

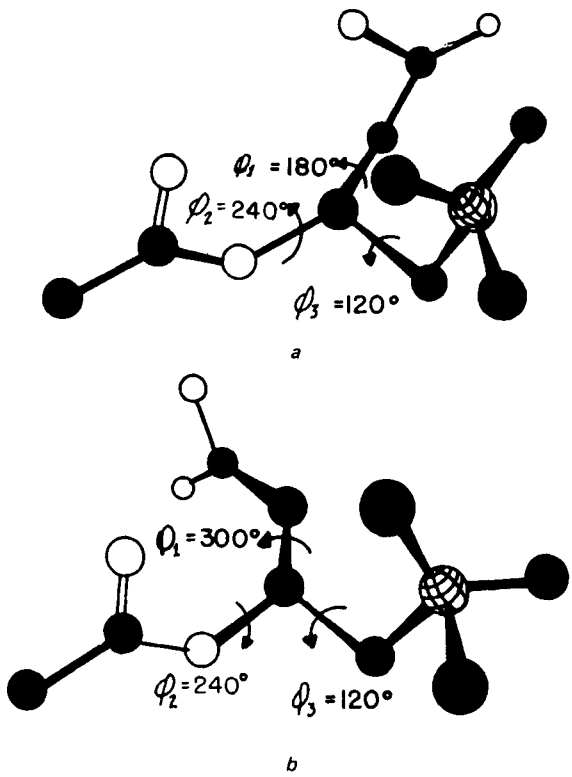

Figure 2—*Preferred conformations for acetylcarnitine. Key: a, folded conformation; and b, extended conformation.*

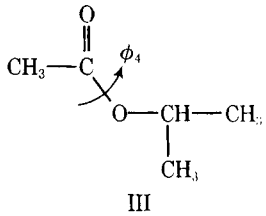
(Fig. 1). In addition, torsional angles for the preferred orientation of the quaternary ammonium group and carboxylate anion were determined. The optimal conformations of the isolated torsional angles, ϕ_1, ϕ_2, and ϕ_4, were determined first and then were used to find ϕ_3. With the whole molecule, slight variations in each torsional angle were examined to optimize all parameters.

The bond angles and bond lengths were derived from crystallographic data (15, 16). The three-dimensional Cartesian coordinates for each atom in the differing conformations were calculated with PROXYZ, QCPE Program 94, using X-ray data (15, 16).

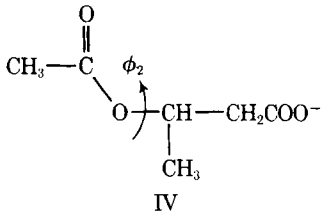
RESULTS

Kier's (14) partitioning method for determining the lowest energy conformer for each torsional angle as the molecule is constructed was followed. For (*R*)-acetylcarnitine, the torsional angle for the ester group, ϕ_4 (C_3-O_6-C_7-O_8), using III was determined first using 30° increments.



III

The lowest energy conformer was 300°. With this value of ϕ_4, ϕ_2 (C_2-C_3-O_6-C_7) was determined by adding on the carboxylate group to give IV.



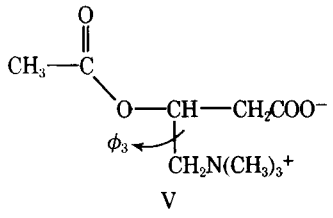
IV

Again, 30° increments in rotation were used and the lowest energy conformer occurred at $\phi_2 = 240°$. With this segment, ϕ_1 (C_1-C_2-C_3-O_6) was

Table I—Comparison of X-Ray and Calculated (EHT) Torsional Angles for (*R*)-Acetylcarnitine

Torsional Angle	Calculated Angle: Folded Conformer	Calculated Angle: Extended Conformer	Angle Observed by X-Ray (16)
ϕ_1 (C_1-C_2-C_3-O_6)	180°	300°	190°
ϕ_2 (C_2-C_3-O_6-C_7)	240°	240°	284.5°
ϕ_3 (C_2-C_3-C_4-N_5)	120°	120°	152.1°
ϕ_4 (C_3-O_6-C_7-O_8)	60°	60°	5.3°

determined to be 300°. Finally, the quaternary ammonium group was added to give V, and the whole molecule, lowest energy conformer was determined by varying ϕ_3 (C_2-C_3-C_4-N_5) in 30° increments.



V

This rotamer was determined to be 120° and corresponds to an extended conformation (Fig. 2). Next, whole molecule rotations were done by varying one of the torsional angles and keeping the others constant. Another low energy conformer was found with a variation in ϕ_1; this conformer was determined to be ϕ_1 (C_1-C_2-C_3-O_6) = 180° and corresponds to a folded conformation. The folded conformer has the onium group and carboxylate group in close proximity, whereas the extended conformer corresponds to a molecule having the charged groups separated (Fig. 2). The EHT molecular orbital method was used in these determinations.

The X-ray data of Sass and Werness (16) on acetylcarnitine indicate a folded conformation. The values interpreted from their data are $\phi \approx 190°$, $\phi_2 = 284.5°$, and $\phi_3 = 152°$. Calculations using the CNDO/2 method also show that the preferred conformer of (*R*)-acetylcarnitine is the folded conformer. Table I shows the X-ray and EHT calculated values for the torsional angles of (*R*)-acetylcarnitine.

DISCUSSION

A drug receptor is generally defined as a macromolecule that, when interacting with a small drug molecule, initiates a biological response. Generally, much is known about the small molecules that interact specifically with the receptor, but there usually is only inferential evidence about the nature of the receptor. An analogy can be drawn between the concept of a receptor and the concept of induced fit that occurs in describing enzyme action. Induced fit explains the stereochemistry necessary for a substrate molecule to fit an enzyme, while the receptor concept describes the structural requirements for a drug. However, in enzymes, the substrate becomes altered by the macromolecule. In receptors, the small molecule is thought to cause a conformational change in the large molecule, thereby initiating the response.

As the small molecule approaches certain features on the macromolecule, it may interact if its structural features are complementary to those of the macromolecule, *i.e.*, if the drug is recognized. A drug molecule can be complementary without having agonist activity, in which case it would

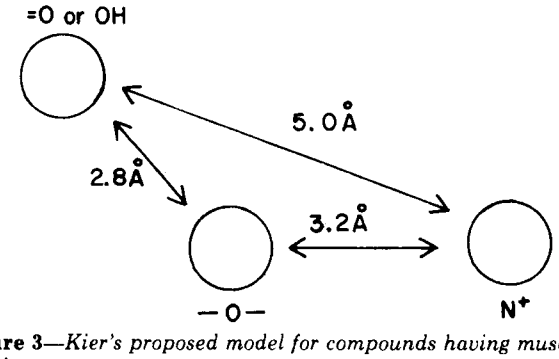


Figure 3—*Kier's proposed model for compounds having muscarinic activity.*

Table II—Comparison of Dihedral Angles of (*R*)-Acetylcarnitine with Chothia–Pauling Model of Acetylcholine

Torsional Angle[a]	Angle for Muscarinic Activity[b] by Chothia–Pauling Model	Angle in (*R*)-Acetylcarnitine[c]
τ_1 (CH_3N-N_5-C_4-C_3)[d]	180°	180°
τ_2 (N_5-C_4-C_3-O_6)	75–137°	240°
τ_3 (C_4-C_3-O_6-C_7)	145–215°	120°
τ_4 (C_3-O_6-C_7-C_9)	180–223°	240°

[a] Atoms numbered according to Fig. 1. [b] All angles are the same dihedral angles reported in Ref. 20 and shown in Fig. 4. [c] Torsional angles transformed from data in Table I. [d] Torsional angle with respect to C_3.

be an antagonist. If the drug is efficacious, specific conformational changes should occur in the macromolecule, leading to a biological action.

For this discussion, the receptor site is described only by the structural requirements necessary for initial recognition of the drug. This definition is limiting and has no applicability to the isolation and determination of the conformational and dynamic properties of the receptor macromolecule. It also does not take into account degrees of biological efficacy. However, the definition is useful in constructing a model of the receptor site topography during the initial approach of the drug. It also allows mapping of areas where primary and secondary interactions must occur for initial complementarity between the drug and its binding site on the macromolecule.

As a result of his EHT calculations for acetylcholine, muscarine, and muscarone, Kier (14) proposed a muscarinic receptor model based on structural similarity among these potent muscarinic compounds. The model defines the distances between three atomic centers as being important to activity: the quaternary nitrogen, the ether oxygen, and a carbonyl or hydroxyl oxygen (Fig. 3). Since three points describe a plane, Kier's model implies that a planar relationship between these groups is required, along with appropriate interatomic distances and electronic properties, for initial recognition by the receptor. As a result of calculations on β-methylacetylcholine, the model was modified (17). The modified distances between atomic centers are (Fig. 3): quaternary nitrogen to ether oxygen, 3.2 ± 0.2 Å; quaternary nitrogen to carbonyl oxygen, 5.0 ± 0.6 Å; and carbonyl oxygen to ether oxygen, 2.8 ± 0.6 Å.

The lowest energy conformer of (*S*)-acetylcarnitine from this study has the following atomic distances between groups: quaternary nitrogen to ether oxygen, 3.59 Å; quaternary nitrogen to carbonyl oxygen, 4.95 Å; quaternary nitrogen to acetyl methyl, 4.64 Å; and carbonyl oxygen to ether oxygen, 2.23 Å. These distances do not match Kier's original cholinergic receptor site model.

In acetylcarnitine, both isomers have a probability of adopting a conformation that enables them to fit Kier's modified receptor model (17).

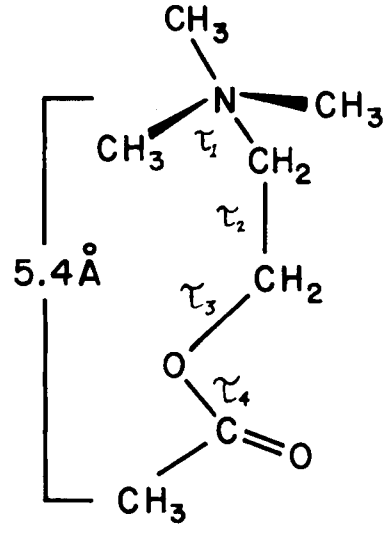

Figure 4—*Chothia–Pauling model for compounds having muscarinic activity. The torsional angles are from Ref. 20. See the text for definitions of these angles.*

To fit, the R-isomer must have the ester methyl group pointing up and the S-isomer must have the methyl group pointing down. These conformations and the receptor model fit are obtained only when ϕ_4 is rotated to 0°. This orientation of the methyl groups may account for the low activity of acetylcarnitine. These conformations are 5 kcal/mole less favorable than the preferred conformation according to EHT calculations. In these conformations, the γ-methylene and carboxylate groups are opposite the ester methyl group for both isomers.

Chothia and coworkers (18–20) also proposed a muscarinic receptor model. Their model was derived from an examination of the X-ray conformations of several cholinergic compounds. It is described in terms of torsional angles (τ) and interatomic distances (Fig. 4). The interatomic distances are: quaternary nitrogen to ether oxygen, 3.3 Å; quaternary nitrogen to carbonyl oxygen, 5.6 Å; and quaternary nitrogen to acetyl methyl, 5.4 Å. It was proposed that for muscarinic activity, the torsional angles shown in Fig. 4 need to have the following values (20): $\tau_1 = 180°$ (with respect to C-3), $\tau_2 = 73–137°$, $\tau_3 = 145–215°$, and $\tau_4 = 180$ or 223°, where the angles are defined, according to the numbering in Fig. 1, as $\tau_1 = CH_3N\text{-}N_5\text{-}C_4\text{-}C_3$, $\tau_2 = N_5\text{-}C_4\text{-}C_3\text{-}O_6$, $\tau_3 = C_4\text{-}C_3\text{-}O_6\text{-}C_7$, and $\tau_4 = C_3\text{-}O_6\text{-}C_7\text{-}C_9$.

The interatomic distances in the lowest energy conformation of (S)-acetylcarnitine from the present study are given for comparison.

For (R)-acetylcarnitine, the torsional angles defined in Ref. 20 are given in Table II. The values of the torsional angles for (R)-acetylcarnitine in Table II were transformed from those in Table I to allow comparison with the data from Ref. 20; however, the same conformation of (R)-acetylcarnitine is described in both Tables I and II.

With (S)-acetylcarnitine, there is very little difference in energy in the conformations for τ_3 between 180 and 300° and for τ_4 between 120 and 240°. (S)-Acetylcarnitine could fit the Chothia–Pauling model for muscarinic activity. However, (R)-acetylcarnitine does not fit because $\tau_2 = 240°$ (Table II and Fig. 4). From EHT, the (R)-acetylcarnitine conformer having $\tau_2 = 137°$ is energetically less favored than the preferred conformation, as shown by the calculated, although exaggerated, value of 300 kcal/mole.

On the basis of this examination, the preferred conformations of (R)- and (S)-acetylcarnitines do not meet the criteria proposed by Kier's model for muscarinic activity. However, the energy barriers to rotation are sufficiently low so that some conformations accommodate the model. However, in these conformations, the methyl group on the acetyl moiety is oriented differently than for acetylcholine. These results may explain the low muscarinic activity found for acetylcarnitine. The Chothia–Pauling model predicts that only the S-isomer will have muscarinic activity.

Some controversy exists concerning whether acetylcarnitine possesses cholinergic activity (2–11). Current evidence suggests that (R)- and (S)-acetylcarnitines possess low cholinergic, muscarinic activity (5, 9). The S-isomer appears to be more potent than the R-isomer, and both isomers are reported to interact at the cholinergic, muscarinic receptor (5). The Chothia–Pauling model correctly predicts activity for the S-isomer but does not predict the interaction of the R-isomer with the receptor. Although the lowest energy conformers of (R)- and (S)-acetylcarnitines do not fit Kier's model, flexibility in the molecule does allow some degree of fit. Kier's model appears to fulfill more satisfactorily the requirements for defining the initial recognition features for interaction. The Chothia–Pauling model appears to be suitable for describing requirements for biological efficacy.

The low order of activity also may be related to the remainder of the carnitine molecule. Acetylcarnitine may be considered as the β-acetic acid derivative of acetylcholine. The steric bulk of this substituent and its highly polar nature may interfere in the interaction and specificity of the conformational perturbation in the receptor.

Scope of Differential UV and Differential Fluorescence Assays for Phenothiazines: Comparison with Official Methods

DONALD F. GURKA *x, RICHARD E. KOLINSKI, JAMES W. MYRICK, and CLYDE E. WELLS

Received September 19, 1979, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication March 4, 1980. *Present address: Environmental Protection Agency, Environmental Monitoring Systems Laboratory, Las Vegas, NV 89114.

Abstract □ Operational difficulties have been encountered with many of the official phenothiazine assay procedures in this laboratory. Although some difficulties were corrected, the procedures still lack specificity. Accordingly, the general scope of differential UV and differential fluorescence methods was investigated. These specific methods are facile, reproducible, and applicable to both composite and single-tablet assays.

Keyphrases □ Phenothiazines—comparison of differential UV and differential fluorescence methods with official assays □ Differential UV and fluorescence spectrophotometry—analysis, phenothiazines, comparison with official methods

The 10-substituted phenothiazines constitute one of the largest drug classes in the official compendia (1, 2). Nineteen different phenothiazine bases of this type are represented by 74 entries in the USP and NF. A recent drug quality assurance program in this laboratory resulted in the semiautomated analysis of 291 phenothiazine samples, in a wide variety of formulations, from 14 manufacturers.

While checking the results from the automated analyzer by the official assay procedures, considerable difficulty was experienced. Many of the official procedures did not work well and had to be amended. Consequently, the general scope of a differential spectrophotometric assay for phenothiazines was investigated (3). Results from this method were compared with those from the automated method and from modifications of the official procedures.

BACKGROUND

The oxidative degradation of 10-substituted phenothiazines has been studied extensively (see Refs. 4 and 5 for recent reviews). In particular, electrochemical oxidation has been studied in great detail (6–8). It was demonstrated that a 10-substituent raises the oxidation potential and directs oxidation to the sulfur atom. Theoretical considerations supported by electron-spin resonance studies have rationalized this oxidation direction in terms of a steric effect on the phenothiazine electronic system (9, 10). Chemical oxidation in these systems also leads predominantly to sulfur oxidation (11). Among the chemical reagents used have been ozone (12), oxygen (13), sodium nitrite (14), dichromate (15), and hydrogen peroxide (16).

Despite the ease of oxidation of these compounds, specific assay procedures that are stability indicating are not abundant in the literature. Although it is stability indicating, Ryan's palladium complex method (17) has not been widely adopted. A quantitative TLC procedure was described for butaperazine (18), but it is too laborious for routine analysis. GLC (19–21) and high-pressure liquid chromatographic (22, 23) methods are not generally applicable to the entire class of 10-substituted phenothiazines in the presence of their degradation products.

With this background in mind, the following considerations of the official phenothiazine assays indicate the need for their revision. The compendial procedures are of three types: measurement at a single UV wavelength, difference measurements at two UV wavelengths, and measurement of the palladium chloride complex at visible wavelengths. The first method is nonspecific and, at the low wavelengths employed, is susceptible to excipient interference. The difference method apparently involves baseline correction for interfering excipients. Use of the selected correction wavelength (~275 nm) can lead to spurious results since sulfoxide impurities can interfere through their nearby absorption maximum (24). The third method, a variation of Ryan's palladium complexation method, is specific. However, this method has not been widely adopted by the compendia (only one-third of the phenothiazine drugs in this study are officially determined by this method). This lack of acceptance may be a result of poor complex solubility, low complex absorptivity, or unstable complexes. These considerations, as well as a recent report (25) that cited extensive degradation of phenothiazine liquid formulations, emphasize the need for a general, specific assay.

EXPERIMENTAL

Apparatus—A UV-visible double-beam spectrophotometer[1] equipped with 1-cm quartz cells was used for the manual assays. The automated system consisted of a liquid sampler, two proportioning pumps, and two manifolds[2]. This system was equipped with a recorder[3] and interfaced with a minicomputer[4]. Absorbances were measured automatically on a single-beam spectrophotometer[5]. Fluorescence intensities were measured automatically on a ratio fluorometer[6]. Both were determined in a 1-cm flowcell. Manual measurements of fluorescence intensities were taken on the same fluorometer utilizing 1-cm rectangular cells. Tablets were disintegrated in an ultrasonic generator[7] or, if possible, on a mechanical shaker[8].

Materials—Alcohol (95%), acetic acid, hydrochloric acid, *n*-heptane, and *n*-butanol were analytical reagent grade[9] and were used as received. Ammonium hydroxide, sodium nitrite, potassium chloride, sodium hydroxide, and ascorbic acid were ACS grade[10] and were used as received. Hydrogen peroxide (30%) was refrigerated and used as needed. Chromatographic siliceous earth[11] was acid-washed grade and was rewashed with 0.1 *N* HCl on the column.

Standards—All standards were pure drug substances obtained from manufacturers whose products were studied in the quality assurance program. Each drug substance was analyzed *versus* the appropriate USP or NF reference standard by the automated procedure. All substances gave assays in the range of 100 ± 0.4%.

Preparation of Reagents—To prepare 0.1 *N* HCl, concentrated hydrochloric acid (10 ml) was diluted to 1 liter with deionized water.

The peracetic acid oxidizing solution was prepared by pipetting 1.5 ml of 30% H_2O_2 into a 250-ml volumetric flask containing 200 ml of acetic acid. The flask was covered and heated on a steam bath for 1 hr. After

Table I—Analysis Parameters for the Modified Official Assay

Drug	Extraction Aliquot Concentration	Assay Concentration, μg/ml
Prochlorperazine maleate or edisylate	3 mg of salt/10 ml	12
Chlorpromazine hydrochloride	2 mg of salt/15 ml	20
Promazine hydrochloride	4 mg of salt/10 ml	40
Trimeprazine tartrate	1.5 mg of salt/10 ml	6

standing overnight at room temperature, the solution was diluted to volume with acetic acid. This solution was discarded after 1 week.

A solution of 0.025% ascorbic acid in 0.1 *N* HCl was prepared by dissolving 250 mg of ascorbic acid in 1 liter of 0.1 *N* HCl.

Three hundred milliliters of 95% alcohol was diluted to 1 liter with pH 2.2 buffer (26) to prepare a solution of alcohol and pH 2.2 buffer.

Equal volumes of *n*-butanol and *n*-heptane were mixed to prepare heptane–butanol (1:1).

The 0.5% $NaNO_2$ oxidizing solution was prepared by dissolving 1 g of sodium nitrite in 200 ml of deionized water.

A solution of 0.1 *N* NaOH was prepared by diluting 5.3 ml of 50% NaOH (w/v) to 1 liter with deionized water.

Modified Official Assay Procedure—Except for the following changes, the official procedures were used as given.

Class I Compounds—Prochlorperazine maleate or edisylate, chlorpromazine hydrochloride, promazine hydrochloride, and trimeprazine tartrate were assayed. To prepare single tablets for assay, the tablet was disrupted ultrasonically in 0.1 *N* HCl. To prepare sample composites, the average tablet weight was determined, and the tablets were ground in a mortar and pestle to pass through a 60-mesh screen. The appropriate weight of tablet powder then was shaken with 0.1 *N* HCl in a volumetric flask (Table I), diluted to volume with 0.1 *N* HCl, and filtered through paper. The first 10 ml of the filtrate was discarded.

An aliquot of the filtrate of the concentration specified in Table I was transferred to a separator. Water (125 ml) and saturated sodium chloride (5 ml) were added, and the solution was made basic with ammonium hydroxide (3 ml). The pH was checked to confirm that the solution was strongly alkaline. The solution then was extracted with four portions of heptane (40, 25, 25, and 25 ml). The combined heptane extracts were extracted with 0.1 *N* HCl (4 × 25 ml), and the combined hydrochloric acid extracts were diluted to the final concentration specified in Table I. The standards were prepared in 0.1 *N* HCl to the same final concentration as that expected for the assay.

Immediately after preparation of the assay and standard solutions, the absorbance was determined as specified in the individual official monograph. With the exception of prochlorperazine maleate and edisylate, all assay and standard operations were carried out in low-actinic glassware. In addition, prochlorperazine maleate and edisylate standards and trimeprazine tartrate standards were carried through the extraction procedure to remove the counterions, which are UV absorbing.

Class II Compounds—Fluphenazine hydrochloride, thiethylperazine maleate, and trifluoperazine hydrochloride were assayed. Sample preparation was the same as that described for the Class I compounds. For thiethylperazine maleate, 20 mg of drug was transferred to a separator. Ten milliliters of 0.1 *N* HCl, 15 ml of water, and 5 ml of saturated sodium chloride were added, after which the procedure in NF XIV was followed. For trifluoperazine hydrochloride tablets, the official NF XIV procedure was used.

For trifluoperazine hydrochloride liquid formulations, an aliquot containing 2 mg of drug dissolved in 10 ml of 0.1 *N* HCl was transferred to a separator. Fifteen milliliters of water, 5 ml of saturated sodium chloride, and 3 ml of stronger ammonia were added. Then the solution was extracted with four portions of heptane (40, 25, 25, and 15 ml). The combined heptane extracts were extracted with 0.1 *N* HCl (4 × 25 ml), and the combined acid extracts were diluted to a final concentration of 10 mg/ml with 0.1 *N* HCl. The absorbance was measured at the wavelength specified in the monograph *versus* a blank of 0.1 *N* HCl. A standard of the same final concentration as expected for the sample was prepared, and its absorbance was read concomitantly. All operations were performed in low-actinic glassware.

For fluphenazine hydrochloride, the official USP procedure was used but the extraction solvent was changed from the specified *n*-hexane to *n*-hexane–*n*-butanol (98:2).

Class III Compounds—Triflupromazine hydrochloride, perphenazine,

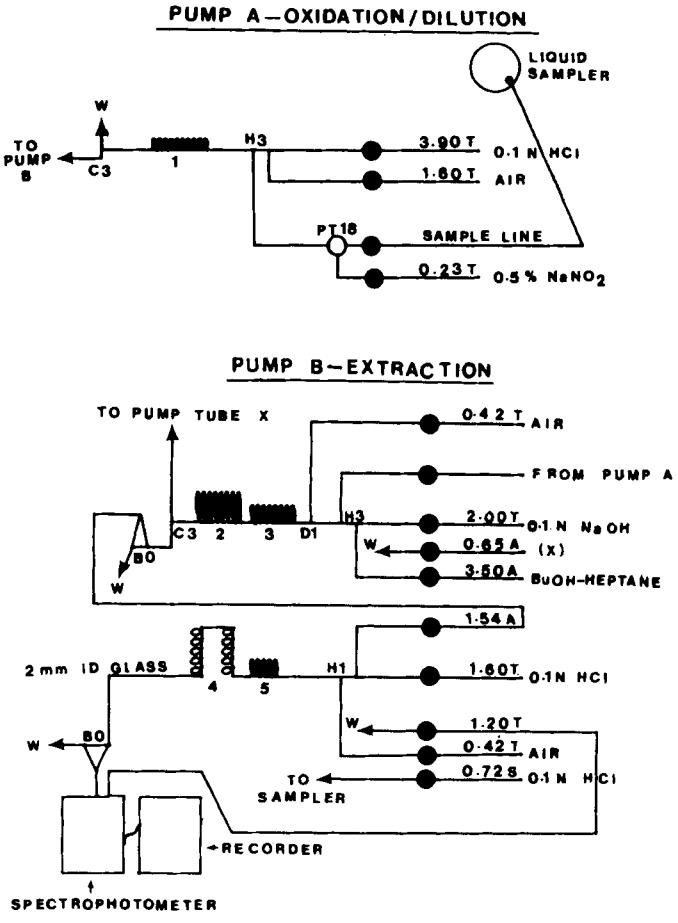

Figure 1—*Diagram of automated analytical system for phenothiazines. Pump tube sizes are listed in milliliters per minute. Key for pump tube materials: T, Tygon; S, silicone; and A, Acidflex. Key for mixing coils: 1, Technicon 105-0085; 2, eight turns of 2.4-mm (0.095 in.) i.d. Teflon tubing wrapped around a 38.1-mm (1.5-in.) diameter core; 3, Technicon 116-101-2 (beaded coil); 4, Technicon 157-0248; and 5, Technicon 116-0127-05 (1 mm i.d.). All points marked W go to the waste container. All connecting tubing should be as short as possible. The spectrophotometer is equipped with a 1-cm flowcell.*

and carphenazine maleate were assayed. The official procedures were used.

Automated Method—To prepare tablet samples, one tablet was placed in a vial and a sufficient amount of 0.025% ascorbic acid in 0.1 *N* HCl was added to yield the final drug concentration specified in Table II. The capped vial was shaken mechanically until tablet disintegration commenced. Then the vial was transferred to an ultrasonic bath, and the bath was operated until disintegration was complete. The vial was shaken mechanically for 30 min. After the solids settled, the supernate was decanted into a sample cup.

To prepare fluphenazine hydrochloride tablet samples, one tablet was placed in a volumetric flask chosen such that its volume yielded a final concentration of 50 μg/ml. Deionized water was added to equal 5% of the total flask volume. The flask was shaken mechanically until the tablet began to disintegrate. Then the flask was transferred to an ultrasonic bath, and the bath was operated until tablet disintegration was complete. The flask was diluted to volume with 95% alcohol and mixed. After the solids settled, the supernate was decanted into a sample cup.

To prepare the liquid formulation samples, a suitable aliquot was transferred in a "to contain" pipet to a volumetric flask. The pipet and volumetric flask were chosen such that the final assay concentration corresponded to that specified in Table II. The pipet contents were washed into the volumetric flask with 0.025% ascorbic acid in 0.1 *N* HCl, and the solution was diluted to volume with the same solvent. The standard solutions were prepared in this solvent at the same final concentration as that expected for the sample assay.

Table II—Differential UV and Semiautomated Analysis Parameters

Drug	Automated[a] Wavelength, nm	Automated[a] Final Concentration, μg/ml	Differential UV[b] Wavelength, nm	Differential UV[b] Final Concentration, μg/ml
I Carphenazine maleate	251	500	372	208
II Chlorpromazine hydrochloride	241, 298	200	344	40
III Promazine hydrochloride	241, 298	200	342	40
IV Thiethylperazine maleate	276	200	350	83
V Thioridazine hydrochloride	276, 342	200	348	40
VI Triflupromazine hydrochloride	273	400	347	40
VII Trimeprazine tartrate	271	100	342	42
VIII Fluphenazine hydrochloride	256	50	349	4.2
IX Methdilazine hydrochloride	251	160	341	58
X Prochlorperazine maleate	257	100	342	42
XI Trifluoperazine hydrochloride	257	40	349	4.0
XII Perphenazine	255	80	343	33

[a] Drugs I–VII were oxidized and double extracted. Drugs IX–XII were extracted and determined directly. For VIII in tablet strengths of ≥2.5 mg, the extracted drug was determined at a concentration of 50 μg/ml. Tablets containing ≤1 mg were oxidized, double extracted, and determined fluorometrically at a concentration of 10 μg/ml. [b] Drugs VIII and XI were analyzed by differential fluorescence; all others were analyzed by the differential UV method.

The assay (Fig. 1) was carried out by placing the sample and standard solutions in 3-ml polystyrene cups on a liquid sampler set at 24 samples/hr with a sample-to-wash ratio of 4:1. The cups were filled in the following order: three cups of standard, five cups of sample, one cup of standard, five cups of sample, *etc.* Two cups of standard were placed at the end of each run.

For drugs requiring oxidation and dilution, the sample was withdrawn and segmented with air, and 0.1 *N* HCl and 0.5% $NaNO_2$ (if necessary) were added. The solution then was mixed, resampled, and made basic with 0.1 *N* NaOH; heptane–butanol was added. After segmentation with air, the solution was mixed in a beaded coil, and the phases were allowed to coalesce in a phasing coil. Then the phases were separated. The organic phase was segmented with air and mixed with 0.1 *N* HCl. The phases were separated again. The drug was extracted into 0.1 *N* HCl, and the absorbance of the aqueous phase was read at the specified wavelength in a spectrophotometer equipped with a 1-cm flowcell.

For drugs requiring only extraction, the oxidation–dilution manifold was not used. The sample was introduced directly into the extraction manifold at the resample pump tube and made basic with 0.1 *N* NaOH, and heptane–butanol was added. After segmentation with air, the solution was mixed in a beaded coil, and the phases were allowed to coalesce in a phasing coil. The phases were separated. The organic phase was segmented with air and mixed with 0.1 *N* HCl. The phases were separated again. The drug was extracted into 0.1 *N* HCl, and the absorbance of the aqueous phase was read at the specified wavelength in a spectrophotometer equipped with a 1-cm flowcell.

Differential UV Method—The chromatographic columns for single-tablet and composite assays were prepared as follows. For 10-mg and higher strength tablets, a 17 × 250-mm column[12] plugged with glass wool was used. Acid-washed siliceous earth (3 g) was added and tamped down. The column was topped with a glass wool plug. Then 60 ml of 0.1 *N* HCl was passed through the column, and the wash was discarded. The column then was ready for use. For tablets of <10-mg strength, this procedure was modified to use a 13 × 200-mm column[12] packed with 1 g of acid-washed siliceous earth.

Single-tablet assays for promazine hydrochloride, chlorpromazine hydrochloride, triflupromazine hydrochloride, thioridazine hydrochloride, and thiethylperazine maleate were conducted as follows. One tablet was disintegrated in 60 ml of 0.1 *N* HCl in an ultrasonic bath. The tablet suspension was shaken for 1 hr on a mechanical shaker. Composites were prepared by determining the average tablet weight and then grinding the tablets to pass through a 60-mesh screen. A sufficient amount of tablet powder was weighed accurately to contain 10–12.5 mg of phenothiazine salt, to which 60 ml of 0.1 *N* HCl was added. The tablet suspension was shaken mechanically for 1 hr. A standard solution was prepared in 0.1 *N* HCl such that 60 ml contained an accurately known amount (10–12.5 mg) of standard.

Single-tablet, composite, and standard solutions were prepared in the following manner. Sixty milliliters of solution containing 10–12.5 mg of phenothiazine salt was passed through a chromatographic column into a 100-ml volumetric flask. Residual drug was washed through the column with three portions (20, 15, and 15 ml) of 0.1 *N* HCl. The combined eluate was diluted to 100.0 ml with 0.1 *N* HCl. Peracetic acid (5.0 ml) was added to 20.0 ml of the eluate[13], and the solution was mixed and diluted to 50.0 ml with 0.1 *N* HCl.

[12] No. K-420530 or equivalent, Kontes, Evanston, Ill.

Table III—Phenothiazine Sulfoxide Absorptivities[a]

Sulfoxide	Wavelength, nm	Δ Absorptivity[b]	Absorptivity[c]
Prochlorperazine	342	7.95 (3)[d]	9.70
Perphenazine	343	12.0 (5)	14.8
Fluphenazine[e]	349	9.16 (4)	11.0
Chlorpromazine	344	13.8 (8)	18.1
Thioridazine	348	10.9 (8)	13.1

Trifluoperazine[e]	349		11.5

[a] Based on grams of phenothiazine salt per liter (1-cm cell). [b] Measured *versus* a blank containing an equal concentration of unoxidized drug. [c] Measured *versus* a solvent blank. [d] Number of determinations. [e] Assayed fluorometrically.

The absorbance of the oxidized composite assay solution was read rapidly *versus* that of a sample blank prepared from 20.0 ml of the assay eluate and 5.0 ml of acetic acid diluted to 50.0 ml with 0.1 *N* HCl. The absorbance of an oxidized standard solution, prepared from 20.0 ml of the standard eluate and 5.0 ml of peracetic acid diluted to 50.0 ml with 0.1 *N* HCl, was measured concomitantly *versus* that of a standard blank prepared from 20.0 ml of the standard eluate and 5.0 ml of acetic acid diluted to 50.0 ml with 0.1 *N* HCl. The absorbance of oxidized single-tablet assay solutions was measured rapidly *versus* that of a solvent blank prepared from 5.0 ml of acetic acid diluted to 50.0 ml with 0.1 *N* HCl. The absorbance of an oxidized standard solution was measured concomitantly *versus* that of a solvent blank. The wavelengths of the assay determination and final assay concentrations are given in Table II. Phenothiazine sulfoxide absorptivities are listed in Table III.

Single-tablet solutions of perphenazine were prepared by disintegrating one tablet in 25 ml of 0.1 *N* HCl in an ultrasonic bath. Composite solutions were prepared by grinding 20 tablets to pass through a 60-mesh screen and adding one tablet weight of composite powder to 25 ml of 0.1 *N* HCl. The single-tablet or composite suspension was shaken mechanically for 1 hr. The suspension was diluted, if necessary, to 80 μg/ml with 0.1 *N* HCl. A perphenazine standard solution of 80 μg/ml in 0.1 *N* HCl was prepared. Then 25 ml of 0.1 *N* HCl containing 2 mg of drug or standard was passed through a chromatographic column into a 50-ml volumetric flask.

Residual drug was washed from the column with three portions (10, 10, and 5 ml) of 0.1 *N* HCl. The combined eluate was diluted to 50.0 ml with 0.1 *N* HCl, and 20.0 ml of the eluate was oxidized with 4.0 ml of peracetic acid. The absorbance of the composite assay solution was measured rapidly at 343 nm *versus* a sample blank prepared from 20.0 ml of the same column eluate and 4.0 ml of acetic acid. The absorbance of an oxidized standard solution was measured concomitantly *versus* that

[13] For thiethylperazine maleate assays, 25.0 ml of the column eluate and 5.0 ml of peracetic acid were used.

Table IV—Percent Recovery of Phenothiazine Salts from Synthetic Formulation Mixtures by the Differential UV–Differential Fluorescence Method

of a standard blank prepared from 20.0 ml of the standard eluate and 4.0 ml of acetic acid. The absorbance of the oxidized single-tablet solution and the absorbance of an oxidized standard were measured *versus* a solvent blank prepared from 20.0 ml of 0.1 *N* HCl and 4.0 ml of acetic acid.

Single-tablet solutions of trimeprazine tartrate were prepared by disintegrating one tablet in 25 ml of 0.1 *N* HCl in an ultrasonic bath. Composite solutions were prepared by grinding 20 tablets to pass through a 60-mesh screen and adding one tablet weight of composite powder to 25 ml of 0.1 *N* HCl. The single-tablet or composite suspension was shaken mechanically for 1 hr. A trimeprazine tartrate standard solution of 100 μg/ml in 0.1 *N* HCl was prepared. Then 25 ml of the standard or assay solution containing 2.5 mg of drug was passed through a chromatographic column into a 50-ml volumetric flask. The assay proceeded as directed in the perphenazine assay beginning with the washing of residual drug. The absorbance was read at 342 nm.

Single-tablet solutions of methdilazine hydrochloride were prepared by disintegrating one tablet in 25 ml of 0.1 *N* HCl in an ultrasonic bath. Composite solutions were prepared by grinding 20 tablets to pass through a 60-mesh screen and adding one tablet weight of composite powder to 25 ml of 0.1 *N* HCl. The single-tablet or composite suspension was shaken mechanically for 1 hr. A methdilazine hydrochloride standard solution of 144 μg/ml was prepared in 0.1 *N* HCl. Then 25 ml of the standard or assay solution containing 3.6 mg of methdilazine hydrochloride was passed through a chromatographic column into a 50-ml volumetric flask. The assay proceeded as directed in the perphenazine assay beginning with the washing of residual drug. The absorbance was read at 341 nm.

Single-tablet solutions of prochlorperazine maleate were prepared by disintegrating one tablet in 50 ml of 0.1 *N* HCl in an ultrasonic bath. Composite solutions were prepared by grinding 20 tablets to pass through a 60-mesh screen and adding one tablet weight of composite powder to 50 ml of 0.1 *N* HCl. The single-tablet or composite suspension was shaken mechanically for 1 hr. The suspension was diluted, if necessary, to 100 μg/ml with 0.1 *N* HCl. A prochlorperazine maleate standard solution (100 μg/ml) was prepared in 0.1 *N* HCl. Then 50 ml of the standard or assay solution containing 5 mg of prochlorperazine maleate was passed through a chromatographic column into a 100-ml volumetric flask. The column was washed with three portions (15, 15, and 10 ml) of 0.1 *N* HCl. The combined eluate was diluted to 100.0 ml with 0.1 *N* HCl, and the assay proceeded as directed in the perphenazine assay beginning with the oxidation of the eluate. The absorbance was read at 342 nm.

Single-tablet solutions of carphenazine maleate were prepared by disintegrating one tablet in 25 ml of 0.1 *N* HCl in an ultrasonic bath. Composite solutions were prepared by grinding 20 tablets to pass a 60-mesh screen and adding one tablet weight of the composite powder to 25 ml of 0.1 *N* HCl. The single tablet or composite suspension was shaken mechanically for 1 hr. A carphenazine maleate standard solution (500 μg/ml) was prepared in 0.1 *N* HCl. Then 25 ml of the standard or the assay solution containing 12.5 mg of carphenazine maleate was passed through a chromatographic column into a 50-ml volumetric flask. Residual drug was washed from the column with three portions (15, 15, and 10 ml) of 0.1 *N* HCl. The combined eluate was diluted to 50.0 ml with 0.1 *N* HCl, and the assay proceeded as directed in the perphenazine assay beginning with the oxidation of the eluate. The absorbance was read at 372 nm.

Liquid formulations of chlorpromazine hydrochloride and thioridazine hydrochloride were assayed as follows. An aliquot of liquid containing 100 mg of drug was transferred in a "to contain" pipet to a suitable volumetric flask, and the pipet contents were rinsed into the flask with 0.1 *N* HCl. The solution was diluted quantitatively and stepwise to a final concentration of 50 μg/ml. Standard solutions of thioridazine hydrochloride and chlorpromazine hydrochloride were prepared at a concentration of 50 μg/ml. Then 20.0-ml aliquots of the thioridazine hydrochloride assay solution were pipetted into each of two flasks; 5.0 ml of peracetic acid was pipetted into one flask, and 5.0 ml of acetic acid was pipetted into the other flask. The absorbance of the oxidized thioridazine hydrochloride solution was read at 348 nm *versus* that of the sample blank. The absorbance of the oxidized thioridazine hydrochloride standard solution was measured concomitantly *versus* that of a standard blank. The absorbance of oxidized chlorpromazine hydrochloride assay and standard solutions was measured at 344 nm *versus* that of their appropriate blanks.

To assay liquid formulations of prochlorperazine maleate, an aliquot of liquid containing 10 mg of drug was transferred in a "to contain" pipet to a suitable volumetric flask. The pipet contents were rinsed into the flask with 0.1 *N* HCl, and the solution was diluted quantitatively and stepwise with 0.1 *N* HCl to a final concentration of 50 μg/ml. A standard solution of prochlorperazine maleate was prepared having a final concentration of 50 μg/ml. Then 20.0-ml aliquots of sample and standard solutions were oxidized with 5.0-ml aliquots of peracetic acid. The absorbance of oxidized standard and oxidized sample solutions was measured concomitantly *versus* that of their appropriate blanks at 342 nm.

Differential Fluorometric Method—The fluorescence of oxidized phenothiazines was reported previously (27), but an assay was not developed at that time. Excitation occurs at 365 nm[14]; emission is at 405 nm[15]. A linear relationship between the meter response and the concentration change was demonstrated in the concentration range of interest.

After insertion of the proper excitation and emission filters, the apertures, range, and sensitivity were set to yield a meter deflection of ~90% with an oxidized drug solution. With these instrumental settings, the fluorescence of the freshly oxidized standard, sample, and blank solutions was measured.

To assay 0.25-mg fluphenazine hydrochloride tablets, one tablet was disintegrated in 25 ml of pH 2.2 buffer in an ultrasonic bath. Then 15.0 ml of 95% alcohol[16] was added and shaken mechanically for 1 hr. The solution was diluted to 50.0 ml with pH 2.2 buffer and filtered through paper[17]; the first 10 ml was discarded. Then 25.0-ml aliquots of the filtrate were pipetted into each of two flasks. One aliquot was oxidized with 5.0 ml of peracetic acid, and 5.0 ml of acetic acid was added to the other aliquot. The fluorescence of the sample and blank solutions was determined in 1-cm rectangular cells. The fluorescence of the oxidized standard and standard blank solutions was measured concomitantly.

For tablets containing 1, 2.5, 5, or 10 mg of fluphenazine hydrochloride or trifluoperazine hydrochloride, one tablet was disintegrated in 60 ml of pH 2.2 buffer in an ultrasonic bath. Then 30.0 ml of 95% alcohol was added, and the solution was shaken mechanically for 1 hr. The solution was diluted to 100.0 ml with pH 2.2 buffer and filtered through paper[17]; the first 10 ml was discarded. An aliquot containing 0.5 mg of drug was pipetted into a 100-ml volumetric flask and diluted to volume with alcohol

[14] Filter 5860, Corning Glass Works, Corning, N.Y.

[15] Ditric Optics Inc., Marlboro, Mass. A narrow band filter reduces sample blanks about 75%.

[16] Alcohol hinders the disintegration and must be added after disintegration is complete. The final concentration of alcohol is important since it enhances the fluorescence intensity.

in pH 2.2 buffer. Then 25.0-ml aliquots were pipetted into each of two flasks. One aliquot was oxidized with 5.0 ml of peracetic acid, and 5.0 ml of acetic acid was added to the other aliquot. A standard assay and standard solution blank were prepared in the same manner. The fluorescence of each solution was determined concomitantly.

To run composite assays, the average tablet weight was determined. Then 20 tablets were ground to pass through a 60-mesh screen. One tablet weight of powder was used in a manner similar to the single-tablet procedure.

To assay liquid formulations of trifluoperazine hydrochloride, an aliquot of liquid containing 50 mg of drug was transferred in a "to contain" pipet to a suitable volumetric flask. The pipet contents were rinsed into the flask with alcohol in pH 2.2 buffer. The solution was diluted quantitatively and stepwise with this solvent to a final concentration of 5.0 μg/ml. A standard trifluoperazine hydrochloride solution was prepared with this solvent at a concentration of 5.0 μg/ml. Then 25.0-ml aliquots of the sample and standard solutions were oxidized with 5.0-ml portions of peracetic acid. The fluorescence of the sample and standard solutions was read rapidly in 1-cm rectangular cells. Sample and standard blanks were prepared from 25.0 ml of solution and 5.0 ml of acetic acid. The fluorescence of each blank was determined, and the sample and standard fluorescences were corrected.

RESULTS AND DISCUSSION

Validation Tests—A tablet placebo was prepared from the known formulation ingredients. To this placebo was added an aliquot containing an amount of drug corresponding to the label declaration. This synthetic mixture then was subjected to the appropriate differential UV or differential fluorescence composite assay. Recovery results are listed in Table IV.

Modified Official Method—The most serious problem encountered with the official assay methods involved the ether extraction steps (Class I compounds only; thioridazine hydrochloride and trifluoperazine hydrochloride ether extractions did not exhibit this problem). The ether extraction procedures require an aeration step to remove residual ether from the final dilute acid extract. Aeration generated colored solutions, and these solutions exhibited badly distorted UV curves (28). The substitution of nitrogen gas for air did not alleviate the problem. It is well known that hydroperoxides rapidly oxidize phenothiazines to their sulfoxides; thus, ether peroxide impurities were suspected (4). To avoid having to purify ether continuously, heptane was used as the solvent. This choice of solvent solved the problem, but mixtures of heptane and dilute acid are prone to emulsion.

The Class II phenothiazines were extracted incompletely by the official procedures. The simple expedient of using saturated sodium chloride solution solved this problem. In this way, the extraction partition coefficient for thiethylperazine maleate was raised 100-fold. In addition, the fluphenazine assays required the addition of 2% *n*-butanol to the *n*-hexane extraction solvent.

The official procedures worked quite well for the Class III compounds, but carphenazine–palladium complexes are very unstable.

The amendments to the official procedures, although improving their utility, do not make these methods specific.

Semiautomated Method—This procedure was developed initially without an oxidation step, but some dosage levels were too low to permit UV measurement. For most of these drugs, oxidation with 0.5% $NaNO_2$ raised absorbances to convenient working levels, but single tablets containing 0.25 or 1.0 mg of fluphenazine hydrochloride could not be assayed by oxidation followed by UV analysis. These tablet strengths eventually were assayed by oxidation followed by fluorometric determination.

With these modifications, the automated system was applicable to every type of formulation encountered. In most cases, coefficients of variation were as good as or better than those of the modified official method. Table V contains a typical comparative precision study. Since the automated procedure, like the official and modified official methods, employs a UV solvent blank, this method also is nonspecific if impurities are present.

Differential UV and Differential Fluorescence Methods—During the differential UV oxidation studies, it was noted that sulfoxide absorbances declined slowly with time; but it has been demonstrated that for each drug in this study, the ratio of standard and sample absorbances is constant for at least 3 hr after oxidation. In addition, absorbances and fluorescence intensities usually rise and reach a maximum value that is

Table VII—Comparative Analysis of Commercial Liquid Formulations

[a] Number of determinations.

sufficiently stable for measurement in ~3 min after oxidation. This rise apparently is due to the expulsion of air bubbles formed as a result of mixing acetic acid and dilute hydrochloric acid.

Differential UV assays results were unaffected by 18 commonly used excipients. However, the differential fluorescence method was affected by one excipient, dibasic calcium phosphate. This problem was corrected by changing the fluorescence assay solvent from 0.1 *N* HCl to pH 2.2 buffer containing ~30% alcohol. Comparative assay results for the three methods are summarized in Tables VI and VII.

CONCLUSIONS

Previously published work on the phenothiazine differential oxidation method suggested its general applicability (3). The inclusion of a siliceous earth filtration step and the introduction of a fluorometric procedure for lower formulation strengths make the method facile and accurate. The method was shown to be reproducible to concentrations as low as 1 μg/ml. The procedure was applied to tablets, sustained-release preparations, concentrates, and syrups. Recoveries from known mixtures ranged from 99 to 101%. These results and the specificity of the differential oxidation procedure suggest its superiority to the official assay procedures.

Pyridones as Potential Antitumor Agents II: 4-Pyridones and Bioisosteres of 3-Acetoxy-2-pyridone

DENG R. HWANG *, GEORGE R. PROCTOR ‡, and JOHN S. DRISCOLL ˣ

Received February 25, 1980, from the *Drug Design and Chemistry Section, Laboratory of Medicinal Chemistry and Biology, Developmental Therapeutics Program, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication March 25, 1980. *Present address: Technicon Inc., Tarrytown, N.Y. ‡Present address: University of Strathclyde, Glasgow, Scotland.

Abstract □ Pyridone structural requirements for activity against murine P-388 leukemia have been extended to isosteric analogs of 3-hydroxy-4-pyridone, a compound previously found to have activity. An amino group can be substituted for the 3-hydroxyl function with retention of activity. A sulfur, but not an amino function, can replace the lactam oxygen in the 2-position. Relocation of the lactam oxygen from the 2- to the 4-position in the pyridine ring also produces active pyridones, including 2-methyl-3-acetoxy-4-pyridone. This compound, which has a T/C value of 179%, is the most active material discovered thus far in the pyridone studies.

Keyphrases □ Pyridones—4-pyridones and bioisosteres of 3-acetoxy-2-pyridone, synthesis and evaluation for antitumor activity □ Antitumor agents, potential—4-pyridones and bioisosteres of 3-acetoxy-2-pyridone, synthesis and evaluation for activity □ Structure–activity relationships—4-pyridones and bioisosteres of 3-acetoxy-2-pyridone, synthesis and evaluation for antitumor activity

It was reported recently that 3-hydroxy- (I) and 3-acetoxy-2-pyridone (II) have reproducible activity against murine P-388 lymphocytic leukemia (1). Eight additional derivatives of 3- and 5-hydroxy-2-pyridone also were active, and a tentative structure–activity relationship was established between antitumor activity and the position of the hydroxyl group relative to the 2-pyridone lactam function. The present investigation extends the study of

[a] Number of determinations.

sufficiently stable for measurement in ~3 min after oxidation. This rise apparently is due to the expulsion of air bubbles formed as a result of mixing acetic acid and dilute hydrochloric acid.

Differential UV assays results were unaffected by 18 commonly used excipients. However, the differential fluorescence method was affected by one excipient, dibasic calcium phosphate. This problem was corrected by changing the fluorescence assay solvent from 0.1 *N* HCl to pH 2.2 buffer containing ~30% alcohol. Comparative assay results for the three methods are summarized in Tables VI and VII.

CONCLUSIONS

Previously published work on the phenothiazine differential oxidation method suggested its general applicability (3). The inclusion of a siliceous earth filtration step and the introduction of a fluorometric procedure for lower formulation strengths make the method facile and accurate. The method was shown to be reproducible to concentrations as low as 1 μg/ml. The procedure was applied to tablets, sustained-release preparations, concentrates, and syrups. Recoveries from known mixtures ranged from 99 to 101%. These results and the specificity of the differential oxidation procedure suggest its superiority to the official assay procedures.

Pyridones as Potential Antitumor Agents II: 4-Pyridones and Bioisosteres of 3-Acetoxy-2-pyridone

DENG R. HWANG *, GEORGE R. PROCTOR ‡, and JOHN S. DRISCOLL ˣ

Received February 25, 1980, from the *Drug Design and Chemistry Section, Laboratory of Medicinal Chemistry and Biology, Developmental Therapeutics Program, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication March 25, 1980. *Present address: Technicon Inc., Tarrytown, N.Y. ‡Present address: University of Strathclyde, Glasgow, Scotland.

Abstract □ Pyridone structural requirements for activity against murine P-388 leukemia have been extended to isosteric analogs of 3-hydroxy-4-pyridone, a compound previously found to have activity. An amino group can be substituted for the 3-hydroxyl function with retention of activity. A sulfur, but not an amino function, can replace the lactam oxygen in the 2-position. Relocation of the lactam oxygen from the 2- to the 4-position in the pyridine ring also produces active pyridones, including 2-methyl-3-acetoxy-4-pyridone. This compound, which has a T/C value of 179%, is the most active material discovered thus far in the pyridone studies.

Keyphrases □ Pyridones—4-pyridones and bioisosteres of 3-acetoxy-2-pyridone, synthesis and evaluation for antitumor activity □ Antitumor agents, potential—4-pyridones and bioisosteres of 3-acetoxy-2-pyridone, synthesis and evaluation for activity □ Structure–activity relationships—4-pyridones and bioisosteres of 3-acetoxy-2-pyridone, synthesis and evaluation for antitumor activity

It was reported recently that 3-hydroxy- (I) and 3-acetoxy-2-pyridone (II) have reproducible activity against murine P-388 lymphocytic leukemia (1). Eight additional derivatives of 3- and 5-hydroxy-2-pyridone also were active, and a tentative structure–activity relationship was established between antitumor activity and the position of the hydroxyl group relative to the 2-pyridone lactam function. The present investigation extends the study of

pyridone antitumor activity to 2-pyridones that are bioisosteres of I and to the 4-pyridone system.

RESULTS

An earlier study (1) established that hydroxyl substitution at the 3-position produced optimal P-388 activity in the 2-pyridone series. For this reason, the 2,3-relationship was maintained in the study of the effect of bioisosteric functional groups on 2-pyridone antitumor activity. The objective of the present 2-pyridone study was the determination of the effect on P-388 activity of replacing the oxygen functionality in I and II with nitrogen- and sulfur-containing groups.

3-Amino-2-pyridone (IV) was synthesized by the nitration of 2-pyridone to produce 3-nitro-2-pyridone (III) and subsequent catalytic reduction to produce IV. Compound IV was reacted with acetic anhydride to give V, an analog of II, and with methyl isocyanate to give VI. Both V and VI are nitrogen isosteres of oxygen analogs previously found to be active (1). The importance of the oxygen functionality in the 2-position of I was studied by replacing it with nitrogen- (VII), chlorine- (VIII), and sulfur- (IX) containing groups. 3-Hydroxy-2-thiopyridone (IX) was *O*-acetylated to produce X, a sulfur analog of II, the most active oxygen-containing compound.

Another objective of this investigation was to study the effect of moving the lactam oxygen function in I from the 2-position to the 4-position to produce the other pyridone isomer. The commercially available pyrone plant product, maltol (XI), provided an entry to the desired 4-pyridone series. By a method similar to that of Fisher and Hodge (2), maltol was methylated to give XII, which was reacted with ammonia to produce the 4-pyridone (XIII). Methoxy cleavage with hydrobromic acid produced the target compound, 2-methyl-3-hydroxy-4-pyridone (XIV). The urethan (XV) and acetoxy (XVI) analogs were prepared for the reason mentioned previously.

Compounds III–XVI were evaluated using the standard National Cancer Institute protocol for P-388 lymphocytic leukemia (3). The data for the reproducibly active members of the series, as well as the activities reported (1) for I and II which are shown for comparison, are given in Table I. Duplicate dose–response tests were carried out with each compound. An active test is defined (3) as one that produces a T/C value[1] of ≥125%. Active compounds are defined as those that give active tests in two separate experiments. The compounds among I–XVI that are not shown in Table I were inactive in duplicate experiments.

DISCUSSION

Both 3-hydroxy-2-pyridone (I) and its acetyl derivative (II) have P-388 activity (Table I), with the latter compound being the best among 10 previously reported active analogs (1). Replacement of the 3-hydroxyl group in I with a nitro group (III) resulted in inactivity. However, an amino group in the same position provided a compound (IV) with approximately the same level of activity as its bioisostere, I. Acetylation of IV to produce V, instead of enhancing activity as in the case of II, abolished activity. While the formation of the methylaminocarbonyl derivative of I increased the activity of the resulting urethan (1), the opposite was the case when IV was treated in a similar manner.

Table I—Pyridones Active against P-388 Lymphocytic Leukemia[a]

Compound	Optimum Dose[b], mg/kg/day	T/C[c]	T − C[d]
I	400	138	−2.4
II	600	163	−2.8
IV	200	133	−4.1
IX	200	139	−0.9
XIV	200	153	0.0
XVI	400	179	−3.1

[a] With 10^6 cells implanted intraperitoneally in CDF_1 mice. [b] Dose giving the maximum T/C value on the QD 1–9 treatment schedule. [c] At least one other active test was obtained in a separate, duplicate experiment. [d] Weight difference, in grams, between treated and control mice 5 days after tumor implantation.

The replacement of the lactam oxygen function of I with an amino group to give VII, the position isomer of active IV and the bioisostere of active I, resulted in inactivity. This result may be related to the fact that 2-hydroxypyridines exist mainly in the lactam form while the amino form predominates in 2-aminopyridines (4). A similar replacement with chlorine (VIII), which possesses no tautomeric possibilities, also resulted in inactivity. However, when the same replacement was made with sulfur to produce 3-hydroxy-2-thiopyridone (IX), activity was retained. 2-Mercapto- as well as 2-hydroxypyridines exist as the amide tautomer (pyridone or lactam form) in >99% (4). Acetylation of IX to form X reduced activity (T/C 133, 120, and 110%), contrary to what was observed with I but similar to the finding with IV.

In the isomeric 4-pyridone series, the starting material, maltol (XI), its *O*-methylated derivative (XII), and the 3-methoxy-4-pyridone (XIII) obtained from XII did not possess P-388 activity. However, demethylation of XIII gave 2-methyl-3-hydroxy-4-pyridone (XIV), a compound with an activity level greater than that of I and similar to that of II, the most active compound in the 2-pyridone series. Preparation of a urethan (XV), which had increased activity relative to I in the 2-pyridone series, abolished activity in the 4-pyridone case. However, XVI, the *O*-acetyl derivative of XIV, was the most active compound in either the 2- or 4-pyridone series, producing T/C values of 179 and 176%. Compound XVI also proved active against the less sensitive murine tumor model, L-1210 lymphoid leukemia (T/C 157 and 138), and presently is being evaluated in the National Cancer Institute tumor panel (5).

The mechanism of antitumor activity for the pyridones has not been established. A similarity with the catechol–*ortho*-quinone series involving possible sulfhydryl reactivity was noted (6). Another possible parallel exists between the antitumor activity observed here and the catechol-*O*-methyl transferase inhibitory activity of the 3-hydroxypyridones demonstrated by Borschardt (7). Aminopyridones also were potent inducers of erythroid differentiation in Friend leukemia cells (8).

In summary, it has been found that relative to the 2-pyridone lead compound, I, an amino group can be substituted for the 3-hydroxy group with retention of activity and that a sulfur, but not an amino or a chloro function, can successfully replace the lactam oxygen in the 2-position. Changing the lactam oxygen from the 2- to the 4-position of the pyridine ring produces 3-hydroxy-4-pyridone derivatives with better P-388 leukemia activity than similar 2-pyridones. 2-Methyl-3-acetoxy-4-pyridone (XVI) is the most active compound found thus far in these studies. The 4-pyrone (XI), which differs from the 4-pyridone (XIV) only in the heterocyclic atom, is inactive. The inactivity of the 3-methoxy analog (XIII) is consistent with previous observations that the two vicinal oxygen functions capable of being oxidized further are required for P-388 activity in the pyridones (1) and in a similar, but nonheterocyclic, series of catechol derivatives (6).

EXPERIMENTAL[2]

3-Nitro-2(1*H*)-pyridone (III)—Compound III, mp 224–225° [lit. (9) mp 224–225°], was prepared from 2-pyridone on a 30-g scale by the method of Binz and Maier-Bode (9); NMR: 6.32 (t, 1, CH), 7.78 (m, 1, CH), 8.33 (m, 1, CH), and 12.77 (broad, 1, NH); UV: 361 (3.83) and 248 (3.43); IR: 1675 and 1640.

Anal.—Calc. for $C_5H_4N_2O_3$: C, 42.83; H, 2.88; N, 20.06. Found: C, 42.94; H, 2.89; N, 20.13.

3-Amino-2(1*H*)-pyridone (IV)—3-Nitro-2(1*H*)-pyridone (7.00 g, 0.05 mole) dissolved in 100 ml of methanol was hydrogenated in a Parr shaker (45 psi) in the presence of 10% palladium-on-carbon (400 mg). The catalyst was filtered, and the solution was stirred with activated carbon. The solution was filtered and evaporated to yield 5.47 g (99%) of a pink-white, light-sensitive solid, mp 123–125°; NMR: 4.66 (broad, 2, NH_2), 6.00 (t, 1, CH), and 6.63 (m, 2, CH); UV: 309 (3.94) and 253.5 (3.75); IR: 1650.

Anal.—Calc. for $C_5H_6N_2O$: C, 54.48; H, 5.49; N, 25.52. Found: C, 54.46; H, 5.56; N, 25.18.

3-Acetamido-2(1*H*)-pyridone (V)—A stirred mixture of sodium acetate (7.84 g, 0.08 mole), acetic anhydride (10 ml), and dry IV (8.45 g, 0.077 mole) was refluxed for 2 hr and then stirred for 16 hr at a temperature just high enough to keep the mixture fluid. The excess acetic anhydride was evaporated *in vacuo*, and the resulting solid was extracted first with hot methylene chloride (100 ml) and then with hot ethyl acetate (125 ml). Evaporation of the solvents gave a pink solid, which was dissolved in a limited amount of methanol and stirred with decolorizing carbon. Filtration of the solution and cooling gave 6.70 g (57%) of white crystals, mp 209–211°; NMR: 2.08 (s, 3, CH_3), 6.13 (t, 1, CH), 7.03 (m, 1, CH), 8.17 (m, 1, CH), and 9.12 and 11.82 (broad, 2, NH); UV: 308 (4.00), 256 (3.91), and 247.5 (3.98); IR: 1635 and 1605.

Anal.—Calc. for $C_7H_8N_2O_2$: C, 55.21; H, 5.29; N, 18.48. Found: C, 55.13; H, 5.31; N, 18.28.

3-[[(Methylamino)carbonyl]amino]-2(1*H*)-pyridone (VI)—Methyl isocyanate (3.00 ml, 0.051 mole) was added by syringe to a cold (2°) stirred solution of IV (5.50 g, 0.05 mole) and triethylamine (0.5 ml) in dry dimethylformamide (30 ml). Stirring was continued for 3 hr in the cold and for 50 hr at room temperature. Evaporation of the solvent *in vacuo* gave a brown solid, which was recrystallized from methanol (charcoal) to give 5.76 g (69%) of a white solid, mp >300°; NMR: 2.60 (d, 3, CH_3), 6.10 (t, 1, CH), 6.87 (broad, 2, CH, NH), 7.97 (m, 1, CH), and 8.15 and 11.70 (broad, 2, NH); UV: 305 (4.04) and 251 (4.01); IR: 1640–1605.

Anal.—Calc. for $C_7H_9N_3O_2$: C, 50.24; H, 5.42; N, 25.22. Found: C, 50.13; H, 5.50; N, 25.21.

3-Acetoxy-2(1*H*)-thiopyridone (X)—Acetic anhydride (3.82 ml, 0.0405 mole) was added by syringe to a dry, stirred solution of IX (5.09 g, 0.04 mole) and pyridine (0.0405 mole, 3.3 ml) in acetone (30 ml), which had been freshly distilled from phosphorus pentoxide. The solution was refluxed for 23 hr under nitrogen, during which time the product precipitated from solution. The mixture was stirred at room temperature for an additional 42 hr. The light-yellow product was filtered and then recrystallized from methanol–ethanol to give 5.82 g (86%) of a light-yellow solid, mp 167–171°; NMR: 2.20 (s, 3, CH_3), 6.68 (t, 1, CH), 7.74 (m, 2, CH), and 13.8 (broad, 1, NH); UV: 361.5 (3.89) and 279.5 (4.05); IR: 1765, 1365, and 1310.

Anal.—Calc. for $C_7H_7NO_2S$: C, 49.67; H, 4.17; N, 8.31. Found: C, 49.78; H, 4.40; N, 8.41.

2-Methyl-3-methoxy-4-pyrone (XII)—Compound XII was prepared in a 73% yield on a 20-g scale from XI by the method of Fisher and Hodge (2). The crude product was used immediately for the next reaction without further purification.

2-Methyl-3-methoxy-4(1*H*)-pyridone (XIII)—Crude XII (20.63 g, 0.146 mole) was dissolved in concentrated ammonium hydroxide (600 ml), and the light-yellow solution was refluxed for 12 hr. The reaction mixture was cooled to room temperature, more ammonium hydroxide was added (50 ml), and stirring was continued for 4 hr. Evaporation of the solvent *in vacuo* gave a yellow solid, which was recrystallized from acetone to give 16.39 g (80.5%) of product. Further recrystallization from acetone–ethanol gave analytically pure XIII, mp 155–156° [lit. (2) mp 155–156°]; NMR ($CDCl_3$): 2.33 (s, 3, CH_3), 3.75 (s, 3, OCH_3), 6.40 (d, 1, CH), 7.48 (d, 1, CH), and 9.97 (broad, 1, NH); UV: 264 (4.14); IR: 1620.

Anal.—Calc. for $C_7H_9NO_2$: C, 60.39; H, 6.52; N, 10.10. Found: C, 60.37; H, 6.63; N, 10.05.

2-Methyl-3-hydroxy-4(1*H*)-pyridone (XIV)—A solution of XIII (8.35 g, 0.06 mole) in 48% hydrobromic acid (120 ml) was heated at 140–150° for 4 hr, cooled to room temperature, and concentrated to 30–40 ml. The resulting red crystalline solid was isolated and dissolved in a small amount of water, and the solution was carefully neutralized with sodium carbonate. At pH 6–7, a red-brown solid precipitated. This solid was filtered, dissolved in boiling water, and decolorized with charcoal. A light red-brown product was isolated (5.81 g, 77%), mp 285–288° dec. [lit. (2) mp >250° dec.]; NMR: 2.13 (s, 3, CH_3), 6.03 (m, 2, CH + exchangeable), and 7.3 (m, 2, CH + exchangeable); UV: 276.5 (4.17); IR: 1635.

Anal.—Calc. for $C_6H_7NO_2$: C, 57.57; H, 5.63; N, 11.24. Found: C, 57.30; H, 5.77; N, 11.28.

2-Methyl-3-[[(methylamino)carbonyl]oxy] -4(1*H*)- pyridone (XV)—To a stirred suspension of XIV (2.78 g, 0.02 mole) in dry dimethylformamide (15 ml) and triethylamine (5 drops) under nitrogen was added 1.21 ml (0.02 mole) of methyl isocyanate. During the addition (syringe through a flask septum), the suspended solid changed from red brown to white. After stirring 21 hr at room temperature, the solvent was evaporated, the resulting solid was triturated well with benzene and then ethyl acetate. A pink-white solid (3.61 g, 99%), mp 280–285° dec., was obtained; NMR: 2.08 (s, 3, CH_3), 2.57 (d, 3, NCH_3), 6.07 (d, 1, CH), 7.45 (broad, 2, CH, NH), and 10.2 (broad, 1, NH); UV: 258.5 (4.16); IR: 1730 and 1620.

Anal.—Calc. for $C_8H_{10}N_2O_3$: C, 52.71; H, 5.53; N, 15.43. Found: C, 52.40; H, 5.50; N, 15.13.

2-Methyl-3-acetoxy-4(1*H*)-pyridone (XVI)—A solution of XIV (3.64 g, 0.029 mole) in acetic anhydride (25 ml) was refluxed (130–140°) for 21 hr under a nitrogen atmosphere. Removal of excess acetic anhydride gave a dark oil, which was dissolved in ethyl acetate and cooled at 0°. A dark-brown solid (1.05 g, 22%) resulted, mp 205–208° [lit. (2) mp 205–208°, (10) 204–205°]; NMR: 1.20 (unresolved d, 6, CH_3), 6.12 (broad, 1, CH), and 7.53 (broad, 1, CH); UV: 260 (4.10); IR: 1760 and 1630.

Anal.—Calc. for $C_8H_9NO_3$: C, 57.46; H, 5.42; N, 8.41. Found: C, 56.57; H, 5.47; N, 8.24.

[2] All melting points were recorded on a Thomas-Hoover capillary apparatus and are uncorrected. Elemental analyses were performed by the Microanalytical Services Section, National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health, Bethesda, Md. Compounds were identified by NMR, UV, and IR spectroscopy. These spectra were determined in dimethyl sulfoxide-d_6, 95% ethanol, and nujol, respectively, unless otherwise indicated. NMR data are delta values relative to tetramethylsilane, UV values are in nanometers (log ϵ), and IR values are in reciprocal centimeters. Compounds I, II, VII–IX, and XI were purchased from Aldrich Chemical Co.

Evaluation of Sustained-Action Chlorpheniramine–Pseudoephedrine Dosage Form in Humans

AVRAHAM YACOBI ×, ROGER G. STOLL, GEORGE C. CHAO, JAMES E. CARTER, DAVID M. BAASKE, BURDE L. KAMATH, ANTON H. AMANN, and CHII-MING LAI

Received November 5, 1979, from the *Department of Pharmaceutical Development, Research and Development, American Critical Care, McGaw Park, IL 60085.* Accepted for publication January 28, 1980.

Abstract □ This investigation compared the bioavailability of chlorpheniramine and pseudoephedrine from a sustained-action capsule and a combination of two reference standard tablets in 24 normal human subjects. The capsule contained 8 mg of chlorpheniramine maleate and 120 mg of pseudoephedrine hydrochloride, and the tablets each contained half of the amount of the chlorpheniramine or pseudoephedrine in the capsule. Because the capsule was a combination product, a new study design had to be developed to accommodate steady-state conditions for both drugs. Each subject received the capsule (every 12 hr) and the combination of the reference tablets (every 6 hr) for 8 days according to a two-way crossover design. Serial blood and urine samples were taken during the entire study. Plasma and urine samples were assayed for chlorpheniramine and pseudoephedrine by sensitive and specific high-pressure liquid chromatographic or GLC methods. There were no significant differences in the plasma concentration profiles of chlorpheniramine and pseudoephedrine at all times, except when the capsule developed peaks or the tablets developed nadirs. The highest mean peak plasma concentrations for the capsule and the tablets were 38.7 and 32.9 ng of chlorpheniramine/ml and 525 and 515 ng of pseudoephedrine/ml, respectively. The mean biological half-lives of chlorpheniramine and pseudoephedrine were 21.6 and 8.0 hr, respectively. The *AUC* and unchanged drug excreted in urine, after a single dose and at steady state, showed that the sustained-action capsule (given every 12 hr) and the reference standard tablets (given every 6 hr) were bioequivalent.

Keyphrases □ Chlorpheniramine—bioavailability in sustained-release dosage form with pseudoephedrine □ Pseudoephedrine—bioavailability in sustained-release dosage form with chlorpheniramine □ Dosage forms, sustained release—bioavailability of chlorpheniramine and pseudoephedrine in combination product □ Bioavailability—chlorpheniramine and pseudoephedrine in sustained-release dosage form

Sustained-action dosage forms often are administered to assure a uniform blood concentration and to provide greater patient convenience and compliance. This dosage form minimizes the occurrence of adverse reactions caused by high plasma concentrations and assures clinical efficacy over the entire regimen. Drugs that are used in sustained-action dosage forms usually possess short half-lives, and their absorption and elimination are affected by physiological factors such as variable urinary pH, enzyme induction or inhibition upon multiple dosing, and variable GI motility.

The physical characteristics of a sustained-release dosage form are such that absorption of the drug is prolonged. The possibility of immediate release of a large amount of drug (dose dumping) is unlikely but requires verification. By considering such factors, a bioavailability study involving multiple doses to achieve steady state will provide a reproducibility test for the *in vivo* performance of a sustained-action dosage form. Pharmacokinetically, such a test will be characterized by more reliable parameters and less variability due to physiological changes.

Ideally, a sustained-action dosage form should release its contents at a constant rate, regardless of changes in the GI pH. Such a dosage form should avoid dose dumping and prevent large fluctuation in plasma concentrations. The objective of this study was to test the bioavailability of chlorpheniramine and pseudoephedrine from a newly developed sustained-action capsule dosage form containing chlorpheniramine and pseudoephedrine by comparison of the plasma concentration *versus* time profile of the drugs following administration of single and multiple doses.

EXPERIMENTAL

In a two-way crossover design study, 24 healthy, nonobese male subjects, 19–41 years old and 62–99 kg (mean 73 kg), were selected randomly. They did not receive any drugs, including enzyme-inducing agents and monoamine oxidase inhibitors, 1 month before and during the study. Eleven subjects were smokers. Alcoholic beverages and those containing caffeine also were withheld during the study.

Each subject received either one sustained-action capsule[1], containing 8 mg of chlorpheniramine maleate and 120 mg of pseudoephedrine hydrochloride, or the combination of one 4-mg chlorpheniramine maleate[2] tablet and one 60-mg pseudoephedrine hydrochloride[3] tablet with 200 ml of water. Either one capsule was given every 12 hr (twice per day) or the combination of the chlorpheniramine and pseudoephedrine tablets was given every 6 hr (four times per day) for 8 days. On Days 1 and 8, only a single capsule or two doses of the combination of the tablets was administered. The subjects were not allowed food overnight, from 10 hr before dosing to 4 hr after administration of the first capsule or first tablet on Days 1 and 8 of the study. A 5-day washout period was allowed between the two treatments.

Heart rate and blood pressure were measured daily during the entire study. Serial blood samples during Day 1 (for 24 hr), Days 2–7 (one sample at the minimum plasma concentration), and Day 8 (for 48 hr) were collected and the plasma was separated. Urine samples were collected during Day 1, at steady state, and for 48 hr after administration of the last capsule and tablet dose. All plasma and urine samples were frozen immediately and were kept frozen until they were assayed.

The plasma chlorpheniramine concentration was determined by a specific high-pressure liquid chromatographic (HPLC) method (1). The recovery and reproducibility of standard samples over the concentration range of 2.5–100 ng/ml were 96.6 and 95.4%, respectively. The plasma pseudoephedrine concentration was determined by GLC with electron-capture detection (2, 3). The recovery and reproducibility of standard samples over the concentration range of 10–700 ng/ml were 99.0 and 93.4%, respectively. Chlorpheniramine and pseudoephedrine concentrations in urine were determined simultaneously by a specific HPLC method (4, 5). The recovery and reproducibility of standard samples were 97.3 and 96.8%, respectively, for chlorpheniramine (0.12–3 μg/ml) and 89.7 and 96.8%, respectively, for pseudoephedrine (3–75 μg/ml). All samples were assayed in duplicate. Samples that showed more than a 15% difference between duplicate assays were reassayed in duplicate, when possible, and the two closest values were taken for final data analysis.

Dissolution testing of the capsule was carried out by a modification of the NF time-release procedure (6). The dissolution fluid consisted of 0.05 *M* potassium phosphate buffer (pH 4.5). There was no variation in the pH during the 7-hr dissolution procedure. The tablet dissolution testing was carried out using the USP XIX rotating-basket procedure. The concentrations of chlorpheniramine and pseudoephedrine in the dissolution fluids were determined by stability-indicating GLC proce-

dures (7). This assay also was utilized to verify potency for each dosage form.

The biological half-life, $t_{1/2}$, of each drug in individual subjects was determined from the postabsorption-distribution phase after administration of the last capsule (168 hr). The ratio of the total body clearance, Cl, to the bioavailability factor, F, was determined by dividing the given dose by the area under the plasma concentration *versus* time profile, AUC, at steady state, AUC_{ss} (168–180 hr). The AUC from 0 to 24 hr or at steady state was determined by the trapezoidal method. The ratio of the volume of distribution, V_d, to F was determined from $Cl/\beta F$, where β is the disposition rate constant and is equal to $0.693/t_{1/2}$. The average plasma concentration at steady state, $\overline{C}$, was determined by dividing AUC_{ss} by the dosing interval, *i.e.*, 12 hr. The relative amount of drug absorbed was evaluated by comparing the AUC at steady state and the amount of drug excreted in the urine at steady state.

A nonparametric Wilcoxon's two-sample test (8) with its application to crossover design by Koch (9) was performed to compare formulations for plasma concentrations, urinary excretion and recovery of unchanged drug, and pharmacokinetic parameters of chlorpheniramine and pseudoephedrine following administration of each dosage form. The same test was used for comparison of the blood pressure and heart rate. The period, group, and formulation effects also were tested.

RESULTS

Figures 1 and 2 depict the average plasma concentration *versus* time profiles of chlorpheniramine and pseudoephedrine, respectively. Data after the first and last doses at steady state are shown. The plasma concentrations were significantly higher for the capsule only at 4, 6, and 7 hr after the single dose and at steady state after the last dose.

Table I summarizes the mean peak plasma concentration, peak time of chlorpheniramine and pseudoephedrine, and results of statistical analysis. The mean peak plasma concentrations of chlorpheniramine at steady state were 38.7 ng/ml (range[4] 17.3–75.8 ng/ml) after administration of the capsule and 32.9 ng/ml (range 17.7–79.5 ng/ml) after the tablet. Without the unusual chlorpheniramine data point[4], the mean peak plasma concentration becomes 35.5 ng/ml, which is not significantly different from the mean values obtained for the standard tablet. The mean peak plasma concentration times differed after the single dose ($p < 0.01$) and was the same after multiple dosing for both drugs.

The higher concentrations of chlorpheniramine and pseudoephedrine attained in this study were not associated with an increase in the incidence or the type of adverse side effects.

Figure 3 depicts the mean minimum plasma concentration of chlorpheniramine and pseudoephedrine following multiple-dose administration of the sustained-release capsule and the reference tablets. There was essentially no significant difference between the values obtained for either dosage form. On the average, the steady-state minimum plasma concentration was achieved after 6 days for chlorpheniramine and 2 days for pseudoephedrine. The minimum plasma chlorpheniramine concentration was ~24 ng/ml and remained within a 10% range at Days 6–8; the minimum plasma concentration of pseudoephedrine increased from 260 ng/ml on Day 7 to ~315 ng/ml on Day 8.

Table II summarizes the mean AUC and amounts of unchanged chlorpheniramine and pseudoephedrine excreted in the urine. There was no significant difference between the two treatments. At steady state, the AUC and the urinary values were almost twice as high for chlorpheniramine and were ~27 and 12% higher for pseudoephedrine than those for the respective single doses. Additionally, at steady state, the amounts excreted in the urine for both drugs were higher at 156–168 hr than at 168–180 hr.

Table III lists the average pharmacokinetic parameters for chlorpheniramine and pseudoephedrine. These parameters were essentially identical for the capsule and reference tablets.

The relative amount of drugs absorbed was evaluated by comparing the AUC or the average steady-state plasma concentrations and the

[4] One subject showed an unusually high plasma concentration of 154 ng/ml 7 hr after the last dose; his second highest plasma concentration was 75.8 ng/ml 6 hr after the last dose.

Table I—Mean Peak Plasma Concentration and Peak Time of Chlorpheniramine and Pseudoephedrine and Results of Statistical Analysis

urinary excretion of the drugs at steady state. Table IV summarizes the ratio of these parameters (capsule to reference tablet) with respect to either drug. The capsule showed slightly higher bioavailability than the reference tablet.

The capsule potency was determined to be 101.2 and 104.0% of the labeled quantity of chlorpheniramine and pseudoephedrine, respectively. The chlorpheniramine and pseudoephedrine tablets contained 98.2 and 99.2%, respectively, of the labeled quantity. The dissolution testing indicated that the capsule released 84.5 and 89.0% of chlorpheniramine and pseudoephedrine, respectively, within 7 hr and that the tablets released 99.1 and 101.4% of chlorpheniramine and pseudoephedrine, respectively, within 15 min.

DISCUSSION

Because the sustained-action formulation tested was a combination product of chlorpheniramine and pseudoephedrine, a new study design had to be developed that would assure steady-state conditions for both drugs and use two reference standard tablets for the bioequivalency tests. A standard three-way crossover design would have made the study unduly

cumbersome. The two-way crossover design allowed for simultaneous administration of the two reference standard tablets to one group and the sustained-action formulation to the other and provided the opportunity for a multiple-dose study within a short time period.

The sustained-action capsule showed gradual *in vivo* absorption and produced plasma concentrations virtually identical to those obtained after administration of the reference tablets. Statistical differences were noted when the capsule reached the peak level at approximately the same time as the every 6-hr regimen reached its nadir. There was no indication of dose dumping after capsule administration. This conclusion is substantiated by sustained plasma concentrations during one dosing interval at steady state, similarity of peak plasma concentrations, and similarity of the time of peak plasma concentrations of either dosage form at steady state.

For both dosage forms, the time to achieve the highest peak plasma concentration was examined. Since the tablets were given every 6 hr, it was expected that the peak after the second 6-hr dose (*i.e.*, the second tablet) would be the highest; this expectation was verified statistically. For both drugs and at steady state, every 6-hr administration of the reference tablets should produce virtually the same peak at the same relative time. This response is apparent in the data and also is the reason for having a shorter peak plasma concentration time at steady state than after the single-dose administration (*i.e.*, the first two doses of the every 6-hr regimen) of the reference tablets.

The gradual *in vivo* absorption of the sustained-action capsule was dictated by its *in vitro* dissolution characteristics (Fig. 4). Identical dissolution profiles were observed at pH 1.5, 4.5, and 7.5. Therefore, no changes in the release rate are expected in the GI tract with respect to changes in pH. Other factors such as the presence or absence of enzymes may influence the dissolution rate of the drugs. The pH-independent dissolution of chlorpheniramine and pseudoephedrine in the capsule assures complete release of the drugs and minimizes the chances for dose dumping, which can cause side effects.

The results showed minimum occurrence of side effects during the 8 days of the study, with no effect on the heart rate or blood pressure by either dosage form. The chlorpheniramine and pseudoephedrine doses used in this study are considered safe. In a more rigorous clinical study, Bye *et al.* (10) observed signs of insomnia which lasted for the first 3 days among subjects who received chronic dosing with a 180-mg sustained-action product of pseudoephedrine. In another study, Dickerson *et al.* (11) found that chronic dosing with 120- and 150-mg sustained-action products of pseudoephedrine increased the pulse rate but decreased blood pressure.

Consistent with the half-lives of chlorpheniramine (22 hr) and pseudoephedrine (8 hr), the minimum steady-state plasma concentrations were achieved in 6 and 2 days, respectively. Both chlorpheniramine and pseudoephedrine are weak bases, and their elimination in urine is pH dependent (4, 12, 13). Day-to-day fluctuations in the urine pH will result in a fluctuation in the plasma concentration as well as in the urinary excretion of unchanged drugs. In this study, the minimum steady-state plasma concentration of both drugs, particularly pseudoephedrine, increased during the 168–180-hr interval; the urinary excretion of unchanged drugs in the same interval diminished. This change occurred just after hospitalization of the subjects and standardization of the food, which may have directly affected the urinary pH. In fact, consistent with the decrease in the urinary excretion of the drugs, the average urinary pH values did increase significantly from 5.8 at the 156–168-hr interval to ~6.1 at the 168–180-hr collection interval in both treatments (Table V).

The steady-state approach allowed determination of the pharmacokinetic parameters and bioequivalency of chlorpheniramine and pseudoephedrine between the sustained-action capsule and the reference standard tablets. The single-dose data after 24-hr blood sampling and urinary collection resulted in smaller *AUC* and urinary excretion values of unchanged drugs for both chlorpheniramine (44 and 50%, respectively) and pseudoephedrine (73 and 88%, respectively). This finding warrants a longer washout period for both drugs after a single dose. However, for chlorpheniramine, the sensitivity of the assay also must be considered.

The average plasma concentrations of chlorpheniramine and pseudoephedrine were the same for both dosage forms. In a group of 16 subjects who received a regimen of pseudoephedrine, the estimated minimum steady-state plasma concentration was 447 ng/ml (11), which is consistent with the present finding. The biological half-life of chlorpheniramine was in agreement with values reported in a study that utilized an identical assay (14). The average biological half-life of pseudoephedrine found in the present study (8.0 hr) was higher than values reported previously (5.9 hr) for 16 subjects (11). However, the higher half-life may account for the higher V_d/F value found in this study (3.4 liters/kg) than in the same 16 subjects (2.6 liters/kg). However, these differences also may be due to the study design and methods for estimation of V_d. The reproducibility of the pharmacokinetic parameters is indicative of completeness of absorption of chlorpheniramine and pseudoephedrine from both dosage forms. The reproducibility of the minimum steady-state plasma concentration also suggests that there was no enzyme induction with respect to chlorpheniramine metabolism or

Table IV—Relative Bioavailability of Chlorpheniramine and Pseudoephedrine after the Sustained-Release Capsule

Parameter	Ratio of Parameters[a] of Capsule to Tablets: Chlorpheniramine	Ratio of Parameters[a] of Capsule to Tablets: Pseudoephedrine
Excretion in urine

[a] Ratio of the mean parameters obtained after administration of the capsule and the combination of the tablets. Ratio of one indicates that two dosage forms are bioequivalent. [b] These parameters are determined at steady state and give the true bioequivalence data.

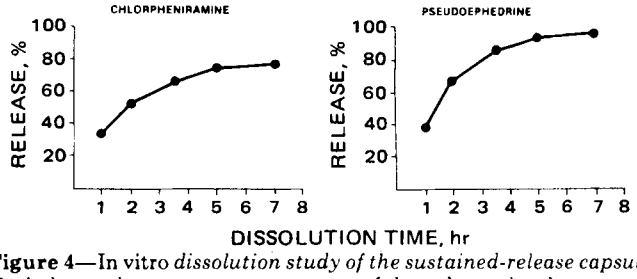

Figure 4—In vitro *dissolution study of the sustained-release capsule. Each data point represents an average of three determinations at each pH. Identical dissolution profiles were obtained at pH 1.5, 4.5, and 7.5.*

Table V—Mean Urine pH at Steady State and Results of Statistical Analysis

Urine Collection Interval, hr	Capsules pH[a]	Capsules p^b	Reference Tablets pH[a]	Reference Tablets p^b
156–168	5.78 ± 0.36		5.84 ± 0.51	
168–174	6.08 ± 0.65	<0.01	6.23 ± 0.68	<0.01
174–180	6.20 ± 0.67	<0.01	6.20 ± 6.16	<0.05
168–180[c]	6.14 ± 0.62	<0.01	6.21 ± 0.55	<0.01

[a] Mean ± *SD*, $n = 24$; there was no statistically significant difference between two treatments. [b] Statistically significant difference from 156–168-hr urine sample pH. [c] Average of 168–174- and 174–180-hr pH values.

changes in urinary excretion of either drug. While the urinary excretion of unchanged chlorpheniramine is a small fraction of the administered dose (4), the urinary excretion of unchanged pseudoephedrine is the major fraction of the administered dose and can be a reliable indicator for bioequivalency tests.

The bioequivalency test for sustained-release dosage forms can be best made at steady state when the amount excreted in urine reflects the amount absorbed. Table II substantiates this premise since the 0–24-hr *AUC* does not accurately reflect the amount of chlorpheniramine absorbed. At steady state, the *AUC* for a single dosing interval was more than twice as large as that found during the 0–24-hr interval following a single dose of the capsule. The slow absorption associated with this sustained-action dosage form makes it difficult to evaluate such systems using a single-dose study design. When the ratio of parameters characterizing the bioavailability of two drugs is one, the dosage forms are considered to be bioequivalent. In this study, the average ratio (capsule to reference tablet) was 1.06. Thus, both the rate of drug absorption as given by the peak plasma concentration and time of peak (Table I) and the extent of absorption (Tables II and IV) showed virtually identical bioavailability for the sustained-action capsule and reference standard tablets.

High-Performance Liquid Chromatographic Assay of Codeine in Acetaminophen with Codeine Dosage Forms

C. Y. KO ˣ, F. C. MARZIANI, and C. A. JANICKI

Received March 4, 1980, from the *Pharmacy Research Department, McNeil Laboratories, Fort Washington, PA 19034.* Accepted for publication March 27, 1980.

Abstract □ An accurate, rapid, and specific high-performance liquid chromatographic (HPLC) assay was developed for codeine in acetaminophen with codeine combination products. The internal standard (chlorpheniramine maleate), codeine, acetaminophen, and several other test compounds or impurities were well separated. A complete analysis took <10 min. The relative standard deviations of the retention time, precision, and accuracy were 0.5, 0.4, and 0.5%, respectively. An excellent linear correlation was obtained between the HPLC and GLC methods.

Keyphrases □ Codeine—high-performance liquid chromatographic analysis of capsules, tablets, and elixirs with acetaminophen and codeine, comparison with GLC analysis □ Acetaminophen—high-performance liquid chromatographic analysis of codeine and acetaminophen in capsules, tablets, and elixirs, comparison with GLC analysis □ High-performance liquid chromatography—analysis, codeine and acetaminophen in capsules, tablets, and elixirs, comparison with GLC analysis

Various analytical methods (1–11) have been reported for codeine, a narcotic analgesic and antitussive drug. Sell and Rajzer (1) determined codeine in nonaqueous media using a differentiating potentiometric titration method. Mulé (2) reported UV, TLC, and GLC methods for the determination of narcotic analgesics in humans. GLC methods (3–5) also were used extensively to determine codeine in various media.

Steady progress in high-performance liquid chromatographic (HPLC) analyses of codeine has been reported (6–11). Following reports that the HPLC technique was useful for codeine analysis (6, 7, 11), reversed-phase and ion-pair HPLC techniques were developed (8, 9). Baker *et al.* (10) recently analyzed codeine using a reversed-phase HPLC system equipped with dual-wavelength UV detection. Gupta (12) reported the simultaneous separation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide using a reversed-phase chromatographic method.

The purpose of this study was to develop an HPLC method that could be used routinely to assay codeine in acetaminophen with codeine combination products. This method is fast, simple, specific, precise, and accurate.

EXPERIMENTAL

Reagents and Materials—The *n*-hexane used was distilled in glass. Ammonium hydroxide was ACS grade. Chloroform[1], methanol[1], and sodium hydroxide[1] were analytical reagent grade. The codeine phosphate,

Table V—Mean Urine pH at Steady State and Results of Statistical Analysis

Urine Collection Interval, hr	Capsules pH[a]	Capsules p^b	Reference Tablets pH[a]	Reference Tablets p^b
156–168	5.78 ± 0.36		5.84 ± 0.51	
168–174	6.08 ± 0.65	<0.01	6.23 ± 0.68	<0.01
174–180	6.20 ± 0.67	<0.01	6.20 ± 6.16	<0.05
168–180[c]	6.14 ± 0.62	<0.01	6.21 ± 0.55	<0.01

[a] Mean ± *SD*, $n = 24$; there was no statistically significant difference between two treatments. [b] Statistically significant difference from 156–168-hr urine sample pH. [c] Average of 168–174- and 174–180-hr pH values.

changes in urinary excretion of either drug. While the urinary excretion of unchanged chlorpheniramine is a small fraction of the administered dose (4), the urinary excretion of unchanged pseudoephedrine is the major fraction of the administered dose and can be a reliable indicator for bioequivalency tests.

The bioequivalency test for sustained-release dosage forms can be best made at steady state when the amount excreted in urine reflects the amount absorbed. Table II substantiates this premise since the 0–24-hr *AUC* does not accurately reflect the amount of chlorpheniramine absorbed. At steady state, the *AUC* for a single dosing interval was more than twice as large as that found during the 0–24-hr interval following a single dose of the capsule. The slow absorption associated with this sustained-action dosage form makes it difficult to evaluate such systems using a single-dose study design. When the ratio of parameters characterizing the bioavailability of two drugs is one, the dosage forms are considered to be bioequivalent. In this study, the average ratio (capsule to reference tablet) was 1.06. Thus, both the rate of drug absorption as given by the peak plasma concentration and time of peak (Table I) and the extent of absorption (Tables II and IV) showed virtually identical bioavailability for the sustained-action capsule and reference standard tablets.

High-Performance Liquid Chromatographic Assay of Codeine in Acetaminophen with Codeine Dosage Forms

C. Y. KO ˣ, F. C. MARZIANI, and C. A. JANICKI

Received March 4, 1980, from the *Pharmacy Research Department, McNeil Laboratories, Fort Washington, PA 19034.* Accepted for publication March 27, 1980.

Abstract □ An accurate, rapid, and specific high-performance liquid chromatographic (HPLC) assay was developed for codeine in acetaminophen with codeine combination products. The internal standard (chlorpheniramine maleate), codeine, acetaminophen, and several other test compounds or impurities were well separated. A complete analysis took <10 min. The relative standard deviations of the retention time, precision, and accuracy were 0.5, 0.4, and 0.5%, respectively. An excellent linear correlation was obtained between the HPLC and GLC methods.

Keyphrases □ Codeine—high-performance liquid chromatographic analysis of capsules, tablets, and elixirs with acetaminophen and codeine, comparison with GLC analysis □ Acetaminophen—high-performance liquid chromatographic analysis of codeine and acetaminophen in capsules, tablets, and elixirs, comparison with GLC analysis □ High-performance liquid chromatography—analysis, codeine and acetaminophen in capsules, tablets, and elixirs, comparison with GLC analysis

Various analytical methods (1–11) have been reported for codeine, a narcotic analgesic and antitussive drug. Sell and Rajzer (1) determined codeine in nonaqueous media using a differentiating potentiometric titration method. Mulé (2) reported UV, TLC, and GLC methods for the determination of narcotic analgesics in humans. GLC methods (3–5) also were used extensively to determine codeine in various media.

Steady progress in high-performance liquid chromatographic (HPLC) analyses of codeine has been reported (6–11). Following reports that the HPLC technique was useful for codeine analysis (6, 7, 11), reversed-phase and ion-pair HPLC techniques were developed (8, 9). Baker *et al.* (10) recently analyzed codeine using a reversed-phase HPLC system equipped with dual-wavelength UV detection. Gupta (12) reported the simultaneous separation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide using a reversed-phase chromatographic method.

The purpose of this study was to develop an HPLC method that could be used routinely to assay codeine in acetaminophen with codeine combination products. This method is fast, simple, specific, precise, and accurate.

EXPERIMENTAL

Reagents and Materials—The *n*-hexane used was distilled in glass. Ammonium hydroxide was ACS grade. Chloroform[1], methanol[1], and sodium hydroxide[1] were analytical reagent grade. The codeine phosphate,

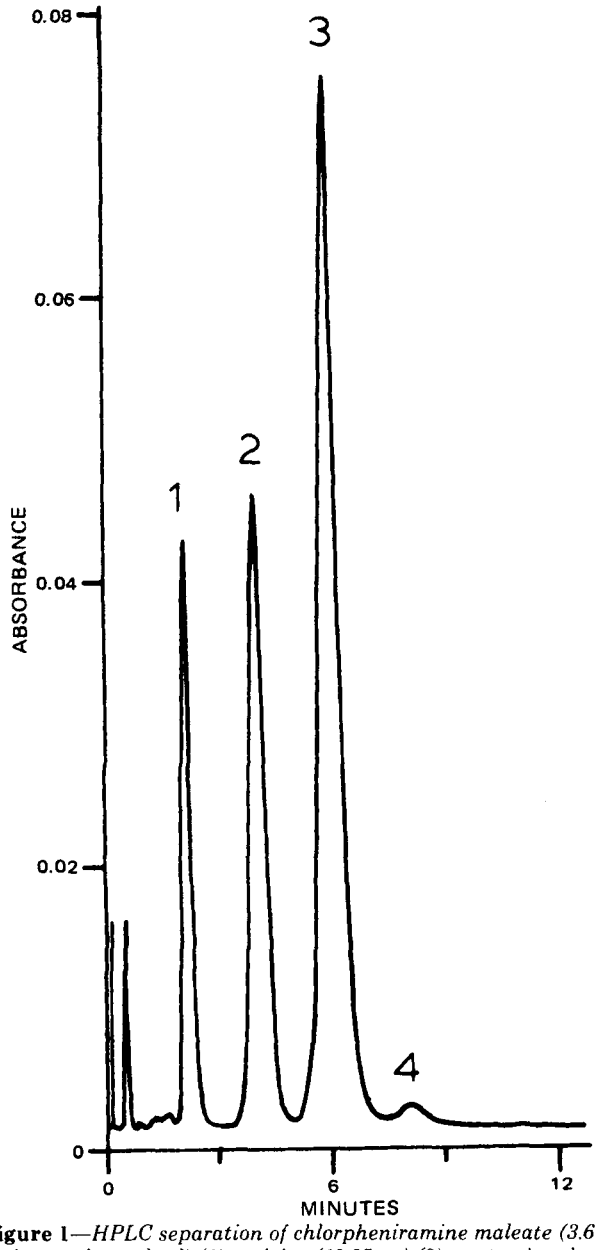

Figure 1—*HPLC separation of chlorpheniramine maleate (3.6 μg as an internal standard) (1), codeine (10.85 μg) (2), acetaminophen (unknown amount) (3), and an unknown compound (4) from an acetaminophen (325 mg) with codeine phosphate (30 mg) tablet sample.*

morphine sulfate, and chlorpheniramine maleate were USP reference standards. Atropine sulfate[2], apomorphine hydrochloride[3], nalorphine hydrochloride[3], naloxone hydrochloride[4], 4-aminophenol[5], acetaminophen[5], and acetaminophen with codeine products[5] were used as received.

Instrumentation—The high-performance liquid chromatograph[6] was equipped with a UV detector (254 nm), a 6000-psi pump, and a loop injector. The output of the UV detector was connected to a recorder and a minicomputer[7]. An automatic sampler[8] also was used.

Silica gel[9], 10 μm, was slurry packed, using a slightly modified packing procedure (13), into a 25-cm × 2.1-mm i.d. stainless steel column. The mobile phase was 23.2% methylene chloride, 4.4% methanol, 72.3% *n*-hexane, and 0.1% ammonium hydroxide. The column flow rate was set at 3.0 ml/min, and the UV detector was set at 0.10 aufs.

Internal Standard Preparation—A 22.5-mg sample of chlorpheniramine maleate was weighed accurately into a 25-ml volumetric flask, chloroform was added, and the flask was shaken until the compound dissolved. The sample was taken to volume with chloroform (0.9 mg/ml).

Codeine Standard Preparation—A 60-mg sample of codeine phosphate (equivalent to 45.20 mg of codeine) was weighed accurately into a 120-ml screw-capped bottle. Exactly 50 ml of chloroform and 40 ml of 0.1 *N* NaOH were added to the sample. It was capped tightly and shaken on a mechanical shaker for 1 hr. After centrifugation, the aqueous layer was aspirated and discarded.

The chloroform layer was filtered through a small pledget of cotton into a clean 60-ml bottle. Fifteen milliliters of the standard solution was pipetted into a 25-ml volumetric flask, 5 ml of the internal standard solution was added, and the solution was diluted to volume with chloroform. Twenty microliters of this solution was injected into the high-performance liquid chromatograph. This volume deposited 3.6 μg of chlorpheniramine maleate and 10.85 μg of codeine on the column.

Sample Preparation—For tablets, 20 tablets were selected randomly, weighed, and triturated to a fine powder. An accurately weighed amount of powder equivalent to 30 mg of codeine phosphate (22.60 mg of codeine) was transferred to a 120-ml screw-capped bottle.

For capsules, 20 capsules were randomly selected and weighed. The average capsule fill was determined. The contents of the capsules were emptied and mixed. An accurately weighed amount of powder equivalent to 30 mg of codeine phosphate (22.60 mg of codeine) was transferred to a 120-ml screw-capped bottle.

For the elixirs, an amount equivalent to 30 mg of codeine phosphate (22.60 mg of codeine) was transferred accurately to a 120-ml screw-capped bottle.

Exactly 25 ml of chloroform and 20 ml of 0.1 *N* NaOH were added to the sample. The bottle was capped tightly, shaken on a mechanical shaker for 1 hr, and centrifuged. The aqueous layer was aspirated and discarded. The chloroform layer (0.904 mg/ml) was filtered through a small pledget of cotton into a clean 60-ml bottle. A 15-ml aliquot of the 0.904-mg/ml chloroform solution was transferred to a 25-ml volumetric flask containing exactly 5 ml of the internal standard solution. It then was diluted to volume with chloroform and shaken. A 20-μl aliquot of this solution was injected into the high-performance liquid chromatograph. Two injections were made for each solution.

Calibration Curve—The relative calibration curve of the internal standard to codeine was prepared as follows. A known concentration of the internal standard was prepared, and different amounts of codeine phosphate were weighed and dissolved with the internal standard solution. The solutions were injected into the high-performance liquid chromatograph, and peak area ratios of codeine to the internal standard *versus* weight ratios of codeine to the internal standard were plotted.

Calculation—The peak area ratio, R, was determined from:

$$R = \frac{\text{area of codeine peak}}{\text{area of internal standard peak}} \qquad \text{(Eq. 1)}$$

The concentration of codeine then was determined from:

$$\text{sample concentration} = \text{codeine standard concentration} \times \frac{R_{\text{sample}}}{R_{\text{standard}}} \qquad \text{(Eq. 2)}$$

The percent of codeine was determined from:

$$\%\ \text{label} = \frac{\text{sample concentration}}{\text{theoretical sample concentration}} \times 100 \qquad \text{(Eq. 3)}$$

Precision Study—Twenty tablets containing acetaminophen with codeine were weighed and triturated to a fine powder. From this powder, seven samples, each containing the equivalent of 30 mg of codeine phosphate (22.60 mg of codeine), were weighed and treated as already described. Duplicate injections were made for each sample.

Accuracy Study—Known weights of codeine phosphate USP and acetaminophen USP were added to four placebo tablets. Samples were prepared as described and then were injected into the high-performance liquid chromatograph.

HPLC and GLC Comparison—The GLC method was similar to the methods described previously (2, 3). The gas–liquid chromatograph[10] was equipped with a flame-ionization detector and a 1.83-m × 2-mm i.d. coiled-glass column packed with 3% OV-17 on Chromosorb W HP (80–100

mesh). The column temperature was set at 205°, and the carrier gas was nitrogen. The initial standard was atropine and was prepared by accurately weighing 50 mg of atropine sulfate into a 120-ml screw-capped bottle. Fifty milliliters of chloroform and 25 ml of 0.1 *N* NaOH were added. The bottle then was shaken for 1 hr and centrifuged, and the aqueous layer was aspirated and discarded. The codeine standard and sample preparations were similar to those already described.

Samples of acetaminophen with codeine elixirs, tablets, and capsules were prepared as described. Before addition of the internal standard solution, the sample was split into two parts. One part was assayed by HPLC, and the other part was assayed by GLC.

RESULTS AND DISCUSSION

Figure 1 shows the excellent separation of codeine from acetaminophen and chlorpheniramine maleate in <10 min. This method also separates structurally related compounds from codeine such as naloxone hydrochloride, apomorphine hydrochloride, nalorphine hydrochloride, and morphine sulfate, as well as 4-aminophenol, the hydrolysis product of acetaminophen. The structurally related compounds were chosen to demonstrate the specificity of the method. Their respective retention times and detection limits are listed in Table I. The relative standard deviations of the retention times all were 0.5% (Table II).

Although both codeine and acetaminophen were well separated from each other, the simultaneous quantitation of a very large amount of acetaminophen and a small amount of codeine was chromatographically difficult. Acetaminophen had a much higher ϵ value than codeine at 254 nm. In addition, the simultaneous quantitative extractions of codeine and acetaminophen were unsuccessful. Either codeine or acetaminophen had to be extracted from the various dosage forms. It was decided to extract codeine quantitatively for HPLC analysis.

8	92.3	95.2	2.9

[a] The linear correlation coefficient was 0.9999, and the average variation was 1.7%.

The amount of ammonium hydroxide in the mobile phase was critical to the separation. Ammonia was lost slowly from the mobile phase. To keep the retention times constant and to maintain effective separation, fresh solvent should be used daily. Sometimes, it was necessary to adjust slightly the amount of ammonium hydroxide (between 0.1 and 0.2%) to obtain effective separation when a new column was used.

Chlorpheniramine maleate was chosen as the internal standard because its peak was sharp and symmetrical and it was well separated from codeine. Furthermore, chlorpheniramine maleate was stable and did not react with the mobile phase, other sample components, and the column packing. In addition, it is available commercially in high purity. The peak heights of chlorpheniramine maleate and codeine decrease slightly with time due to changing column conditions in the presence of ammonium hydroxide. However, the peak areas and their ratio remain unchanged, which is critical to an accurate assay. The precision of the method showed a relative standard deviation of 0.4% (n = 7) (Table III).

The accuracy of the assay is shown in Table IV. A relative standard deviation of 0.5% (n = 4) was obtained. When the internal standard method was not used, the relative standard deviations of precision and accuracy were >1.0%. For a routine assay with the automatic sampler, the standard codeine with the internal standard was injected as every third sample to ensure reliable results. In addition, the calibration curve obtained for the internal standard to codeine was linear.

The results of the comparison of the HPLC and GLC methods are shown in Table V. Three dosage forms with different amounts of acetaminophen with codeine were used. For 22 samples, the GLC assay results varied on an average of 1.7% from those of the HPLC assay. A linear correlation coefficient of 0.9999 was obtained. The precision of the GLC

assay was ~2%. Besides assaying for composite granulations, the HPLC assay also is applicable to content uniformity analysis.

In conclusion, the HPLC method is simple, precise, fast, specific, and accurate. A complete analysis takes ~10 min. All test compounds and known impurities can be detected. Since the analysis is conducted at ambient temperature, no thermal degradation of codeine is expected.

High-Performance Liquid Chromatographic Analysis of Nitroglycerin Ointment

LOREN GELBER

Received August 24, 1979, from the *Winchester Engineering and Analytical Center, Food and Drug Administration, Winchester, MA 01890.* Accepted for publication March 22, 1980.

Abstract □ The assay of ointments containing nitroglycerin is described. Sample preparation by direct dissolution in warm dimethyl sulfoxide appeared to be more accurate than extraction. Anisole was used as an internal standard. Chromatographic conditions included a C_{18} microporous silica column and a methanol–water mobile phase (40:60). Detection at 215 nm was superior to detection at 254 nm.

Keyphrases □ Nitroglycerin—ointment, reversed-phase high-performance liquid chromatographic analysis □ Ointments—nitroglycerin, reversed-phase high-performance liquid chromatographic analysis □ High-performance liquid chromatography—analysis, nitroglycerin ointment

The use of topical nitroglycerin for patients with congestive heart failure was reported recently (1). Existing methods for the analysis of nitroglycerin (2–9) lack specificity (7), are too time consuming for convenient uniformity determinations, or require prolonged heating that could lead to decomposition of nitroglycerin, which occurs at 50–60° (10).

Several high-performance liquid chromatographic (HPLC) assays for nitroglycerin dosage forms were reported recently (11, 12). These methods can separate nitroglycerin from its mono- and dinitrate degradation products. Since HPLC has none of the disadvantages of the other methods, its applicability to the analysis of nitroglycerin ointment was studied. A sample preparation method was developed so that the method of Crouthamel and Dorsch (11) could be applied to ointment samples. It was chosen for initial investigation because it uses an octadecylsilane column, which is widely available in HPLC laboratories, and a simple, less expensive, water–methanol mobile phase. The method of Baske *et al.* (12) uses a less retentive phenyl column and a more expensive and complex water–acetonitrile–tetrahydrofuran mobile phase. Contrary to a previous observation (12), no problems of clogging of inlet filters were encountered.

EXPERIMENTAL

Materials—The water used was HPLC grade[1]. The methanol was distilled in glass[2]. Dimethyl sulfoxide (I), butylated hydroxyanisole[3], isooctane, sodium acetate, acetic acid, potassium nitrate, ammonium hydroxide, lanolin, and petrolatum[4] were ACS reagent grade.

A 10% nitroglycerin on lactose triturate[5] was used as a standard and was calibrated by the USP phenoldisulfonic acid method for the assay of nitroglycerin (2). It assayed at 9.62%. The standard solutions were 1 mg/ml in methanol for Method 1, 2 mg/ml in I for Method 2, and 2 mg/ml in the internal standard solution for Method 2a.

Instrumentation—Two liquid chromatographic systems were used. The first system consisted of a dual-head reciprocating piston positive-displacement pump[6], a septumless syringe-loaded loop injector with a 10-μl loop[7], a variable-wavelength detector operated at 254 or 216 nm[8], a 10-mv recorder[9], and a 15-cm × 4-mm column of a slurry of chemically bonded octadecyl reversed-phase material[10] packed in aqueous sodium acetate and methanol according to the manufacturer's directions. The second system contained a dual-head reciprocating piston pump[11], an automatic injector[12], a variable-wavelength detector operated at 215 nm[13], a flat-bed recorder[14], and a 15-cm × 4.6-mm column of chemically

High-Performance Liquid Chromatographic Analysis of Nitroglycerin Ointment

LOREN GELBER

Received August 24, 1979, from the *Winchester Engineering and Analytical Center, Food and Drug Administration, Winchester, MA 01890.* Accepted for publication March 22, 1980.

Abstract □ The assay of ointments containing nitroglycerin is described. Sample preparation by direct dissolution in warm dimethyl sulfoxide appeared to be more accurate than extraction. Anisole was used as an internal standard. Chromatographic conditions included a C_{18} microporous silica column and a methanol–water mobile phase (40:60). Detection at 215 nm was superior to detection at 254 nm.

Keyphrases □ Nitroglycerin—ointment, reversed-phase high-performance liquid chromatographic analysis □ Ointments—nitroglycerin, reversed-phase high-performance liquid chromatographic analysis □ High-performance liquid chromatography—analysis, nitroglycerin ointment

The use of topical nitroglycerin for patients with congestive heart failure was reported recently (1). Existing methods for the analysis of nitroglycerin (2–9) lack specificity (7), are too time consuming for convenient uniformity determinations, or require prolonged heating that could lead to decomposition of nitroglycerin, which occurs at 50–60° (10).

Several high-performance liquid chromatographic (HPLC) assays for nitroglycerin dosage forms were reported recently (11, 12). These methods can separate nitroglycerin from its mono- and dinitrate degradation products. Since HPLC has none of the disadvantages of the other methods, its applicability to the analysis of nitroglycerin ointment was studied. A sample preparation method was developed so that the method of Crouthamel and Dorsch (11) could be applied to ointment samples. It was chosen for initial investigation because it uses an octadecylsilane column, which is widely available in HPLC laboratories, and a simple, less expensive, water–methanol mobile phase. The method of Baske *et al.* (12) uses a less retentive phenyl column and a more expensive and complex water–acetonitrile–tetrahydrofuran mobile phase. Contrary to a previous observation (12), no problems of clogging of inlet filters were encountered.

EXPERIMENTAL

Materials—The water used was HPLC grade[1]. The methanol was distilled in glass[2]. Dimethyl sulfoxide (I), butylated hydroxyanisole[3], isooctane, sodium acetate, acetic acid, potassium nitrate, ammonium hydroxide, lanolin, and petrolatum[4] were ACS reagent grade.

A 10% nitroglycerin on lactose triturate[5] was used as a standard and was calibrated by the USP phenoldisulfonic acid method for the assay of nitroglycerin (2). It assayed at 9.62%. The standard solutions were 1 mg/ml in methanol for Method 1, 2 mg/ml in I for Method 2, and 2 mg/ml in the internal standard solution for Method 2a.

Instrumentation—Two liquid chromatographic systems were used. The first system consisted of a dual-head reciprocating piston positive-displacement pump[6], a septumless syringe-loaded loop injector with a 10-μl loop[7], a variable-wavelength detector operated at 254 or 216 nm[8], a 10-mv recorder[9], and a 15-cm × 4-mm column of a slurry of chemically bonded octadecyl reversed-phase material[10] packed in aqueous sodium acetate and methanol according to the manufacturer's directions. The second system contained a dual-head reciprocating piston pump[11], an automatic injector[12], a variable-wavelength detector operated at 215 nm[13], a flat-bed recorder[14], and a 15-cm × 4.6-mm column of chemically

bonded octadecyl reversed-phase material[15] commercially packed and used with a 4-cm × 4.6-mm precolumn dry packed with pellicular octadecyl reversed-phase material[16].

Chromatographic Conditions—The mobile phase was methanol–water (40:60) and was suction filtered through a 0.9-μm filter[17]. This mobile phase was chosen since it was the strongest mobile phase that gave adequate resolution of nitroglycerin from I. Anisole was the internal standard since it was well resolved from the peak of interest and from I or excipient peaks and is very stable and readily available. Diazepam, suggested as an internal standard by Crouthamel and Dorsch (11), was not resolved from nitroglycerin in System 1. The flow rate was 0.8 ml/min with a pressure of 800 psi for System 1 and 2 ml/min with 4400 psi for System 2.

Typical chromatographic parameters for System 1 were $k' = 5.4$ for nitroglycerin and 7.1 for anisole, $N = 2000$ for nitroglycerin and 2500 for anisole, and $R = 3.1$. For System 2, $k' = 8.6$ for nitroglycerin and 12.4 for anisole, $N = 3430$ for nitroglycerin and 5230 for anisole, and $R = 5.95$. The N and R values were evaluated using half-width formulas (13). Tailing (evaluated by dropping a vertical line from the peak maximum, drawing a horizontal line at the 10% peak height, and dividing the distance from the vertical line to the peak back by the distance from the vertical line to the peak front) was 3.4 for nitroglycerin and 3.3 for anisole in System 1 and 1.9 for nitroglycerin and 1.0 for anisole in System 2 (Fig. 1).

Procedure—*Method 1*—About 1 g of ointment (equivalent to 20 mg of nitroglycerin) and 20 ml of isooctane were shaken mechanically for 40 min. After the contents of the flask were transferred to a separator, the flask was washed with water to dissolve the remaining lactose; each water wash was used to extract gently the isooctane. The pooled water was shaken with isooctane. The original flask was washed twice with methanol. Both methanol portions were combined, used to extract the isooctane, and filtered[18]. This procedure was repeated twice, and the extract was taken to 25.0 ml with methanol.

Method 2—About 1 g of ointment was weighed accurately into a beaker, 10.0 ml of I was added, and the solution was heated on a steam bath for 5 min with occasional gentle agitation. After cooling, the coagulated solids were removed with a capillary pipet or left in the beaker when the solution was decanted into a glass-stoppered erlenmeyer flask. An internal standard solution was prepared by combining 0.1 ml of anisole with 10 ml of methanol and diluting 3 ml of the resulting solution to 75 ml with I. An aliquot of 0.50 ml of the internal standard solution was added to 2.0 ml of the sample or standard to produce solutions for injection.

Method 2a—About 1 g of ointment was weighed accurately into a 50-ml glass-stoppered centrifuge tube, 20.0 ml of the internal standard solution (0.0003 ml of anisole/ml in I) was added, and the solution was heated for 5 min on a steam bath with occasional vigorous shaking. The solution then was shaken mechanically for 30 min, which resulted in a ball of coagulated solid floating on top of the liquid, so that the clear liquid could be removed easily with a capillary pipet for injection into the liquid chromatograph.

System 1 was used to evaluate Methods 1 and 2; System 2 was used to evaluate Method 2a.

2	94.9	100.1
	90.3	105.4

[a] Manufacturer 1.

RESULTS AND DISCUSSION

Table I shows that Method 2, which makes a lipophilic sample suitable for injection into a reversed-phase HPLC system without extraction, is more accurate than Method 1. This fact is indicated most clearly by results of spiked samples, consisting of ~0.5–0.6 g of ointment and 100 mg of standard triturate (10 mg of nitroglycerin), taken through the method. Table II demonstrates that Method 2a gives improved extraction of nitroglycerin from the ointment and more precision due to the presence of the internal standard from the beginning of sample preparation and the increased agitation.

While detection at 254 nm is possible at the concentrations used here, the signal-to-noise ratio is low due to the fact that the UV spectrum of nitroglycerin exhibits a minimum at this wavelength. As shown in Table

	99.3
3	99.3
	97.9

[a] Average = 99.1%; coefficient of variation = 1.14%.

III, detection at 216 nm gives comparable quantitative results (data were obtained with the same solutions). At 254 nm, peak heights were ~0.01 absorbance unit; at 216 nm, they were ~0.82 absorbance unit. This difference represents approximately an 80-fold enhancement in detection.

Thus, Method 2a and detection at 215 nm were best and were subjected to further validation. The three products tested were all currently marketed, nitroglycerin ointments. Three substances that represented expected excipients, lanolin, butylated hydroxyanisole, and petrolatum, were analyzed individually by this method at levels likely to be used in commercial formulations. Petrolatum gave no peaks, and lanolin gave only a peak before I. Butylated hydroxyanisole gave a peak with a k' value six times that of nitroglycerin and a height 1.4% of that of nitroglycerin (at 254 nm, the butylated hydroxyanisole peak was 4.5% of that of nitroglycerin). This finding indicates that none of the excipients interferes with the method.

By combining individual weighings of the appropriate excipients, authentic mixtures were prepared and assayed (Table IV). The average recovery of 99.1% with a coefficient of variation of 1.14% indicates that the accuracy and reproducibility of the method are acceptable for the analysis of this type of product. With authentic mixtures, the method demonstrated linearity from 0.25 to 1.50 mg/ml, representing 25–150% of the label declaration of 2% nitroglycerin [correlation coefficient >0.9997 (14); levels measured were 0.25, 0.50, 0.75, 1.00, 1.25, and 1.50 mg/ml]. These results indicate that sample preparation Method 2a with detection at 215 nm is appropriate for the analysis of nitroglycerin ointments.

Preliminary testing indicates that the system can be used for the analysis of isosorbide dinitrate, pentaerythritol tetranitrate, and erythritol trinitrate, which are well resolved from one another and from nitroglycerin. With a 50:50 methanol–water mobile phase, k' values of 6.7, 17, and 18.9 were obtained for these three glycosides, respectively; the k' value of nitroglycerin was 9.5. The analysis of these cardiac glycosides in sustained-release preparations will be reported later.

Pharmacokinetics of Nicotine in Rats after Single-Cigarette Smoke Inhalation

K. S. ROTENBERG *, R. P. MILLER ‡, and J. ADIR §x

Received September 17, 1979, from the *Clinical Pharmacokinetics Laboratory, Department of Pharmaceutics, School of Pharmacy, University of Maryland, Baltimore, MD 21201.* Accepted for publication March 31, 1980. *Present address: Division of Biopharmaceutics, Food and Drug Administration, Rockville, MD 20014. ‡Present address: Department of Pharmacy, School of Pharmacy, West Virginia University, Morgantown, WV 26506. §Present address: Stauffer Chemical Company, Farmington, CT 06032.

Abstract □ The amount of nicotine absorbed following cigarette smoke inhalation was evaluated by comparing the area under the plasma concentration–time curve and urinary recovery with those observed after its intravenous injection to rats. Nicotine was absorbed rapidly, with the maximum plasma concentration occurring immediately after cessation of cigarette smoke exposure. On the average, 68% of the nicotine delivered to the inhalation chamber was absorbed. The absorption and elimination of nicotine, as well as the formation and elimination of its metabolites, followed first-order kinetics, and the derived pharmacokinetic parameters were similar to those observed after the intravenous administration of nicotine.

Keyphrases □ Nicotine—comparison of pharmacokinetic parameters following single-cigarette smoke inhalation and intravenous administration, cotinine as major nicotine metabolite, rats □ Pharmacokinetics—comparison of nicotine pharmacokinetic parameters following single-cigarette smoke inhalation and intravenous administration, cotinine as major metabolite of nicotine, rats □ Cotinine—major metabolite of nicotine, comparison of pharmacokinetic parameters following single-cigarette smoke inhalation and intravenous administration, rats

Reports of the effect of inhalation of tobacco smoke on a wide range of biological systems have increased. The principal concern has been the effect of smoke inhalation on the structure and function of the lungs (1–3), cardiovascular response (4), and teratogenicity (5). These studies have renewed interest in the metabolic fate of nicotine.

Recent studies in these laboratories investigated the pharmacokinetics of nicotine in rats following intravenous injection (6, 7). However, little is known about the rate of absorption of nicotine from cigarette smoke. Most studies on nicotine absorption reported only the blood nicotine concentrations following smoking in humans (8, 9), dogs (10), and cats (11). Armitage *et al.* (8) showed that habitual smokers retained 82–92% and that nonsmokers retained 30–66% of the inhaled nicotine, but they did not assess the absorption rate of nicotine in these subjects. McGovern *et al.* (12), using an isolated perfused rabbit lung preparation, found that nicotine absorption from tobacco smoke was rapid, with peak levels occurring almost immediately after cigarette smoke administration had ceased.

The purpose of this investigation was to characterize the rate and extent of absorption of nicotine in rats after single-cigarette smoke inhalation and to compare its disposition kinetics with those observed after intravenous administration.

EXPERIMENTAL

Chemicals—[*methyl*-^{14}C]Nicotine was obtained commercially[1] and had a specific activity of 61.6 μCi/mg. Radiochemical purity was established by TLC and radioscanning techniques. With acetone–benzene–ammonia–ethanol (40:50:5:5) as the solvent, the compound migrated as a single radioactive spot with an R_f value corresponding to authentic nicotine. Unlabeled nicotine[2] for use as a standard was obtained commercially, and unlabeled cotinine was prepared from nicotine by the method of Bowman and McKennis (13).

Cigarettes—The cigarettes[3] were stored in a desiccator that provided an atmosphere of 65% humidity. They were reported to contain 9.5 mg of nicotine/g of tobacco and to have a smoke condensate pH of 4.9. Analysis in these laboratories using a spectrophotometric assay (14) verified the nicotine content of the cigarettes.

One cigarette was spiked with ^{14}C-labeled nicotine using an infusion pump[4] equipped with a glass tube (17 cm × 8 mm i.d.) to hold the cigarette in place. Another infusion pump[5] was fitted with a 1-ml gas-tight syringe[6] containing the ^{14}C-labeled nicotine solution. The two pumps were set facing each other such that the needle delivering the radiolabeled nicotine solution mounted on one pump penetrated the cigarette mounted on the other pump. This setting allowed the delivery of the spiking solution to the entire length of the cigarette, after which the cigarette was rotated 90° and allowed to dry. This process was repeated until 225 μCi of [*methyl*-^{14}C]nicotine was delivered, yielding a final specific activity of 17.11 μCi/mg. Following spiking, the cigarette was replaced in the desiccator.

Smoke Exposure Apparatus—The intermittent smoke generation–inhalation system[7] (15–17) used was designed to simulate the smoking of a single cigarette. Briefly, a 2-sec negative pressure allowed 35 cm^3 of cigarette smoke to enter an exposure chamber where it was distributed rapidly, forming a 10% smoke aerosol. The rats were placed in restraining cylinders attached to the exposure chamber with only their noses protruding into the chamber. The smoke remained in the chamber for 20 sec, after which air was forced into the chamber to expel the smoke and to maintain an atmosphere of fresh air for 38 sec. This 1-min cycle (puff) was repeated until the cigarette burnt down to a 23-mm butt after a total of 10 puffs were delivered into the exposure chamber.

The exposure unit was modified by attaching a cambridge filter[8] to the exposure chamber. This filter is capable of trapping 99.9% of the total particulate matter, including nicotine, from the smoke forced out of the exposure chamber (18). This modification allowed for an account of the material balance and, hence, calculation of the amount of nicotine delivered to the inhalation chamber and the amount absorbed by rats.

The restraining cylinders also were modified by drilling an orifice at the proximal part to the exposure chamber through which the animal's previously implanted cannula was brought out. Thus, blood samples could be collected during the smoke inhalation period.

Animals—Male Fischer-344 rats[9], 226–263 g, were housed in stainless steel cages and had free access to food[10] and water. At least 48 hr prior to the study, each animal was placed under light ether anesthesia and a chronic cannula was implanted into the abdominal aorta (19). The study was initiated with eight rats, but only four rats completed the study due to a malfunction of the cannula.

Protocol—Rats were placed in the restraining cylinders 30 min prior to lighting the cigarette to condition them to the smoke exposure–inhalation system (20). The cigarette was consumed in 10 min (10 puffs), after which the rats were transferred to plastic metabolism cages for the remainder of the experiment. Blood samples (0.2 ml) were collected into heparinized syringes at 4, 8 (smoking phase), 15, 30, 45, 60, and 90 min and 2, 3, 5, 8, 14, 16.5, 24, and 30 hr (postsmoking phase). The plasma was

Table I—Nicotine Absorbed following Cigarette Smoke Inhalation by Rats

Rat[a] (weight, kg)	Amount Absorbed Based on *AUC*[b]		Amount Absorbed Based on Urinary Recovery[b]	
	dpm/kg	mg/kg	dpm/kg	mg/kg
1 (0.240)	5.061×10^6	0.04	5.258×10^6	0.04
2 (0.235)	7.752×10^6	0.06	5.234×10^6	0.04
3 (0.226)	7.911×10^6	0.06	8.472×10^6	0.06
4 (0.263)	8.199×10^6	0.06	5.765×10^6	0.04
Mean (0.241)	7.231×10^6 [c]	0.06	6.182×10^6[c]	0.05
SEM (0.008)	0.729×10^6	0.01	0.773×10^6	0.01

[a] Eight rats were placed in the inhalation chamber, but four did not complete the study because of malfunction of the indwelling cannula. [b] No significant differences were observed at the $p = 0.05$ level between the amount calculated from plasma concentrations *versus* time and the urinary recovery data. [c] If it is assumed that the same amount of nicotine also was absorbed by the four rats that did not complete the study, the total amount absorbed represents 69.8 (*AUC* method) and 66.3% (urinary recovery method) of the amount of nicotine delivered to the inhalation chamber, with a mean of 68%.

separated from whole blood by centrifugation and stored at −20° until the time of analysis. Urine was collected in containers immersed in ice for up to 48 hr and frozen until the time of analysis. The separation and quantitation of nicotine and its metabolites were described earlier (6, 7).

Pharmacokinetic Analysis—The concentration–time profiles of nicotine, cotinine, and other metabolites for each rat were plotted on semilogarithmic graph paper, which provided an insight to the operative pharmacokinetic models. These plots also were employed to obtain initial estimates for curve fitting of the data using the SAAM 26 digital computer program (21). Each data point was assigned a statistical weight proportional to the reciprocal of the square of a standard deviation representing 10% of the data point.

The puffing profile of the smoke inhalation machine was incorporated into the pharmacokinetic model used to fit the data both during and after cigarette smoke inhalation. The amount of nicotine absorbed by inhalation (A_{ih}) was computed from (22):

$$A_{ih} = \text{dose}_{iv}(AUC_{ih}/AUC_{iv}) \qquad \text{(Eq. 1)}$$

where dose_{iv} is the dose injected by intravenous administration and AUC_{ih} and AUC_{iv} are the areas under the plasma concentration–time curve ($0 \rightarrow \infty$) following cigarette smoke inhalation and intravenous administration, respectively. The dose and *AUC* from the 0.08-mg/kg iv study reported earlier (7) were used in Eq. 1. An alternative method for calculating A_{ih} is provided by (22):

$$A_{ih} = \text{dose}_{iv}\, Nu_{\infty,ih} f_{iv}/Nu_{\infty,iv} f_{ih} \qquad \text{(Eq. 2)}$$

where Nu_∞ is the amount of nicotine ultimately excreted in urine at time infinity and f_{ih} and f_{iv} represent the fractions of total radioactivity excreted as nicotine following cigarette smoke inhalation and intravenous administration, respectively. The dose and $Nu_{\infty,iv}$ from the 0.08-mg/kg dose reported earlier (7) were used in these calculations.

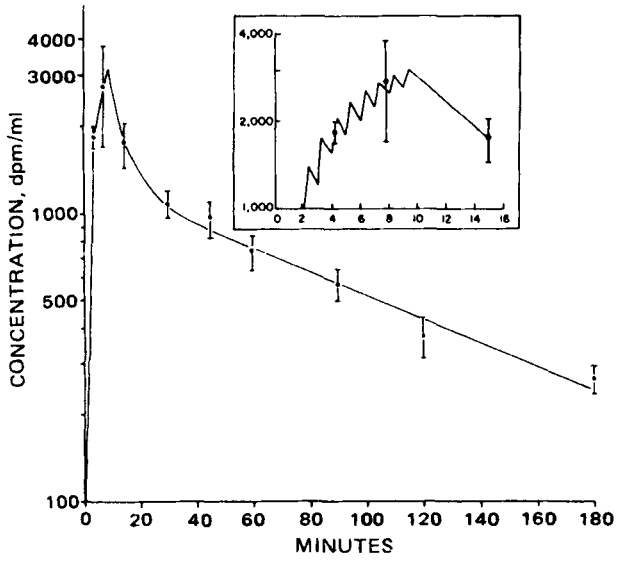

Figure 1—*Semilogarithmic plot of plasma nicotine concentration (mean ± SEM) as a function of time following cigarette smoke absorption of nicotine. Inset shows nicotine absorption during the smoke exposure period.*

The plasma nicotine concentration (C_n) *versus* time data for each rat were fitted to a two-compartment open model with a first-order rate constant of absorption described by (22):

$$C_n = Ae^{-k_a t} + Be^{-\alpha t} + Ce^{-\beta t} \qquad \text{(Eq. 3)}$$

where *A*, *B*, and *C* are constants, k_a is the absorption rate constant, and α and β are hybrid rate constants describing the rapidly and slowly declining phases of the plasma concentration, respectively. The dose absorbed by each rat (calculated using Eqs. 1 and 2) was divided by 10 (each representing one puff) and was included in the data-fitting procedure.

The first-order rate constant of elimination (K_e) and the ratio of the fraction (F) of nicotine converted to cotinine to the volume of distribution of the latter compound (V_d) were obtained by curve fitting of the plasma cotinine concentration–time data to the one-compartment open model with a first-order rate constant of formation (K_f) as reported earlier (6, 7). Also, the pharmacokinetic parameters of the origin activities were estimated as described previously (6, 7).

Renal clearance (*Cl*) was calculated for nicotine and its metabolites employing (22):

$$Cl_{r,i} = Xu_{i,t_1 \rightarrow t_2}/AUC_{i,t_1 \rightarrow t_2} \qquad \text{(Eq. 4)}$$

where i represents nicotine, cotinine, or origin activity, Xu is the amount excreted between t_1 and t_2, and *AUC* is the area under the plasma concentration–time curve over the same time interval.

Statistical Analysis—The t test was used to evaluate differences in the pharmacokinetic parameters of nicotine and its metabolites between the cigarette smoke inhalation and the intravenous administration studies at the $p < 0.05$ and < 0.01 levels (23).

RESULTS AND DISCUSSION

Nicotine—About 4% (2.0×10^7 dpm) of the nicotine present in the mainstream of cigarette smoke (4.9×10^8 dpm) was delivered to the inhalation chamber. This amount represents the sum of the nicotine absorbed by the rats, retained on the filter (4.7×10^6 dpm), and present in the washing of the chamber[11] (1.3×10^6 dpm). The amount of nicotine absorbed calculated from Eqs. 1 and 2 is shown in Table I. Since there were no significant differences between the two methods of computation, the amount of nicotine absorbed can be obtained by either the plasma concentration *versus* time plots or the urinary recovery data. The amount of nicotine absorbed ranged from 0.04 to 0.06 mg/kg[12], representing an average of 68% of the amount of nicotine delivered. This value is similar to that reported by Armitage *et al.* (8), who showed that nonsmokers absorbed between 30 and 60% of the nicotine delivered to their mouths.

The mean plasma nicotine concentration–time profile shown in Fig. 1 indicates that nicotine is absorbed rapidly by inhalation. During the 10 puffs needed to consume the cigarette, the plasma nicotine levels paralleled the intermittent pattern of the smoke exposure machine (shown in the inset of the figure). A maximum of 3000 dpm/ml (79.2 ng/ml) was achieved at the cessation of the cigarette smoke exposure. Following this rapid absorption, which appeared to be described ade-

[11] After delivery of each puff into the airtight exposure chamber, the smoke remained in the chamber for 20 sec. Fresh air then was forced in the chamber, which caused the unabsorbed nicotine (as well as other particulate matter) to be retained on the filter or absorbed onto the inside walls of the chamber, both of which were assayed for radioactivity.

[12] The similarity in the dose and pharmacokinetic parameters obtained in this study and those observed in the 0.08-mg/kg iv study reported earlier (7) warranted the use of the intravenous data in Eqs. 1 and 2.

Table II—Pharmacokinetic Parameters of Nicotine following Cigarette Smoke Inhalation by Rats

Rat	k_a, min^{-1}	α, min^{-1}	β, min^{-1}	$AUC_{0\to\infty}$, (dpm hr)/(ml kg)	Cl_r, ml/hr/kg
1	0.084	—[a]	0.0090	7.64×10^3	402.0
2	0.089	0.0753	0.0105	11.70×10^3	221.0
3	0.404	0.1380	0.0062	11.94×10^3	160.0
4	0.082	0.6470	0.0076	12.37×10^3	119.0
Mean	0.165	0.2870	0.0083	10.91×10^3	226.0
SEM	0.080	0.1810	0.0009	1.10×10^3	62.0

[a] Although the α-phase in this rat was discernible by examination of the log concentration–time plot, it did not include sufficient data points to enable computer estimation of this parameter.

Table III—Pharmacokinetic Parameters of Cotinine following Cigarette Smoke Inhalation of Nicotine by Rats

Rat	t_{max}, hr	K_f, hr^{-1}	K_e, hr^{-1}	$AUC_{0\to\infty}$[a], (dpm hr)/(ml kg)	Cl_r, ml/hr/kg	$\frac{AUC_{cot}}{AUC_{nic}}$	F/V_d, kg/liter[b] From *AUC*	F/V_d, kg/liter[b] From Urinary Excretion
1	1.50	1.544	0.118	56.35×10^3	14.71	7.88	0.303	0.292

[a] Obtained by extrapolation of the plasma cotinine concentration data to infinity. [b] There were no significant differences between the F/V_d values calculated from the *AUC* and those from the urinary excretion data.

quately by first-order kinetics, plasma nicotine concentrations declined biexponentially in a fashion similar to that of intravenous administration.

The pharmacokinetic parameters derived from these data are reported in Table II. The mean half-life of absorption ($t_{1/2,k_a}$) was 6.6 min; the mean half-life values of the rapidly and slowly declined phases ($t_{1/2,\alpha}$ and $t_{1/2,\beta}$) were 5.1 and 86.5 min, respectively. There were no significant differences in α and β between the present cigarette smoke inhalation study and the intravenous studies reported previously (6, 7).

Armitage *et al.* (8) estimated that the half-life of nicotine following cigarette smoke inhalation in humans, assuming a one-compartment open model, ranged from 24 to 84 min, with a mean of 40 min. Unfortunately, these investigators carried out their experiment for only 1 hr; nicotine distribution may not have been completed at this time and their reported half-lives may have been underestimated. The results in Table II also indicate that the renal clearance of nicotine following cigarette smoke inhalation ranged from 119 to 402 (mean 226) ml/hr/kg. This renal clearance accounted for ~9% of the total plasma clearance of nicotine observed at the same dose following intravenous administration (7).

Cotinine—Figure 2 shows the plasma concentration–time profile of this major metabolite of nicotine (mean ± *SEM*). The formation of cotinine is rapid. Approximately 20% of the maximum cotinine concentration was achieved within the first 3 min of cigarette smoke inhalation. The pharmacokinetic parameters of cotinine are reported in Table III. The time to reach the maximum plasma concentration (t_{max}) ranged from 1.5 to 2.0 hr. When statistical analysis was performed on t_{max}, there were no significant differences between intravenous administration and cigarette smoke inhalation of nicotine.

The mean half-life of formation of cotinine was 30.6 min and that of its elimination ranged from 5.9 to 9.0 hr. There were no significant differences among the means between cigarette smoke inhalation and intravenous administration with respect to the rate constants of formation and elimination (Table III). The renal clearance of cotinine ranged from 8.9 to 17.48 ml/hr/kg. This range is ~6% of the renal clearance of nicotine, indicating that cotinine is cleared by the kidney at a much slower rate than nicotine. There were no significant differences between the means of renal clearance following cigarette smoke inhalation and intravenous administration of nicotine (Table III).

To determine if changes occurred in the formation of cotinine from nicotine following cigarette smoke inhalation compared to the intravenous study, the ratio AUC_{cot}/AUC_{nic} was examined. The ratio ranged from 7.5 to 10.6 (Table III) and appeared to be slightly lower ($p < 0.01$) than that observed after the intravenous administration of nicotine at a comparable dosage (7). It is not clear whether this difference is biologically significant or is indicative of a first-pass metabolism of nicotine in the lungs. McGovern *et al.* (12) found no significant first-pass effect of nicotine in the isolated rabbit lung preparation.

Changes in the fraction of nicotine converted to cotinine (F), as well as in the apparent volume of distribution of cotinine, also were evaluated by examining the F/V_d ratio. This ratio (Table III) ranged from 0.21 to 0.47 kg/liter. There were no significant differences in the F/V_d ratios between those calculated from the plasma and urine data. However, these ratios were somewhat lower ($p < 0.05$) than those observed following the intravenous administration of similar doses of nicotine (7). This observation implies an increase in the volume of distribution or a decrease in the fraction of the dose converted to cotinine.

Table IV—Pharmacokinetic Parameters of Origin Activity following Cigarette Smoke Inhalation by Rats

Rat	t_{max}, hr	$t_{1/2}$, hr	$AUC_{0\to\infty}$, (dpm hr)/(ml kg)	Cl_r, ml/hr/kg	$\frac{AUC_{orig\ act}}{AUC_{nic}}$
1	1.50	24.75	65.38×10^3	117.29	9.14
2	0.75	28.88	112.66×10^3	75.96	9.48
3	0.50	24.79	68.96×10^3	160.04	7.00
4	0.75	26.67	157.53×10^3	38.14	12.58
Mean	0.88	26.27	101.13×10^3	97.86	9.55
SEM	0.22	0.98	21.65×10^3	26.28	1.15

Other Metabolites—Some of the nicotine metabolites remained at the origin of the thin-layer plate, and their possible compositions were discussed previously (6, 7). It is evident from the time course of these metabolites (Fig. 3) that ~25% of their maximum concentration (c_{max}) was formed within the first 3 min following the inhalation of cigarette smoke. Table IV reports the pharmacokinetic parameters derived from these data. There were no significant differences in t_{max} between intravenous administration and cigarette smoke inhalation. This observation suggests that the rate constants of formation and elimination have not

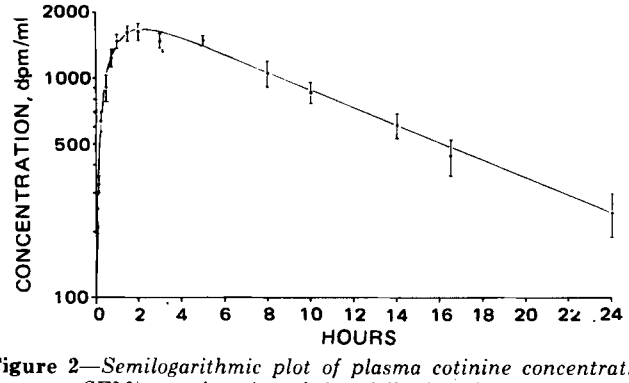

Figure 2—*Semilogarithmic plot of plasma cotinine concentration (mean ± SEM) as a function of time following cigarette smoke absorption of nicotine.*

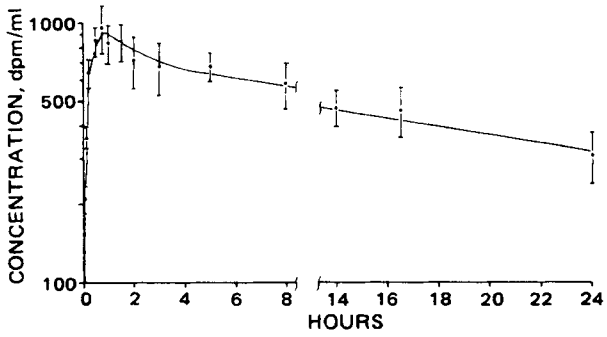

Figure 3—*Semilogarithmic plot of plasma origin activity concentration (mean ± SEM) as a function of time following cigarette smoke absorption of nicotine.*

changed between cigarette smoke inhalation and intravenous administration. Although the origin activity is composed of more than one metabolite, an overall half-life of elimination was determined for comparative purposes. The overall half-life of elimination mean (±*SEM*) was 26.27 (±0.98) hr. There were no significant differences in this parameter between the intravenous administration of nicotine (7) and the present study.

The amount of origin activity formed following cigarette smoke inhalation was compared to that observed after intravenous nicotine administration (7) by assessing the ratio of $AUC_{\text{orig act}}$ to AUC_{nic} in each study. The ratios (range of 7.0–12.6 with an overall mean of 9.5) were not significantly different from those obtained in the intravenous study (7). Therefore, the formation of the origin activity appears to be independent of the route of administration of nicotine. The renal clearance of the origin activity also appears to be independent of the route of administration, since there were no significant differences in this parameter between cigarette smoke inhalation and intravenous administration studies (7).

Urinary Excretion of Nicotine and Metabolites—The 48-hr excretion of nicotine and its metabolites following cigarette smoke inhalation is shown in Table V. There were no significant differences among the mean recoveries of radiolabeled substances in the urine between intravenous administration and cigarette smoke inhalation. The average recovery was ~66% of the amount absorbed. Approximately 16 and 13% of the total radioactivity excreted in urine consisted of nicotine and cotinine, respectively, while 33% was composed of the origin activity. No significant differences were found when these values were compared to the intravenous results. Consistent with the plasma concentration data, the ratios of cotinine or the origin activity to that of nicotine excreted in the urine in the present study also were not significantly different from those found in the intravenous study (7).

CONCLUSION

This study indicates that the absorption of nicotine present in the mainstream of cigarette smoke is rapid and does not seem to undergo first-pass metabolism through the lungs. In addition, the pharmacokinetics of nicotine and its metabolites were essentially similar to those observed previously following the intravenous injection of a single dose of nicotine (6, 7). The effect of multiple-cigarette smoke inhalation on the pharmacokinetics of these compounds is being investigated.

Table V—Urinary Excretion of Nicotine and Its Metabolites in Rats 48 hr after Cigarette Smoke Inhalation

Rat	Percent of Absorbed Dose Excreted in Urine as Total Radioactivity	Percent of Total Radioactivity Excreted in Urine as		
		Nicotine	Cotinine	Origin Activity
1	78.5	23.4	13.1	37.0
2	51.0	18.0	14.0	37.3
3	80.9	9.3	9.2	17.9
4	53.1	11.5	15.0	40.6
Mean	65.9	15.6	12.8	33.2
SEM	8.0	3.2	1.3	5.2

Degradation of Chlorambucil in Aqueous Solution

HANS EHRSSON ˣ, STAFFAN EKSBORG, INGER WALLIN, and STEN-OVE NILSSON

Received April 9, 1979, from *Karolinska Pharmacy, Fack, S-104 01 Stockholm 60, Sweden.* Accepted for publication March 31, 1980.

Abstract □ The stability of chlorambucil and its degradation product 4-[*p*-(2-chloroethyl-2-hydroxyethylamino)phenyl]butyric acid (I) was studied using reversed-phase high-pressure liquid chromatography. The degradation rate of chlorambucil was unaffected by pH between pH 5 and 10 but decreased at lower pH. The degradation rates of chlorambucil and I differed only slightly (pH > 6). The proteolytic properties of the compounds were studied using spectrophotometric and partition techniques.

Keyphrases □ Chlorambucil—degradation in aqueous solution, influence of pH and temperature □ Degradation—chlorambucil and metabolites, in aqueous solution, effect of pH and temperature □ Antineoplastic agents—chlorambucil, degradation in aqueous solution, influence of pH and temperature

Nitrogen mustards are important drugs in the treatment of neoplastic diseases. A detailed and accurate knowledge of their chemical properties is important for an understanding of their behavior *in vivo*.

BACKGROUND

The nitrogen mustards are believed to react *via* an intermediate aziridinium ion (1) according to Scheme I. The aliphatic nitrogen mustards given an accumulation of the aziridinium ion, B, during the initial phase of degradation since Step I is faster than Step II (2). The aromatic nitrogen mustards differ in this respect from the aliphatic compounds (3). However, chlorambucil was proposed to follow a reaction profile similar to that of the aliphatic nitrogen mustards based on results obtained using a spectrophotometric procedure involving the reaction of the alkylating agents with 4-(*p*-nitrobenzyl)pyridine (4). However, this technique is not selective since both the parent compound and the degradation product, C (Scheme I), are derivatized and codetermined (5).

The influence of pH on the degradation rate of chlorambucil was studied previously (6), and a continuous increase in the stability of chlorambucil from pH 7 to 4.5 was observed. However, this study was performed at such a high concentration that the results might have been affected by aggregation phenomena (*cf.*, 7).

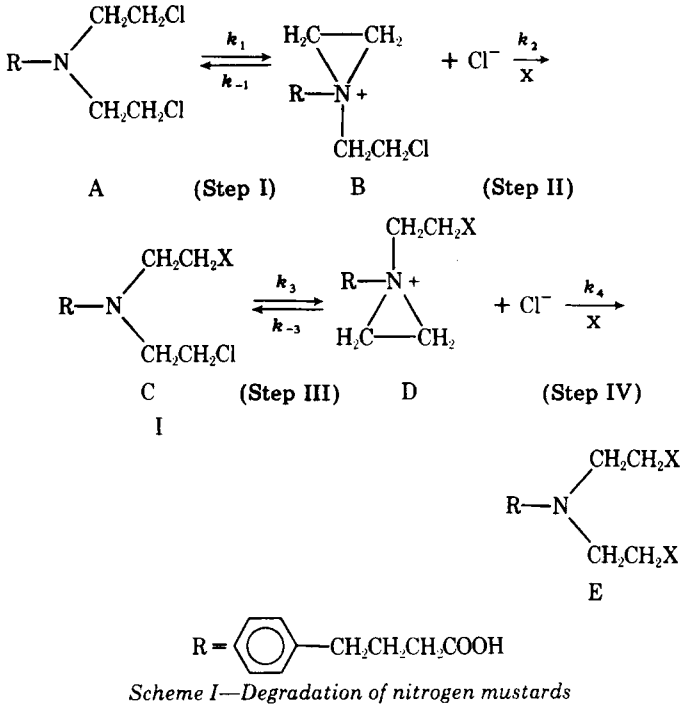
The present investigation considered the stability of chlorambucil and its degradation product 4-[*p*-(2-chloroethyl-2-hydroxyethylamino)-phenyl]butyric acid between pH 1.5 and 10 using a selective and sensitive high-pressure liquid chromatographic (HPLC) technique. The sensitivity of the technique made study of low concentrations possible, where chlorambucil is present only as the monomer.

EXPERIMENTAL

All experiments were carried out at 25.00 ± 0.05° and at the same ionic strength (0.1) unless otherwise stated.

Preparation of 4-[*p*-(2-Chloroethyl-2-hydroxyethylamino)-phenyl]butyric Acid (I)—Chlorambucil (10 mg in methanol, 0.5 ml) was mixed with 100 ml of distilled water. The solution was kept at 25° for 2 hr (final pH of 4) and extracted with ethyl acetate (100 ml). The extract was evaporated to 0.2 ml under a nitrogen atmosphere and separated by TLC[1]. The silica gel zone containing I was scraped from the plate, packed into a Pasteur pipet, and eluted with methanol (5 ml). The yield was 15% as determined spectrophotometrically. The mass spectrum was consistent with the expected structure. Prominent peaks were located at *m/e* (relative intensity, %) 250 (17), 249 (62), 191 (19), 177 (17), 176 (100), 132 (19), 131 (35), 118 (55), 117 (14), and 91 (18).

[1] Silica gel 60, F_{254}, 2 mm, Merck, Darmstadt, West Germany. The eluting solvent was toluene–methanol–heptane–isopropylacetone (8:6:3:4). The spots were 4-[*p*-[di(2-hydroxyethyl)amino]phenyl]butyric acid (R_f 0.4), I (R_f 0.6), and chlorambucil (R_f 0.7).



Scheme I—Degradation of nitrogen mustards

Spectrophotometric Determination of Acid Dissociation Constants—A stock solution of chlorambucil or I in ethanol (3.4×10^{-3} *M*) was diluted (1:40) with 1 *M* HCl, phosphate buffer, or citrate buffer. The absorbance was determined at 257 nm[2]. The slit width of the spectrophotometer was kept constant within each experimental series. The absorbance of at least three dilutions was measured at each pH value[3].

Determination of Acid Dissociation Constants by Partition Studies—Partition experiments were performed in centrifuge tubes using equal volumes (10 ml) of hexane and buffer and mechanical shaking for 30 (pH < 3.5) or 15 (pH > 3.5) min. Chlorambucil was dissolved initially in the organic phase to a concentration of 1.2×10^{-4} *M*.

The concentration of chlorambucil was determined spectrophotometrically (257 nm) in both phases. The organic phase was measured directly. Chlorambucil in the aqueous phase was measured by extraction into methylene chloride, buffering to pH 3.4, and mechanical shaking for 30 min.

Degradation Studies—Chlorambucil or I in methanol (0.1 ml) was mixed with the appropriate buffer (10 ml) to give a final alkylating agent concentration of 3×10^{-5} *M*, unless otherwise stated.

The solutions were analyzed by reversed-phase HPLC[4].

RESULTS AND DISCUSSION

Proteolytic Properties—The general proteolysis of an amino acid is summarized in Scheme II. The compound may occur in four forms: ammonium ($^+HR_2NMCOOH$), carboxylate (R_2NMCOO^-), uncharged ($R_2NMCOOH$), and zwitterion ($^+HR_2NMCOO^-$). The microscopic constants k'_1, k'_2, k'_{12}, and k'_{21} were defined previously (8).

[2] Zeiss PMQ III spectrophotometer.

[3] Orion Research model 701 digital pH meter equipped with an Ingold combined electrode type 401.

[4] The detector (Altex model 153) measured at 253.7 nm. The cell volume was 8 μl, and the path length was 10 mm. The pump was model LDC 711. A stainless steel 150-mm long × 4-mm i.d. column and a Rheodyne (model 70-10) injection valve with a 300-μl sample loop were used. The chromatographic support, LiChrosorb RP-18 (Merck, Darmstadt, West Germany), had a mean particle diameter of 5 μm. Methanol–water containing 0.01 *M* phosphoric acid was used as the mobile phase.

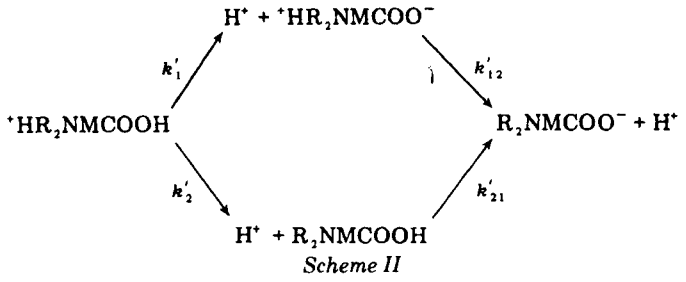

Scheme II

Spectrophotometric Determination of Acid Dissociation Constants—The absorption spectrum of chlorambucil and 4-[*p*-(2-chloroethyl-2-hydroxyethylamino)phenyl]butyric acid (1) were strongly pH dependent due to proteolysis of the amino group. Spectrophotometric determination of the microscopic constants with graphic evaluation according to a literature method (8) is illustrated in Fig. 1. The fraction of species with an unprotonized amino group, α_{R_2N}, was calculated from:

$$\alpha_{R_2N} = \frac{[R_2NMCOOH + R_2NMCOO^-]}{C_M} = \frac{A - A_A}{A_B - A_A} \quad \text{(Eq. 1)}$$

where C_M is the total concentration and A, A_A, and A_B are the absorbances at 257 nm in buffer, 1 *M* HCl, and buffer at pH 8.5, respectively. From the spectral data, it was concluded that $C_M = [^+HR_2NMCOOH]$ in 1 *M* HCl and that $C_M = [R_2NMCOO^-]$ in buffer at pH 8.5. Furthermore, M_{R_2N} was defined by:

$$M_{R_2N} = \frac{a_h([R_2NMCOOH] + [R_2NMCOO^-])}{[^+HR_2NMCOOH] + [^+HR_2NMCOO^-]} \quad \text{(Eq. 2)}$$

From Fig. 1 and Ref. 8, it was concluded that the pk'_2 value of chlorambucil is 2.49 ± 0.02. A similar evaluation for I gave a pk'_2 value of 3.63 ± 0.04. It was not possible to evaluate the pk'_{12} values from the graphs with sufficient precision, but the most likely pk'_{12} for chlorambucil was >4.2; for I, it was >6. An evaluation of pk'_1 for the two compounds also was not possible. However, since pM_{R_2N} was almost constant when α_{R_2N} was within the range of 0.1–0.6, it was concluded that zwitterion formation was negligible, *i.e.*, $pk'_1 \gg pk'_2$ (*cf.*, 9).

Determination of Acid Dissociation Constants for Chlorambucil by Partition Studies—Chlorambucil probably partitions from an aqueous phase into an organic phase in the uncharged form. The distribution ratio, D, then is given by:

$$D = \frac{[R_2NMCOOH]_{org}}{[R_2NMCOOH] + [R_2NMCOO^-] + [^+HR_2NMCOOH] + [^+HR_2NMCOO^-]} \quad \text{(Eq. 3)}$$

which can be rewritten as:

$$D = \frac{k_d}{1 + k'_{21}/a_h + a_h/k'_2 + k'_{21}/k'_{12}} \quad \text{(Eq. 4)}$$

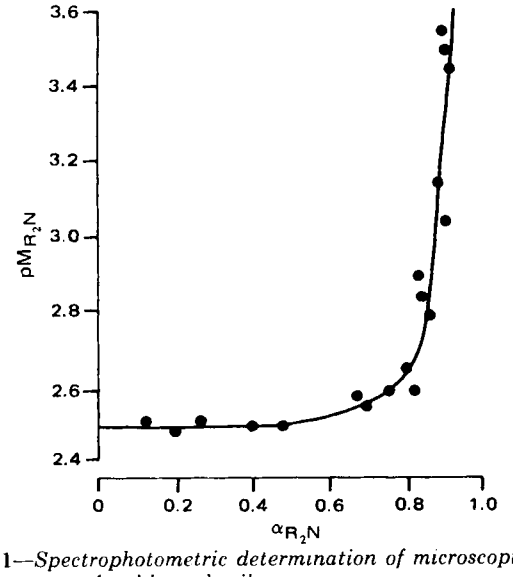

Figure 1—*Spectrophotometric determination of microscopic dissociation constants for chlorambucil.*

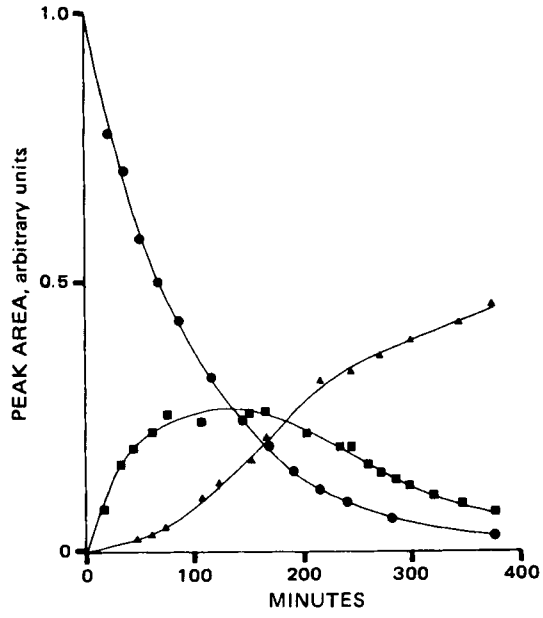

Figure 2—*Time course for chlorambucil and degradation products in aqueous solution. Key:* ●, *chlorambucil (A, Scheme I);* ■, *I (C, Scheme I); and* ▲, *4-[p-[di(2-hydroxyethyl)amino)phenyl]butyric acid (E, Scheme I). The molar absorbance and yield from the chromatographic column were considerably lower for E compared to A and C.*

where k_d, the partition coefficient, is defined by:

$$k_d = \frac{[R_2NMCOOH]_{org}}{[R_2NMCOOH]} \quad \text{(Eq. 5)}$$

Since zwitterion formation was negligible as revealed by spectrophotometric determination of acid dissociation constants, $k'_{21}/k'_{12} \ll 1$. At low pH, *i.e.*, $k'_{21}/a_h \ll 1$, Eq. 4 can be reduced to:

$$\frac{1}{D} = \frac{1}{k_d} + \frac{a_h}{k'_2 k_d} \quad \text{(Eq. 6)}$$

A plot of $1/D$ *versus* a_h for pH 1.2–2.4 gave a straight line with a small positive intercept. However, evaluation of the partition coefficient, k_d, was not possible from the intercept. The value for $-\log(k_d \times k'_2)$ was calculated from the slope as 1.04 ± 0.02; by substituting k_2 with the value determined spectrophotometrically, log k_d was evaluated as 1.45 ± 0.04.

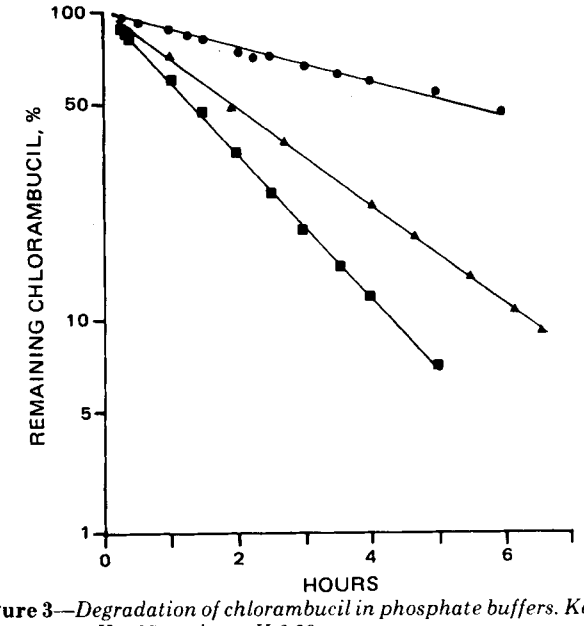

Figure 3—*Degradation of chlorambucil in phosphate buffers. Key:* ●, *pH 1.92;* ▲, *pH 2.95; and* ■, *pH 6.99.*

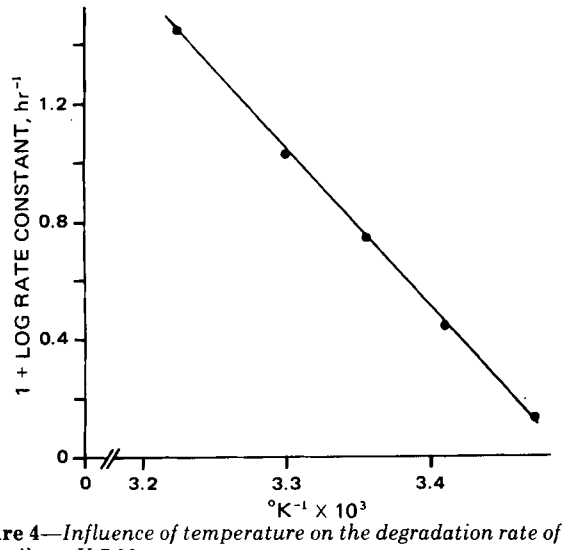

Figure 4—*Influence of temperature on the degradation rate of chlorambucil at pH 7.00.*

At high pH, *i.e.*, $a_h/k_2' \ll 1$, Eq. 4 can be rewritten as:

$$\frac{1}{D} = \frac{1}{k_d} + \frac{k_{21}'}{a_h k_d} \qquad \text{(Eq. 7)}$$

A plot of $1/D$ *versus* $1/a_h$ for pH 4.8–5.9 gave a straight line, indicating the validity of Eq. 7. From the slope and the previously evaluated value of k_d, the pk_{21}' value of 4.46 ± 0.04 was determined.

Degradation of Chlorambucil—The degradation of chlorambucil in pure aqueous solution was studied by reversed-phase HPLC. The time course of peak areas for chlorambucil and its degradation products, C and E (X = OH, Scheme I), is given in Fig. 2. The concentration of C was ~30% of the initial chlorambucil concentration after 2 hr (assuming the same molar absorbance of A and C).

The rate of loss of the alkylating activity [established by the 4-(*p*-nitrobenzyl)pyridine method] was slower initially, as reported previously by Williamson and Witten (3), who concluded that significant amounts of the aziridinium ion (B, Scheme I) accumulated during the initial degradation of chlorambucil. However, this conclusion might be incorrect since a similar rate profile is observed for a codetermination of chlorambucil and C.

A pseudo-first-order plot of the degradation of chlorambucil in phosphate buffers is shown in Fig. 3. Linear relationships were observed throughout the reaction. No change in degradation rates was observed compared to reactions in pure aqueous solutions, indicating no buffer catalysis at the pH values used. The same rate constant for chlorambucil degradation was obtained within the concentration range of 3×10^{-6}–3×10^{-5} *M*, establishing that no aggregation phenomena occurred.

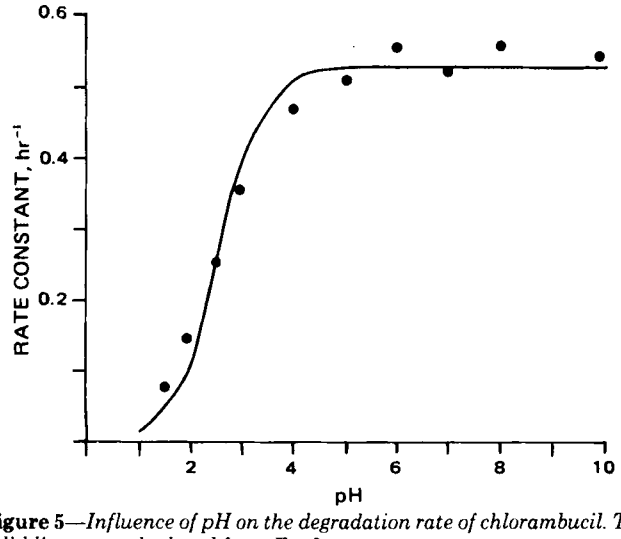

Figure 5—*Influence of pH on the degradation rate of chlorambucil. The solid line was calculated from Eq. 8.*

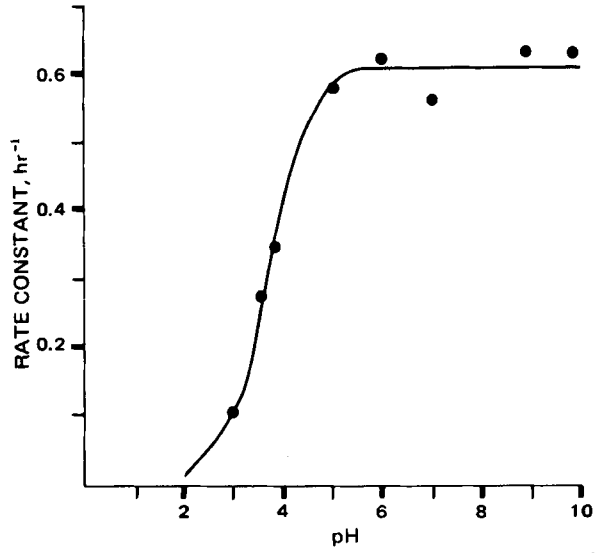

Figure 6—*Influence of pH on the degradation rate of I. The solid line was calculated from Eq. 8.*

Table I—Pseudo-First-Order Rate Constants for Degradation of Chlorambucil and I

Compound	pk_2'	k_1^*, hr^{-1} [a]
Chlorambucil	2.49 ± 0.02	0.54 ± 0.02 (n = 12)
I	3.63 ± 0.04	0.61 ± 0.04 (n = 6)

[a] Determined at pH 6–10.

Influence of Temperature—The relationship between the logarithm of the first-order rate constant and the reciprocal of temperature is given in Fig. 4. The activation energy was 102 kJ/mole, in general agreement with the data given by Linford (10).

Influence of pH on Degradation Rate of Chlorambucil and I—The degradation rate of chlorambucil was unaffected by pH in the range of pH 5–10 but decreased below pH 5 (Fig. 5). The solid line is calculated using (2):

$$k_1^* = \frac{k_2' k_1}{k_2' + a_h} \qquad \text{(Eq. 8)}$$

where k_1^* is the observed pseudo-first-order rate constant, k_1 is the pseudo-first-order rate constant for the alkylating compound with an unprotonized nitrogen atom, and k_2' is the apparent acid dissociation constant for the amino group.

The good agreement between the calculated and experimental values suggests that the nitrogen mustard group is stable when present in the protonized form and that the degree of protonization of the carboxylic group (pk_{21} 4.46) does not affect its stability. These results contradict those of Linford (6) who observed a continuous increase in the stability of chlorambucil in the pH range of 7–4.5. This finding probably was due to the high concentrations used, where the degradation rate was affected by aggregation phenomena (7).

The degradation rates of I and chlorambucil differed only slightly (Table I). These results are in contrast to those found for *N*-ethyl-*N*-(2-chloroethyl)aniline, which has a degradation rate considerably higher than does *N*,*N*-di(2-chloroethyl)aniline (11).

The influence of pH on the degradation rate of I is given in Fig. 6. The rate profile was similar to that of chlorambucil but the rate declined at higher pH, reflecting the higher base strength of the amino group.

GLC Determination of Aprindine in Human Plasma Using a Nitrogen–Phosphorus Flame-Ionization Detector

J. F. NASH ˣ and R. H. CARMICHAEL

Received November 30, 1979, from *Lilly Research Laboratories, Indianapolis, IN 46206.* Accepted for publication April 1, 1980.

Abstract □ A procedure for the determination of aprindine in human plasma was developed. After the addition of *N,N*-diethyl-*N'*-(1,2,3,4-tetrahydro-2-naphthyl)-*N'*-phenyl-1,3-propanediamine as an internal standard, the plasma was buffered to pH 8.0, and the drug and the internal standard were extracted into ethyl acetate–hexane (9:1 v/v). The compounds then were extracted from the organic phase into 0.02 *N* HCl. The acidic solution was made basic with 0.2 *M* tribasic sodium phosphate, and aprindine and the internal standard were extracted into a small volume of hexane. The compounds were analyzed by GLC using a nitrogen–phosphorus flame-ionization detector. The drug concentration and instrument response were linear for 0.10–1.00 μg of aprindine/ml, the slope was 1.1416 (0.0141), the *y* intercept was 0.0096 ± 0.0082, and the correlation coefficient was 0.99960 ± 0.00002. The sensitivity of the method was 0.02 μg of aprindine/ml. The within-day coefficient of variation was 9.50, 3.10, 3.14, and 2.21% for 0.05, 0.20, 0.40, and 0.80 μg of aprindine/ml, respectively. The between-day coefficient of variation was 17.4, 3.40, 2.07, and 1.54% at the same concentrations. Total precision values of 19.9, 4.60, 4.26, and 2.69% were obtained. The overall relative error of the method was +1.33, +2.00, −0.07, and +0.25% at these concentrations.

Keyphrases □ Aprindine—GLC analysis in human plasma using nitrogen–phosphorus flame-ionization detection □ GLC—analysis, aprindine, nitrogen–phosphorus flame-ionization detection, human plasma □ Antiarrhythmic agents—aprindine, GLC analysis using nitrogen–phosphorus flame-ionization detection, human plasma

Aprindine[1] (*N,N*-diethyl-*N'*-2-indanyl-*N'*-phenyl-1,3-propanediamine), an oral, long-acting, antidysrhythmic agent, has been used in Europe since the early 1970's. A sensitive (0.1 μg/ml), specific, and precise (coefficient of variation 5%) GLC method was developed (1) and then modified (2) that satisfactorily monitors plasma aprindine levels in patients. Lagerström and Persson (3) reported a sensitive (0.5 μg/ml) high-performance liquid chromatographic assay for monitoring plasma aprindine levels. These methods appear to be suitable for monitoring plasma aprindine levels of ≥0.5 μg/ml. However, for pharmacokinetic and bioavailability studies following unit doses of 10, 25, or 50 mg of aprindine, a more sensitive method was necessary.

This report describes a GLC method using a dual nitrogen–phosphorus flame-ionization detector that optimizes the sensitivity and specificity of the measurement of aprindine and still retains the precision of the assay.

[1] Christiaens Pharmaceutical Co., Brussels, Belgium.

EXPERIMENTAL

Chemicals and Reagents—Ethyl acetate[2], hexane[2], and methanol[2] were distilled in glass; all other chemicals and reagents were analytical reagent grade. Aprindine hydrochloride[3], *N,N*-diethyl-*N'*-(1,2,3,4-tetrahydro-2-naphthyl)-*N'*-phenyl-1,3-propanediamine hydrochloride[4], and [*N-phenyl*-1-^{14}C]aprindine hydrochloride[5] with a specific activity of 29.4 μCi/mg were synthesized.

The aprindine standard solution (10 μg/ml) was prepared by weighing accurately 1.12 mg of aprindine hydrochloride into a 100-ml volumetric flask and diluting the solution to volume with distilled water.

The *N,N*-diethyl-*N'*-(1,2,3,4-tetrahydro-2-naphthyl)-*N'*-phenyl-1,3-propanediamine solution (the internal standard) (5 μg/ml) was prepared by weighing accurately 1.11 mg of the hydrochloride salt of the internal standard into a 200-ml volumetric flask and diluting the solution to volume with distilled water.

GLC System—Table I summarizes the GLC equipment, materials, and conditions for the identification and analysis of aprindine in plasma. Disposable 15-ml centrifuge tubes with plastic-lined screw caps[6] were used throughout the extraction.

Procedure—A plasma calibration curve was prepared by pipetting 1.0 ml of fresh, human, drug-free plasma into each of five disposable 15-ml centrifuge tubes and adding 250 μl of the internal standard solution to give a concentration of 1.25 μg/ml. The first tube served as the blank. Ten microliters of the aprindine standard solution was added to the second tube, 25 μl was added to the third tube, 50 μl was added to the fourth tube, and 100 μl was added to the fifth tube. These plasma standards contained aprindine concentrations of 0.00, 0.10, 0.25, 0.50, and 1.00 μg/ml, respectively.

Borate buffer USP, 0.5 ml, was mixed thoroughly with the plasma standards. Then 10 ml of ethyl acetate–hexane (9:1 v/v) was shaken with each tube of plasma standard for 2 min, and the phases were separated by centrifugation. Approximately 8 ml of the supernate was pipetted into a clean 15-ml centrifuge tube, with care taken not to remove any of the aqueous phase. The compounds were extracted into 5 ml of 0.02 *N* HCl, the contents of the tube were centrifuged, and the organic layer was discarded. The aqueous solution was made basic by mixing with 1.5 ml of 0.2 *M* tribasic sodium phosphate, the drug and the internal standard were extracted into 0.3 ml of hexane, and the phases were separated again by centrifugation. Two microliters of the hexane solution was injected onto the chromatographic column.

When assaying plasma samples, a 1.0-ml sample was placed into a 15-ml disposable centrifuge tube and 250 μl of the internal standard solution was added. After 0.5 ml of borate buffer was added, the plasma samples were handled as were the calibration curve samples.

A least-squares line was prepared by analysis of the calibration curve of the peak height ratio of aprindine to the internal standard *versus*

concentration. The concentration of aprindine in the plasma samples was determined from their peak height ratios and the least-squares line.

RESULTS AND DISCUSSION

With [*N-phenyl*-1-^{14}C]aprindine hydrochloride, it was found that ~80% of the aprindine in spiked plasma samples was recovered following the described procedure (Table II).

During the development of the method, aprindine adsorbed irreversibly to the glass surface during the evaporation of hexane in the final concentration step. Silylation of the dry-down tubes and/or addition of 20 μl of dimethylformamide to the hexane only partially prevented the binding. Therefore, only a small volume of hexane was used as the collection solvent for the compounds. When the final hexane layer was not concentrated, the binding of aprindine to glass was prevented and the

reproducibility of the method was improved greatly while suitable sensitivity was maintained.

Table III shows that the data from three typical plasma calibration curves were linear over at least a 10-fold concentration range with an intercept of near zero. The small standard deviations of the data used to prepare the least-squares lines and the correlation coefficients indicate the reproducibility of the method.

Figure 1 shows typical chromatograms of blank human plasma and a plasma calibration curve obtained by using the nitrogen–phosphorus flame-ionization detector. Chromatograms of blank human plasma and a plasma calibration curve obtained using a flame-ionization detector are given in Fig. 2. Comparison of the nitrogen–phosphorus chromatograms to the flame-ionization chromatograms shows that the former detector was 16 times more sensitive under the conditions stated for the detection of aprindine (calculated by noting four times the peak height of aprindine standards at four times the instrument attenuation). It was necessary to acid wash glassware and to optimize the nitrogen–phosphorus detector daily, as reported by Pierce *et al.* (4), to maintain good reproducibility and sensitivity.

The major metabolite of aprindine, desethylaprindine (1), eluted at ~60 sec, which separated it from the aprindine (150 sec) and the internal standard (190 sec). When humans were given therapeutic doses of aprindine hydrochloride, desethylaprindine was never seen in their plasma; however, the metabolite was seen and quantitated in dog plasma after the dogs were dosed with the drug[7]. Standard vacuum containers[8], used to collect blood samples, produced no interference in the determination of aprindine by this method.

Gas–liquid chromatograms–mass spectrograms (methane as positive ion for chemical ionization) of plasma extracts were similar to solid-probe

spectrograms of aprindine. The protonated $[M + H]^+$ ion at *m/e* 323 and fragmentation ions at *m/e* 113, 117, and 207 confirmed the presence and integrity of aprindine in the plasma of subjects administered the drug.

The accuracy and precision of the method were determined by preparing four plasma pools of known aprindine concentrations. The same analyst assayed five replicates from each pool on each of 3 days (Table IV). Good reproducibility was indicated by the within-day coefficients of variation of 9.50, 3.10, 3.14, and 2.21% for 0.05, 0.20, 0.40, and 0.80 μg of aprindine/ml, respectively, as well as by the between-day variations of 17.4, 3.40, 2.07, and 1.54% at the same concentrations. The total coefficients of variation were 19.9, 4.60, 4.26, and 2.69%, respectively. The overall relative errors at 0.05, 0.20, 0.40, and 0.80 μg of aprindine/ml were +1.33, +2.00, −0.07, and +0.25%, respectively.

Because of the specificity, sensitivity, precision, and accuracy of the reported method for the determination of aprindine in plasma, bioavailability and pharmacokinetic studies of aprindine can be undertaken at therapeutic doses. These studies will be reported later.

NOTES

Measurement of Pilocarpine and Its Degradation Products by High-Performance Liquid Chromatography

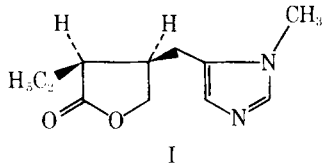
JAMES J. O'DONNELL ˣ, ROBERT SANDMAN, and MICHAEL V. DRAKE

Received January 22, 1980, from the *Department of Ophthalmology, University of California Medical Center, San Francisco, CA 94143.* Accepted for publication March 21, 1980.

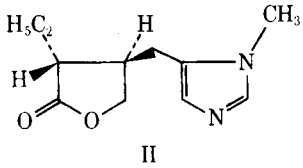
Abstract □ An assay method for pilocarpine using reversed-phase high-performance liquid chromatography is presented. This method also measures isopilocarpine, the stereoisomer of pilocarpine, and the degradation products pilocarpic acid and isopilocarpic acid. Maximum sensitivity was obtained with optical absorbance at 216 nm.

Keyphrases □ Pilocarpine—reversed-phase high-performance liquid chromatographic analysis □ High-performance liquid chromatography—analysis, *pilocarpine*, isopilocarpine, pilocarpic acid, and isopilocarpic acid □ Ophthalmic drugs—pilocarpine, high-performance liquid chromatographic analysis

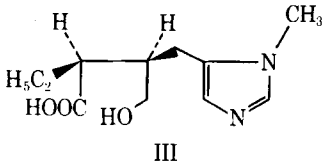
Pilocarpine (I) is a natural alkaloid used for the parasympathomimetic treatment of glaucoma. Isopilocarpine (II), the therapeutically inactive stereoisomer of pilocarpine, is present in nature and in commercial preparations of pilocarpine (1, 2). The degradation products,



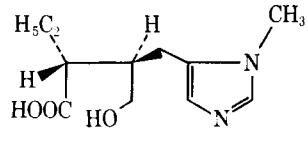
I



II



III



IV

pilocarpic acid (III) and isopilocarpic acid (IV), also are found in commercial products (3). This report presents an efficient and sensitive assay for I–IV using reversed-phase high-performance liquid chromatography (HPLC). This method is a modification of a procedure described recently (4).

EXPERIMENTAL

Pilocarpine hydrochloride USP[1] and isopilocarpine hydrochloride[2] were obtained commercially. Pilocarpic acid and isopilocarpic acid were prepared by hydrolysis of pilocarpine and isopilocarpine in 0.1 *N* NaOH. Isocratic reversed-phase chromatography was accomplished by pumping[3]

spectrograms of aprindine. The protonated $[M + H]^+$ ion at *m/e* 323 and fragmentation ions at *m/e* 113, 117, and 207 confirmed the presence and integrity of aprindine in the plasma of subjects administered the drug.

The accuracy and precision of the method were determined by preparing four plasma pools of known aprindine concentrations. The same analyst assayed five replicates from each pool on each of 3 days (Table IV). Good reproducibility was indicated by the within-day coefficients of variation of 9.50, 3.10, 3.14, and 2.21% for 0.05, 0.20, 0.40, and 0.80 μg of aprindine/ml, respectively, as well as by the between-day variations of 17.4, 3.40, 2.07, and 1.54% at the same concentrations. The total coefficients of variation were 19.9, 4.60, 4.26, and 2.69%, respectively. The overall relative errors at 0.05, 0.20, 0.40, and 0.80 μg of aprindine/ml were +1.33, +2.00, −0.07, and +0.25%, respectively.

Because of the specificity, sensitivity, precision, and accuracy of the reported method for the determination of aprindine in plasma, bioavailability and pharmacokinetic studies of aprindine can be undertaken at therapeutic doses. These studies will be reported later.

NOTES

Measurement of Pilocarpine and Its Degradation Products by High-Performance Liquid Chromatography

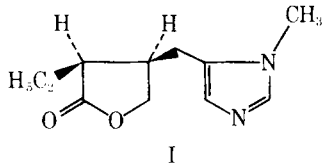
JAMES J. O'DONNELL ˣ, ROBERT SANDMAN, and MICHAEL V. DRAKE

Received January 22, 1980, from the *Department of Ophthalmology, University of California Medical Center, San Francisco, CA 94143.* Accepted for publication March 21, 1980.

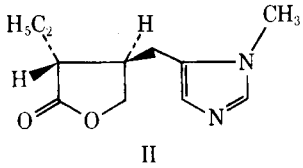
Abstract □ An assay method for pilocarpine using reversed-phase high-performance liquid chromatography is presented. This method also measures isopilocarpine, the stereoisomer of pilocarpine, and the degradation products pilocarpic acid and isopilocarpic acid. Maximum sensitivity was obtained with optical absorbance at 216 nm.

Keyphrases □ Pilocarpine—reversed-phase high-performance liquid chromatographic analysis □ High-performance liquid chromatography—analysis, *pilocarpine*, isopilocarpine, pilocarpic acid, and isopilocarpic acid □ Ophthalmic drugs—pilocarpine, high-performance liquid chromatographic analysis

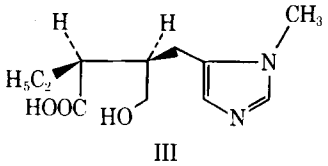
Pilocarpine (I) is a natural alkaloid used for the parasympathomimetic treatment of glaucoma. Isopilocarpine (II), the therapeutically inactive stereoisomer of pilocarpine, is present in nature and in commercial preparations of pilocarpine (1, 2). The degradation products,



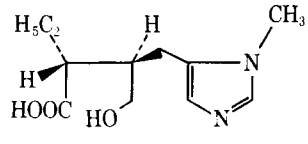
I



II



III



IV

pilocarpic acid (III) and isopilocarpic acid (IV), also are found in commercial products (3). This report presents an efficient and sensitive assay for I–IV using reversed-phase high-performance liquid chromatography (HPLC). This method is a modification of a procedure described recently (4).

EXPERIMENTAL

Pilocarpine hydrochloride USP[1] and isopilocarpine hydrochloride[2] were obtained commercially. Pilocarpic acid and isopilocarpic acid were prepared by hydrolysis of pilocarpine and isopilocarpine in 0.1 *N* NaOH. Isocratic reversed-phase chromatography was accomplished by pumping[3]

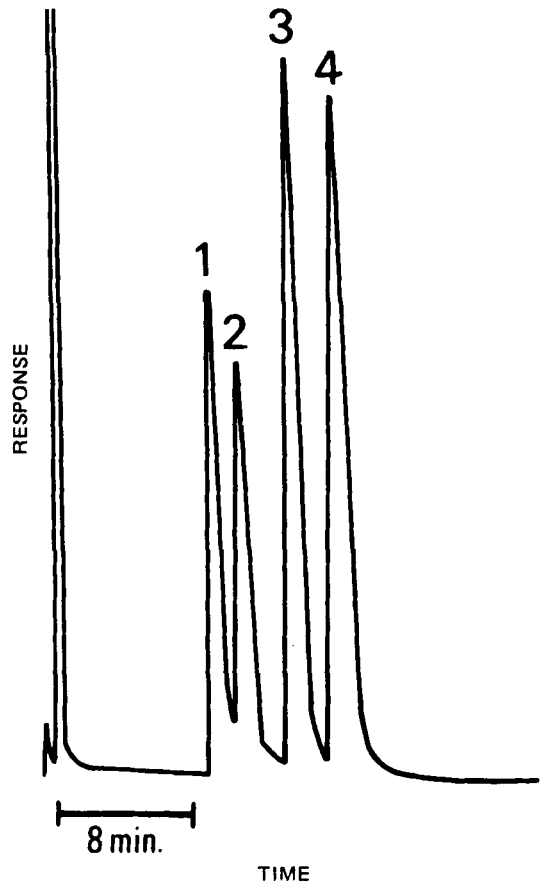

Figure 1—*HPLC separation of isopilocarpine (1), pilocarpine (2), pilocarpic acid (3), and isopilocarpic acid (4).*

97% H_2O–3% CH_3OH containing 5% KH_2PO_4 (pH 2.5) through a C_{18} column[4] at 1.5 ml/min at ambient temperature. The compounds were detected[5] by their optical absorbance at 216 nm.

RESULTS AND DISCUSSION

The chromatographic separation of pilocarpine, isopilocarpine, pilocarpic acid, and isopilocarpic acid is shown in Fig. 1. The maximum sensitivity obtainable in this system with a peak height signal of twice the short-term baseline noise is 300 ng. Detection of isopilocarpine in pilocarpine dosage forms is a problem in pilocarpine analysis. Since the isopilocarpine and pilocarpine peaks overlap, the lower limit of detection of isopilocarpine in the presence of pilocarpine by this method is one part of isopilocarpine in 100 parts of pilocarpine.

Despite long ophthalmic use, sensitive measurement of pilocarpine and its metabolites has been possible only recently. The USP method uses extraction and an insensitive colorimetric determination (5). Polarographic (6), GLC (7, 8), and NMR (3) assays have been reported. HPLC offers the convenience of speed, selectivity, sensitivity, mild and nondestructive conditions, and direct measurement. Ion-exchange HPLC (1, 2, 9) has the disadvantages of variable retention time, poor resolution, and destructive alkaline pH. The method used here was adapted from a reported reversed-phase HPLC method that used refractive index detection (4). Optical absorbance detection at 216 nm was used for increased ease and sensitivity. External standards can be used for pilocarpine analysis.

Sensitive measurement of pilocarpine and its metabolites will allow studies of the purity of dosage forms and investigation of the pharmacokinetics of pilocarpine.

Synthesis of 1-Aryl-3-formyl-3-methyltriazenes, Potential Metabolites of 1-Aryl-3,3-dimethyltriazenes

LUCIA LASSIANI *, **CARLO NISI** *x, **FABIO SIGON** *, **GIANNI SAVA** ‡, **and TULLIO GIRALDI** ‡

Received January 9, 1980, from the *Istituto di Chimica Farmaceutica and the ‡Istituto di Farmacologia, Università di Trieste, 34127, Trieste, Italy. Accepted for publication March 20, 1980.

Abstract □ Some *para*-substituted 1-aryl-3,3-dimethyltriazenes were oxidized with *tert*-butyl hydroperoxide in the presence of vanadium pentoxide as a catalyst. Under these conditions, the corresponding 1-aryl-3-formyl-3-methyltriazenes, 1-aryl-3-*tert*-butylperoxymethyl-3-methyltriazenes, and *p*-nitrobenzenes were obtained. The 1-aryl-3-formyl-3-methyltriazenes might play a role in the metabolic oxidation of the 1-aryl-3,3-dimethyltriazenes, which are active as mutagenic, carcinogenic, and antitumor agents.

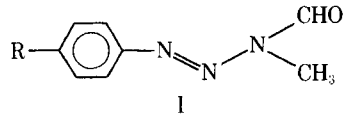
Keyphrases □ 1-Aryl-3-formyl-3-methyltriazenes—synthesis as potential metabolites of 1-aryl-3,3-dimethyltriazenes □ Antitumor agents—1-aryl-3,3-dimethyltriazenes, synthesis of 1-aryl-3-formyl-3-methyltriazenes as potential metabolites □ Metabolites, potential—1-aryl-3-formyl-3-methyltriazenes, synthesis as oxidation products of 1-aryl-3,3-dimethyltriazenes

Dimethyltriazenes have been reported to cause mutagenic (1), carcinogenic (2), and antineoplastic (3) effects, and their mechanism of action has been investigated. Their local carcinogenic effects have been attributed to aryldiazonium cations generated by hydrolysis (4), whereas their antitumor and systemic carcinogenic effects have been attributed to the methylation of cellular components by monomethyltriazenes (5) produced by microsomal oxidative *N*-demethylation (4, 6).

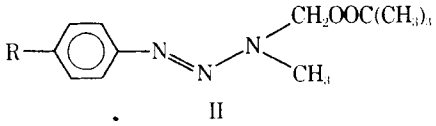
BACKGROUND

However, it is possible that some biological effects observed for dimethyltriazenes are due to other metabolites formed by oxidation of the nitrogen atoms or methyl groups in the triazene moiety. The *N*-hydroxymethyltriazenes suggested as intermediates in the microsomal *N*-demethylation of dimethyltriazenes (6) recently were synthesized (7) and isolated as metabolites (8). Therefore, it seemed interesting to attempt the chemical oxidation of dimethylaryltriazenes because of the potential of the resulting compounds as possible metabolites or as antitumor agents themselves.

The possibility of performing the oxidation without the destructive reactions reported using Udenfried's system (9) was investigated. Of the several attempts using hydrogen peroxide, oxygen, *m*-chloroperoxybenzoic acid, and *tert*-butyl hydroperoxide in the presence of molybdenum dioxyacetylacetonate (10) or vanadium pentoxide, only the latter combination of oxidizing agent and catalyst was successful and gave satisfactory yields. In this way, the *N*-formyl derivatives (I*a*–I*d*), peroxides (II*a*–II*d*), and *p*-nitrobenzenes resulting from the oxidative breakdown of the triazene function were obtained.



I



II

I*a* and II*a*: R = NO_2
I*b* and II*b*: R = Cl
I*c* and II*c*: R = Br
I*d* and II*d*: R = I

The reported structures were assigned on the basis of elemental analyses as well as NMR, IR, and mass spectral data. For I*a*–I*d*, the presence of a formyl group and a single methyl group was indicated by a singlet at δ ~9.30 for one proton and a singlet at δ ~5.40 for three protons, respectively. Furthermore, a strong band at ~1700 cm^{-1}, attributable to C=O stretching, was observed in the IR spectra. For II*a*–II*d*, the NMR spectra showed the presence of a singlet for nine protons at δ ~1.25, a singlet for three protons at δ ~3.30, and a singlet for two protons at δ ~5.50. Further investigation is in progress to evaluate the antitumor effect of these formyltriazenes and their possible role in the metabolism of dimethyltriazenes.

EXPERIMENTAL[1]

General Procedure—A 3,3-dimethyl-1-aryltriazene (5 mmoles) and vanadium pentoxide (50 mg) were suspended in 25 ml of benzene, and 6 ml of 80% *tert*-butyl hydroperoxide (47 mmoles) was added dropwise with stirring. The temperature was raised to 45°, and stirring was maintained for 26–30 hr, or for 50 hr for I*d* and II*d*, to ensure complete disappearance of the starting triazene. The starting material was detected by TLC on silica gel plates developed with 5% hexane in benzene (v/v) or 30% ethyl acetate in hexane for II*b*. The reaction mixture was filtered, and the filtrate was evaporated under reduced pressure.

Compounds I*a* and II*a*—The residue dissolved in 2 ml of acetone was chromatographed on silica gel. The elution with 1% acetone in benzene (v/v) afforded three fractions detected by TLC. The first fraction, which contained only 1,4-dinitrobenzene, was discarded. The second fraction, after evaporation of the solvent under reduced pressure, gave 30 mg of II*a*. The third fraction, which contained a mixture of I*a* and II*a*, was chromatographed again, after evaporation, on silica gel with ethyl acetate in hexane (1:2 v/v) as the eluent.

The first fraction yielded 350 mg of 1-(4-nitrophenyl)-3-*tert*-butylperoxymethyl-3-methyltriazene (II*a*), mp 86°, after crystallization from hexane; UV: 345 nm; NMR: δ 1.24 (s, 9H), 3.32 (s, 3H), 5.48 (s, 2H), and 7.45–8.35 (m, 4H); mass spectrum: *m/e* 282 (M).

Anal.—Calc. for $C_{12}H_{18}N_4O_4$: C, 51.05; H, 6.42; N, 19.84. Found: C, 51.08; H, 6.40; N, 19.81.

The second fraction, after evaporation, yielded 200 mg of 1-(4-nitrophenyl)-3-formyl-3-methyltriazene (I*a*) after crystallization from methanol, mp 117–119°; UV: 215 and 302 nm; IR: 1700–1720 (C=O) cm^{-1}; NMR: δ 3.44 (s, 3H), 7.73–8.44 (m, 4H), and 9.35 (s, 1H); mass spectrum: *m/e* 208 (M).

Anal.—Calc. for $C_8H_8N_4O_3$: C, 46.15; H, 3.87; N, 26.91. Found: C, 46.03; H, 3.85; N, 26.95.

Compounds I*b* and II*b*—To obtain I*b*, the residue was dissolved in 2 ml of benzene and chromatographed on silica gel. Elution with 5% hexane in benzene (v/v) afforded three fractions detected by TLC. The first fraction, which contained *p*-chloronitrobenzene, was discarded. The second fraction contained II*b*, and the third fraction, after evaporation under reduced pressure, gave 150 mg of 1-(4-chlorophenyl)-3-formyl-3-methyltriazene (I*b*) as a crystalline residue, mp 89°, after crystallization twice from methanol; UV: 223 and 283 nm; IR: 1733 (C=O) cm^{-1}; NMR: δ 3.36 (s, 3H), 7.28–7.72 (m, 4H), and 9.26 (s, 1H).

Anal.—Calc. for $C_8H_8ClN_3O$: C, 48.62; H, 4.08; N, 21.26. Found: C, 48.65; H, 4.11; N, 21.28.

[1] Melting points were determined in open glass capillaries using a Büchi apparatus and are uncorrected. IR spectra were obtained as potassium bromide disks with a Perkin-Elmer model 225 spectrometer. UV spectra of methanol solutions were determined on a Hitachi Perkin-Elmer model 124 spectrometer. NMR spectra were recorded on a Perkin-Elmer R12B spectrometer, in deuterochloroform, with tetramethylsilane as the internal standard. Mass spectra were recorded on a Hitachi Perkin-Elmer RMU-6L spectrometer. Silica gel (Merck) of 230–240 mesh activated 5 hr at 200° and HF (254 + 366) were used for column chromatography and TLC, respectively.

To obtain IIb, the residue dissolved in 2 ml of benzene was chromatographed on silica gel. The elution with hexane–ether (7:1 v/v) afforded a first fraction containing a mixture of *p*-chloronitrobenzene and IIb. The second fraction was evaporated under reduced pressure. The residue, after crystallization from hexane chilled in a dry ice–acetone bath to avoid losses, gave 150 mg of 1-(4-chlorophenyl)-3-*tert*-butylperoxymethyl-3-methyltriazene (IIb), mp 44.5°; UV (ethanol): 218, 222, and 282 nm; NMR: δ 1.23 (s, 9H), 3.30 (s, 3H), 5.52 (s, 2H), and 7.35–7.43 (m, 4H).

Anal.—Calc. for $C_{12}H_{18}ClN_3O_2$: C, 53.04; H, 6.68; N, 15.46. Found: C, 53.03; H, 6.64; N, 15.50.

Compounds Ic and IIc—The residue dissolved in 2 ml of benzene was chromatographed on silica gel. Three fractions resulted from elution with 5% hexane in benzene (v/v). The first fraction was *p*-bromonitrobenzene. The second fraction, after evaporation of the solvent under reduced pressure, gave 200 mg of 1-(4-bromophenyl)-3-*tert*-butylperoxymethyl-3-methyltriazene (IIc), mp 54°; UV: 218, 222, and 281 nm.

Anal.—Calc. for $C_{12}H_{18}BrN_3O_2$: C, 45.58; H, 5.74; N, 13.29. Found: C, 45.80; H, 5.84; N, 13.10.

The third fraction gave 200 mg of 1-(4-bromophenyl)-3-formyl-3-methyltriazene (Ic), mp 102–104°, after crystallization from methanol and from hexane; UV: 224 and 284 nm; IR: 1733 (C=O) cm^{-1}; NMR: δ 3.37 (s, 3H), 7.55 (m, 4H), and 9.24 (s, 1H).

Anal.—Calc. for $C_8H_8BrN_3O$: C, 39.69; H, 3.33; N, 17.36. Found: C, 39.63; H, 3.30; N, 17.30.

Compounds Id and IId—The residue was suspended in 2 ml of methanol and filtered. The filtrate was chromatographed on silica gel, and elution with 5% hexane in benzene gave three fractions. The first fraction, which contained *p*-iodonitrobenzene, was discarded. The second fraction, after evaporation of the solvent, gave 250 mg of 1-(4-iodophenyl)-3-*tert*-butylperoxymethyl-3-methyltriazene (IId), mp 56°; UV: 224 and 284 nm.

Anal.—Calc. for $C_{12}H_{18}IN_3O_2$: C, 39.68; H, 4.99; N, 11.57. Found: C, 39.80; H, 4.93; N, 11.30.

The third fraction gave 50 mg of 1-(4-iodophenyl)-3-formyl-3-methyltriazene (Id), mp 123–124°, after crystallization from methanol; UV: 230 and 293 nm; IR: 1700 (C=O) cm^{-1}; NMR: δ 3.38 (s, 3H), 7.25–7.95 (m, 4H), and 9.30 (s, 1H).

Anal.—Calc. for $C_8H_8IN_3O$: C, 33.24; H, 2.79; N, 14.54. Found: C, 33.23; H, 2.69; N, 14.45.

Stability of Solid Drugs: Degradation of Ergocalciferol (Vitamin D_2) and Cholecalciferol (Vitamin D_3) at High Humidities and Elevated Temperatures

L. T. GRADY and K. D. THAKKER ˣ

Received November 1, 1979, from the *United States Pharmacopeia, Rockville, MD 20852.* Accepted for publication March 17, 1980.

Abstract □ Ergocalciferol and cholecalciferol powders were studied at 25 and 40° and at different humidities. Ergocalciferol decomposed rapidly at 25 and 40° when stored in dry air. Decomposition of ergocalciferol led to the formation of products of higher polarity. Cholecalciferol was not as labile under dry conditions, but decomposed rapidly at high temperature.

Keyphrases □ Vitamin D—ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3), effects of temperature and humidity on decomposition □ Stability—ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3), effects of humidity and temperature □ Ergocalciferol—stability, effects of temperature and humidity □ Cholecalciferol—stability, effects of temperature and humidity

Ergocalciferol and cholecalciferol are fat-soluble vitamins essential for their antirachitic activity. The adverse effects of light, air, and temperature on solutions of these 9,10-secosterols are well documented (1–4).

Previous studies on the solid-state decomposition of ergocalciferol (initially a white, crystalline powder) showed the formation of a yellow powder having a lowered melting point (5). These observations also were made in this laboratory. GLC analysis of ergocalciferol and cholecalciferol resulted in the decomposition of the parent product, with the formation of two peaks (6). These two peaks were identified as pyro- and isopyro vitamin D[1], formed as a result of thermal cyclization of vitamin D (6). The decomposition of ergocalciferol in powder preparations was reported to depend directly on the surface acidity of the excipients and their ability to adsorb moisture (7).

These studies on the decomposition of vitamin D are valuable but do not predict its stability under normal storage conditions. A labile reference material such as vitamin D must be stored at optimum conditions. Therefore, to determine these conditions, the effects of temperature and humidity on the stability of ergocalciferol and cholecalciferol in the absence of light were investigated.

[1] Vitamin D refers to vitamins D_2 and D_3.

Stability of Solid Drugs: Degradation of Ergocalciferol (Vitamin D_2) and Cholecalciferol (Vitamin D_3) at High Humidities and Elevated Temperatures

L. T. GRADY and K. D. THAKKER ˣ

Received November 1, 1979, from the *United States Pharmacopeia, Rockville, MD 20852.* Accepted for publication March 17, 1980.

Abstract □ Ergocalciferol and cholecalciferol powders were studied at 25 and 40° and at different humidities. Ergocalciferol decomposed rapidly at 25 and 40° when stored in dry air. Decomposition of ergocalciferol led to the formation of products of higher polarity. Cholecalciferol was not as labile under dry conditions, but decomposed rapidly at high temperature.

Keyphrases □ Vitamin D—ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3), effects of temperature and humidity on decomposition □ Stability—ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3), effects of humidity and temperature □ Ergocalciferol—stability, effects of temperature and humidity □ Cholecalciferol—stability, effects of temperature and humidity

Ergocalciferol and cholecalciferol are fat-soluble vitamins essential for their antirachitic activity. The adverse effects of light, air, and temperature on solutions of these 9,10-secosterols are well documented (1–4).

Previous studies on the solid-state decomposition of ergocalciferol (initially a white, crystalline powder) showed the formation of a yellow powder having a lowered melting point (5). These observations also were made in this laboratory. GLC analysis of ergocalciferol and cholecalciferol resulted in the decomposition of the parent product, with the formation of two peaks (6). These two peaks were identified as pyro- and isopyro vitamin D[1], formed as a result of thermal cyclization of vitamin D (6). The decomposition of ergocalciferol in powder preparations was reported to depend directly on the surface acidity of the excipients and their ability to adsorb moisture (7).

These studies on the decomposition of vitamin D are valuable but do not predict its stability under normal storage conditions. A labile reference material such as vitamin D must be stored at optimum conditions. Therefore, to determine these conditions, the effects of temperature and humidity on the stability of ergocalciferol and cholecalciferol in the absence of light were investigated.

[1] Vitamin D refers to vitamins D_2 and D_3.

EXPERIMENTAL

Reagents—Ergocalciferol and cholecalciferol USP[2] were used as received. Hexane[3] and 1-pentanol[4] were high-pressure liquid chromatographic (HPLC) grade.

Controlled-Temperature and Humidity Microenvironments—Commercial constant-humidity ovens[5] were used to achieve 40° with 85% relative humidity (RH) and 40° with 45% RH. For all of the other controlled-temperature–humidity microenvironments, saturated salt solution systems (8) were used to achieve constant humidity in a thermostatically regulated room (25 ± 1°).

A glove box[6] was used to achieve dry, anaerobic conditions as follows. It first was allowed to equilibrate to very low humidity by placing flat dishes of silica gel in it for 2 days. The dry air then was evacuated, and dry nitrogen was flushed throughout the glove box; this evacuation–flushing cycle was repeated twice. While the glove box was used, dry nitrogen was bled into it continuously at a low rate to ensure an anaerobic environment above the samples.

Sample Assay—The assay to determine the percentage of vitamin D remaining in the preweighed samples after storage at specified time intervals was based on the method described by deVries *et al.* (9). The gradient elution high-pressure liquid chromatograph[7] was equipped with a variable-wavelength UV detector[8], a recorder[9], and an integrator[10]. A commercial liquid chromatographic column[11] packed with microporous silica was the stationary phase. A mixture of 1-pentanol and dry hexane (9) was the mobile phase. The concentration of 1-pentanol in hexane was varied (0.05–0.1% v/v) when necessary to meet the system suitability test.

System Suitability Test—A mixture of cholecalciferol and its known isomers, *e.g.*, precholecalciferol lumisterol, isotachysterol, tachysterol, and 7-dehydrocholesterol, was available from samples left from a previous collaborative study (9). This mixture was injected onto the HPLC column. The resolution, R, between cholecalciferol and tachysterol and the resolution between precholecalciferol and *trans*-cholecalciferol were determined by:

$$R = 2D/B + C \qquad \text{(Eq. 1)}$$

where D is the distance between the peak maxima and B and C are the peak widths of the two peaks.

The system conditions were adjusted to obtain $R > 1.0$ for cholecalciferol–tachysterol peaks and $R > 0.8$ for precholecalciferol–*trans*-cholecalciferol peaks. Under these conditions, separation of all isomers listed was possible; their elution order remained fixed so that the peaks could be identified by comparison with reported chromatograms (9).

Procedure—About 1–2 mg of ergocalciferol or cholecalciferol was weighed on an electronic balance[12] as quickly as possible and transferred to a disposable, aluminum weighing boat. Weighings were done in subdued light only. The samples were introduced immediately into the various controlled-temperature–humidity microenvironments. At the designated time intervals, the samples were removed from the microenvironments, dissolved promptly in the mobile phase, and transferred to a 10-ml volumetric flask. The sample dish was washed successively with small volumes of the mobile phase to ensure quantitative transfer. After the volume was adjusted to 10 ml, ~10 μl was injected onto the chromatographic column with a loop injector[13].

Standard Solution—About 1–2 mg of ergocalciferol USP or cholecalciferol USP, accurately weighed, was transferred to a 10-ml volumetric flask and dissolved in the mobile phase. After the volume was adjusted to 10.0 ml, 10 μl of the resulting solution was injected into the HPLC column[11] with a loop injector[13]. The standard solution was prepared fresh daily and was injected at least three times for each assay.

Calculations—The integrator counts for the peak due to ergocalciferol or cholecalciferol (duplicate injections) were compared with the area counts obtained for the peak due to ergocalciferol USP or cholecalciferol USP in the standard solution, and the percentage of ergocalciferol or cholecalciferol remaining in the samples was calculated with a correction applied for the weights of the powders.

Other Tests—Reversed-phase HPLC separation of ergocalciferol and its decomposition products also was performed. The same liquid chromatograph[7] was used as in the assay of decomposed samples. The stationary phase consisted of octadecylsilane chemically bonded to microporous silica[14], and the mobile phase was methanol–acetonitrile (50:50 v/v).

TLC also was used to separate ergocalciferol and the decomposition products. The following four systems were used on silica gel[3] plates: 1, cyclohexane–ether (1:1 v/v); 2, chloroform; 3, chloroform–ether–methanol (4:4:2 v/v/v); and 4, toluene–hexane–ether (2:2:1 v/v/v). All solvents were chromatographic grade[4].

RESULTS

Table I shows the stability of ergocalciferol and cholecalciferol at room temperature for 56 days. In general, ergocalciferol was more labile at room temperature in the presence of a desiccant. After 21 days, samples stored in dry air (in a desiccator) had only ~66% remaining; those stored under very moist air (85% RH) or anaerobic (dry) conditions (dry nitrogen box) had >95% remaining. On the other hand, cholecalciferol was more stable

Table III—Degradation of Ergocalciferol and Cholecalciferol on Different Container Surfaces

Container	Isomer Remaining after 7 Days at 40° and 45% RH, %	
	Ergocalciferol	Cholecalciferol
Aluminum weighing boats	16, 17	69, 62
Glass weighing dishes	19, 20	69, 69
Polystyrene weighing boats (disposable)	38, 35	66, 72
High-density polyethylene bottles	26, 30	73, 73
Polypropylene bottles (multiple-unit containers)	45	76

at room temperature. After 21 days, cholecalciferol samples stored under all three conditions had >99% remaining, indicating no degradation.

After 15 days, ergocalciferol samples that were stored in a desiccator acquired a yellow tinge, which deepened as time progressed. On thin-layer chromatograms, separation of ergocalciferol and the decomposition products was obtained in System 1, but the new spot due to the decomposition product remained at the origin. There were no extra peaks on the chromatograms of ergocalciferol (obtained during adsorption chromatography), although the samples turned distinctly yellow. However, separation of ergocalciferol and the degradation products was obtained on reversed-phase liquid chromatograms. The decomposition products from a yellowed sample of ergocalciferol eluted with the solvent front (Fig. 1).

Table II shows the stability of ergocalciferol and cholecalciferol at 40°. Both compounds were less stable at elevated temperatures. After 7 days, samples of ergocalciferol stored at 40° and 85% RH had 87% remaining; those stored at 40° and 45% RH had only 20% remaining. Both samples had turned yellow. Cholecalciferol showed the reverse trend. After 7 days, samples stored at 40° and 85% RH had 15% of the cholecalciferol remaining; those stored at 40° and 45% RH had about 65% of the cholecalciferol remaining.

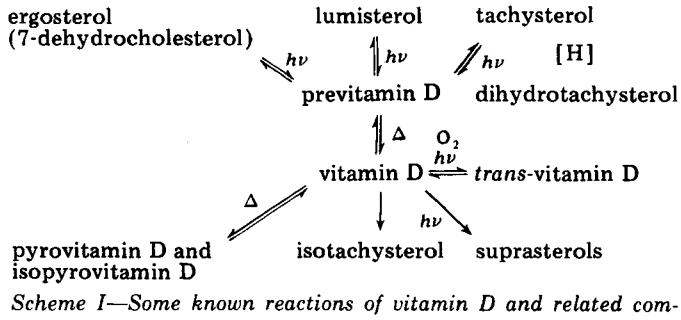
Table III shows the stability of ergocalciferol and cholecalciferol (at 40° and 45% RH for 7 days) on different types of containers (surfaces) used as sample dishes. Both ergocalciferol and cholecalciferol were more stable when stored on plastic containers than when stored on glass or aluminum weighing dishes. In all cases, cholecalciferol was more stable than ergocalciferol.

DISCUSSION

Solutions of ergocalciferol and cholecalciferol undergo thermal, photochemical, and oxidative reactions that lead to a host of degradation products (1–4). Scheme I shows the known pathways of decomposition for these compounds.

Powder preparations of ergocalciferol were reported to undergo isomerization, which resulted in the formation of 5,6-*trans*-vitamin D_2 (7). Neither this isomer nor any known ergocalciferol isomer (Scheme I) was present in any decomposed sample. Since Scheme I lists reactions involving the sterol nucleus, which require considerable freedom of molecular motion, the absence of these isomers in decomposed ergocalciferol samples indicates that such freedom of molecular motion is not available to molecules of ergocalciferol for solid-state decomposition.

The effect of moisture on reactions of ergocalciferol is apparent. Moisture adsorbed on the surface of the molecules seems to inhibit the decomposition of ergocalciferol. Such inhibition by moisture adsorbed by the excipients was reported for some powder preparations of ergocalciferol (7). Furthermore, the decomposition is faster in the presence of air since oxygen is required. In short, it can be inferred that the solid-state decomposition reactions of ergocalciferol in the absence of light is of a dry, oxidative type.



Scheme I—Some known reactions of vitamin D and related compounds

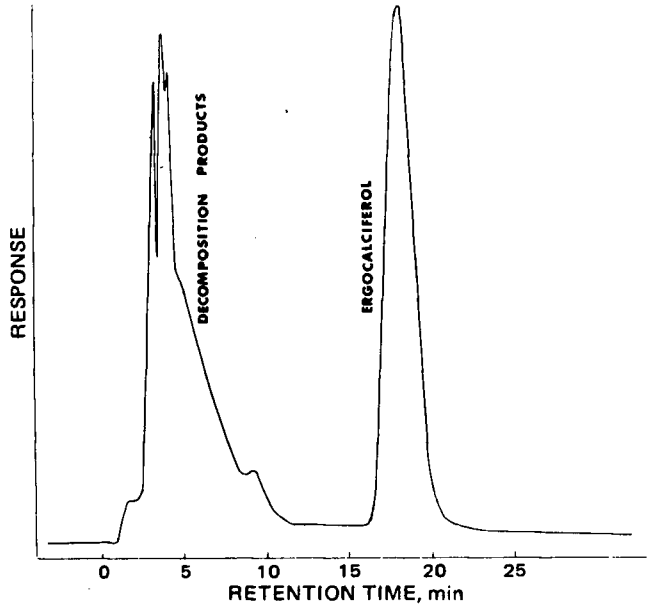


Figure 1—*Chromatogram of a partially decomposed, yellowed sample of ergocalciferol on Micropak MCH-10. The mobile phase was methanol–acetonitrile (50:50 v/v).*

The decomposition reactions of cholecalciferol apparently differ from these of ergocalciferol (Tables I–III). Cholecalciferol was more stable than ergocalciferol under all but one condition. The sharp decomposition of ergocalciferol in a dry aerobic atmosphere was not seen with cholecalciferol. Decomposition of cholecalciferol was a little faster at the more humid of the two conditions at 40°. This finding was the exact opposite of the behavior seen for ergocalciferol.

Since the only structural difference between the two molecules is in the side chain, the solid-state decomposition reactions of both compounds must involve the side chain only. This observation also is consistent with the observation that no known isomers involving reactions of the sterol nucleus are found. If the sterol nucleus were to take part in the solid-state decomposition of ergocalciferol and cholecalciferol, such differences as were obtained on decomposition of these two compounds (Table II) would not have been obtained. A double bond in the side chain of ergocalciferol must make it a substrate for attack by oxygen. Since the solid-state reactions must occur with little freedom of movement, the decomposition reactions of ergocalciferol (involving the double bond of the side chain and oxygen) may occur *via* a free radical pathway. Free radical reactions can be accomplished in the solid state and may be effected more readily by the presence of molecules with high dipole moment. Cholecalciferol is stable at room temperature but is quite labile at 40°; thus, the decomposition reaction of cholecalciferol seems to have a low activation energy.

The nature of the decomposition products of ergocalciferol or cholecalciferol is not known, and their chromatographic behavior is puzzling. Normal-phase liquid chromatography and TLC revealed that the decomposition products bound strongly to the silica supports. Reversed-phase liquid chromatography of the same decomposition products revealed that they had a highly polar nature as seen by their fairly high solubility in methanol. These observations cannot be clarified further until more information is gathered to allow proposal of a mechanism for decomposition reactions of ergocalciferol and cholecalciferol.

Synthesis and Antidepressant Activity of 5-(4-Dimethylaminobenzyl)imidazolidine-2,4-dione

F. L. WESSELS ˣ, T. J. SCHWAN, and S. F. PONG

Received November 21, 1979, from the *Scientific Affairs Department, Norwich-Eaton Pharmaceuticals, Division of Morton-Norwich Products, Inc., Norwich, NY 13815.* Accepted for publication March 24, 1980.

Abstract □ 5-(4-Dimethylaminobenzyl)imidazolidine-2,4-dione was prepared by catalytic hydrogenation of the corresponding benzylidene compound. Antidepressant testing in mice indicated that its ED_{50} values for antagonism of tetrabenazine-induced ptosis and potentiation of levodopa-induced behavioral changes were 42 and 17 mg/kg po, respectively. *In vitro* neurochemical studies demonstrated that this compound did not inhibit the uptake of selected biogenic amines into crude synaptosomes of mouse whole brain, and it did not have significant monoamine oxidase inhibitory activity *in vivo* and *in vitro*. Thus, this compound possesses potential antidepressant activity with a mechanism different from that of the tricyclic antidepressants and monoamine oxidase inhibitors.

Keyphrases □ 5-(4-Dimethylaminobenzyl)imidazolidine-2,4-dione—synthesis and testing for antidepressant activity □ Antidepressant activity—5-(4-dimethylaminobenzyl)imidazolidine-2,4-dione, *in vitro* and *in vivo* testing

The tricyclic antidepressant drugs are the most useful drugs for the treatment of depression. However, these drugs are not effective in all patients and are not without compromising side effects (1, 2). Monoamine oxidase inhibitors also are effective antidepressants; however, because of their propensity to cause hypertensive crisis, they now have limited use in the treatment of depression (3).

As part of a program directed at the discovery and development of novel agents affecting the central nervous system (CNS), 5-(4-dimethylaminobenzyl)imidazolidine-2,4-dione (I) was synthesized as a chemical intermediate and unexpectedly demonstrated antidepressant activity in selected experimental models (4). This paper presents the synthesis and results of pharmacological testing of this compound.

EXPERIMENTAL[1]

Synthesis of 5-(4-Dimethylaminobenzyl)imidazolidine-2,4-dione (I)—A mixture of 69.3 g (0.30 mole) of 5-(4-dimethylaminobenzylidene)imidazolidine-2,4-dione (IV) (5), 600 ml of 1 *N* KOH, and 15 g of wet No. 28 Raney nickel catalyst was shaken with hydrogen at 3–4 atm for 28 hr until the theoretical quantity was consumed. The catalyst was washed with two 100-ml portions of 1 *N* KOH, and the filtrate and combined washings were acidified with acetic acid to give the crude product (60 g). Recrystallization from methanol gave 35 g (50%) of I, mp 180–186°; IR: 3.10, 3.21 (NH), 5.66, 5.90 (C=O), and 6.20 (C=C) μm; NMR (dimethyl sulfoxide-d_6): δ 2.75–2.85 [m, 8, $(CH_3)_2N$ and aryl CH_2], 4.20 (t, 1, CH_2CHNH), 6.60, 7.01 (d, 4, J = 9 Hz, aromatic CH), 7.78 (broad exchangeable s, 1, imidazolidine 1-NH), and 11.0 (broad exchangeable m, 1, imidazolidine 3-NH).

Anal.—Calc. for $C_{12}H_{15}N_3O_2$: C, 61.78; H, 6.48; N, 18.02. Found: C, 61.79; H, 6.45; N, 18.02.

Tetrabenazine Antagonism—The method used was similar to that described by Barnett *et al.* (6). Groups of five unfasted male mice (TAC:SW/N fBr), 20–27 g, were pretreated with the test compound at 50 mg/kg po as a 0.5% suspension in 0.5% methylcellulose 4000 cps[2] or methylcellulose alone. Thirty minutes later, each animal received tetrabenazine methanesulfonate[3] (36 mg/kg ip in saline) or saline at a volume of 10 ml/kg. After an additional 30 min, the degree of palpebral narrowing was estimated as a measure of ptosis and compared to the methylcellulose and tetrabenazine control groups. The degree of ptosis was evaluated using a rating scale of 0–4, with a score of 4 representing a normal palpebral opening and scores of 3, 2, 1, and 0 representing slight, moderate, marked, and complete active closure of the palpebral opening, respectively. The percent prevention of ptosis was calculated as described by Barnett *et al.* (6).

Compound I at a dose of 50 mg/kg antagonized the effect of tetrabenazine by 50% or greater and, therefore, was evaluated further for dose-response effect as an ED_{50} value. The method described by Litchfield and Wilcoxon (7) was used for determining the ED_{50} value.

Levodopa Potentiation—The levodopa potentiation model is a reflection of increased dopaminergic activity, and the method used was that described by Everett (8). Groups of unfasted male mice [TAC:(SW)fBr] were administered pargyline[4] at a dose of 40 mg/kg po (0.4% in 0.5% methylcellulose) 4 hr prior to the administration of graded doses of test drugs or methylcellulose only. One hour after administration of the test drugs, levodopa (100 mg/kg ip, 1% in saline) was administered to all mice.

Observations of the levodopa-induced response were recorded 25 min after administration on a scale similar to that described by Everett (8). The degree of potentiation was scored as: 0 = no unusual irritability; 1 = increased alertness and responsiveness to touch; 2 = aggressive response to touch (hyperreactive); and 3 = markedly aggressive response to touch, spontaneous fighting with salivation and piloerection, or near prostrate. The percent of levodopa potentiation was calculated as described by Everett (8). The ED_{50} values were obtained using the method described by Litchfield and Wilcoxon (7).

Tryptamine Potentiation—Tedeschi *et al.* (9) hypothesized that tryptamine increases brain serotonin levels but that convulsions do not occur because the destruction of serotonin by monoamine oxidase keeps pace with its formation. The interruption of the metabolism of serotonin (*i.e.*, by monoamine oxidase inhibitors) and tryptamine will cause convulsions. The method used was similar to that described by Tedeschi *et al.* (9). Groups of 10 unfasted male mice [TAC:(SW)fBr] were administered the test compounds suspended in 0.5% methylcellulose at a dose 10 times their levodopa potentiation ED_{50} values. Four hours later, tryptamine[5] was administered at 50 mg/kg iv. The compounds were considered to potentiate tryptamine if >50% of the animals in the treated group convulsed.

[1] Melting points were determined on a Mel-Temp apparatus and are corrected. The IR spectrum was determined as a mineral oil mull using a Perkin-Elmer 137B spectrophotometer. The NMR spectrum was obtained on a Varian A-60 instrument and was compared with tetramethylsilane as the internal standard.

Synthesis and Antidepressant Activity of 5-(4-Dimethylaminobenzyl)imidazolidine-2,4-dione

F. L. WESSELS ˣ, T. J. SCHWAN, and S. F. PONG

Received November 21, 1979, from the *Scientific Affairs Department, Norwich-Eaton Pharmaceuticals, Division of Morton-Norwich Products, Inc., Norwich, NY 13815.* Accepted for publication March 24, 1980.

Abstract □ 5-(4-Dimethylaminobenzyl)imidazolidine-2,4-dione was prepared by catalytic hydrogenation of the corresponding benzylidene compound. Antidepressant testing in mice indicated that its ED_{50} values for antagonism of tetrabenazine-induced ptosis and potentiation of levodopa-induced behavioral changes were 42 and 17 mg/kg po, respectively. *In vitro* neurochemical studies demonstrated that this compound did not inhibit the uptake of selected biogenic amines into crude synaptosomes of mouse whole brain, and it did not have significant monoamine oxidase inhibitory activity *in vivo* and *in vitro*. Thus, this compound possesses potential antidepressant activity with a mechanism different from that of the tricyclic antidepressants and monoamine oxidase inhibitors.

Keyphrases □ 5-(4-Dimethylaminobenzyl)imidazolidine-2,4-dione—synthesis and testing for antidepressant activity □ Antidepressant activity—5-(4-dimethylaminobenzyl)imidazolidine-2,4-dione, *in vitro* and *in vivo* testing

The tricyclic antidepressant drugs are the most useful drugs for the treatment of depression. However, these drugs are not effective in all patients and are not without compromising side effects (1, 2). Monoamine oxidase inhibitors also are effective antidepressants; however, because of their propensity to cause hypertensive crisis, they now have limited use in the treatment of depression (3).

As part of a program directed at the discovery and development of novel agents affecting the central nervous system (CNS), 5-(4-dimethylaminobenzyl)imidazolidine-2,4-dione (I) was synthesized as a chemical intermediate and unexpectedly demonstrated antidepressant activity in selected experimental models (4). This paper presents the synthesis and results of pharmacological testing of this compound.

EXPERIMENTAL[1]

Synthesis of 5-(4-Dimethylaminobenzyl)imidazolidine-2,4-dione (I)—A mixture of 69.3 g (0.30 mole) of 5-(4-dimethylaminobenzylidene)imidazolidine-2,4-dione (IV) (5), 600 ml of 1 *N* KOH, and 15 g of wet No. 28 Raney nickel catalyst was shaken with hydrogen at 3–4 atm for 28 hr until the theoretical quantity was consumed. The catalyst was washed with two 100-ml portions of 1 *N* KOH, and the filtrate and combined washings were acidified with acetic acid to give the crude product (60 g). Recrystallization from methanol gave 35 g (50%) of I, mp 180–186°; IR: 3.10, 3.21 (NH), 5.66, 5.90 (C=O), and 6.20 (C=C) μm; NMR (dimethyl sulfoxide-d_6): δ 2.75–2.85 [m, 8, $(CH_3)_2N$ and aryl CH_2], 4.20 (t, 1, CH_2CHNH), 6.60, 7.01 (d, 4, J = 9 Hz, aromatic CH), 7.78 (broad exchangeable s, 1, imidazolidine 1-NH), and 11.0 (broad exchangeable m, 1, imidazolidine 3-NH).

Anal.—Calc. for $C_{12}H_{15}N_3O_2$: C, 61.78; H, 6.48; N, 18.02. Found: C, 61.79; H, 6.45; N, 18.02.

Tetrabenazine Antagonism—The method used was similar to that described by Barnett *et al.* (6). Groups of five unfasted male mice (TAC:SW/N fBr), 20–27 g, were pretreated with the test compound at 50 mg/kg po as a 0.5% suspension in 0.5% methylcellulose 4000 cps[2] or methylcellulose alone. Thirty minutes later, each animal received tetrabenazine methanesulfonate[3] (36 mg/kg ip in saline) or saline at a volume of 10 ml/kg. After an additional 30 min, the degree of palpebral narrowing was estimated as a measure of ptosis and compared to the methylcellulose and tetrabenazine control groups. The degree of ptosis was evaluated using a rating scale of 0–4, with a score of 4 representing a normal palpebral opening and scores of 3, 2, 1, and 0 representing slight, moderate, marked, and complete active closure of the palpebral opening, respectively. The percent prevention of ptosis was calculated as described by Barnett *et al.* (6).

Compound I at a dose of 50 mg/kg antagonized the effect of tetrabenazine by 50% or greater and, therefore, was evaluated further for dose-response effect as an ED_{50} value. The method described by Litchfield and Wilcoxon (7) was used for determining the ED_{50} value.

Levodopa Potentiation—The levodopa potentiation model is a reflection of increased dopaminergic activity, and the method used was that described by Everett (8). Groups of unfasted male mice [TAC:(SW)fBr] were administered pargyline[4] at a dose of 40 mg/kg po (0.4% in 0.5% methylcellulose) 4 hr prior to the administration of graded doses of test drugs or methylcellulose only. One hour after administration of the test drugs, levodopa (100 mg/kg ip, 1% in saline) was administered to all mice.

Observations of the levodopa-induced response were recorded 25 min after administration on a scale similar to that described by Everett (8). The degree of potentiation was scored as: 0 = no unusual irritability; 1 = increased alertness and responsiveness to touch; 2 = aggressive response to touch (hyperreactive); and 3 = markedly aggressive response to touch, spontaneous fighting with salivation and piloerection, or near prostrate. The percent of levodopa potentiation was calculated as described by Everett (8). The ED_{50} values were obtained using the method described by Litchfield and Wilcoxon (7).

Tryptamine Potentiation—Tedeschi *et al.* (9) hypothesized that tryptamine increases brain serotonin levels but that convulsions do not occur because the destruction of serotonin by monoamine oxidase keeps pace with its formation. The interruption of the metabolism of serotonin (*i.e.*, by monoamine oxidase inhibitors) and tryptamine will cause convulsions. The method used was similar to that described by Tedeschi *et al.* (9). Groups of 10 unfasted male mice [TAC:(SW)fBr] were administered the test compounds suspended in 0.5% methylcellulose at a dose 10 times their levodopa potentiation ED_{50} values. Four hours later, tryptamine[5] was administered at 50 mg/kg iv. The compounds were considered to potentiate tryptamine if >50% of the animals in the treated group convulsed.

[1] Melting points were determined on a Mel-Temp apparatus and are corrected. The IR spectrum was determined as a mineral oil mull using a Perkin-Elmer 137B spectrophotometer. The NMR spectrum was obtained on a Varian A-60 instrument and was compared with tetramethylsilane as the internal standard.

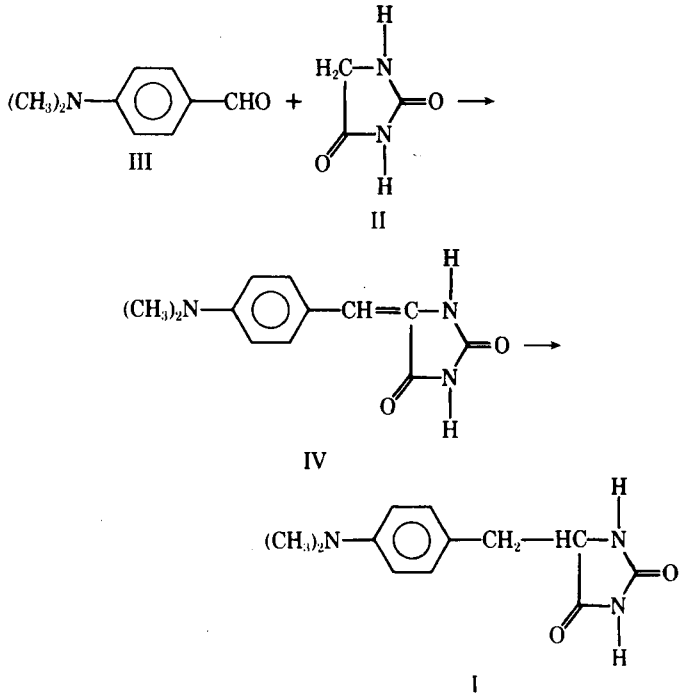
[a] Dose of the compound that inhibited tetrabenazine-induced ptosis in 50% of the mice. The 95% confidence limits are indicated in the parentheses. [b] Dose of the compound that potentiated the response of levodopa in 50% of the mice. The 95% confidence limits are indicated in the parentheses. [c] Dose of the compound that potentiated the response of tryptamine in mice. Tested at a dose 10 times or greater than the levodopa ED_{50}. [d] Concentration of the compound that caused 50% inhibition of the uptake in mice crude synaptosomes of norepinephrine, 5-hydroxytryptamine, and dopamine (mean ± *SE*). [e] Concentration of the compound that inhibited monoamine oxidase by 50% (mean ± *SE*). [f] Dose of pargyline was 100 mg/kg, approximately four times the antitetrabenazine ED_{50} value.

Inhibition of Biogenic Transmitter Uptake into Crude Synaptosomes of Mouse Brain *In Vitro*—A modification of the technique described by Kuhar (10) was used. The procedure included isolation of crude synaptosomes of mouse whole brain by differential centrifugation, incubation of synaptosomes with the test compound and a tracer amount of tritiated neurotransmitter[6] (norepinephrine, 5-hydroxytryptamine, and dopamine), separation of the free neurotransmitter by vacuum filtration, and radioactivity measurement of the bound neurotransmitter remaining on the cellulose membrane[7] filter by means of liquid scintillation spectrophotometry. The micromolar concentrations of test compound producing 50% inhibition of neurotransmitter uptake (IC_{50}) were estimated from log dose–response curves based on at least three concentrations with at least three determinations at each concentration.

***In Vitro* Monoamine Oxidase Inhibition in Mouse Liver—**The method used was essentially that described by Wurtman and Axelrod (11) with [side chain-2-^{14}C]tryptamine as the substrate. The micromolar concentrations of test compound producing 50% inhibition of monoamine oxidase (IC_{50}) were estimated from log dose–response curves on three concentrations with three determinations at each concentration.

RESULTS AND DISCUSSION

Condensation of imidazolidine-2,4-dione (II) with the aldehyde (III) gave rise to a benzylidene compound (IV) (5) which, upon catalytic hydrogenation in the presence of Raney nickel, afforded 5-(4-dimethylaminobenzyl)imidazolidine-2,4-dione (I) (Scheme I).



Scheme I

In preliminary testing at a dose of 50 mg/kg po, I inhibited tetrabenazine-induced ptosis by >90%. Therefore, a dose–response effect (7) was established and an antitetrabenazine ED_{50} value of 42 mg/kg was estimated (Table I).

This antidepressant activity of I was evaluated further using the levodopa potentiation test, which provides a measure of antidepressant activity more clearly related to CNS events (8) than to responses involving peripheral biogenic amines, such as the eyelid (ptosis) response to tetrabenazine. The usefulness of the levodopa potentiation model rests on its being a behavioral response and a reflection of the CNS effects of increased dopaminergic activity (8). However, this test is particularly sensitive to monoamine oxidase inhibitors because of the requirement for monoamine oxidase inhibitor pretreatment. In this test, I potentiated the levodopa response, and the estimated oral ED_{50} value was 17 mg/kg. Two tricyclic antidepressants, desipramine and imipramine, as well as a monoamine oxidase inhibitor, pargyline, also were effective with oral ED_{50} values of 1.1, 5.0, and 5.1 mg/kg, respectively.

Since the levodopa test is highly susceptible to monoamine oxidase inhibition, and since I was found to be an active potentiator of levodopa, I was evaluated for potentiation of tryptamine-induced convulsions. When administered intravenously, tryptamine causes an increase in brain 5-hydroxytryptamine levels (9). However, convulsions do not occur because the rate of destruction of 5-hydroxytryptamine by monoamine oxidase is directly related to the formation of 5-hydroxytryptamine. But in the presence of a monoamine oxidase inhibitor, with the metabolism of 5-hydroxytryptamine interrupted, tryptamine causes convulsions. This action is presumptive evidence of monoamine oxidase inhibitory activity (9). In this test, I at a dose of 174 mg/kg po (greater than 10 times the levodopa potentiating ED_{50}), as well as the tricyclic antidepressants, did not potentiate the tryptamine response, indicating that the potentiation of levodopa action was not a function of monoamine oxidase inhibition. On the other hand, pargyline at a dose of 100 mg/kg po did potentiate the tryptamine response, indicating the involvement of monoamine oxidase inhibition.

Compound I then was evaluated for effects on the uptake of selected biogenic amines *in vitro* (10). At a concentration of 100 μM, I did not prevent the uptake of norepinephrine, 5-hydroxytryptamine, and dopamine into crude synaptosomes prepared from the whole mouse brain, whereas the reference drugs all were effective. Desipramine inhibited norepinephrine uptake with an IC_{50} value of 6.6 μM, imipramine inhibited 5-hydroxytryptamine uptake with an IC_{50} value of 0.11 μM, and benzotropine inhibited dopamine uptake with an IC_{50} value of 0.17 μM.

In vitro monoamine oxidase of mouse liver (11) was inhibited by I with an IC_{50} value of 44 μM. However, I was more than 100 times less active than pargyline (IC_{50} 0.14 μM) under the same conditions.

Table I summarizes the results of the pharmacological evaluation presented in this paper.

Evaluation of 2-Azabicyclo[2.2.2]octane Analogs of 4-Anilidopiperidine Analgesics

RONALD F. BORNE ˣ, SAY-JONG LAW, JOHN C. KAPEGHIAN, and LAWRENCE W. MASTEN

Received January 14, 1980, from the *Departments of Medicinal Chemistry and Pharmacology, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication March 28, 1980.

Abstract □ Eight analogs of the fentanyl-type analgesics, in which the piperidine ring is restricted into a boat conformation, were evaluated for analgesic activity. All analogs were less active than fentanyl, but interesting conformational and structural relationships were observed. Results of the study are discussed.

Keyphrases □ Analgesic activity—evaluation of 2-azabicyclo[2.2.2]-octane analogs of 4-anilidopiperidines, mice □ 4-Anilidopiperidines—2-azabicyclo[2.2.2]octane analogs, evaluation for analgesic activity, mice □ Structure–activity relationships—evaluation of 2-azabicyclo[2.2.2]-octane analogs of 4-anilidopiperidines for analgesic activity, mice

Studies designed to clarify the structural and conformational factors influencing the interactions of centrally acting analgesic agents with analgesic receptors have received considerable attention (1), and the recent discovery of the natural opiates has intensified this interest (2). Structural modification of methadone and methadone derivatives led to the development of a new series of agents, the acyclic basic anilides (3), which are represented by diampromide (I). Subsequent development (4) of the 4-anilidopiperidines, represented by fentanyl (II), led to a potent new class of analgesics. Differences in the modes of receptor binding of the various classes have been suggested.

BACKGROUND

The acyclic basic anilides have been proposed to differ from the methadone-type analgesics (5), and the 4-anilidopiperidines apparently differ from the acyclic basic anilides and the 4-phenylpiperidines, although they more closely resemble the former group (6). Differences in the modes of receptor binding between the acyclic basic anilides and the 4-anilidopiperidines have been proposed on the basis of structure–activity relationships and may be due to differences in receptor conformations (6). Based on spectroscopic evidence (7), a conformation of I has been suggested in which, among other features, the protonated basic center lies in close proximity to the anilido nitrogen. The preferred conformation of II has been suggested (6) as that in which the anilido function assumes the equatorial position of the chair form of the piperidine ring. Such a conformation would place the protonated basic center at a greater distance from the anilido nitrogen in II than in I. Additionally, this conformation of II would differ from the preferred conformation of the 4-phenylpiperidines, which has been suggested to be a skew boat conformation (8). However, the possibility that boat-type conformations of II may contribute to receptor interactions has not been tested directly. Analogs of fentanyl in which the flexibility of the piperidine ring has been restricted through incorporation of the tropane nucleus, designed to simulate frozen chair conformations of fentanyl, were reported recently (9). The 3-β-(propanilido) isomers were more potent than the 3-α-(propanilido) isomers and were nearly as potent as fentanyl itself.

The 2-azabicyclo[2.2.2]octane ring system was employed previously to restrict acetylcholine (10) and procaine (11) in *trans-* and *gauche-*conformations. More recently, this ring system was employed to restrict the piperidine ring of prodine-type analgesics in boat conformations (12). This report concerns the pharmacological evaluation of boat conformers of fentanyl-type analgesics. Casy *et al.* (6) reported the effects of substituents on the ring nitrogen atom of 4-anilidopiperidines and noted that analgesic activity increases significantly in the order $CH_3 < CH_2C_6H_5 < CH_2CH_2C_6H_5$. The analogs prepared in this study would permit the evaluation of this effect as well as the effect of positional isomerism in the boat conformers III–X. The synthesis and stereochemical analyses of these analogs were reported previously (13).

EXPERIMENTAL

The analgesic potency of the fentanyl analogs was determined by a modification of the D'Amour–Smith tail-flick method (14) using male albino ICR mice[1], 25–30 g, and an analgesiometer. All mice had their tails blackened with a black magic marker at least 15 min prior to testing to ensure a short, uniform tail-flick response time. The challenge to thermal stimulus occurred 30 min postinjection with the vehicle alone or the respective drugs. A control group of 10 mice was used to establish the baseline response time.

The criterion for analgesia (antinociception) was defined as a tail-flick response time greater than or equal to the mean response time of the

control group plus two standard deviations of their mean. Groups of eight mice were used for each dose of drug. Morphine sulfate alone and together with fentanyl citrate served as the positive controls. All AD_{50} values and their 95% confidence limits were determined by the method of Litchfield and Wilcoxon (15).

All injections were made intraperitoneally with saline as the vehicle. The drug preparation was injected at 0.01 ml/g. The *N*-methyl analogs (III, IV, VII, and VIII) were administered as the hydrochloride salts, while the *N*-phenethyl analogs (V, VI, IX, and X) were administered as suspensions of free bases in 4% polysorbate–saline because of the difficulty in producing homogeneous solutions at neutral pH in pure saline. Compounds that produced no analgesia at 100 mg/kg were tested further for possible antagonism to the narcotics. For the antagonism study, at least four mice per group were pretreated with 5.0 mg of morphine sulfate/kg or 500 μg of fentanyl citrate/kg 5–10 min before injection of the test compound and subsequent analgesic testing 30 min postinjection.

RESULTS AND DISCUSSION

The results of the analgesic evaluation and antagonism study are summarized in Tables I and II, respectively. Both *N*-methyl-5-propanilido analogs (III and IV) were analgesically inactive at 100 mg/kg. With the *exo*-isomer (III), central nervous system effects were observed clearly. Mice treated at that dose showed decreased motor activity, labored respiration, and tremor. No blockade of the morphine analgesic effect was demonstrated for III and IV, although most of the animals treated with morphine and III (100 mg/kg) failed to produce the Straub tail effect.

Both *N*-methyl-6-propanilido analogs (VII and VIII) showed analgesic activity with AD_{50} values of 60.0 and 71.5 mg/kg, respectively. However, in both cases, no Straub tail effect was produced along with the analgesic effect. Both of these agents also were highly toxic, with LD_{50} values of 62.5 and 91.0 mg/kg, respectively. The animals evidenced severe dyspnea and convulsions at higher doses. In the *exo*-isomer (VII), overlap occurred between the confidence intervals for the AD_{50} and LD_{50}. This overlap was possible since analgesic testing of the survivors at a given dose contributed data to the AD_{50} determination.

Unlike the *N*-methyl derivatives, water-soluble hydrochloride salts of the *N*-phenethyl analogs could not be prepared, suggesting large differences in hydrophobic properties in the two series. Of the four isomeric *N*-phenethyl analogs (V, VI, IX, and X), only X showed activity (AD_{50} value of 43.0 mg/kg). Compound X also had a relatively wider safety margin (therapeutic index > 3) as compared to the two active *N*-methyl-6-propanilido analogs (VII and VIII). Toxicity was observed only when the dosage was raised to 150 mg/kg, resulting in extreme excitation, convulsions, and lethality in two of eight mice. The three analgesically inactive *N*-phenethyl analogs (V, VI, and IX) produced only mild dyspnea and convulsions, and no deaths occurred in all dosage groups tested. These analogs also were unable to antagonize the analgesic activity of fentanyl.

Prior to the utilization of 4% polysorbate 60–saline as a suspending vehicle for the four *N*-phenethyl analogs, suspensions of V, VI, IX, and X in 3% acacia–saline were used for administration *via* the intracerebroventricular route. The intracerebroventricular injections were made after careful removal of the skin from the top of the skull with a razor. Injections were made at a point of 1 mm posterior to the bregma and 1 mm laterally to the right of the midline of the skull (16). Five microliters then was injected (for a 25-g mouse) slowly ~1 mm into the right lateral ventricle.

Analgesia was determined at 20 and 60 min postinjection. While the AD_{50} values of morphine sulfate and fentanyl citrate were 0.21 mg/kg and 14 μg/kg by this administration route, the experiment did not lead to an AD_{50} determination of the analogs due to the limitations of concentration. Table III summarizes the results of this analgesic study. Each dosage shown was the highest attainable for that particular compound in a single intracerebroventricular injection.

Table II—Results of Antagonism Study for 2-Azabicyclo[2.2.2]-octane Analogs of Fentanyl-Type Analgesics

Agonist	Antagonist	Dose of Antagonist, mg/kg	Analgesic Response	Lethality
Morphine[a]	III·HCl	100	6/6	2/8
Morphine	IV·HCl	100	8/8	0/8
Fentanyl[b]	V	100	4/4	0/4
Fentanyl	VI	50	2/2	2/4
Fentanyl	IX	25	4/4	0/4
X[c]	Naloxone	4.0	0/4	0/4

[a] Dose of morphine sulfate = 5.0 mg/kg. [b] Dose of fentanyl citrate = 500 μg/kg. [c] Dose of X = 75 mg/kg.

Table I—Analgesic Activity of the 2-Azabicyclo[2.2.2]octane Analogs of Fentanyl-Type Analgesics and the Positive Controls with 95% Confidence Limits

Compound	AD_{50}	LD_{50}	AD_{50} of Positive Control
III·HCl	Inactive at 100 mg/kg	—[a]	M[b] = 1.32 mg/kg (0.84–2.07)
IV·HCl	Inactive at 100 mg/kg	—[a]	M = 1.32 mg/kg (0.84–2.07)
VII·HCl	60.0 mg/kg (44.1–81.4)	62.5 mg/kg (55.5–70.3)	M = 1.32 mg/kg (0.84–2.07)
VIII·HCl	71.5 mg/kg (61.1–83.7)	91.0 mg/kg (84.9–97.5)	M = 3.0 mg/kg (2.3–4.0)
V	Inactive at 100 mg/kg	—[a]	M = 5.0 mg/kg (1.55–16.0)
VI	Inactive at 100 mg/kg	—[a]	M = 5.0 mg/kg (1.55–16.0) F[c] = 68.5 μg/kg (52.3–89.7)
IX	Inactive at 100 mg/kg	—[a]	M = 5.0 mg/kg (1.55–16.0) F = 68.5 μg/kg (52.3–89.7)
X	43.0 mg/kg (31.2–59.3)	—[d]	M = 5.0 mg/kg (1.55–16.0) F = 68.5 μg/kg (52.3–89.7)

[a] No deaths occurred at 100 mg/kg. [b] M = morphine sulfate. [c] F = fentanyl citrate. [d] Death occurred in two of eight mice at a dose of 150 mg/kg.

Table III—Analgesic Response to the Isomeric *N*-Phenethyl 2-Azabicyclo[2.2.2]octane Analogs of Fentanyl-Type Analgesics in Mice *via* Intracerebroventricular Route with 3% Acacia–Saline as the Vehicle [a]

Compound	Dose, mg/kg	Analgesic Response	
		20 min	60 min
V	3.0	0/4	0/4
VI	5.0	1/4	0/4
IX	20.0	0/4	0/4
X	5.0	1/4	2/4

[a] Morphine sulfate AD_{50} = 0.21 mg/kg; fentanyl citrate AD_{50} = 14.0 μg/kg.

Several conclusions can be drawn from these studies.

1. Since the most potent analog (as the free base) of the eight isomeric compounds prepared had a potency ratio of <1/600 (on the basis of the AD_{50} values determined) when compared to fentanyl citrate, the boat conformations do not appear to contribute to receptor interactions of the fentanyl-type analgesics; this finding suggests the importance of chair conformations in this class of analgesics. A recent report (9) on tropane analogs of fentanyl supports this conclusion.

2. The argument that boat conformations do not contribute to analgesic activity can be applied more readily for V and VI, the two *N*-phenethyl analogs of the 4-substituted piperidine-type analgesics. Analogous structures such as the 2,5-dimethyl derivatives of fentanyl were examined by Riley *et al.* (17) for analgesic activity. Although the exact configurations of the two ring methyl groups were not elucidated, ring methylation at C-2 and C-5 of fentanyl does not seem to destroy the analgesic effect since this compound was still 5% as active as fentanyl. Since V and VI can be regarded as analogs having the C-2 and C-5 methyl groups linked together, with the resultant restriction of the piperidine ring into a boat conformation, the liability of boat conformations was even more obvious.

3. The lack of analgesic activity of III and IV, the two *N*-methyl analogs of the 4-substituted piperidine-type analgesics, is consistent with the report (6) that, unlike the prodine-type analgesics, fentanyl-type analgesics possessing *N*-methyl substituents display weak analgesic activity at best.

4. Since three of the four *N*-methyl and *N*-phenethyl analogs that correspond to 3-substituted piperidine-type analgesics displayed moderate activity and since the *N*-phenethyl analog X was only slightly more active than the corresponding *N*-methyl analogs, positional isomerism apparently accounts for a fundamental alteration in the mode of binding of the molecules at the analgesic receptor.

5. The similar order of analgesic activity observed for the four *N*-phenethyl analogs (V, VI, IX, and X) when the intracerebroventricular route was employed suggests that the differences in apparent analgesic activity truly reflect differences in intrinsic activity and not large differences in disposition. To support this argument, attempts were made to determine the pKa values and partition coefficients of these four analogs. Due to their highly hydrophobic nature and thus their limited solubility, the pKa values that were obtained by following the method of Mathison and Tidwell (18) were questionable, and these determinations were discontinued. A similar fate was encountered in the partition coefficient study. The solubility (in pH 7.4 buffer saturated with octanol) of VI was lower than 2×10^{-6} *M* (or 0.0008 mg/ml). This value was determined by measuring, in duplicate, the UV absorbance (λ_{max} 252.5) prior to and after filtration. The absorbance of the mixture (previously stirred overnight at room temperature) before filtration was invariably far more intense than that after filtration, suggesting that the octanol-saturated buffer was still saturated with VI at that concentration.

6. The abolition of the analgesic effect of X by naloxone and the observation of the Straub tail effect at all doses of X producing analgesia implied the mediation of analgesia through binding to the opiate receptor.

What is Odoratin?

Keyphrases □ Odoratin—recommended assignment of name only to isolate from *Cedrela odorata* □ Undecanortriterpenoids—odoratin, recommended assignment of name only to isolate from *Cedrela odorata* □ *Cedrela odorata*—recommended assignment of odoratin as name for isolate from *Cedrela odorata* only

To the Editor:

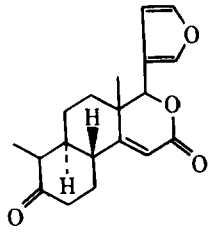
In 1966, Chan *et al.* (1, 2) assigned the name odoratin (I) to a novel undecanortriterpenoid isolated from the West Indian cedar *Cedrela odorata* L. (Meliaceae). To our knowledge, this was the first time that the name odoratin was assigned to any plant principle.

Two years later, Ortega *et al.* (3) isolated a novel pseudoguaianolide (II) from the Mexican Compositae *Hymenoxys odorata* DC. and also assigned it the trivial name odoratin.

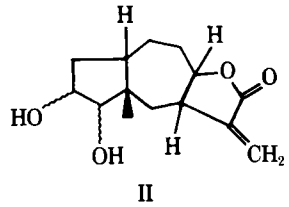
In 1973, Bose *et al.* (4, 5) reported the isolation of a novel chalcone from *Eupatorium odoratum* L. (Compositae), which was shown to be 6′-hydroxy-4,2′,3′,4′-tetramethoxychalcone (III), and confused the literature further by naming it odoratin.

Finally, Galina and Gottlieb (6) and Hayashi and Thomson (7) simultaneously reported the isolation of a novel isoflavone from *Pterodon apparicioi* Pedersoli (Leguminosae) and *Dipteryx odorata* Willd. (Leguminosae), respectively. This compound also was assigned (7) the name odoratin (IV) and subsequently was synthesized (8).

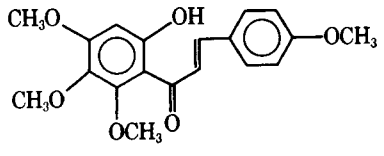
In spite of the repetitive assignments of the trivial name odoratin to four classes of natural products over an 8-year period, odoratin recently has been used again to designate the chalcone (III) isolated from *Eupatorium odoratum* (9) and the pseudoguaianolide (II) isolated from *Baileya pauciradiata* Harv. and Gray (Compositae) (10).



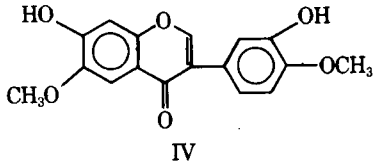
I



II



III



IV

Because of the confusion created by this failure to check the literature prior to the assignment of a trivial name, we suggest that the name odoratin be retained for the first isolate, the undecanortriterpenoid represented by I. Structures II–IV should be referred to by the systematic names 3,4,8β-trihydroxyambros-11(13)-en-12-oic acid γ-lactone (II), 6′-hydroxy-4,2′,3′,4′-tetramethoxychalcone (III), and 7,3′-dihydroxy-6,4′-dimethoxyisoflavone (IV).

Monitoring *In Vivo* Disintegration Time of Tablets by External Scintigraphy

Keyphrases □ Disintegration—monitoring of *in vivo* tablet disintegration time by external scintigraphy □ Scintigraphy, external—monitoring of *in vivo* tablet disintegration time □ Tablets—disintegration *in vivo*, monitoring by external scintigraphy

To the Editor:

Several investigators developed techniques for the determination of *in vivo* disintegration times of pharmaceutical solid formulations. One technique had the tablet attached at the end of a string. The tablet was administered orally; at predetermined time intervals, the tablet was pulled back, and the degree of disintegration was observed (1). In another case, the tablet was recovered by inducing vomiting (1). Other techniques involved direct visualization of the tablet in the stomach by means of a gastroscope or a fiberscope (1, 2) or by using roentgenography or fluoroscopy with or without a radiopaque material

in the tablet formulation (1, 3–7). Casey *et al.* (8) used technetium 99m to label capsules and a γ-camera to monitor the *in vivo* disintegration of the formulation. Alpsten *et al.* (9) labeled capsules with chromium 51 and monitored the *in vivo* disintegration with a shielded scintillation crystal probe.

The major disadvantages of these techniques were that they were invasive, causing discomfort to the animal model or to the human subject; they did not allow continuous observation of the solid formulation in the stomach; they exposed the subject to high doses of X-ray radiation; and they always tampered considerably with the physical integrity of the tablet or capsule formulation.

This communication presents a noninvasive method for monitoring the *in vivo* disintegration time of tablets. This method involves external scintigraphy for monitoring the *in vivo* disintegration times of tablets (10), combined with a new method for labeling the tablet with a short-lived radionuclide. This labeling process interferes to a lesser degree with the physical integrity of the formulation.

In a typical experiment, the tablet[1] was labeled with iodine 131 by exposing it to vapors of iodine 131 (5 mCi) in carbon tetrachloride[2] for 5 hr in a glass chamber. The $^{131}I_2$ was adsorbed onto the tablet surface, and some diffused into the tablet. The extent of the penetration of the $^{131}I_2$ into the tablet was examined by autoradiography. Slices ~2 mm thick were taken from different labeled tablets at different distances from the center of the tablet using a microtome[3]. Due to friability of the tablet, it was impossible to obtain thinner slices or more than one slice per tablet. Each slice was placed on medical X-ray film[4] for ~1 hr. The *in vitro* disintegration time of the labeled tablets was found to be within the range of the nonlabeled tablets.

The labeled tablet (~100,000 cpm) was administered orally to an anesthetized[5] animal with a pill gun. The animal was placed in a supine position on a table, and the abdomen then was positioned under the collimated detector of a multicrystal scintillation camera[6]. Data were accumulated for up to 30 min. During that period, scintiphotographs of the abdominal area were taken (Figs. 1A–1D). In a second animal, data were accumulated for 50 min (Figs. 1E–1H). Figure 1A shows the scintigraphic image of the tablet outside of the stomach of the dog, while Figs. 1B–1D show the tablet inside the dog at various times. The onset of the tablet disintegration is shown in Fig. 1D, while a better picture of the disintegration is given in Figs. 1E–1H, taken from another dog.

This method for measuring the disintegration time of tablets *in vivo* has good potential in the assessment of tablet formulations for the following reasons. The labeling of the tablet is achieved by exposing the tablet to vapors of $^{131}I_2$ in carbon tetrachloride. Iodine 131 is adsorbed onto the tablet surface and, to a lesser extent, is diffused into the tablet. This labeling process interferes the least, compared to other techniques, with the physical integrity of the formulation. The technique is based on external scintigraphy and does not require sacrifice of the experimental animal. If the scintillation camera is coupled with a video recording device for replay capability and a computer for image processing, then it is possible to follow the disintegration process minute by minute and to determine accurately the onset and end of the disintegration process within the animal's stomach.

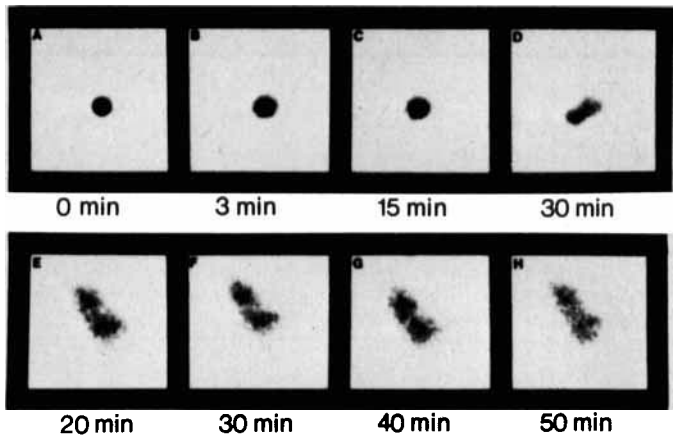

Figure 1—*Sequence scintiphotographs of a tablet ingested by a dog. Key: A–D, Dog 1, and E–H, Dog 2.*

Further research is in progress to assess the effect of the labeling process on the physical integrity of the formulation and the effectiveness of this process with respect to the penetrability and uniformity of diffusion of the label into various types of tablets.

REVIEWS

Pharmaceutical Handbook, 19th ed. Edited by AINLEY WADE. The Pharmaceutical Press, 1 Lambeth High St., London SE1 7JN, England. 1980. 783 pp. 18 × 20 cm. Price $35.00. (Available from Rittenhouse Book Distributors, 251 S. 24th St., Philadelphia, PA 19103.)

Developed as a companion to *Martindale: The Extra Pharmacopoeia*, the *Pharmaceutical Handbook* contains a wealth of information of use to students, practicing pharmacists, and practitioners of allied professions. The 19th edition is the most recent volume in a series that originated in 1906.

The *Handbook* has been thoroughly revised and updated since its previous edition in 1970. The 117-page section on the preparation and supply of medicines has been rewritten. A new checklist of potential incompatibilities of additives to intravenous preparations has been included, and the table of drug interactions has been extended.

The other major sections of the book cover diverse topics such as computers and their applications in pharmacy, sterilization methods and tests, disinfectants and antiseptics, physiological values for body fluids, drug absorption, poisoning, microbiology, immunology, nomenclature of organic compounds, and weights and measures.

The 24-page section of miscellaneous data includes geometrical formulas, mathematical notations, signs, and symbols, calculus equations, the Russian and Greek alphabets, a table for the determination of body surface area from height and weight, and a periodic table. A glossary of proprietary names and equivalent approved names lists trade names for single-entity preparations available in the United Kingdom along with their approved names.

A 136-page glossary gives concise definitions of medical and pharmaceutical terms along with definitions of radiological terms, terms used in foreign prescriptions, and units and measures. The book concludes with a 38-page index.

The *Handbook* is a convenient reference source that contains valuable information which otherwise could be found only by consulting many other sources.

Staff Review

Substituent Constants for Correlation Analysis in Chemistry and Biology. By CORWIN HANSCH and ALBERT LEO. Wiley, 605 Third Ave., New York, NY 10016. 1979. 339 pp. 21 × 28 cm. Price $24.95.

This book is organized into two sections: a descriptive section that lightly covers the fundamentals of chemical structure–physical parameter theory and estimation (65 pages) and a set of tables, in the form of computer printouts, that contain fragment constants and partition coefficients which were extracted from the literature. The tables are provided as separate appendixes. The first appendix contains about 100 pages and is entitled Electronic, Steric, and Hydrophobic (π) Constants. The second appendix contains about 160 pages and is entitled Partition Coefficients. The last appendix contains four pages and is entitled Hydrophobic Fragment Constants.

The expressed purpose of this book (the authors refer to it as a monograph) is "to provide a comprehensive listing of parameters of proven value for the correlation of structure with chemical or biologic reactivity." The tables provided seem to represent the most complete source of information yet organized for such use, and the book therefore admirably accomplishes its stated goal. The tables are not the easiest to decipher, given their computerized structure, but they nevertheless are a rich source of well-referenced information on the influences of structure on physical and chemical events. Partitioning data listed are for diverse solvent systems.

The opening, narrative section of the book has very brief discussions of electronic, steric, and hydrophobic parameters; molar refractivity and parachor; and cluster analysis. These discussions are provided at the advanced undergraduate level. They provide a minimal preparation for the use of the extensive tabulations that follow. To an extent, this aspect of the book is disappointing since the discussions are largely phenomenological and fail to deal with physicochemical events, such as hydrophobicity, in terms of present understanding of their fundamental molecular origins.

While limitations and/or uncertainties in parameter estimations are presented fairly, severe mechanistic shortcomings of quantitative structure–activity relationship approaches are skirted completely. The idea of the prospective use of quantitative structure–activity relationships is sold; the fact that applications have been largely retrospective goes unmentioned.

On balance, the book contains much useful information in tables and material in short chapters which should be part of the coursework of medicinal chemistry and pharmaceutics programs. It makes a valuable library addition but should be considered for personal collections only by those emphasizing quantitative structure–activity relationships in their teaching or research.

Toxic Plants. Edited by A. DOUGLAS KINGHORN. Columbia University Press, 562 W. 113th St., New York, NY 10025. 1979. 195 pp. 15 × 23.5 cm. Price $20.00.

This book is the result of a symposium on toxic plants held at the University of Miami in 1977 as part of the annual Society for Economic Botany meeting. It features contributions by eight major authors on various aspects of plant poisoning. It is an up-to-date treatment providing chemical, biochemical, and toxicological information on a wide range of poisonous plants.

The problem of poisonous plants is described in general in the first chapter. Problems related to phytotoxicology are discussed such as plants with known toxic constituents that are not always poisonous, the uneven quality of the existing literature, the need for accurate identification to access information, the question of labeling poisonous ornamental plants, and the difficulty of improving the present body of information.

The remaining chapters cover and update several specific and important areas of interest in poison plants such as toxic mushrooms (amatoxins, phallotoxins, phallolysin, antamanide, ibotenic acid, muscimol, psilocybin, muscarine, gyromitrin, and coprine); toxins and teratogens of the Solanaceae and Liliaceae (nonalkaloidal toxins, tropane alkaloids, pyridine/piperidine alkaloids, and steroidal alkaloids); pokeweed and other lymphocyte mitogens (lectins, mitogens, Abrus lectin, abrin, and Hura and Robinia lectins); a literature review and clinical management of household ornamental plants potentially toxic to humans; cocarcinogenic irritant Euphorbiaceae (phorbol esters, ingenol esters, daphnane esters, and diterpene esters); the poisonous Anacardiaceae (botany, phenolic compounds, and immunological studies); and contact hypersensitivity and photodermatitis evoked by Compositae (sesquiterpene lactones and acetylenic compounds).

Overall, the chapters provide recent data, data of significance to human poisonings, and much insight into the complexity of poisoning by natural products. Chemical structures are provided for many classical poisons as well as for some recently characterized molecules. Finally, clinical management is provided where available on a number of poisonous plants.

This book will be of interest to numerous specialists such as botanists, chemists, pharmacognosists, and horticulturalists as well as those in the medical and health professions. The topics discussed are a welcome addition to the relatively sparse literature in the field.

REVIEWS

Pharmaceutical Handbook, 19th ed. Edited by AINLEY WADE. The Pharmaceutical Press, 1 Lambeth High St., London SE1 7JN, England. 1980. 783 pp. 18 × 20 cm. Price $35.00. (Available from Rittenhouse Book Distributors, 251 S. 24th St., Philadelphia, PA 19103.)

Developed as a companion to *Martindale: The Extra Pharmacopoeia*, the *Pharmaceutical Handbook* contains a wealth of information of use to students, practicing pharmacists, and practitioners of allied professions. The 19th edition is the most recent volume in a series that originated in 1906.

The *Handbook* has been thoroughly revised and updated since its previous edition in 1970. The 117-page section on the preparation and supply of medicines has been rewritten. A new checklist of potential incompatibilities of additives to intravenous preparations has been included, and the table of drug interactions has been extended.

The other major sections of the book cover diverse topics such as computers and their applications in pharmacy, sterilization methods and tests, disinfectants and antiseptics, physiological values for body fluids, drug absorption, poisoning, microbiology, immunology, nomenclature of organic compounds, and weights and measures.

The 24-page section of miscellaneous data includes geometrical formulas, mathematical notations, signs, and symbols, calculus equations, the Russian and Greek alphabets, a table for the determination of body surface area from height and weight, and a periodic table. A glossary of proprietary names and equivalent approved names lists trade names for single-entity preparations available in the United Kingdom along with their approved names.

The *Journal of Pharmaceutical Sciences* (ISSN 0022-3549) is published monthly by the American Pharmaceutical Association (APhA) at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of APhA.

Offices—Editorial, Advertising, and Subscription: 2215 Constitution Ave., N.W., Washington, DC 20037. All Journal staff may be contacted at this address. Printing: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $60, educational institutions $60, individuals *for personal use only* $30; single copies $5. All foreign subscriptions add $5 for postage. Subscription rates are subject to change without notice. Members of APhA may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $80 (foreign $85) APhA membership dues.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. APhA cannot accept responsibility for foreign delivery when its records indicate shipment was made.

Change of Address—Members and subscribers should notify at once both the Post Office and APhA of any change of address.

Photocopying—The code at the foot of the first page of an article indicates that APhA has granted permission for copying of the article beyond the limits permitted by Sections 107 and 108 of the U.S. Copyright Law provided that the copier sends the per copy fee stated in the code to the Copyright Clearance Center, Inc., 21 Congress St., Salem, MA 01970. Copies may be made for personal or internal use only and not for general distribution.

Microfilm—Available from University Microfilms International, 300 N. Zeeb Road, Ann Arbor, MI 48106.

SCIENTIFIC INFORMATION IN FORMULATING PUBLIC POLICY

In the August issue of this journal, we published an editorial relating to the publicity and controversy surrounding the issuance of a report, entitled "Toward Healthful Diets," by the Food and Nutrition Board of the National Academy of Sciences–National Research Council. Although our editorial touched on the significant recommendations concerning human diet, health, and nutrition contained in the report, we directed our principal focus at the alleged bias and conflict-of-interest charges which were widely discussed in the public press.

We also expressed our sorrow at the damage this brouhaha was having on the public image of the prestigious sponsoring organization. In fact, the editorial was entitled "Maintaining NAS–NRC Credibility," because of our emphasis on this aspect and our gratuitous suggestions as to how the NAS–NRC might reorient its committee appointment process to minimize future reoccurrences.

The NAS President, Philip Handler, responded to our comments and we are pleased to publish his letter in the *Open Forum* section of this month's journal. His letter serves to bring out several points that were not included in our editorial—either (*a*) because of our inadvertent oversight, or (*b*) because those points were personally unknown to us. In the first category, Dr. Handler correctly points out that even those scientists who have disagreed with the report recommendations "*have not found the Board's work or its assessment unsound or unscientific.*" In the second category, Dr. Handler explains that the problem of apparent bias "*cropped up through news reports that stopped short of the full truth*" by pointing out that some members were identified with one side of the issue but neglecting to point out that other members were equally identified with the other side of the issue. Hence, Dr. Handler tells us, the Board did, in fact, have the balanced "mix of people" that we urged in the conclusion of our editorial.

Referring to the technical dispute concerning the FNB report, President Handler poignantly states in his letter, "*The scientific disagreement has turned not on the evidence but on what advice to offer the public at large under these shaky circumstances.*"

Whether, as scientists, we like it or not, and whether or not we feel that is how decision-making should operate, this last observation of Dr. Handler's reflects more and more how the system of public policy is functioning in today's world.

Indeed, in early October a symposium—and by sheer coincidence also sponsored by the NAS–NRC—was held on the subject of "The Role of Scientific Information in Decision-Making." The announcement publicizing the conference explained that 10 years ago words like benzene, DES, 2,4,5-T, and chlorofluorocarbons were found only in chemistry textbooks. But today they are seen in front-page stories in newspapers across the country. All of these terms became familiar for the same reason—the government has restricted the use of these substances based on scientific evidence of adverse effects.

The symposium further brought out that the pertinent scientific information is only a single dimension in a total process that involves many considerations including legal, economic, environmental, political, statistical, and various other factors.

We feel that it is important for all of us to recognize that such is the total process by which public policy decision-making is performed today. Indeed, this is how the process currently operates under the best of circumstances; often there is no scientific input at all and the decision may simply turn on one or two of these other factors, such as the political considerations.

At any rate, the day is now gone when public policy decisions are determined solely by scientific data and technical findings. Moreover, leaving our bias for science aside for the moment, this writer is inclined to conclude that this latter development is a good thing. For all its virtues, science provides too narrow a perspective, and the best decisions are going to be those that embody all considerations—including, but not limited to, the scientific aspects.

SCIENTIFIC INFORMATION IN FORMULATING PUBLIC POLICY

In the August issue of this journal, we published an editorial relating to the publicity and controversy surrounding the issuance of a report, entitled "Toward Healthful Diets," by the Food and Nutrition Board of the National Academy of Sciences–National Research Council. Although our editorial touched on the significant recommendations concerning human diet, health, and nutrition contained in the report, we directed our principal focus at the alleged bias and conflict-of-interest charges which were widely discussed in the public press.

We also expressed our sorrow at the damage this brouhaha was having on the public image of the prestigious sponsoring organization. In fact, the editorial was entitled "Maintaining NAS–NRC Credibility," because of our emphasis on this aspect and our gratuitous suggestions as to how the NAS–NRC might reorient its committee appointment process to minimize future reoccurrences.

The NAS President, Philip Handler, responded to our comments and we are pleased to publish his letter in the *Open Forum* section of this month's journal. His letter serves to bring out several points that were not included in our editorial—either (*a*) because of our inadvertent oversight, or (*b*) because those points were personally unknown to us. In the first category, Dr. Handler correctly points out that even those scientists who have disagreed with the report recommendations "*have not found the Board's work or its assessment unsound or unscientific.*" In the second category, Dr. Handler explains that the problem of apparent bias "*cropped up through news reports that stopped short of the full truth*" by pointing out that some members were identified with one side of the issue but neglecting to point out that other members were equally identified with the other side of the issue. Hence, Dr. Handler tells us, the Board did, in fact, have the balanced "mix of people" that we urged in the conclusion of our editorial.

Referring to the technical dispute concerning the FNB report, President Handler poignantly states in his letter, "*The scientific disagreement has turned not on the evidence but on what advice to offer the public at large under these shaky circumstances.*"

Whether, as scientists, we like it or not, and whether or not we feel that is how decision-making should operate, this last observation of Dr. Handler's reflects more and more how the system of public policy is functioning in today's world.

Indeed, in early October a symposium—and by sheer coincidence also sponsored by the NAS–NRC—was held on the subject of "The Role of Scientific Information in Decision-Making." The announcement publicizing the conference explained that 10 years ago words like benzene, DES, 2,4,5-T, and chlorofluorocarbons were found only in chemistry textbooks. But today they are seen in front-page stories in newspapers across the country. All of these terms became familiar for the same reason—the government has restricted the use of these substances based on scientific evidence of adverse effects.

The symposium further brought out that the pertinent scientific information is only a single dimension in a total process that involves many considerations including legal, economic, environmental, political, statistical, and various other factors.

We feel that it is important for all of us to recognize that such is the total process by which public policy decision-making is performed today. Indeed, this is how the process currently operates under the best of circumstances; often there is no scientific input at all and the decision may simply turn on one or two of these other factors, such as the political considerations.

At any rate, the day is now gone when public policy decisions are determined solely by scientific data and technical findings. Moreover, leaving our bias for science aside for the moment, this writer is inclined to conclude that this latter development is a good thing. For all its virtues, science provides too narrow a perspective, and the best decisions are going to be those that embody all considerations—including, but not limited to, the scientific aspects.

Maintaining NAS–NRC Credibility: A Reply

The editorial in your August issue, "Maintaining NAS–NRC Credibility," leaves the mistaken impression that the National Academy of Sciences–National Research Council has no system for protecting against the introduction of bias in its studies. You then go on to endorse a system that would identify experts' biases and then balance those when a committee is appointed by finding "the right mix of people." That is precisely the system that the NAS–NRC has been using for many years.

Our system is designed to protect against both the reality and the appearance of bias, but it failed to eliminate the appearance of bias within the Food and Nutrition Board recently because of a previously unrecognized gap in our procedures. I remain convinced that appearances, and only appearances, have been offended in this instance. Even fellow scientists who have disagreed with the Board's recommendations in "Toward Healthful Diets" have not found the Board's work or its assessment unsound or unscientific; all agree that the available evidence is inconclusive. The scientific disagreement has turned not on the evidence but on what advice to offer the public at large under these shaky circumstances.

The real issue is: How did the apparent bias gain such importance in the public eye when it had such limited importance in reality? The problem cropped up through news reports that stopped short of the full truth by pointing out that some members of the Food and Nutrition Board had connections with organizations that produce foods high in cholesterol. Almost universally ignored was the fact that some of this group (even some of the *same* individuals who consult for "procholesterol" companies) had connections with firms that deliberately produce foods *low* in cholesterol and saturated fats. The members of the Board are experts in nutrition and health, and their advice is sought on that basis by government, by industry, and by independent organizations such as ours. Their credibility and, consequently, that of the report and of the Academy itself became an issue only when the news media failed to provide a balanced perspective or the whole truth.

With hindsight, it might have been prudent to ask some members at the Food and Nutrition Board to step aside so as to ensure that the report proper and not its authors would be the center of attention and debate. But the professional credentials of those Board members are impressive and impeccable—and in the end, that must be what counts.

Metabolism of Carprofen, a Nonsteroidal Anti-Inflammatory Agent, in Rats, Dogs, and Humans

F. RUBIO ˣ, S. SEAWALL, R. POCELINKO *, B. DeBARBIERI, W. BENZ, L. BERGER, L. MORGAN, J. PAO, T. H. WILLIAMS, and B. KOECHLIN

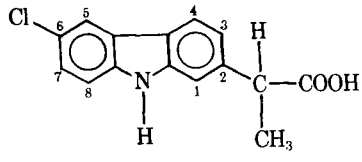
Received January 3, 1980, from the *Roche Research Center, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication May 29, 1980. *Present address: Department of Clinical Pharmacology, American Cyanamid Company, Pearl River, NY 10905.

Abstract □ The metabolic disposition of ^{14}C-labeled carprofen [(±)-6-chloro-α-methylcarbazole-2-acetic acid] was investigated in rats, dogs, and humans. Carprofen is eliminated predominantly by biotransformation in these three species. In dogs and rats, the direct conjugation of carprofen to form an ester glucuronide and oxidation to the C-7 and the C-8 phenols followed by their conjugation represent the major metabolic pathways. Small amounts of the α-hydroxy derivative also are formed by these species and are excreted free in the urine. In dogs, biliary secretion predominates, and 70% of an intravenous dose of carprofen is excreted in the feces while 8–15% of the dose is excreted in the urine. In rats, fecal excretion due to biliary secretion varies from 60 to 75%, and urinary excretion accounts for 20–30% of an intravenous dose. In humans, direct conjugation of carprofen represents the only significant pathway of metabolism. Between 65 and 70% of the orally administered carprofen was found to be excreted as the ester glucuronide in the urine, and most of the remaining dose was estimated to be secreted as this metabolite in the bile. Due to enterohepatic circulation, only a fraction of the biliary metabolite was recovered in the feces in humans. Less than 5% of the dose was excreted in human urine as free, intact carprofen. In dogs and humans, plasma levels of carprofen and of total radioactivity exhibit a multiphasic decline. In the three human subjects studied, the terminal component declined with a 13–26-hr half-life; the terminal half-life was ~40 hr in dogs.

Keyphrases □ Carprofen—metabolism in rats, dogs, and humans □ Metabolism—carprofen in rats, dogs, and humans □ Anti-inflammatory agents—carprofen, metabolism in rats, dogs, and humans

Carprofen [(±)-6-chloro-α-methylcarbazole-2-acetic acid], a nonsteroidal drug, exhibits anti-inflammatory activity in several screening tests in rats (1, 2).

Fluorometric (3, 4) measurements of blood carprofen levels in human volunteers (5) and in dogs[1] receiving single doses of the drug showed a biexponential decline composed of a fast initial component and a very slow terminal component. Comparison of blood levels measured after single and multiple doses indicated predictable drug accumulation (6). As in dogs and rats, a small volume of distribution was consistent with the high drug concentration in the central plasma compartment that was observed in these subjects.



carprofen

The objectives of the present study were to establish and to compare the biotransformation of carprofen in dogs, rats, and human volunteers using ^{14}C-labeled drug and to determine further the disposition of the drug in these three species. A preliminary report on these investigations was published previously (7).

EXPERIMENTAL

Dose—[^{14}C]Carprofen, labeled in the α-position ($C_{15}H_{12}ClNO_2$, mol. wt. 273.2), was synthesized[2] with specific activities of 14.2 and 51.98 mCi/mmole. The radiopurity was at least 95%, and it was checked periodically by TLC. To minimize radiodecomposition during storage, the compound was dissolved in 10% ethanol in benzene. For the metabolic experiments, the specific activity was reduced to $1.0–6.0 \times 10^6$ dpm/mg for the dog and rat studies and to 0.5×10^6 dpm/mg for the human studies.

For the oral and intravenous dosing of dogs and rats, solutions were prepared containing 2.5 mg of [^{14}C]carprofen (0.0092 mEq)/ml in a mixture of five parts of propylene glycol, one part of 0.1 *N* NaOH (0.1 mEq), and four parts of distilled water.

Table I—TLC of Carprofen and Metabolites (R_f Values [a])

Solvent System	Carprofen	Carprofen Ester	I	I Ester	III	III Ester	IV	IV Ester
1 Chloroform–ethanol–formic acid (90:10:5)	0.48	0.69	0.27	0.55	0.36	0.53	0.36	0.51
2 Chloroform–ethanol–acetic acid (90:10:1)	0.38		0.0		0.28	0.53	0.22	
3 Chloroform–methanol–acetic acid (70:30:5)	0.79				0.76		0.76	
4 Chloroform–methanol–concentrated ammonia (70:30:1)	0.13		0.09 (trail)		0.13		0.13	
5 Chloroform–ethanol–formic acid (85:15:10)	0.65		0.44					
6 Chloroform–methanol–acetic acid (85:15:5)	0.60				0.51		0.51	

[a] These R_f values represent averages of several TLC runs and are reproducible within 10%. The metabolite esters all are methyl esters.

For oral administration to human subjects, radioactive carprofen was incorporated into tablets that were identical with the formulation used clinically. Each tablet contained 50 mg of [^{14}C]carprofen with a specific activity of 0.5 μCi/mg.

Animal Experiments—Two male beagle dogs, 12.8 and 10.1 kg, received a single intravenous dose of 1 mg of [^{14}C]carprofen/kg (Experiments D-I and D-V). Subsequently, the same dogs received a 1-mg/kg oral dose of this drug (D-II and D-VI). Two other dogs (D-III and D-XI) received single intravenous 10-mg/kg doses as a solution of 25 mg (0.092 mEq)/ml.

Blood specimens (5–10 ml, heparinized) were drawn by heart puncture or from the jugular vein at the indicated intervals. Aliquots of whole blood were taken for determination of the total carbon 14 content and for the hematocrit. The remaining blood was centrifuged. The radioactivity in the plasma was quantitated and fractionated, and the carbon 14 levels in the erythrocytes were calculated.

The dogs were kept in metabolism cages; urine (under toluene) and feces were collected for 96 hr at 24-hr intervals. Feces were homogenized in five volumes of 70% aqueous ethanol, and the radioactivity of these homogenates was determined using 10-fold dilutions.

In two additional male dogs weighing 10.5 (Experiment D-IV) and 7.6 (Experiment D-X) kg, the bile ducts were cannulated. The dogs were anesthetized by intravenous injection of 25–30 mg of pentobarbital sodium/kg. Anesthesia was maintained by additional 2.5-mg/kg pentobarbital sodium injections given about every 2 hr after the initial administration, as required. After intravenous injection of single 1-mg/kg doses of [^{14}C]carprofen, bile was collected for 5 hr at 0.5-hr intervals. Blood specimens were collected periodically from the cannulated femoral vein during the experiment.

After 5 hr, the dogs were sacrificed. The major tissues were excised, rinsed with ice-cold saline, and frozen. Aliquots (2–5 g) were homogenized with 10–20 volumes of ice-cold, aqueous, 0.2 *M* acetate buffer (pH 5) in a high-speed homogenizer.

Male 180–200-g Sprague–Dawley rats[3] were injected intravenously (tail vein) with 5 mg of [^{14}C]carprofen/kg in the described solution. Groups of three rats were sacrificed by decapitation after 10 min, 1 hr, and 4 hr, and plasma and the major tissues were collected. The tissues were homogenized as described, individually or as pools.

The bile ducts in two rats (320 g) were cannulated under light ether anesthesia, 5-mg/kg doses of [^{14}C]carprofen were administered intravenously, and bile was collected at 2-hr intervals for 6–7 hr, with the rats being in a conscious state and confined in restraining cages. Other animals were kept anesthetized with pentobarbital sodium (40 mg/kg), and their temperature was maintained at 37° during bile cannulation. In some experiments, Charles River CD rats of different ages and weights were used.

Urinary and fecal excretion (0–96 hr) of a 5-mg/kg iv dose of [^{14}C]-carprofen was determined in another group of three male rats.

Clinical Study[4]—Three male volunteers, 59–87 kg and 43–58 years old, were administered single 50-mg tablets of [^{14}C]carprofen orally with 240 ml of water. They fasted from 8 hr before until 4 hr after drug ingestion.

Blood specimens (10–15 ml, oxalated) were drawn before dosing and at 0.25, 0.5, 1, 2, 4, 6, 8, 12, and 24 hr and daily at 24-hr intervals after dosing for a minimum of 8 days or until no more radioactivity was detectable.

Urine was collected for intervals of 0–2, 2–4, 4–6, 6–9, 9–12, and 12–24 hr and as 24-hr pooled daily specimens thereafter until no more radioactivity was detected (for ~8–10 days). The creatinine content of each specimen was measured to provide an indication of completeness of urine collection. Feces were collected as 24-hr portions.

Quantification of Radioactivity—The isotope disintegration rates of all specimens were determined by liquid scintillation spectrometry[5] using the external standard channels ratio technique. Counting mixtures were prepared as follows. One milliliter of an aqueous tissue homogenate was mixed with 1.5 ml of distilled water and 10 ml of scintillation fluid[6] to produce a stable gelatinous suspension. Silica gel zones scraped from thin-layer chromatograms were suspended similarly in a mixture of 2.5 ml of water and 10 ml of scintillation fluid. Plasma aliquots of 0.1–1 ml were diluted to 2.5 ml with water and mixed with 10 ml of scintillation fluid. Aqueous solutions, diluted urine not exceeding 2 ml, and solvent extracts were mixed directly with the scintillation fluid.

Isotope disintegration rates in whole blood aliquots of 0.1–0.5 ml were determined following combustion[7].

Extraction and Fractionation of Drug Components from Urine, Bile, and Plasma—Intact carprofen and its unconjugated metabolites were extracted quantitatively (>95%) with 10 ml of ether from 0.5–1.0 ml of plasma diluted to 2 ml with 1.0 *M* acetate buffer (pH 5). The drug was extracted with two equal volumes of ether from urine titrated to pH 5. The extracted aqueous phase was titrated to pH 1 and was reextracted with ethyl acetate or with butanol at pH 5, using two extractions with equal solvent volumes. Diluted bile fractions, combined with 1 ml of 1.0 *M* acetate buffer (pH 5), were extracted twice with two volumes of ether to remove the free drug. The conjugates remaining in the aqueous phase were fractionated by cleaving first the ester glucuronide of carprofen at pH 11 (titration with 6 *N* NaOH) for 2 hr at room temperature and then the ethereal glucuronides by readjusting the pH to 5, adding 0.1 ml of glusulase enzyme[8], and incubating for 2 hr at 37°. Each treatment was followed by ether extraction of the freed metabolites at pH 5. The extracts were evaporated under nitrogen at 40–50°. The residues were taken up in 250 μl of ethanol immediately before aliquots were taken for measurement of the isotope disintegration rate and for TLC.

Suitable aliquots of these concentrated extracts were subjected to TLC on precoated silica gel 60 F254 plates[9] using the solvent systems listed in Table I. For preparative isolation (quantities up to 1 mg), each extract concentrate was streaked as a band across the plate; after development, the silica gel bands corresponding to the purified components were scraped off, suspended in a buffer, and extracted with a solvent.

The presence of intact [^{14}C]carprofen and other radioactive metabolites in plasma or tissue homogenates was determined by one-dimensional TLC of pH 5 ether extracts with System 1 and subsequent scanning[10]. These components were quantitated by two-dimensional TLC with System 2 and then System 4, scraping, and measurement of the isotope disintegration rates of the silica gel areas bearing the detected components.

Carprofen β-glucuronide ester in human plasma and urine was extracted (following removal of the free drug by ether extraction at pH 5) with ethyl acetate at pH 1. After cleavage of this ester at alkaline pH as

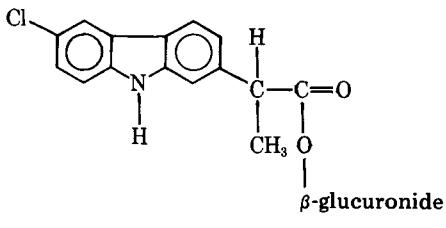
[a] In microgram equivalents per gram. [b] Assuming that plasma is 5% of the total body weight. [c] n.m. = nonmeasurable. [d] Assuming that muscle tissue is 40% of the total body weight. [e] Assuming that fat tissue is 5% of the total body weight.

described, glucuronic acid was identified by TLC on cellulose-precoated plates with the solvent system *n*-butanol–acetic acid–water (2:1:1) followed by naphthoresorcinol spray. Glucuronic acid was quantitated by the naphthoresorcinol assay (8, 9) following cleavage of the conjugate by mammalian liver β-glucuronidase[11].

Representative portions of all human urine specimens collected during the first 24 hr from each subject were pooled. One 2-ml aliquot of these pools and of each subsequent 24-hr urine portion (up to 120 hr) were extracted directly with ether at pH 5. A second aliquot was cleaved with sodium hydroxide as described, and the deconjugated carprofen was extracted with ether at pH 5. Both extracts were subjected to one- and two-dimensional TLC, and carprofen was quantitated as described.

To check specifically for the presence of Metabolites I and III in human urine, 10-ml portions of 0–72-hr urine pools (1% of each fraction) were extracted after both alkaline and glusulase cleavage, and the two extracts were subjected to one- and two-dimensional TLC in the presence of



carprofen ester glucuronide

[11] Calbiochem, La Jolla, Calif.

nonlabeled standards of these metabolites. Since the recoveries of urinary carprofen varied from 85 to 95%, the values reported are uncorrected.

Analysis of Feces—Ten milliliters of a fecal homogenate in 70% ethanol was diluted with 10 ml of 1 *M* phosphate buffer (pH 7), and the dilution (35% ethanol) was extracted twice with 20 ml of ether followed by a backwash with 10 ml of water. The residue of the combined ether extracts was redissolved in 5 ml of ethanol–aqueous 0.1 *N* HCl (4:1). This solution was equilibrated twice with 10 ml of hexane. The hexane extracts were washed consecutively with a second 5-ml portion of the same ethanol–hydrochloric acid mixture and then were discarded. Both ethanol–hydrochloric acid solutions were diluted with 5 ml of 0.1 *N* HCl and extracted twice with 10 ml of a 3:2 mixture of ether and hexane. These extracts, containing 60–70% of the original radioactivity of a typical fecal homogenate, were combined, concentrated, and analyzed by one- and two-dimensional TLC essentially as described for the solvent extracts of urines.

Metabolite Characterization—UV spectra of solutions of ~5 μg/ml in 0.1 *N* HCl and in 0.1 *N* NaOH in 20% aqueous ethanol were measured using a microcell (0.5 ml) assembly in a spectrophotometer[12].

The fluorescence spectra of the individual metabolites of carprofen, dissolved in ethanol–1% acetic acid, were determined in a spectrofluorometer[13].

High-resolution and low-resolution mass spectra[14] were obtained. The ionizing energy was 70 ev, and the interface temperature was 270°. The

[12] DU, Beckman Instruments.

[13] Farrand.

[14] High-resolution mass spectra were obtained with a CEC 21-110 and low-resolution mass spectra were obtained with a Hitachi RMU-6L coupled to a Perkin-Elmer 990 gas chromatograph.

Table IV—UV and Fluorescent Spectra of Carprofen and Its Metabolites

Compound	Fluorescence (1% Acetic Acid in Ethanol)		UV Absorption			
			0.1 *N* HCl–20% Ethanol		0.1 *N* NaOH–20% Ethanol	
	$\lambda_{act}/\lambda_{emit}$, nm	TM[a]/μg/ml	A_{max}[b], nm	E[b], × 10^4	A_{max}[b], nm	E[b], × 10^4
I	295/375	123	240	5.10	240	5.21
			300	2.10	300	2.13
III	340/395	52 → 180[c]	245	5.35	255	5.02
			295	1.47	300	1.1

			310	1.66	340	1.75
Carprofen	295/375	102	240	4.26	240	4.37
			300	1.67	300	1.75

[a] TM = fluorescence intensity reading. [b] E = molar absorptivity; A_{max} = wavelength of absorbance peak. [c] The first TM value represents the reading taken immediately after placing the sample into the light path of the fluorometer; the second TM value represents the final constant reading taken after leaving the sample in the light path for 5–10 min.

metabolite structures given in the text are based on integer masses combined with other information. GLC was performed on 3% OV-17 on 80–100-mesh Gas Chrom Q (183-cm × 4-mm i.d. column) at 250° or with temperature programming (4°/min to 300°) using a flame-ionization detector. The carrier gas was helium at 30 ml/min.

[^{14}C]Carprofen and its metabolites were esterified with diazomethane freshly prepared from *N,N*-nitrosomethylurea in ether in the presence of 40% KOH and distilled directly into the methanolic drug solution. Trimethylsilyl derivatives were prepared by reacting the compound under strictly anhydrous conditions with *N,O*-bis(trimethylsilyl)acetamide in silylation grade pyridine[15] for 30 min at room temperature. Methyl esters and trimethylsilyl methyl esters of carprofen and of some of its metabolites were separated and characterized by GLC[16] on a 122-cm column of 3% OV-17 on Gas Chrom Q (60–80 mesh) at a column temperature of 250° and a port temperature of 285°. The flame-ionization detector was operated at 300° at a hydrogen flow rate of 2.5 ml/min. The nitrogen carrier gas flow rate was 3.0 ml/min.

RESULTS

Dog Experiments—*Excretion*—The cumulative excretion of total radioactivity by the dogs after intravenous and oral administration of 1 or 10 mg of labeled carprofen/kg accounted for 67–71% of the dose in the feces and for 7–19% in the urine (Table II). Twenty-four and 27% of the dose were excreted in the bile of two anesthetized bile duct-cannulated dogs within the first 5 hr after the intravenous administration of 1 mg of labeled carprofen/kg (Table III). Most of the radioactive fraction excreted in the feces by the intact dog after the intravenous dose (Table II) represented bile-secreted material since <1% of the dose was present in the intestinal contents in the bile duct-cannulated dogs within 5 hr after the dose of carprofen (Table III).

Identification of Urinary Metabolites of [^{14}C]*Carprofen*—The urinary metabolite patterns after a 1-mg/kg dose and after a 10-mg/kg dose were very similar. Dog urine excreted the 1st day after a 10-mg/kg iv dose of [^{14}C]carprofen (containing 9.41% of the dose) was fractionated. Direct extraction of the urine at pH 5 with ether removed 51% of the total urinary radioactivity. Subsequent extraction with butanol at pH 5 or with ethyl acetate at pH 1–2 removed an additional 28%. TLC of the ether extract in System 1 separated two quantitatively equal components of R_f 0.29 and 0.18, respectively. Intact carprofen (R_f 0.48) was absent.

UV-absorbing impurities were separated by preparative TLC with System 2, whereby the radioactive components remained at the origin. They were extracted together from the plate and separated from one another and from a remaining UV impurity by preparative TLC with System 5. Final purification, adequate for physical–chemical characterization, was achieved by extraction of each component from ether into 0.2 *N* NaOH, acidification of the alkaline extract, and reextraction into ether. Of these two radioactive excretion products, only the R_f 0.29 product represented a genuine metabolite of carprofen (Metabolite I); the R_f 0.18 component (Compound II) was an artifact[17].

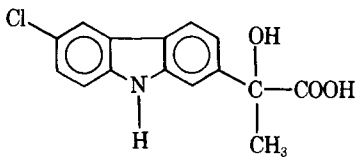
Metabolite I—The UV spectrum of Metabolite I was independent of pH, and the maxima and respective molar absorptivities were similar to those of intact carprofen (Table IV and Fig. 1A). The two fluorescence spectra also were indistinguishable. These characteristics pointed to an intact, unsubstituted carbazole moiety.

The methyl ester of Metabolite I differed by TLC (Table I) from the free acid; on GLC, it appeared as a homogeneous peak with an R_t value of 8.2 min, distinct from that of carprofen methyl ester (R_t 5.5 min).

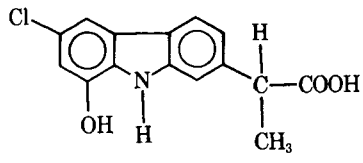
The mass spectrum of Metabolite I (the free acid) indicated a molecular ion at *m/e* 289 ($C_{15}H_{12}ClNO_3$), representing addition of one oxygen to carprofen, and a fragment at *m/e* 271 ($C_{15}H_{10}ClNO_2$), arising from the

[16] Model 402, Hewlett-Packard.

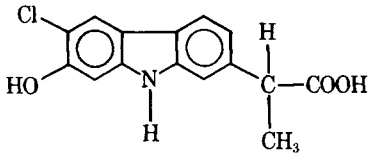
[17] Compound II proved to be derived from a labeled contaminant of the [^{14}C]-carprofen dose, which was not detected on TLC. Since the addition of carrier carprofen to prepare the doses did not reduce the specific activity of this contaminant to that of [^{14}C]carprofen, the specific activity of isolated Compound II, identified as α-hydroxy-α-desmethylcarprofen (by NMR, GLC–mass spectrometry, and synthesis), was several times that of the administered [^{14}C]carprofen. The fact that the same contaminant also is present, although to a lesser extent (0.5%), in unlabeled carprofen preparations is evidenced by the excretion of the same α-hydroxy-α-desmethylcarprofen derivative by dogs dosed with unlabeled drug.



Metabolite I



Metabolite III



Metabolite IV

loss of water. GLC–mass spectrometry of the methyl ester revealed a molecular ion of *m/e* 303 ($C_{16}H_{14}ClNO_3$), indicative of the addition of one oxygen atom to the carprofen ester ($C_{16}H_{14}ClNO_2$). The fragmentation pattern suggested an unsubstituted carbazole ring structure, consistent with the UV spectral evidence.

The GLC–mass spectral pattern, TLC properties, and NMR spectra of Metabolite I and the authentic α-hydroxy derivative of carprofen, whose structure had been unambiguously established as that of a tertiary α-hydroxy compound by its synthesis from the α-keto acid by the Grignard reaction, were identical.

Metabolites III and IV—The polar urinary radioactivity extracted from dog urine with *n*-butanol at pH 5 did not migrate on TLC with System 1. However, it was converted to a compound with a higher R_f value when exposed to either alkaline or acidic conditions and, partly, after incubation with glusulase at pH 5. The converted (high R_f) fraction was extractable with ether at pH 1 and 5. It was prepared for further characterization (from dog urine preextracted with ether at pH 5 to remove Metabolite I and Compound II) in 83% yield by slow, repeated equilibration of the acidified urine (0.4 *N* HCl) with ether.

UV-absorbing contaminants were removed by equilibrating the ether solution with 0.2 *M* phosphate buffer (pH 7) and by extracting the metabolites into 0.2 *N* NaOH and returning them to ether at pH 5 with a recovery of 85%. Preparative TLC with System 2 achieved complete resolution of Metabolites III (R_f 0.27–0.32) and IV (R_f 0.21–0.25), representing 16 and 2.4% of the urinary radioactivity, respectively. Metabolite III discolored when it was left on a TLC plate and was unstable in alkaline solution. With adequate precautions, preparative TLC produced both metabolites in sufficiently pure form for physical–chemical identification.

Metabolite III exhibited a major absorption maximum in acidic solution at 245 nm which was shifted to 255 nm at alkaline pH (Table IV and Fig. 1C). This bathochromic shift indicated a phenolic structure. Spectrofluorometric analysis revealed maxima at 290 and 340 nm, both with emission maxima at 395 nm. The fluorescence intensity increased during the exposure of the solution to the 290-nm light source to a value that remained stable.

Methylation resulted in a major reaction product, which was purified by preparative TLC (R_f 0.56 in System 1). Its high-resolution mass spectrum revealed a molecular ion of *m/e* 303.0688 ($C_{16}H_{14}ClNO_3$), compatible with a methyl ester of a monohydroxy derivative of carprofen. Substitution in the carbazole ring was supported by the fragment of *m/e* 217.0308 ($C_{12}H_8ClNO$), which retains the added oxygen and arises from loss of the $C_4H_6O_2$ side chain, consistent with the phenolic structure evidenced by the pH-dependent UV spectrum of this metabolite.

To determine the position of this phenolic function, Metabolite III methyl ester was dissolved in 0.35 ml of deuterochloroform, and its PMR spectrum was determined. A single scan revealed a methyl ester band at δ 3.68 and a CH_3CH doublet (J = 6.5 Hz) at 1.59, indicating that the side chain was intact. A time-averaged spectrum of 229 scans of the δ 5–10 region revealed the following parameters: δ 6.81 (d, 1H, J *meta* = 2 Hz,

Table V—Excretion of Carprofen and Metabolites by Humans, Dogs, and Rats

[a] The mean ± range is given for two values, and the mean ± *SD* is given for three values. [b] The dash indicates that the amounts found were <0.1% of the dose. [c] Quantitative distribution of carbon 14 component in human feces represents an estimate in one subject. [d] In these specimens, the TLC system did not differentiate between free III and free IV.

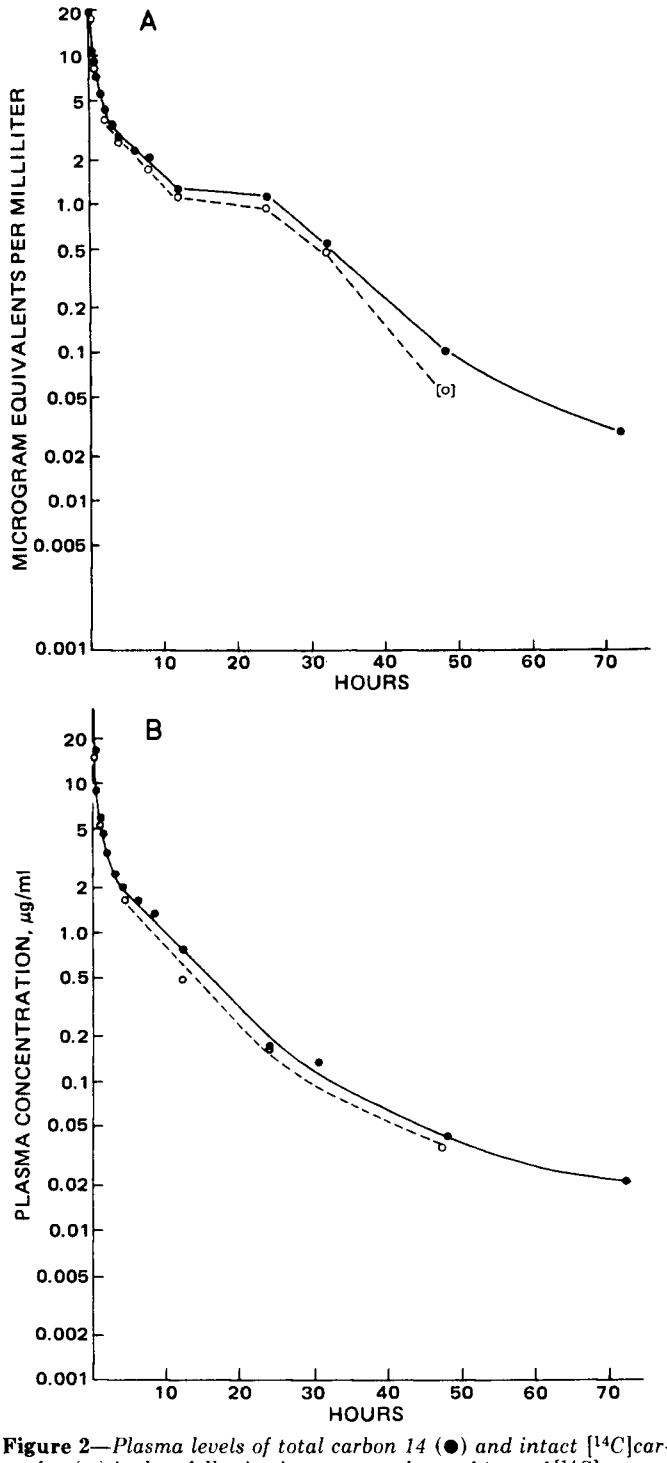

Figure 2—*Plasma levels of total carbon 14 (●) and intact [^{14}C]carprofen (○) in dogs following intravenous doses of 1 mg of [^{14}C]carprofen/kg. Key: A, Experiment D-I; and B, Experiment D-V.*

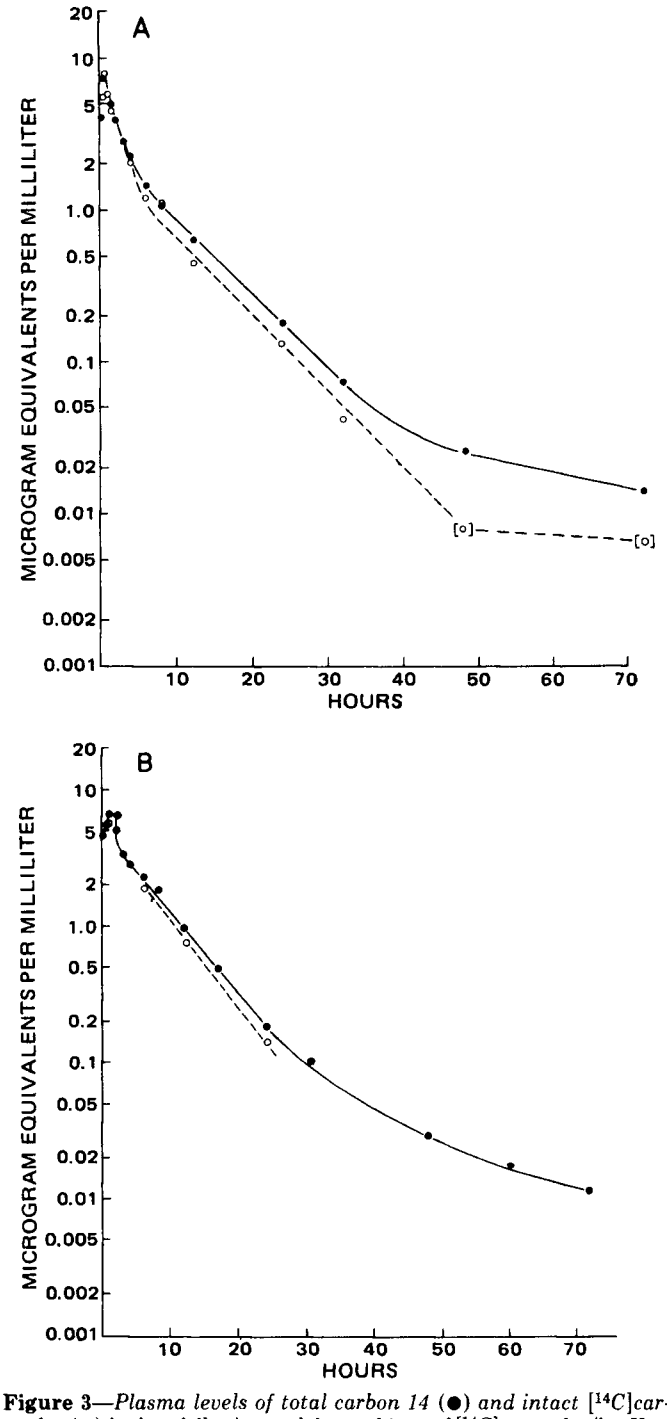

Figure 3—*Plasma levels of total carbon 14 (●) and intact [^{14}C]carprofen (○) in dogs following oral doses of 1 mg of [^{14}C]carprofen/kg. Key: A, Experiment D-II; and B, Experiment D-VI. Brackets indicate an estimated value.*

H-7), 7.17 (broad d, 1H, *J ortho* = 8 Hz, H-3), 7.38 (broad s, 1H, H-1), 7.59 (broad s, 1H, H-5), 7.90 (d, *J ortho* = 8 Hz, H-4), and 8.17 (broad, NH). The chemical shifts of the aromatic protons (H-1, H-3, and H-4) correspond (within ±0.02 ppm) with those of the parent ester and clearly showed that the alkyl-substituted ring was not hydroxylated. However, the bands at δ 6.81 and 7.59 were at δ 7.33 and 7.99 in the parent and indicated large significant upfield shifts of 0.52 (*ortho*) and 0.40 (*para*) ppm, respectively, which were attributed to the new hydroxyl group at C-8. This conclusion was confirmed by a resolved *meta*-splitting ($J_{5,7}$ = 2 Hz) observed in the H-7 signal. Thus, hydroxylation occurred definitely at C-8, and Metabolite III was characterized conclusively as 6-chloro-8-hydroxy-α-methylcarbazole-2-acetic acid.

The UV and fluorescence spectra of Metabolite IV differed from those of Metabolite III (Table IV and Fig. 1D). The UV spectrum of Metabolite IV exhibited a bathochromic shift from maxima at 240 and 310 nm to maxima at 245 and 340 nm. The fluorescence spectrum showed activation/emission maxima at 310/360 nm with a high intensity that was stable when exposed to light.

The high-resolution mass spectrum of the purified methyl ester of Metabolite IV indicated a molecular ion of *m/e* 303.0681 ($C_{16}H_{14}ClNO_3$), isomeric with that of Metabolite III methyl ester. The fragment of *m/e* 217.0206 ($C_{12}H_8ClNO$), arising from loss of the side chain ($C_4H_6O_2$), demonstrated oxygen addition in the carbazole moiety. These data support a structure for Metabolite IV of a phenolic monohydroxy derivative distinct from Metabolite III.

The position of the phenolic hydroxy function of Metabolite IV was elucidated by the NMR spectrum of its dimethyl derivative. Thus, the

methoxy methyl ester of Metabolite IV dissolved in dimethyl sulfoxide-d_6 provided a methyl ester band at δ 3.59 and a CH_3CH doublet (J = 7 Hz) at 1.45, indicating that the side chain was intact. The rest of the spectrum was assigned as follows: δ 3.91 (q, 1H, J = 7 Hz, CH_3CH), 3.93 (s, 3H, CH_3O ether), 7.04 (dd, 1H, J *meta* = 1.5 and J *ortho* = 8 Hz, H-3), 7.13 (s, 1H, H-8), 7.34 (d, 1H, J *meta* = 1.5 Hz, H-1), 7.96 (d, 1H, J *ortho* = 8 Hz, H-4), 8.13 (s, 1H, H-5), and 11.19 (s, 1H, NH). The chemical shifts and multiplicities of the bands assigned to H-1, H-3, and H-4 indicated definitely that the alkyl-substituted ring was not hydroxylated. The singlet character of the bands at δ 7.13 and 8.13 showed that oxygenation had occurred at C-7. Therefore, Metabolite IV is the 7-hydroxy derivative of carprofen.

The amounts of Metabolites I, III, and IV excreted in the 0–24-hr dog urines are included in Table V.

Metabolites in Bile and Feces of Dogs—The distribution of the biliary metabolites in two dogs (D-IV and D-X) is shown in Table V. A small portion of the biliary carbon 14 was present as pH 5 ether-extractable metabolites, predominantly as intact [^{14}C]carprofen. The other components appeared to be identical to the metabolites seen in urine according to TLC evidence (Systems 1 and 2). About 50% of the biliary carbon 14 consisted of the ester glucuronide of [^{14}C]carprofen, while 12% represented conjugates of Metabolites III and IV (in a ratio of 8:1) that were cleaved by glusulase.

About half of the fecal radioactivity was ether extractable at pH 5. This extract contained similar parts of carprofen and the phenolic fraction (mixture of Metabolites III and IV).

Plasma Levels and Tissue Distribution—The levels of total radioactivity and of intact [^{14}C]carprofen measured in the plasma of two dogs (D-I and D-V) following 1-mg/kg iv doses of [^{14}C]carprofen are presented in Fig. 2. In the first 48 hr, most of the radioactivity in the plasma represented intact drug. A minor ether-extractable metabolite with an R_f value (0.27–0.29) in System 1 corresponding to that of Metabolite I was detected in the 3–12-hr plasma samples of these intravenously dosed dogs. No radioactivity was found in the erythrocytes.

The plasma levels of carprofen showed a triexponential decline that was most distinct in Experiment D-V (Fig. 2B). In this study, the half-lives of the three phases were 0.5, 6, and 40 hr. In Experiment D-I (Fig. 2A), the plasma levels, after an initial decline, plateaued between 12 and 24 hr and then declined again.

Following oral administration of the same dose as a solution to the same two dogs (D-II and D-VI), plasma levels peaked at 0.5–1 hr, indicating that absorption of the drug was rapid (Fig. 3). Absorption, as estimated from comparison of the intravenous and oral areas under the total plasma carbon 14 level curves, was 106% in D-VI. In D-II, the lower value of 50% appeared to be related to a secondary drug uptake, reflected in the plateau of the intravenous curve.

Evaluation of the plasma levels obtained after a 10-times higher intravenous dose of 10 mg/kg (D-III and D-XI) indicated that in the 1–10-mg/kg dose range, the plasma levels were proportional to dose whereas the disposition rates were independent of the dose.

The distribution of total carbon 14 into the major tissues of two bile duct-cannulated dogs (D-IV and D-X) 5 hr after intravenous doses of 1 mg of [^{14}C]carprofen/kg is shown in Table III. Very low concentrations of carbon 14 in all of these tissues relative to plasma were evident. Of the radioactivity in the liver and in the kidneys, close to 70% represented intact carprofen. Both tissues contained trace levels of Metabolite I.

Rat Experiments—*Excretion*—After intravenous administration of [^{14}C]carprofen, the radioactivity was excreted predominantly in the

feces. Experiments in bile duct-cannulated animals showed this finding to result almost exclusively from biliary secretion of labeled carprofen metabolites.

The distribution of the radioactivity between feces (bile) and urine varied depending on the age and size of the rats (Table VI). In 337-g Charles River rats, 75% of a 3-mg/kg dose was excreted in the feces within 72 hr (45% in the bile in 4 hr) and 20% was excreted in the urine, with both forms of excretion being rapid and almost complete within 24 hr. In the larger and older Charles River rats (>700 g), only 58% of the same dose was excreted in the feces within 72 hr (23% in the bile in 4 hr) and 31%

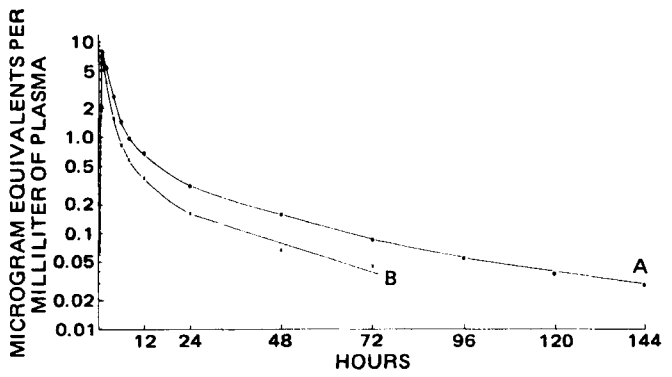

Figure 6—*Plasma levels in Subject 2 of total radioactivity* (●, *A*) *and of* [^{14}C]*carprofen* (×, *B*) *following a 50-mg oral dose of* [^{14}C]*carprofen. Data expressed as log of microgram equivalents per milliliter of plasma are plotted* versus *time in hours.*

was excreted in the urine, both at a slower rate of excretion. The biliary metabolite fraction contained exclusively conjugates, including the carprofen ester glucuronide and the ethereal glucuronides of the phenolic Metabolites III and IV, identified by cochromatography (in three systems) with the metabolites isolated from dog bile and urine. The quantitative distribution of the secreted metabolites appeared to vary depending on the strain and age (size) of the rats. Relatively less hydroxylated metabolites were secreted in the bile of the old (large) rats than in the bile of the young (small) rats. A somewhat larger fraction was secreted as the carprofen ester glucuronide by male rats of the Carworth Farm Sprague–Dawley (CF-D) strain than by the Charles River CD strain. No sex differences were evident.

Analysis of the intestinal and fecal carbon 14 fractions of the rats indicated a progressive deconjugation of the biliary metabolites and a decrease of the ratio of carprofen to the phenolic metabolites (III and IV) as the radioactivity moved from bile (ratio of 4.2) to the large intestine (ratio of 0.8) and feces (ratio of 0.31). This finding suggests a selective reabsorption of enterically deconjugated carprofen.

TLC of an extract obtained with ethyl acetate at pH 1 from a 0–24-hr rat urine specimen (containg 16.3% of a 5-mg/kg [^{14}C]carprofen dose) distinguished labeled components, which, from their R_f values in System 1, appeared to include intact carprofen, Metabolites III and/or IV, Metabolite I, and a polar component that remained at the origin (Table V).

Tissue Distribution—The tissue distribution of total carbon 14 and of [^{14}C]carprofen and the tissue to plasma carbon 14 ratios in rats at 10 min and 1 and 4 hr after intravenous administration of 5 mg of [^{14}C]-carprofen/kg are presented in Table VII. At each time, the carbon 14 levels were highest in the plasma. Intact carprofen prevailed in the plasma and tissues at all times. The residual radioactivity consisted mostly of ether-unextractable polar material.

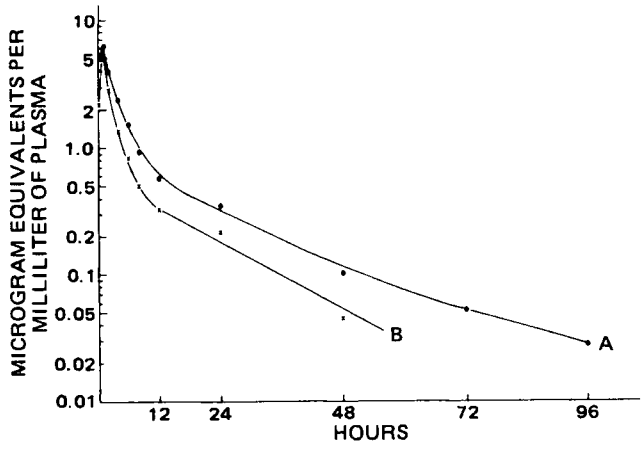

Figure 7—*Plasma levels in Subject 3 of total radioactivity* (●, *A*) *and of* [^{14}C]*carprofen* (×, *B*) *following a 50-mg oral dose of* [^{14}C]*carprofen. Data expressed as log of microgram equivalents per milliliter of plasma are plotted* versus *time in hours.*

Human Studies—*Excretion*—After oral administration of 50 mg of [^{14}C]carprofen, the main portion of the dose was excreted in the urine (75% of the dose in Subjects 1 and 2 and 55% in Subject 3). The ester glucuronide of carprofen represented >90% of the urinary carbon 14, and intact carprofen represented 3–5%. Only trace amounts of free Metabolite I and of conjugated Metabolite III could be detected (Table V). A semilog plot of intact carprofen and of its ester glucuronide, expressed as the percentages remaining to be excreted, *versus* time (Fig. 4) produced parallel curves for each component, reflecting biexponential excretion. The fast excretion rate was characterized by half-lives of 2.4–3.6 hr, whereas the terminal phase exhibited apparent half-lives of 24–25 hr in Subjects 1 and 2 and of 13 hr in Subject 3. These half-lives are in close agreement with the plasma half-lives for carprofen.

The fecal excretion of radioactivity represented 17–20% of the dose and extended from Day 2 to Day 10 in Subjects 1 and 2. In Subject 3, 33% of the radioactivity was excreted in the feces at a considerably faster rate than in the other two subjects.

The fraction extracted from the ethanolic homogenates of the human feces by the described procedures contained 60–70% of the fecal radioactivity. Of this fraction, 25–30% (~7% of the administered dose) was separated and identified as intact carprofen by TLC and by high-resolution mass spectrometry. The TLC pattern of the fecal extracts suggested the presence of small quantities of Metabolite I and two additional components not detected in dogs and rats. UV and mass spectral analysis of the two additional components yielded spectra similar to those of carprofen, suggesting that these metabolites may represent lipid-soluble addition products rather than true metabolites of carprofen.

Plasma Levels—Intact drug was the dominant radioactive component in human plasma during the first 12 hr. A polar component increased with time to more than half of the total radioactivity in plasma. One of these polar metabolites, identified in Subject 1 as the β-glucuronide ester of carprofen, declined rapidly with a half-life close to 2 hr.

The elimination rate in plasma of both carprofen and total radioactivity decreased with time (Figs. 5–7). A biphasic fall off of the plasma levels of carprofen occurred in all three subjects. The initial plasma carprofen levels declined with a half-life of 1.8–2.2 hr to reach values corresponding to ~5% of the peak levels within 12 hr. During the terminal phase, the levels declined with half-lives of 25–27 hr in Subjects 1 and 2 and ~13 hr in Subject 3. No drug-related radioactivity was detectable in the red cells throughout the experiment[18].

DISCUSSION

The disposition of [^{14}C]carprofen is similar in rats, dogs, and humans. It has many characteristics in common with the disposition of other acidic nonsteroidal anti-inflammatory compounds (10–16). Like most members of this class of drugs, carprofen is strongly bound to plasma proteins (17), and this binding is associated with a high ratio of the concentration of carprofen in plasma relative to its concentration in tissues. Intact carprofen accounts for most of the radioactivity in plasma and in the major tissues of rats and dogs. Drug elimination from plasma is characterized in dogs and humans by a bi- or multiphasic decline.

The main metabolites, primarily conjugates, do not accumulate and are rapidly eliminated, except for a small polar metabolite fraction that persists in human plasma.

Carprofen is eliminated from rats, dogs, and humans primarily by biotransformation. Probably <5% of the dose is cleared directly as the free, intact drug. The carprofen found in the feces probably arose from deconjugation of the ester glucuronide, which predominated in the bile (Table V).

The ester glucuronide of the intact drug represents the major metabolite in rats, dogs, and humans. The rapid formation and the characteristic rate and mode of elimination of this metabolite determine the pharmacokinetics of the drug. In rats and dogs but to a very minor extent in humans, oxidation in positions 7 and 8 of the carbazole moiety to phenolic derivatives (probably *via* a common arene oxide precursor) and their conjugation to form ethereal glucuronides represent alternate pathways. A small percentage of the dose also is metabolized by side chain oxidation to the α-hydroxy derivative, which is excreted free in the urine by dogs and rats. In rats and dogs, the ester glucuronide of carprofen and the ethereal glucuronides of the two phenolic metabolites are eliminated predominantly by biliary secretion.

Human subjects, in contrast to rats and dogs, excrete most of an oral carprofen dose as urinary ester glucuronide. However, the relatively small fecal ^{14}C-labeled component apparently represents only a fraction of a substantially larger biliary component because of enterohepatic circulation. A comparison of the initial 90% decline of the drug in plasma with the 50–60% of the dose excreted in the urine during the same 12-hr period suggests that the remaining 30–40% of the dose had been eliminated with the bile. This estimate of extensive biliary excretion of metabolites in humans was supported by analysis of biliary aspirates from an intubated human volunteer[19].

Extensive enterohepatic circulation in humans was suggested by the protracted fecal excretion of radioactivity in two of the three subjects discussed in the present report. Furthermore, the slow terminal decline of plasma levels and of the urinary excretion rates in these two subjects may be related to a continuous reabsorption of the biliary fraction. The extent of this reabsorption determines the fraction of the primary biliary portion that is excreted in the feces and the fraction that ultimately is excreted in the urine. In the third subject, the enterohepatic process may be concluded to have been less pronounced, resulting in a higher and more rapid fecal excretion and in a shorter apparent half-life of the radioactivity in plasma.

Negligible Excretion of Unchanged Ketoprofen, Naproxen, and Probenecid in Urine

R. A. UPTON ˣ, J. N. BUSKIN, R. L. WILLIAMS, N. H. G. HOLFORD, and S. RIEGELMAN

Received March 20, 1980, from the *Drug Studies Unit, University of California, San Francisco, CA 94143.* Accepted for publication May 5, 1980.

Abstract □ On the average, 0.6% of a dose of ketoprofen or naproxen or 1.2% of a dose of probenecid was found in the urine of normal male volunteers assayed immediately after its collection. Between ~60 and 85% of the dose of these drugs can be excreted in the urine as conjugates, which rapidly hydrolyze at body temperature, at room temperature, and even during frozen storage, thereby regenerating the parent drug. Since urine collections involved sample retention in the bladder at 37° for collection intervals as long as 2–3 hr, the given percentages excreted unchanged probably are overestimates. It is possible that no unchanged ketoprofen, naproxen, or probenecid is excreted in urine. This study contrasts with previous reports of up to 50% of a dose of ketoprofen and 15–17% of doses of naproxen and probenecid being excreted in urine as the parent compound. Those reports probably reflect primarily the duration of frozen sample storage between collection and assay along with the urine collection schedules employed, the speed of the clinical procedures, and the analytical procedures used. Attention should be given to potential conjugate hydrolysis whenever the pharmacokinetics of carboxylic acids are studied.

Keyphrases □ Ketoprofen—urinary excretion of unchanged drug □ Naproxen—urinary excretion of unchanged drug □ Probenecid—urinary excretion of unchanged drug

Previous reports suggested that up to 50% of a dose of ketoprofen (1–4), 15% of a dose of naproxen (5–7), and 17% of a dose of probenecid (8–10) are excreted in urine as the unchanged drug. It also has been claimed that the percentage of each of these drugs excreted unchanged is variable among individuals or within individuals (2, 5, 10) and that the percentage excreted unchanged might be depressed with concurrent administration of other drugs (6). In contrast, this report presents evidence that, even in normal individuals, the renal excretion of ketoprofen, naproxen, and probenecid is negligible. Data reported previously probably reflected the collection, storage, and handling of urine samples instead of the urinary excretion of these compounds.

EXPERIMENTAL

The data were derived from several studies in which ketoprofen, naproxen, or probenecid was given orally to adult male volunteers judged to be normal after a physical examination, an extensive blood screen, and urinalysis. Participants received other drugs only where specifically stated.

Urine was analyzed within 30 min of serial collections from 0 to 1, 1 to 2, 2 to 3, 3 to 4, and 4 to 6 hr after the 13th dose of a regimen of 50 mg of ketoprofen[1] given every 6 hr or after the 13th dose of a regimen of 500 mg of probenecid[2] given every 6 hr. Urine was analyzed within 30 min of collection from 0 to 1, 1 to 2, 2 to 3, 3 to 6, 6 to 8, 8 to 10, and 10 to 12 hr after the seventh dose of a regimen of 500 mg of naproxen[3] given every 12 hr.

Ketoprofen, naproxen, probenecid, and their conjugates were analyzed by a sensitive high-pressure liquid chromatographic (HPLC) assay described previously (11). Conjugates were analyzed as the parent drug after simple alkaline hydrolysis (11).

	11	1.4	33.4
	12	1.0	40.2
Mean ± *SD*		1.2 ± 0.2	43.5 ± 12.1

RESULTS

Table I shows the percentage of a dose of ketoprofen, naproxen, or probenecid appearing unchanged or as alkali-hydrolyzable conjugates in urine at steady-state plasma concentrations. On the average, only 0.6% of the ketoprofen dose, 0.6% of the naproxen dose, and 1.2% of the probenecid dose appeared in urine as the unchanged drug, but 74, 57, and 44% of these drugs were excreted as conjugates, respectively. None of the five people taking ketoprofen alone and none of the four subjects taking naproxen alone excreted >0.9% of unchanged drug in the urine.

The three individuals taking probenecid were simultaneously following the described ketoprofen regimen. None excreted >1.4% of the dose of probenecid (mean, 1.2%) or >0.2% of the ketoprofen dose as the unchanged drugs.

In an additional three individuals taking the ketoprofen regimen with aspirin[4] (975 mg every 6 hr), the maximum urinary excretion of unchanged ketoprofen observed was 0.9% of the dose (0.8 ± 0.1%), but 59.7 ± 3.6% was excreted as conjugates. When three of the four individuals taking naproxen undertook a further naproxen regimen together with 300 mg of cimetidine[5] given every 6 hr, the maximum urinary excretion of naproxen was 0.7% (0.5 ± 0.2%), and 65.6 ± 8.3% was excreted as conjugates. The data on the urinary excretion of ketoprofen, naproxen, and probenecid were derived from 14 volunteers.

Some samples were stored at −15° for assay at various dates after collection (Table II). Over a period of <2 months, the ketoprofen and naproxen content of these samples increased up to threefold at the apparent expense of the alkali-hydrolyzable conjugates, presumably as a result of conjugate hydrolysis, even in the frozen state. Furthermore, since a different sample of the same urine collection was stored for each repetition of the assay, the progressive accumulation in content of the unchanged drug (Table II) was specifically an effect of storage rather than of repeated freezing and thawing, which also appear to have an effect. When samples were frozen and then thawed after 12 hr, a period during which (by reference to Table II) one might expect a negligible increase in unchanged drug specifically due to storage, the content of unchanged ketoprofen increased by 14.2 ± 5.9% (n = 4), and the content of naproxen increased by 17.1 ± 14.6% (n = 3).

[a] Micrograms per milliliter of unchanged drug after alkaline hydrolysis (11).

Because all samples other than those assayed on Day 0 were stored frozen, their assay was subject to the effects not only of storage but also of freezing and thawing. As a result, elucidation of the kinetics of conjugate hydrolysis might be complex, requiring more detailed data than are presented here. However, regardless of whether the hydrolysis rates observed are interpreted as zero or first order, they are sufficient to account for the levels of unchanged drug that have been reported in the literature. A zero-order rate of production of 17 ng/ml/day (the average zero-order rate from Table II) leads to a 5% apparent excretion of unchanged ketoprofen in an individual who had taken a 50-mg dose and produced 1.5 liters of urine to be assayed 3 months later. A first-order daily rate of production of 0.9 ng of ketoprofen/μg of conjugates (Table II) would lead to an apparent 6% excretion of unchanged ketoprofen when the urine of an individual excreting 74% (Table I) of the dose as conjugates is assayed after frozen storage for 3 months. Similar calculations show that an apparent excretion of naproxen of ~4% could arise by delaying the assay of urine samples by 3 months. These calculations indicate that after 8 months of frozen storage, 13% of the dose as unchanged ketoprofen might be expected.

Figure 1 shows the apparent urinary excretion of unchanged ketoprofen by 12 volunteers (each taking three single 50-mg doses) whose 24-hr urine was stored at −15° for 20–100 days between collection and assay. A linear correlation between the apparent ketoprofen excretion by each volunteer[6] and the time of storage of the urine is significant ($r = 0.6$, $p < 0.0005$, $n = 32$). As predicted, after 3 months of storage, ~4–5% of the dose appeared to be in the urine as unchanged ketoprofen. In another study, 12 additional volunteers (each taking three single 50-mg doses), whose urine was frozen shortly after collection and thawed for the first time after 8 months, appeared to excrete 9.6 ± 2.0% ($n = 36$) of the dose unchanged.

Greater rates of hydrolysis were observed at room temperature (Table III). Samples doubled in their content of unchanged ketoprofen or naproxen within 4–5 hr. (The pH of eight urine samples taken from three volunteers at various times within 24 hr after dosage ranged between 5.4 and 6.7 immediately after collection.) Therefore, analytical units not alerted to the potential facile hydrolysis of ketoprofen or naproxen conjugates during extended processing of urine in the clinic or during sample workup might report even higher percentages of the drug excreted unchanged than the figures discussed here.

Furthermore, hydrolysis rates even higher than those at room temperature were observed at 37° (Table IV). Therefore, the extent of excretion of unchanged ketoprofen, naproxen, and probenecid shown in Table I, while less than that reported previously, probably is still an overestimate since urine collections at 2–3-hr intervals involve sample retention in the bladder at 37° for sufficient time for significant conjugate hydrolysis. It is possible that no unchanged drug is excreted into urine.

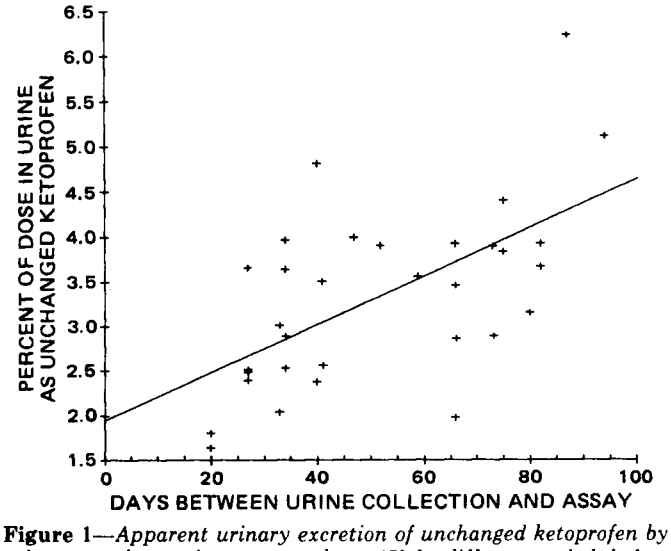

Figure 1—*Apparent urinary excretion of unchanged ketoprofen by volunteers whose urine was stored at −15° for different periods before assay.*

[6] Data on the third dose of four of the individuals are incomplete.

[a] As the equivalent concentration of unchanged drug.

For ketoprofen and naproxen, at least three conjugates apparently are excreted in urine. If urine is assayed by the previously reported HPLC method (11) with the hydrolysis step omitted and acidic extraction conditions used as for plasma analysis, peaks are seen at 1.8 (largest), 2.0, and 2.9 (smallest) times the retention time for ketoprofen or at 2.5 (largest), 3.1 (smallest), and 4.1 times the retention time for naproxen. After extracts of urine from subjects taking either ketoprofen or naproxen were chromatographed, fractions of the eluent, each containing one of the three peaks, were collected. An aliquot of each eluent fraction was rechromatographed to ensure that fractions were not cross-contaminated with other conjugates or with the parent drug. The remaining part of each fraction underwent alkaline hydrolysis and then reextraction.

Further chromatography revealed a ketoprofen or a naproxen peak alone. For the first and second conjugate peaks of ketoprofen and the first and third conjugate peaks of naproxen, the conjugate gave rise to the parent compound on an equal peak area basis (to within 20%). For the other peaks (the smallest) from either compound, this finding was less certain due to the less straightforward concentration and extraction procedures that were necessary. Equivalence of peak areas confirms that conjugation does not involve the major chromophoric moiety but rather the carboxylic function and, hence, the ease of subsequent conjugate hydrolysis.

DISCUSSION

A negligible fraction of the dose of ketoprofen, naproxen, or probenecid is excreted in the urine as the unchanged drug, but a large fraction (up to 85%) appears as conjugates. Glucuronides of ketoprofen (12) and naproxen (8) were reported previously. Evidence in this study suggests that there are at least three conjugates of ketoprofen and three of naproxen. These conjugates are rapidly hydrolyzed to the parent compound by mild alkaline conditions (11). Hydrolysis of one or more conjugates of each drug appears to occur even in urine stored frozen, the most commonly employed mode of storage. Furthermore, freezing and thawing appear to promote hydrolysis, and even more rapid hydrolysis occurs at room temperature or at 37°.

Earlier reports of significant urinary excretion of unchanged ketoprofen, naproxen, and probenecid probably reflect not only the time of frozen storage between collection and assay but also the urine collection schedules employed, the speed of the clinical procedures, and the analytical procedures used, particularly the conditions and speed of the sample workup. The previously reported variability in ketoprofen, naproxen, and probenecid urinary excretion (2, 5, 10) probably is related to variability in these conditions, especially the time between collection and assay. Differences between different experimental groups might have

Table IV—Urine Sample Content after Storage at 37°

[a] As the equivalent concentration of unchanged drug.

a similar source, particularly where clinical and analytical schedules were not both randomized.

Since virtually no naproxen appears to be excreted unchanged in urine, reports of a decrease in naproxen excretion with concomitant doses of other drugs such as probenecid (6) must be questioned. The apparent decrease in unchanged naproxen excretion probably is a direct consequence of reduced naproxen conjugate excretion, which results in a diminished rate of postexcretion conjugate hydrolysis. The previously reported increase in renal clearance of probenecid with metabolic alkalosis (6, 9, 13) induced by intravenous sodium bicarbonate may largely result from improved conditions for conjugate hydrolysis in the alkaline urine in the bladder.

The ease of hydrolysis of the conjugates described probably is attributable to their being carboxylic acid esters. The greater apparent excretion of unchanged drug found for probenecid possibly is related to its being a benzoic acid, a stronger acid than the alkanoic acids, and it therefore forms a conjugate more susceptible to hydrolysis in urine between the times of excretion and assay. Data describing urinary excretion of other carboxylic acids, including many nonsteroidal anti-inflammatory drugs, should be interpreted with caution unless adequate attention was given to potential conjugate hydrolysis both *in vivo* and *in vitro*. The best safeguard at present is immediate assay after short urine collection intervals. If this procedure is not possible, immediate frozen storage for short periods might yield insignificant hydrolysis. It is conceivable, but by no means can it be assumed, that temperatures of $<-15°$ might permit negligible hydrolysis.

The virtual absence of unchanged compound in the urine may arise because alternative forms of elimination are extremely rapid. However, the total plasma clearances of ketoprofen and naproxen are only 5 and 0.7 liters/hr, respectively (5, 13). Even if these clearances are considered to be totally metabolic, extraction ratios of only 0.06 and 0.01 are apparent, respectively (assuming 1:1 partitioning of these drugs between plasma and the red blood cells). Ketoprofen, naproxen, and probenecid all are highly lipophilic compounds, a characteristic discusssed in a previous report (11), where it was noted that they can be extracted into ether and can be retained on lipophilic chromatographic columns even when they are almost completely ionized in water. Such compounds are potentially highly susceptible to renal tubular reabsorption (10). Perhaps reabsorption from the glomerular filtrate is so efficient that virtually no ketoprofen, naproxen, or probenecid is excreted into urine as such.

Since plasma rather than urine concentrations are more central to most pharmacokinetic interpretations, a similar ease of hydrolysis in plasma samples might lead to even more misleading descriptions of the general pharmacokinetic behavior of these drugs. However, in analyzing ketoprofen or naproxen in plasma immediately upon collection of blood samples, the ratio of the total concentration (parent drug and its conjugates) to that of unchanged ketoprofen or naproxen, respectively, was only 1.42 ± 0.14 (11 samples from one subject at various times up to 24 hr postdosing) or 1.10 ± 0.05 (39 samples from three subjects). If immediate assay did in fact reflect the relative proportions of compounds in the bloodstream, then even complete hydrolysis upon storage would affect the apparent ketoprofen or naproxen plasma levels only slightly, at least by comparison with the potential change in urine concentrations. After ~2 months of storage at −15° there appeared to be little change in the ketoprofen samples (total drug to parent drug ratio of 1.37 ± 0.08), but repeating the analysis for ketoprofen in five samples between 3 and 6 months after collection (involving further freezing and thawing) revealed that the content of unchanged ketoprofen had increased by 10–25%. Repeated analysis for naproxen only 2 months after collection showed that the conjugates had almost disappeared, with a commensurate increase (~10%) in the content of unchanged drug.

Simultaneous High-Performance Liquid Chromatographic Determination of Suxibuzone and Its Metabolites in Plasma and Urine

TERUYOSHI MARUNAKA ˣ, TOSHIAKI SHIBATA, YOSHINORI MINAMI, YUKIHIKO UMENO, and TAKASHI SHINDO

Received March 5, 1980, from the *Research Laboratory, Taiho Pharmaceutical Co., Ltd., Kawauchi-cho, Tokushima, 771-01, Japan.* Accepted for publication May 2, 1980.

Abstract □ A high-performance liquid chromatographic method is described for the simultaneous determination of the anti-inflammatory agent suxibuzone and its metabolites, 4-hydroxymethylphenylbutazone, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone, in plasma and urine. Acidified plasma or urine is extracted with benzene–cyclohexane (1:1). The organic extract is reduced to dryness, and the resulting residue is redissolved in methanol. Aliquots of this solution are chromatographed on a reversed-phase column using a mobile phase of methanol–0.5 *M* KH_2PO_4 (linear gradient from 0 to 100% methanol at 8%/min with a flow rate of 2.0 ml/min) on a high-performance liquid chromatograph equipped with a UV absorbance detector (254 nm). Detection is limited to 0.10 μg/ml for suxibuzone and 4-hydroxymethylphenylbutazone and to 0.05 μg/ml for the other metabolites.

Keyphrases □ Suxibuzone—simultaneous high-performance liquid chromatographic determination with metabolites in plasma and urine □ Metabolites—suxibuzone, simultaneous high-performance liquid chromatographic determination with parent drug in plasma and urine □ High-performance liquid chromatography—analysis, suxibuzone and metabolites in plasma and urine

Suxibuzone [4-butyl-4-(hydroxymethyl)-1,2-diphenyl-3,5-pyrazolidinedione hydrogen succinate] is a new derivative of phenylbutazone that was developed as an anti-inflammatory agent. It was reported that suxibuzone was equipotent to phenylbutazone in pharmacological activity and that its toxicity was one-third to one-fifth of that of phenylbutazone in experiments with animals, indicating greater safety (1–3).

Suxibuzone is metabolized in the body mainly to phenylbutazone through 4-hydroxymethylphenylbutazone as an intermediate, with the phenylbutazone then proceeding to oxyphenbutazone and γ-hydroxyphenylbutazone (Scheme I) (4).

BACKGROUND

An assay for suxibuzone and its metabolites in plasma and urine was reported (4) in which suxibuzone and its metabolites are determined by GLC as their trimethylsilyl derivatives.

For the assay of phenylbutazone and its metabolites in plasma and urine after phenylbutazone administration, several UV (5–13), GLC (14–19), and high-performance liquid chromatographic (HPLC) (20, 21) methods have been reported. The UV method reported by Burns *et al.* (5) has many sensitivity and specificity problems. With the GLC methods, phenylbutazone and oxyphenbutazone were determined as their methyl derivatives by Midha *et al.* (16), phenylbutazone and the heptafluorobutyryl derivative of oxyphenbutazone were determined by Bruce *et al.* (17), and Tanimura *et al.* (18) assayed phenylbutazone and the trimethylsilyl derivatives of oxyphenbutazone and γ-hydroxyphenylbutazone.

An HPLC method using an adsorption chromatographic column (SIL-X) was used to determine phenylbutazone and oxyphenbutazone (20, 21).

In the present study, an HPLC method using a reversed-phase column for determination of suxibuzone and its metabolites, 4-hydroxymethylphenylbutazone, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone, in plasma and urine after administration of suxibuzone was examined; an accurate and sensitive assay for their measurements was established.

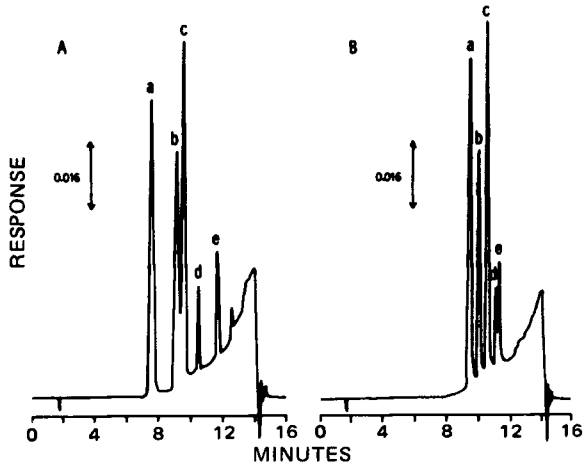

Figure 1—*High-performance liquid chromatograms of authentic samples using a mobile phase of methanol–water (A) and methanol–0.05 M KH_2PO_4 (B) with a linear gradient (0–100% methanol at 8%/min with a flow rate of 2.0 ml/min). Key: a, γ-hydroxyphenylbutazone; b, oxyphenbutazone; c, phenylbutazone; d, suxibuzone; and e, 4-hydroxymethylphenylbutazone.*

EXPERIMENTAL

Materials—Suxibuzone[1], phenylbutazone[1], oxyphenbutazone[1], and γ-hydroxyphenylbutazone[1] were used as received. 4-Hydroxymethylphenylbutazone[2] was synthesized and purified. Benzene, cyclohexane, and methanol were liquid chromatographic grade[3], and the other chemicals used were analytical grade[3].

HPLC Conditions—The high-performance liquid chromatograph[4] was equipped with a high-pressure injection port[5], gradient elution equipment[6], and a fixed-wavelength (254-nm) UV absorbance detector[7].

A reversed-phase chromatographic column[8] (30 cm × 3.9 mm i.d.) was used for the separation and was maintained at room temperature. The mobile phase was a linear gradient of methanol and 0.05 *M* KH_2PO_4 (0 to 100% methanol at 8%/min) at a flow rate of 2.0 ml/min. The mobile phase was degassed by applying a vacuum (~100 mm) to the solvent reservoir for ~2 min before use.

A computer system[9] was employed for quantitative calculation.

GLC Conditions—The gas chromatograph[10] was equipped with a

flame-ionization detector. The GLC conditions were described previously (4).

Mass Spectrometric Conditions—A mass spectrometer[11] with an electron-impact ion source was used for identification of suxibuzone and its metabolites. The mass spectrometric analysis was carried out under the following conditions: ionization energy, 75 ev; ionization current, 200 μamp; and acceleration voltage, 10 kv.

Analytical Procedure—Samples of 1.0 ml of plasma or 2.0 ml of urine

[a] Each value is the mean of three HPLC determinations.

were diluted with distilled water, adjusted to pH 2.0 with 5 *N* HCl, and extracted with benzene–cyclohexane (1:1 v/v) (20 ml for plasma and 30 ml for urine) for 20 min. The organic layer containing suxibuzone and its metabolites was separated by centrifugation at 2000×*g*. This extraction was repeated once. The combined organic layer was evaporated to a suitable volume under nitrogen at 30°, transferred to a test tube (10-ml capacity), and dried under nitrogen. The residue was dissolved in 100 μl of methanol, and 2–10 μl of this solution was injected into the liquid chromatograph with a 10-μl syringe[12].

Calibration curves for the determination of suxibuzone, 4-hydroxymethylphenylbutazone, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone by HPLC were prepared by plotting the peak area against the concentration of each compound. All of these calibration curves were linear.

The procedure for GLC determination was the same as that reported previously (4).

RESULTS AND DISCUSSION

An efficient solvent system (4), benzene–cyclohexane (1:1 v/v) acidified

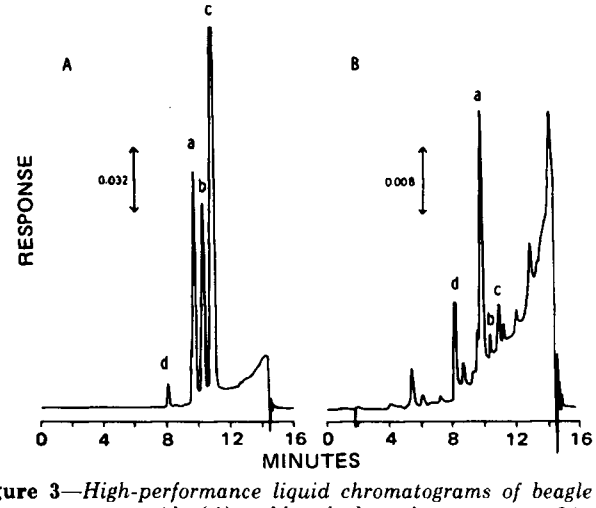

Figure 3—*High-performance liquid chromatograms of beagle dog plasma extracts at 4 hr (A) and beagle dog urine extracts at 24–48 hr (B) following a single oral dose of 142 mg of suxibuzone/kg. Key: a, γ-hydroxyphenylbutazone; b, oxyphenbutazone; c, phenylbutazone; and d, unknown metabolite.*

[12] Model 10A-RN-GP, Scientific Glass Engineering Ltd., North Melbourne, Australia.

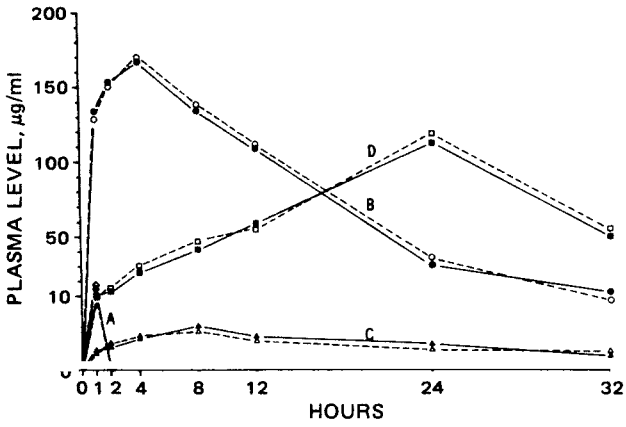

Figure 4—*Comparison of plasma levels of suxibuzone and its metabolites determined by HPLC (closed symbols) and GLC (open symbols) methods following a single oral dose of 142 mg of suxibuzone/kg to a beagle dog. with hydrochloric acid, was used for the extraction of suxibuzone and its metabolites from plasma and urine. Chloroform, methylene chloride, and ethylene dichloride could not be used as the solvent because of the decomposition, such as oxidation, of the extract during the extraction and evaporation.

A reversed-phase column[8] was used for the HPLC separation. Chromatographic separation of suxibuzone, 4-hydroxymethylphenylbutazone, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone was first examined using authentic samples. When a linear gradient system with methanol–0.01 *M* sodium acetate buffer (pH 4.0) was used as the mobile phase, suxibuzone and 4-hydroxymethylphenylbutazone were not separated, even when the initial methanol concentration was varied. As shown in Fig. 1, a linear gradient system with methanol–water or methanol–0.05 *M* KH_2PO_4 (0–100% methanol at 8%/min) gave good separation of suxibuzone and the four metabolites. Each compound gave only one chromatographic peak under this condition. Furthermore, no interfering peaks of biological extracts from the plasma and urine of a beagle dog were observed in either of these mobile phases.

On the basis of these results and the knowledge that phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone are major metabolites of suxibuzone (4), the linear gradient system with methanol–0.05 *M* KH_2PO_4 as the mobile phase, which had given the best separation of these compounds, was employed for subsequent experiments.

Methanol was used as a solvent for redissolving the residue obtained by the evaporation to dryness of the benzene–cyclohexane extract from plasma and urine since suxibuzone and its metabolites all are readily soluble in this solvent. The dissolution was made immediately before the chromatographic assay. No decomposition of suxibuzone and its metabolites in methanol was observed. Similar assay results also were obtained when water was used as a solvent for the sample residue.

The chromatogram of suxibuzone, 4-hydroxymethylphenylbutazone, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone extracted from beagle dog plasma following addition of 5.0 μg/ml of each compound and the chromatogram of a control plasma extract are shown in Fig. 2. The chromatogram of the beagle dog urine extract was similar to that of the plasma extract. The retention times of suxibuzone, 4-hydroxymethylphenylbutazone, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone were 11.0, 11.2, 10.5, 10.0, and 9.4 min, respectively, and the time required for the assay was 15 min. Each fraction eluted from the HPLC column was collected separately, and the substances were confirmed by mass spectrometric analysis; suxibuzone: *m/e* 438 [M^+], 308, 264, and 183; 4-hydroxymethylphenylbutazone: *m/e* 338 [M^+], 308, 264, and 183; phenylbutazone: *m/e* 308 [M^+], 252, and 183; oxyphenbutazone: *m/e* 324 [M^+], 268, and 199; and γ-hydroxyphenylbutazone: *m/e* 324 [M^+], 309, 280, 266, and 183.

Table II—Comparison of Urine Levels of Suxibuzone and Its Metabolites Determined by HPLC and GLC Methods following a Single Oral Dose of 142 mg of Suxibuzone/kg to a Beagle Dog

Compound	Mole Percent of Dose					
	0–12 hr		12–24 hr		24–48 hr	
	HPLC	GLC	HPLC	GLC	HPLC	GLC
Suxibuzone	ND[a]	ND	ND	ND	ND	ND
4-Hydroxymethylphenylbutazone	ND	ND	ND	ND	ND	ND
Phenylbutazone	0.04	0.05	0.98	1.04	1.23	1.27
Oxyphenbutazone	ND	ND	0.11	0.09	0.31	0.33
γ-Hydroxyphenylbutazone	0.85	0.82	1.96	1.93	19.11	18.99

[a] Not detectable.

The detection limits under these HPLC conditions were 0.1 μg/ml for suxibuzone and 4-hydroxymethylphenylbutazone and 0.05 μg/ml for the other suxibuzone metabolites. The present method had an accuracy of ±2.3–3.1% and very good reproducibility.

Known amounts (5, 25, and 50 μg/ml) of suxibuzone and the four metabolites were added to the plasma and urine (1.0 ml) of beagle dogs, and the recovery of each compound was determined. The results are given in Table I.

One metabolite, *p*,γ-dihydroxyphenylbutazone (4), showed an extraction recovery of <20–30% using benzene–cyclohexane; therefore, this metabolite could not be assayed quantitatively by the present method. A GLC method (4) showed the same result. Although chloroform and ethylene dichloride were able to extract this metabolite efficiently, these solvents were unsuitable because of its decomposition. The retention time for *p*,γ-dihydroxyphenylbutazone under the present HPLC conditions was 10.2 min, and this metabolite had no effect on the separation of suxibuzone and the other metabolites.

A 142-mg/kg (0.32-mmole) dose of suxibuzone was administered orally to the beagle dog, and the concentration of suxibuzone and its metabolites in the plasma and urine was determined using the present method. The chromatogram of the plasma extract at 4 hr and that of the urine extract at 24–48 hr after administration are shown in Figs. 3A and 3B, respectively. With the beagle dog, 4-hydroxymethylphenylbutazone was not detected, as was reported previously (4). The concentrations of suxibuzone and its metabolites in plasma and urine determined by the HPLC method were compared with those reported previously for a GLC determination (4) (Fig. 4 and Table II). The overall difference between the value obtained by the two methods was 4.6%.

The present assay then was applied to the plasma and urine of other animals and humans to which suxibuzone and its metabolites were added. The results obtained for the chromatographic separation, recovery, and sensitivity were in good agreement with those obtained with beagle dog plasma and urine.

The present method is simple and rapid and has high accuracy and sensitivity. It should be useful for basic and clinical pharmacological investigations on suxibuzone.

Kinetics of Hydrolysis of Methenamine

J. G. STROM, Jr., and H. WON JUN ˣ

Received March 19, 1979, from the *Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication April 25, 1980.

Abstract □ The kinetics of degradation of methenamine were studied in citrate–phosphate buffers between pH 2.0 and 7.4 at 37.5°. GLC was used to monitor the rate of hydrolysis. The conversion of methenamine to formaldehyde was found to be pH dependent in the buffers of constant ionic strength, with the reaction half-life decreasing from 13.8 hr at pH 5.8 to 1.6 hr at pH 2.0. The kinetics of degradation also were measured at 47, 57, and 67°, and the reaction obeyed the Arrhenius relationship. At pH 2.0, the activation energy was calculated to be 23.5 kcal/mole; at pH 5.1, it was 12.0 kcal/mole.

Methenamine (hexamethylenetetramine) is a urinary antibacterial useful in the long-term therapy of chronic urinary tract infections. The antibacterial activity of methenamine is derived from formaldehyde produced upon hydrolysis of methenamine in the bladder. The amount of hydrolysis is a function of the acidity of the urine (1).

BACKGROUND

Methenamine was introduced for the treatment of urinary infections in 1894 (2). Although this drug has been used for over 80 years and its pharmacological activity depends on the extent and rate of hydrolysis of the parent compounds in acidic media (3), there are few reported studies on the *in vitro* hydrolysis of methenamine. In 1935, Philippi and Löbering (4) studied the hydrolysis of methenamine in buffer solutions. Their assay method was based on the formation of a silver nitrate–methenamine complex. According to Slowick and Kelley (5), this procedure produces inaccurate and undependable results, so the findings of Philippi and Löbering (4) probably are in error.

A paper published by Tada (6) summarized work done from 1951 to 1958 (7–10) in Japan and listed the rates of decomposition of methenamine in hydrochloric acid at pH ≤1.6. Decomposition also was measured in acetic acid–sodium acetate buffer solutions in the pH range of ~4–6. Tada's (6) assay involved the titration of excess acid not consumed in the degradation reaction. Titration procedures normally are tedious and time consuming.

Investigations into the pharmacology of methenamine have been difficult because all of the methods are based on the measurement of formaldehyde liberated from methenamine. Early studies used methods that were relatively insensitive. Many of the analytical procedures are not applicable in the presence of intact methenamine (11). Most studies on urinary formaldehyde concentrations used the colorimetric method of Tanenbaum and Bricker (12). The acidity of the reagents used in this method recently was found to convert 20–30% of the residual methenamine to formaldehyde (13).

Useful scientific data for methenamine compounds generally are not available. The pharmacokinetics and mechanisms of action of this drug have not been well elucidated. Because of the use of other urinary tract antibacterials like nitrofurantoin and the sulfonamides, few recent studies on methenamine have been reported.

This report presents a study of the hydrolysis of methenamine between pH 2.0 and 7.4 in aqueous buffers. The rate of hydrolysis of methenamine was followed by measuring the change in the concentration of intact methenamine determined by the specific and accurate GLC procedure of Strom and Jun (14).

EXPERIMENTAL

Apparatus—The gas chromatograph[1] was equipped with a dual flame-ionization detector. A 1.8-m × 6-mm i.d. glass column was packed with 3% OV-17 on 80–100-mesh Chromosorb W-HP. The operating temperatures were 245° for the injection port, 190° (isothermal) for the column oven, and 250° for the detector. Nitrogen at a flow rate of 45 ml/min was the carrier gas. The flow rates of hydrogen and compressed air were adjusted to optimum sensitivity. The electrometer range was 10^{-10} amp/mv.

Calibration Curve—Methenamine[2] was recrystallized from absolute ethanol. Methylparaben[3] (methyl *p*-hydroxybenzoate), the internal standard, was used as received. Aliquots of 0.5, 1.5, 2.5, 5.0, 7.5, and 10 ml of methenamine solution (2 mg/ml in water containing 2 mg of methylparaben/ml) were added to individual 10-ml volumetric flasks and diluted to volume with water (containing 2 mg of methylparaben/ml). Each solution (1 μl) was injected into the chromatograph. The calibration curve was obtained by plotting the known concentration of methenamine *versus* the corresponding peak height ratio (methenamine/methylparaben).

Buffer Solutions—All buffer solutions were prepared in deionized, distilled water and were adjusted to an ionic strength of 0.5 with potassium chloride. Buffer solutions in the pH range of 2.0–7.4 were prepared by combining various amounts of 0.1 *M* citric acid and 0.2 *M* dibasic sodium phosphate stock solutions (15).

Stability Studies—*Effect of pH*—Amounts of methenamine equal to 0.75 mg/ml were weighed and placed in volumetric flasks. At time zero, the methenamine was dissolved in buffer solutions of pH 2.0, 2.4, 3.4, 4.6, 5.1, 5.5, 5.8, or 7.4 previously equilibrated at 37.5°. After dilution with the respective buffers, 10.0-ml samples were removed and placed in 16 × 125-mm culture tubes with polytef-lined screw caps. These tubes were placed into a constant-temperature water bath.

At suitable time intervals, one culture tube was removed and cooled to room temperature by quenching in an ice bath. One milliliter of the internal standard solution (22 mg of methylparaben/ml in methanol) was added, and the sample was subjected immediately to the GLC analysis. The pH was measured at the beginning and end of each run, and no significant change was found.

Effect of Temperature—Methenamine at 0.75 mg/ml also was studied kinetically at 47, 57, and 67° in pH 2.0, 5.1, and 7.4 buffers.

RESULTS AND DISCUSSION

Figure 1 shows a typical gas chromatogram obtained for an aqueous solution of methenamine (t_R = 0.8 min) and methylparaben, the internal standard (t_R = 1.7 min). Both methenamine and the internal standard gave sharp, well-resolved peaks (resolution, R_s = 5.4) with no tailing. A

Kinetics of Hydrolysis of Methenamine

J. G. STROM, Jr., and H. WON JUN ˣ

Received March 19, 1979, from the *Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication April 25, 1980.

Abstract □ The kinetics of degradation of methenamine were studied in citrate–phosphate buffers between pH 2.0 and 7.4 at 37.5°. GLC was used to monitor the rate of hydrolysis. The conversion of methenamine to formaldehyde was found to be pH dependent in the buffers of constant ionic strength, with the reaction half-life decreasing from 13.8 hr at pH 5.8 to 1.6 hr at pH 2.0. The kinetics of degradation also were measured at 47, 57, and 67°, and the reaction obeyed the Arrhenius relationship. At pH 2.0, the activation energy was calculated to be 23.5 kcal/mole; at pH 5.1, it was 12.0 kcal/mole.

peak that appeared repeatedly in all kinetic runs had a retention time of 1.25 min (point C in Fig. 1). This peak, possibly the hydrolysis product formaldehyde or, more probably, a polymer of formaldehyde, would be well resolved from both methenamine (R_s = 4.4) and from the internal standard (R_s = 2.2). A plot of the ratio of the peak height of methenamine to the height of the internal standard *versus* the concentration of methenamine produced a linear relationship between 0.10 and 2.00 mg/ml. The calibration curve had a slope of 0.89 ml/mg, an intercept of 3.24×10^{-2}, and a correlation coefficient of 0.9997.

The kinetics of hydrolysis of methenamine were followed at various pH values by monitoring the decrease of the ratio of the peak height for the peak at the methenamine retention time to the peak height of the internal standard as a function of time. A plot of the hydrolysis data obtained at various pH values is shown in Fig. 2.

The logarithms of the difference of the final peak height ratio, H_∞ (the peak height ratio at the end of 10 half-lives), and the peak height ratio at any time, H_t, *versus* time produced linear plots. The apparent first-order rate constants were calculated from the slopes of the linear regression lines fitted to:

$$\ln(H_t - H_\infty) = \ln(H_0 - H_\infty) - kt \qquad \text{(Eq. 1)}$$

where H_0 is the peak height ratio at time zero and k is the apparent first-order rate constant. At all of the pH values studied, H_∞ was essentially zero after storage for several days at the selected temperature, indicating that the reaction went to completion. The rate constants derived from the data are presented in Table I.

A concentration of 0.75 mg/ml was chosen as the initial concentration because this value is the expected physiological concentration following a normal dose in humans (16). Six hours would be the maximum time a solution of methenamine would remain in the bladder. No decomposition (*i.e.*, no change in the peak height ratio) was observed in the pH 7.4 buffer over a 6-hr period.

Table I—Apparent First-Order Rate Constants for Hydrolysis of Methenamine in Buffer at 37.5°

pH	k, $hr^{-1} \times 10^2$	$t_{1/2}$, hr	r^a
2.0	43.3	1.60	0.9978
2.4	32.7	2.12	0.9848
3.4	22.4	3.09	0.9920
4.6	18.6	3.73	0.9993
5.1	8.36	8.29	0.9882
5.5	6.35	10.9	0.9856
5.8	5.01	13.8	0.9935
7.4	—[b]	—	

[a] Correlation coefficient for the linear regression line. [b] No observable degradation over the time interval studied.

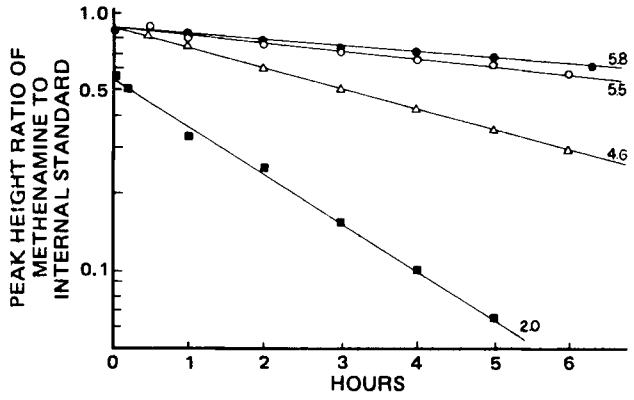

Figure 2—*Semilogarithmic plots of the ratio of the height of the GLC peak for methenamine to the peak for the internal standard* versus *time at specified pH values. Each point is an average of two kinetic runs. Key: ●, pH 5.8; ○, pH 5.5; △, pH 4.6; and ■, pH 2.0.*

The effect of temperature on the hydrolysis rate was investigated at pH 2.0, 5.1, and 7.4 at several temperatures. Table II lists the apparent first-order rate constants calculated at each temperature for each pH value. There was no observable change in the peak height ratio in pH 7.4 buffer at any temperature over a 6-hr period. Arrhenius plots of the logarithms of the observed rate constants *versus* $1/T$ produced straight lines (Fig. 3). The activation energy for the reaction then was calculated from the slopes of the lines fitted to the data (Table II).

The studies of Tada (6) showed that:

$$k_{obs} = (k_w + k_h[H^+])f^+ \qquad \text{(Eq. 2)}$$

where k_{obs} is the observed rate constant; k_w and k_h are the rate constants for the water solvolysis reaction and the hydrogen-ion-catalyzed reaction, respectively; and f^+ is the fraction of methenamine present in the protonated form. Tada (6) calculated k_w and k_h values at 30° of 6.05×10^{-6} sec^{-1} and 6.33×10^{-4} liter/mole/sec, respectively. Tada (6) also determined the dissociation constant of protonated methenamine to be 7.0×10^{-6}, from which values of f^+ as a function of pH can be calculated. This relationship is shown graphically in Fig. 4. The value from Table I for hydrolysis at pH 2.0 and 37.5° was set equal to the value from Tada (6) at pH 2.0 and 30°, and the remaining values from Table I were scaled

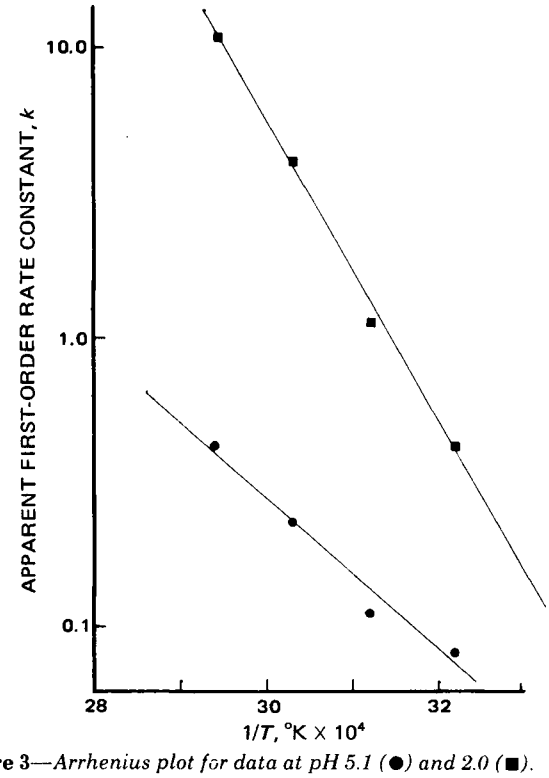

Figure 3—*Arrhenius plot for data at pH 5.1 (●) and 2.0 (■).*

Table II—Apparent First-Order Rate Constants and Thermodynamic Parameters for the Hydrolysis of Methenamine at Various Temperatures

pH	k, $hr^{-1} \times 10$				E_a, kcal/mole	ln A^a	r^b
	37.5°	47°	57°	67°			
2.0	4.33	11.5	41.9	111.0	23.5	37.2	0.9985
5.1	0.836	1.11	2.33	4.27	12.0	16.8	09853

[a] A is the frequency factor. [b] The correlation coefficient for the linear regression line obtained by fitting the data to the Arrhenius relationship.

accordingly and plotted in Fig. 4. The scaled values from this study agreed very well with the values predicted by Tada (6).

The Arrhenius activation energy (E_a) of 23.5 kcal/mole at pH 2.0 and an ionic strength of 0.5 compared favorably with Tada's (6) value of 23.3 kcal/mole in highly acidic media at an ionic strength of 3.08. This E_a value can be largely associated with the hydrogen-ion-catalyzed reaction. The E_a value of 12.0 kcal/mole calculated at pH 5.1 would be almost entirely a function of the rate constant of the water reaction, k_w.

The conversion of methenamine to formaldehyde in biological fluids, particularly urine, is of clinical importance since formaldehyde is the pharmacologically active product and is effective against urinary bacteria only above a concentration of ~20 μg/ml (17). Methenamine solution remains in the bladder for only a certain time (~6 hr), and it is necessary to know the amount of conversion that occurs over that period. It also would be useful for successful therapy to know the effect of the urinary pH on the rate of that conversion. Several recent reports discussed hydrolysis of methenamine in urine (18–20). Possible errors from the assay method used in these studies were minimized in part by use of the Jackson and Stamey method (13), a modification of the Tanenbaum and Bricker (12) procedure, or by use of the Chen and Chafetz method (21). A possibly better method would be use of the Jackson and Stamey procedure to quantitate the free formaldehyde concentration simultaneously with the GLC procedure for intact methenamine.

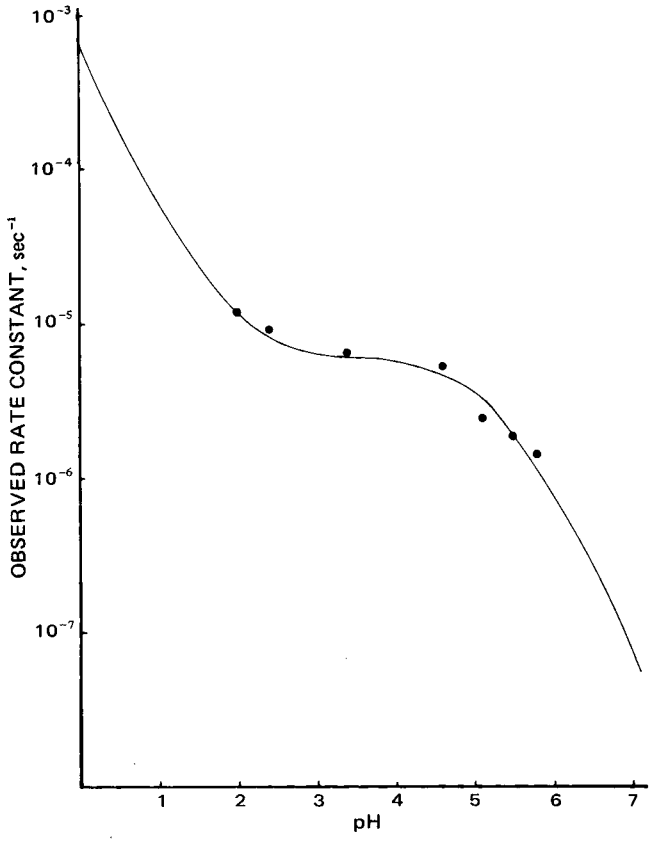

Figure 4—*The pH–rate profile of methenamine degradation. The solid line is the predicted relationship from the work of Tada (6). The points are the data from Table I scaled to 30°.*

According to the data of the present study, methenamine should circulate in the blood as the intact drug and be rapidly converted to formaldehyde when it reaches the acidic urine. If the drug were converted at a similar rate in the urine as in the buffers of this study, sufficient formaldehyde would be produced within 2 hr at pH ≤5.8. However, it may not be possible to make quantitative predictions of the *in vivo* behavior of methenamine from the data of this study because of possible kinetic salt effects. Tada's (6) work demonstrated a linear increase in the observed rate constant with an increase in the ionic strength up to a value of 3 or 4. This effect was shown for about 15 mono- and divalent salts, such as sodium chloride, sodium iodide, potassium chloride, potassium iodide, lithium chloride, calcium chloride, and ammonium chloride.

The reported study demonstrated that the GLC procedure can be used to observe and quantitate the degradation kinetics of methenamine *in vitro* in a buffer system.

Quantitation of Carbenicillin Disodium, Cefazolin Sodium, Cephalothin Sodium, Nafcillin Sodium, and Ticarcillin Disodium by High-Pressure Liquid Chromatography

V. DAS GUPTA [x] **and KENNETH R. STEWART** [*]

Received February 22, 1980, from the *College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication May 2, 1980. *Ben Taub General Hospital Pharmacy, Houston, TX 77030.

Abstract □ High-pressure liquid chromatographic (HPLC) methods for the quantitation of carbenicillin, cefazolin, cephalothin, nafcillin, and ticarcillin were developed. The stability of 2% solutions of the antibiotics in normal saline and in 5% dextrose in water were studied at 24 and 5°. The assays were conducted using a previously reported colorimetric method, and some assays also were performed using HPLC. For discolored solutions of cephalothin, the colorimetric method was not stability indicating. The percent relative standard deviations by HPLC based on six injections were 1.69, 0.94, 1.30, 1.59, and 1.6 for carbenicillin, cefazolin, cephalothin, nafcillin, and ticarcillin, respectively. Both carbenicillin and ticarcillin apparently may be mixtures of two isomers at equilibrium with each other. The shelflives recommended by the manufacturers at 5° may be too conservative.

Keyphrases □ Carbenicillin disodium—high-pressure liquid chromatographic analysis □ Cefazolin sodium—high-pressure liquid chromatographic analysis □ Cephalothin sodium—high-pressure liquid chromatographic analysis □ Nafcillin sodium—high-pressure liquid chromatographic analysis □ Ticarcillin disodium—high-pressure liquid chromatographic analysis □ Antibiotics—carbenicillin disodium, cefazolin sodium, cephalothin sodium, nafcillin sodium, and ticarcillin disodium, high-pressure liquid chromatographic analysis

The preparation of intravenous admixtures is a common service provided by hospital pharmacies in the United States. Most pharmacists are concerned about the stability of the solutions after mixing. Some of these solutions contain antibiotics such as carbenicillin disodium, cefazolin sodium, cephalothin sodium, nafcillin sodium, and ticarcillin disodium in normal saline or in 5% dextrose in water. The stability studies must be conducted using a stability-indicating assay.

Pharmaceutical manufacturers have begun to report limited information on the stability of antibiotics in intravenous admixtures. For example, the following information has been reported in the package inserts. Intravenous solutions of carbenicillin disodium (1), cefazolin sodium (2), cephalothin sodium (3), and ticarcillin disodium (4) are stable for 1 day at room temperature and for 3, 4, 4, and 3 days, respectively, when stored in a refrigerator. The intravenous solution of nafcillin sodium has been reported to be stable for 3 days at room temperature and for 7 days when stored in a refrigerator (5).

BACKGROUND

Brief studies on the stability of frozen and refrigerated solutions of cefazolin sodium (6, 7) and cephalothin sodium (8, 9) have been reported. These reports did not describe the methodology in detail, especially the analytical techniques. One study (9) recommended expiration dates of 2 days at 5° and of 6–24 hr at 25° for a 1% solution of cephalothin sodium in normal saline or in 5% dextrose in water. Other reports (6–8) recommended an expiration date of 4 days for both cefazolin sodium and cephalothin sodium when stored in a refrigerator. Longer expiration dates were recommended for frozen solutions.

Zia and Zargarbashi (10) reported the kinetics of carbenicillin sodium in aqueous solution at 35°. The degradation products of cephalothin and cefazolin in alkaline and neutral aqueous solutions at 35° were reported also (11).

Several analytical techniques have been used for the stability studies. A fluorometric method for cephalothin and cefazolin was reported (12). Zia and Zargarbashi (10) preferred the iodometric method, and Yamana and Tsuji (11) used anion-exchange chromatography for cephalothin and high-pressure liquid chromatography (HPLC) for cefazolin. One method for the quantitation of cefazolin was based on a reaction with hydroxylamine hydrochloride (13). This method was modified (14) and applied to other penicillins including carbenicillin and cephalothin.

The high experimental errors inherent in microbiological assays were reported (15), and the factors affecting the iodometric assay technique and its limitations were described (16, 17).

The purposes of this investigation were to develop accurate and reproducible stability-indicating assays for the quantitation of carbenicillin disodium (I), cefazolin sodium (II), cephalothin sodium (III), nafcillin

[a] By the HPLC method. [b] Normal saline. [c] Not assayed on this day. [d] Solution had discolored to light yellow. The intensity of the color increased with further storage. [e] Five percent dextrose in water. [f] There was precipitation in the bag (light yellow).

sodium (IV), and ticarcillin disodium (V) using HPLC and to study the stability of some intravenous admixtures containing these antibiotics. All of the antibiotics studied have a β-lactam ring.

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were USP, NF, or ACS quality and were used without further purification. The sterile powders of carbenicillin disodium[1], cefazolin sodium[2], cephalothin sodium[2], nafcillin sodium[3], and ticarcillin disodium[4] were used as received. The powder of III contained sodium bicarbonate and the powder of IV contained sodium citrate as a buffering agent. The presence of buffering agents did not interfere in these investigations.

Apparatus—The high-pressure liquid chromatograph[5] was equipped with a multiple-wavelength detector[6], a recorder[7], and an integrator[8].

Column—A semipolar[9] column (30 cm long × 4 mm i.d.) was used.

Chromatographic Conditions—The chromatographic conditions are reported in Table I.

Preparation of Solutions—The standard solutions in water were prepared fresh. Their concentrations are reported in Table I. Solutions of other concentrations were prepared fresh as needed using a simple solution method.

Preparation of Antibiotic Solutions (Similar to Intravenous Admixtures)—Solutions of I–V (2.00%)[10] were prepared in either sterile normal saline[11] or in sterile 5% dextrose in water[11]. The final solutions were not sterile. All solutions were divided into two parts and transferred to the original containers[12]. One set of the solutions was stored at room temperature (24 ± 1°), and the other set was stored in a refrigerator (5 ± 1°). The solutions were assayed at appropriate intervals.

Assay Procedures—*Colorimetric Procedure*—The colorimetric procedure was reported previously (14). The method has been claimed to be stability indicating. The results are reported in Tables II and III.

HPLC Procedures—At appropriate intervals, solutions of antibiotics also were assayed using HPLC methods developed in this laboratory. Before analysis, all solutions were diluted with water to the appropriate concentrations (identical to the standard solutions; see Table I). A 20.0-μl aliquot of the assay solution was injected into the chromatograph using the described conditions (Table I). For comparison, an identical volume of the appropriate standard solution was injected after the assay solution eluted.

Calculations—Since preliminary investigations indicated that the peak areas (also peak heights) were related directly to the concentration (ranges tested were: I, 8–16 μg; II, 0.8–1.6 μg; III, 0.5–1.2 μg; IV, 1.3–2.0 μg; and V, 8–16 μg), the results were calculated using:

$$\text{percent of label claim} = \frac{(Ph)_a}{(Ph)_s} \times 100 \qquad \text{(Eq. 1)}$$

where $(Ph)_a$ is the peak height of the assay solution and $(Ph)_s$ is the peak height of the standard solution of identical concentration. For I and V, heights of the taller peaks (peak 1) were compared. The results are presented in Tables II and III and Figs. 1–3. The pH values are presented in Table IV.

RESULTS AND DISCUSSION

Carbenicillin—The results (Table II) indicate that the manufacturer-recommended expiration date of 1 day at room temperature is reasonable. At room temperature, a 2.00% solution of carbenicillin appears to have greater stability in normal saline (60.1% potency after 15

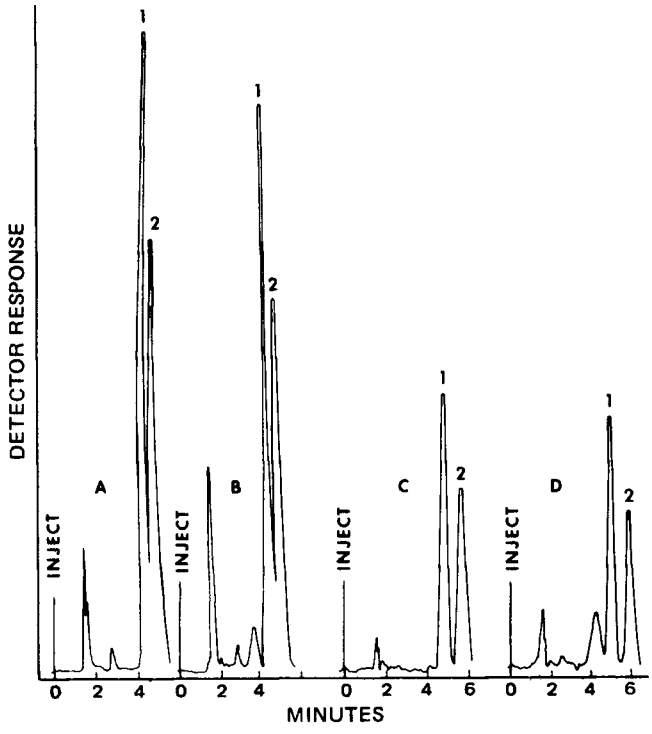

Figure 1—*Sample chromatograms. Peaks 1 and 2 in chromatograms A and B are from ticarcillin (V); in chromatograms C and D, they are from carbenicillin (I). Key: A and C, standard solutions of V and I, respectively; and B and D, 5-day-old solutions of V and I, respectively, in normal saline (storage at 24°). The chromatographic conditions are given in Table I.*

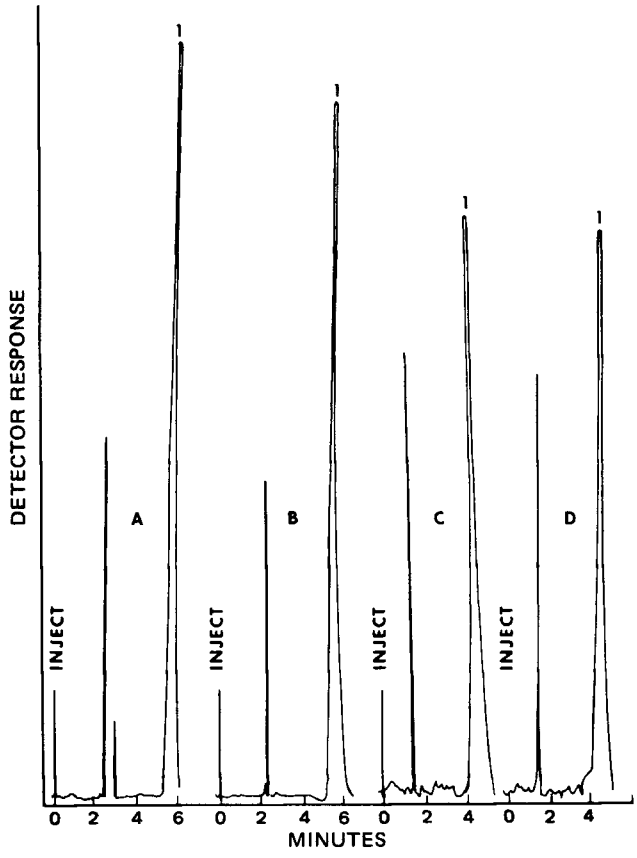

Figure 2—*Sample chromatograms. Peak 1 in chromatograms A and B is from cefazolin (II); in chromatograms C and D, it is from nafcillin (IV). Key: A and C, standard solutions of II and IV, respectively; B, 5-day-old solution of II in normal saline (storage at 24°); and D, 15-day-old solution of IV in normal saline (storage at 5°). The chromatographic conditions are given in Table I.*

days of storage) *versus* 31.4% (after only 11 days of storage) in 5% dextrose in water. After 7 days, the potency retained in dextrose solution was about the same as that after 15 days in normal saline.

Both solutions were stable (based on 90% potency) for 15 days at 5°. Therefore, the manufacturer-recommended expiration date of 3 days (1) is too conservative.

The colorimetric assay reported previously (14) appears to be stability indicating. The results by the literature method and by the HPLC method were almost the same (Table II), considering experimental errors. Nevertheless, the HPLC method gave more information than the assay results alone. For example, it appears that carbenicillin is a mixture of two isomers (peaks 1 and 2 in Fig. 1C), and the percent decomposition in both isomers was the same. The isomers apparently are at equilibrium with each other, which is normal.

For the HPLC method, the percent relative standard deviation based on six injections was 1.69.

Cefazolin—The results (Table II) indicate that the cefazolin solutions, both in normal saline and in dextrose, were stable for at least 5 days (based on 90% potency) at room temperature and for 15 days at 5°. Therefore, the recommended (2) expiration dates of 1 and 4 days at room temperature and at refrigerator temperature, respectively, are very conservative.

Of the five antibiotics studied, cefazolin appears to have the greatest stability (Tables II and III). This result may have been due to the fact that the pH values of cefazolin solutions increased during storage (Table IV), while the pH values of all of the other solutions decreased (Table IV).

Table III—Colorimetric Assay Results for Solutions (2 g/100 ml) Stored at 4 ± 1°

Antibiotic	Solvent	Percent of Potency Retained (Based on Label Claim) after 4 days	7 days	15 days
Carbenicillin	NS[a]	98.4	97.5	94.0
Cefazolin	NS	99.5	94.7	94.7
Cephalothin	NS	96.5	96.3	95.0
Nafcillin	D5W[b]	97.4	96.0	91.8
Ticarcillin	NS	97.9	94.6	91.0

Antibiotic	Solvent	Percent of Potency Retained (Based on Label Claim) after 3 days	4 days	7 days	8 days	9 days	9 days (HPLC)[c]	15 days	15 days (HPLC)[c]	24 days
Carbenicillin	D5W	100.0	—[d]	99.6	—[d]	99.2	99.7	90.9	—[d]	—[d]
Cefazolin	D5W	—[d]	99.7	—[d]	97.1	96.5	95.2	95.0	—[d]	95.1
Cephalothin	D5W	—[d]	100.0	—[d]	96.4	96.8	96.5	95.0	93.5	—[d]
Nafcillin	NS	99.8	—[d]	98.3	—[d]	—[d]	94.9	95.5	95.4	94.1
Ticarcillin	D5W	99.3	—[d]	98.4	—[d]	—[d]	96.6	97.6	93.3	—[d]

[a] Normal saline. [b] Five percent dextrose in water. [c] By the HPLC method. [d] Not assayed on this day.

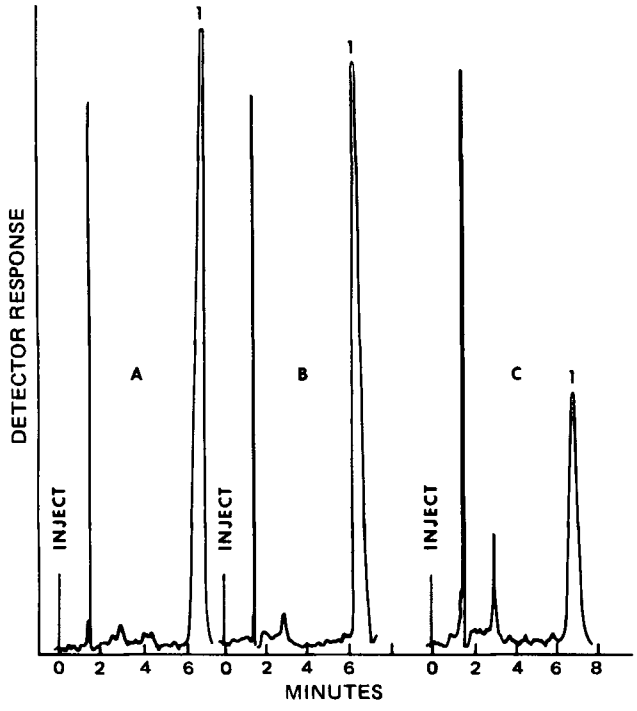

Figure 3—*Sample chromatograms. Peak 1 is from cephalothin (III). Key: A, standard solution; B, 15-day-old solution of III in 5% dextrose in water (storage at 5°); and C, 11-day-old solution of III in 5% dextrose in water (storage at 24°). The chromatographic conditions are given in Table I.*

The results using the HPLC method (Table II) were similar to those obtained using the literature method (14). Since these solutions did not decompose much, there was no significant difference between the chromatogram of a standard solution (Fig. 2A) and a chromatogram from a 5-day-old solution in normal saline when stored at room temperature (Fig. 2B).

For the HPLC method, the percent relative standard deviation based on six injections was 0.94.

Cephalothin—The results at room temperature (Table II) indicate that the manufacturer-recommended (3) expiration date of 1 day is reasonable. However, if stored in a refrigerator, the solutions were stable for at least 15 days (Table II), compared to the manufacturer-recommended (3) shelflife of 4 days. Moreover, the solutions that were stored in a refrigerator remained colorless during the investigation. However, at room temperature, the solutions started discoloring to a light-yellow color within 48–72 hr. The intensity of this color increased on further storage.

Once the solutions became discolored, the colorimetric analysis gave misleading results (Table II). For example, after 5 days of storage at 24°, cephalothin in normal saline and in dextrose solutions indicated a potency of ~78% (Table II). When assayed using the HPLC method (Fig. 3), the potencies were 62.2 and 56.1% for solutions in normal saline and dextrose, respectively (Table II). After 11 days, the solution with dextrose indicated 60.6% potency by the colorimetric method compared to 40.9% by the HPLC method. Therefore, the literature method (14) probably is unreliable for stability studies of III once the solutions become discolored.

For the HPLC method, the percent relative standard deviation based on six injections was 1.3.

Nafcillin—The results at room temperature (Table II) indicate that the expiration date of 3 days recommended by the manufacturer (5) is reasonable. However, when stored in a refrigerator, the solutions were stable for at least 15 days (Table III). The manufacturer recommends (5) an expiration date of 7 days.

The results with the HPLC method were similar (Table II) to those with the colorimetric method (14). For the HPLC method, the percent relative standard deviation based on six injections was 1.59.

Ticarcillin—The results at room temperature (Table II) indicate that the manufacturer-recommended shelflife (4) of 1 day is reasonable. However, when stored in a refrigerator, the solutions were stable for at least 15 days (Table III). Therefore, the recommended shelflife of 3 days is too conservative.

Table IV—Change in pH of the Antibiotic Solutions (2 g/100 ml) with Various Storage Times and Temperatures

Antibiotic	Solvent	pH Value (±0.1) after Initial	1 day at 24°	7 days at 24°	7 days at 5°
Carbenicillin	NS[a]	6.5	6.0	5.6	6.4
Cefazolin	NS	4.4	5.8	6.4	5.2
Cephalothin	NS	7.5	6.4	4.6[b]	7.3
Nafcillin	D5W[c]	6.6	6.4	5.6	6.4
Ticarcillin	NS	6.1	5.8	5.6	5.9

Antibiotic	Solvent	pH Value (±0.1) after Initial	1 day at 24°	15 days at 24°	15 days at 5°
Carbenicillin	D5W	6.5	5.9	5.1	5.9
Cefazolin	D5W	4.6	5.6	6.2	5.6
Cephalothin	D5W	7.6	6.3	4.6[b]	6.9
Nafcillin	NS	6.6	6.4	4.6[d]	6.1
Ticarcillin	D5W	6.2	5.7	5.1	5.6

[a] Normal saline. [b] Solution had discolored to yellow. [c] Five percent dextrose in water. [d] Precipitation occurred (light yellow).

The colorimetric analysis appears to be stability indicating, but the HPLC method gave some new information. Ticarcillin appears to be a mixture of two isomers (Figs. 1A and 1B). These isomers are at equilibrium, as explained for carbenicillin, since the percent decomposition in both isomers was similar.

For the HPLC method, the percent relative standard deviation based on six injections was 1.6.

The data could not be treated mathematically since the pH values of the solutions were not constant (Table IV). The degradation products of cefazolin and cephalothin were reported previously (11). General information about the degradation of carbenicillin (10) and other penicillins (18) is available in the literature.

High-Pressure Liquid Chromatographic Determination of Salicylsalicylic Acid, Aspirin, and Salicylic Acid in Human Plasma and Urine

L. I. HARRISON ˣ, M. L. FUNK, and R. E. OBER

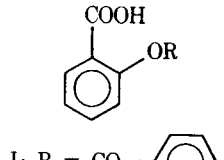
Received March 10, 1980, from the *Drug Metabolism Department, Riker Laboratories, Inc., Subsidiary of 3M, 3M Center, St. Paul, MN 55144.* Accepted for publication May 2, 1980.

Abstract □ A high-pressure liquid chromatographic method was developed for the separation and quantitation of salicylsalicylic acid (I), aspirin (II), and salicylic acid (III) in human plasma and urine. The method for plasma involves the selective extraction of I–III and an internal standard, α-phenylcinnamic acid, into methylene chloride from acidified plasma, followed by evaporation of the organic phase and dissolution of the residue in methanol. A 25-μl aliquot is analyzed on a reversed-phase column with UV detection. Urine is treated similarly with hexane as the extracting solvent. If 300 nm is used as the monitoring wavelength, the assays of I and III are linear over the concentration range of 1–150 μg/ml in both plasma and urine. If 280 nm is used as the monitoring wavelength, II can be quantitated along with I and III; however, detector sensitivities of I and III are two to three times greater at 300 nm. The accuracy and precision of the methods for I–III are adequate for clinical pharmacokinetic studies. Following therapeutic doses of I in humans, the method was applied successfully to the determination of I and III in plasma and urine.

Keyphrases □ Aspirin—high-pressure liquid chromatographic analysis with salicylsalicylic acid and salicylic acid in human plasma and urine □ Salicylsalicylic acid—high-pressure liquid chromatographic analysis with aspirin and salicylic acid in human plasma and urine □ Salicylic acid—high-pressure liquid chromatographic analysis with salicylsalicylic acid and aspirin in human plasma and urine □ High-pressure liquid chromatography—analysis, salicylsalicylic acid, aspirin, and salicylic acid in human plasma and urine

Salicylsalicylic acid (I) was developed as a salicylate alternative for aspirin (II) and sodium salicylate. Although I was available as early as 1920, its usefulness in salicylate therapy has been explored only recently (1). Double-blind clinical trials have shown that I causes significantly less GI bleeding and gastric erosions at anti-inflammatory doses than does II (2–6). The therapeutic response of arthritic patients to I appears to be equivalent to that of II (6–11). Thus, I appears to be an important salicylate derivative and offers efficacy with diminished GI distress.

Compound I is hydrolyzed in the body to give salicylic acid (III). Metabolic studies of I measured only levels of III following single and multiple doses of I (5, 11–16). Studies of plasma and urine levels of I used the difference between levels of III before and after hydrolysis as an estimate of the concentrations of I (11, 16). A high-pressure liquid chromatographic (HPLC) assay was described recently for monitoring I as an impurity in aspirin tablets (17). The present report describes a specific and sensitive HPLC assay for the quantitation of I–III in biological samples.



I: R = CO— (OH)

II: R = $COCH_3$

III: R = H

[a-d] See Table I.

EXPERIMENTAL

Materials—All solvents were glass distilled and suitable for liquid chromatographic analyses[1], and all reagents were analytical grade. Analytically pure standards of I[2]–III and α-phenylcinnamic acid[3] were used. Aqueous solutions were prepared in distilled water. Drug-free plasma and urine were obtained from normal human volunteers.

A high-pressure liquid chromatograph[4] equipped with a septumless injector[5] and a variable-wavelength UV detector[6] were used. The detector was operated at either 0.02 or 0.04 aufs. The mobile phase of methanol–1% acetic acid (60:40 v/v) was pumped at 2.0 ml/min (2800 psi) through a stainless steel column (30 cm × 4 mm i.d.) packed with a high-efficiency, reversed-phase packing[7].

Methods—α-Phenylcinnamic acid served as the internal standard. To a 0.5-ml aliquot of plasma were added 0.9 ml of 0.27 *N* HCl, 10 μg of α-phenylcinnamic acid (100 μl of a 0.1-mg/ml solution in methanol), and 10 ml of methylene chloride. The tubes were shaken for 15 min on a mechanical shaker at 125 cycles/min and centrifuged for 5 min at 750×*g*.

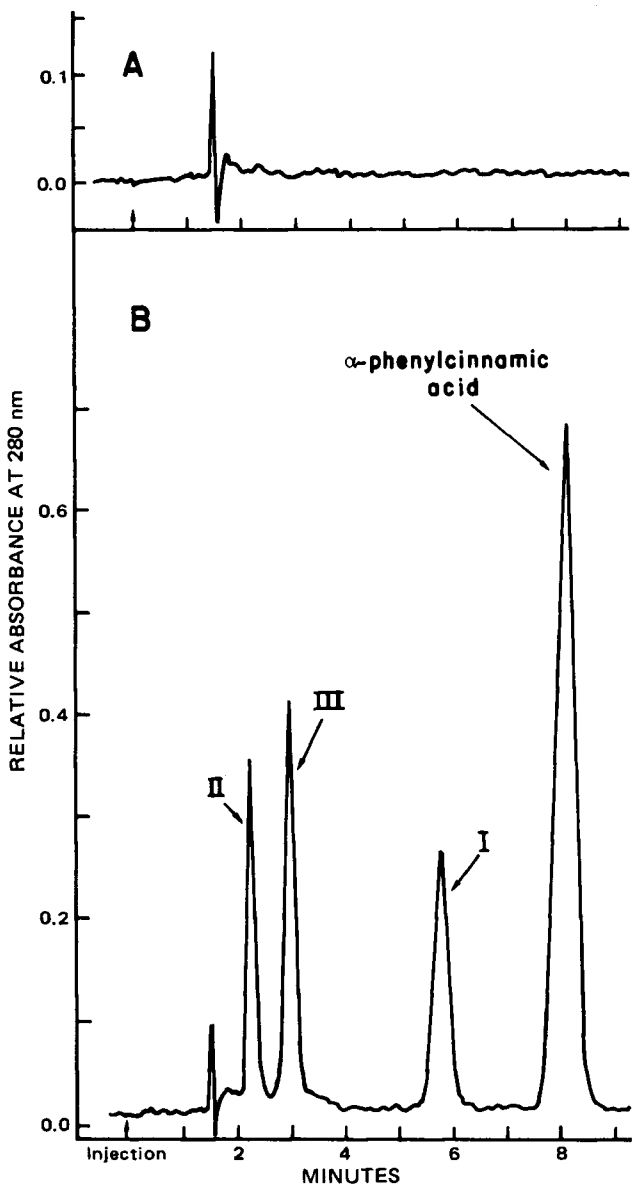

Figure 2—*HPLC assay of I–III at 280 nm. Key: A, drug-free human plasma; and B, plasma containing 20 μg of I–III and α-phenylcinnamic acid/ml.*

The methylene chloride phase was separated and evaporated to dryness[8]. The residue was dissolved in 0.5 ml of methanol, and 25 μl was injected into the chromatograph.

A similar procedure was used for the urine extraction, except that 2-ml urine aliquots were extracted with 10 ml of hexane. A solvent less polar than methylene chloride was required for the urine extractions to eliminate interfering substances.

Plasma and urine standards were prepared by adding I and III (and in some cases II) dissolved in 100 μl of methanol to aliquots of drug-free human plasma and urine. UV absorbance was measured at 300 nm. Peak height ratios were used to determine concentrations.

RESULTS AND DISCUSSION

Reversed-phase HPLC was an effective method to quantitate I and III simultaneously in human plasma and urine. Figure 1 shows a representative chromatogram. Baseline separation between I, III, and α-phenylcinnamic acid (the internal standard) was achieved. No interference by endogenous materials from either drug-free human plasma or urine was seen (Fig. 1). Under the experimental conditions, the elution

[a–d] See Table I.

volumes for I, III, and the internal standard were 11.5 (5.8 min), 6.0 (3.0 min), and 16 (8.0 min) ml, respectively.

The assay of I and III was linear over the concentration range of 1–150 μg/ml in both plasma and urine. The minimum detectable level of I and III was 1 μg/ml. However, this sensitivity could be increased by adding <500 μl of methanol at the final extraction step. The accuracy and precision of the method were tested at three concentrations of I and III in plasma. Both compounds were present in all plasma samples; five samples of each concentration were assayed on the same day (Table I).

The coefficient of variation was ≤4% for all three levels of I and III. Thus, good precision was demonstrated. The accuracy of the method is indicated by the mean error between the detected and theoretical values. The mean error was small in most cases, except for III at 5 μg/ml. Similar accuracy and precision were seen with urine samples (Table II).

Compound II was quantitated along with I and III by changing the wavelength to 280 nm (Fig. 2). Compound II had weak UV absorbance at 300 nm (Fig. 1) and could not be quantitated at that wavelength. The elution volume for II was 4.5 ml (2.3 min). Since the elution volumes for I, III, and the internal standard were unchanged, the analysis time remained at 9 min/sample. The assay at 280 nm for II (and also for I and III) was linear over the concentration range of 2–100 μg/ml. The accuracy and precision of the method at 280 nm were tested at three concentrations of I–III in plasma and were similar to those observed at 300 nm (Table III).

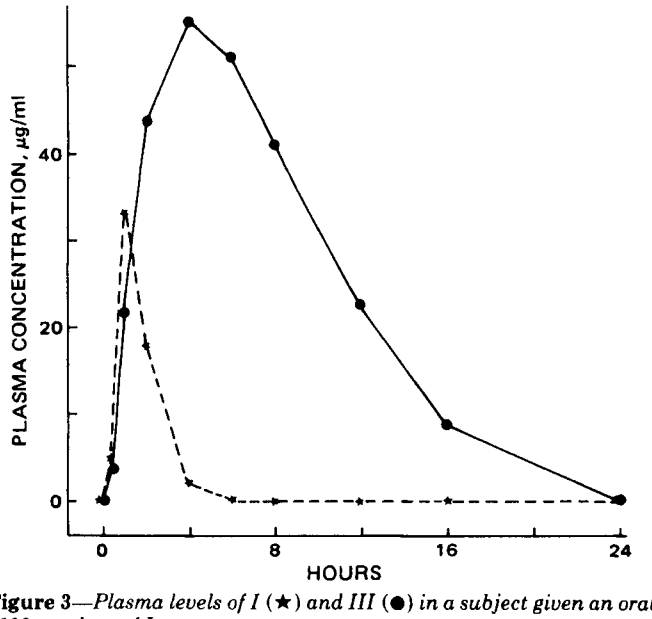

Figure 3—*Plasma levels of I (★) and III (●) in a subject given an oral 1000-mg dose of I.*

For maximum sensitivity, I and III should be quantitated at 300 nm and II should be quantitated at 280 nm. As shown in Fig. 2, the 280-nm wavelength can be used to quantitate I–III simultaneously in plasma, although the absorbances of I and III at 280 nm under the present experimental conditions were only 65 and 35%, respectively, of the absorbances at 300 nm.

The HPLC method was used in the analysis of plasma and urine samples from a 10-subject absorption study of I. The healthy male volunteers were given a single, oral, 1000-mg dose of I as two tablets[9]. Heparinized blood samples were taken immediately before dosing and at 0.5, 1, 2, 4, 6, 8, 12, 16, and 24 hr postdosing. The plasma levels of I and III were determined by the HPLC method at 300 nm and are plotted for a representative subject in Fig. 3. A peak plasma level for I of 33.4 μg/ml was reached in this subject at 1 hr postdosing, and the decrease in plasma levels followed a monoexponential decline with an estimated plasma half-life for I of 0.8 hr. The *in vivo* hydrolysis of I to III resulted in a peak plasma level of III of 55.2 μg/ml at 4 hr; the plasma half-life of III was 3.5 hr. The 24-hr urinary excretions of I and III in this subject were 10.0 and 29.8 mg, respectively.

During this absorption study, analytical results showed that the assay yielded only minimal day-to-day and operator-to-operator variations. Eleven plasma standard curves were run for each compound over a 2-month period. The coefficient of correlation of each plasma standard curve was 0.997 or better for I; it was 0.994 or better, with one exception (0.989), for III. Zero was contained within the standard error of the intercept. Linear regression of a line forced through the origin for the mean standard curve gave slopes of 0.035 ± 0.0031 (mean ± *SD*) for I and 0.084 ± 0.0062 for III. Comparable agreement was obtained for four urine standard curves.

Several multiple-dose studies at anti-inflammatory doses have shown that the assay is more than adequate to determine plasma concentrations of I in humans. However, simultaneous quantitation of III may require sample dilution to keep the level of III below 150 μg/ml. The HPLC assay requires 9 min/sample. Approximately 30 samples can be extracted and analyzed daily.

Preparation, Characterization, and Stability of New Prostaglandin E_2 Gel for Local Administration

A. S. HARRIS *x, A. KIRSTEIN-PEDERSEN ‡, P. STENBERG §, U. ULMSTEN ¶, and L. WINGERUP ¶

Received March 18, 1980 from **Perstorp AB, Box 5000, S-28400 Perstorp, Sweden*, the ‡*Department of Pharmacology, University of Aarhus, DK-8000 Aarhus C, Denmark*, and the §*Hospital Pharmacy and* ¶*Departments of Obstetrics and Gynecology, Malmö General Hospital, S-214-01 Malmö, Sweden.* Accepted for publication May 2, 1980.

Abstract □ A new gel delivery system for the local application of prostaglandin E_2 consists of drug incorporated in the matrix of a cross-linked starch polymer. The properties of the starch powder provide a stabilizing milieu for the labile prostaglandin E_2 and, by addition of saline, a ready-to-use gel for immediate local administration. The gel offers advantages over existing preparations in terms of chemical and microbiological stability, homogeneity, and dosage safety. This report outlines the pharmaceutical aspects involved in the development of the delivery system.

Keyphrases □ Prostaglandin E_2—preparation, characterization, and stability of gel delivery system □ Drug delivery systems—prostaglandin E_2 gel, preparation, characterization, and stability

The discovery, isolation, and characterization of the various prostaglandins have created substantial interest in their physiological role and therapeutic applications (1). Their use in human reproduction (2) clearly demonstrates their clinical value. However, the broad spectrum of pharmacological responses and the general instability of the prostaglandins have made it difficult to achieve specific therapeutic aims without significant side effects.

BACKGROUND

In the E series, for example, the cervical ripening effect of prostaglandin E_2 first was observed in early studies using intravenous infusion prior to therapeutic abortion or induction of labor in patients at term (3). The large dose required to achieve these effects was associated with frequent systemic side effects such as vomiting and diarrhea (4). The most recent phase in such use of prostaglandin E_2 has been a low dose local (intracervical or vaginal) administration in a viscous gel or a lipid-based pessary (5, 6).

The prostaglandin E_2 regimen is simple and highly acceptable to patients, causing no significant side effects and improving the prospects of labor. There is now extensive evidence of the efficacy and safety of this method (7–9). The obstacle to wider utilization lies in the inherent lability of prostaglandin E_2 compared to the less effective prostaglandin $F_{2\alpha}$ (10). Existing formulations in simple gels and pessaries do not provide sufficient long-term stability and involve problems concerning homogeneity, sterility, and dosage safety (11, 12).

The absence of a suitable delivery vehicle and a standardized preparation of the gel has discouraged commercial production and hindered clinical usage of the prostaglandin E_2 technique. This report presents a new prostaglandin E_2 gel delivery system and affords a definite solution to the problems afflicting the practical handling of the drug for local administration. This system consists of drug distributed in the matrix of a cross-linked starch derivative. The properties of the starch powder provide a stabilizing milieu for the labile prostaglandin E_2 and, by addition of saline, a ready-to-use gel for immediate local administration.

The safety and efficacy of the starch gel prepared with prostaglandin E_2 in cervical ripening were established in clinical trials (13), and this paper outlines the pharmaceutical aspects involved in the development of such a delivery system.

EXPERIMENTAL

Materials—Prostaglandin E_2[1](I) was used in the crystalline form. [1-^{14}C]Prostaglandin E_2[2] (specific activity 2.07 GBq/mmole) was supplied as a solution in ethanol–water (7:3). The cross-linked starch polymer[3] was supplied as a dry powder (particle size 50–100 μm). All reagents were analytical grade.

Gel Formulations—The prostaglandin E_2 gel powder was prepared under aseptic conditions. A freshly prepared, sterile-filtered solution of I (50 mg) in 80% (v/v) aqueous ethanol (25 ml) was added to 50 g of the heat-sterilized (160° for 1 hr) cross-linked starch powder. During the subsequent manual mixing for 10 min, the starch material swelled to twice its original volume. After lyophilization and homogenization, the prostaglandin E_2 gel powder was dispensed in 0.5-g portions (0.5 mg of I/dose) in sterile, disposable, 10-ml syringes.

The radiolabeled prostaglandin E_2 gel powder was prepared in a similar manner with the addition of 92.5 KBq of [1-^{14}C]prostaglandin E_2 to the solution of I. For practical reasons, this batch was prepared at one-half the scale (*i.e.*, 50 doses) and under nonaseptic conditions.

The ready-to-use-gel for clinical administration was prepared by adding 2.2 ml of sterile saline *via* a hypodermic needle to the prostaglandin E_2 gel powder in the syringe. A uniform gel consistency was obtained without agitation within 30 sec.

The prostaglandin E_2 gel fortified with X-ray contrast medium was prepared by adding 1 ml of saline and 2 ml of contrast medium (6.75 g of metrizamide[4] dissolved in 7.8 ml of 0.6 m*M* sodium bicarbonate) to

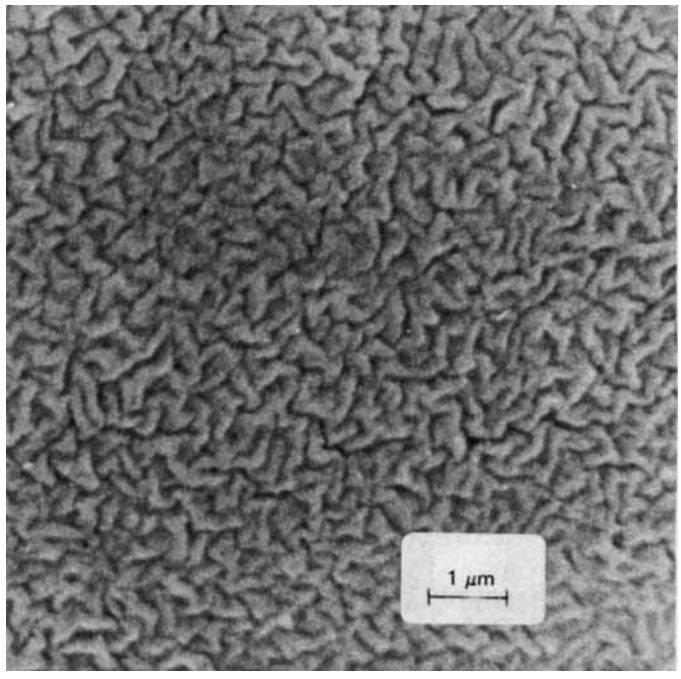

Figure 2—*Scanning electron micrograph of the sphere surface structure (×10,000).*

the prostaglandin E_2 gel powder. The gel was administered to a 28-year-old II-gravida at a gestational age of 30 weeks with an intrauterine dead fetus.

Characterization of Prostaglandin E_2 Gel Powder—The water content in the powder was determined by Karl Fischer titration. Particle-size fractionation was performed using a mechanical oscillating sieve[5]. The pH measurements were made using a standard pH meter[6]. The absorption capacity was determined using the method described by Granath and Flodin (14). Micrographs were taken using a scanning electron microscope[7]. Sterility tests on five batches were performed according to the European Pharmacopoeia.

Homogeneity Studies—Twenty samples of 100.0 mg of the radiolabeled I gel powder were selected randomly according to the table of random numbers[8]. After addition of 10 ml of gel scintillation fluid[9] to each sample, the radioactivity was measured using a liquid scintillation spectrometer[10]. The absence of quenching due to the starch powder was verified by measuring the radioactivity in successively increasing amounts (10–300 mg) of the I gel powder from the same samples.

The distribution of I in the swollen, ready-to-use gel was determined in a similar manner by measuring the radioactivity of ~300.0-mg portions of the gel when expelled in a standard manner from the syringe.

Stability Studies—Compound I was tested for stability in the dry powder and in the swollen, ready-to-use viscous gel. Stability was monitored at 4 and 23° in the dry powder for 12 months and at 4, 20, and 37° in the freshly prepared, ready-to-use viscous gel for 24 hr.

Assay and Analytical Procedure—Compound I was determined by extraction from the gel, separation from the degradation products by TLC, and spectrophotometric assay[11] after conversion to prostaglandin B_2 by alkali treatment.

Aqueous ethanol (80% v/v) was prepared, and 2.00 ml was added to 500.0 mg of the dry I gel; after vortexing for 2 min, 50 μl of the supernate was applied to a silica gel thin-layer plate[12] together with standards of 80% (v/v) aqueous ethanol solutions of known concentrations of I. The plate was developed in a solvent system of chloroform–methanol–acetic acid–water (90:9:1:0.65). This system separates I from its major degradation products, prostaglandin A_2 and the ethyl esters (15).

The zone of I was visualized by spraying the standards at the edge of the plate with 10% phosphomolybdic acid in ethanol. The areas corresponding to I were removed from the plate, and I was eluted with methanol (3 × 2.00 ml). The sample was treated with potassium hydroxide to give a final concentration of 1 *M* and then was heated at 50° for 1 hr. The absorbance at 277 nm was read against a blank (containing a corresponding amount of silica gel treated similarly) and compared with the standards.

RESULTS AND DISCUSSION

The described formulation procedure results in an off-white, free-flowing powder consisting of microspheres of 50–100 μm in diameter (Fig. 1). Each microsphere is a highly hydrophilic, three-dimensional network of a cross-linked starch derivative. Scanning electron micrographs show a regular matrix surface structure (Fig. 2). The hydrophilic nature of the starch microspheres is illustrated by the absorption capacity in polar liquids. For example, upon addition of saline, the I gel powder swells to assume a gel consistency, with absorption up to eight times the original weight of the dry powder. Upon addition of 80% aqueous ethanol, the starch powder swells to about twice its own volume as the microspheres enlarge in size. The solution is absorbed by the microspheres and incorporated as intraparticulate liquid. The solution of I thus is distributed

Table I—Stability of Prostaglandin E_2 (I) in the Freshly Prepared Ready-to-Use I Gel [a]

Incubation, hr	Recovered I, %		
	+4°	+20°	+37°
4	99.1 ± 7.0	99.3 ± 6.9	91.8 ± 5.6
24	94.7 ± 5.4	88.5 ± 4.8	78.0 ± 1.5

[a] Each value is the mean ± *SD* of four samples from the same batch.

throughout the gel bed. During the subsequent lyophilization, the solvent is removed and the starch microspheres are restored to their original size, thereby facilitating the even distribution of I throughout the starch gel powder.

The water content of the I gel powder is ~2–4% and, when protected from moisture, does not significantly alter during storage in plastic syringes.

The results of studies to determine the intrabatch distribution of I in the dry radiolabeled I gel powder prepared at the 50-dose scale showed a relative standard deviation of 2.1% (mean ± *SD*, 24,053 ± 507 dpm/100 mg of dry powder). This value reveals good homogeneity and suggests that the I gel powder can be manufactured commercially with a satisfactory intrabatch variation. The homogeneous nature of the swollen I gel is illustrated by the distribution of radioactivity throughout the gel bed, having a relative standard deviation of 15% (mean count ± *SD*, 11,836 ± 1800 dpm/300 mg). This finding suggests that, in clinical routine, I is distributed satisfactorily in the gel when administered, for example, into the cervical canal.

The solid-state stability of I in the gel delivery system is shown in Fig. 3. The stability profile presents a promising trend and shows little difference between storage temperatures of 4 and 23° for up to 1 year. This finding may be of significance when considering storage conditions for preparations to be used clinically. The stability pattern of the bulk drug presents an increasing degradation rate beginning at 6 months at room temperature (16) and has a 6-month shelflife. In sharp contrast, I in the gel delivery system was quite stable at room temperature for at least 1 year. The starch gel powder functions not only as a delivery vehicle for I but also as a stabilizer for this labile substance. The mechanism controlling the long-term stability of I probably is related to the inherent hydrophilic nature of the starch powder. The degradation rate of the bulk I powder seems to increase and indeed be catalyzed by the presence of the degradation products.

It is likely that I is distributed throughout the starch gel powder and is diluted to such an extent that the degradation products formed have no catalytic effect on the stability profile of I. Moreover, the individual microspheres probably present a very large surface area onto which I adheres to increase the dilution effect. Furthermore, the three-dimensional network probably provides a means of distributing I throughout the whole matrix of the starch microspheres, thereby stabilizing the drug by enclosure. Work is in progress to determine the precise mechanism involved in stabilizing I.

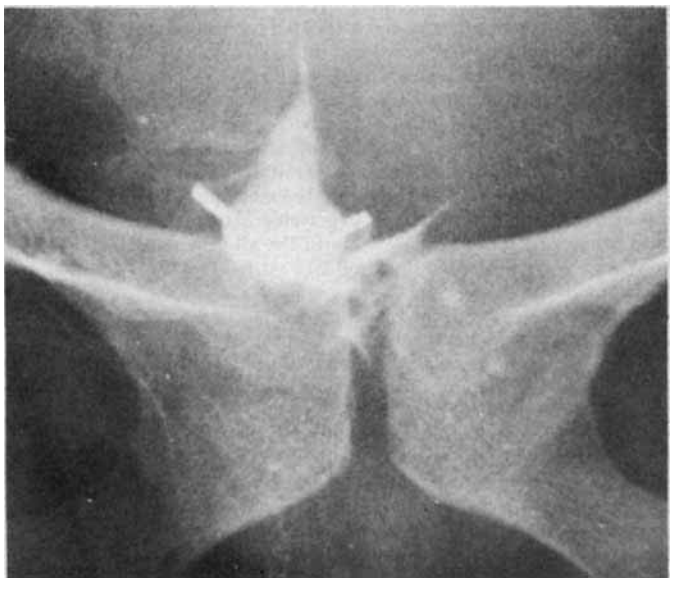

Figure 4—*X-ray picture illustrating the intracervically located gel. Clips were applied at the level of the external os.*

The stability of I in the freshly prepared gel after addition of saline is shown in Table I. Even at elevated temperatures, I is stable in the gel preparation for at least 4 hr, after which the degradation pattern follows the trend seen for the drug in other solvent systems (17). In clinical practice, once the gel is constituted by addition of saline, no further preparative steps are necessary, and the preparation is ready for use. Therefore, the stability of the drug in the swollen gel at room temperature is satisfactory for a sufficient period prior to administration.

The results of sterility testing of five batches showed no microbiological contamination throughout the testing period of 1 year. Thus, the more standardized method of preparation of the I gel powder, compared with more involved methods of I gel preparation, and the dry form of the final product contribute to lowering the risk of microbiological contamination during preparation and subsequent storage.

After the addition of 2.2 ml of saline, the viscous I gel has a final pH of 6.9; therefore, from this point of view, the preparation presents no risk for tissue irritation in the cervix canal when used clinically. Figure 4 shows an *in vivo* X-ray photograph of the viscous I gel located in the cervical canal of a 28-year-old II-gravida. The X-ray, taken 10 min after intracervical administration, shows that the gel clearly adheres to the surface of the cervical canal walls and illustrates the unique property of the gel in facilitating strict intracervical delivery of I.

The new prostaglandin E_2 gel delivery system offers the following advantages over existing gel preparations: (*a*) the final dosage form is a sterile, homogeneous, and clinically ready-to-use preparation for local administration; (*b*) the shelflife of the preparation is at least 12 months at room temperature; and (*c*) the delivery system has a gel consistency, so strict intracervical administration is possible.

Effects of Short-Term Dietary Exposure to Polychlorinated Biphenyls on Pharmacokinetics of Intravenous Pentobarbital in Rats

V. J. STELLA ˣ and C. K. CHU *

Received October 29, 1979, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication May 9, 1980. *Present address: Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.

Abstract □ The intravenous pharmacokinetics of pentobarbital (30 mg/kg as pentobarbital sodium) in rats were studied at 0, 1, 2, 3, and 10 days after pretreatment with 0, 1, 5, 25, and 125 ppm of polychlorinated biphenyls in food. The polychlorinated biphenyls then were removed from the food, and the residual effects of the exposure on pentobarbital pharmacokinetics were studied at 15, 25, 45, and 70 days after initiation of the polychlorinated biphenyl exposure. The pharmacokinetics of pentobarbital were approximated to a one-compartment model. After pretreatment at 1 and 5 ppm for up to 10 days, all pentobarbital pharmacokinetic parameters obtained were comparable to control values. Pretreatment at 125 ppm significantly reduced the biological half-life and raised the total body elimination rate constant, total body clearance, and intrinsic clearance of pentobarbital after a 1-day exposure; all parameters apparently reached a new steady-state value by Days 5–10. Enhanced pentobarbital elimination at 25 ppm was observed after a 3-day exposure, but, again, the elimination parameters appeared to have reached a steady state after 5–10 days of pretreatment. Upon removal of the polychlorinated biphenyls, the various pharmacokinetic parameters showed a lag phase *prior* to a gradual return to control values. The study shows that intrinsic clearances rather than total body clearances or half-lives are more appropriate in assessing enzymatic induction in agents undergoing facile liver metabolic clearance that borders on blood flow rate dependency.

Keyphrases □ Polychlorinated biphenyls—effect of short-term dietary exposure on pharmacokinetics of intravenous pentobarbital, rats □ Pentobarbital—effect of short-term dietary exposure to polychlorinated biphenyls on pharmacokinetics following intravenous administration, rats □ Pharmacokinetics—pentobarbital, effect of short-term dietary exposure to polychlorinated biphenyls following intravenous administration, rats

The objective of this study was to observe the effects of short-term exposure to a class of environmental contaminants and hepatic enzyme inducers, polychlorinated biphenyls, on the pharmacokinetics of pentobarbital in rats. Pentobarbital, whose pharmacokinetics in rats (1) and humans (2) have been documented, is eliminated primarily *via* side-chain hydroxylation by liver microsomal enzymes (3–8). These enzyme systems are induced by exposure to polychlorinated biphenyls (9–14). Therefore, pentobarbital pharmacokinetics can be used as a probe for measuring the inducing effects of polychlorinated biphenyls on the liver microsomal enzymes in rats.

Drug pharmacokinetics can be altered by factors such as diet, age, sex, genetics, disease states, and environmental factors. Exposure to environmental contaminants such as polychlorinated biphenyls, which accumulate in human tissues (11, 15–21) and induce human hepatic enzymes (22–26), could drastically reduce the disposition half-life of drugs. Therefore, a thorough understanding of drug pharmacokinetics as affected by polychlorinated biphenyls and other environmental contaminants is useful in predicting their possible effects on drug therapy.

In a previous study (14), the effects of long-term (0–140-day) dietary exposure to a polychlorinated biphenyl mixture (0–25 ppm) on the pharmacokinetics of intravenously administered pentobarbital in rats were quantitated. The present study examined the effects of short-term dietary exposure to polychlorinated biphenyls (0–125 ppm for 0–10 days) on the elimination kinetics of intravenously administered pentobarbital in rats. The polychlorinated biphenyls were removed from the food at the end of 10 days, and the residual effects of the exposure were followed for 70 days. This procedure allowed a time profile to be established for the inducing effects of the polychlorinated biphenyls. Some qualitative observations concerning the time profile for the alteration of pentobarbital pharmacokinetics by polychlorinated biphenyl exposure are presented. The significance of the effects of accidental human exposure to polychlorinated biphenyls also is discussed.

EXPERIMENTAL

Animals—Male Sprague–Dawley rats[1], 201–225 g, were housed in stainless steel cages in groups of four. All animals were fed standard laboratory rat food[2] for 1 week before the prepared polychlorinated biphenyl[3]-containing diet was introduced. Tap water was available *ad libitum*. Groups of animals then were put on the prepared diet for 0, 1, 2, 3, 5, 10, 15, 25, 45, or 70 days. The rats were exposed (for a maximum of 10 days) to the polychlorinated biphenyl-containing powdered rat food prepared as described previously (13, 14). For animals on the 15-, 25-, 45-, and 70-day diet schedules, the polychlorinated biphenyl-containing powdered rat food was removed after 10 days and replaced with polychlorinated biphenyl-free powdered rat food.

The polychlorinated biphenyl diet was initiated in the afternoon, and all blood sampling studies were carried out in the mornings of the specified days. For example, rats on a 1-day diet were given the polychlorinated biphenyl-containing food in the afternoon of Day 0, and the pharmacokinetics of intravenously administered pentobarbital were studied on the following morning (*i.e.*, the morning of Day 1). Similarly, rats on a 15-day diet were exposed to polychlorinated biphenyl-containing food from the afternoon of Day 0 until the afternoon of Day 10, when powdered polychlorinated biphenyl-free rat food replaced the contaminated food.

For each time period, the rats were divided into groups of eight and were fed powdered laboratory rat food containing 0, 5, 25, or 125 ppm of polychlorinated biphenyls. An additional group of eight animals fed 1 ppm of polychlorinated biphenyl-containing food was included in the 10- and 70-day studies.

Five rats from each group were studied at the end of each time period. Pentobarbital sodium[4], 30 mg/kg (equivalent to 27.7 mg of pentobarbital/kg), was administered to each rat intravenously *via* the dorsal vein of the penis (27). The blood sampling procedure was similar to that described previously (14). Blood samples were collected in microcapillary tubes pretreated with 10% sodium ethylenediaminetetraacetate at 5, 7, 10, 15, 20, 30, 45, 60, and 90 min postdosing. Rats were sacrificed after

each pretreatment period. The livers were removed, patted dry, and weighed.

Pentobarbital Assay—The plasma pentobarbital concentration was assayed as described previously (14) but with the following modifications. To each 100 μl of plasma sample were added 25 μl of the internal standard (0.099 mg of secobarbital/ml in methanol) and 50 μl of 4 *M* monobasic sodium phosphate. The mixture was extracted with 1.0 ml of water-saturated ether on a vortex mixer for 1 min. After centrifugation, the ether extract was removed to a glass-stoppered 5-ml conical centrifuge tube.

Just before injection in the gas chromatograph, 25 μl of alkaline aqueous 0.02 *M* trimethylanilinium hydroxide was added to the sample, which then was agitated and centrifuged. The trimethylanilinium hydroxide solution was prepared by the method of Stella (28). The ether layer was removed by aspiration, and 1–2 μl of the aqueous lower layer was injected in a gas chromatograph. Chromatographic conditions and column packings were as described previously (14). A standard curve of the peak height ratios of pentobarbital sodium to secobarbital *versus* plasma concentrations of pentobarbital (2–80 μg/ml) was prepared and used to determine pentobarbital in unknown samples.

Pharmacokinetic Data Analysis—In an earlier study (14), a fast distribution phase was observed in the disposition kinetics of pentobarbital in the rat. The distribution kinetics, apart from being rapid, were not affected significantly by the polychlorinated biphenyl pretreatments (14). Based on these observations, the data in this study were treated as a one-compartment model by linear least-squares fitting of the postdistribution data points on a semilog plot. The B and β values obtained from the intercept and slope of the log concentration–time curve were used to calculate the volume of distribution (extrapolated), V_d(ext), and the total body clearance, Cl_{TB} (14). The total body clearance of any compound that is eliminated solely *via* liver metabolism is given by:

$$Cl_{TB} = QE \qquad \text{(Eq. 1)}$$

where Q is the liver blood flow rate and E is the liver extraction constant (29). The extraction constant is not an independent variable but varies with Q, the fraction of unbound drug in the blood (f), and the intrinsic clearance of the drug (Cl_{int}) (29, 30). If the measured intrinsic clearance ($Cl_{int}f$) is represented by Cl_{INT}, then for a drug metabolized exclusively by the liver, the total body clearance, which approximates the hepatic clearance, can be expressed by:

$$Cl_{TB} = Q\frac{Cl_{INT}}{Q + Cl_{INT}} \qquad \text{(Eq. 2)}$$

The intrinsic clearance, defined as the clearance of a drug when there are no flow limitations (29), is a measure of the available metabolic activity of the liver and the properties of the enzyme system associated with hepatic removal. The Cl_{INT} values were calculated from Eq. 2 using blood flow rates calculated from the individual liver to body weight ratios for the particular animal and a blood flow rate of ~2 ml/min/g of liver (30).

The mean values and standard deviations for all parameters for each pretreatment were calculated and compared statistically to the same parameter for the same-day control group. Multiple means within a day were analyzed by a randomized analysis of variance. When the analysis indicated that a significant difference existed, the means of each group were compared by a two-tailed Dunnett multiple mean test (31). This test is for multiple mean comparisons to a control.

RESULTS AND DISCUSSION

Tables I and II summarize the half-lives ($t_{1/2}$) and total body clearances (Cl_{TB}) of intravenously administered pentobarbital in rats pretreated with different polychlorinated biphenyl doses over various time periods compared to the controls. The elimination rate of pentobarbital was increased significantly in rats pretreated for 1 day at 125 ppm of polychlorinated biphenyl in the food. On Day 1, $t_{1/2}$ was reduced significantly to 39 ± 3 min compared to the control group, which showed a $t_{1/2}$ of 53 ± 7 min; the $t_{1/2}$ appeared to reach a constant value of 23 ± 1 min by Days 5–10. The Cl_{TB} values also increased from 21 ml/min/kg of body weight on Day 1 and seemed to approach a constant clearance of 43–47 ml/min/kg of body weight in <1 week. No significant changes in the elimination kinetics of pentobarbital were observed for rats pretreated at the 1- and 5-ppm levels relative to control rats.

Enhanced pentobarbital elimination for rats pretreated with 25 ppm of polychlorinated biphenyls in food was observed after 2–3 days of pretreatment. The elimination parameters again began to plateau after ~5–10 days of pretreatment, as was the case with the 125-ppm polychlorinated biphenyl-pretreated rats. The $t_{1/2}$ was lowered significantly to 38 ± 5 min relative to the control value of 52 ± 4 min after 3 days of pretreatment and remained rather constant at 35 ± 4 min after ~5–10 days. The Cl_{TB} value was similarly significantly increased to 28 ml/min/kg of body weight after 5 days on a polychlorinated biphenyl-contaminated diet and appeared to begin leveling off at a clearance of 24–28 ml/min/kg of body weight after ~5–10 days of the diet.

Upon removal of the polychlorinated biphenyls from the diet after 10 days (Tables III and IV), the enhanced pentobarbital elimination as measured by $t_{1/2}$ and Cl_{TB} started to decline toward the control values after apparent time lags of ~10 and ~20 days for the 25- and 125-ppm polychlorinated biphenyl-pretreated animals, respectively. The lag time for the loss of residual effects appeared to be dose dependent. Induced enzyme activity as shown by enhanced pentobarbital elimination due to exposure to 25 ppm of polychlorinated biphenyls receded within 60 days following removal of polychlorinated biphenyls from the diet. Rats pretreated at the 125-ppm level still demonstrated an elevated, but not statistically significant, enhancement of pentobarbital elimination at 70 days, *i.e.*, 60 days after removal of the polychlorinated biphenyls from the food.

The Cl_{TB} values (Tables II and IV) for the control group decreased slightly but insignificantly over the 70 days of the study; in the 5-ppm

[a] All values are means ± *SD* in milliliters per minute per kilogram of body weight ($n = 5$). [b] Results are significantly different from the same-day control group at the level indicated. [c] Animals were treated with polychlorinated biphenyls at the levels indicated for 10 days, at which time the polychlorinated biphenyl-contaminated food was replaced with polychlorinated biphenyl-free food.

treated animals, the Cl_{TB} remained at a level similar to the control animals prior to exposure. This finding may suggest some minimal induction by the polychlorinated biphenyls at 5 ppm. However, as suggested by the Dunnett test, no statistically significant differences were seen between the controls and the 5-ppm treated animals at any time.

Figure 1 shows the induction time profiles for β. The dotted lines represent the range (mean ± *SD*) for the β values of the control animals

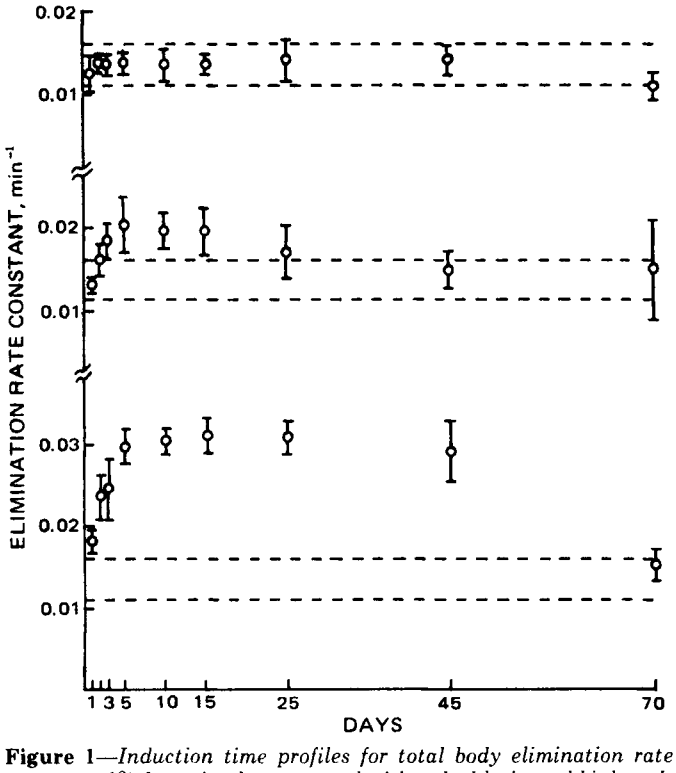

Figure 1—*Induction time profiles for total body elimination rate constants (β) for animals pretreated with polychlorinated biphenyls at 5 ppm (top profile), 25 ppm (middle profile), and 125 ppm (bottom profile) over 70 days. The polychlorinated biphenyl diet was provided up to 10 days, after which time it was replaced with polychlorinated biphenyl-free food. Dotted lines represent the range of the mean control value obtained by averaging the control values at the 10 times studied* (i.e., *mean* ± SD).

averaged over all of the time periods studied. There were no significant effects of polychlorinated biphenyl exposure as measured by β in rats pretreated at the 5-ppm level. Figure 1 also shows that the enhanced elimination of pentobarbital in rats at 25 ppm of polychlorinated biphenyls was observed only after a lag time of ~1–3 days. This pattern resembles the 5-ppm polychlorinated biphenyl-pretreated rats in the earlier study (14), which did not show any effects of polychlorinated biphenyl induction until exposure for >35 days. The increased elimination rate of pentobarbital in rats pretreated with 125 ppm of polychlorinated biphenyls was statistically significant, even after 1 day. The enhanced elimination resulted from exposure to the higher polychlorinated biphenyl doses.

After removal of the polychlorinated biphenyl-contaminated diet on Day 10, induced enzyme activity as measured by β appeared to recede completely by Day 70 in the 25-ppm polychlorinated biphenyl-pretreated rats. Despite the still elevated, but not statistically significant, elimination for pentobarbital in rats pretreated with 125 ppm of polychlorinated biphenyls at Day 70, an apparent decrease in the induced enzyme activity as measured by the same parameters was noticeable.

Body Weights and Liver Weights—No significant trend of body weight increase was observed in rats pretreated at the different levels of polychlorinated biphenyls compared to the control rats. However, the mean liver weight to body weight ratios were higher in rats pretreated at 125 ppm of polychlorinated biphenyls (Table V) throughout induction and remained elevated until ~35 days after the removal of polychlorinated biphenyls (*i.e.*, at Day 45). The liver weights and the liver weight to body weight ratios in the 25-ppm pretreated rats were not significantly different from the control group. Dose-dependent liver weight increases were reported for mice pretreated with polybrominated biphenyls at 100- and 200-ppm dietary levels (32).

It has been shown that exposure to up to 1000 ppm of polychlorinated biphenyls for periods of up to months results in modest proliferation of the smooth endoplasmic reticulum and lipid vacuolation of liver cells but causes no cellular injury in the liver (33–36). Thus, this small increase in the liver weight and the liver weight to body weight ratio probably is an adaptive response, as suggested by Bruckner *et al.* (13) rather than a hepatotoxic effect. Other investigators also suggested that such changes in hepatic morphology upon exposure to polychlorinated biphenyls represent an adaptive response to eliminate foreign compounds by increasing their rate of metabolism (37). The observed enhanced rate of elimination of pentobarbital in polychlorinated biphenyl-pretreated rats probably reflects the increased activities of certain metabolic enzymes due to the exposure.

Intrinsic Clearances—Both the biological half-life and total body clearance values are limited in use as an index of intrinsic hepatic metabolism (38). The former is a complex parameter and depends on the distribution characteristics as well as the elimination of the substance under investigation. The latter can approximate hepatic clearance only

[a] All values are means ± *SD* as (liver weight/body weight) × 100 (n = 5). [b] Animals were treated with polychlorinated biphenyls at the levels indicated for 10 days, at which time the polychlorinated biphenyl-contaminated food was replaced with polychlorinated biphenyl-free food.

if the drug is eliminated and metabolized exclusively by the liver. Even for pentobarbital, whose route of elimination is primarily hepatic, an estimation of the total body clearance still may not suffice as the index for intrinsic metabolic activity. As seen by examining Eq. 2, total body clearance is governed not only by the intrinsic clearance but also by the liver blood flow rate. Only when this rate is very much larger than the intrinsic clearance does the total body clearance directly reflect the intrinsic metabolic activity of the liver or the intrinsic clearance. On the other hand, when the intrinsic clearance is very large compared to the blood flow rate through the liver, the total body clearance becomes limited by the flow rate and is no longer proportional to the intrinsic clearance. To quantitate the apparent metabolic activity of the liver enzymes using pharmacokinetic parameters, estimation of the intrinsic clearance is more appropriate.

By using a literature value of 2 ml/min/g of liver for the liver blood flow rate and the measured experimental total body clearances, intrinsic clearances were estimated; the induction time profiles are presented in Fig. 2. The absence of induction of the hepatic metabolic enzymes due to 5-ppm polychlorinated biphenyl exposure as measured by the intrinsic clearances is readily seen in Fig. 2. Again, a statistically significant induction at the 25-ppm pretreatment level is seen after a 3-day lag time and an immediate (<1 day) and more pronounced induction is seen at the 125-ppm polychlorinated biphenyl pretreatment level. The absolute values of Cl_{INT} are dependent on the value used for the liver blood flow rate. Recently developed pharmacokinetic techniques (30, 39, 40) and more traditional measurements (41–44) suggested that the value of ~2 ml/min/g of liver is a reasonable estimate of the liver blood flow rate in rats. Determination of the intrinsic clearances for pentobarbital in rats using the oral and intravenous pharmacokinetic techniques (30, 39, 40) will be presented later.

If $t_{1/2}$, β, or Cl_{TB} is used as a measure of polychlorinated biphenyl induction of pentobarbital elimination, it can be seen from Fig. 1 and Tables I–IV that the percent change in the parameters relative to controls reaches a steady-state level ~5–10 days after an apparent initial lag phase. This also was seen in an earlier chronic exposure study (14). A possible explanation might be that the liver, in response to an inducer, increases the synthesis of microsomal enzymes in an amount proportional to the dose of the inducer. Since the pentobarbital total body clearance, even in the absence of induction, is a reasonably high percentage of the liver blood flow, the percentage increase in the inducing effect of the polychlorinated biphenyls is not reflected totally in the total body clearance.

For example, the steady-state total body clearance after the 10-day exposure at 125 ppm amounted to ~46 ml/min/kg. When this parameter is used as a measure of induction and compared with the control value (19 ml/min/kg), a 142% increase is indicated. If the intrinsic clearances are used instead, the results indicate an increase of 229% (80.8 ml/min/kg in treated animals *versus* 24.5 ml/min/kg in the controls). Thus, the total body clearances do not always reflect the large increases in intrinsic

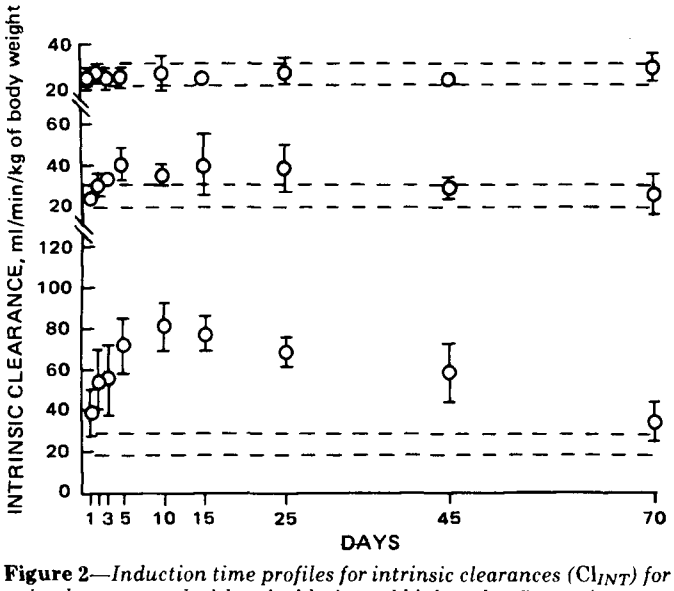

Figure 2—*Induction time profiles for intrinsic clearances* (Cl_{INT}) *for animals pretreated with polychlorinated biphenyl at 5 ppm (top profile), 25 ppm (middle profile), and 125 ppm (bottom profile) in food over 70 days. The polychlorinated biphenyl diet was provided up to 10 days, after which time it was replaced by a polychlorinated biphenyl-free diet. Dotted lines represent the range of the mean control value obtained by averaging the control values at the 10 times studied* (i.e., *mean* ± SD).

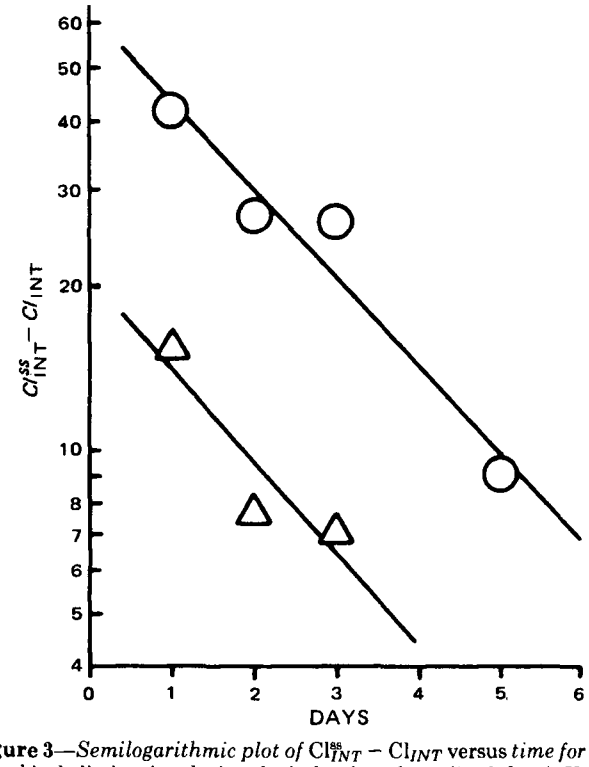

Figure 3—*Semilogarithmic plot of* $Cl_{INT}^{ss} - Cl_{INT}$ versus *time for pentobarbital elimination during the induction phase (0–10 days). Key:* △, *data for the 25-ppm pretreatment, and* ○, *data for the 125-ppm pretreatment.*

clearances, which are more realistic indexes of the degree of induction. This is especially true if the probe molecule under control conditions undergoes a facile liver metabolic clearance that borders on liver blood flow rate dependency.

The lack of significant short-term effects of the 1- and 5-ppm pretreatments on pentobarbital pharmacokinetics suggests that a critical mass of inducer is needed to initiate liver microsomal enzyme stimulation. At the 25-ppm level, an increase in the pentobarbital intrinsic clearance was seen only on Day 5 of exposure, whereas a significant increase in the intrinsic clearance was seen on the 1st day of exposure at the 125-ppm level. These results are consistent with the need for a critical mass of inducer to accumulate before induction is initiated.

Levy and coworkers (45–51) recently published several reports dealing with the time profiles of drug induction. An attempt was made to fit the induction time profile seen in the present work by estimating an average steady-state intrinsic clearance, Cl^{ss}_{INT} (38.4 ml/min/kg for 25 ppm and 80.8 ml/min/kg for 125 ppm), and plotting log ($Cl^{ss}_{INT} - Cl_{INT}$) *versus* time for the induction phase. Good first-order plots were obtained (Fig. 3), giving apparent induction half-lives of ~2 days for both the 25- and 125-ppm data. Similarly, postinduction data were treated by plotting log ($Cl_{INT} - Cl^{0}_{INT}$) *versus* time, where Cl^{0}_{INT} is the mean value of the intrinsic clearance for the control animals. Although half-lives for the loss of residual induction effects of ~11 days were obtained for both the 25- and 125-ppm data, care must be taken in interpreting these values because of the limited number of points available in the postinduction phase.

Based on the observations in this study, the following tentative conclusions can be made about polychlorinated biphenyl induction of pentobarbital elimination.

1. Induction by the polychlorinated biphenyls shows an apparent lag time that appears to be dose dependent.
2. The kinetics of induction, once initiated, appear to be first order, and the induction half-life seems to be dose independent.
3. The extent of induction is polychlorinated biphenyl dose dependent, but there is an apparent minimum exposure below which significant induction is not seen.
4. After removal of the polychlorinated biphenyls, there appears to be a lag time before the various induced pharmacokinetic parameters begin to return to control values (Figs. 1–3).
5. An apparent half-life for the loss of residual induction effects seems to be dose independent.

Although these conclusions must be tempered because of the limited number of data points and doses studied, it is interesting to speculate on their significance. If relationships such as those implied here can be substantiated, they may allow prediction of the time course of induction by various levels and times of exposure of enzyme-inducing agents such as polychlorinated biphenyls and of the effect of this induction on the pharmacokinetics of drugs such as pentobarbital. A better understanding of this phenomenon will allow more quantitative prediction of the therapeutic consequences of accidental acute or chronic exposure to agents such as polychlorinated biphenyls and other environmental enzyme inducers.

Effect of Short-Term Exposure to Polychlorinated Biphenyls on First-Pass Metabolism of Pentobarbital in Rats

V. J. STELLA [x] and C. K. CHU *

Received October 29, 1979, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication May 9, 1980. *Present address: Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.

Abstract □ The enhancement of the first-pass metabolism of orally administered pentobarbital in rats was examined after a 10-day exposure to food contaminated with polychlorinated biphenyls at 25 and 125 ppm. The degree of the first-pass effect and the influence of the polychlorinated biphenyl exposure were quantitated by comparing the areas under the plasma concentration–time curves after oral and intravenous dosing in control and treated animals. By using the clearance model and assuming that pentobarbital was eliminated totally by liver metabolism, the experimentally determined oral availability was predicted adequately from both the oral and intravenous data. The enhanced first-pass effect was principally in the intrinsic clearance term, although liver blood flow rates also appeared to be enhanced in animals treated with polychlorinated biphenyls at 125 ppm.

Keyphrases □ Polychlorinated biphenyls—effect of short-term exposure on first-pass metabolism of pentobarbital, rats □ Pentobarbital—effect of short-term exposure to polychlorinated biphenyls on first-pass metabolism, rats □ First-pass metabolism—pentobarbital, effect of short-term exposure to polychlorinated biphenyls, rats

Induction of liver microsomal enzymes by polychlorinated biphenyls, a class of environmental contaminants, has been reported in both humans and rats (1–11). Enhanced metabolism of drugs that are eliminated *via* these enzymes can have clinical implications because the hepatic clearance of drugs, such as pentobarbital (12–14), that are metabolized mainly by liver enzymes can be altered by exposure to these enzyme inducers. Such exposure may require therapeutic dosage adjustments of affected drugs to maintain comparable clinical effectiveness to the preexposure period.

In this study, the enhancement of the first-pass metabolism of pentobarbital in rats was examined after a 10-day exposure to a polychlorinated biphenyl-contaminated diet. It was determined previously (15) that the extent of enzyme induction due to polychlorinated biphenyl exposure is dose dependent and that a 10-day exposure results in an apparent steady-state level of enzyme induction. Therefore, the purpose of this study was to investigate the dose dependency and predictability of enhanced first-pass metabolism and bioavailability parameters for pentobarbital as a result of hepatic enzyme induction by polychlorinated biphenyls.

EXPERIMENTAL

Male Sprague–Dawley rats[1], 201–225 g, were housed in stainless steel cages in groups of four. All animals were fed standard laboratory rat food[2] for 1 week, and tap water was available *ad libitum*. After this preconditioning period, the rats were divided randomly into groups and fed powdered laboratory rat food containing 0, 25, or 125 ppm of polychlorinated biphenyls[3]. Food preparation was the same as described previously (16).

Four rats from each group were studied at the end of 10 days. The same dose of pentobarbital sodium[4], 30 mg/kg (equivalent to 27.7 mg of pentobarbital/kg), was administered orally to one group of rats and intravenously to another group of rats receiving the same polychlorinated biphenyl pretreatment. The oral dose was introduced *via* gastric intubation, and the intravenous dose was administered *via* the dorsal vein of the penis (17).

Blood samples were collected in microcapillary tubes pretreated with a 10% sodium ethylenediaminetetraacetate solution following the oral dose at 15, 30, 45, 60, 75, 90, 120, 150, and 180 min and similarly following the intravenous dose at time intervals as described previously (15). Because of anticipated faster pentobarbital elimination in the animals pretreated with 125 ppm of polychlorinated biphenyls, the last two time points were replaced for this group by additional samples at 5 and 10 min.

After centrifugation, the plasma samples were kept frozen until analysis. Plasma pentobarbital concentrations were assayed as described previously (15). All animals were sacrificed at the end of the blood sampling study. The liver was removed from each animal, patted dry, and weighed.

Experimental systemic availability of pentobarbital was evaluated in rats on the 10-day diet from the ratios of the area under the plasma level–time curves of the oral dosing compared to that from the intravenous dosing schedule:

$$\text{systemic availability} = (AUC_{\text{oral}})_0^\infty/(AUC_{\text{iv}})_0^\infty \qquad \text{(Eq. 1)}$$

where AUC represents the area under the plasma level–time curve. The AUC values were estimated by the trapezoidal method with extrapolation to infinite time from the last data point using standard procedures (18). The total body and intrinsic clearances (Cl_{TB} and Cl_{INT}, respectively) for these animals were evaluated using (19–24):

$$Cl_{TB} = \text{dose}/(AUC_{\text{iv}})_0^\infty \qquad \text{(Eq. 2)}$$

$$Cl_{\text{INT}} = \text{dose}/(AUC_{\text{oral}})_0^\infty \qquad \text{(Eq. 3)}$$

where Cl_{TB} and Cl_{INT} are related by:

$$Cl_{TB} = \frac{QCl_{\text{INT}}}{Q + Cl_{\text{INT}}} \qquad \text{(Eq. 4)}$$

where Q is the liver blood flow rate. The assumption of these equations is that extrahepatic elimination is negligible (19, 20, 23).

The mean values and standard deviations for all parameters for each treatment were calculated and compared statistically to the same parameter for the control. Multiple means were analyzed by a one-way randomized analysis of variance. When analysis indicated that a significant difference existed, the means of each group were compared by a two-tailed Dunnett multiple mean test (25). This test is for multiple mean comparisons to a control.

RESULTS AND DISCUSSION

The plasma level–time curves of pentobarbital sodium administered orally and intravenously at the same dosage (30 mg/kg) to animals on the polychlorinated biphenyl-free control diet are shown in Fig. 1. The bioavailability of pentobarbital in the orally dosed group of animals was

incomplete. Since pentobarbital is well absorbed from the GI tract (26–28) and eliminated almost exclusively (>95%) *via* liver metabolism in the rat (14), the observed reduction in oral bioavailability may be attributed to the first-pass metabolism by the liver, *i.e.*, the first-pass effect.

The disposition profiles of orally and intravenously administered pentobarbital in rats pretreated with 25 or 125 ppm of polychlorinated biphenyls in food for 10 days are given in Figs. 2 and 3. A more pronounced first-pass effect in rats exposed to 25 ppm of polychlorinated biphenyls in food can be discerned from the reduced ratio of the areas under the plasma level–time curves (AUC_{oral}/AUC_{iv}). Rats pretreated with 125 ppm of polychlorinated biphenyls showed an even greater reduction in the *AUC* ratio. This finding indicated an even lower apparent bioavailability of the intact pentobarbital. By comparing AUC_{oral} to AUC_{iv} within a pretreatment group, the effect of clearance in reducing AUC_{iv} when compared to control animals is taken into account.

Table I summarizes the pharmacokinetic parameters for intravenously and orally administered pentobarbital in rats pretreated at two levels of polychlorinated biphenyls for 10 days compared to control rats. Pentobarbital was ~76% bioavailable in rats on the control diet. Upon exposure to polychlorinated biphenyls, increases in the degree of the first-pass effect were observed for both the 25- and 125-ppm pretreatments.

The relationship between the systemic availability after oral dosing and the total body clearance for exclusively liver-metabolized drugs was discussed by various investigators (18–24) and is defined by Eqs. 1–4. By rearrangement of Eqs. 1–4, an expression predicting the systemic availability can be obtained using Cl_{TB} values from the intravenous data:

$$\text{systemic availability} = 1 - Cl_{TB}/Q \qquad \text{(Eq. 5)}$$

Table I compares the predicted oral bioavailability for pentobarbital (calculated by Eq. 5 using the Cl_{TB} values from the intravenous data and the blood flow rates, which were calculated from the liver weights and the literature blood flow of 2 ml/min/g of liver) with the experimentally determined oral pentobarbital bioavailabilities for the variously treated animals. The predicted systemic bioavailability of pentobarbital was calculated from the individual Cl_{TB} and calculated Q values for individual animals and not from the mean Cl_{TB} and mean liver blood flow rates. Excellent agreement between the predicted and experimental bioavailability is seen. This result again illustrates the usefulness of intravenous data in assessing apparent systemic availabilities when the drug of interest is eliminated only by liver metabolism (18–24).

Rearrangement of Eqs. 1–4 yields a third expression for computing bioavailability from the liver blood flow rate and intrinsic clearance estimated from oral data:

$$\text{systemic availability} = Q/(Q + Cl_{INT}) \qquad \text{(Eq. 6)}$$

The percent systemic availability values calculated from Eq. 6 were 76.7 ± 2.1, 71.6 ± 3.1 (NS), and 47.8 ± 5.2 ($p < 0.01$) for the control and the 25- and 125-ppm polychlorinated biphenyl-pretreated rats, respectively. Again, these values were calculated from individual animal Q and Cl_{INT} values. These numbers showed excellent agreement with those estimated from the experimental *AUC* ratios.

The total body and intrinsic clearances in Table I were obtained from the dose and the areas under the intravenous and oral plasma level–time curves, respectively, using Eqs. 2 and 3. The induction effects due to polychlorinated biphenyl exposure at the 25- and 125-ppm levels as demonstrated by the Cl_{TB} values increased only by 31 and 193% relative to the controls, respectively. However, the Cl_{INT} values indicate ~47 and

Table I—Pharmacokinetic Parameters [a] for Intravenously and Orally Administered Pentobarbital in Rats Pretreated at Two Levels of Polychlorinated Biphenyls for 10 Days Compared to the Control Animals

Parameter	Control	25-ppm Pretreatment	125-ppm Pretreatment
Cl_{TB} [b], ml/min/kg of body weight	19.3 ± 3.8	25.3 ± 4.0 (NS)	56.5 ± 6.4 ($p < 0.01$) [c]
Cl_{INT} [d], ml/min/kg of body weight	24.4 ± 1.0	35.8 ± 6.7 (NS)	107.3 ± 20.8 ($p < 0.01$) [c]
Liver weight/body weight, %	4.2 ± 0.3	4.3 ± 0.3 (NS)	5.2 ± 0.6 ($p < 0.01$) [c]
Liver blood flow rate [e], ml/min/kg of body weight	82.7 ± 6.2	86.5 ± 6.0 (NS)	106.0 ± 12.2 ($p < 0.01$) [c]
Systemic availability calculated from AUC_{oral}/AUC_{iv} ratios, %	76.0 ± 8.7	71.2 ± 24.2 (NS)	53.9 ± 9.5 ($p < 0.05$) [c]
Systemic availability calculated from Eq. 5, %	77.6 ± 5.0	69.8 ± 2.9 (NS)	49.5 ± 8.3 ($p < 0.01$) [c]

[a] All values are means ± SD ($n = 4$). [b] Calculated from dose/AUC_{iv}. [c] Results are significantly different from the control group of animals at the level indicated. [d] Calculated from dose/AUC_{oral}. [e] Calculated from the literature value of 2.0 ml/min/g of liver.

340% increases over the control values at the 25- and 125-ppm pretreatment levels, respectively. Therefore, the degree of enzyme induction due to exposure to polychlorinated biphenyls is underestimated if only Cl_{TB} values are considered. This point was adequately discussed previously (15).

The relationship of liver blood flow to systemic availability and the clearance terms in Eqs. 5 and 6 provides a means of estimating liver blood flow rates from the experimentally determined bioavailability data. Rearrangement of Eqs. 5 and 6 and Eqs. 1–3 give:

$$Q = \frac{D}{(AUC_{iv})_0^\infty - (AUC_{oral})_0^\infty} \qquad \text{(Eq. 7)}$$

The blood flow rates calculated from Eq. 7 for the present data are given in Table II.

The estimated values compare favorably with the blood flow rates calculated using the literature value of 2 ml/min/g of liver (29). The agreement between the experimental and predicted liver blood flow for the control, 25-, and 125-ppm data supports the possibility of increased liver blood flow with enlarged livers without an increase in the flow per gram of liver.

The hepatic clearance of pentobarbital, the primary route of elimination in rats, can be approximated by the Cl_{TB} value (19, 20, 23). By converting clearances from milliliters per minute per kilogram of body weight to milliliters per minute per gram of liver in individual rats, the relationship between the hepatic clearance (equivalent to the total body clearance in this case) and the intrinsic clearance can be depicted as shown in Fig. 4. The lines represent the relationship between these parameters drawn by substituting a literature blood flow rate of 1.2 ml/min/g of liver (30) and 2 and 3 ml/min/g of liver (29) for Q in Eq. 4. Close agreement between the data points and the prediction using 2 ml/min/g of liver (29) for Q is readily seen and again supports the possibility of increased liver blood flow in polychlorinated biphenyl-treated rats with enlarged livers without an increase in the flow per gram of liver.

The clearance model suggests that substances that are highly extracted by the liver and, therefore, have a high intrinsic clearance relative to the blood flow display a higher sensitivity to blood flow changes. For instance, *d*-propranolol has a high intrinsic clearance (219 ml/min). The enhanced clearance subsequent to phenobarbital treatment is mainly (57%) due to the increase in the hepatic blood flow rate (31). On the other hand, antipyrine has a lower intrinsic clearance (54 ml/min); upon phenobarbital induction, only ~15% of the enhanced clearance results from increased blood flow. At the high level of polychlorinated biphenyl pretreatment, the intrinsic clearance of pentobarbital is increased due to the increased activity of the metabolic enzymes. A higher sensitivity to blood flow changes, reflected by the slightly higher blood flow, therefore is expected to contribute to the enhanced clearance with the 125-ppm pretreatment relative to the 25-ppm pretreatment.

In conclusion, this study showed that hepatic enzyme induction precipitated by environmental factors can significantly affect the bioavailability of drugs that are eliminated largely *via* facile hepatic metabolism. The reduction in the apparent oral bioavailability of pentobarbital in rats increased with the level of polychlorinated biphenyl exposure. As anticipated, the reduction in the apparent bioavailability or the increase in the first-pass effect was more pronounced at the 125-ppm pretreatment level than at the 25-ppm pretreatment level. Although inter- and intraspecies differences do prevail with such dose–effect relationships and extrapolation of the current findings to human subjects may not be valid, the potential clinical implications should not be overlooked. Accidental

Table II—Calculated Liver Blood Flow Rates in Rats Pretreated with Two Doses of Polychlorinated Biphenyls in Food for 10 Days Compared to Control Animals

Liver Blood Flow Rate	Control	25-ppm Pretreatment	125-ppm Pretreatment
Calculated from literature value of 2 ml/min/g of liver	82.7 ± 6.2	86.5 ± 6.0 (NS)	106.0 ± 12.2 ($p < 0.01$)
Calculated from Eq. 7	77.4 [a]	85.8 [a]	121.5 [a]
	1.84 [b]	1.99 [b]	2.33 [b]

[a] Milliliters per minute per kilogram of body weight. [b] Milliliters per minute per gram of liver.

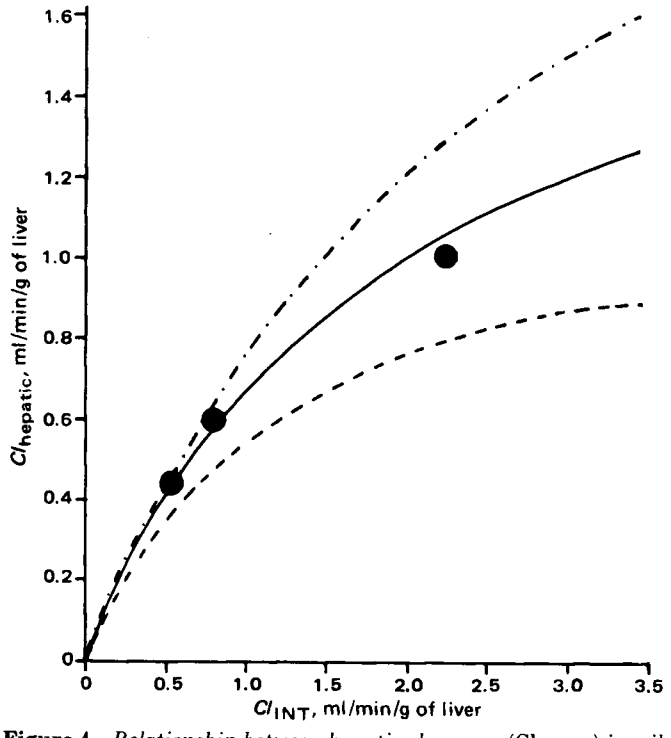

Figure 4—*Relationship between hepatic clearance* ($Cl_{hepatic}$) *in milliliters per minute per gram of liver and intrinsic liver clearance* (Cl_{INT}) *in milliliters per minute per gram of liver. The points are experimentally determined values from oral and intravenous studies, and the lines are for liver blood flow values of 1.2 (– –), 2 (——), and 3 (· – · – ·) ml/min/g of liver.*

exposure of humans to enzyme inducers such as polychlorinated biphenyls may lower the oral bioavailability of facile liver-metabolized drugs and require dosage adjustments.

The apparent agreement of the bioavailability estimation from intravenous or oral data with that determined experimentally from *AUC* values tends to support the validity of the clearance model in assessing systemic availability due to the first-pass effect for drugs exclusively metabolized by the liver. Estimation of the liver blood flow for the control and polychlorinated biphenyl-treated animals showed excellent agreement with literature values. This finding suggests that the blood flow rate on a liver weight basis does not change with induction but that the total hepatic blood flow may be affected by enzyme inducers.

Effects of Antibiotics on Platelet Functions in Human Plasma *In Vitro* and Dog Plasma *In Vivo*

M. I. GENUA *, J. GIRALDEZ *, E. ROCHA *x, and A. MONGE ‡

Received November 20, 1979, from the **Clínica Universitaria and the* ‡*Facultad de Farmacia, Universidad de Navarra, Pamplona, Spain.* Accepted for publication May 1, 1980.

Abstract □ The effects of 31 antibiotics on platelet aggregation in human plasma in the presence of adenosine 5′-diphosphate were studied. The marked activity of tetracycline hydrochloride led to a study of its effects on various platelet functions *in vivo* in dogs.

Keyphrases □ Antibiotics—effects on platelet functions □ Platelet aggregation—effect of antibiotics

Many compounds, including some antibiotics (1–6), interfere with platelet activity under certain conditions. The present investigation was concerned with whether antibiotics in current clinical use affect platelet aggregation, either *in vitro* in human plasma or *in vivo* in dog plasma. When such an effect was found, the mechanism was studied; the investigation was broadened to include other platelet functions such as platelet adhesiveness, platelet factor 3 liberation, platelet mobility in an electric field, and the aggregation of platelets filtered in Sepharose gel.

EXPERIMENTAL

The *in vitro* experiments were carried out with plasma from apparently healthy subjects. The aggregation results correspond to the mean values of at least three trials.

The *in vivo* experiments were carried out on five dogs with similar physical characteristics. The results correspond to the mean values of three trials.

Plasma Samples—Human plasma samples were obtained by forearm venipuncture. The blood was collected in silanized tubes containing 3.8% sodium citrate (1:9) to obtain both platelet-rich plasma and platelet-poor plasma for the aggregation studies.

Dog plasma samples were obtained in a similar manner from mongrel dogs weighing 16–20 kg.

Platelet-rich plasma was obtained by sedimentation or centrifugation of samples at 800 rpm for 10 min for human plasma and for 8 min for dog

[a] The *a* value is 10% of the concentration of the drug in its dosage form, *A* is the percent inhibition of adenosine 5′-diphosphate-induced platelet aggregation by the antibiotic at concentration *a*, *b* is the maximum concentration that the drug reaches in human plasma through the administration of a therapeutic dose, and *B* is the percent inhibition of adenosine 5′-diphosphate-induced platelet aggregation by the antibiotic at concentration *b*.

plasma, with platelet-poor plasma added to give a concentration of 250,000 platelets/mm^3.

Platelet-poor plasma was obtained by centrifugation of human and dog samples at 4000 rpm for 30 min.

Antibiotics—The 31 antibiotics used were penicillin G sodium, penicillin G potassium, penicillin G benzathine, cloxacillin sodium, ampicillin sodium, metampicillin sodium, carbenicillin disodium, cephalothin sodium, cephaloridine, cefazolin, cephapirin sodium, cephacetrile, cephradine, cefamandole, cefoxitin, streptomycin sulfate, kanamycin sulfate, gentamicin sulfate, amikacin sulfate, dibekacin sulfate, colistin sulfate, lincomycin hydrochloride, rifamycin sodium, spectinomycin, tetracycline hydrochloride, oxytetracycline, erythromycin, chloramphenicol, fosfomycin, vancomycin, and amphotericin B[1].

Aggregating Agents—Adenosine 5′-diphosphate was used at a concentration of 2×10^{-5} *M* in pH 7.4 phosphate buffer for the *in vitro* tests and at 10^{-4} *M* in pH 7.4 phosphate buffer for the *in vivo* tests. Epinephrine at a concentration of 10^{-4} *M* in phosphate buffer was used. An initial collagen solution was prepared by the addition of 5 ml of 0.1 *N* acetic acid (pH 3.5) to 10 mg of collagen, followed by dilution with pH 7.4 phosphate buffer to give a final concentration of 0.2 mg of collagen/ml. The solution then was incubated at 37° for at least 30 min until opalescence was observed.

Platelet Aggregation—Platelet aggregation was measured by the absorbance method of Born and Cross (7) using a platelet aggregation meter[2,3].

In the *in vitro* tests[2], 0.1 ml of the test sample was added to a polyethylene cell containing 0.8 ml of platelet-rich plasma. The cell was incubated for 90 sec at 37°. At this point, 0.1 ml of a solution of adenosine 5′-diphosphate, epinephrine, or collagen in buffer was added.

[1] The trade names are Unicilina, Cidan-cilina, Bencetacil Simple, Orbenin, Cilleral, Actuapen, Pyopen, Keflin, Kefloridine, Cefamecin, Brisfirina, Celospor, Velocef, Mandokef, Mefoxitin, Neodual Estrepto, Kanahidro, Genticina, Biclin, Klobamicina, Colimicina, Lincocin, Rifocina, Kempi, Tetralen, Terramicina, Pantomicina, Chloromycetin, Fosfocina, Diatracin, and Fungizona, respectively.

[2] Evans EE1 169.

[3] Dual-channel Aggro-Meter.

Table II—Percent Inhibition of Human Platelet Aggregation Induced by Adenosine 5′-Diphosphate, Epinephrine, and Collagen *In Vitro*

Antibiotic	Adenosine 5′-Diphosphate	Epinephrine	Collagen
Cephaloridine	25	0	15
Rifamycin sulfate	20	5	15
Tetracycline hydrochloride	30	10	55
Amphotericin B	20	0	30

In the *in vivo* tests[3], 0.05 ml of the aggregating agent was added to 0.4 ml of platelet-rich dog plasma treated with tetracycline, using a procedure similar to that used for the *in vitro* tests.

Platelet Factor 3—The liberation of platelet factor 3 was studied by the Hardisty–Hutton method (8).

Platelet Electrophoretic Mobility—Alteration in the charge of the platelet cell membrane was studied by the determination of platelet mobility in an electric field using a cytopherometer[4]. Platelet-rich dog plasma (0.5 ml) was diluted with 9.5 ml of isotonic saline. The time required for platelets to travel a specified distance at the current strength used was determined.

Platelet Adhesiveness—Platelet adhesiveness was determined by the method of Salzman (9).

Platelet Filtration—Silanized K 15/30 columns, 30 cm × 1.5 cm i.d.[5], were used. Nylon filters with 40-μm diameter pores were placed in the bottom of the columns. The 2B Sepharose gel[5] was dissolved 1:4 in normal saline, kept at 4° for 24 hr, and cleared of bubbles before use.

The columns were filled with the gel to a height of ~16 cm. Then 6 ml of normal saline was added to cover the gel until the columns were used. From 4 to 6 ml of platelet-rich plasma was used for each filtration, which was carried out at a rate of 6–9 drops/min. The eluate was collected in 2-ml fractions in polyethylene tubes in ethylenediaminetetraacetic acid (0.077 *M*) and subsequently was centrifuged for 20 min at 3000 rpm.

The sedimented platelets were diluted with phosphate buffer to a final concentration of 400,000 platelets/mm^3. The aggregation of normal filtered platelets in plasma from dogs treated with tetracycline and of platelets from untreated dogs was studied, and the results were compared.

Statistical Analysis—The statistical analysis was performed using a *t* test.

RESULTS AND DISCUSSION

Most of the antibiotics studied inhibited the aggregation of platelets induced by 2×10^{-5} *M* adenosine 5′-diphosphate (Table I) at 10% of the concentration of the dosage form. At the maximum drug concentration in human plasma after the administration of a therapeutic dose, four drugs (cephaloridine, rifamycin sodium, tetracycline hydrochloride, and amphotericin B) inhibited adenosine 5′-diphosphate-induced aggregation by more than 20% and only one compound (tetracycline hydrochloride) clearly maintained its inhibitory effect *in vitro* in the presence of epinephrine (10%) and collagen (55%) (Table II).

The study of the various aggregating agents in dog blood led to the

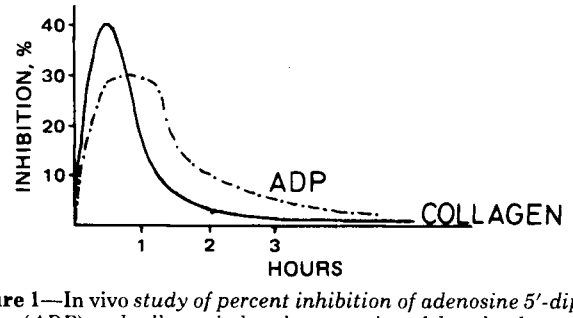

Figure 1—In vivo *study of percent inhibition of adenosine 5′-diphosphate- (ADP) and collagen-induced aggregation of dog platelets treated with tetracycline hydrochloride according to the time elapsed since its administration.*

[4] Zeiss 477500.

[5] Pharmacia, Uppsala, Sweden.

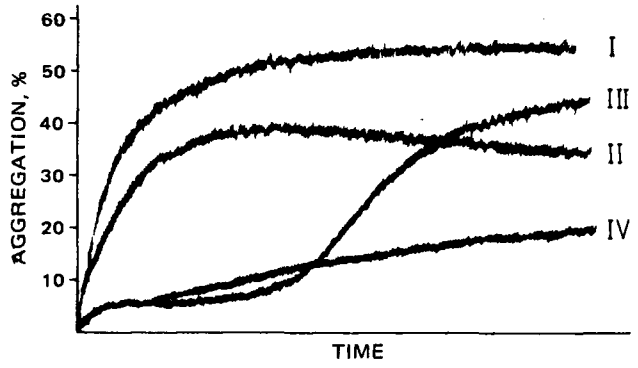

Figure 2—*Aggregation induced by adenosine 5′-diphosphate in filtered dog platelets (I) and in filtered dog platelets previously treated with tetracycline hydrochloride (II) and aggregation induced by collagen in filtered dog platelets (III) and in filtered dog platelets previously treated with tetracycline hydrochloride (IV).*

conclusion that solutions of 10^{-4} *M* adenosine 5′-diphosphate gave identical results to solutions of 2×10^{-5} *M* adenosine 5′-diphosphate in human plasma. The 0.2-mg/ml collagen solutions used in human plasma gave similar results in dog plasma, although the latency period for aggregation with platelet-rich dog plasma was approximately twice that obtained with platelet-rich human plasma. No significant aggregation in platelet-rich dog plasma was obtained with epinephrine, so this aggregating agent was not used for *in vivo* tests in dogs.

Platelet aggregation *in vivo* was studied at 0, 30, 60, and 90 min and 2, 24, 48, and 72 hr after intramuscular administration of tetracycline hydrochloride. As shown in Fig. 1, tetracycline hydrochloride inhibited 40% of collagen-induced platelet aggregation in blood extracted 30 min after the intramuscular administration of 5 mg of antibiotic/kg and 30% of adenosine 5′-diphosphate-induced platelet aggregation in blood extracted 30 and 45 min after a similar dose of the antibiotic. Platelet factor 3 values in dog plasma were similar to those found in human plasma. In dogs treated with tetracycline hydrochloride, factor 3 release was decreased significantly ($p < 0.0001$), with a mean value of 32.5 sec, compared to liberation in untreated dogs, where the mean value was 26 sec.

Electrophoretic mobility was identical for platelets from treated and untreated dogs, indicating unaltered platelet membrane potentials. The results were $x/N = 12.65 \pm 0.05$ and $x_1/N = 13.15 \pm 0.05$, where x is the time required for dog platelets to travel 64 μm (32 μm to the left and 32 μm to the right by varying the polarity), x_1 is the time required for tetracycline-treated dog platelets to travel the same distance, and N is the number of determinations (in this case, 20).

To determine whether the alteration in platelet aggregation produced by tetracycline was due to the platelets themselves or to the surrounding plasma, the platelets were filtered. The activity of normal filtered platelets with tetracycline-treated dog plasma and of tetracycline-treated platelets with untreated dog plasma in the presence of adenosine 5′-diphosphate and collagen was studied; the aggregation of untreated filtered platelets was greater than that of tetracycline-treated platelets (30% inhibition in the presence of adenosine 5′-diphosphate and 85% in the presence of collagen) (Fig. 2).

In conclusion, high concentrations of antibiotics usually completely inhibit the *in vitro* aggregation of platelets induced by adenosine 5′-diphosphate. At concentrations equivalent to plasma levels after administration of a therapeutic dose, only cephaloridine, rifamycin sodium, tetracycline hydrochloride, and amphotericin B partially inhibit adenosine 5′-diphosphate-induced aggregation and only tetracycline hydrochloride maintains this activity in the presence of other aggregating agents. In addition, tetracycline hydrochloride exerts an inhibitory effect *in vivo* on platelet aggregation in dog blood, affecting the platelets themselves and not the surrounding plasma, as shown by the results obtained with platelets filtered in Sepharose columns. It appears to alter the liberation of platelet factor 3.

Binding of Toxic Metabolites of Isoniazid by Aconiazide

HANS R. HELD * and SILVIO LANDI *‡x

Received October 17, 1979, from **Connaught Laboratories Limited, Willowdale, Ontario, Canada*, and the ‡*Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada.* Accepted for publication May 12, 1980.

Abstract □ Isoniazid, the hydrazide of isonicotinic acid, is widely used in the treatment and prophylaxis of tuberculosis. The toxicity and carcinogenicity of isoniazid have been attributed to the action of its metabolites, hydrazine and acetylhydrazine. Aconiazide, the isonicotinylhydrazone of 2-formylphenoxyacetic acid, has been used in the treatment and prophylaxis of tuberculosis. Aconiazide is hydrolyzed in the body to isoniazid and 2-formylphenoxyacetic acid. 2-Formylphenoxyacetic acid has been shown to bind hydrazine and acetylhydrazine. This binding could explain the lower toxicity of aconiazide and also could provide a reason for postulating its lack of carcinogenicity.

Keyphrases □ Isoniazid—binding of toxic metabolites by aconiazide □ Aconiazide—binding of toxic metabolites of isoniazid, potential as antitubercular agent □ Antitubercular agents, potential—aconiazide, binding of toxic metabolites of isoniazid

Isoniazid (isonicotinic acid hydrazide) was introduced in 1952 as a drug for the treatment of tuberculosis and it soon became recognized as the most effective drug for the treatment and prevention of tuberculosis. It later became apparent that prolonged treatment with isoniazid may affect the peripheral and central nervous systems, and

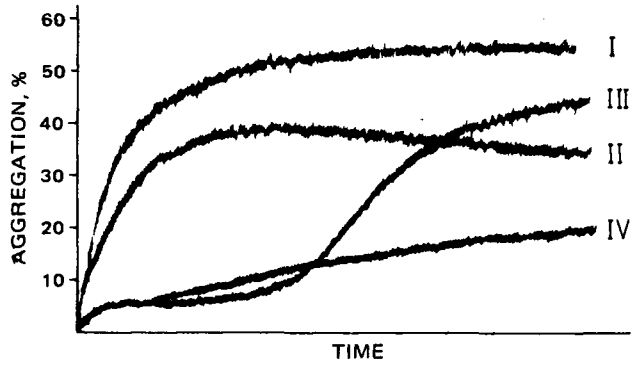

Figure 2—*Aggregation induced by adenosine 5′-diphosphate in filtered dog platelets (I) and in filtered dog platelets previously treated with tetracycline hydrochloride (II) and aggregation induced by collagen in filtered dog platelets (III) and in filtered dog platelets previously treated with tetracycline hydrochloride (IV).*

conclusion that solutions of 10^{-4} *M* adenosine 5′-diphosphate gave identical results to solutions of 2×10^{-5} *M* adenosine 5′-diphosphate in human plasma. The 0.2-mg/ml collagen solutions used in human plasma gave similar results in dog plasma, although the latency period for aggregation with platelet-rich dog plasma was approximately twice that obtained with platelet-rich human plasma. No significant aggregation in platelet-rich dog plasma was obtained with epinephrine, so this aggregating agent was not used for *in vivo* tests in dogs.

Platelet aggregation *in vivo* was studied at 0, 30, 60, and 90 min and 2, 24, 48, and 72 hr after intramuscular administration of tetracycline hydrochloride. As shown in Fig. 1, tetracycline hydrochloride inhibited 40% of collagen-induced platelet aggregation in blood extracted 30 min after the intramuscular administration of 5 mg of antibiotic/kg and 30% of adenosine 5′-diphosphate-induced platelet aggregation in blood extracted 30 and 45 min after a similar dose of the antibiotic. Platelet factor 3 values in dog plasma were similar to those found in human plasma. In dogs treated with tetracycline hydrochloride, factor 3 release was decreased significantly ($p < 0.0001$), with a mean value of 32.5 sec, compared to liberation in untreated dogs, where the mean value was 26 sec.

Electrophoretic mobility was identical for platelets from treated and untreated dogs, indicating unaltered platelet membrane potentials. The results were $x/N = 12.65 \pm 0.05$ and $x_1/N = 13.15 \pm 0.05$, where x is the time required for dog platelets to travel 64 μm (32 μm to the left and 32 μm to the right by varying the polarity), x_1 is the time required for tetracycline-treated dog platelets to travel the same distance, and N is the number of determinations (in this case, 20).

To determine whether the alteration in platelet aggregation produced by tetracycline was due to the platelets themselves or to the surrounding plasma, the platelets were filtered. The activity of normal filtered platelets with tetracycline-treated dog plasma and of tetracycline-treated platelets with untreated dog plasma in the presence of adenosine 5′-diphosphate and collagen was studied; the aggregation of untreated filtered platelets was greater than that of tetracycline-treated platelets (30% inhibition in the presence of adenosine 5′-diphosphate and 85% in the presence of collagen) (Fig. 2).

In conclusion, high concentrations of antibiotics usually completely inhibit the *in vitro* aggregation of platelets induced by adenosine 5′-diphosphate. At concentrations equivalent to plasma levels after administration of a therapeutic dose, only cephaloridine, rifamycin sodium, tetracycline hydrochloride, and amphotericin B partially inhibit adenosine 5′-diphosphate-induced aggregation and only tetracycline hydrochloride maintains this activity in the presence of other aggregating agents. In addition, tetracycline hydrochloride exerts an inhibitory effect *in vivo* on platelet aggregation in dog blood, affecting the platelets themselves and not the surrounding plasma, as shown by the results obtained with platelets filtered in Sepharose columns. It appears to alter the liberation of platelet factor 3.

numerous reports indicated that isoniazid could induce hepatitis (1, 2). Furthermore, it has been well established that isoniazid is carcinogenic in animals (3).

Isoniazid (I) is metabolized to isonicotinyl acetylhydrazine (II), which is metabolized further to isonicotinic acid (III), acetylhydrazine (IV), and hydrazine (V). Free IV and V undergo enzymatic conversion to hepatotoxic (4) and carcinogenic products (3). Therefore, there is obviously a need for antituberculous drugs with the same efficacy as I but with no carcinogenicity and reduced toxicity.

In a search for such drugs, many derivatives of I have been prepared. One compound, aconiazide (the isonicotinylhydrazone of 2-formylphenoxyacetic acid, VI) (5–12),

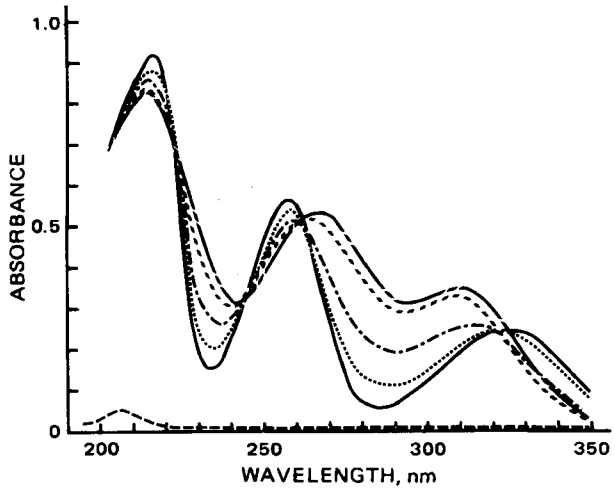

Figure 2—*UV spectra of 2-formylphenoxyacetic acid (0.05 mM) (—), hydrazine (0.05 mM) (– –), and a mixture of the two compounds taken after 30 min (• • •), 4 hr (• – •), 24 hr (– – –), and 3 days (— – —) after its preparation. All solutions were prepared in 0.1% $NaHCO_3$.*

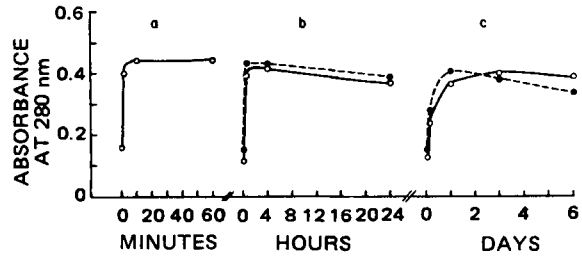

Figure 3—*Reaction of 2-formylphenoxyacetic acid (0.05 mM) with different concentrations of hydrazine in 0.1% $NaHCO_3$ at 23 (—) and 37° (– –). Key: a, 5 mM; b, 0.5 mM; and c, 0.05 mM.*

formed from I and 2-formylphenoxyacetic acid (VII), showed antituberculous activity in animals (6) and humans (8) equivalent to that of I and had a much lower toxicity (5, 7, 8). Aconiazide[1] was used in humans in Canada as a substitute for I (8). The manufacturing of this antituberculous drug was discontinued for economic reasons, although it is still listed in the Compendium of Pharmaceuticals and Specialties (9). However, economic considerations alone should not prevent the use of an antituberculous drug that may have no carcinogenic activity and reduced side effects as compared with I. Therefore, studies were undertaken to determine if the carcinogenic metabolites (IV and V) of I could be bound and hence inactivated by VII, which is a component of VI.

EXPERIMENTAL

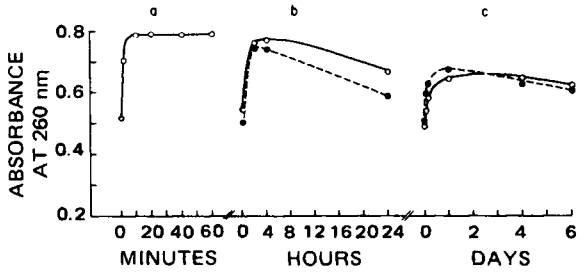

Figure 5—*Reaction of aconiazide (0.05 mM) with different concentrations of hydrazine in 0.1% $NaHCO_3$ at 23 (—) and 37° (- -). Key: a, 5 mM; b, 0.5 mM; and c, 0.05 mM.*

299.28), 2-formylphenoxyacetic acid[4] (VII) (mol. wt. 180.16), acetylhydrazine[5] (IV) (mol. wt. 74.08), and hydrazine[6] (V) (95%) were obtained commercially.

Buffer Solutions—A 0.1% $NaHCO_3$ solution was used to dissolve the reagents and record their UV spectra (Figs. 1–8). The pH of a freshly prepared sodium bicarbonate solution was ~8.4; a 1.25% phosphate buffer of pH 7.2 also was used. It was prepared by dissolving 27.4 g of monobasic potassium phosphate and 72.6 g of dibasic sodium phosphate in 8 liters of water.

UV Spectrophotometry—Due to the sensitivity and characteristics of their UV absorption spectra, the progression of the binding of hydrazine (V) or acetylhydrazine (IV) by 2-formylphenoxyacetic acid (VII) or its isonicotinylhydrazone (VI) can be followed easily. A UV spectrophotometer[7] was used to obtain the spectra.

The progression of the reaction between IV or V and VII in solution was studied by recording the absorbance at 280 nm at various intervals. The progression of the reaction between IV or V and VI in solution was studied at various intervals by recording the absorbance at 260 nm.

RESULTS

Reaction of 2-Formylphenoxyacetic Acid (VII) with Hydrazine (V)—Figure 1 shows the UV spectra of VII and of V at 0.05 and 25 m*M*, respectively. The UV spectrum of a solution containing both substances also is shown. From this spectrum, it appears that a compound, most likely a hydrazone of VII, formed within 2 min after mixing VII and V at final concentrations of 0.05 and 25 m*M*, respectively.

Figure 2 shows the UV spectrum of a solution containing VII and V, both at concentrations of 0.05 m*M*, taken at various time intervals. At this concentration of V (0.05 m*M*), the same new compound was formed but at a much slower rate than when a higher concentration of V (25 m*M*) was used (Fig. 1).

The speed at which VII (0.05 m*M*) reacts with V at different concentrations can be seen more clearly if the absorbance at 280 nm is plotted *versus* time. In fact, Fig. 3 shows that at 23°, the reaction was complete in ~20 min, 2 hr, and 3 days for V at concentrations of 5, 0.5, and 0.05 m*M*, respectively. At 37°, the reaction was approximately two to three times faster than at room temperature and was complete in ~1 hr and 1 day for V at concentrations of 0.5 and 0.05 m*M*, respectively.

Reaction of Aconiazide (VI) with Hydrazine (V)—Figure 4 shows the UV absorption spectra of a solution of VI at 0.05 m*M*[8] (15 μg/ml) and of VI in an excess of V (25 m*M*). Figure 4 also shows that a new compound formed from VI and V within 2 min after these two substances were mixed. Since this new compound has its UV maxima at exactly the same wavelengths as the compound formed from VII and V (Fig. 1), it indicated that the 2-formylphenoxyacetic acid component of VI had reacted with V. Furthermore, Fig. 5 shows that the reaction between VI and V slowed down in exactly the same way as was observed for VII and V when lower concentrations were used.

Reaction of 2-Formylphenoxyacetic Acid (VII) with Acetylhydrazine (IV)—Figure 6 shows the UV absorption spectra of solutions of VII and of IV at 0.05 and 25 m*M*, respectively. Figure 6 also shows the UV spectrum of a solution containing both substances. From this spectrum, it appears that a compound, most likely an acetylhydrazone of VII,

[4] Aldrich Chemical Co., Milwaukee, Wis.
[5] Acethydrazide, Aldrich Chemical Co., Milwaukee, Wis.
[6] Distillation Products Industries, Eastman Organic Chemicals Department, Division of Eastman Kodak Co., Rochester, N.Y.
[7] Pye Unicam SP1800 with linear recorder model AR25.
[8] This concentration can be expected in the serum of patients treated with VI.

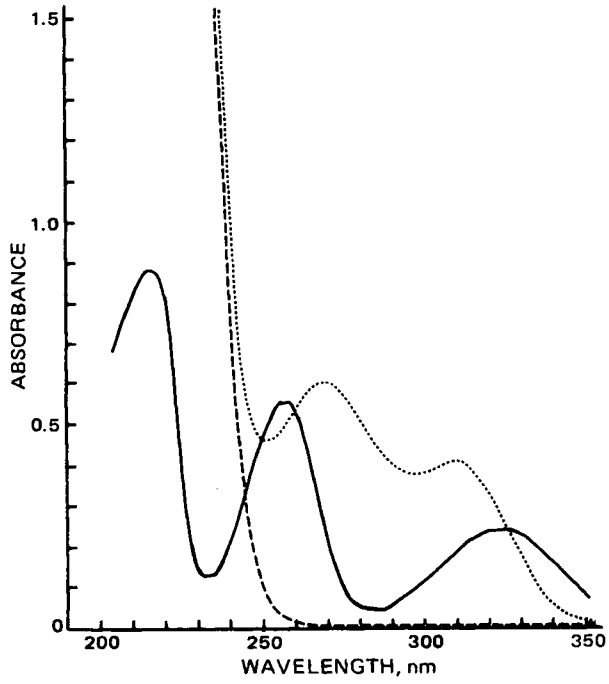

Figure 6—*UV spectra of 2-formylphenoxyacetic acid (0.05 mM) (—), acetylhydrazine (25 mM) (- -), and a mixture of 2-formylphenoxyacetic acid (0.05 mM) and acetylhydrazine (25 mM) (· · ·). The spectrum of the mixture was taken 4 hr after preparation. All solutions were prepared in 0.1% $NaHCO_3$.*

formed within 4 hr after mixing of VII and IV at final concentrations of 0.05 and 25 m*M*, respectively.

Figure 7 shows the speed at which VII reacted with IV at three concentrations (25, 0.5, and 0.1 m*M*). By comparing this reaction with the reaction of VII with V (Figs. 1–3), it is obvious from Figs. 6 and 7 that IV reacted with VII at a much slower rate than V.

Reaction of Aconiazide (VI) with Acetylhydrazine (IV)—Figure 8 shows the UV absorption spectra of VI and of IV at 0.05 and 25 m*M*, respectively. Figure 8 also shows the UV spectrum of a solution containing both substances. From this spectrum, it appears that a new compound formed within 4 hr after mixing VI and IV at final concentrations of 0.05 and 25 m*M*, respectively. Since this new compound has its UV maxima at exactly the same wavelengths as the compound formed from VII and IV (Fig. 6), it can be surmised that the 2-formylphenoxyacetic acid component of VI had reacted with IV.

Reaction of 2-Formylphenoxyacetic Acid (VII) with Hydrazine (V) and Acetylhydrazine (IV) at pH 7.2—The reactions between VII and V or IV were carried out in freshly prepared 0.1% $NaHCO_3$ at a pH of ~8.4. Therefore, it was of interest to find out if the same reactions also would occur at the physiological pH of 7.2 in a phosphate-buffered solution. At this pH, the reactions were not different from those obtained in 0.1% $NaHCO_3$, except that they proceeded at a significantly faster rate.

DISCUSSION

Aconiazide (VI) is formed from I and VII, and VII is a derivative of

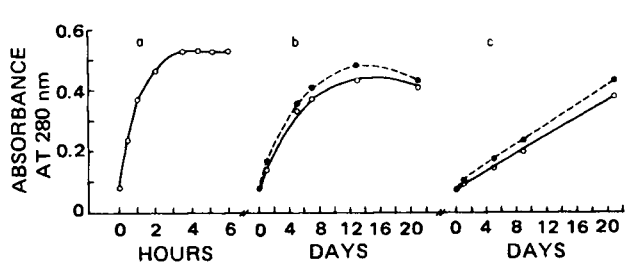

Figure 7—*Reaction of 2-formylphenoxyacetic acid (0.05 mM) with different concentrations of acetylhydrazine in 0.1% $NaHCO_3$ at 23 (—) and 37° (- -). Key: a, 25 mM; b, 0.5 mM; and c, 0.1 mM.*

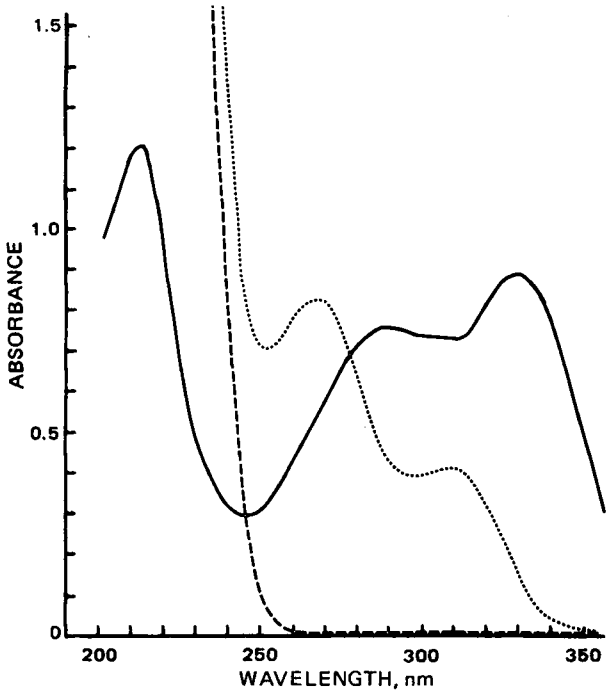

Figure 8—*UV spectra of aconiazide (0.05 mM) (—), acetylhydrazine (25 mM) (– –), and a mixture of aconiazide (0.05 mM) and acetylhydrazine (25 mM) (· · ·). The spectra of the solutions were taken 4 hr after preparation in 0.1% $NaHCO_3$.*

salicylaldehyde. It is well known that aldehydes react with hydrazines. Therefore, the reaction between VII and V or IV, as evidenced by the spectra in Figs. 1–3 and Figs. 4 and 5, respectively, could result in the formation of the hydrazone or acetylhydrazone of VII. Regardless of whether VII or VI was used in the presence of V or IV, the same new compounds were formed, although their levels of absorbance in the 265- and 305-nm regions were different (Figs. 1 and 4 and Figs. 6 and 8). This difference in the level of absorbance is due to the fact that I, which also has an absorption maximum around 265 nm (Fig. 4), is liberated from VI.

The reaction product between VII and V, namely, the sodium salt of the hydrazone of VII, could easily be obtained in crystalline form by mixing a fairly strong solution of the sodium salt of VII with an excess of V and evacuating the mixture to dryness. The preparation so obtained showed a UV absorption spectrum identical to the spectra shown in Figs. 1 and 2.

The fact that V and IV react with VI to form new compounds indicates that VII has a greater affinity for V and IV than for isoniazid (I). One interesting feature of VI is that for each liberated amount of I, the equivalent amount of VII is liberated simultaneously, making it available to bind an equivalent amount of the toxic metabolites released from I, namely, V and IV. This binding could account for the lower toxicity of VI compared to I (7, 8).

It also was shown conclusively that lung tumors can be induced in mice fed isoniazid (I) over 6–12 months and that the tumors are caused by the metabolites of I, namely, acetylhydrazine (IV) and hydrazine (V) (1, 13–15). The demonstration by UV spectrophotometry that a dissociation product of aconiazide (VI) (namely, 2-formylphenoxyacetic acid, VII) binds the carcinogenic metabolites of I strongly suggests that VI may not be carcinogenic. Hence, a comparative study between VI and I in animals is warranted to ascertain whether VI is carcinogenic.

Should these studies show that aconiazide (VI) is noncarcinogenic, and since clinical studies (8), although limited, have shown that VI is as effective as and less toxic than isoniazid (I) in patients with tuberculosis, there should be no reason why VI could not be used as a substitute for I.

Identification of Canine Urinary Metabolites of the Antiprotozoal Agent 3a,4,5,6,7,7a-Hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole

W. J. A. VANDENHEUVEL ˣ, DAVID ONOFREY, J. S. ZWEIG, JOSEPH PILE, NAOMI KIRKMAN-BEY, and B. H. ARISON

Received November 14, 1979, from *Merck Sharp & Dohme Research Laboratories, Rahway, NJ 07065.* Accepted for publication May 12, 1980.

Abstract □ Metabolite fractions from the urine of a dog dosed with 3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole (MK-0436) were obtained by the use of high-performance liquid chromatography. These fractions were of suitable purity for structural elucidation. Data obtained by mass spectrometry and NMR spectroscopy allowed the identification of seven major metabolites of this drug. Biotransformation in each case involved hydroxylation (mono or di) of the hexahydrobenzisoxazole ring.

Keyphrases □ 3a,4,5,6,7,7a-Hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole—identification of urinary metabolites, dogs □ Metabolites—of 3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole, identification, dog urine □ Antiprotozoal agents—3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole, identification of urinary metabolites by NMR spectroscopy, mass spectrometry, and capillary column GLC–mass spectrometry

3a,4,5,6,7,7a-Hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole (MK-0436, I) is an antiprotozoal agent (1) active against *Trypanosoma cruzi* (2) (Fig. 1). This nitroimidazole displayed antibacterial activity during mutagenicity testing[1] using the host-mediated mouse test and the Ames test with S9 liver microsomes (3) but not when the simple Ames spot test (4) was employed (5). These observations led to the presumption that metabolites of I might be antibacterial.

Several metabolite-containing fractions from the urine of a dog given I were found to possess antibacterial activity, and several canine metabolites (both unconjugated and the aglycones from conjugated metabolites) were partially characterized as mono- and dihydroxy species with substitution at positions 4, 5, 6, and/or 7 of the hexahydrobenzisoxazole ring (5). Further characterization of the metabolite mixture and unequivocal identification of several major metabolites of this drug are presented here.

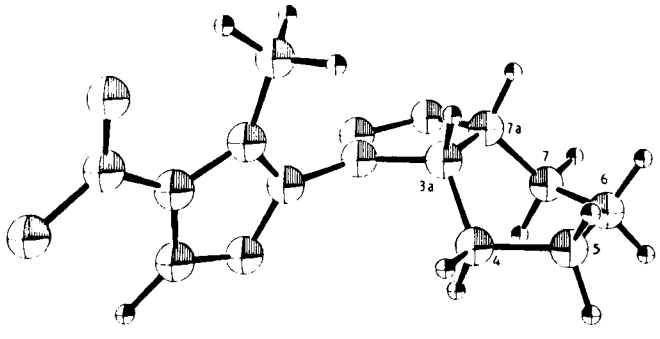

Figure 1—*Computer-generated ORTEP plot of I.*

[1] H. Skeggs, Merck Sharp & Dohme Research Laboratories, West Point, PA 19486, personal communication.

EXPERIMENTAL

Two methanol solutions containing canine urinary metabolites of I (those originally present in the urine as unconjugated metabolites and the aglycones of those originally present as conjugates) were obtained as described previously (5). The two solutions were stored at 4°, and aliquots were taken for isolation and chromatographic purification of the metabolites.

Aliquots of the aglycone metabolite fraction (dissolved in methylene chloride) were subjected to high-performance liquid chromatography (HPLC) using a C_8 reversed-phase preparative column[2] with a step gradient (4.4 ml/min) of methanol–water (1:4) for 40 min, methanol–water (1:2) for 40 min, and methanol for 20 min. Fourteen fractions were collected in each of seven chromatographic runs. The initial column system conditions were regenerated following each run by passage of methanol–water (1:4) through the column for 15 min.

Five fractions (II–VI) yielded sufficient quantities of metabolites to pursue structural elucidation. Aliquots of the metabolite fraction from unhydrolyzed urine also were subjected to HPLC for metabolite isolation using a semipreparative C_{18} reversed-phase column[3]. The quantities of metabolites obtained were, except in one case, too small for successful characterization. Because the amount of bioactivity in the aglycone fraction was approximately twice that found in the nonconjugate fraction, efforts were concentrated on the former. Analytical HPLC was carried out on a C_{18} reversed-phase column[4] with methanol–water (1:4) at a flow rate of 1.5 ml/min. UV detection at 330 nm was used in all HPLC work.

GLC[5] and GLC–mass spectrometric[6] analyses were carried out on trimethylsilylated [bis(trimethylsilyl)trifluoroacetamide[7]–pyridine (3:1) for 3 hr at room temperature] metabolites using 10- or 15-m × 0.3-mm SE-30 glass capillary columns at 240° with helium as the carrier gas. The mass spectrometer[6] was operated with a 70-ev ionizing potential and a 0.8-mamp emission current. Direct-probe mass spectrometry[8] was carried out with a 70-ev ionizing potential, a 60-μamp trap current, and a 3.5-kv accelerating voltage. NMR spectra[9] were obtained from samples dissolved in deuterochloroform.

RESULTS AND DISCUSSION

HPLC (Fig. 2) and GLC (Fig. 3) (trimethylsilyl derivatives) analyses of the aglycone fraction resulting from enzyme hydrolysis of the urinary conjugates demonstrated that it was a multicomponent mixture. Although GLC–mass spectrometry indicated that most of the eluted components (trimethylsilyl derivatives) were drug related [earlier work showed the presence of at least six metabolites of I (5)], it was not possible to discern exact structures on the basis of the mass spectrometric data alone. NMR spectroscopic examination was needed to establish the metabolite structures unequivocally; but to utilize this technique, it was necessary to isolate and purify the metabolites. HPLC appeared to be the method of choice.

Preparative HPLC, followed in some cases by further purification on an analytical HPLC column, gave five metabolite fractions (II–VI in Fig.

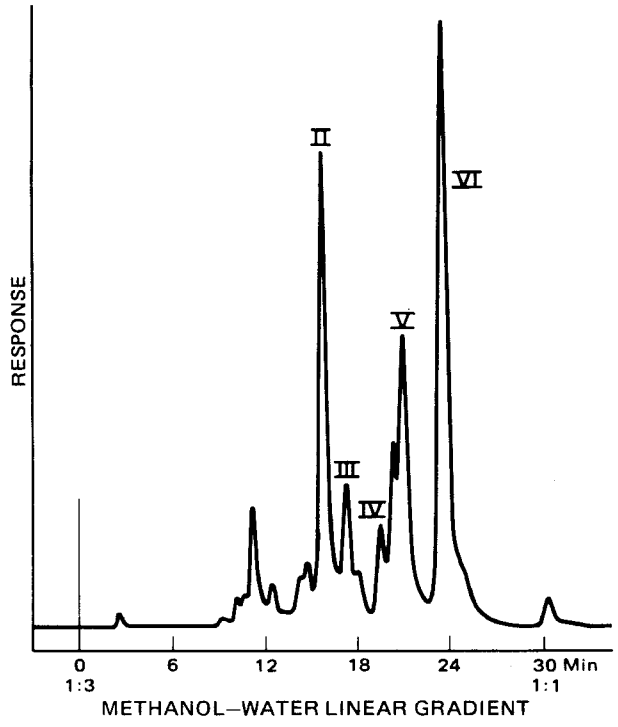

Figure 2—*High-performance liquid chromatogram (C_{18} reversed-phase column) of aglycone fraction (arising from enzyme hydrolysis of canine urinary conjugates).*

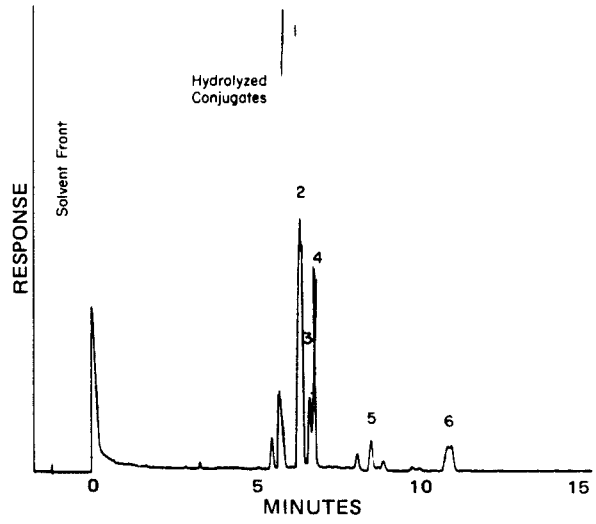

Figure 3—*Gas–liquid chromatogram produced from analysis of the trimethylsilylated aglycone fraction (arising from enzyme hydrolysis of canine urinary conjugates).*

2) of quality and quantity suitable for NMR examination. These fractions were examined first by direct-probe mass spectrometry. The resulting data (major, pertinent ions) are summarized in Table I. Capillary column GLC–mass spectrometric analysis of these samples (following trimethylsilylation) also showed that each sample contained mono- and/or dihydroxylated analogs of the parent drug [molecular ions for the derivatives of *m/e* 426 (dihydroxy metabolites) or *m/e* 338 (monohydroxy metabolites)].

The NMR spectrum (Fig. 4) of I must be understood before structural assignments for the metabolites of this drug can be made. Since previous work demonstrated that the metabolic transformations occurred on carbons 4–7 (5), knowledge of the signal characteristics for the protons on the cyclohexane (hexahydrobenzisoxazole) ring was crucial. The parent drug exhibited proton absorption at δ 8.07 (imidazole H, not shown in Fig. 4), 4.43 (H_{7a}), 4.33 (NCH_3), 3.53 (H_{3a}), 2.29 (H_{7eq}), 2.14 (H_{4eq}), 1.82 (H_{7ax}), 1.67 (H_{6eq} and H_{5eq}), 1.53 (H_{6ax}), and 1.25 (H_{4ax} and H_{5ax}). The assignments, derived from inspection and double-irradiation experiments, provided the basis for the NMR characterization of the metabolites (Table II). The observed coupling constants in the sequence C_7H_2–$C_{7a}H$–$C_{3a}H$–C_4H_2 are consistent with a *cis*-ring fusion and a twist chair configuration for the six-membered ring. Spectrometric and chromatographic details for each isolated metabolite fraction will be given.

Metabolite Fraction II—GLC of the trimethylsilyl derivative of this fraction showed one main component (~80%) and two minor components (~10% each). GLC–mass spectrometry of the major component indicated a molecular ion of *m/e* 426, showing it to be a dihydroxylated metabolite of I. This also was true for the minor components. Direct-probe mass spectrometry of underivatized II gave spectra (Table I) with intense ions of *m/e* 282 (molecular ion of dihydroxy metabolites), and there was no evidence of monohydroxy metabolites (molecular ions of *m/e* 266). HPLC also indicated one major component and two minor components in the sample. The NMR spectrum of II showed two resonances that were not seen in the parent drug in the δ 3.5–4.0 region, indicating incorporation of two hydroxyl groups. Double-irradiation experiments established that the two carbinol methines were vicinal and that one was vicinal to H_{3a}. These findings allowed identification of the major metabolite as a 4,5-dihydroxy analog of I. Since $J_{4,5}$ and $J_{5,6ax}$ are large (>8 Hz), an axial–axial stereochemical relationship is indicated; thus, II must be the 4,5-di(equatorial)hydroxy derivative.

Metabolite Fraction III—Analytical HPLC of this fraction showed one major component and two minor components. However, capillary column GLC indicated the presence of only one minor component (~10%) and one major component (~90%). GLC–mass spectrometry of the trimethylsilylated sample showed that the more abundant component possessed a molecular ion of *m/e* 338, demonstrating that it is a monohydroxy analog of I. The minor component exhibited a molecular ion of *m/e* 426; thus, it is the bis(trimethylsilyl) derivative of a dihydroxy metabolite. The direct-probe mass spectrometric data for III (Table I) also demonstrate that this metabolite fraction is predominantly a

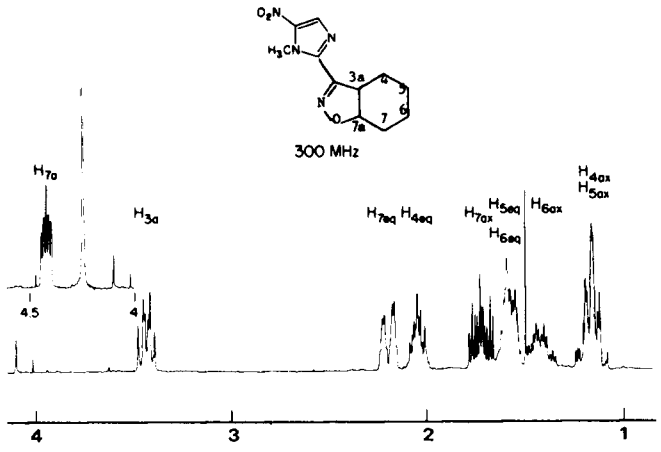

Figure 4—*NMR spectrum of I.*

monohydroxy metabolite contaminated with some dihydroxylated drug.

Metabolite III is assigned as the 6-(axial)hydroxyl derivative of I based on the absence of the characteristic 12.5-Hz coupling constant in the H_{7ax} resonance (Fig. 5). This large splitting is characteristic of an axial–axial relationship and has been identified as J_{H7ax}, J_{H6ax} in the parent drug. As expected, the multiplicities of the H_{3a} and H_{7a} signals are essentially unchanged from those of I, indicating that no substitution has occurred on the neighboring C-7 and C-4 atoms.

Metabolite Fraction IV—As with Fraction III, the direct-probe mass spectrometric data from Fraction IV (Table I) showed that the latter is composed mainly of monohydroxy metabolites plus a lesser amount of dihydroxy metabolites. Capillary column GLC of the trimethylsilyl derivative of IV showed a major component and three minor components, with the minor components each having an area of ~10% of that of the major peak. GLC–mass spectrometry of the major component gave a molecular ion of *m/e* 338, consistent with a monohydroxylated derivative of I. The multicomponent nature of the metabolite fraction (with one major component) also was indicated by analytical HPLC.

The major component of Fraction IV was characterized by NMR spectroscopy as having a single equatorial hydroxyl group at C-5. This conclusion was reached following elimination of other structural possibilities. The C-4 and C-7 sites were eliminated as possible positions of hydroxylation since the H_{3a} and H_{7a} signals retained the same multiplicity as in the parent drug. This required that the neighboring C-4 and C-7 positions be unsubstituted. The two C-6 possibilities were ruled out by Metabolites III and V, in which substitution at C-6 was firmly established by the reduced multiplicity of the recognizable axial H_7 signal. Finally, the linewidth of the carbinol CH group after deuterium oxide exchange ($W_{1/2}$ 20–24 Hz) necessitated at least one large vicinal constant, which is compelling evidence for an axial configuration.

[a] Model compounds prepared by Dr. H. Mrozik, Synthetic Organic Department, Merck Sharp & Dohme Research Laboratories. [b] Tentative assignments. [c] Same as the minor component of metabolite Fraction V.

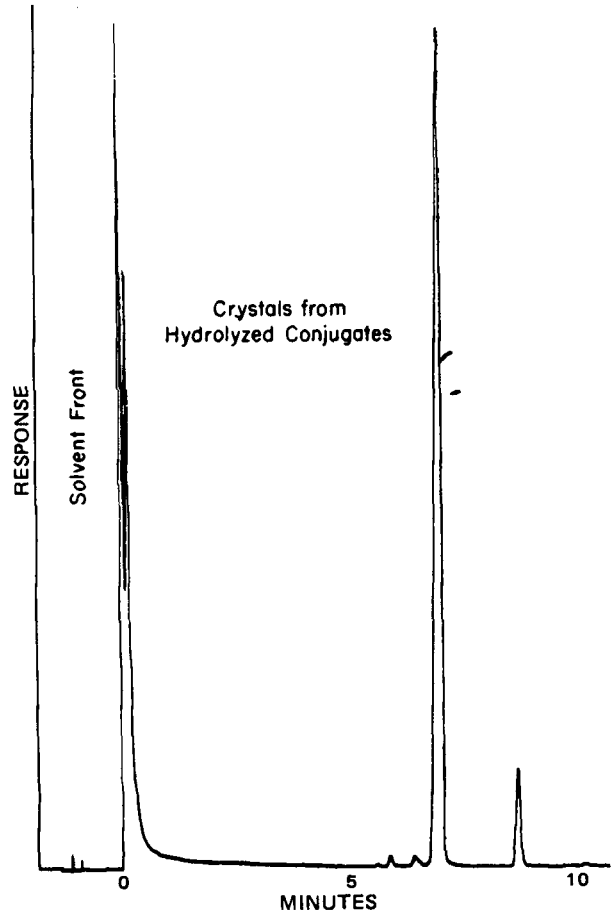

Figure 6—*Gas–liquid chromatogram produced by analysis of the trimethylsilylated metabolite Fraction VII.*

Metabolite Fractions V and VI—HPLC suggested that Fraction V contained one major and one minor component. GLC of the trimethylsilyl derivative showed three peaks with a relative area ratio of approximately 2:4:3. GLC–mass spectrometry of the three peaks gave molecular ions for each of *m/e* 338, as required for monohydroxylated metabolites; however, the fragmentation patterns in each case were somewhat different, suggesting isomeric species. Direct-probe mass spectrometry (Table I) of this metabolite fraction indicated the presence of monohydroxy metabolites only.

Analytical HPLC of Fraction VI and GLC of the trimethylsilyl product indicated a single component of >90% purity. GLC–mass spectrometry indicated a molecular ion at *m/e* 338, required for a monohydroxy compound. The direct-probe mass spectra from Fraction VI also showed that only monohydroxy (and no dihydroxy) metabolites were present (Table I).

The NMR spectra of Fractions V (major component) and VI showed an H_{7a} signal with reduced multiplicity, indicating substitution on a neighboring carbon atom. Since both spectra contained a normal H_{3a} resonance, it follows that the site of hydroxylation is C-7 and that the two metabolites are related as stereoisomers. Stereochemical assignments are not clearcut since the coupling constants between H_{7a} and the two C-7 protons are essentially the same in the parent molecule and differ by only 1 Hz in these two metabolites. However, there is reason for associating the larger J value with an axial H_7 [*i.e.*, a 7-(equatorial)hydroxyl group] since this would correspond to the findings for Metabolite III in which the assignments are unequivocal.

Inspection of the NMR features of the minor component in metabolite Fraction V eliminated C-4 and C-7 as possible sites for the hydroxylation since both the H_{3a} and H_{7a} signals retained a full complement of lines. Irradiation of the equatorial H_7 signal at δ 2.63 reduced the multiplicity of the axial H_7 to a doubled doublet (J = 11.5 and 4.5 Hz). Since the 4.5-Hz coupling constant represents $J_{7,7a}$ and J = 11.5 Hz arises from an axial–axial relationship, it follows that the axial H_7 has suffered a loss of spin interaction with its equatorial neighbor at C-6. Therefore, the minor component in Fraction V was assigned the C-6 equatorial hydroxy structure.

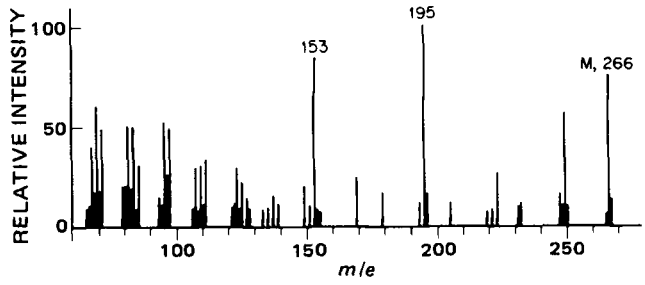

Figure 7—*Mass spectrum from metabolite Fraction VII.*

Metabolite Fraction VII—A small quantity (0.1 mg) of material crystallized in the bottom of the centrifuge tube (stored at 4°) containing the methanol solution of the aglycone metabolite fraction. GLC analysis of the crystals (Fraction VII) following their trimethylsilylation gave the chromatogram shown in Fig. 6. The major and minor components exhibited molecular ions of *m/e* 338 and 426, respectively, characterizing them as mono- and dihydroxy derivatives of I. The major component exhibited the same retention time as the shoulder (peak 3) on the leading edge of peak 4 in Fig. 3. Direct-probe mass spectrometry of underivatized VII gave the spectrum presented in Fig. 7. The molecular ion of *m/e* 266 confirmed that the spectrum arose from a monohydroxylated derivative of I, and the intense fragment ions of *m/e* 153 and 195 demonstrate that the hydroxyl group is substituted on C-4–C-7 of the hexahydrobenzisoxazole ring (5).

NMR examination of VII also indicated the presence of two components in the approximate ratio of 9:1. Signals for the major component matched those for the minor component of Fraction V. This finding indicates that the hydroxyl group in the major component is at C-6 and is in the equatorial configuration. The NMR data for the minor component in Fraction VII indicated it to be a dihydroxy metabolite of I, but no positional or conformational assignments could be made, except that substitution is on C-4–C-7 of the hexahydrobenzisoxazole ring.

Metabolite Fraction VIII—Both HPLC and GLC (following trimethylsilylation) of this nonconjugated metabolite fraction from unhydrolyzed dog urine indicated the presence of a major drug-related component (which appeared to be a dihydroxy metabolite) plus at least two related minor components. The dihydroxy nature of this metabolite also was suggested by direct-probe mass spectrometric data (Table I). Although only limited NMR data were obtained for Fraction VIII, analysis of the spectral features allowed a tentative structural assignment to the major component as 5-(axial),7a-dihydroxy-substituted drug. Key observations that led to this conclusion were: (*a*) the absence of a resonance in the δ 4.5–4.7 region diagnostic for H_{7a}; (*b*) a reduced multiplicity of the H_{3a} and both H_7 signals, indicative of hydroxylation on a neighboring carbon; and (*c*) the appearance of a new, weakly coupled, single proton peak at δ 4.18.

Observations *a* and *b*, taken together, constitute compelling evidence for hydroxylation at C_{7a}. The multiplicities of the H_{3a} and both H_7 signals require that C-4 and C-6 are unsubstituted, thus leaving C-5 as the site for the second hydroxyl group. The new carbinol CH group appears essentially as a broadened singlet with a width at half height of 9.5–10.0 Hz. This indicates that its couplings with the four neighboring protons at C-4 and C-6 all are small, strongly implying an equatorial configuration. Based on this tentative structural assignment, this is the first metabolite of I in which hydroxylation of the drug has occurred at a site other than C-4–C-7, but it is still on the hexahydrobenzisoxazole or cyclohexane ring portion of the drug.

When it was found that hydroxy metabolites of I are bioactive (5), several hydroxy analogs of the drug were synthesized[10]. Although NMR spectroscopy (and mass spectrometry) showed that these analogs were not identical to the metabolites, their NMR spectral data are presented in Table II for comparison.

This and other studies (5–8) have demonstrated that hydroxylation is a common metabolic route for cyclohexanes. Both mono- and dihydroxy metabolites are observed, and the latter probably arise from sequential hydroxylation steps. Thus, Elliott *et al.* (6) showed that cyclohexanol, a urinary metabolite of cyclohexane in the rabbit, is metabolized further to yield *trans*-cyclohexane-1,2-diol.

[10] H. Mrozik, P. Eskola, P. Kulsa, B. H. Arison, W. J. A. VandenHeuvel, J. A. Conroy, and B. M. Miller, Merck Sharp & Dohme Research Laboratories, Rahway, NJ 07065, unpublished data.

Agosin *et al.* (9) reported that the epimastigotes of *T. cruzi* possess an active drug-detoxifying (hydroxylating) system associated with the microsomal fraction, with properties like those of a monooxygenase system linked to cytochrome P-450. These authors speculated that the ability of *T. cruzi* to hydroxylate drugs to inactive metabolites may partially explain why no chemotherapeutic agents that cure Chagas' disease have been found; however, I, for which hydroxylation is a major route of metabolism in dogs (and mice) (5), is active against *T. cruzi* in mice (2, 5). Furthermore, since a synthetic dihydroxy derivative of this compound (the 6,7-*cis*-diol) exhibits severalfold greater activity than the parent drug (5), the possibility is raised that the enzyme system suggested (9) to detoxify other chemotherapeutic agents actually may enhance the bioactivity of I. Thus, the proposal of Agosin *et al.* (9) is of limited validity.

Antimicrobial Activity of *N*-Chloramine Compounds

H. H. KOHL ˣ, W. B. WHEATLEY, S. D. WORLEY, and N. BODOR *

Received October 12, 1979, from the *Department of Chemistry, Auburn University, Auburn, AL 36830.* Accepted for publication May 9, 1980. *Present address: Department of Medicinal Chemistry, University of Florida, Gainesville, FL 32610.

Abstract □ Cellular mechanisms of action of two representative *N*-chloramines were studied. Both compounds, 3-chloro-4,4-dimethyl-2-oxazolidinone (I) and *N*-chlorosuccinimide (III), inhibited bacterial growth and exerted profound inhibition of bacterial DNA, RNA, and protein synthesis at a concentration of 10^{-5} *M*. Enzymes containing sulfhydryl groups generally were significantly inhibited by these chloramines at 10^{-4} *M*. Dihydrofolate reductase, which contains no sulfhydryl groups, also was inhibited but at much higher chloramine concentrations (10^{-2} *M*); ribonuclease, which also contains no sulfhydryl groups, was unaffected. All of these inhibitory effects of the chloramines could be prevented if sulfhydryl-containing reagents (mercaptoethanol or dithiothreitol) were added before or together with the chloramine. Once inhibition was produced by the chloramine, it was not reversible by later addition of the sulfhydryl reagents. These results suggest that these chloramines act at sulfhydryl sites as well as at other sites in both cells and purified enzymes.

Keyphrases □ *N*-Chloramines—antimicrobial activity, inhibition of bacterial DNA, RNA, and protein synthesis □ Antimicrobial activity—*N*-chloramine-induced inhibition of bacterial DNA, RNA, and protein synthesis □ Enzyme inhibition—*N*-chloramine-induced inhibition of sulfhydryl-containing enzymes in bacteria

Recent studies of the chemical (1–5) and antimicrobial (6–8) properties of *N*-chloramine compounds suggested that many of these compounds may be potentially useful antibacterial agents. Preliminary results indicated that these *N*-chloramines are effective antibacterial agents. It was hypothesized that the bactericidal actions of *N*-chloramines are derived from the direct transfer of positive chlorine ions from the *N*-chloramines to an appropriate cellular receptor (5).

The present study was an attempt to elucidate the cellular processes affected by these agents which might account for their observed antimicrobial properties. In seeking the mechanisms of action of such agents, the determination of the primary targets in terms of overall cellular function is vitally important. This paper reports the effects of two representative *N*-chloramines on overall DNA, RNA, and protein synthesis in bacteria. A more specific action in terms of direct inhibition of cellular enzymes also is discussed.

EXPERIMENTAL

Bacterial Cultures—Bacteria [*Escherichia coli* (ATCC 25922) and *Staphylococcus epidermidis* (ATCC 12228)] were grown and harvested as described previously (9). The bacterial cells then were resuspended in fresh nutrient medium[1] at a density of 3×10^8 colony-forming units/ml. Bacterial purity and the absence of contamination were established routinely by the Gram stain and by colony characteristics on blood agar plates.

DNA, RNA, and Protein Synthesis—All stock solutions of 3-chloro-4,4-dimethyl-2-oxazolidinone (I), 4,4-dimethyl-2-oxazolidinone (II), and *N*-chlorosuccinimide (III) were prepared in 0.1 *M* phosphate buffer (pH 7). The stock solutions were diluted with distilled, deionized water.

The bacterial suspensions were added to test tubes containing the respective agents diluted in water. All determinations were made in duplicate or triplicate along with controls containing an identical volume of bacteria without the agents. The bacteria then were incubated at 37° for 1 hr with various concentrations of the *N*-chloramines. Then 1–2 μCi of the following radioisotopes[2] were added: [*methyl*-^{3}H]thymidine, 90

These results suggest that these chloramines act at sulfhydryl sites as well as at other sites in both cells and purified enzymes.

Keyphrases □ *N*-Chloramines—antimicrobial activity, inhibition of bacterial DNA, RNA, and protein synthesis □ Antimicrobial activity—*N*-chloramine-induced inhibition of bacterial DNA, RNA, and protein synthesis □ Enzyme inhibition—*N*-chloramine-induced inhibition of sulfhydryl-containing enzymes in bacteria

Recent studies of the chemical (1–5) and antimicrobial (6–8) properties of *N*-chloramine compounds suggested that many of these compounds may be potentially useful antibacterial agents. Preliminary results indicated that these *N*-chloramines are effective antibacterial agents. It was hypothesized that the bactericidal actions of *N*-chloramines are derived from the direct transfer of positive chlorine ions from the *N*-chloramines to an appropriate cellular receptor (5).

The present study was an attempt to elucidate the cellular processes affected by these agents which might account for their observed antimicrobial properties. In seeking the mechanisms of action of such agents, the determination of the primary targets in terms of overall cellular function is vitally important. This paper reports the effects of two representative *N*-chloramines on overall DNA, RNA, and protein synthesis in bacteria. A more specific action in terms of direct inhibition of cellular enzymes also is discussed.

EXPERIMENTAL

Bacterial Cultures—Bacteria [*Escherichia coli* (ATCC 25922) and *Staphylococcus epidermidis* (ATCC 12228)] were grown and harvested as described previously (9). The bacterial cells then were resuspended in fresh nutrient medium[1] at a density of 3×10^8 colony-forming units/ml. Bacterial purity and the absence of contamination were established routinely by the Gram stain and by colony characteristics on blood agar plates.

DNA, RNA, and Protein Synthesis—All stock solutions of 3-chloro-4,4-dimethyl-2-oxazolidinone (I), 4,4-dimethyl-2-oxazolidinone (II), and *N*-chlorosuccinimide (III) were prepared in 0.1 *M* phosphate buffer (pH 7). The stock solutions were diluted with distilled, deionized water.

The bacterial suspensions were added to test tubes containing the respective agents diluted in water. All determinations were made in duplicate or triplicate along with controls containing an identical volume of bacteria without the agents. The bacteria then were incubated at 37° for 1 hr with various concentrations of the *N*-chloramines. Then 1–2 μCi of the following radioisotopes[2] were added: [*methyl*-^{3}H]thymidine, 90

Table I—Incorporation of ^{3}H-Labeled Precursors into DNA, RNA, and Protein of *E. coli* [a]

Reaction Time at 37°, hr	Thymidine (DNA)	Uridine (RNA)	Leucine (Protein)
1	9,120	6,100	3,410
2	20,500	12,900	7,500
3	31,221	18,928	11,500
3, acid blank	295	190	300
3. ice blank	210	220	310

[a] The values are in counts per minute, which represent the average of triplicate determinations; each value was within 10% of the average shown.

Ci/mmole; [5,6-^{3}H]uridine, 42 Ci/mmole; and [4,5-^{3}H]-L-leucine, 40 Ci/mmole. Incorporation was allowed to proceed for 2 hr at 37°. Five milliliters of ice-cold trichloroacetic acid (10% w/v) containing nonradioactive thymidine, uridine, and leucine (10^{-4} *M*) was added. This addition terminated the incorporation reactions and precipitated DNA, RNA, and protein. The added nonradioactive thymidine, uridine, or leucine helped to displace adsorbed but unincorporated radioactivity and contributed to the low blank values seen in Table I.

Samples were refrigerated for 30 min, and the precipitated material was suspended mechanically using a vortex mixer. This material then was filtered through glass fiber filters[3]. Each filter was washed with 70 ml of 1.3 *N* HCl followed by 40 ml of absolute ethanol. The filters were dried under a heat lamp and placed into liquid scintillation vials. A solubilizing agent[4] (0.5 ml) was added to the vials and left overnight to digest the radioactive film on the filter surface. Scintillation fluid[5] (15 ml) was added, and the vials were mixed gently. Complete solubilization was assured by removing the filters and noting the residual radioactivity remaining on the filter. At least 95% of the radioactivity associated with the filters usually was solubilized by this process.

Radioactivity was counted in the solution phase using a liquid scintillation spectrometer[6]; the counting efficiency was established by the channels ratio method and was verified periodically through the use of a tritiated toluene standard. Toluene-soluble tritium was counted at an efficiency of 45%. Counting of the toluene-insoluble material contained on the filter could be done at 7% efficiency. Further details concerning these procedures may be obtained from the literature (9–12).

Thymidine is a specific precursor of DNA, while uridine and leucine are incorporated into RNA and protein, respectively. The specific nature of these processes was confirmed in this study by both chemical and enzymatic techniques as outlined previously (10, 13, 14).

The effect of the chloramines on the uptake of [^{3}H]thymidine into the acid-soluble pool of *E. coli* was studied. The concentrations of radioactive precursors found in the acid-soluble pool reflect the level of precursor transport into the bacterial cell (15). Acid-soluble radioactive thymidine was measured as follows. Bacteria were incubated at 37° for 60 min in contact with the chloramine (5×10^{-5} *M*) and radioactive thymidine or with thymidine alone (controls). Tubes containing bacteria then were centrifuged and washed three times with ice-cold bacterial nutrient broth containing 0.1 *M* thymidine. Tubes were drained thoroughly, and 5 ml of ice-cold 0.2 *N* perchloric acid was added to the precipitated bacterial pellets. After 15 min, the perchloric acid solutions were collected, and the tubes were rinsed with an additional 2 ml of 0.2 *N* perchloric acid. Radioactivity in the combined 0.2 *N* perchloric acid solutions was determined by liquid scintillation counting.

The effects of I–III on the activities of several enzymes were studied. The following enzymes were obtained commercially[7] and used without further purification: malate dehydrogenase (EC 1.1.37), fumarase (EC 4.2.1.2), and pancreatic ribonuclease (EC 3.1.4.22). Dihydrofolate reductase (EC 1.5.1.3) was purified from a methotrexate-resistant strain of *Lactobacillus casei* (15). Lactate dehydrogenase (EC 1.1.1.27) and creatine phosphokinase (EC 2.7.3.2) were studied using a reconstituted lyophilized bovine enzyme control serum[8].

Enzyme Assays—Chloramines were added to buffered enzyme solutions and allowed to incubate at room temperature for 30 min before being assayed. The specific assays employed the following literature methods: malic dehydrogenase (16), lactic dehydrogenase (17), creatine phosphokinase (18, 19), pancreatic ribonuclease (20), dihydrofolate reductase (21), and fumarase (22).

RESULTS

The data shown in Table I demonstrate increasing tritium incorporation into the DNA, RNA, and protein of *E. coli* for up to 3 hr at 37° in all three processes. The low counts observed by the addition of acid at zero time or by placing the tube in an ice bath to quench the reactions indicate that the washing procedure used is effective in removing adsorbed but unincorporated radioactivity. Variation of the bacterial stock solution from 0.3 to 0.9 ml also showed proportionally increased incorporation of the radioactive precursor when studied for 1 hr of incubation. Similar results were seen using *S. epidermidis*.

The percent inhibitions of DNA, RNA, and protein synthesis by the *N*-chloramines shown in Tables II–V represent the mean of two experiments, each of which was carried out in triplicate. The individual values of these triplicate determinations were within 10% of the mean values indicated. Table II shows progressively increasing inhibitory effects with increasing concentration of 3-chloro-4,4-dimethyl-2-oxazolidinone (I) for all three cellular processes studied using *E. coli*. Similar conclusions are apparent from the data of Table III with *S. epidermidis*.

Tables IV and V show the effects of the chloramine molecule *N*-chlorosuccinimide (III) on the same two bacterial species shown in Tables II and III. The effects of III were similar to those seen using I, namely, progressively increasing inhibition for all three cellular biochemical processes with increasing chloramine concentration. The effects of 4,4-dimethyl-2-oxazolidinone (II), the unchlorinated precursor molecule of I, also were studied, and it was completely inert (Tables II and III). The

[a] Mixed together and added to bacteria as a mixture. [b] Dithiothreitol added to bacteria first, followed by chloramine. [c] Compound I added to the bacteria containing tritiated thymidine and incubated at 37° for 1 hr followed by the addition of dithiothreitol. Fresh bacteria were added, and the incorporation of tritiated thymidine was measured 2 hr later.

unchlorinated precursor molecule (II) was studied under exactly the same conditions as the chloramines (I and III).

Table VI shows that addition of dithiothreitol can protect against the inhibition of DNA synthesis in bacteria. This result was seen when I was combined with dithiothreitol and then added to bacteria or, alternatively, when the bacteria were supplemented with dithiothreitol before the addition of I. Similar protective actions of dithiothreitol using III also have been demonstrated. Again, II had no inhibitory action. Addition of dithiothreitol or mercaptoethanol also could protect against the inhibition of RNA and protein synthesis.

The inhibitory actions of I are not due to chemical alteration of the tritiated thymidine, uridine, or leucine by the chloramine in which these precursors are rendered inert. This conclusion was reached since the chloramines, when added to bacteria with tritiated thymidine and incubated for 60 min at 37°, showed no significant inhibition of incorporation after fresh bacteria were added and incorporation was allowed to proceed for 2 additional hr (Table VI). Residual chloramine was inactivated by adding dithiothreitol immediately before the addition of fresh bacteria. Experiments using tritiated thymidine, uridine, and leucine with I or III gave similar results under identical experimental conditions. However, partial inactivation of the tritiated precursors at far higher chloramine concentrations (1×10^{-2} *M*) was observed.

The data obtained indicate that while the bacterial synthesis of DNA was significantly inhibited based on a *t* test for paired samples ($p < 0.001$), the chloramine did not produce statistically significant inhibition of the uptake or transport of tritiated thymidine into the bacterial cells. Bacteria were incubated together with 5×10^{-5} *M* I and [^{3}H]thymidine for 1 hr at 37°. The amount of tritiated precursor found in the bacterial acid-soluble pool is a direct reflection of the extent of thymidine transport into the bacterial cell (15). Similar results also were obtained using tritiated uridine and leucine.

These chloramines were effective inhibitors of sulfhydryl-containing enzymes (Table VII). Three general groups of enzymes were compared: (*a*) enzymes containing sulfhydryl groups at their active sites [malic dehydrogenase (23), lactic dehydrogenase (24), and creatine phosphokinase (25)]; (*b*) enzymes containing no sulfhydryl groups at their active sites but having sulfhydryl groups at other sites [fumarase (26)]; and (*c*) enzymes containing no sulfhydryl groups at any site [ribonuclease (27) and dihydrofolate reductase (21)].

The enzymes in the first group are inhibited easily (Table VII). The sulfhydryl group does not have to be present at the active site for inhibition to occur since fumarase also is quite sensitive. Some enzymes containing no sulfhydryl groups (dihydrofolate reductase) also can be inhibited but only at much higher chloramine concentrations ($\geq 10^{-2}$ *M*). However, ribonuclease was not inhibited, even at 10^{-2} *M*. All of the chloramine-induced enzymatic inhibitions could be prevented if the chloramines were mixed first with twice the concentration of the sulfhydryl-containing reagent dithiothreitol. The limiting amount of dithiothreitol that was capable of preventing chloramine-induced enzymatic inhibition was not explored. Reactivation of the inhibited enzymes by later addition of sulfhydryl agents after first reacting the enzyme with chloramine was not achieved. The unchlorinated precursor (II) was not effective in inhibiting any of the sulfhydryl-containing enzymes (Table VII).

The effects of increasing I concentrations on the overall growth of *E. coli* also were studied but are not presented in tabular form. Inhibition of bacterial growth was studied by incubating inoculated cultures of *E. coli* at 37° and monitoring the effect on turbidity (absorbance increase) at 450 nm against time at 10-hr intervals. The bacterial growth data represent the mean of triplicate determinations. Varying concentrations of I were added to the bacterial suspensions, and bacterial growth was followed for 4 days. The chloramine appeared to act as a bacteriostatic agent, at concentrations ranging from 5×10^{-5} to 4×10^{-4} *M*, in that bacterial growth was delayed. At concentrations of 5×10^{-4} *M* and higher, no bacterial growth was evident. When the organisms exposed to these higher doses were subcultured, no growth was apparent. These results suggest death of the organisms and show that I exerts bactericidal actions at higher concentrations.

Chemical Verification—Bacterial incorporation was allowed to proceed for 3 hr using radioactive thymidine, uridine, or leucine in different tubes. Cold 0.2 *N* perchloric acid was added, and the precipitates were washed twice with 0.2 *N* perchloric acid. The supernates were discarded, and the precipitates were dissolved and incubated in 0.3 *N* KOH for 1 hr at 37°. The material was reprecipitated with 0.7 *N* perchloric acid,

[a] I. [b] II (unchlorinated precursor).

collected on filters, and counted as described previously. The potassium hydroxide treatment resulted in >90% breakdown of the radioactive polymer produced with radioactive uridine.

The polymers produced with radioactive thymidine or leucine were not significantly affected by the alkaline treatment. RNA is known to be degraded by alkali, whereas DNA and protein are not affected (10, 13, 14). Heat treatment (70°) of the radioactive polymers with 0.5 *N* perchloric acid for 30 min resulted in the breakdown of the polymer produced using thymidine, while the polymer produced with leucine was unaffected. DNA is known to be degraded under these conditions of heating in the presence of acid (10, 13, 14).

Enzymatic Verification—The filters containing the radioactive polymers were immersed in solutions of deoxyribonuclease[7], ribonuclease[7], and a mixture of proteolytic enzymes[7] for 1 hr at 37°. The polymer produced using thymidine was degraded by deoxyribonuclease but was not affected by ribonuclease or the proteolytic enzymes. The polymer produced using uridine was degraded only by ribonuclease, and the polymer resulting from leucine incorporation was degraded only by proteolytic enzymes. These reactions strongly support the specific nature of these incorporation processes. (Further details may be obtained from Ref. 10.)

DISCUSSION

The data presented here and previous data (1–5) indicate that chloramines exert both bacteriostatic and bactericidal actions. The extent of the antimicrobial actions depends on the ratio of the bacterial concentration to that of chloramine and the length of exposure. These parameters also control the extent of enzyme inhibition. Both the antibacterial effects and the enzymatic inhibitory actions appear to be due to the powerful oxidative action of the chlorine component of the chloramine molecules. Support for this view is contributed by the facts that the unchlorinated precursor molecule is inactive and that the inhibitory effects of I and III can be abolished completely by first mixing the chloramine with the sulfhydryl compounds dithiothreitol or mercaptoethanol.

Thus, the present study indicates that one cellular mechanism for these antibacterial actions might be that these chloramines effectively attack the sulfhydryl groups, which can lead to enzymatic inactivation or denaturation. A natural consequence of such actions would be interference with major cellular processes (not shown previously) such as DNA, RNA, and protein synthesis, which depend on the subtle interaction of many sulfhydryl-containing enzymes. All three processes appear to be inhibited, and the antimicrobial actions apparently are not due to the selective inhibition of any one specific cellular function that is vastly more sensitive than the others. The data in Tables II and III suggest that DNA synthesis is slightly more sensitive to the action of I than is RNA or protein synthesis. The basis of action of these chloramine agents appears to be similar to that proposed for the bactericidal actions of chlorine (28).

The data in Tables II–V suggest that these chloramines inhibit bacterial synthesis of DNA, RNA, and protein. These results have several possible causes:

1. Chemical alteration of the radioactive precursors by the chloramine, resulting in the decreased incorporation into DNA, RNA, or protein. However, the data presented in Table VI show that this is not true. When bacteria, radioactive precursors, and chloramine were first incubated, no inhibition of incorporation was found after inactivating the chloramine by adding dithiothreitol and then adding fresh, viable bacteria. If the chloramines had reacted with the radioactive precursors and rendered them inert, normal incorporation would not have been demonstrated after inactivating the residual chloramine and adding fresh viable bacteria.

2. Chloramine inhibition of the transport of the radioactive precursor into the bacterial cell. However, the data discussed previously do not support inhibition of precursor transport but rather synthesis inhibition.

The data in Table VII demonstrate that enzymes containing sulfhydryl sites are inhibited by I at 10^{-4} *M*. Other enzymes without sulfhydryl sites (dihydrofolate reductase) may be inhibited at far higher concentrations (10^{-2} *M*) of chloramine, while another enzyme (ribonuclease) appears to be completely resistant. Attempts were made to protect the sulfhydryl groups of malate dehydrogenase and fumarase by reacting these enzymes with agents that reversibly combine with sulfhydryl groups (29). Both enzymes were incubated with 5,5-dithiobis(2-nitrobenzoic acid) and with *p*-hydroxymercuribenzoate. Chloramine was added later, and the incubation was continued. Dithiothreitol then was added to remove the protective agents and to inactivate any residual chloramine. No protective effects were evident against the actions of chloramine by these reversible sulfhydryl agents. It generally can be concluded that the sulfhydryl groups are attacked by these chloramine agents but that other sites also are attacked since non-sulfhydryl-containing enzymes are inhibited and since the chloramines still are capable of causing enzyme inhibition, even when the sulfhydryl groups are protected. The chloramine-induced inhibitions were not reversed simply by adding sulfhydryl reagents to bacteria or to purified enzymes after first incubating with chloramine.

While some enzymes containing sulfhydryl groups are inhibited by chloramines, this fact may not mean that all sulfhydryl-containing enzymes are inhibited, although they could be. Reversal of antibacterial activity by dithiothreitol also does not prove that a compound reacts by a sulfhydryl inhibition.

High-Pressure Liquid Chromatographic Determination of Ftorafur [1-(Tetrahydro-2-furanyl)-5-fluorouracil] and GLC–Mass Spectrometric Determination of 5-Fluorouracil and Uracil in Biological Materials after Oral Administration of Uracil plus Ftorafur

TERUYOSHI MARUNAKA *x, YUKIHIKO UMENO *, KOZO YOSHIDA *, MASAHIRO NAGAMACHI *, YOSHINORI MINAMI *, and SETSURO FUJII ‡

Received November 14, 1979, from the **Research Laboratory, Taiho Pharmaceutical Co., Ltd., Tokushima, 771-01, Japan,* and the ‡*Division of Regulation of Macromolecular Function, Institute for Protein Research, Osaka University, Osaka, Japan.* Accepted for publication May 19, 1980.

Abstract □ Oral adminstration of uracil plus ftorafur [1-(tetrahydro-2-furanyl)-5-fluorouracil] has a greater antitumor effect than that of ftorafur alone. A high-pressure liquid chromatographic method was developed for the determination of ftorafur in plasma and visceral tissues with a sensitivity of 0.025 μg/ml or g of wet weight. A combination of GLC–mass fragmentography and GLC–mass spectrometry with total-ion monitoring was developed for the specific, simultaneous determination of 5-fluorouracil, an active metabolite, and uracil as their trimethylsilylated derivatives. The detection limits for 5-fluorouracil and uracil in the first method were 0.001 μg/ml for plasma and 0.001–0.005 μg/ml for visceral tissues, and those in the second method were 0.2 μg/ml or g of wet weight. The precision and sensitivity of the assay appear to be satisfactory for determination of the levels of these compounds in plasma and visceral tissues.

Keyphrases □ Ftorafur—high-pressure liquid chromatographic analysis in biological materials □ 5-Fluorouracil—GLC–mass spectrometric analysis in biological materials □ Uracil—GLC–mass spectrometric analysis in biological materials □ High-pressure liquid chromatography—analysis, ftorafur in biological materials □ GLC–mass spectrometry—analysis, 5-fluorouracil and uracil in biological materials □ Antineoplastic agents—uracil plus ftorafur, high-pressure liquid chromatographic and GLC–mass spectrometric analysis in biological materials

5-Fluorouracil and its derivatives have been widely used in cancer chemotherapy. Ftorafur [1-(tetrahydro-2-furanyl)-5-fluorouracil], a masked form of 5-fluorouracil, is an effective antitumor agent. It can be given orally and has lower toxicity than 5-fluorouracil (1–3).

Fujii and coworkers (4–8) recently reported that oral administration of uracil plus ftorafur (4:1 mole/mole) was more effective than that of ftorafur or 5-fluorouracil alone and resulted in a higher level of 5-fluorouracil, an active substance, in tumor tissues than did administration of an equimolar amount of ftorafur or 5-fluorouracil.

For elucidation of the mechanism of action of uracil, it seemed important to establish a quantitative method for the determination of the concentrations of uracil, ftorafur, and 5-fluorouracil in the blood and visceral tissues after uracil plus ftorafur treatment. A method already was reported for the determination of ftorafur and 5-fluorouracil in plasma and visceral tissues after administration of ftorafur in studies on a new antitumor agent, 1,3-bis(tetrahydro-2-furanyl)-5-fluorouracil (9–11); ftorafur was determined by TLC scanning densitometry or high-pressure liquid chromatography (HPLC), and 5-fluorouracil was determined by a microbiological assay using a sensitive bacterial strain or GLC–mass fragmentography with selected-ion monitoring.

Several other methods also have been reported: separate microbiological assays of ftorafur and 5-fluorouracil in plasma and visceral tissues (12, 13), simultaneous HPLC analysis of ftorafur and 5-fluorouracil in plasma and urine using a reversed-phase column (14, 15), and assay of ftorafur by GLC and of 5-fluorouracil by GLC–mass fragmentography in plasma and urine (16, 17).

The present paper describes a precise and sensitive method for the assay of ftorafur, 5-fluorouracil, and uracil in plasma and visceral tissues. Ftorafur is separated from the other compounds by solvent extraction and analyzed by HPLC using an adsorption chromatographic system. 5-Fluorouracil and uracil are silylated and then analyzed by GLC–mass fragmentography. Uracil also is determined simultaneously by GLC–mass spectrometry with total-ion monitoring.

EXPERIMENTAL

Materials—Ftorafur was synthesized and purified (18). 5-Fluorouracil[1], uracil[1], [1,3-$^{15}N_2$]-5-fluorouracil[2] (95% enrichment), and [1,3-$^{15}N_2$]uracil[3] (95% enrichment) were used as received. *N,O*-Bis(trimethylsilyl)trifluoroacetamide[4] and pyridine[4] were derivatizing agents for silylation. Chloroform, methanol, ethanol, and ethyl acetate were liquid chromatographic reagent grade[5]. The other chemicals[5] were analytical reagent grade. Ethylene dichloride[5] was dehydrated and distilled before use.

The samples of blood and visceral tissues were from male AH-130 tumor-bearing rats (160–180 g, 6–7 weeks old).

HPLC Conditions—The liquid chromatograph[6] was equipped with a high-pressure injection valve[7] and a UV detector[8] operating at 254 nm. An adsorption chromatographic column[9] (25 cm × 6.2 mm i.d.) was used for separation with a mobile phase of ethylene dichloride–ethanol (24:1 v/v) at a flow rate of 1.7 ml/min. The column was maintained at room temperature. A gradientor[10] was used for controlling the mobile phase concentration. For quantitative calculations, a computer system[11] was employed.

GLC–Mass Fragmentographic and GLC–Mass Spectrometric Conditions—A mass spectrometer[12] with an electron-impact ion source connected to a gas chromatograph[13] was used.

The coiled glass column (1.0 m × 2.0 mm i.d.) of the gas chromatograph was packed with 3% OV-17 on Chromosorb W AW[14] (80–100 mesh) and

was conditioned at 280° for 24 hr. The injector, column, and ion source temperatures were 210, 150, and 230°, respectively. After 5-fluorouracil, uracil, and their internal standard had been detected, the temperature of the column was raised to 280° for 3 min to burn out the remaining materials and then was returned to the operational temperature before the next analysis. The carrier gas was helium, and the flow rate was 30 ml/min.

For mass fragmentography, the mass spectrometer was set at the following conditions: ionization energy, 70 ev; ionization current, 300 μamp; accelerating voltage, 3.0 kv; and ion multiplier voltage, 1.4 kv. The peaks of the molecular ions of the trimethylsilyl derivatives of 5-fluorouracil, uracil, and the respective internal standards ([1,3-$^{15}N_2$]-5-fluorouracil and [1,3-$^{15}N_2$]uracil), *m/e* 274, 256, 276, and 258, respectively, were selected for mass fragmentographic analysis. When necessary, uracil was simultaneously analyzed by GLC–mass spectrometry.

Analytical Procedure—Blood samples were collected in heparinized containers and centrifuged to separate the plasma. Visceral tissues were collected by the freeze-clamping technique and rapidly bled or perfused with cold physiological saline to remove blood. The plasma and visceral tissues then were frozen until analysis.

The plasma (0.5 ml) was diluted to 2.0 ml with distilled water containing 0.1 μg of [1,3-$^{15}N_2$]-5-fluorouracil and 0.5 μg of [1,3-$^{15}N_2$]uracil as internal standards. A sample of 0.5–1.0 g of visceral tissue was homogenized in an ice bath with physiological saline containing 0.1 μg of [1,3-$^{15}N_2$]-5-fluorouracil and 5.0 μg of [1,3-$^{15}N_2$]uracil and then centrifuged at 2000×*g* for 20 min; 1.0 ml of the resulting supernate was diluted to 2.0 ml with distilled water. The samples of plasma and visceral tissue homogenates were adjusted to pH 4.0 with 5 *N* HCl and shaken vigorously with 20 ml of chloroform at room temperature for 10 min.

This extraction was repeated again, and the combined chloroform extracts containing ftorafur were evaporated to dryness at <25°, transferred to a 10-ml test tube by washing with chloroform, and dried under nitrogen. The residue was dissolved in 100 μl of ethylene dichloride, and 20 μl of this solution was injected into the liquid chromatograph.

The aqueous layer containing 5-fluorouracil and uracil separated from the chloroform layer was neutralized with sodium hydroxide solution, adjusted to pH 6.0 with 0.2 ml of 0.5 *M* NaH_2PO_4, and centrifuged at 2000×*g* for 15 min to remove protein. The supernate was extracted with 40 ml of ethyl acetate by vigorous shaking for 20 min. The ethyl acetate layer was evaporated at 40°, transferred to a 1.0-ml reaction vial by washing with methanol, and dried under nitrogen at 40°. The residue was dried thoroughly over phosphorus pentoxide under reduced pressure and subjected to silylation at 70° for 20 min by addition of a freshly prepared solution of 100 μl of pyridine containing 20% *N,O*-bis(trimethylsilyl)-trifluoroacetamide. Then 1–3 μl of the solution was injected into the gas chromatograph–mass spectrometer.

Calibration Curves—Calibration curves were prepared by adding known amounts of ftorafur (20.0, 10.0, 5.0, 1.0, 0.5, 0.1, and 0.05 μg/ml), 5-fluorouracil (1.0, 0.5, 0.25, 0.10, 0.05, 0.01, and 0.005 μg/ml), and uracil (50.0, 25.0, 10.0, 5.0, 2.5, 1.0, 0.5, 0.25, 0.10, 0.05, 0.01, and 0.005 μg/ml) to plasma (1.0 ml) and organ homogenates (1.0 ml from 1.0 g of wet weight) and then analyzing by the same extraction procedure.

The calibration curve for the determination of ftorafur by HPLC was prepared by plotting the peak area against the concentration of ftorafur. Calibration curves for 5-fluorouracil and uracil analyzed by GLC–mass fragmentography and GLC–mass spectrometry were obtained by plotting the ratio of the peak heights of the respective trimethylsilyl derivatives to those of the trimethylsilyl derivatives of the internal standards, [1,3-$^{15}N_2$]-5-fluorouracil and [1,3-$^{15}N_2$]uracil, using GLC–mass fragmentography against the concentrations of these compounds. All of the calibration curves gave good results.

RESULTS AND DISCUSSION

The investigation of the simultaneous determination of ftorafur, 5-fluorouracil, and uracil by HPLC using a reversed-phase column and by GLC based on silylation or on-column methylation with a flame-ionization detector showed that a suitable HPLC retention time of each compound could not be obtained and that ftorafur and 5-fluorouracil were difficult to separate by GLC after silylation, while 5-fluorouracil and uracil were not separated by on-column methylation. Thus, reversed-phase HPLC and GLC were not suitable for the simultaneous assay of ftorafur, 5-fluorouracil, and uracil.

Two independent assay procedures were investigated next on the basis of the physicochemical properties of these compounds. Ftorafur could be recovered from aqueous solution with an organic solvent, and 5-fluorouracil and uracil remained in the aqueous layer. Therefore, extraction

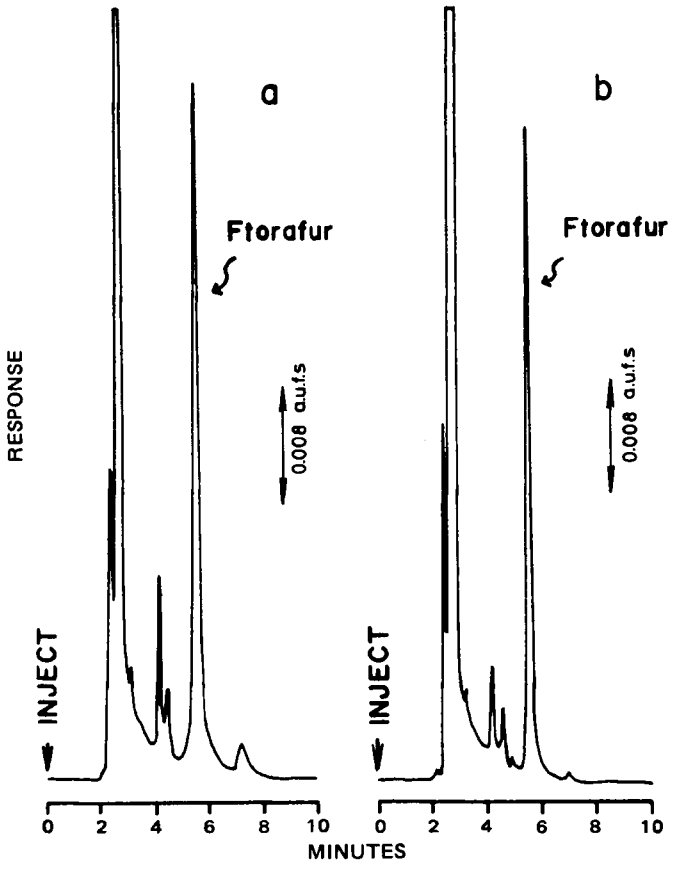

Figure 1—*High-pressure liquid chromatograms showing the separation of ftorafur extracted from plasma* (a) *and tumor tissue* (b) *of AH-130 tumor-bearing rats after addition at 5.0 μg/ml or g of wet weight. with chloroform from an aqueous solution acidified with hydrochloric acid was employed for quantitative separation of ftorafur from 5-fluorouracil and uracil. Ftorafur then was determined by HPLC using an adsorption column, and 5-fluorouracil and uracil were analyzed by GLC–mass fragmentography and GLC–mass spectrometry.

A Zorbax SIL column was used for the separation of ftorafur extracted from chloroform. Ftorafur was well separated from biological constituents when a mixture of a nonpolar solvent (*e.g.*, chloroform, methylene chloride, ethylene dichloride, or *n*-hexane) containing 1–5% alcohol (*e.g.*,

Table I—Recoveries of Ftorafur, 5-Fluorouracil, and Uracil from Plasma and Visceral Tissues of AH-130 Tumor-Bearing Rats

Tissue	Recovery[a], %		
	Ftorafur	5-Fluorouracil	Uracil
Saline	100.7 ± 1.5	91.4 ± 3.2	84.1 ± 3.1
Plasma	100.3 ± 1.2	86.1 ± 3.7	81.5 ± 3.8
Heart	99.9 ± 1.4	72.0 ± 4.1	66.8 ± 4.3
Intestine	100.1 ± 1.2	76.8 ± 3.5	69.3 ± 3.2
Kidney	99.8 ± 1.6	67.5 ± 4.8	65.0 ± 3.7
Liver	99.6 ± 1.8	63.5 ± 5.1	62.4 ± 4.1
Lung	100.5 ± 1.3	71.0 ± 3.5	64.7 ± 4.9
Muscle	101.1 ± 1.3	79.0 ± 3.4	73.3 ± 3.3

methanol, ethanol, or isopropanol) was the mobile phase. Of the solvent systems tested, ethylene dichloride–ethanol (24:1) was chosen as the mobile phase because it gave suitable chromatographic separation and analysis time.

The supernate of each organ homogenate must be extracted with chloroform; otherwise, the large amounts of lipid-soluble materials extracted with chloroform disturb the HPLC analysis.

Known amounts of ftorafur were added to plasma and homogenates of various organs of AH-130 tumor-bearing rats. The HPLC separation of ftorafur extracted from plasma and tumor tissue is shown in Fig. 1. The retention time of ftorafur was 6.3 min. As shown in Table I, the recoveries of ftorafur from plasma and each organ were quantitative, and the detection limit for ftorafur using this HPLC method was 0.025 μg/ml or g of wet weight for plasma and visceral tissues. The reproducibility was ±1.5–2.1%.

5-Fluorouracil and uracil have similar physicochemical properties. Thus, the addition of 0.5 *M* NaH_2PO_4 to the aqueous layer containing 5-fluorouracil and uracil and subsequent extraction with ethyl acetate as described previously (10, 11) resulted in good, constant recoveries.

The silylation procedure with *N,O*-bis(trimethylsilyl)trifluoroacetamide was sensitive, giving excellent GLC–mass fragmentographic and GLC–mass spectrometric separations of 5-fluorouracil and uracil extracted with ethyl acetate.

The internal standards, [1,3-$^{15}N_2$]-5-fluorouracil and [1,3-$^{15}N_2$]uracil, which are labeled with the stable isotope of nitrogen, were used for the simultaneous determination of 5-fluorouracil and uracil by the multiple-ion detection technique. The mass fragment ions detected for GLC–mass fragmentography were the molecular ion peaks (M^+) in the mass spectra of the trimethylsilyl derivatives of 5-fluorouracil and uracil since their base peaks ($M - CH_3$) were not separated clearly in some samples.

The best ion multiplier voltage of the mass spectrometer was 1.4 kv for the simultaneous determination of 5-fluorouracil and uracil by GLC–mass fragmentography. At this voltage, these compounds could be measured at concentrations of 0.001–2.5 μg/100 μl of silylating solvent. Under this condition, the concentrations of 5-fluorouracil could be analyzed in most samples, but the concentrations of uracil exceeded the upper detection limit. In particular, an extremely large difference was observed between the concentrations of 5-fluorouracil and uracil in tumor tissue having a large pool of uracil and those in the plasma collected soon after coadministration of uracil and ftorafur. In such samples, the two compounds could not be measured simultaneously at the ion multiplier voltage of 1.4 kv since the concentration of uracil was saturated. This problem could be overcome by two analytical runs at different values of the ion multiplier voltage: 5-fluorouracil was measured at an ion multiplier voltage of 1.4 kv, and uracil was measured at 1.2 kv. However, in this study, simultaneous detection by GLC–mass fragmentography and GLC–mass spectrometry was used, and conditions were developed for the simultaneous measurement of 5-fluorouracil and uracil in all kinds of samples.

Known amounts of 5-fluorouracil and uracil were added to plasma and homogenates of various organs of AH-130 tumor-bearing rats, and the samples were analyzed. The GLC–mass fragmentographic separation

[a] Average of three determinations.

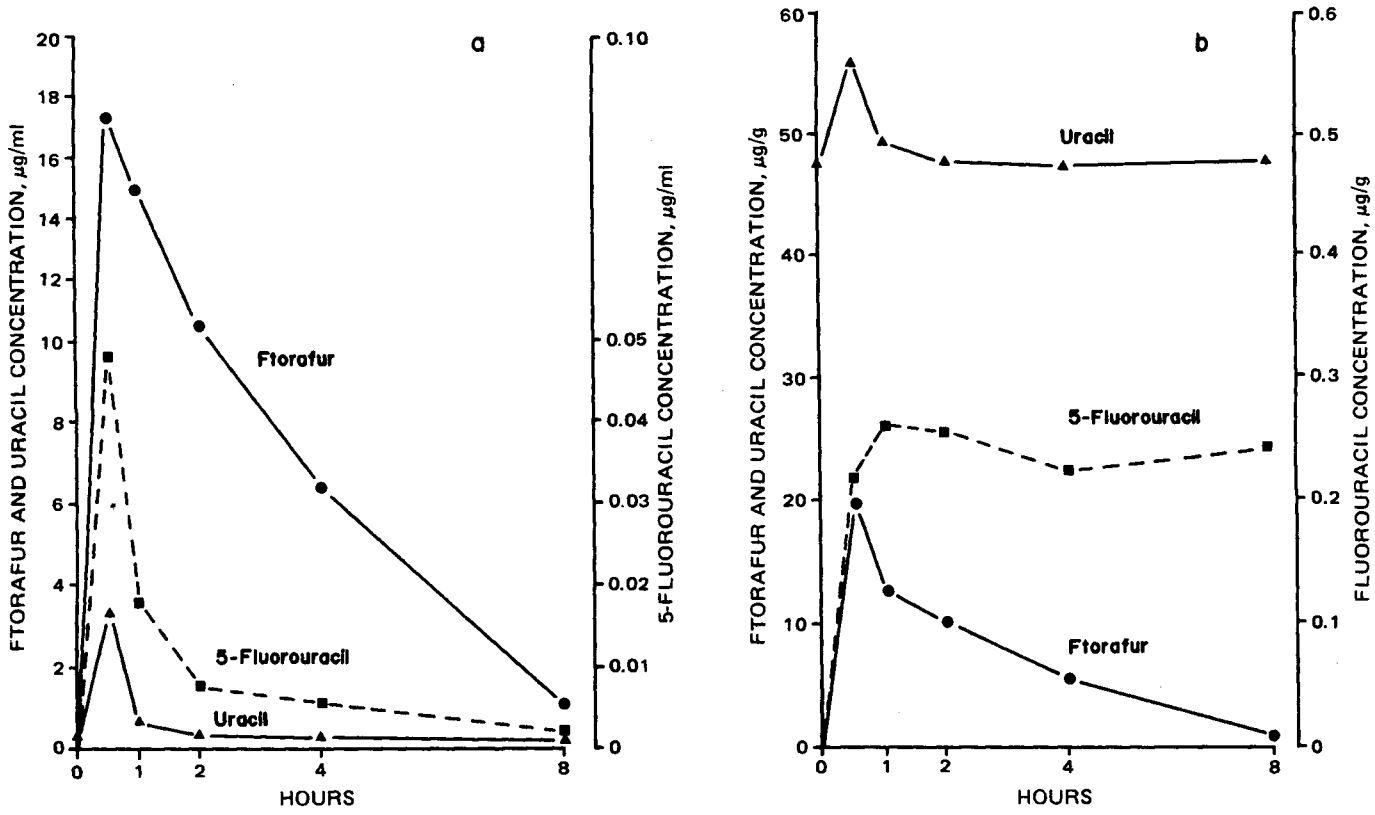

Figure 4—*Plasma levels* (a) *and tumor levels* (b) *of ftorafur, 5-fluorouracil, and uracil after a single oral dose of uracil (33.6 mg) plus ftorafur (5.0 mg) (4:1 mole/mole) to AH-130 tumor-bearing rats.*

of the trimethylsilyl derivatives of 5-fluorouracil, uracil, and their internal standard extracted from plasma and tumor tissue is shown in Fig. 2. The GLC–mass spectrometric separation of uracil extracted from tumor tissue is shown in Fig. 3. The retention times of 5-fluorouracil and uracil as their trimethylsilyl derivatives were 1.5 and 1.8 min, respectively. The recoveries from plasma were 86.1 ± 3.7% for 5-fluorouracil and 81.5 ± 3.8% for uracil, and those from visceral tissues were ~75% for 5-fluorouracil and ~70% for uracil. Since uracil forms pools naturally in all biological materials, the recovery of uracil was determined in a separate experiment by GLC–mass fragmentography and GLC–mass spectrometry utilizing [1,3-$^{15}N_2$]uracil and 5-chlorouracil (ion peak detected was *m/e* 275, M − CH_3) as internal standards.

The detection limits for 5-fluorouracil and uracil for GLC–mass fragmentography were 0.001 μg/ml for plasma and 0.001–0.005 μg/g of wet weight for visceral tissues; the detection limit for GLC–mass spectrometry was 0.2 μg/ml or g of wet weight. The reproducibility of this method was ±2.2–3.4%.

As reported previously (10, 11), the decomposition of ftorafur and 5-fluorouracil nucleosides or nucleotides had no significant effect on the assay of 5-fluorouracil. To examine the effect of decomposition of uracil nucleosides or nucleotides, authentic samples of these compounds were dissolved in physiological saline, plasma, and tissue homogenates of the liver and tumor and then analyzed for their uracil concentration. The results showed no significant differences between the values of the control and test samples and that decomposition of uracil nucleosides and nucleotides had no appreciable influence on the measurement of uracil with the present method.

The results obtained with the present method showed that the pools of uracil in various tissues were fairly high, as reported by Fujimoto *et al.* (19). Thus, the following experiments were conducted. First, changes in the uracil concentration were examined by incubation of plasma and tissue homogenates of the liver and tumor with shaking at various temperatures before measurement. As shown in Table II, the uracil concentration did not differ significantly from control values after incubation at various temperatures for plasma and at 5 or −20–−30° (frozen) for the liver and tumor. However, the uracil concentration increased with incubation at room temperature or 37° for the liver and tumor. This change in the uracil concentration probably is due mainly to the enzymatic decomposition of nucleosides and nucleotides.

Next, plasma and tissue homogenates of the tumor and liver were acidified with hydrochloric acid and extracted with chloroform, and the supernate of the aqueous layer was incubated with shaking at 37° for 24 hr. No significant difference between the concentration of uracil in the control and test samples was observed. Thus, as well as causing deproteinization, extraction with chloroform in hydrochloric acid inactivated enzymes that hydrolyzed the glycoside bonds of nucleosides and nucleotides.

On the basis of these observations, it was concluded that the present method, in which tissues were homogenized in an ice bath at a temperature below 5° and the supernate was acidified with hydrochloric acid and extracted with chloroform, did not involve any procedure that affects the determination of 5-fluorouracil and uracil.

The present method also can be applied to plasma and visceral tissues of other animals. The results obtained for the chromatographic separation, recoveries, and sensitivities were in good agreement with those obtained with AH-130 tumor-bearing rats. It is not ethically possible to obtain all kinds of human tissues; however, results with plasma and tumor tissue from humans gave similar results to those obtained with animals, indicating the applicability of the present method to human tissues.

Uracil plus ftorafur (4:1 mole/mole) was given orally to AH-130 tumor-bearing rats, and the time course of changes in the concentrations of ftorafur, 5-fluorouracil, and uracil in plasma and tumor tissue was measured by the present method (Fig. 4). Since the concentration of uracil represents the sum of the original amount and that resulting from uracil plus ftorafur treatment, individual differences in the original pools of uracil, especially in organs, sometimes were so large that they masked the time course of change in exogenous uracil after administration of uracil plus ftorafur. However, it should be possible to measure the time course using a labeled compound.

Because ftorafur and 5-fluorouracil are metabolized together with uracil, the present method for the simultaneous determination of ftorafur, 5-fluorouracil, and uracil in plasma and visceral tissues should be useful. Furthermore, this method will be helpful for basic and clinical pharmacological studies on uracil plus ftorafur and ftorafur alone.

Use of Stable Isotopes in the Study of Pharmacokinetics of Drugs by Mass Fragmentography II: Detailed Examination of Pharmacokinetics of a Single Oral Dose of Phenytoin in Humans

SHIGEO BABA ˣ, TSUYOSHI GOROMARU, KAZUSHIGE YAMAZAKI, and YASUJI KASUYA

Received May 14, 1979, from the *Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan.* Accepted for publication May 16, 1980.

Abstract □ To study the pharmacokinetics of phenytoin in detail, a mass fragmentographic method was applied for the precise, sensitive, and specific analysis of phenytoin, 5-(4-hydroxyphenyl)-5-phenylhydantoin, and 5-(4-hydroxyphenyl)-5-phenylhydantoin glucuronide in plasma and urine after administration of a single oral dose of phenytoin to two healthy volunteers. Salivary phenytoin concentrations also were measured. Phenytoin and 5-(4-hydroxyphenyl)-5-phenylhydantoin were analyzed after the addition of deuterium-labeled internal standards and conversion to volatile methyl derivatives for mass fragmentographic analysis. The lower limit of detection was ~10 ng/ml. The simultaneous pharmacokinetic analysis of the plasma levels and urinary excretion data of phenytoin and its major metabolite, 5-(4-hydroxyphenyl)-5-phenylhydantoin, yielded detailed information about the pharmacokinetics of phenytoin.

Keyphrases □ Mass fragmentography—application to pharmacokinetic study of single oral phenytoin dose using stable isotope labeling, humans □ Phenytoin—pharmacokinetics, application of mass fragmentography after single oral dose using stable isotope labeling, humans □ Pharmacokinetics—phenytoin, application of mass fragmentography after single oral dose using stable isotope labeling, humans

GLC–mass spectrometry coupled with selected-ion monitoring is used increasingly in drug research because of its high sensitivity and specificity. In this technique, stable isotope-labeled carriers serve as ideal internal standards to correct for losses of the compound under study in the initial isolation procedures. The usefulness of mass fragmentography in conjunction with stable isotope labeling has been of recent interest in the measurement of trace amounts of substances in biological materials (1–3). This method was used in these laboratories for the metabolic study of drugs in animals and humans (4–6). The mass fragmentographic technique also has been applied for the sensitive, specific, and reliable determination of plasma testosterone levels in humans (7).

Pharmacokinetic studies represent one field in which the sensitivity and specificity of the mass fragmentographic technique offer an advantage. Sullivan and coworkers (8, 9) successfully used stable isotope-labeled drugs together with mass fragmentography to study steady-state pharmacokinetics. An investigation of the elimination kinetics of drugs was carried out in these laboratories by measuring the nanogram levels of a drug and its major metabolites in human urine using this technique (10).

The present paper describes the use of deuterium-labeled phenytoin (I) and its major metabolite, 5-(4-hydroxyphenyl)-5-phenylhydantoin (II), along with mass fragmentography to follow saliva, plasma, and urinary concentrations of I and II for a reasonable period after a single oral administration of I to humans. A detailed analysis and interpretation of the pharmacokinetic data of I from two healthy volunteers also are presented.

EXPERIMENTAL

Synthesis of Deuterated Internal Standards—*Pentadeuterophenytoin (I-*d_5*)*—Deuterobenzophenone (benzophenone-d_5) was prepared by refluxing a mixture of 9.50 g of hexadeuterobenzene[1] (99.5 atom % D) and 2.44 g of benzoyl chloride[2] for 5 hr with 2.70 g of anhydrous aluminum chloride. The I-d_5 then was synthesized from the benzophenone-d_5 according to the method described by Baty and Robinson (11).

Use of Stable Isotopes in the Study of Pharmacokinetics of Drugs by Mass Fragmentography II: Detailed Examination of Pharmacokinetics of a Single Oral Dose of Phenytoin in Humans

SHIGEO BABA ˣ, TSUYOSHI GOROMARU, KAZUSHIGE YAMAZAKI, and YASUJI KASUYA

Received May 14, 1979, from the *Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan.* Accepted for publication May 16, 1980.

Abstract □ To study the pharmacokinetics of phenytoin in detail, a mass fragmentographic method was applied for the precise, sensitive, and specific analysis of phenytoin, 5-(4-hydroxyphenyl)-5-phenylhydantoin, and 5-(4-hydroxyphenyl)-5-phenylhydantoin glucuronide in plasma and urine after administration of a single oral dose of phenytoin to two healthy volunteers. Salivary phenytoin concentrations also were measured. Phenytoin and 5-(4-hydroxyphenyl)-5-phenylhydantoin were analyzed after the addition of deuterium-labeled internal standards and conversion to volatile methyl derivatives for mass fragmentographic analysis. The lower limit of detection was ~10 ng/ml. The simultaneous pharmacokinetic analysis of the plasma levels and urinary excretion data of phenytoin and its major metabolite, 5-(4-hydroxyphenyl)-5-phenylhydantoin, yielded detailed information about the pharmacokinetics of phenytoin.

Keyphrases □ Mass fragmentography—application to pharmacokinetic study of single oral phenytoin dose using stable isotope labeling, humans □ Phenytoin—pharmacokinetics, application of mass fragmentography after single oral dose using stable isotope labeling, humans □ Pharmacokinetics—phenytoin, application of mass fragmentography after single oral dose using stable isotope labeling, humans

GLC–mass spectrometry coupled with selected-ion monitoring is used increasingly in drug research because of its high sensitivity and specificity. In this technique, stable isotope-labeled carriers serve as ideal internal standards to correct for losses of the compound under study in the initial isolation procedures. The usefulness of mass fragmentography in conjunction with stable isotope labeling has been of recent interest in the measurement of trace amounts of substances in biological materials (1–3). This method was used in these laboratories for the metabolic study of drugs in animals and humans (4–6). The mass fragmentographic technique also has been applied for the sensitive, specific, and reliable determination of plasma testosterone levels in humans (7).

Pharmacokinetic studies represent one field in which the sensitivity and specificity of the mass fragmentographic technique offer an advantage. Sullivan and coworkers (8, 9) successfully used stable isotope-labeled drugs together with mass fragmentography to study steady-state pharmacokinetics. An investigation of the elimination kinetics of drugs was carried out in these laboratories by measuring the nanogram levels of a drug and its major metabolites in human urine using this technique (10).

The present paper describes the use of deuterium-labeled phenytoin (I) and its major metabolite, 5-(4-hydroxyphenyl)-5-phenylhydantoin (II), along with mass fragmentography to follow saliva, plasma, and urinary concentrations of I and II for a reasonable period after a single oral administration of I to humans. A detailed analysis and interpretation of the pharmacokinetic data of I from two healthy volunteers also are presented.

EXPERIMENTAL

Synthesis of Deuterated Internal Standards—*Pentadeuterophenytoin (I-*d_5*)*—Deuterobenzophenone (benzophenone-d_5) was prepared by refluxing a mixture of 9.50 g of hexadeuterobenzene[1] (99.5 atom % D) and 2.44 g of benzoyl chloride[2] for 5 hr with 2.70 g of anhydrous aluminum chloride. The I-d_5 then was synthesized from the benzophenone-d_5 according to the method described by Baty and Robinson (11).

The overall yield was 5.1% based on benzene-d_6, mp 301°, 99.3 atom % D.

5-(4-Hydroxyphenyl)-5-pentadeuterophenylhydantoin (II-d_5)—Condensation of 3.07 g of anisoyl chloride with 9.50 g of hexadeuterobenzene[1] (99.5 atom % D) by refluxing for 5 hr with stirring in the presence of anhydrous aluminum chloride produced 2.68 g of 4-methoxybenzophenone-d_5, mp 151°. This compound (2.63 g) then was refluxed at 120° in 50 ml of nitrobenzene for 4 hr with 6.00 g of aluminum chloride to convert it to the phenol. The reaction mixture was poured into ice-cold water and extracted with dichloroethane. Filtration of the dichloroethane layer, extraction with 5% NaOH, acidification with 5% HCl, and reextraction into dichloroethane followed by drying over sodium sulfate and evaporation under reduced pressure gave 1.01 g of 4-hydroxybenzophenone-d_5, mp 140°.

Compound II-d_5 was obtained when 1.00 g of 4-hydroxybenzophenone-d_5 was subjected to reaction with 13.00 g of acetamide, 2.50 g of ammonium carbonate, and 0.40 g of potassium cyanide in a 50-ml sealed tube at 100° for 48 hr (12). After cooling, the reaction mixture was transferred into water, and the product was extracted with ether under alkaline conditions. Evaporation of the ether and recrystallization from aqueous ethanol gave 0.60 g of II-d_5, mp 320° dec., 98.7 atom % D. The overall yield of this reaction was 2% based on benzene-d_5.

Mass Fragmentography—Mass fragmentographic measurements were made with a gas chromatograph–mass spectrometer[3] equipped with a multiple-ion detector. The electron energy was set at 20 ev, and the trap current was set at 60 μamp. The multiple-ion detector was focused on the ions of the methyl derivatives at *m/e* values of 266 (I) and 271 (I-d_5) for the determination of I and at 296 (II) and 301 (II-d_5) for the determination of II to measure the peak height ratio.

GLC was performed on a glass column (2 m × 3 mm i.d.) packed with 1.5% SE-30 on Chromosorb W (80–100 mesh). The column temperature was 250° for I and 290° for II. The temperature of the flash heater was 280° for I and 300° for II, and the separator was at 280° for I and at 300° for II. The temperature of the ion source was 310°. The helium carrier gas flow rate was ~20 ml/min.

Sample Preparation for Mass Fragmentography—*Phenytoin (I)*—A 0.5–1.0-ml plasma sample was diluted with three volumes of water in a 30-ml centrifuge tube, and 1.0 ml of the internal standard (1.0 μg of I-d_5) was added. After 1.0 ml of 0.5 *N* HCl was added, the plasma sample was extracted with 2 × 5 ml of chloroform. The chloroform phase was collected and dried over anhydrous sodium sulfate. After evaporation of the solvent, the residue of the chloroform extract was dissolved in 0.1 ml of methanol, and 0.2 ml of diazomethane in ether was added. The sample then was allowed to stand for 15 hr at 4°, and the organic solvents were evaporated.

The residue was dissolved in a small amount (0.1–0.2 ml) of acetone and subjected to TLC on Kieselgel 60 F_{254} plates[4] (5 cm × 20 cm × 0.25 mm thick). The plate was developed with benzene–acetone–acetic acid (50:25:1 v/v/v), and the UV-positive zone corresponding to standard 3-methyl-I (monomethyl-I) with R_f 0.77 was scraped off. The methyl derivatives of I and I-d_5 were eluted with 10 ml of acetone, and the solvent was evaporated. The residue was dissolved in 0.1 ml of methanol, and 1 μl of the sample was subjected to GLC–mass spectrometry. The observed peak height ratio of *m/e* 266 to *m/e* 271 was determined in triplicate. Saliva (0.7–1.0 ml) and urine (1.0–10.0 ml) samples were not diluted with water and were processed as for plasma I samples.

5-(4-Hydroxyphenyl)-5-phenylhydantoin (II)—To a 0.5–1.0-ml plasma sample were added three volumes of water and 1.0 ml of the internal standard (1.0 μg of II-d_5). The subsequent procedures were the same as the isolation procedures described for plasma I levels, except that the UV-positive zone corresponding to standard *O*-methyl-3-methyl-II (dimethyl-II) with R_f 0.72 was scraped off. For the mass fragmentographic analysis, 1 μl of the sample was introduced into the gas chromatograph–mass spectrometer. The observed peak height ratio of *m/e* 296 to *m/e* 301 was determined in triplicate. Urine (1.0–10.0 ml) samples were not diluted with water and were processed as for plasma II samples.

5-(4-Hydroxyphenyl)-5-phenylhydantoin Glucuronide (III)—A 0.5–1.0-ml plasma sample was diluted with three volumes of water, and 1.0 ml of the internal standard (1.0 μg of II-d_5) was added in a 30-ml centrifuge tube. The plasma sample was treated with 1.0 ml of 10 *N* HCl for 1 hr on a boiling water bath (90–95°) and neutralized with 3 ml of sodium hydroxide solution. The subsequent procedures were the same as the isolation procedures described for plasma II samples. Urine (1.0 ml) samples were not diluted with water and were processed as described for plasma III samples.

Preparation of Calibration Curve—To each of six standards containing 0.05, 0.1, 0.5, 1.0, 5.0, and 10.0 μg of I or II in 0.1 ml of methanol was added 10 μg of I-d_5 or II-d_5 in 0.1 ml of methanol. After evaporation of the solvent to dryness, the residue was dissolved in 0.1 ml of methanol. To each sample was added 0.2 ml of freshly prepared diazomethane in ether. After standing for 15 hr at 4°, the excess diazomethane and the organic solvents were evaporated to dryness under reduced pressure, and the residue was dissolved in 0.1 ml of methanol. A 1-μl volume of the methanol solution was analyzed by GLC–mass spectrometry. The mass fragmentographic analysis was performed using the methyl derivatives by measuring the molecular ions at *m/e* 266 for monomethyl-I, *m/e* 271 for monomethyl-I-d_5, *m/e* 296 for dimethyl-II, and *m/e* 301 for dimethyl-II-d_5. The peak height ratios of I to I-d_5 and of II to II-d_5 were measured.

Determination of Accuracy—*Phenytoin (I)*—Compound I in amounts of 0.05, 0.5, 2.5, 5.0, and 10.0 μg in 1.0 ml of methanol was mixed with 10 μg of I-d_5 dissolved in 1.0 ml of methanol, and the solution was concentrated to ~20 μl. To the concentrated solution were added 0.5-ml aliquots of pooled plasma, and the sample was allowed to stand for 30 min at room temperature. The sample then was processed as described for the sample preparation for mass fragmentography.

5-(4-Hydroxyphenyl)-5-phenylhydantoin (II)—Compound II in amounts of 0.05, 0.5, 1.0, and 5.0 μg in 1.0 ml of methanol was mixed with 1.0 μg of II-d_5 dissolved in 1.0 ml of methanol, and the solution was concentrated to ~20 μl. To the concentrated solution were added 1.0-ml aliquots of pooled plasma, and the sample was allowed to stand for 30 min at room temperature. One set of plasma samples was treated with 1.0 ml of 10 *N* HCl for 1 hr on a boiling water bath and neutralized with 3 ml of sodium hydroxide solution. The other set was not treated with hydrochloric acid. The samples then were processed as described for the sample preparation for mass fragmentography.

Urine samples (1.0-ml aliquots of human urine) also were used for the accuracy determination. The procedures were essentially the same as those described for the plasma samples.

Drug Administration—Two healthy adult male volunteers, 25 (KY) and 36 (YK) years old, weighed 60 and 65 kg, respectively. They had not taken any drugs during the preceding two months. A single oral dose of I as its sodium salt, prepared by dissolving 250 mg of I and 37.5 mg of sodium hydroxide in 100 ml of water, was given in the morning after an overnight fast. The drug solution container was rinsed with 100 ml of water, and the rinsings also were swallowed. Each subject received 400 ml of water 1 hr before dosing and 100 ml of water at hourly intervals for 4 hr after dosing. The subjects urinated completely just prior to drug intake. No food was permitted for 4 hr after drug administration.

Sample Collection—Ten milliliters of heparinized blood samples was taken just prior to dosing and at 1, 2, 3, 4, 5, 6, 7, 8, 10, 12, 24, 48, 72, 96, and 120 hr after dosing. Plasma was separated and kept in a frozen state until analysis. Saliva samples (5 ml) were collected at the time of blood sampling. The saliva pH was measured, and the samples were kept frozen until analysis. Complete collections of urine were made at 0–2, 2–4, 4–6, 6–8, 8–12, 12–36, 36–60, 60–84, 84–108, and 108–132 hr after dosing. The urine volumes and pH were measured, and the samples were kept frozen until analysis. Compound I in saliva and I–III in plasma and urine samples were analyzed in duplicate by mass fragmentography. The initial extraction and isolation procedures were described under *Sample Preparation for Mass Fragmentography*.

RESULTS

Prerequisites for Mass Fragmentographic Analysis—*Preparation of Methyl Derivatives*—In the mass spectra of I and II, relatively abundant molecular ions (*m/e* 252 for I: Σ% 14.3; *m/e* 268 for II: Σ% 33.9)

[a] Mean of triplicate measurements.

were observed. However, without derivative formation, both I and II did not possess good GLC properties. On the other hand, the methyl derivatives were suitable for GLC analysis, and molecular ions of monomethyl-I (*m/e* 266) and dimethyl-II (*m/e* 296) were prominent in the mass spectra. The abundance of the molecular ions was Σ% 19.7 for monomethyl-I and Σ% 26.5 for dimethyl-II, providing good potential for use in mass fragmentography.

Selective-ion recordings of I and II showed that no contaminating by-products with retention times close to those of the methyl derivatives of I and II were seen in the mass fragmentograms. After the initial extraction and purification procedures, there was no interference for both I and II in the molecular ion peaks from other materials in the saliva, plasma, or urine extract at these masses.

Sensitivity—The sensitivity of the procedure described here was judged based on the signal to noise ratio. The lower limit of detection of the mass spectrometer was 100 pg for I and II.

Calibration Curve—Compounds I-d_5 and II-d_5 were used as internal standards. Known mixtures of I and I-d_5 and of II and II-d_5 were prepared so that the sample size (1 μl) injected into the gas chromatograph–mass spectrometer covered the I or II range of 0.5–100 ng with a fixed amount (100 ng) of I-d_5 or II-d_5. Each mixture then was analyzed as the methyl derivative, using the *m/e* settings for the molecular ions at 266 (I), 271 (I-d_5), 296 (II), and 301 (II-d_5). In constructing calibration curves, corrections were made for the contributions of the molecular ion to the *m/e* values 5 mass units higher (I → I-d_5 and II → II-d_5) and 5 mass units lower (I-d_5 → I and II-d_5 → II). There was a good correlation between the mixed molar ratio and the observed peak height ratio. Least-squares analysis of the observed ratio gave a regression line with a slope of 1.000.

Table IV—Saliva to Plasma Ratio of I

Hours	Subject YK	Subject KY
4	0.070	0.088
5	0.075	0.091
6	0.070	0.081
7	0.072	—
8	0.065	0.075
10	0.067	0.075
12	—	0.080
24	0.055	0.076
48	0.085	0.069
72	0.130	—
96	0.220	0.073

Accuracy—The accuracy of measurements was determined for I and II added to aliquots of pooled plasma or urine. The plasma or urine samples contained 10 (I-d_5) or 1.0 (II-d_5) μg of the internal standard and different amounts of I (0.05–10.0 μg) or II (0.05–5.0 μg). The amount of I or II then was measured by the present method. The amounts of I and II added were in good agreement with the amounts of I and II measured (Tables I and II). The relative error was <3% for I and <5% for II. In the subsequent experiment, hydrochloric acid was used for the hydrolysis of III. Treatment of plasma or urine samples with hydrochloric acid did not affect the measurement of II in these samples (Table II).

Pharmacokinetics of Phenytoin—A single oral dose of 250 mg of I as its sodium salt dissolved in water was administered to two male volunteers, 25 (KY) and 36 (YK) years old. Time courses of I–III concentrations in plasma, saliva, and urine then were followed by the present method.

Plasma Concentration—Plasma was analyzed for I–III at various times for 120 hr after the administration of I (Table III). In Subject YK, there was a relatively rapid rise in the plasma I concentration to 3.9 μg/ml at 1 hr, giving a peak level of 4.3 μg/ml at 4 hr. In Subject KY, the plasma I concentration became 5.0 μg/ml at 4 hr, and this plasma level was maintained until 10 hr after the administration of I. Semilogarithmic plots of the plasma concentrations *versus* time indicated that, after absorption, a distribution phase was not visible and that the terminal decline phase was monoexponential at time points later than 48 hr for Subjects YK and KY.

Plasma III concentrations were the highest (1.6 μg/ml) at 8 hr in Subject YK, and the plasma decline of III thereafter was parallel to that of I. In Subject KY, a higher peak plasma III concentration of 2.2 μg/ml was obtained at 10 hr, and the plasma III levels exceeded the plasma I levels at 48 hr and later.

There was an excellent parallelism in the time course of the plasma

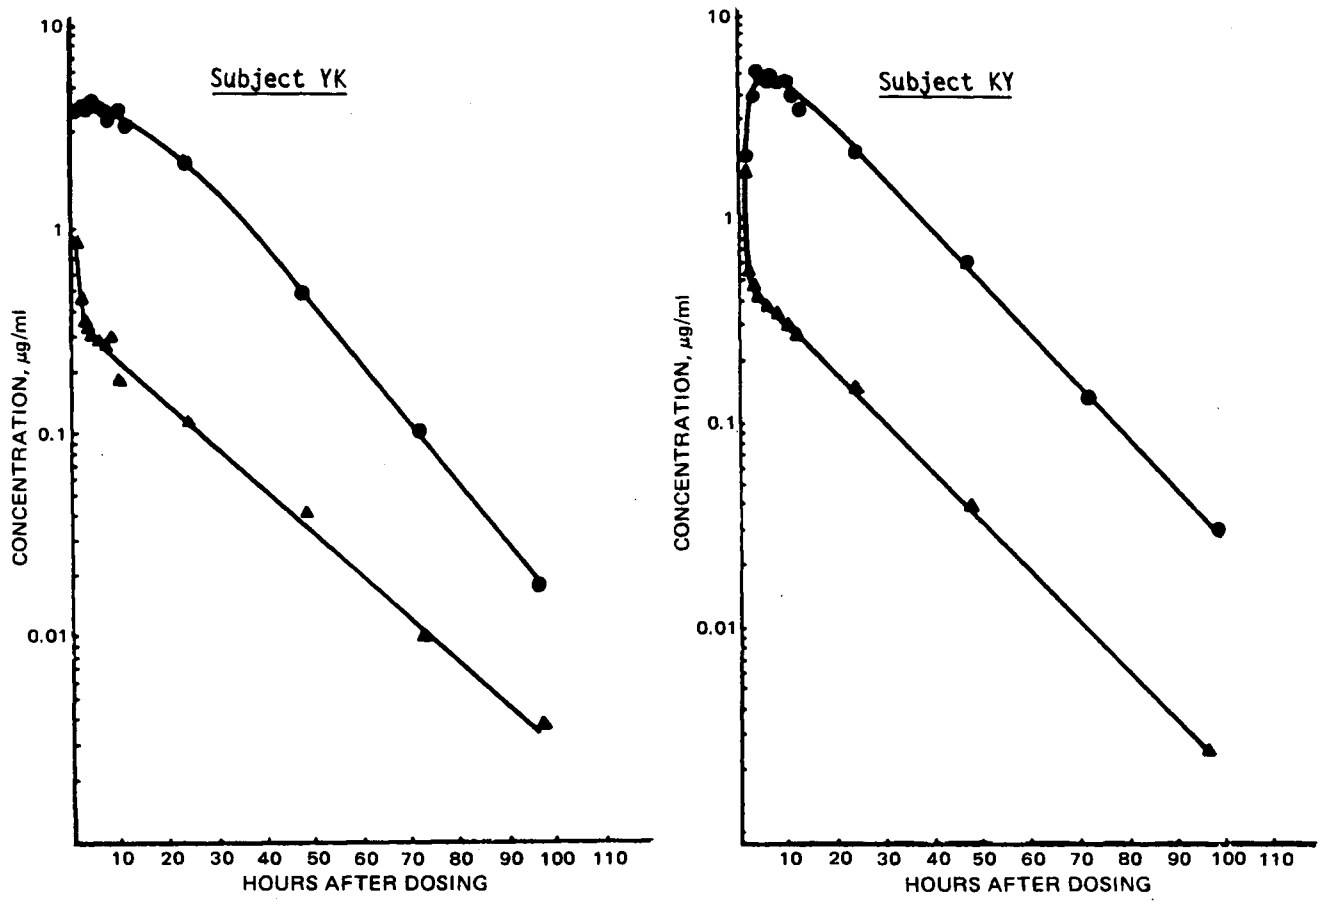

Figure 1—*Semilogarithmic plot of plasma* (●) *and saliva* (▲) *concentrations of I* versus *time after a single oral 250-mg dose of I.*

concentrations of II to that of III in both subjects. However, the levels of II were much lower in Subject YK than in Subject KY. At each time point, the plasma level of II was about 0.033 of the plasma level of III in Subject YK; in Subject KY, the level of II was ~0.1 of the level of III.

Saliva Concentration—Saliva samples were obtained at each time point of blood sampling. The results of measurements of saliva I concentrations are shown in Fig. 1, together with the time course of plasma I concentrations for comparison. Both subjects showed a rapid drop in saliva concentrations of I during the first 3 hr after administration of I; thereafter, the log concentration–time curves could be computed as straight lines. There was a close similarity in the decline of the slope of the saliva elimination curve to that of the plasma elimination curve for I. The slopes of the saliva and plasma elimination curves coincided with each other, especially in Subject KY, with the saliva to plasma ratios after 3 hr being consistent (Table IV). In Subject YK, there was only a slight fluctuation in the saliva to plasma ratio at each time point between 4 and 48 hr, while the ratio became higher at 72 and 92 hr.

Urinary Excretion—Urine samples were collected at appropriate time periods until 132 hr after the administration of I. The urinary pH and flow rate at each urine collection period are presented in Table V. These urine samples were analyzed for I–III, and the urinary excretion data are summarized in Tables VI–VIII. During the first 12 hr, fluctuations in the elimination rate were largely reflected in the excretion rate plots of I–III. After this period, plots of urinary excretion rates against the midpoints of urine collection periods were not scattered so much.

Subject YK excreted a much higher percentage of administered I as III (81%) than did Subject KY (56%) up to 132 hr. The excretion of unconjugated II and unmetabolized I was very small in both subjects, with the percentage being ~1% of the administered I dose. The concentration of conjugated II in plasma and urine was calculated by subtracting the unconjugated II from the total II measured after acid hydrolysis. However, a minor metabolite of I, 5-(3,4-dihydroxy-1,5-cyclohexadien-1-yl)-5-phenylhydantoin, is partially converted to II (13, 14). Therefore, in the present assay, the total plasma or urine II includes these minor pathways.

The sigma-minus plots shown in Fig. 2 apparently were much less sensitive to fluctuations in the elimination rate of I. Figure 2 shows that the slopes of the terminal monoexponential phase in the plots of the log amount remaining to be excreted against time for I–III were parallel to each other in both subjects. This finding indicates that the slopes of the terminal straight lines for the metabolites (II and III) reflect the elimination rate constant for the substrate (I). The half-lives of I calculated

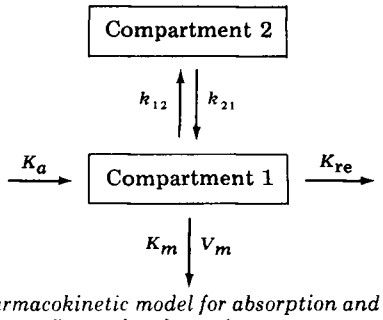
from these slopes were 9.4 hr for Subject YK and 11.5 hr for Subject KY.

Pharmacokinetic Parameters—Linear regression of $(t_{n+1} - t_n)/(\ln C_n - \ln C_{n+1})$ on $(C_nC_{n+1})^{1/2}$ was used to differentiate between first-order and Michaelis–Menten elimination kinetics (15), where C_n and C_{n+1} are the plasma concentrations at time points t_n and t_{n+1}, respectively. The regression line of the plasma data (Table III) beginning at 12 hr after administration of I gave an apparent straight line whose slope was not equal to zero. Therefore, preliminary estimates of the maximum rate of the process (V_m) and the Michaelis–Menten constant (K_m) were obtained from the y-axis intercept and the slope of the line (16). Since it already was reported that I follows a two-compartment open model after intravenous administration (17), the observed set of plasma data in the present study was fitted to a two-compartment open model with Michaelis–Menten elimination kinetics (Scheme I).



Scheme I—Pharmacokinetic model for absorption and elimination of I. Key: K_a, *apparent first-order absorption rate constant;* k_{12}, *apparent first-order distribution rate constant from Compartment 1 to Compartment 2;* k_{21}, *apparent first-order distribution rate constant from Compartment 2 to Compartment 1;* K_{re}, *apparent first-order rate constant for renal excretion of I;* V_m, *maximum rate of metabolism of I; and* K_m, *Michaelis–Menten constant.*

The differential equations for the model shown in Scheme I are:

$$\frac{dC_1}{dt} = K_aC_0e^{-K_at} - \left(k_{12} + \frac{V_m}{K_m + C_1}\right)C_1 + k_{21}C_2 - K_{re}C_1 \quad \text{(Eq. 1)}$$

$$\frac{dC_2}{dt} = k_{12}C_1 - k_{21}C_2 \quad \text{(Eq. 2)}$$

where C_0 is the fraction absorbed (F) times the administered dose (D) divided by the volume of distribution (V_d), C_1 is the drug concentration in Compartment 1, C_2 is the drug concentration in Compartment 2, t is time, K_a is the first-order absorption rate constant, k_{12} is the first-order distribution rate constant from Compartment 1 to Compartment 2, k_{21} is the first-order distribution rate constant from Compartment 2 to Compartment 1, and K_{re} is the first-order rate constant for renal excretion of I.

Equations 1 and 2 were numerically integrated by a computer[5] using

[5] CMB model 2001-32 personal computer.

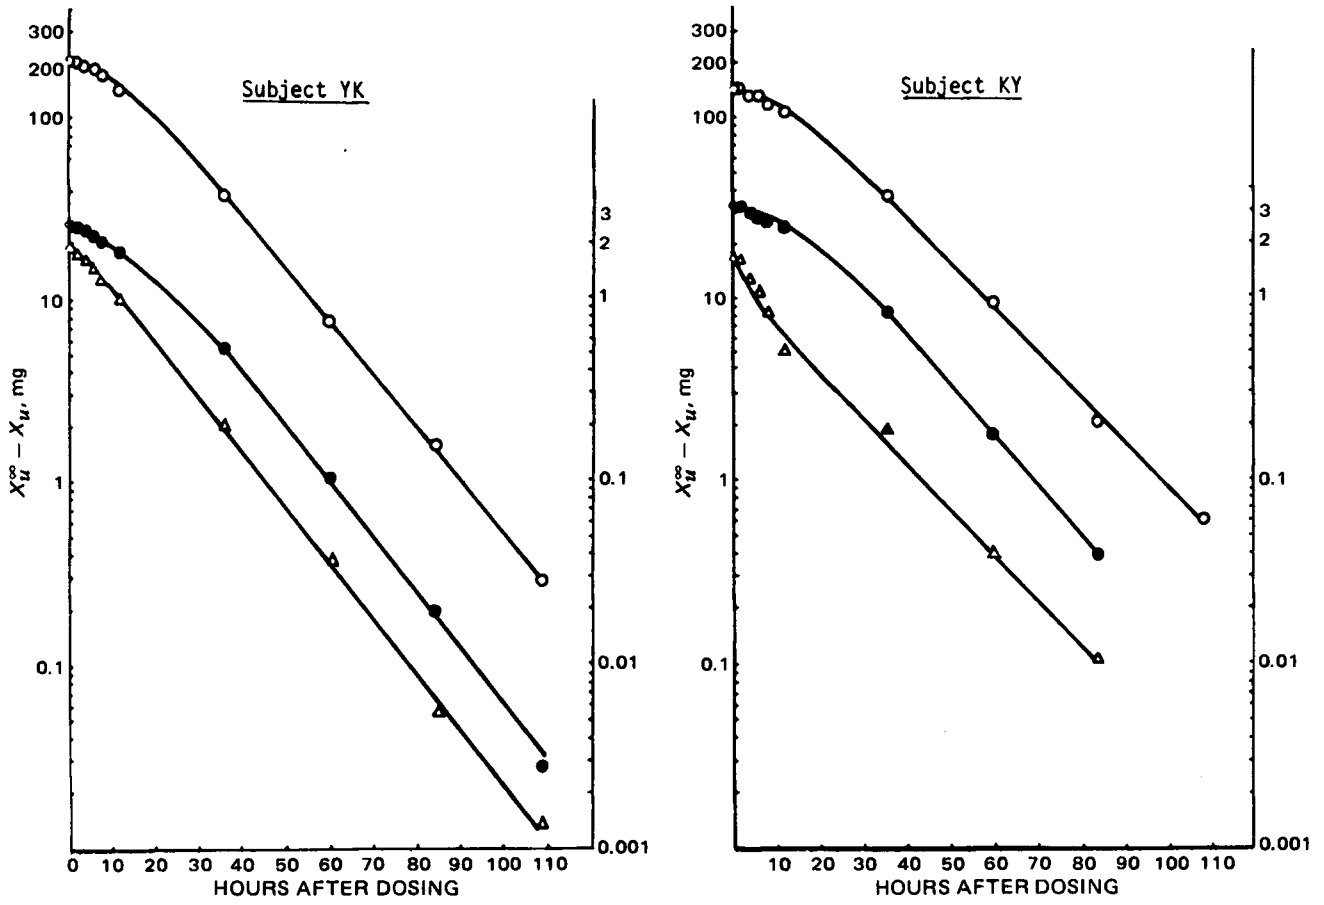


Figure 2—*Semilogarithmic plot of amounts of I–III remaining to be excreted* ($X_u^\infty - X_u$) versus *time for the determination of the elimination rate constant from urinary excretion data. Key:* △, *I (right axis);* ●, *II (right axis); and* ○, *III (left axis).*

the Runge–Kutta method, and the values for the pharmacokinetic parameters (K_a, V_m, K_m, k_{12}, k_{21}, and V_d) were obtained by a least-squares estimation using the steepest descent method. The estimate of the elimination half-life ($t_{1/2}$) was obtained from $t_{1/2} = 0.693/(V_m/K_m)$, without consideration of the minor contribution of K_{re}. The total plasma clearance (Cl_{pl}) was expressed as the amount absorbed divided by the area under the plasma concentration curve, assuming 100% absorption (18). The area under the plasma concentration–time curve (AUC) from t = 0–120 (infinity) was measured by the trapezoidal rule.

Renal clearance (Cl_{re}) for I and II was obtained from the slope of the straight line resulting from a plot of the average excretion rate ($\Delta X_u/\Delta t$) *versus* the plasma concentration at the midpoint of the urine collection period (19). The rate constant for renal excretion of I (K_{re}) was determined by employing $K_{re} = Cl_{re}/V_d$. These pharmacokinetic parameters are listed in Table IX. There were no large differences in V_m, K_m, $t_{1/2}$, Cl_{pl}, and V_d between the two subjects. On the other hand, the values for K_a, K_{re}, AUC, and Cl_{re} were considerably different, except that only a small difference was observed for the AUC value for I.

Table IX—Pharmacokinetic Parameters Derived after Single Oral 250-mg Dose of I

Subject	K_a, hr^{-1}	V_m, μg/ml/hr	K_m, μg/ml	$t_{1/2}$, hr	k_{12}, hr^{-1}

DISCUSSION

The usefulness of a mass fragmentographic technique in conjunction with stable isotope labeling in the pharmacokinetic study of I was a major interest in the present study. Various analytical techniques such as GLC, radioimmunoassay, enzyme immunoassay, liquid chromatography, and spectrophotometry are used frequently for monitoring plasma levels of I during chronic therapy, and comparisons of these analytical methods have been reported (20, 21). The pharmacokinetics of I have been examined by GLC (22–24), colorimetry (25, 26), radioimmunoassay (17), and a radioisotope tracer technique (27, 28). However, the sensitivity or specificity of these methods often does not provide reliable and precise determination of I in biological samples. In addition, no detailed information is available regarding the simultaneous pharmacokinetic analysis of plasma levels and urinary excretion data of I together with its major metabolite II. The present single-dose study in two healthy male volunteers was designed to give information about the precise and detailed pharmacokinetics of I determined from both blood level curves and urinary excretion data for I and II.

The metabolic fate of I has been studied extensively (29–31). Butler (32) showed that I is *para*-hydroxylated in the liver to yield II. This metabolite is conjugated with glucuronic acid, is present in plasma largely as the conjugate, and is excreted in the urine. The colorimetric method described by Dill *et al.* (33) and GLC measurement using derivatization with either trimethylsilyl groups (34) or flash methylation (35) are not sensitive enough to detect unconjugated II in plasma.

A mass fragmentographic method using deuterium-labeled internal standards was described recently (11, 36) for the sensitive quantitative determination of I and II in human plasma. The lower limit of detection was ~0.01 μg/ml for I and II using an extractive alkylation technique (36). Rane *et al.* (37) studied the fate of transplacentally transferred I in newborn infants by a mass fragmentographic method. The molecular ions

Table X—Ratio of II to I in Plasma

t, hr	Subject YK	Subject KY
4	0.013	0.023
12	0.014	0.029
24	0.019	0.040
48	0.026	0.055

were used for the detection of the monomethyl derivatives of I and the internal standard (I-d_{10}). The analytical procedure permitted precise determinations of I in plasma in concentrations down to 0.01 μg/ml. The high sensitivity generally can be obtained by introducing appropriate volatile derivatives for mass fragmentographic analysis.

The mass fragmentographic method described here was satisfactory for the sensitive and specific measurement of I in saliva, plasma, and urine and I and II in plasma and urine. Compound I and its internal standard (I-d_5) were analyzed as the monomethyl derivatives, and II and its internal standard (II-d_5) were converted to the dimethyl derivatives by simple derivatization with diazomethane. The lower limit of detection in this study was ~0.01 μg/ml for both I and II, which was comparable to that reported previously (11, 36, 37).

In the present study, I was administered as the sodium salt dissolved in water, and relatively high saliva I concentrations were observed during the first 3 hr after drug administration (Fig. 1). This result must have been due to residual I in the mouth, although care was taken to avoid this influence by administration of 100 ml of water immediately after drug intake. After this period, the saliva I concentration declined in parallel with the plasma I concentration. Several recent studies (38–40) demonstrated a significant linear correlation between salivary concentrations of I and the plasma total and plasma free concentrations. The data in Table III substantiate the close relationship between the whole salivary and the plasma free I concentrations.

Pharmacokinetic studies in humans usually have been performed with drugs that are present unchanged in the blood or are excreted unchanged in the urine. However, it sometimes is important to carry out simultaneous analysis of blood levels and urinary excretion of both the unchanged drug and its metabolites to determine correct pharmacokinetic parameters, especially when interindividual variations in the pharmacokinetics of a drug are to be investigated. The analysis and interpretation of pharmacokinetic data presented here give some insight into interindividual differences in the metabolic disposition of I.

The shape and peak concentrations of the plasma concentration curves for unchanged I did not differ considerably between Subjects YK and KY. Furthermore, the slopes of the sigma-minus plots for unchanged I (Fig. 2) were very similar in the two subjects. Although there was an approximately twofold difference in the rate constant for renal excretion of I (K_{re}) between Subjects YK and KY, this difference contributed little to the difference in the overall elimination of I since extensive metabolism of I was the predominant route of its elimination. Consequently, it may be stated from these findings that the pharmacokinetic behavior of I in Subjects YK and KY was practically the same.

However, the precise analysis of plasma concentration–time data for I–III revealed that the kinetics of urinary excretion characterized by renal clearance values (Cl_{re}) not only for I but also for II and III differed considerably between the two subjects (Table IX), although both subjects gave normal creatinine clearances of 95.2 (YK) and 105.2 (KY) ml/min. This difference was reflected by the difference in *AUC*. Bochner *et al.* (22) suggested that I is actively secreted in the renal tubules, a process that may differ between subjects. Such a mechanism may explain the difference in renal clearance observed in this study.

It is well known that the clearance of I decreases as the dose of I is increased (41–43). Therefore, it is not unreasonable to assume that the ratio of II to I in plasma could serve as an indicator to predict when one will show these dose-dependent kinetics, regardless of the mechanisms involved. Along this line, Hoppel *et al.* (44) used a mass fragmentographic method to determine II and III in the plasma of patients treated with I. However, no apparent relationship was found in the ratio of the plasma concentrations of I and II at similar doses. Comparison of the ratio of II to I in plasma in the present single-dose study revealed that the ratio tended to increase with the time after administration of I and that the ratio was about two times higher in Subject KY than in Subject YK at each time point (Table X). When the ratio of II to I was compared by calculating the ratio of the *AUC* values for II and I, there also was an approximately twofold difference between the two subjects (KY = 0.035 and YK = 0.016). This in part explains the interindividual differences in the ratios between I and unconjugated II in plasma at a constant dose reported by Hoppel *et al.* (44).

In summary, the mass fragmentographic method described in this study adequately meets the criterion of reliability for the precise, sensitive, and specific determination of I and its main metabolite (II) in biological samples. The pharmacokinetics of I were examined in detail based on the analysis of blood level and urinary excretion data from a single oral dose study in two healthy volunteers.

Correlation of *In Vivo* Bioavailability of Erythromycin Stearate Tablets with *In Vitro* Tests

S. STAVCHANSKY *x, J. T. DOLUISIO *, A. MARTIN *, C. MARTIN *, B. CABANA ‡, S. DIGHE *‡, and A. LOPER *

Received February 8, 1980, from the **Drug Dynamics Institute, College of Pharmacy, University of Texas at Austin, Austin, TX 78712,* and the ‡*Division of Biopharmaceutics, Food and Drug Administration, Rockville, MD 20852.* Accepted for publication May 21, 1980.

Abstract □ Correlations between the bioavailability parameters for erythromycin stearate tablets from five manufacturers and *in vitro* tests of these tablets were examined using forward (stepwise), multiple linear regression analysis. Bioavailability parameters were determined in clinical studies employing a balanced, incompete block design. *In vitro* tests used disintegration, dissolution, and dissolution/dialysis as the independent variables in regression equations. Significant correlations were found between linear combinations of these parameters and the time to peak and the peak serum levels. The inclusion of an *in vitro* disintegration test to describe peak serum levels of erythromycin is noteworthy since it has been suggested that disintegration tests are of less value than dissolution tests in predicting tablet performance *in vivo*. The multiple regression techniques employed in the present investigation may be useful for selection of appropriate physicochemical tests for continued monitoring of the bioavailability of erythromycin stearate tablets.

Keyphrases □ Erythromycin stearate—correlation of bioavailability of tablets with *in vitro* tests □ Antibiotics—erythromycin stearate, correlation of bioavailability of tablets with *in vitro* tests □ Multiple regression analysis—correlation of bioavailability of erythromycin stearate tablets with *in vitro* tests

Erythromycin stearate is erratically absorbed from the GI tract (1) and is subject to degradation by acids (2). Food and the volume of fluid taken with erythromycin stearate tablets affect the serum erythromycin levels in humans (3). The bioavailability variations, coupled with the numerous erythromycin stearate products marketed, create a potential bioequivalence problem. The difficulties encountered with clinical studies in terms of cost and human safety provide an impetus for prediction of product bioavailability from *in vitro* tests.

BACKGROUND

Bivariate correlations of *in vivo* with *in vitro* results have been reported for a variety of drugs. Dissolution rates of three brands of prednisone tablets indicated the clinical efficacy of the tablets (4). Chloramphenicol bioavailability was correlated with *in vitro* dissolution tests by Ogata *et al.* (5). Aguiar *et al.* (6) reported correlations of both the deaggregation and dissolution rates of four commercial lots of chloramphenicol capsules with human plasma levels.

An *in vitro* dissolution rate test that quantitatively predicted the GI absorption of aspirin from three different dosage forms was developed by Levy *et al.* (7). A linear correlation between salicylate excretion following oral administration of two aspirin tablets and the rate of tablet dissolution also was shown (8). In addition, a linear correlation was found between *in vivo* aspirin absorption and the *in vitro* dissolution rate using a rotating-flask apparatus (9). Similar linear correlations also were demonstrated for salicylamide tablets and suspensions (10).

Bergan *et al.* (11) compared the *in vitro* dissolution rates of two tetracycline and seven oxytetracycline products with their absorption characteristics in healthy human volunteers. Correlations were significant for some of these tetracycline products but not for others. Smolen and Weigand (12) developed a flow-through dissolution apparatus which could be optimized through feedback control to simulate *in vivo* drug release properties. They found that systematic adjustment of dissolution conditions resulted in improved *in vitro* to *in vivo* correlations.

These studies, with the exception of the chloramphenicol deaggregation studies, used *in vitro* dissolution results to predict drug absorption *in vivo*. However, bioavailability is a complex parameter which is influenced by the physicochemical properties of the drug, the dosage form, and the physiological conditions of the system. Thus, dissolution testing should be complemented by other *in vitro* tests to increase the prediction ability of *in vivo* drug absorption from *in vitro* results. Data on dissolution, dialysis, disintegration, and other physical tests are presented, and the usefulness of multiple linear regression analysis in the correlation between *in vivo* bioavailability and *in vitro* parameters for five commercially available erythromycin stearate tablets is demonstrated.

EXPERIMENTAL

***In Vitro* Studies**—*In vitro* tests were performed on selected lots of 250-mg film-coated erythromycin stearate tablets from five manufacturers. All tablets were from the same lots as those used in the clinical studies (13). Tablet hardness was measured with a motorized pendulum tablet hardness tester[1]. When the tablet was harder than 16 kg, a spring-type hand-held tester was used[2]. Weight variation was determined by weighing 10 tablets from each lot.

Four disintegration methods were investigated using the USP XIX apparatus at 37 ± 2°. In Method 1, tablets were run for 30 min in a 0.2% aqueous NaCl solution adjusted to pH 3 with dilute hydrochloric acid. These tablets then were placed in a pH 7.35 phosphate buffer solution containing 6.8 g of monobasic potassium phosphate and 190 ml of 0.2 *N* NaOH adjusted to 1000 ml with water. Method 2 involved placing the tablets in USP XIX simulated gastric fluid test solution (pH 1.22) for 30 min and then removing the tablets and placing them in USP XIX simulated intestinal fluid test solution (pH 7.55) for the time required to bring about disintegration. Method 3 was the same as Method 2, except that no enzymes were used in the simulated gastric and intestinal fluids. Method 4 also was the same as Method 2, except that the time in the gastric fluid was increased to 1 hr.

Dissolution studies on the five erythromycin stearate lots were per-

Heterogeneous Model of Drug Release from Polymeric Matrix

S. K. CHANDRASEKARAN ˣ **and R. HILLMAN**

Received December 10, 1979, from *Alza Research, Palo Alto, CA 94304.* Accepted for publication May 22, 1980.

Abstract □ The kinetics of drug release from a polymeric matrix originally proposed by Higuchi were extended for the case of high drug loading (relative to the solubility of the drug in the polymer). The model of a granular matrix in which an effective porosity and tortuosity are assumed to modify the normal Higuchi kinetics is reviewed. A new model, which allows the prediction of the kinetics of drug release from properties of the polymer and drug, is based on the assumption that the permeability of the dispersed matrix is a function of drug loading.

Keyphrases □ Release rates—heterogeneous model of drug release from polymeric matrix □ Kinetics—heterogeneous model of drug release from polymeric matrix □ Diffusion—heterogeneous model of drug release from polymeric matrix

The kinetics of release of a solute dispersed in a polymeric matrix are of general interest in the controlled delivery of drugs (1). When the total loading of the solute (dissolved plus dispersed), C_0, is higher than its solubility in the matrix, C_s, the kinetics of release have been described by Higuchi (2). In this model, when the matrix is placed in an infinite sink, it is assumed that solid drug dissolves and diffuses from the surface layer of the matrix; when this layer becomes exhausted of drug, the next layer begins to be depleted.

BACKGROUND

In a planar system, the release of solute per unit time, dM_t/dt, is described by:

$$\frac{dM_t}{dt} = A\left[\frac{D(2C_0 - C_s)C_s}{t}\right]^{1/2} \quad \text{(Eq. 1)}$$

where A is the area of the slab, D is the diffusivity of the drug in the matrix, C_0 is the drug loading, and C_s is the solubility of the drug in the matrix at time t.

When the drug loading becomes much greater than the solubility and a granular matrix (with the possibility of interparticle contact) is formed, Eq. 1 usually is modified to give (2–4):

$$\frac{dM_t}{dt} = A\left[\frac{\frac{\epsilon}{\tau}D(2C_0 - \epsilon C_s)C_s}{t}\right]^{1/2} \quad \text{(Eq. 2)}$$

which becomes:

$$\frac{dM_t}{dt} = A\left(\frac{2\epsilon DC_0C_s}{\tau}\right)^{1/2} t^{-1/2} \quad \text{(Eq. 3)}$$

in the case where $C_0 \gg \epsilon C_s$. Thus, Eq. 1 is modified by an effective porosity, ϵ, which can be related to the volume fraction of drug in the matrix, and an effective tortuosity, τ, which describes the tortuous diffusion path a solute molecule must follow. In addition, the D value is taken as the diffusivity of the solute in the receptor solution. In other words, it is assumed that the solute is released by leaching through channels that are formed in the continuous matrix.

When Eq. 3 is rewritten as:

$$Q = Kt^{-1/2} \quad \text{(Eq. 4)}$$

with:

$$Q = \left(\frac{1}{A}\right)\frac{dM_t}{dt} \quad \text{(Eq. 5)}$$

and:

$$K = \left(\frac{2\epsilon DC_0C_s}{\tau}\right)^{1/2} \quad \text{(Eq. 6)}$$

it can be seen that this model predicts that the release rate constant changes in proportion to the square root of the initial drug loading, C_0. The ratio ϵ/τ then expresses the fractional area available for release.

There are several conceptual and practical drawbacks to the model. One would expect that by introducing flux enhancers or increasing the amount of drug in the matrix, the structure of the matrix, and, hence, the diffusivity of the drug in the matrix should be changed. In this model, the diffusivity is assumed to be independent of the drug concentration. Practically, it is difficult to measure the tortuosity and porosity of a polymer matrix. It is far more desirable to relate drug release to the molecular weight of the drug, the loading of drug in the matrix, and the diffusivity of the drug in pure polymer, all easily obtainable properties.

Davis (5) proposed an equation relating the diffusivity of several drugs in polyacrylamide and povidone gels based on the concentration and molecular weight of the drug in the polymer matrix and the diffusivity of the drug in the receptor solvent. The diffusion coefficient of the drug in the polymer, D_p, is related to the diffusion coefficient of the drug in pure solvent, D_0, by:

$$\log D_p = \log D_0 - k_sP \quad \text{(Eq. 7)}$$

where P is the volume percent of polymer and k_s is defined by:

$$k_s = -\frac{d \log D_p}{dP} \quad \text{(Eq. 8)}$$

and can be shown empirically to be a function of the molecular weight of the solute, M:

$$k_s = k_1 + k_2M \quad \text{(Eq. 9)}$$

Combining Eqs. 7 and 9 gives:

$$D_p = D_0 \exp[-(k_1 + k_2M)P] \quad \text{(Eq. 10)}$$

where k_1 and k_2 are empirical constants.

Davis pointed out that the logarithmic relationship between the diffusivity and the polymer concentration could be anticipated from previous work (6) on porosity in polymer networks. Thus, the exponential term in Eq. 10 could be redefined as porosity, which is defined by the space available for collision-free diffusion. The fundamental drawback in Davis' work is that it is based on an empirical correlation where four constants must be determined experimentally.

An attempt was made in this study to develop a heterogeneous model of drug diffusion from a dispersed polymer matrix for which fewer experimental measurements related directly to fundamental physicochemical properties are required.

THEORY

The polymer matrix is visualized as a heterogeneous system consisting of a continuous (polymer) phase with a discontinuous drug phase as

400	1.45	1.99
450	1.8	2.45

particles dispersed uniformly throughout the matrix. Initially, the particles will be assumed to be a uniform array of spheres in the matrix. This assumption allows use of Maxwell's work on the conductivity of a dilute suspension of homogeneous nonpolarizable spheres (7). These assumptions are made to reduce the many particle problem to the case of one particle in a homogeneous field. This work also has been extended to the thermal conductivity of heterogeneous mixtures (8).

From Fick's law, the permeability of a dispersed polymer matrix can be expressed by:

$$P = \frac{D_p V_p \left(\frac{dc}{dx}\right)_p + D_d V_d \left(\frac{dc}{dx}\right)_d}{V_p \left(\frac{dc}{dx}\right)_p + V_d \left(\frac{dc}{dx}\right)_d} \qquad \text{(Eq. 11)}$$

or:

$$P = \frac{D_p V_p F_p + D_d V_d F_d}{V_p F_p + V_d F_d} \qquad \text{(Eq. 12)}$$

where:

$$F_d = \left(\frac{dc}{dx}\right)_d \qquad \text{(Eq. 13)}$$

$$F_p = \left(\frac{dc}{dx}\right)_p \qquad \text{(Eq. 14)}$$

Equation 11 expresses the permeability (P) as a function of the volume fraction of polymer (V_p) and drug (V_d), the diffusivity of the drug through the pure polymer phase (D_p) and the dispersed polymer phase (D_d), and the overall concentration gradient (F_p and F_d) in the two phases.

From Maxwell's work, the average gradient ratio for spheres can be expressed as:

$$F_d = \left[1 + \left(k\frac{D_p}{D_d} - 1\right)V_d\right]^{-1} \qquad \text{(Eq. 15)}$$

assuming $F_p = 1$. Substituting Eq. 15 into Eq. 12 and rearranging terms yield:

$$\frac{P}{P_p} - 1 = 3V_d\left[\frac{(kD_d/D_p) + 2}{(kD_d/D_p) - 1} - V_d\right]^{-1} \qquad \text{(Eq. 16)}$$

where P is the net normalized permeability of the dispersed matrix, P_p is the normalized permeability of the polymer matrix, V_d is the volume fraction of dispersed particles, and k is the partition coefficient.

With the assumption that $kD_d/D_p \gg 1$, Eq. 16 reduces to:

$$\frac{P}{P_p} = \frac{1 + 2V_d}{1 - V_d} \qquad \text{(Eq. 17)}$$

The volume fraction of the dispersed particles can be related to the total loading of particles by:

$$V_d = \frac{C_0}{\rho} \qquad \text{(Eq. 18)}$$

where ρ is the density of the dispersed phase.

Equation 17 now becomes:

$$\frac{DC}{D_p C_p} = \frac{\rho + 2C_0}{\rho - C_0} \qquad \text{(Eq. 19)}$$

where D_pC_p is the normalized permeation rate in the pure polymer (*i.e.*, very low solute loadings) and DC is the normalized rate in the dispersed matrix at a particle loading of C_0.

The basic Higuchi model now may be modified for the release of drug from a dispersed polymer matrix to account for the change in diffusivity. Again, the basic Higuchi model can be written as:

$$\frac{1}{A}\frac{dM_t}{dt} = \left(\frac{2DC_0C_s}{t}\right)^{1/2} \qquad \text{(Eq. 20)}$$

Accounting for the effect of the addition of a dispersed phase by substituting Eq. 19 into Eq. 20 yields:

$$\frac{1}{A}\frac{dM_t}{dt} = \left[2D_pC_pC_0\left(\frac{\rho + 2C_0}{\rho - C_0}\right)\right]^{1/2} t^{-1/2} \qquad \text{(Eq. 21)}$$

The release rate constant, K', for a porous matrix becomes:

$$K' = \left[2D_pC_pC_0\left(\frac{\rho + 2C_0}{\rho - C_0}\right)\right]^{1/2} \qquad \text{(Eq. 22)}$$

and:

$$\frac{1}{A}\frac{dM_t}{dt} = K't^{-1/2} \qquad \text{(Eq. 23)}$$

Thus, the release rate of drug from a porous matrix can be calculated from the density of the dispersed phase, the drug loading, and the permeability of the drug in the pure polymer.

RESULTS AND DISCUSSION

There are few data in the literature on the incorporation of a drug or a solute at high loadings into polymeric films or matrixes. Samuelov *et al.* (3) recently published data on the release rate characteristics of salicylic acid and tripelennamine from polyethylene glycol–ethylcellulose films as a function of solute loading, and an attempt was made to utilize their data to test the validity of the proposed model. The release rate constant, K', was computed using Eq. 22, and the results of these computations as a function of solute loading are presented in Tables I–IV.

The release rate constants measured by Samuelov *et al.* (3) also are shown.

The release rate constants for salicylic acid in polyethylene glycol–ethylcellulose and pure ethylcellulose films are shown in Tables I and II. The density of the salicylic acid was taken as 1.443 g/cm^3, and the normalized permeation rate, D_pC_p, of salicylic acid in the polymer was calculated from the lowest solute loading (55 mg/ml) and used in all subsequent computations. The agreement between the release rate constants determined experimentally and those calculated from the model is good.

Similarly, the release rate constants for tripelennamine in polyethylene glycol–ethylcellulose and pure ethylcellulose films are presented in Tables III and IV. The normalized permeation rate of tripelennamine in the polymer was calculated from the lowest solute loading (55 mg/ml), and the density of the dispersed solute was taken as 1.35 g/cm^3. The agreement between theory and experiment again is good.

Friedman *et al.* (9) prepared timed-release dosage forms using ethylcellulose as the polymeric matrix and salicylic acid and caffeine as model drugs. They determined drug release rates for different initial drug concentrations, and their experimental results are presented in Tables V and VI. The values of the release rate constant, K', computed using Eq. 22 also are shown. The diffusivity in the polymer of caffeine and salicylic acid was 2.26×10^{-11} and 1.96×10^{-11} cm^2/sec, respectively. The agreement between the release rate constants determined experimentally and those calculated from the model is good.

There is a good correlation between the model predictions and the measured release rate constants for the drugs. The deviation at very high drug loadings (>30%) can be attributed to interparticle contact. The interparticle contact leads to the formation of channels in the membrane through which the drug can be leached. Therefore, a model of a porous network must be applied. However, up to this limit, the release of drug can be predicted simply from a knowledge of drug loading, drug density, and the permeation rate of the drug in the pure polymers (very low loadings). Comparison of Tables I and II or Tables III and IV shows that plasticized films (with polyethylene glycol) have significantly higher release rate constants than do pure ethylcellulose films. Thus, the diffusivity and solubility of the drug are altered by the addition of plasticizers. The theory could be suitably modified to predict the release rate based on flux enhancer content and will be the subject of a subsequent communication.

Clearly, many properties of the polymer matrix can influence the permeation of drug including the geometry of the dispersed phase (shape, size, and size distribution), the composition of the dispersed phase, and interactions between the phases. However, the simplified model proposed here apparently gives a good correlation to experimental evidence.

Keyphrases □ Quinazolones—substituted derivatives, synthesis and evaluation for antibacterial, antifungal, and antiacetylcholinesterase activities □ Antibacterial activity—evaluation of substituted quinazolone derivatives □ Antifungal activity—evaluation of substituted quinazolone derivatives □ Antiacetylcholinesterase activity—evaluation of substituted quinazolone derivatives

Various quinazolone derivatives were investigated recently for biological and pharmacological activities such as antibacterial (1–4), antifungal (5, 6), antitubercular (7), antiamoebic (8), antiviral (9), anti-inflammatory (10), anticonvulsant (11, 12), hypotensive (13), and sedative (14, 15) activities. Parmar and coworkers (16, 17) reported the antiacetylcholinesterase activity of quinazolone derivatives.

Since the 1,3,4-thiadiazole nucleus already is well known for its biological activity (18–20), it was decided to combine different 5-chloroacetylamino-2-alkyl-1,3,4-thiadiazole

derivatives with the quinazolone nucleus and to study the biological activities of the quinazolone derivatives in continuation of previous work (21–23).

The present report describes the synthesis, characterization, and *in vitro* antibacterial, antifungal, and antiacetylcholinesterase activities of these quinazolone derivatives (II) (Schemes I–III).

EXPERIMENTAL[1]

Chemistry—Several 6-bromo- and 6,8-dibromo-2-mercapto-3-aryl/cyclohexyl-4-(3*H*)-quinazolones (Ib) were synthesized by condensation of 5-bromo- and 3,5-dibromo-2-aminobenzoic acids (Ia) with different substituted aryl isothiocyanates in ethanol. With the method of Gagiu and Mavrodin (24), different 5-chloroacetylamino-2-alkyl-1,3,4-thiadiazole derivatives (Id) were obtained in good yield by refluxing 2-alkyl-5-amino-1,3,4-thiadiazoles (Ic) in dry benzene with chloroacetyl chloride. The intermediate 2-alkyl-5-amino-1,3,4-thiadiazoles were prepared by a literature method (25). When the 2-mercapto-3-aryl/cyclohexyl-4-

[1] All compounds were analyzed for their nitrogen content. Melting points were taken in open capillary tubes with a partial immersion thermometer and are corrected. IR spectra were obtained with a Perkin-Elmer model 137 Infracord spectrophotometer, equipped with sodium chloride optics, in potassium bromide films in the 700–3500-cm^{-1} range.

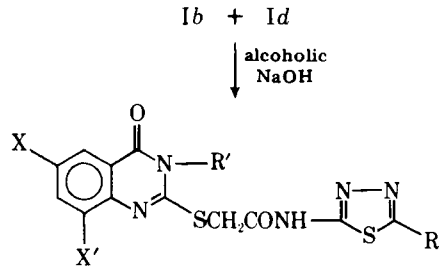
[a] Griseofulvin, a potent fungicide, was used as a control.

(3*H*)-quinazolones were refluxed in alcoholic sodium hydroxide with different 5-chloroacetylamino-2-alkyl-1,3,4-thiadiazoles, 24 new 6-bromo- and 6,8-dibromo-2-[*N*-(2′-alkyl-1′,3′,4′-thiadiazol-5′-yl)carbamoylmethylthio]-3-aryl/cyclohexyl-4-(3*H*)-quinazolones (II) with varying alkyl groups in the thiadiazole nucleus and different aryl functions in the quinazolone nucleus were obtained (Table I).



II

Scheme III

Synthesis—*6-Bromo- and 6,8-Dibromo-2-mercapto-3-aryl/cyclohexyl-4-(3H)-quinazolones (Ib)*—These compounds were prepared by the method described by Bhargava and Lakhan (26).

To a solution of 5-bromo-2-aminobenzoic acid (0.01 mole) in absolute ethanol (50 ml) was added 1.41 g (0.01 mole) of cyclohexylisothiocyanate. The resulting solution was heated under reflux on a steam bath for 5 hr, at which time a crystalline solid mass was obtained. The solid mass was separated by filtration, washed with cold ethanol, and recrystallized from ethanol.

Various other quinazolones (Ib) were prepared in a similar manner.

6-Bromo- and 6,8-Dibromo-2-[N-(2'-alkyl-1',3',4'-thiadiazol-5'-yl)carbamoylmethylthio] -3- aryl/cyclohexyl -4- (3H)-quinazolones (II)—To a solution of sodium hydroxide (0.4 g, 0.1 mole) in 30 ml of 80% ethanol was added 3.47 g (0.01 mole) of 6-bromo-2-mercapto-3-benzyl-4-(3*H*)-quinazolone, and the mixture was stirred until a clear solution was obtained. 5-Chloroacetylamino-2-methyl-1,3,4-thiadiazole (1.92 g, 0.01 mole) was added, and the solution was heated under reflux for 5 hr. After cooling, the reaction mixture was poured into 200 ml of ice-cold water; the solid mass was filtered, washed with cold water, and crystallized from ethanol.

Other quinazolone derivatives (II) were prepared in a similar manner and are listed in Table I.

All of the synthesized quinazolone derivatives (II) (Table I) were characterized by their sharp melting points and elemental analyses. The IR spectra of the final compounds (II) showed the characteristic absorption bands of C=N (~1600 cm^{-1}), CH_2CON (~1680 cm^{-1}), CONH (~1660 cm^{-1}), and C=O (1700 cm^{-1}). Absence of the SH vibration at 2550 cm^{-1} provided further support for their molecular structure. These absorption bands correspond to the characteristic quinazolone bands (27).

Biological Screening—All compounds reported in Table I were assayed *in vitro* for antibacterial activity against six bacteria: *Staphylococcus aureus*[2] (NCTC 7447), *Bacillus pumilus*[2] (NCTC 8241), *Bacillus subtilis*[2] (NCTC 8236), *Sarcina lutea*[2] (ATCC 9341), *Salmonella typhi*[3] H091 (NCTC 3111), and *Mycobacterium tuberculosis*[3] ($H_{37}Rv$). Their antifungal activity was screened against several fungi: *Aspergillus niger*[4] (ATCC 12845), *Microsporum canis*[3] (VM 200-USPHS), *Aspergillus fumigatus*[3] (68LI), *Fusarium moniliforme*[4] (ATCC 10052), *Penicillium nonatum*[4] (ATCC 9179), and *Rhizopus stolonifer*[4] (ATCC 10404).

Of the 24 quinazolone derivatives (Table I), 14 also were tested for their antiacetylcholinesterase activity (Table II).

Determination of Antibacterial Activity—The *in vitro* antibacterial activity was determined by an agar plate diffusion method (28). The agar medium was inoculated with 1 ml of a 24-hr-old culture of the test organism. Filter paper disks (5 mm in diameter) saturated with the test compounds (10 mg/ml in ethanol) were placed on nutrient agar after the ethanol was dried. After incubation for 36 hr, the zones of inhibition around the disks were measured.

All experiments were performed in duplicate, and the results are recorded in Table III.

Determination of Antifungal Activity—The agar plate diffusion technique (29) was employed for the determination of the antifungal activity of the synthesized compounds. Three concentrations (1:1000, 1:10,000, and 1:100,000) were used. One milliliter of each compound was poured into separate petri dishes. Approximately 20–25 ml of molten Czapek-Dox agar medium was added to each petri dish.

All experiments were performed in triplicate. The average percentage inhibition given by the various compounds after 1 week is given in Table IV.

Determination of Antiacetylcholinesterase Activity—Male rats, ~150–200 g, were decapitated, and the brains were removed quickly, weighed, and homogenized in a glass homogenizer[5] using a polytef pestle. A 1% (w/v) homogenate in phosphate saline was used without further purification as the enzyme source.

The enzyme activity was assayed essentially according to the method proposed by Diggle and Gage (30), which is a modification of Hestrin's (31) method. The 2.7-ml assay system contained 0.5 ml of phosphate saline, 1.0 ml of acetylcholine bromide solution, 0.2 ml of inhibitor solution in propylene glycol, and 1.0 ml of the enzyme source. The enzyme was kept with the inhibitor at 37° for 5 min. The reaction was started with the addition of acetylcholine (only in experimental tubes).

The tubes were kept at 37° for 15 min, after which the reaction was stopped by the addition of 2.0 ml of alkaline hydroxylamine hydrochloride. Thereafter, 1.0 ml of acetylcholine solution was added to the control tubes. Then 1.0 ml of diluted hydrochloric acid was added to all of the tubes, followed by the addition of 1.5 ml of ferric chloride solution and water to bring the volume to 7.5 ml in each tube. The absorbance was recorded in a spectrophotometer[6] at 540 nm. The inhibition obtained was recorded in Table II along with the I_{50} values of the quinazolone derivatives, which indicate the concentration required to produce 50% enzyme inhibition.

RESULTS AND DISCUSSION

The results shown in Table III indicate that all of the compounds exhibited antibacterial activity against at least one type of bacteria. In comparison to the 6-bromo quinazolone derivatives (II–XIII), 6,8-dibromo quinazolone derivatives (XIV–XXV) were more effective antibacterial compounds. When the benzyl or 4-methoxyphenyl group was substituted at the 3-position in the quinazolone nucleus, the activity increased (II–IV, XI–XVI, and XXIII–XXV). 2-Ethylphenyl-substituted quinazolone derivatives (V–VII and XVII–XIX) exhibited comparatively poor antibacterial activity. All compounds exhibited increased antibacterial activity against *S. lutea* (ATCC 9341). Compounds XI, XVI, and XXIII exhibited good antibacterial activity.

From the toxicity data given in Table IV, it is evident that all of the compounds possess variable antifungal activity against the fungi tested. The 6,8-dibromo quinazolone derivatives were more effective antifungal agents than the 6-bromo quinazolone derivatives. Substitution of the benzyl group at the 3-position of the quinazolone nucleus led to II–IV and XIV–XVI, which were more effective antifungal compounds. Furthermore, the electron-donating group 2-ethylphenyl decreased the fungitoxicity of the test compounds while the electron-withdrawing group 4-methoxyphenyl increased the fungitoxicity. Cyclohexyl substitution at the 3-position of the quinazolone nucleus rendered VIII–X and XX–XXII less fungitoxic against the fungi tested.Compounds XI and XXIII were better antifungal agents.

The results of the antiacetylcholinesterase test *in vitro* against 14 synthesized quinazolone derivatives are recorded in Table II. The screening data indicate that all of these derivatives exhibited marginal activity. Compounds XVIII and XXIV were more active, while II was inactive. Furthermore, 6,8-dibromo-substituted quinazolone derivatives were more potent in comparison to 6-bromo-substituted derivatives. Compounds III, XV, and XXII exhibited equal I_{50} values, as did XII, XVII, and XXV and also VIII, IX, and XIII.

Comparison of Polyethylene Glycol and Polyoxyethylene Stearate as Excipients for Solid Dispersion Systems of Griseofulvin and Tolbutamide I: Phase Equilibria

RABINDER KAUR *, D. J. W. GRANT *x, and T. EAVES ‡§

Received March 4, 1980, from the **Department of Pharmacy, University of Nottingham, University Park, Nottingham NG7 2RD, England,* and the ‡*Hoechst Pharmaceuticals Research Laboratories, Walton Manor, Milton Keynes, Buckinghamshire MK7 7AJ, England.* Accepted for publication May 27, 1980. §Present address: Merrell International, Slough, Berkshire SL1 1YY, England.

Abstract □ Phase equilibrium diagrams were constructed based on hot-stage microscopy and differential scanning calorimetry of solid dispersions of griseofulvin or tolbutamide in polyethylene glycol 2000 or polyoxyethylene 40 stearate. The solid dispersions were prepared by physical mixing, fusion, and coprecipitation from ethanol. The phase diagrams were largely independent of the method of preparation of the dispersion systems. The diagrams were of the monotectic type for polyethylene glycol 2000 with each drug and for griseofulvin with each excipient, with the monotectic species being the pure drug. Polyoxyethylene 40 stearate with tolbutamide gave eutectic systems in which liquid polyoxyethylene 40 stearate dissolved up to 20% of the tolbutamide. The phase diagrams showed greater solubility of tolbutamide in liquid polyoxyethylene 40 stearate than in polyethylene glycol 2000 but showed a similar solubility of griseofulvin in each excipient. Solid solution formation was not detected.

Keyphrases □ Excipients—polyethylene glycol and polyoxyethylene stearate, comparison as excipients for solid dispersion systems of griseofulvin and tolbutamide, phase equilibria □ Polyethylene glycol—comparison with polyoxyethylene stearate as excipient for solid dispersion systems of griseofulvin and tolbutamide, phase equilibria □ Polyoxyethylene stearate—comparison with polyethylene glycol as excipient for solid dispersion systems of griseofulvin and tolbutamide, phase equilibria

The use of a eutectic mixture containing a water-soluble compound to increase the dissolution rate and bioavailability of a sparingly soluble drug first was demonstrated by Sekiguchi and Obi (1). As the water-soluble matrix dissolves, the insoluble drug is exposed to the dissolution medium in a very fine state of subdivision. This type of formulation, a solid dispersion system, has been investigated extensively and has been extended to include solid solutions of drug in water-soluble excipients (2). Solid solutions should offer greater increases in the dissolution rate and bioavailability than eutectic mixtures, because the drug is dispersed as single molecules in solid solutions but as solid microscopic particles in the latter case.

BACKGROUND

Solid dispersions of griseofulvin in polyethylene glycols of high molecular weight (3, 4) have excited much interest. The dissolution rate and bioavailability of griseofulvin from such solid dispersions clearly are greater than those of the micronized or microcrystalline drug (5). These phenomena previously were attributed to the formation of solid solutions, but Chiou (6) recently showed that griseofulvin has negligible or very limited solid solubility in polyethylene glycol dispersion systems. The marked enhancement of the dissolution and absorption rates of griseo-

Table I—Effect of Pretreatment on the Melting Ranges

Compound	Ground Materials	Recrystallized from Ethanol	After Fusion and Cooling
I	53–58°	53–58°	54–58°
II	46–50°	46–50°	37–45°
Griseofulvin	220–222°	220–222°	220–224°
Tolbutamide	127–133°	127–133°	125–131°

fulvin dispersed in polyethylene glycol seems to be primarily a result of the reduced size of the griseofulvin crystals; however, other factors, such as increased wettability, reduction or absence of aggregation and agglomeration, and solubilization of the drug by the carrier at the diffusion layer of particles also may contribute (6).

The formation of solid dispersions of tolbutamide in polyethylene glycol polymers also increases the dissolution rate of this drug (7), and this increase has been attributed to the formation of a solid solution, the dispersion of the drug in a fine state of subdivision, or improved wetting of the drug particles. Polyethylene glycol is a hydrophilic polymer with no hydrophobic or lipophilic moiety and, therefore, is not surface active. Esterification with a long-chain *n*-acyl residue (such as stearate, to form, for example, polyoxyethylene stearate) produces a water-soluble, surface-active macromolecule, which might offer certain advantages as an excipient in solid dispersion systems of drugs, such as griseofulvin or tolbutamide, that are poorly soluble in water. The nonpolar hydrophobic moiety, *e.g.*, $C_{17}H_{35}$, might promote solid solution formation, with consequent advantages for drug release, as well as surface activity, a potent factor in enhancing rates of dissolution and absorption. The possibility of solid solution formation is considered in the present report, and the consequences of surface activity are discussed elsewhere (8).

Polyoxyethylene 40 stearate has been evaluated by the joint Food and Agriculture Organization and World Health Organization Expert Committee on Food Additives (9) and is claimed to be acceptable for daily intake of up to 25 mg/kg. Further biological data, including biochemical aspects, toxicological studies, and observations in humans, also have confirmed the relative nontoxicity of polyoxyethylene 40 stearate (10–15).

Polyoxyethylene 40 stearate is a mixture of monoacid stearates of polyoxyethylene polymers consisting of 40 oxyethylene units on the average, and its mean molecular weight is similar to that of polyethylene glycol 2000. It is a solid that melts at 45–52° and is miscible with water in all proportions. Its hydrophile–lipophile balance value is 16.9, and it stabilizes oil-in-water emulsions.

Using thermal methods of analysis, the physicochemical interactions between two model drugs and polyoxyethylene 40 stearate (average molecular weight of 2044) were compared with those between the drugs and polyethylene glycol 2000. The model drugs, griseofulvin and tolbutamide, were chosen based on their low solubility in water and biological fluids.

Dispersion systems containing each drug and each excipient were prepared (*a*) by grinding the drug and excipient together, (*b*) by fusing the drug and excipient together and then grinding the mass, and (*c*) by coprecipitating the drug and excipient from the same solvent (ethanol) followed by grinding. Mixtures covering the entire range of composition, including the single components, were subjected to differential thermal analysis and hot-stage microscopy, from room temperature to temperatures above those of complete melting. The solid–liquid phase diagrams were plotted and compared.

The next report in this series (8) compares the influence of polyoxyethylene 40 stearate (II) with that of polyethylene glycol 2000 (I) on the dissolution rate of the two drugs from certain dispersion systems and assesses the factors responsible for the differences. A preliminary report of the work was published previously (16).

EXPERIMENTAL

Materials—The following materials and drugs were of food or pharmaceutical grade and were used as supplied: polyoxyethylene 40 stearate[1] (II), polyethylene glycol 2000[2] (I), griseofulvin[2], and tolbutamide[2]. Ethanol (95%) was spectroscopic grade. The pH 7 buffer was phosphate buffer BP (17). The pH 1 buffer was 0.1 *M* HCl. All water was double distilled from an all-glass still.

[2] Hoechst UK Ltd., Milton Keynes, Bucks, England.

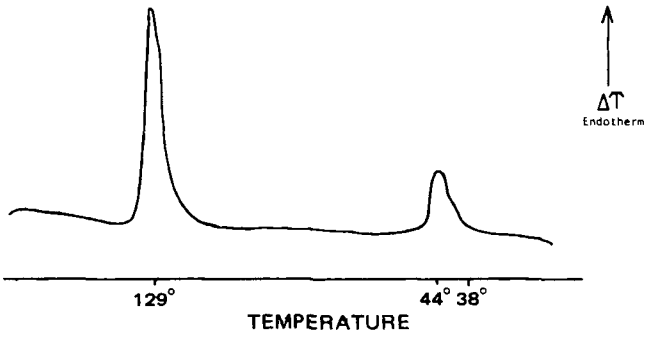

Figure 1—*Differential thermal analysis curve of a coprecipitated dispersion of tolbutamide (90% w/w) and II (10% w/w).*

Preparation of Dispersion Systems—*Physical Mixtures*—The physical mixtures were prepared by thoroughly grinding together weighed quantities of the drug and excipient for 5 min using a glass pestle and mortar. Homogeneity of the mixtures was tested by subjecting the samples to thermal microscopy and to differential thermal analysis.

Fused Mixtures—The fused mixtures were prepared by heating 1–2 g of the corresponding ground physical mixture in a wide test tube to a few degrees above the melting point of the excipient, *i.e.*, <65°, with rotation of the tube for 30 sec. The sample was allowed to cool in a desiccator at 4°. The resulting solid then was scraped out of the tube and ground using a glass pestle and mortar.

Coprecipitated Mixtures—Coprecipitated mixtures were prepared by dissolving weighed quantities of the drug and excipient in ethanol, mixing thoroughly, and allowing the solvent to evaporate slowly in a rotary film evaporator[3] at ~40° under vacuum. The resulting semisolid mass was dried under vacuum[4] at 20° in the presence of phosphorus pentoxide. The dry solid was ground using a glass pestle and mortar.

Differential Thermal Analysis—Five milligrams of sample was heated at 5°/min in a thermal analyzer[5] coupled to a two-channel potentiometric recorder[6]. Alumina was used as the reference material, and static air was the gas phase. The instrument was calibrated using benzoic acid[7] (thermochemical grade).

The onset of each peak was characterized by the temperature at the point of intersection of the line of the steepest slope and the baseline. The completion of each peak was characterized by the temperature at the summit. These two temperatures were used to define the melting ranges from differential thermal analysis.

Hot-Stage Microscopy—About 1 mg of sample was placed between a microscope slide and a cover slide and heated at 1–5°/min under a hot-stage microscope[8] fitted with polarizers. The onset of melting was characterized by the first appearance of liquid, and the completion of melting was considered as the final disappearance of solid. These two temperatures were used to define the melting ranges from hot-stage microscopy.

Preparation of Dispersion Systems for Differential Thermal Analysis and Hot-Stage Microscopy—The excipients under study are waxy at room temperature and crystalline and brittle at the temperature of solid carbon dioxide. Therefore, differential thermal analysis and hot-stage microscopy of the excipients were compared after grinding at each temperature followed by standing for 30 min in a desiccator. Since no significant difference in melting was found, grinding subsequently was carried out at room temperature.

Using differential thermal analysis and hot-stage microscopy, the phase equilibria of physical, fused, and coprecipitated mixtures of each drug (tolbutamide and griseofulvin) with each excipient (I and II) were studied.

RESULTS

Melting Behavior of Original Materials—Compounds I and II, griseofulvin, and tolbutamide, when subjected to differential thermal analysis, each gave a single peak corresponding to fusion. Furthermore,

when heated slowly under hot-stage microscopy, each substance melted over the same temperature range as that defined by the beginning and summit of the corresponding peak in differential thermal analysis. The two techniques afforded the melting ranges shown in Table I. Reductions in the melting point were observed only with tolbutamide and II after fusion and cooling.

Melting Behavior of Drug–Excipient Mixtures—Whether prepared by physical mixing, fusion–cooling, or coprecipitation, dispersion systems of each drug (griseofulvin or tolbutamide) in each excipient (I or II), exhibited two transitions in differential thermal analysis (Fig. 1). These transitions corresponded to fusion of the excipient and drug, respectively, as observed under hot-stage microscopy over the temperature range studied. The lower temperature transition always corresponded to fusion of I or II, and the higher temperature transition always corresponded to fusion of griseofulvin or tolbutamide. This behavior and the corresponding binary phase diagram were qualitatively independent and quantitatively almost independent of the method used to prepare a given drug–excipient mixture. Typical phase equilibrium diagrams are shown in Figs. 2–5.

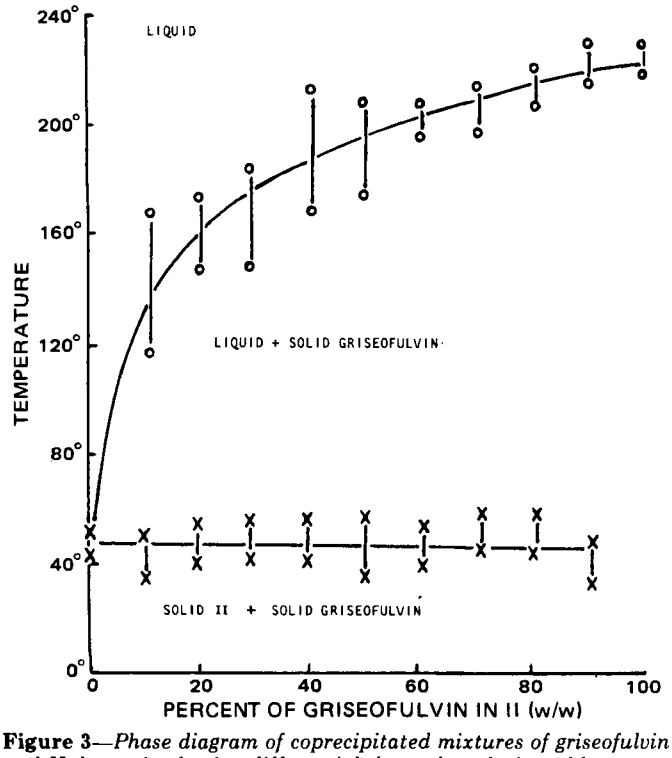

Figure 3—*Phase diagram of coprecipitated mixtures of griseofulvin and II determined using differential thermal analysis and hot-stage microscopy.*

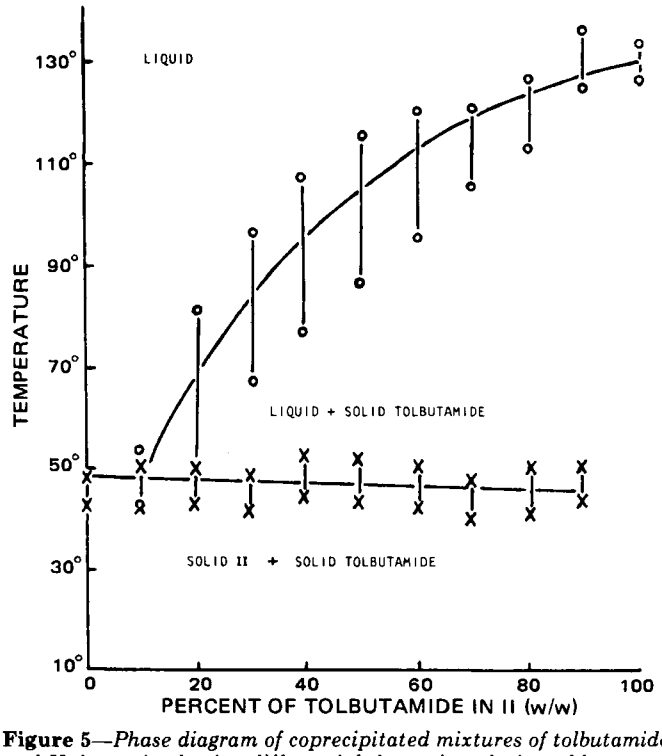

Figure 5—*Phase diagram of coprecipitated mixtures of tolbutamide and II determined using differential thermal analysis and hot-stage microscopy.*

Table II—Classification of Phase Equilibrium Diagrams

Drug	Excipient I			Excipient II		
	Physical Mixing	Fusion	Coprecipitation	Physical Mixing	Fusion	Coprecipitation
Griseofulvin	A	A	A	A	A	A
Tolbutamide	A	A	A	B	B	B

Hot-stage microscopy of the mixtures of all compositions showed a constant melting point of I at 48–58° and of II at 42–52°, corresponding to the endothermic peaks in differential thermal analysis (the solidus or melting point). Hot-stage microscopy showed that, in general, increasing amounts of drug dissolved in the liquid excipient as the temperature increased so that the drug crystals disappeared completely at a temperature (the liquidus or freezing point) between the melting point of the excipient and the melting point of the pure drug. The freezing point was quoted as that temperature above which no more crystals were visible between crossed polarizers. If this transition was not sharp, the sample was allowed to cool gradually and the freezing point was recorded as that temperature at which drug crystals just became visible. Crystals of griseofulvin and tolbutamide have distinctive crystalline habits, which are clearly recognizable compared with the amorphous appearance of the excipients. As the drug crystals dissolved in the liquid excipient on heating, their corners and edges were eroded first, as is normally encountered (18).

When the proportion of each drug in each solid dispersion system was increased, hot-stage microscopy and differential thermal analysis showed, in general, that the solidus temperature (freezing point of the drug) increased. This solidus transition appeared as a second endothermic peak in differential thermal analysis, but the instrument, unlike hot-stage microscopy, was unable to detect this transition for a drug content of <~50% (w/w). Thus, in general, the two techniques were confirmatory or complementary, and no evidence of polymorphism was apparent from either method.

Each of the 12 phase diagrams (2 drugs × 2 excipients × 3 methods of mixing) fell into one of two groups, arbitrarily designated as Types A and B (Table II). Type A was a monotectic system and occurred with all six griseofulvin systems and with the three tolbutamide–I systems. It was characterized by the absence of complete dissolution of the drug in the molten excipient at the melting point of the excipient. Examples of a Type A phase equilibrium diagram are shown in Figs. 2–4. There was very limited solubility of solid griseofulvin in just molten I (Fig. 2) or just molten II (Fig. 3).

Type B diagrams were shown by the three tolbutamide–II systems and were characterized by features common to both eutectic and monotectic behavior. Figure 5 gives an example for the coprecipitated tolbutamide–II system. The liquid II at its melting point (~50°) was capable of dissolving ~10% (w/w) tolbutamide. This contrasts sharply with the immeasurably low solubility of the drug in liquid I at its melting point (Fig. 4).

For any one of the four drug–excipient pairs, the methods of preparing the dispersion systems gave almost identical diagrams with the following exceptions:

1. Physical and fused mixtures of tolbutamide and II gave approximately twice the solubility of tolbutamide in just molten II, as did the coprecipitated mixtures; *i.e.*, concentrations of ~20% were obtained.

2. Physical mixtures of griseofulvin and I showed a more steeply rising liquidus curve than did the fused or coprecipitated systems.

Liquid mixtures containing 1% (w/w) griseofulvin or tolbutamide in I or II froze to a solid, which microscopic examination showed to consist of drug crystals dispersed in the excipient. Therefore, the extent of solid solubility of each drug in each excipient was judged to be negligible (<1% w/w).

DISCUSSION

The only form of tolbutamide encountered under the conditions of the present work was the commercial form which melted at 127° (19), namely, Modification A (20) or I (21, 22). This polymorph is the most stable at room temperature (21, 22). In view of the reported polymorphism of tolbutamide (19–22), it may seem surprising that no polymorphic transitions were observed in the present work; this finding is illustrated by the differential thermal analysis plot shown in Fig. 1. The most likely explanation is that either polymeric polar excipient (polyethylene glycol 2000 or polyoxyethylene 40 stearate) stabilizes the original commercial modification (I or A) relative to the other modifications produced under different conditions (19–22). In an analogous manner, the presence of the polar polymer povidone, for example, slows down the rate of transformation of the polymorphic form (II) of sulfameter to form III in aqueous suspension (23).

All of the phase diagrams involving I or griseofulvin, either separately or together, were of the monotectic type (Figs. 2–4). This type of system has not been reported previously in pharmacy but is well known to metallurgists, *e.g.*, the silicon–tin system (24).

A monotectic phase diagram has the form of a eutectic diagram in which one arm is missing and in which the lower melting component replaces the eutectic composition. The rising liquidus curve on the left of each monotectic diagram corresponds to the solubility curve of the drug in the liquid excipient.

Comparison of the phase diagrams (Figs. 2–5) shows that the differences between I and II as excipients for solid dispersion systems are much less marked for griseofulvin than for tolbutamide dispersions. The position and shape of the rising curve at the left of each phase diagram show a greater solubility of tolbutamide in liquid II than in I (Figs. 4 and 5) but a similar solubility of griseofulvin in each (Figs. 2 and 3).

The phase diagrams for the tolbutamide–II dispersions prepared in three ways can be considered to be eutectic systems in which the liquidus (freezing-point curve of tolbutamide) and the solidus (melting-point curve of II) have become superimposed. The first molten II (at ~40°) is capable of dissolving completely up to 10 or 20% (w/w) tolbutamide, depending on the preparation method.

However, the phase diagrams of the dispersion systems are changed little by the preparation method and appear to be dominated by the solvent properties of liquid I or II for each drug. The presence of a small amount of I or II with each drug causes little depression of the melting point of the drug, and, conversely, the presence of a small amount of griseofulvin or tolbutamide hardly affects the melting point of the excipient. This behavior contrasts sharply with the dispersion systems using small molecules as excipients, *e.g.*, urea (25, 26), succinic acid (27), and citric acid (28). These systems are eutectic with or without the formation of solid solutions. All of the dispersion systems of griseofulvin or tolbutamide with I or II showed negligible formation of solid solutions (<1% w/w), in contrast to the small molecule systems. This absence of solid solutions in polyethylene glycol–griseofulvin systems also was reported on the basis of X-ray diffraction evidence (6).

Finally, the phase diagrams obtained for fused–cooled and coprecipitated mixtures of each drug with each excipient were similar to those of physical mixtures of the two components, and there was no evidence of the formation of solid complexes between the two components. This absence of chemical interactions between the drug–excipient pairs on fusion, which was reported earlier for polyethylene glycol with griseofulvin (3) and tolbutamide (29), indicates that I or II can only influence the dissolution rate of the drugs by altering their surface properties such as the surface area or the nature of the drug–water interface. These factors were considered in a separate report (8).

Comparison of Polyethylene Glycol and Polyoxyethylene Stearate as Excipients for Solid Dispersion Systems of Griseofulvin and Tolbutamide II: Dissolution and Solubility Studies

RABINDER KAUR *, D. J. W. GRANT *x, and T. EAVES ‡§

Received March 4, 1980, from the **Department of Pharmacy, University of Nottingham, University Park, Nottingham NG7 2RD, England,* and the ‡*Hoechst Pharmaceuticals Research Laboratories, Walton Manor, Milton Keynes, Buckinghamshire MK7 7AJ, England.* Accepted for publication May 27, 1980. §Present address: Merrell International, Slough, Berkshire SL1 1YY, England.

Abstract □ The effects of joining a long-chain ester group with the polyethylene glycol molecule were studied in solid dispersion systems by comparing the dissolution and solution properties of such systems prepared from polyethylene glycol 2000 with those prepared from the nontoxic, water-soluble, solid excipient polyoxyethylene 40 stearate. Solid dispersion systems of griseofulvin and tolbutamide were prepared by physical mixing, fusion, or coprecipitation from ethanol. The compacted dispersion systems dissolved by progressive erosion, releasing floccules of microcrystals. The released microcrystals of tolbutamide (3–10 μm) were smaller than the original drug particles (~20 μm), but those of griseofulvin were of similar size to the original particles. In general, the rate and extent of release of each drug were greater from polyoxyethylene 40 stearate than from polyethylene glycol 2000 dispersions. The aqueous solubility and dissolution rate of nondisintegrating disks of each pure drug increased only slightly in the presence of polyethylene glycol 2000 but increased considerably with increasing concentration of polyoxyethylene 40 stearate due to micellar solubilization. Thus, polyoxyethylene 40 stearate generally is superior to polyethylene glycol 2000 in promoting the dispersion of the drugs in solids, disintegration of the compacted solids, and solubilization of the drugs during dissolution.

Keyphrases □ Excipients—polyethylene glycol and polyoxyethylene stearate, comparison as excipients for solid dispersion systems of griseofulvin and tolbutamide, dissolution and solubility studies □ Polyethylene glycol—comparison with polyoxyethylene stearate as excipient for solid dispersion systems of griseofulvin and tolbutamide, dissolution and solubility studies □ Polyoxyethylene stearate—comparison with polyethylene glycol as excipient for solid dispersion systems of griseofulvin and tolbutamide, dissolution and solubility studies

Solid dispersion systems may provide a means of increasing the dissolution rate and improving the bioavailability of drugs that are poorly soluble in water (1, 2). Polyethylene glycol has proven to be a valuable water-soluble matrix material for dispersion systems. In particular, the dissolution rate and bioavailability of griseofulvin from polyethylene glycol dispersions are greater than those of the micronized or microcrystalline drug (2). Chiou (3) recently showed that griseofulvin has negligible or very limited solid solubility in polyethylene glycol dispersion systems, a fact supported by phase equilibrium diagrams (4). Chiou (3) suggested that the marked enhancement of the dissolution and absorption rates of griseofulvin dispersed in polyethylene glycol primarily is a result of the reduced size of the griseofulvin crystals. However, other factors, such as increased wettability, solubilization of the drug by the carrier at the diffusion layer, and the reduction or absence of aggregation and agglomeration, also may contribute.

The formation of solid dispersions of tolbutamide in polyethylene glycol polymers also increased the dissolution rate of this drug, an effect that has been attributed to the formation of a solid solution, the dispersion of the drug in a fine state of subdivision, or improved wetting of the drug particles (5). However, in previous studies in these laboratories (4), solid solution formation was not found.

BACKGROUND

Esterification of polyethylene glycol (I) with a long-chain *n*-acyl residue such as stearate to form polyoxyethylene stearate, for example, produces a nontoxic (6), surface-active macromolecule, which may be a better excipient in dispersion systems than the non-surface-active material, I. This hypothesis is being tested by comparing the properties of dispersion systems of the poorly water-soluble drugs griseofulvin and tolbutamide in polyoxyethylene 40 stearate (II) with those in I. A previous report (4) showed no evidence of solid solution formation, even with II (<1% drug). Tolbutamide was more soluble in II than in I at the same temperature, but griseofulvin showed similar solubility in each liquid excipient. Griseofulvin with either II or I and tolbutamide with I gave monotectic systems, which may be considered as eutectic systems where the eutectic composition is pure griseofulvin or pure tolbutamide. © 1980, American Pharmaceutical Association

II gave a eutectic system for which II completely dissolved up to 20% of the tolbutamide.

Compound II is a surface-active agent with a critical micelle concentration in water of 0.014% (w/v); I is not surface active. Surface activity has long been recognized as a potent factor in enhancing dissolution and absorption rates. For example, the addition of a surfactant, *e.g.*, cetomacrogol or lysolecithin, to the dissolution medium increases the dissolution rate of sparingly soluble drugs, such as griseofulvin (7, 8), by micellar solubilization and improved wettability. Furthermore, the addition of aqueous surfactants during recrystallization increases the *in vitro* dissolution of drugs that are poorly soluble in water (9). Since the amount of surfactant released is insufficient to increase significantly the solubility of the drug in the bulk solution, the presence of the surfactant within and outside the crystals might increase the solubility of the drug in the diffusion layer during dissolution.

The objective of the present study was to probe the advantages, if any, of II over I as an excipient for solid dispersion systems of drugs that are poorly soluble in water. The drugs studied were griseofulvin and tolbutamide. *In vitro* release rates of the drug and the contributing processes are compared, and attempts are made to ascertain which factors are involved. A preliminary account of this work was published previously (10).

EXPERIMENTAL

Materials—The following materials and drugs were of food or pharmaceutical grade and were used as supplied: polyoxyethylene 40 stearate[1] (II), polyethylene glycol 2000[2] (I), griseofulvin[2], and tolbutamide[2]. Ethanol (95%) was spectroscopic grade. The pH 7 buffer was phosphate buffer BP (11). The pH 1 buffer was 0.1 *M* HCl. All water was double distilled from an all-glass still.

Preparation of Dispersion Systems—Physical mixtures, fused mixtures, and coprecipitated mixtures of griseofulvin or tolbutamide with I or II were prepared as described previously (4).

Preparation of Solid Compacts—Nondisintegrating disks contained 250 g of powdered griseofulvin or tolbutamide. For griseofulvin, it was necessary to grind up the first disks prepared and to recompress the powder, because the initial compression produced flaky or fragile disks. Disintegrating disks contained 1 g of the dispersion system consisting of the drug and the excipient. The disks (13 mm in diameter) were prepared by compression of powdered materials under vacuum for 5 min in a die[3] assembly for preparing potassium bromide disks for IR spectrophotometry. The load was 10 tons for nondisintegrating disks and 1 ton for disintegrating disks, corresponding to compaction pressures of 739 and 73.9 MN/m^2, respectively. To prevent the dispersion systems from sticking to the platen and anvil in the die, small pieces of greaseproof paper, used for interleaving membrane filters, were placed between each metal surface and the dispersion system.

Dissolution Rate Determination—A modified beaker–stirrer method was employed (12). The Pyrex glass beaker had an internal diameter of 13.8 cm, a height of 20.2 cm, and a capacity of 3 liters. The compact was secured to the center of the base of the beaker with a thin film of silicon paste, and 2 liters of dissolution medium was added. The stirrer motor[4], rotating at 300 rpm, drove a stirrer blade (0.5 × 2.4 cm), which was centrally placed 5 cm above the base of the beaker. Samples (4 ml) were withdrawn by a syringe fitted with a membrane filter[5] (pore diameter 0.45 μm) and were analyzed by UV spectrophotometry[6] at 296 nm for griseofulvin and 228 nm for tolbutamide. The volumes withdrawn were not replaced. For this system, the absorbance values of I and II at the concentrations released were negligible at the λ_{max} values for griseofulvin and tolbutamide. The dissolution profiles were repeated and good agreement was found. Each point reported is the mean of at least two determinations.

Solubility Measurements—The solubility of each drug in aqueous solution at 37° was determined by shaking an excess of powdered drug with the solvent, sampling the solution by means of a calibrated plastic syringe fitted with a membrane filter[5] (pore diameter 0.45 μm), diluting the sample quantitatively, and determining the absorbance by UV spectrophotometry[6] at the λ_{max} values. Two equilibration procedures were compared. In the first procedure, equilibration was achieved by shaking the solutions in a water bath at 37° for 3 and 5 days. Identical results after each period indicated that equilibrium had been attained. In the second procedure, the solid drug was shaken with the solvent in a water bath at 45° for 4 hr and then at 37° for 24 hr. Both methods of equilibration gave identical results. Based on this finding, the second method was adopted, because it was quicker and less liable to permit decomposition of the dissolved drug or the dissolved excipient.

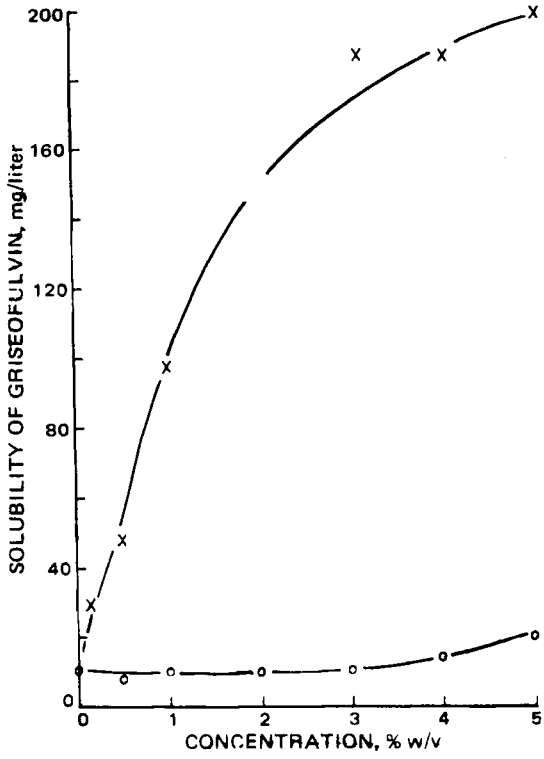

Figure 1—*Solubility of griseofulvin in aqueous solutions of II (×) or I (○) at 37°.*

Surface Tension Measurements—The Du Noüy tensiometer[7] (13) was used, and triplicate readings were taken.

Viscosity Measurements—Viscosity measurements were taken on aqueous solutions of I and II using a cone and plate rheometer[8].

Particle-Size Analysis—The particle-size analysis was carried out using an electronic particle counter[9] with 0.9% (w/v) aqueous NaCl[10], previously saturated with the drug, as the electrolyte.

Optical Microscopy—The drug particles released from dispersion systems were suspended in water saturated with the drug in question. A drop of the suspension on a microscope slide was examined and photographed using a light microscope with a camera attachment.

RESULTS

Effects of Excipients on Aqueous Solubility of Drugs and on Surface Tension and Viscosity of Water—Compounds I and II were reported by the manufacturers to be miscible with water in all proportions. This claim was confirmed for the samples purchased.

Figures 1 and 2 show that the presence of dissolved I or II increased the solubility of griseofulvin or tolbutamide in water. However, a given concentration of II brought about a much greater increase in the solubility of each drug than did the same concentration of I. For example, griseofulvin and tolbutamide were more soluble in 0.5% (w/v) II than in the same concentration of I by factors of about four and two, respectively; at the 5% (w/v) level, the factors were even greater (about 12 and five).

The presence of I or II lowered the surface tension of water (Fig. 3), and the effect was much greater for II. The sharp discontinuity in the curve for II occurs at the critical micelle concentration (CMC) (0.014% w/v). The absence of a discontinuity for I agrees with the fact that it is not a surface-active material and is unlikely to form micelles.

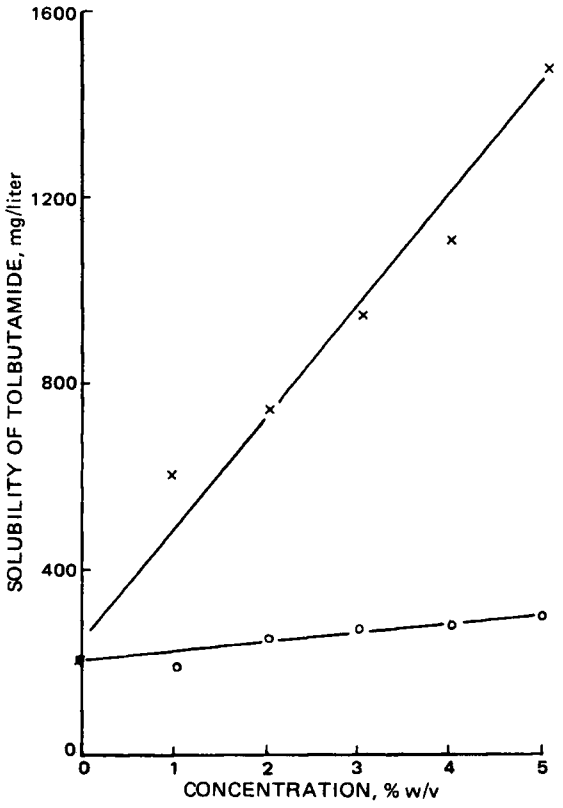

Figure 2—*Solubility of tolbutamide in aqueous solutions of II (×) or I (○) at 37°.*

From the negative gradients of the lines in Fig. 3, the surface excesses of the excipients were calculated by means of the Gibbs absorption isotherm and were found to be 0.178 and 1.09 moles/m^2 for I and II, respectively. From these values, the apparent area per molecule of excipient at the air–water interface was calculated to be 9.32 nm^2 for I and 1.53 nm^2 for II.

The viscosity of water (69 cps at 37°) was increased by the presence of II or I. At 37°, the viscosities were: 1% II, 70 cps; 10% (w/v) II, 103 cps; 1% I, 78 cps; and 10% (w/v) I, 98 cps. The viscosity was an approximately linear function of concentration within the 1–10% (w/v) range.

Dissolution Profiles of Nondisintegrating Disks of Pure Griseofulvin and Tolbutamide—The rate and extent of dissolution of nondisintegrating disks of griseofulvin (Fig. 4) and tolbutamide (Fig. 5) in water were reduced by increasing concentrations of I in the dissolution medium but were increased by increasing concentrations of II.

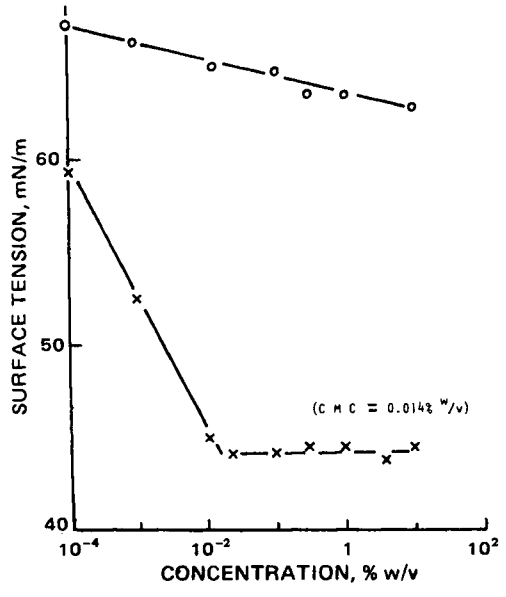

Figure 3—*Effect of concentration (log scale) of I (○) and II (×) on the surface tension of water at 37°.*

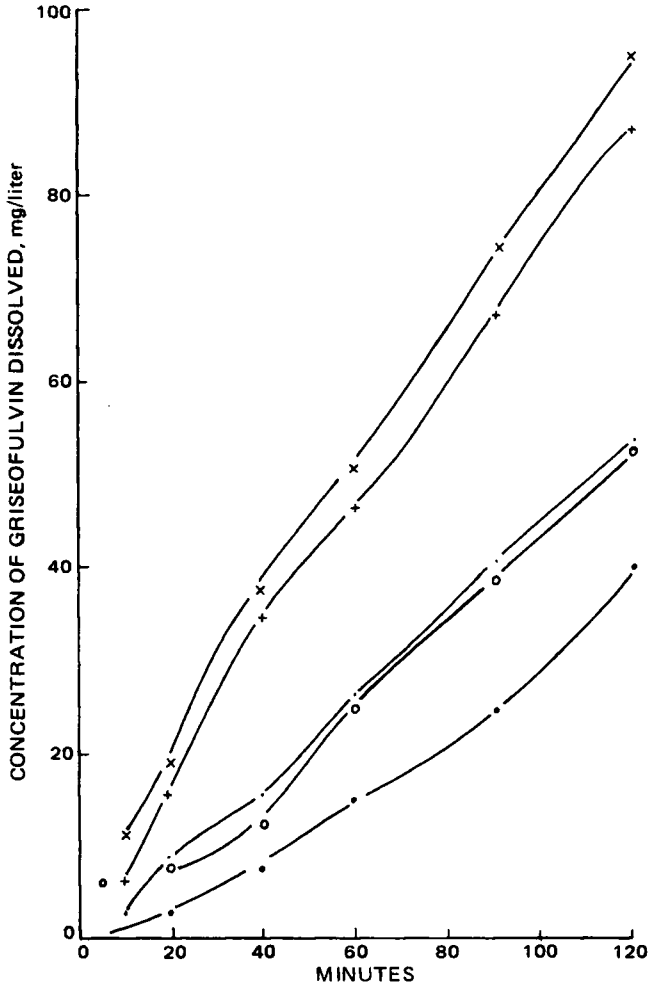

Figure 4—*Dissolution profile of nondisintegrating disks of griseofulvin in water (·), aqueous I at 0.1% (w/v) (○) and 1.0% (w/v) (●), and aqueous II at 0.1% (w/v) (+) and 1.0% (w/v) (×).*

Dissolution Profiles of Fused Dispersion Systems—Since just molten II dissolved up to 20% (w/w) tolbutamide (4), fused mixtures containing 10% (w/w) tolbutamide were selected for the preparation of compacts for dissolution in water and in pH 1 and 7 buffers. The negligible solubility of griseofulvin in just molten II (4) suggested that less of this drug would be more comparable with the tolbutamide preparations, so the fused griseofulvin mixtures chosen contained 2% (w/w) griseofulvin.

The compacted preparations disintegrated gradually by progressive erosion of the exposed surface, and the compacts of both drugs had disintegrated completely within 30 min. The concentration of drug released plateaued (Table I) after 60–120 min at values close to those corresponding to 100% release (10 mg/liter for griseofulvin and 50 mg/liter for tolbutamide). Microscopic examination of the solutions showed the absence of drug particles. The amount of drug in the 1-g compacts (100 mg of tolbutamide or 20 mg of griseofulvin) was insufficient to saturate the dissolution medium (2 liters).

Table I shows that the initial dissolution rate of griseofulvin (2% w/w) from fused dispersions in II was similar to that from fused dispersions in I, but the initial dissolution rate of tolbutamide (10% w/w) was ~45% greater from fused dispersions in II than from those in I. Thus, the dissolution of tolbutamide from fused dispersions was favored by II.

When 1 g of a fused mixture of griseofulvin or tolbutamide with I or II was added to 100 ml of water, a cloudy or frothy suspension was rapidly produced. On standing for a few hours, it gave a clear supernate and a fine powder at the bottom of the flask. By microscopic examination, it could be seen that, as a eutectic mixture was exposed to water, the excipient dissolved in water and a microcrystalline dispersion of the drug in water was obtained. After standing, some microcrystals grew to large macrocrystals at the expense of the smaller crystals. However, if 1 g was exposed

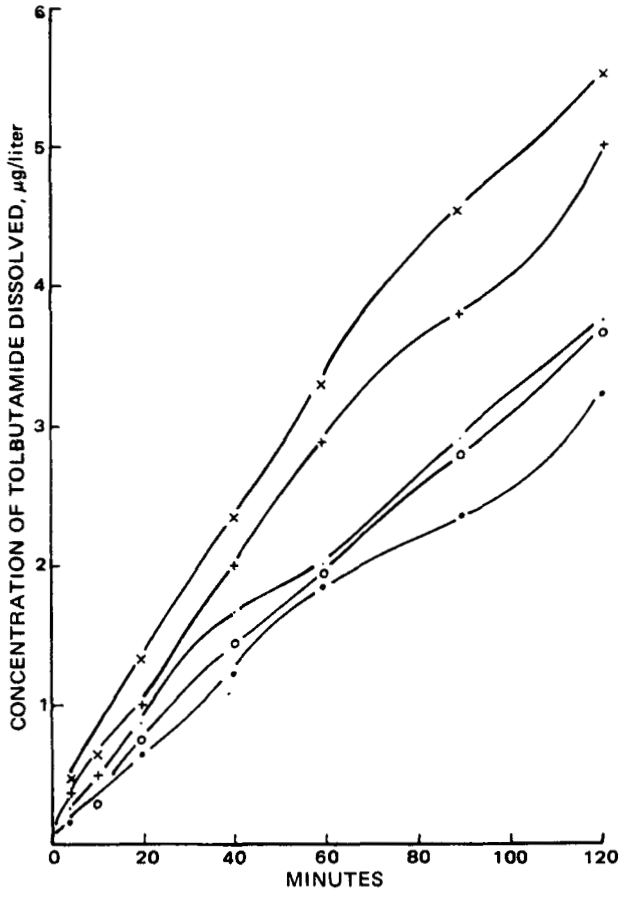

Figure 5—*Dissolution profile of nondisintegrating disks of tolbutamide in water (·), aqueous I at 0.1% (w/v) (○) and 0.5% (w/v) (●), and aqueous II at 0.1% (w/v) (+) and 0.5% (w/v) (×).*

to 1 liter or more of water, then no microcrystals or crystals were observed, because there was sufficient solvent to dissolve all of the drug from the eutectic mixture.

Dissolution Profiles of Coprecipitated Dispersion Systems—The composition of coprecipitated mixtures chosen for the dissolution rate analysis was 60% (w/w) griseofulvin or tolbutamide. Thus, 1 g contained 600 mg of either drug. This composition was a compromise between the need for an appreciable dilution of the solid drug and the need for an acceptable tablet or capsule weight in an eventual pharmaceutical preparation.

Microscopic examination of the coprecipitated mixtures showed agglomerates of micro- and macrocrystals of drug interspersed with the excipient.

In contact with the aqueous dissolution medium, the compacts disintegrated by progressive erosion of the exposed surface. Small floccules of drug crystals were obtained, not a uniform microcrystalline dispersion of the drug. The compacted preparation of each drug disintegrated completely, leaving no drug particles.

For a given dissolution medium, the amount of each drug released at any given time from a II coprecipitate was greater than that from the corresponding I coprecipitate (Figs. 6 and 7). The concentration of griseofulvin released in neutral dissolution medium reached a plateau after 60 min from II coprecipitates (Fig. 6). The plateau effect was not observed with the tolbutamide coprecipitates; this drug continued to be released after 120 min (Fig. 7). The amount of drug incorporated into the 1-g compacts (600 mg of tolbutamide or griseofulvin) was in excess of the amount required to saturate 2 liters of water (the volume of the dissolu-

Table I—Initial Dissolution Rate and Final Mean Concentration Attained between 60 and 120 min after Introducing Fused Dispersions (1 g) Containing Griseofulvin or Tolbutamide in Polyethylene Glycol 2000 (I) or Polyoxyethylene 40 Stearate (II) into Aqueous Solution (2 Liters)

Fused Dispersion System	Initial Dissolution Rate, mg/liter/min			Final Mean Concentration, mg/liter

2% (w/w) Griseofulvin + I	0.62	—	0.52	10.2	—	10.1
2% (w/w) Griseofulvin + II	0.53	0.57	0.54	8.1	8.8	8.9
10% (w/w) Tolbutamide + I	2.66	—	2.83	60.4	—	49.6
10% (w/w) Tolbutamide + II	3.96	3.99	4.02	55.7	52.0	51.5

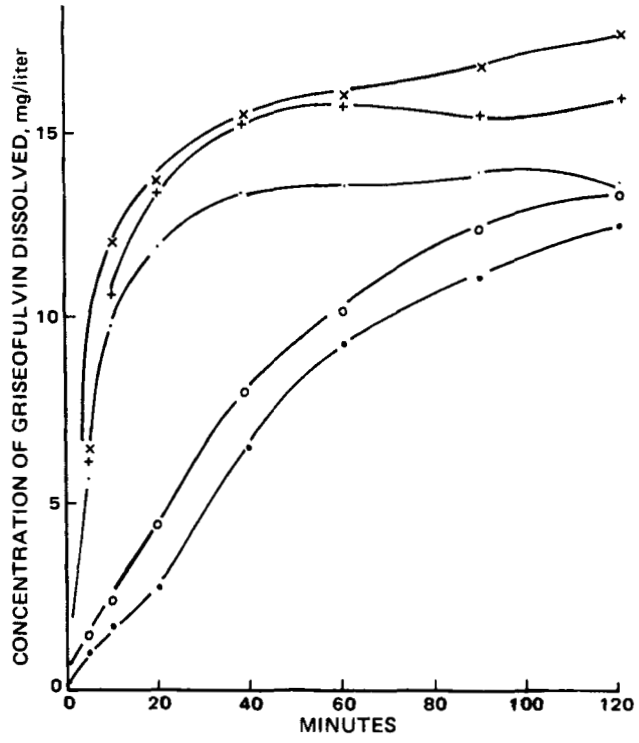

Figure 6—*Dissolution profiles of coprecipitated dispersions of griseofulvin (60% w/w) with I in pH 1 buffer (○) and pH 7 buffer (●) and of griseofulvin (60% w/w) with II in water (·), pH 1 buffer (×), and pH 7 buffer (+).*

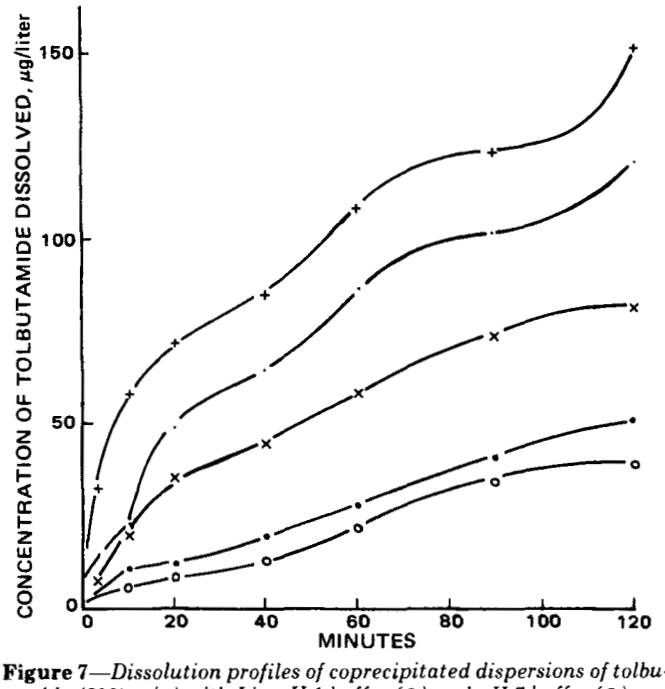

Figure 7—*Dissolution profiles of coprecipitated dispersions of tolbutamide (60% w/w) with I in pH 1 buffer (○) and pH 7 buffer (●) and of tolbutamide (60% w/w) with II in water (·), pH 1 buffer (×), and pH 7 buffer (+).*

Table II—Initial Dissolution Rate and Final Mean Concentration Attained between 60 and 120 min after Introducing Coprecipitated Dispersions (1 g) Containing Griseofulvin in Polyoxyethylene 40 Stearate (II) into Aqueous Solution (2 Liters)

Coprecipitated Dispersion	Initial Dissolution Rate, mg/liter/min		Final Mean Concentration, mg/liter	
	pH 1	pH 7	pH 1	pH 7
12.5% (w/w) Griseofulvin in II	0.507	0.322	18.2	14.9
60% (w/w) Griseofulvin in II	1.22	0.980	16.9	12.9

tion medium). Therefore, the II that was dissolved from the compact was solubilizing each drug.

To test the effect of the griseofulvin concentration, 1-g compacts of a coprecipitate containing 12.5% (w/w) of this drug in II were studied (Table II). The amount of drug (125 mg) corresponds to a dosage level currently administered to patients. The 12.5% (w/w) griseofulvin coprecipitates disintegrated completely within 20 min, and microcrystals of griseofulvin were found at the bottom of the beaker after 180 min of dissolution. The concentration of drug released between 60 and 120 min from coprecipitates containing 12.5% (w/w) griseofulvin was much the same (~15 mg/liter) as from those containing 60% (w/w) of the drug. However, the initial dissolution rate from the 12.5% coprecipitates was about one-third of that from the 60% coprecipitates. Thus, a fivefold reduction in the concentration of the drug in II coprecipitates reduced the initial dissolution rate only threefold.

Changes in Particle-Size Distribution of Drugs before Formulation and during Disintegration—Fused dispersion systems containing 2% (w/w) griseofulvin or 10% (w/w) tolbutamide in II disintegrated rapidly, releasing drug particles whose size distribution was analyzed within 25–30 min of exposure of the dispersion systems to water. Different cooling rates of the fused mixtures during preparation of the dispersion systems prior to compression might be expected to affect the particle-size distribution of the drugs. Comparison of the size distribution of griseofulvin particles released from the dispersion systems with that of the micronized drug originally supplied showed only relatively small differences, which bore no obvious relationship to the cooling rate. Thus, fused-cooled and coprecipitated dispersions released griseofulvin particles that were similar in appearance to those of the original (micronized) griseofulvin. These particles were difficult to discern under the microscope.

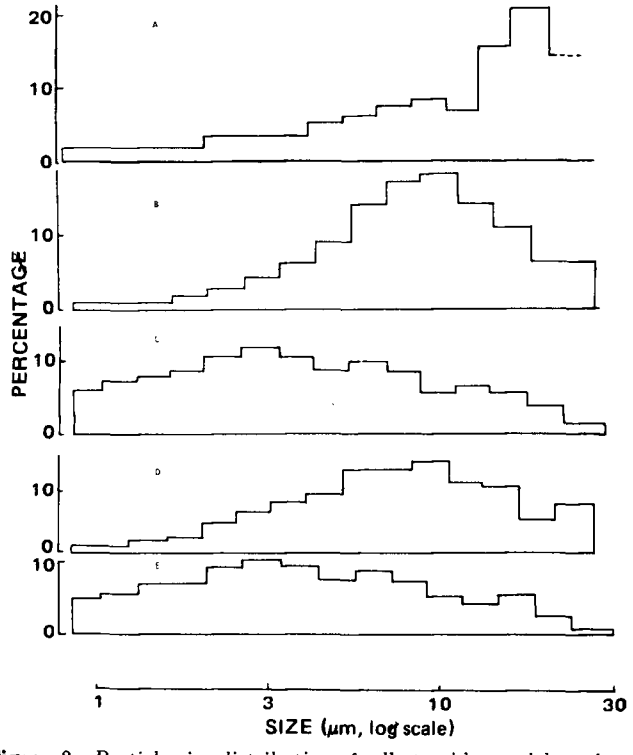

Figure 8—*Particle-size distribution of tolbutamide particles released (into electrolyte saturated with tolbutamide) from the original powder (A) and from fused mixtures of tolbutamide (10%) in II cooled slowly in a paraffin bath (B), cooled by natural cooling to 20° (C), cooled by refrigeration at 4° (D), and cooled rapidly in solid carbon dioxide to −78° (E).*

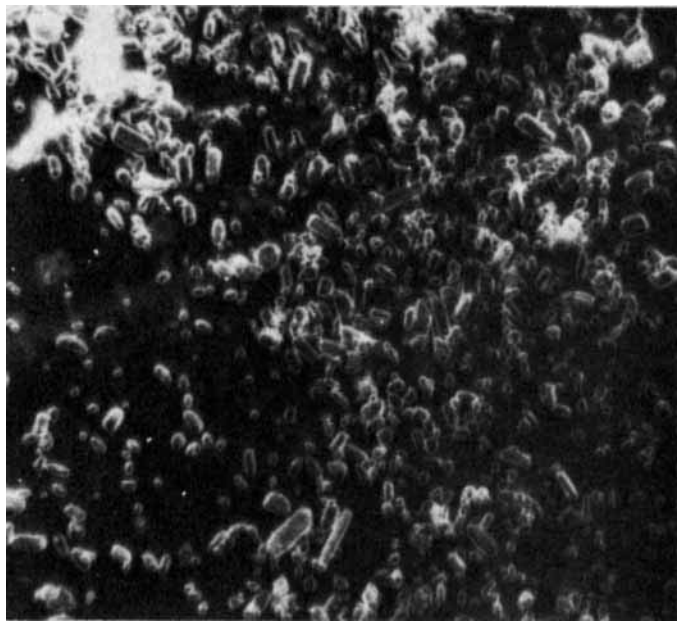

Figure 9—*Micrograph of tolbutamide particles released from a coprecipitated dispersion of tolbutamide (10% w/w) and II into aqueous sodium chloride solution (0.9% w/w) previously saturated with tolbutamide (×100).*

Although dispersion in II did not reduce significantly the particle size of micronized griseofulvin, it did reduce the particle size of commercial tolbutamide. Figures 8 and 9 show that the tolbutamide powder supplied consisted of particles with a mean diameter of ~20 μm or more, and the distribution suggests that some particles with a mean diameter of >30 μm were present, beyond the upper range of the particle counter. Figure 8 shows that the tolbutamide particles released from the fused and cooled dispersion systems in II were considerably smaller, with the mean particle diameters being 3–10 μm. There were relatively small differences between

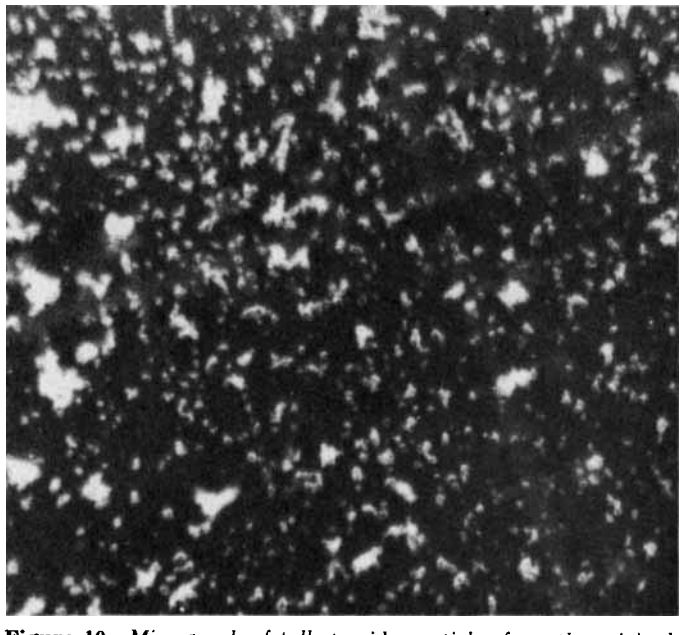

Figure 10—*Micrograph of tolbutamide particles from the original commercial sample of the drug from which the dispersion systems were prepared. The particles were suspended in aqueous sodium chloride solution (0.9% w/w) previously saturated with tolbutamide (×100).*

the size distribution elicited by different cooling rates, but no obvious relationships were apparent. The microscopic appearance of the small tolbutamide particles released from the fused–cooled dispersion systems in II was indistinguishable from that of tolbutamide released from coprecipitated dispersions in II (Fig. 10). The original tolbutamide particles clearly were much larger (Fig. 9).

DISCUSSION

The presence of I in water exerts little solubilizing action on griseofulvin (Fig. 1) or tolbutamide (Fig. 2). This finding agrees with a previous report (3) on the influence of longer polyoxyethylene molecules (polyethylene glycol 6000) on the solubility of griseofulvin. On the other hand, the presence of II in water considerably increases the solubility of both griseofulvin (Fig. 1) and tolbutamide (Fig. 2) by a process of micellar solubilization (Fig. 3) at II concentrations greater than 0.014% (w/v) (the critical micelle concentration). This finding agrees with the reported influence (14) of various nonionic surface-active agents, including some related polyoxyethylene derivatives, on the solubility of griseofulvin.

The presence of II in the aqueous dissolution medium also increases the dissolution rate of solid compressed disks of both drugs (Figs. 4 and 5). The experiments show that micellar solubilization, by increasing the drug solubility at the solid–liquid interface, plays a major role in increasing the dissolution rate of the drugs from solid dispersions of II. However, the presence of 0.1–1.0% (w/v) I in the aqueous dissolution medium actually reduces the dissolution rate of solid compressed disks of griseofulvin or tolbutamide (Figs. 4 and 5). This effect may result from the marked increase in viscosity of the aqueous dissolution medium, which is brought about by the presence of I. Since the diffusivity of small molecules frequently is inversely proportional to the solution viscosity, the effect of I suggests that dissolution of both griseofulvin and tolbutamide is diffusion controlled. The increase in viscosity then would reduce the diffusion rate of the drug in the diffusion layer and thereby reduce the dissolution rate. Evidently, the marked increase in viscosity (a 12% increase is produced by 1% I) more than compensates for the small increase in the solubility of each drug (increase of ~5% produced by 1% I).

Although the viscosity of water is increased by both II and I, the effect is greater for I at low concentrations since the viscosity of water is virtually unaffected by the presence of up to 1% II. Thus, solubilization and viscosity phenomena both favor II over I in promoting dissolution of the drugs, whereas viscosity increases actually disfavor solutions of I compared with pure solvent or buffer solutions (Figs. 4 and 5). This discussion readily explains the greater release rate of griseofulvin and tolbutamide from coprecipitates with II than from coprecipitates with I as the excipient (Figs. 6 and 7). The excipients dissolve rapidly due to their high solubility in water, and this dissolution creates the conditions in solution that influence the dissolution rate.

The difference between I and II as excipients for fused dispersion systems was less marked for griseofulvin than for tolbutamide. This result is apparent in the dissolution behavior of fused drug–excipient mixtures (Table I) and in the phase diagrams of the dispersion systems (4). The mean particle size of griseofulvin was changed little by incorporation into fused II dispersions and subsequent release by dissolution, but that of tolbutamide (Fig. 8) was reduced greatly. These differences may be accounted for by the low solubility of griseofulvin in each molten excipient and by the much greater solubility of tolbutamide in molten II than in molten I (4). On rapid cooling of a solution, the deposited solute, in this case solid tolbutamide, usually has a reduced particle size, because the rate of crystal nucleation is increased relative to the rate of crystal growth (15). When the dispersion systems are prepared by coprecipitation from ethanol, the differences in the dissolution rate between I and II as excipients are as large for griseofulvin as for tolbutamide (Figs. 6 and 7). In these cases, the particles of solid drug are deposited from solution in ethanol, and this process is largely independent of the precise nature of the excipient. Other factors, particularly solubility in and the viscosity of the dissolution medium, then can exert an overwhelming influence.

The release rate of tolbutamide from dispersion systems in polyethylene glycol 4000 or 6000 was found to be greater from coprecipitated dispersions than from fused dispersions (7). The state of subdivision, *i.e.*, the total surface area of the drug, seems the most likely explanation for differences arising from the method of preparation of the dispersion systems.

Polymorphic changes did not occur in the preparation of the dispersion systems (4) and, therefore, cannot be used to explain any of the phenomena reported here.

The surface activity of II may be advantageous in promoting the bioavailability of griseofulvin. For instance, II may be capable of acting like bile salts, which can solubilize and increase the dissolution rate of griseofulvin and other drugs (16–18). In this connection, polyoxyethylene 40 stearate, like the triglycerides, possesses a fatty acid residue, although the ability of triglycerides to increase the bioavailability of griseofulvin is claimed to be due solely to enhanced dissolution and not to enhanced absorption of the dissolved drug (19).

Propoxyphene and Norpropoxyphene: Influence of Type of Controlled-Release Formulation on Intra- and Intersubject Variations

HELLE BECHGAARD *x **and S. BAGGESEN** ‡

Received December 17, 1979, from the *Controlled Release Division and the ‡Quality Assurance Department, A/S Alfred Benzon, 29 Halmtorvet, DK-1700 Copenhagen V, Denmark. Accepted for publication May 22, 1980.

Abstract □ Two types of controlled-release formulations of propoxyphene hydrochloride, one with a buffer system in the pellet core, were studied with regard to intra- and intersubject variations of C_{max} and T_{max} of propoxyphene as well as propoxyphene plus norpropoxyphene in 35 volunteers after administration of a single 150-mg dose. Statistically significant differences between the formulations in intrasubject variance were revealed, and the availability rate of the buffered product showed significantly better reproducibility, presumably due to the established low sensitivity of its release rate to the *in vitro* environment, *i.e.*, pH.

Keyphrases □ Propoxyphene—influence of type of controlled-release formulation on drug release, pH dependency □ Dosage forms, controlled release—propoxyphene, influence of type of formulation on drug release, pH dependency □ Release rates—propoxyphene, influence of type of controlled-release formulation, pH dependency

The analgesic α-*d*-propoxyphene currently is available in two types of multiple-unit controlled-release formulations. One formulation is supported with a buffer system in the pellet core (1) to secure a pH-independent drug release. The other formulation does not have such a system. *In vitro* studies have shown a pronounced difference in the sensitivity of these two formulations to the nature of the dissolution medium, particularly its pH (Fig. 1).

The present study concerns the significance *in vivo*, in terms of intra- and intersubject variations, of these formulation-related differences in *in vitro* drug release with respect to selected pharmacokinetic parameters.

EXPERIMENTAL

Subjects—Thirty-five volunteers [15 females and 20 males, 18–60 years old (median 24 years old) and 47.4–83.5 kg (median 65 kg)] served as test subjects. Prior to the study, the subjects were found to be healthy by clinical examination and various laboratory tests, including serum creatinine, serum bilirubin, liver enzymes, and hemoglobin. Twenty-four subjects were nonsmokers, and 11 were smokers. Four females were taking oral contraceptives. Informed consent was obtained from all of the subjects.

Blood Sampling—Venous heparinized blood samples (~20 ml) were drawn before (0 hr) and 2, 3, 4, 6, 8, and 12 hr after drug administration. Immediately after sampling, the plasma was separated by centrifugation and frozen at −20° until it was assayed. No deterioration was found with storage.

Assay of Plasma Samples—The plasma concentrations of propoxyphene and norpropoxyphene were measured by a mass fragmentographic method (2). The lower detection limit of the method was 4 ng/ml for propoxyphene and 3 ng/ml for norpropoxyphene. The coefficient of variation was <6%.

Propoxyphene Products—Seven batches of Formulation A[1] and two batches of Formulation B[2] were used. Formulation A (without a buffer system) consisted of a sugar core coated with the drug and a lacquer. Formulation B consisted of the drug and a buffer system in a homogeneous core coated with a lacquer (1). The release rate patterns of both formulations (containing 150 mg of α-*d*-propoxyphene hydrochloride) were designed to yield a controlled, sustained release (Table I). Both formulations were supplied in identical red, hard gelatin capsules.

Dosage Schedule—Except for the contraceptive pill, no drugs were allowed for 7 days before the study. During the study, alcoholic beverages and smoking were not permitted.

Subjects fasted overnight before each treatment and were not permitted to eat until 2 hr after dosing, at which time a standardized breakfast with 300 ml of fluid was given. During the remaining observation period, the ambulatory subjects had free access to fluid and food intake and in this respect imitated the clinical situation. Single 150-mg doses of controlled-release propoxyphene hydrochloride were administered at 9 am with 300 ml of tap water.

Experimental Designs—The study involving Formulation A was performed as an unbalanced, incomplete block design with at least 7 days between dosage days. Each subject received one to three different batches. The study involving Formulation B was performed as a nonrandomized crossover trial with at least 7 days between the two dosage days.

Calculations and Statistical Analyses—The peak plasma concentration (C_{max}) and the time to the peak concentration (T_{max}) of propoxyphene and propoxyphene plus its major metabolite, norpropoxyphene, were used as dependent variables in the statistical analyses.

The intra- and intersubject variations, expressed as the variances in the variance components model (Eq. 1), were estimated using the standard computer program GLIM (3). To estimate intersubject variance corrected for interbatch variation and the standard errors of these parameters, the method described by Searle (4) was applied to the data obtained for Formulation A. The estimation was straightforward in the balanced design for the study involving Formulation B.

A comparison between formulations was made by standard variance ratio F tests for intrasubject variance and by an approximate variance ratio test (5) for intersubject variance. For each formulation, the variation of each dependent pharmacokinetic characteristic (y_{ij}) is expressed by:

$$y_{ij} = \mu + \pi_i + \beta_j + \epsilon_{ij} \qquad \text{(Eq. 1)}$$

for subject i receiving a dose from batch j, where π_i, β_j, and ϵ_{ij} are the values of the independent, normally distributed, random variables with

zero means and variances and are the intersubject, interbatch, and intrasubject variance components, respectively.

The intrasubject variance results from differences in the response from the same subject at different times, but it also is due to subject–batch interactions, to intrabatch variation, and to errors of measurement. The different kinds of variation cannot be separated further on the basis of the existing data.

The fit of the model was assessed with a normal probability plot of residuals in the case where C_{max} was the dependent variable.

Since T_{max} is a discrete variable and thus is in disagreement with the normality assumption of the model, it is irrelevant to test the fit of the model in this case. For the same reason, the variance ratio F test used for comparison of the intersubject variance must be considered as an approximate test with T_{max}.

Dissolution Procedure—The cumulative release of propoxyphene was determined at 1, 2, and 6 hr by means of the NF XIV rotating-bottle procedure (6), which was modified to maintain a constant pH during the dissolution test and to include only one measurement per dosage unit. The rotation speed was 30 ± 1 rpm, and the dissolution medium was 25 ml of sulfate buffer at pH 1.2 or 2.0 or citrate buffer at pH 4.5, thermostated at 37 ± 0.1°. The amount of propoxyphene released was determined by measuring the absorbance at 257 nm (Table I).

RESULTS

Batch Testing *In Vitro*—The release rate pattern of each batch was analyzed (Table I) and found to be in compliance with the specifications for the products, *i.e.*, at least 90% of the capsules released an amount of propoxyphene within 60 ± 15 mg at 1 hr, 93 ± 20 mg at 2 hr, and 132 ± 20 mg at 6 hr. The release data were normally distributed. Both products released 100% of the propoxyphene within 10 hr.

The observed intrabatch standard deviation for Formulation B was statistically significantly lower at 2 ($p < 0.05$) and 6 ($p < 0.001$) hr than the standard deviation for Formulation A (Table I).

pH Dependency *In Vitro*—The amount of propoxyphene released after 1 hr was tested at pH 1.2, 2.0, and 4.5 (Fig. 1). The sensitivity to the pH of the dissolution medium was pronounced for Formulation A, ranging from 40 to 10% of drug released at pH 1.2 and 4.5, respectively. In contrast, virtually no pH-dependent change in released propoxyphene was observed with Formulation B.

Outliers—Three subjects (A5, A17, and B31) were outliers with respect to specific values of C_{max} and T_{max} since the normality assumption of the variance components model (Eq. 1) for these values was not met (Table II). In the statistical tests involving these parameters, as well as for consideration of the ranges (Figs. 1–4), outliers were excluded. No clinical reasons or connection to the smoking or taking of contraceptive pills by the subjects could be applied to the outliers.

Plasma Propoxyphene—The peak concentration of propoxyphene displayed a considerable within-subject variation, with the widest range being 61–123 ng/ml after administration of Formulation A compared to a variation of 107–130 ng/ml after administration of Formulation B (Fig. 2). Total variation, including intra- and intersubject variations, ranged from 32 to 123 ng/ml after administration of Formulation A and from 40 to 134 ng/ml after administration of Formulation B (Fig. 2).

Table II—Comparison of Formulations A [a] and B [b] with Respect to Residual Variance (Intrasubject Variance)

		Formulation A		Formulation B			
	Parameter	Residual Variance, ng^2/ml^2	*DF*	Residual Variance, ng^2/ml^2	*DF* [c]	Variance Ratio, A/B	Outliers: Formulation, Subject, Value

[a] Diffucap. [b] Repro-Dose. [c] Subject 33 was excluded due to a missing blood sample 4 hr after ingestion of Batch 87056. [d] Not significant. [e] Or later.

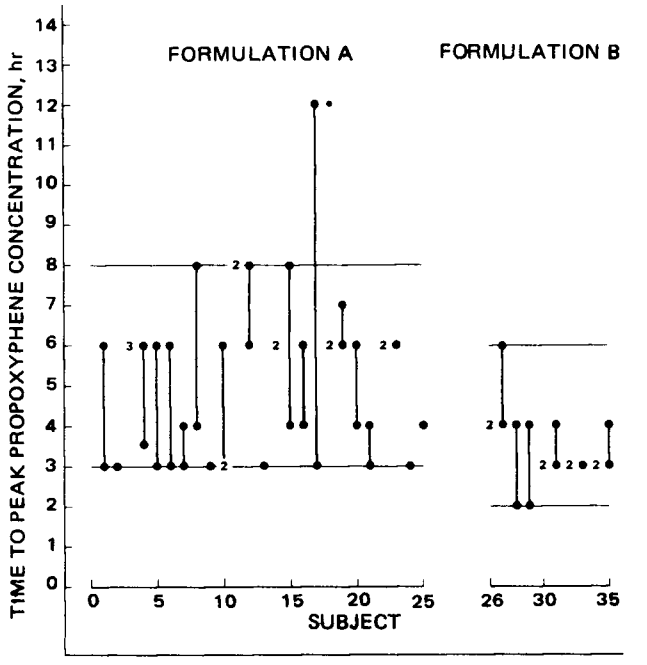

Figure 3—*Individual time to peak concentrations of propoxyphene after administration of 150 mg of propoxyphene hydrochloride from a batch of Formulation A or B. The symbol 2 indicates equal T_{max} values obtained with different batches; * represents an outlier.*

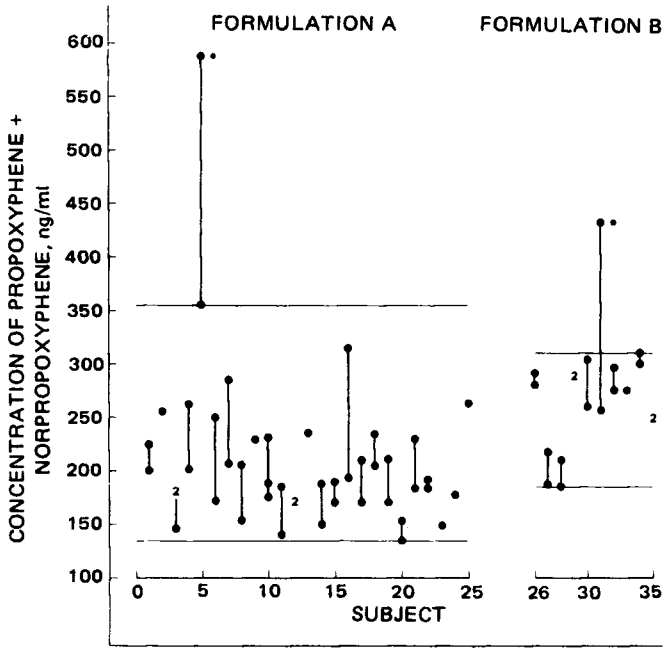

Figure 4—*Individual peak concentrations of propoxyphene plus norpropoxyphene after administration of 150 mg of propoxyphene hydrochloride from a batch of Formulation A or B. The symbol 2 indicates equal C_{max} values obtained with different batches; * represents an outlier.*

The maximum range of T_{max} within a subject was 4 hr or more after ingestion of Formulation A and only 2 hr after ingestion of Formulation B (Fig. 3).

In total, the time to the peak concentration ranged from 3 to 8 hr and from 2 to 6 hr after ingestion of Formulations A and B, respectively (Fig. 3).

Comparison of the two types of controlled-release products with respect to intrasubject variation showed a statistically significantly ($p < 0.01$) lower variance of T_{max}, with a variance 6.8 times greater after administration of Formulation A than after Formulation B (Table II). With respect to C_{max}, the difference in the intrasubject variation between the two formulations was less pronounced; the variance ratio between Formulations A and B was 2.9 but was not statistically significant (Table II). The difference between the two formulations with respect to intersubject variations in C_{max} and T_{max} also was not statistically significant.

Propoxyphene plus Norpropoxyphene—As with propoxyphene, the amount of propoxyphene and its major metabolite, norpropoxyphene, displayed a pronounced intrasubject variation in C_{max}, reaching a maximum of 193–313 ng/ml and of 259–305 ng/ml after administration of Formulations A and B, respectively (Fig. 4). Overall, the peak concentrations ranged from 134 to 355 ng/ml after ingestion of Formulation A and from 184 to 311 ng/ml after administration of Formulation B (Fig. 4).

The maximum range of T_{max} within a subject was >8 hr after administration of Formulation A and only 2 hr after administration of Formulation B (Fig. 5). The total ranges of T_{max} were from 3 to 12 hr or more and from 3 to 6 hr after ingestion of Formulations A and B, respectively (Fig. 5).

Compared to Formulation B, the intrasubject variances of C_{max} and T_{max} were statistically significantly ($p < 0.01$) larger after administration of Formulation A by factors of 6.7 and 11.9, respectively (Table II).

As in the case of propoxyphene alone, no statistically significant difference in the intersubject variance components for C_{max} and T_{max} of propoxyphene plus norpropoxyphene was found.

DISCUSSION

No statistically significant difference was found in either the intra- or intersubject variation of C_{max} of propoxyphene after administration of the two formulations, although the intrasubject variance ratio between Formulations A and B was 2.9 (Table II).

The total range, including the intra- and intersubject variations, of C_{max} of propoxyphene showed a threefold variation (Fig. 2), which was a narrower range compared to the one observed after ingestion of plain propoxyphene products, where C_{max} values showed five- to 10-fold ranges (2, 7–9). Hence, the C_{max} value of propoxyphene for the two controlled-release formulations seems to be subject to a significantly smaller intersubject variation compared to plain products, contrary to what usually is assumed (10). This finding indicates that with controlled-release products, an optimal effect might be obtained by a standard dose regimen with a minimized risk of toxic peak concentrations of propoxyphene. Because single-dose studies are not always applicable to multiple-dose conditions, *i.e.*, the clinical situation, this assumption has to be confirmed.

Among the physiological factors that may influence the bioavailability of a drug from an oral, controlled-release dosage form are the gastric

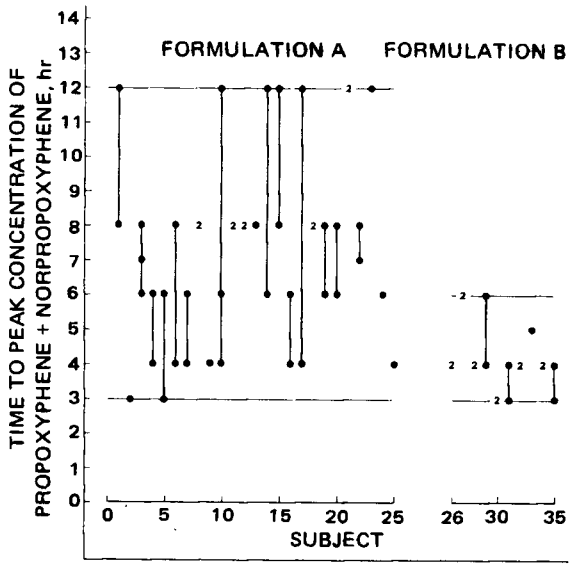

Figure 5—*Individual time to peak concentrations of propoxyphene plus norpropoxyphene after administration of 150 mg of propoxyphene hydrochloride from a batch of Formulation A or B. The symbol 2 indicates equal T_{max} values obtained with different batches; * represents an outlier.*

emptying time, intestinal motility, surface area, specific absorption site, blood flow, and first-pass metabolism (11, 12). The influence of the gastric emptying time and intestinal motility on intra- and intersubject variations in the rate and extent of availability largely can be avoided by the use of multiple-unit, controlled-release dosage forms (11, 13). These dosage forms are comprised of subunits, *e.g.*, pellets or microencapsulated crystals, that are dispersed and distributed throughout the GI tract when the capsule or tablet disintegrates (14).

In the present single-dose study dealing with intra- and intersubject variations in the rate of availability, both formulations were multiple-unit dosage forms, but they showed a highly significant difference in release properties with respect to pH dependency (Fig. 1). When a multiple-unit dosage form is under consideration, the importance of pH dependency is expected to be closely related to the pharmacokinetic characteristics of the drug (*i.e.*, saturable or with an absorption rate-dependent first-pass metabolism) since the influence of gastric emptying on intra- and intersubject variations can be eliminated. However, corroboration of such suggestions is not obtained easily from the literature.

The intrasubject variance of C_{max} of propoxyphene plus norpropoxyphene was significantly lower ($p < 0.01$), by factor of 6.7, after administration of Formulation B (Table II). The rate of appearance of norpropoxyphene in the circulation is a function both of the absorption rate of propoxyphene and of its *N*-demethylation. Because the highest intrasubject variance was observed after ingestion of the formulation whose drug release was most sensitive to the pH of the environment, *i.e.*, Formulation A (Fig. 1), the possibility of an absorption rate-dependent first-pass metabolism cannot be excluded.

With respect to T_{max} of both propoxyphene and propoxyphene plus norpropoxyphene, a significantly ($p < 0.01$) lower intrasubject variance, by factors of 6.7 and 11.9, respectively, was observed after ingestion of Formulation B (Table II). Expressed in terms of intrasubject ranges, identical ranges, *i.e.*, 2 hr for both parameters, were observed after administration of Formulation B. In contrast, the ranges observed for Formulation A were larger and not the same; the ranges were 4 and 8 hr or more, respectively (Figs. 3 and 5). The greater reproducibility of the rate of availability after administration of Formulation B can be ascribed directly to its lower sensitivity to the surrounding pH with respect to drug release. Thus, the significance of the type of controlled-release formulation with regard to minimizing the intrasubject variance in C_{max} and T_{max} has been demonstrated.

Clinically, increased predictability of the time of onset of action presumably is the primary advantage of the improved reproducibility of the plasma concentration pattern with Formulation B compared to Formulation A.

Reversible Ring-Opening Reactions of Nimetazepam and Nitrazepam in Acidic Media at Body Temperature

NOBUO INOTSUME and MASAHIRO NAKANO *x

Received January 4, 1980, from the *Faculty of Pharmaceutical Sciences, Hokkaido University, Sapporo 060, Japan.* Accepted for publication May 23, 1980. *Present address: Department of Pharmacy, Kumamoto University Hospital, Honjo 1-chome, Kumamoto 860, Japan.

Abstract □ Hydrolytic reactions of nimetazepam and nitrazepam in acidic solutions at body temperature were studied spectrophotometrically. The open-ring compounds produced by hydrolysis were in equilibrium with the corresponding closed-ring compounds (protonated nimetazepam and nitrazepam). Forward-reaction rate constants of both drugs were greater than the rate constant of diazepam. In nimetazepam, the forward-reaction rate constant was smaller than the reverse-reaction rate constant; in nitrazepam, the reverse-reaction rate constant was much smaller than the forward-reaction rate constant, and possible amide bond cleavage was indicated. The activation energies of the forward and reverse reactions of nimetazepam and the forward reaction of nitrazepam were calculated from Arrhenius-type plots, whereas no clear temperature dependency was observed in the reverse-reaction rate constant of nitrazepam. The effect of pH on these reactions also was examined. In addition, the pKa values of nimetazepam and nitrazepam were calculated to be 2.53 and 2.77, respectively.

Keyphrases □ 1,4-Benzodiazepines—nimetazepam and nitrazepam, kinetics and mechanisms of reversible hydrolysis □ Nimetazepam—kinetics and mechanisms of reversible hydrolysis, pKa determination □ Nitrazepam—kinetics and mechanisms of reversible hydrolysis, pKa determination □ Hydrolysis—nimetazepam and nitrazepam, kinetics and mechanisms, reversible reaction

The hydrolytic cleavage of benzodiazepines has been considered to take place only at elevated temperatures (1–4). On the other hand, pyrazolodiazepinones have been shown to be hydrolyzed easily at ambient temperatures (5). During permeation studies of benzodiazepines at 30°, chemical changes of some benzodiazepines were noted in the receptor solution, which was kept acidic (6). This observation prompted a kinetic investigation of the hydrolytic reaction in acidic media at 37°, and the results indicated that diazepam undergoes reversible ring-opening reactions at its azomethine bond, even at 37° (7).

Since reactions of drugs in acidic media may cause errors in the measurement of dissolution rates in acidic dissolution media and also may influence absorption from the GI tract following oral administration of acid-labile drugs, it is worthwhile to examine the relationship between the chemical structures of benzodiazepines and the rate and extent of hydrolytic reactions. The present report compares the rate constants of nimetazepam (*N*-methylnitrazepam) and nitrazepam with the rate constant of diazepam (7) and relates the different rate constants to structural differences.

EXPERIMENTAL

Materials—Nimetazepam[1], nitrazepam[2], 2-glycylamino-5-nitrobenzophenone hydrochloride[2], and 2-amino-5-nitrobenzophenone[1] were used as received, and their identity and purity were verified by their NMR spectra. Chloroform and ethanol were distilled prior to use. Other chemicals were reagent grade[3] and were used without further purification.

[2] Nippon Roche K.K., Tokyo, Japan.
[3] Wako Pure Chemical Industries, Osaka, Japan.

Kinetic Studies—The kinetic studies of the hydrolysis of nimetazepam and nitrazepam were carried out spectrophotometrically. Detailed procedures were given previously (7). For experiments at pH 2.2, 2.8, 3.3, and 7.4, 0.1 *M* citric acid–0.2 *M* Na_2HPO_4 or 0.1 *M* phosphate buffers were used.

By employing the molar absorptivity of nimetazepam, nitrazepam, the chloroform-unextractable species from nimetazepam, and 2-glycylamino-5-nitrobenzophenone, the concentration of each species was computed from the observed absorbance in the UV spectra. The forward- and reverse-reaction rate constants (k_f and k_r) for the reversible first-order reactions were obtained from (8):

$$\log \frac{P_t - P_\infty}{P_0 - P_\infty} = -\frac{k_f + k_r}{2.303} t \qquad \text{(Eq. 1)}$$

$$K_{eq} = \frac{k_f}{k_r} = \frac{P_0 - P_\infty}{P_\infty} \qquad \text{(Eq. 2)}$$

where P_0, P_t, and P_∞ are the concentrations or fractions of unreacted nimetazepam or nitrazepam at time zero, t, and infinity, respectively, and K_{eq} is an equilibrium constant.

Separate determinations of protonated nimetazepam and the chloroform-unextractable species in the kinetic studies in the constant-temperature bath and partition kinetic experiments were carried out as reported previously (7).

Determination of pKa of Nimetazepam and Nitrazepam—Stock solutions of nimetazepam and nitrazepam in ethanol were diluted with 0.1 *N* HCl, pH 7.4 phosphate buffer, and 1 *M* sodium acetate–1 *N* HCl of at least seven pH values around pH 2.5 and 2.7, respectively. The absorbance of the diluted solutions was measured quickly at 280 nm to minimize errors due to changes in the chemical species by hydrolysis. The pKa values were calculated according to the standard spectrophotometric method (9).

RESULTS

Nature of Reaction and Properties of Reaction Products of Nimetazepam—The spectral change of nimetazepam in 0.1 *N* HCl at 37° is shown in Fig. 1. Following chloroform extraction of the acidic solution of nimetazepam that had equilibrated for >210 min, the spectrum of the aqueous layer was quite different from that of the equilibrated solution (before extraction). This observation indicates the presence in the equilibrated solution of at least two species that differed markedly in their partition coefficients.

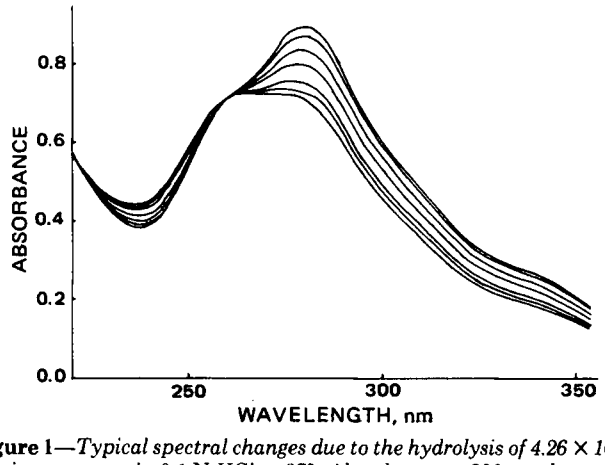

Figure 1—*Typical spectral changes due to the hydrolysis of 4.26 × 10^{-5} M nimetazepam in 0.1 N HCl at 37°. Absorbance at 280 nm decreased with time [measured at 0, 5, 15, 30, 60, 90, and 210 (∞) min].*

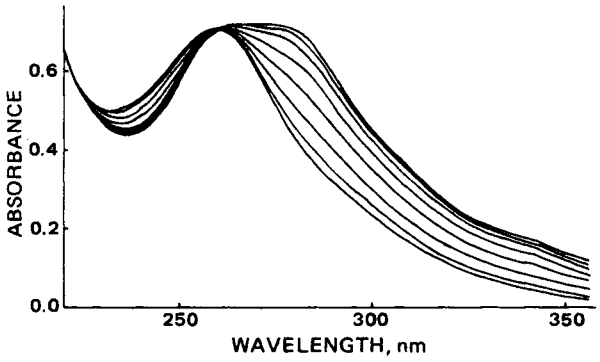

Figure 2—*Typical spectral changes due to the ring-closure reaction of the chloroform-unextractable species at 4.19 × 10^{-5} M formed from nimetazepam in 0.1 N HCl saturated with chloroform at 37°. Absorbance at 280 nm increased with time [measured at 0, 5, 15, 30, 50, 80, 120, and 240 (∞) min].*

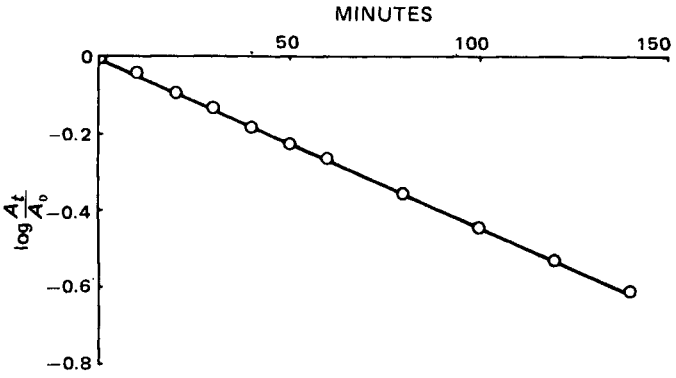

Figure 4—*Changes in absorbance (A) with time of the chloroform-unextractable species in the aqueous layer (0.1 N HCl) in the partition kinetics experiment using chloroform at 37°. Nimetazepam solution (1.36 × 10^{-4} M) was incubated in 0.1 N HCl at 37° for 5.5 hr prior to the partition experiment.*

Since nimetazepam was extracted quantitatively into chloroform immediately after acidification of the aqueous nimetazepam solution, protonated nimetazepam was shown to be chloroform unextractable. The species that remained in the aqueous solution after chloroform extraction was essentially unextractable with chloroform since a second extraction did not significantly affect the spectrum of the aqueous layer.

The reversible nature of the reaction was demonstrated by the formation of protonated nimetazepam from the chloroform-unextractable species. A spectrum of this species with a λ_{max} value of 259.5 nm, which was taken immediately following extraction (Fig. 2, 0 min), changed with time to give a spectrum (Fig. 2, 240 min) that was quite similar to that of the equilibrium mixture starting from protonated nimetazepam (Fig. 1, 210 min). The spectrum in the equilibrium state changed quickly to that of nimetazepam when the pH value of the medium was raised to pH 7.4 by the addition of 2.5 and 0.0025 *N* NaOH and pH 7.4 phosphate buffer. In addition, a spectrum of the species extracted with chloroform from the equilibrated mixture starting from the chloroform-unextractable species was identical to that of nimetazepam extracted with chloroform from an acidic solution of nimetazepam immediately after dilution of the stock nimetazepam solution. Figure 3 depicts the changes in the concentration of both species obtained by separate determinations of each species. An approach to and eventual attainment of the equilibrium are apparent.

Results of the partition kinetics experiments are shown in Fig. 4. An essentially first-order decrease in the amount of the chloroform-unextractable species indicates that nimetazepam is removed from the system as soon as it is formed and that the reaction can go to completion. This process may be used to synthesize nimetazepam from the chloroform-unextractable species in aqueous solutions. Since all of the chloroform-unextractable species was converted to nimetazepam, the reaction is quantitatively reversible.

Nature of Reaction and Properties of Reaction Products of Nitrazepam—The spectral change of nitrazepam in 0.1 *N* HCl at 37° (Fig. 5) differed from the changes of nimetazepam and diazepam. Although the isosbestic points of nitrazepam in Fig. 5 were observed initially at 251 and 363 nm (not shown), they gradually moved to 252 and 346 nm after incubation for 11 hr, and the spectral change continued for >29 hr. Appearance of a new λ_{max} at 358 nm when the test solution was incubated for 18 days at 37° indicates formation of a benzophenone derivative, 2-amino-5-nitrobenzophenone, which was produced by hydrolysis of both the azomethine and amide bonds of nitrazepam. Authentic 2-amino-5-nitrobenzophenone has a λ_{max} at 362 nm.

A spectrum obtained from an equilibrated solution of authentic 2-glycylamino-5-nitrobenzophenone, an opened form of nitrazepam, with an original λ_{max} of 263.5 nm was quite similar to that of the test solution incubated for 11 hr (protonated nitrazepam) (Fig. 5, 11 hr). In addition, a spectrum of the equilibrated nitrazepam in 0.1 *N* HCl rapidly changed to that of nitrazepam by the addition of 2.5 and 0.0025 *N* NaOH and pH 7.4 phosphate buffer. This result indicates the reversibility of the reaction of nitrazepam in the acidic solution.

Although a quinazoline derivative with a λ_{max} at ~295 nm in 0.1 *N* HCl was reported to be produced by incubation of nitrazepam in 0.1 *N* HCl at 90° for 28 hr (2), no increase in absorbance at 295 nm was noted in the spectrum of nitrazepam (Fig. 5). Furthermore, Fig. 5 has an isosbestic point at 251 nm. This observation indicates that this reaction is essentially one step. Therefore, ring contraction upon closure to quinazoline may be negligible under mild conditions.

Structural Assignment of Chloroform-Unextractable Species—Similar to the case of diazepam, although definite identification of the chloroform-unextractable species from nimetazepam is yet to be achieved, the observations discussed earlier ruled out 2-methylamino-5-nitrobenzophenone, which is not expected to be cyclized, as the

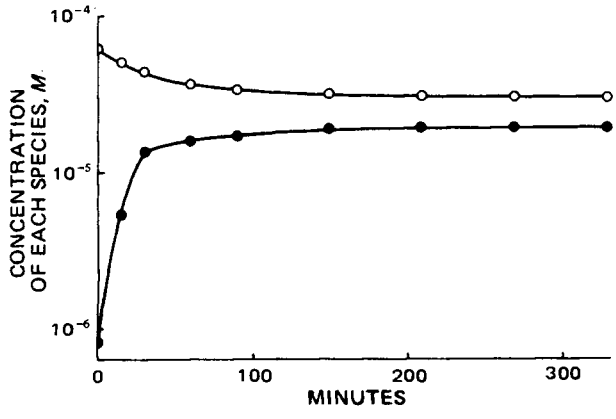

Figure 3—*Separately determined concentrations of protonated nimetazepam (○) and the chloroform-unextractable species (●) for the hydrolysis of 8.29 × 10^{-5} M nimetazepam in 0.1 N HCl at 37°.*

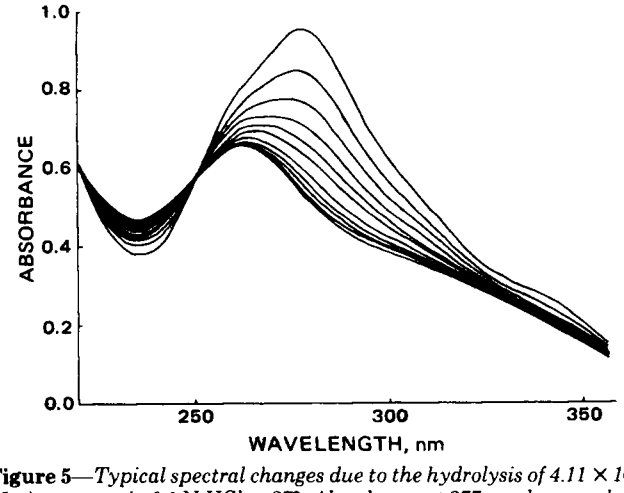

Figure 5—*Typical spectral changes due to the hydrolysis of 4.11 × 10^{-5} M nitrazepam in 0.1 N HCl at 37°. Absorbance at 277 nm decreased with time (measured at 0, 0.67, 1.5, 2.5, 3.5, 5, 7, 9, 13, 18, and 27 hr).*

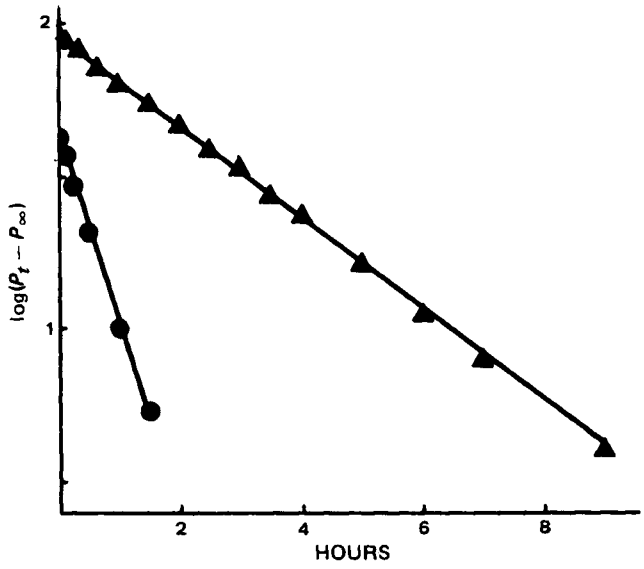

Figure 6—*Plots according to Eq. 1 for 4.26 × 10^{-5} M nimetazepam (●) and 4.11 × 10^{-5} M nitrazepam (▲) in 0.1 N HCl at 37°.*

chloroform-unextractable species. Since assignment of an open-ring compound at the azomethine bond as the structure of the chloroform-unextractable species did not contradict any spectrophotometric and partition characteristics of the species, 2-glycyl(methyl)amino-5-nitrobenzophenone was tentatively assigned to the chloroform-unextractable species.

In nitrazepam, the same reaction as for diazepam and nimetazepam is likely to take place initially, but an additional hydrolysis of the amide bond to produce 2-amino-5-nitrobenzophenone seems to occur, as judged from spectral changes.

As with diazepam, the chloroform-unextractable species could not be isolated as such from aqueous solutions because of the reversible nature of the reaction in 0.1 *N* HCl and because they are rapidly cyclized to form nimetazepam and nitrazepam at pH values above their pKa values. Thus, any attempt to extract the ionized form of the chloroform-unextractable species into organic solvents after neutralization failed.

Quantitative Aspects—The linear relations were obtained in plots according to Eq. 1 (Fig. 6). The reversible first-order reactions with respect to nimetazepam and nitrazepam are indicated. Reaction rate constants calculated for nimetazepam according to Eqs. 1 and 2 are recorded in Table I. Although the general magnitude of the rate constants reasonably agreed, they differed somewhat from each other depending on the experimental method employed. In any case, both the forward- and the reverse-reaction rate constants of nimetazepam were greater than those of diazepam (7), and the rate constant of ring closure was greater than that of the ring-opening reaction. The former observation was attributed to a greater effect of the nitro group than the chloro group on the reactivity. The latter observation indicates a greater concentration of the closed-ring compound (protonated nimetazepam) than the open-ring compound in the equilibrium state at 37°.

Effect of Temperature—The rate constants at 25, 50, and 61° for nimetazepam and at 25 and 50° for nitrazepam were calculated from spectral changes similar to those at 37°. Arrhenius-type rate constant *versus* temperature plots for nimetazepam (Fig. 7) indicate that the reverse-reaction rate constants of nimetazepam were greater than the forward-reaction rate constants below 50° and that the former constant was smaller than the latter constant at temperatures above 50°. This result indicates a greater concentration of the open-ring compound than the closed-ring compound (protonated nimetazepam) at equilibrium at temperatures above 50°.

In nitrazepam, the rate constants of the reverse reaction at 25, 37, and 50° were much smaller than those of the forward reaction and were within the range of experimental error; therefore, no clear dependency of the reverse-reaction rate constants on temperature was noted. The activation energies (mean ± *SE*) calculated were 16.1 ± 0.3 and 11.7 ± 0.8 kcal/mole for the forward and reverse reactions of nimetazepam, respectively. These values were smaller than corresponding values in diazepam (7). The activation energy (mean ± *SE*) for the forward reaction of nitrazepam was 17.2 ± 2.1 kcal/mole.

Effect of pH—Preliminary studies indicated that spectral changes

Table I—Rate Constants of Ring-Opening and Ring-Closure Reactions Estimated by Four Procedures

Estimation Procedure	Rate Constant at 37°, hr^{-1}	
	Ring Opening	Ring Closure
Spectral change starting from protonated nimetazepam (Fig. 1)	0.61	0.82
Spectral change starting from chloroform-unextractable species (Fig. 2)	0.53	0.91
Assay of nimetazepam extracted into chloroform layer (Fig. 3)	0.45	0.74
Decrease in absorbance in aqueous layer during partition kinetics experiments (Fig. 4)	—	0.61

similar to those shown in Figs. 1 and 5 took place in the buffers at pH 2.2 and 3.3 for nimetazepam and at pH 2.8 for nitrazepam. However, the changes in absorbance were smaller than those in 0.1 *N* HCl, indicating that the reactions proceeded to a lesser extent. At pH values higher than the pKa values of nimetazepam and nitrazepam, little change in the absorbance with time was observed. As already indicated, open-ring compounds, once formed in the acidic solutions, reverted back to nimetazepam and nitrazepam when the pH values of the media were increased.

pKa Values of Nimetazepam and Nitrazepam—The calculated pKa values were 2.53 for nimetazepam and 2.77 for nitrazepam. The latter value is smaller than the reported pKa value (3.2) of nitrazepam (10).

DISCUSSION

At body temperature, the reversible reactions involving hydrolysis of 4,5-azomethine bonds of nimetazepam and nitrazepam are expected to take place. The result that the forward-reaction rate constant of nimetazepam is greater than that of diazepam may be explained by the lower electron density of the A-ring of nimetazepam (nitrobenzene group) caused by the higher electron-withdrawing tendency of the nitro group in nimetazepam relative to that of the chlorine in diazepam. The same mechanism may be applicable to the acidic hydrolysis of *m*-nitrobenzoate, which was hydrolyzed faster than *m*-chlorobenzoate to the same degree (11).

The result that the forward-reaction rate constant of nimetazepam is greater than that of nitrazepam may be explained by the higher electron density of the A-ring of nitrazepam caused by the delocalization of the lone electron on the amide nitrogen. In nimetazepam, the lone electron

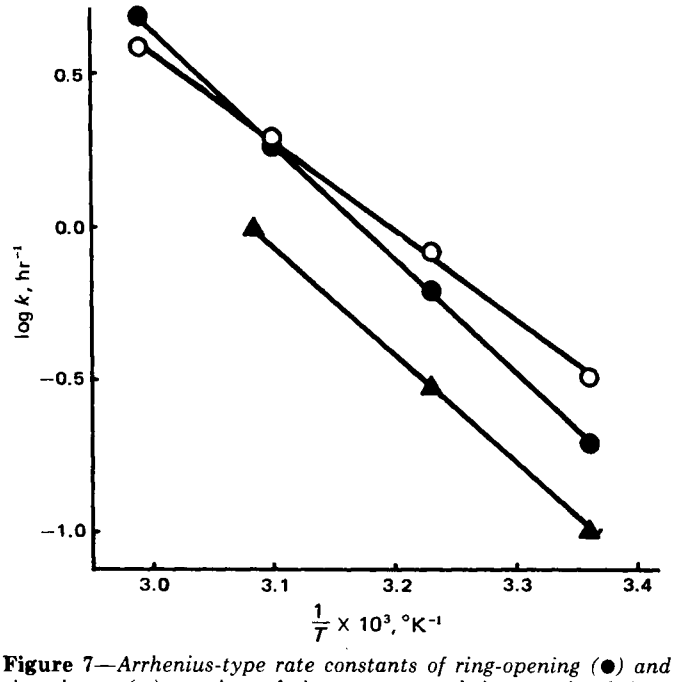

Figure 7—*Arrhenius-type rate constants of ring-opening (●) and ring-closure (○) reactions of nimetazepam and ring-opening (▲) reaction of nitrazepam in 0.1 N HCl.*

on the amide nitrogen is fixed by the methyl group. This difference is not unique in nimetazepam and nitrazepam because the same trend was observed with diazepam and desmethyldiazepam. Diazepam in acidic solution reached equilibrium after incubation for 11 hr (7), whereas desmethyldiazepam in acidic solution did not reach equilibrium, even after incubation for 210 hr[4].

Since further hydrolysis of the amide bond of the chloroform-unextractable species from nitrazepam to 2-amino-5-nitrobenzophenone is expected to be irreversible, such a hydrolysis in the stomach may reduce the amount of the chloroform-unextractable species that reverts back to the original drug and then is absorbed from the intestine. However, since the irreversible hydrolysis of the amide bond of nitrazepam proceeds only at a slow rate, it is not expected to affect the bioavailability of orally administered nitrazepam. The rate constant of formation of 2-amino-5-nitrobenzophenone was not determined in the present study. However, the magnitude of this rate relative to that of the reverse-reaction rate, the dissolution rate of the drug in the stomach, the forward-reaction rate constant, and the stomach-emptying rate is expected to affect the bioavailability of nitrazepam.

Based on the experimental data obtained in the present *in vitro* study, it may be postulated that after administration of dosage forms of nimetazepam and nitrazepam, some nimetazepam and nitrazepam dissolved in the stomach is hydrolyzed to the open-ring compounds because of the acidic pH of the stomach contents. When the open-ring compounds empty from the stomach to the intestine, they are expected to revert back to the parent drugs upon increase in the pH value of the media. Therefore, there can be little loss in drug bioavailability.

Structure–Activity Relationships of Pyrrole Amidine Antiviral Antibiotics III: Preparation of Distamycin and Congocidine Derivatives Based on 2,5-Disubstituted Pyrroles

MEIR BIALER *§x, BORIS YAGEN *, RAPHAEL MECHOULAM *, and YECHIEL BECKER ‡

Received March 17, 1980, from the **Department of Natural Products, Pharmacy School, and the* ‡*Department of Molecular Virology, Medical School, Hebrew University, Jerusalem, Israel.* Accepted for publication May 22, 1980. §Present address: Pharmacy Department, Pharmacy School, Hebrew University, Jerusalem, Israel.

Abstract □ Isomers of distamycin A and tripyrrole congocidine containing 2,5-disubstituted pyrroles were synthesized along with distamycin and congocidine homologs containing a single pyrrole ring. Selected compounds were evaluated for their cytotoxicity and antiviral activity. All of the tripyrrole derivatives tested in this series were nontoxic but were less active than distamycin A. The monopyrrole derivative, *N*-methyl-5-nitropyrrole-2-carboxamido-β-propionamidine hydrochloride, was nontoxic and was almost as active antivirally as distamycin A.

Keyphrases □ Antibiotics—distamycin A and congocidine derivatives based on 2,5-disubstituted pyrroles, synthesis and evaluation for cytotoxicity and antiviral activity, structure–activity relationships □ Structure–activity relationships—distamycin A and congocidine derivatives based on 2,5-disubstituted pyrroles, antiviral activity □ Distamycin—derivatives based on 2,5-disubstituted pyrroles, synthesis and evaluation for cytotoxicity and antiviral activity, structure–activity relationships □ Congocidine—derivatives based on 2,5-disubstituted pyrroles, synthesis and evaluation for cytotoxicity and antiviral activity, structure–activity relationships

Distamycin A (I), a basic oligopeptide antibiotic isolated from the fermentation medium of *Streptomyces distallicus* (1), has interesting antibacterial (2) and antiviral activities. As an antiviral drug, distamycin A inhibits the multiplication of DNA viruses and certain retroviruses (3–7). The mechanism of its antiviral activity is believed to be related to its ability to bind to single- and double-stranded DNA molecules, with a particularly high affinity for adenine–thymine-rich DNA sequences. Subsequent formation of a DNA–distamycin A complex destroys the DNA molecule, which serves as a template for the enzyme DNA polymerase (3–7). Distamycin A has been used clinically in cases of herpes virus infections (8).

Distamycin A belongs to a group of compounds known as pyrrole amidine antiviral antibiotics. Another member of this group is congocidine (netropsin, II) (6, 7). This

Structure–Activity Relationships of Pyrrole Amidine Antiviral Antibiotics III: Preparation of Distamycin and Congocidine Derivatives Based on 2,5-Disubstituted Pyrroles

MEIR BIALER *§x, BORIS YAGEN *, RAPHAEL MECHOULAM *, and YECHIEL BECKER ‡

Received March 17, 1980, from the **Department of Natural Products, Pharmacy School, and the* ‡*Department of Molecular Virology, Medical School, Hebrew University, Jerusalem, Israel.* Accepted for publication May 22, 1980. §Present address: Pharmacy Department, Pharmacy School, Hebrew University, Jerusalem, Israel.

Abstract □ Isomers of distamycin A and tripyrrole congocidine containing 2,5-disubstituted pyrroles were synthesized along with distamycin and congocidine homologs containing a single pyrrole ring. Selected compounds were evaluated for their cytotoxicity and antiviral activity. All of the tripyrrole derivatives tested in this series were nontoxic but were less active than distamycin A. The monopyrrole derivative, *N*-methyl-5-nitropyrrole-2-carboxamido-β-propionamidine hydrochloride, was nontoxic and was almost as active antivirally as distamycin A.

Keyphrases □ Antibiotics—distamycin A and congocidine derivatives based on 2,5-disubstituted pyrroles, synthesis and evaluation for cytotoxicity and antiviral activity, structure–activity relationships □ Structure–activity relationships—distamycin A and congocidine derivatives based on 2,5-disubstituted pyrroles, antiviral activity □ Distamycin—derivatives based on 2,5-disubstituted pyrroles, synthesis and evaluation for cytotoxicity and antiviral activity, structure–activity relationships □ Congocidine—derivatives based on 2,5-disubstituted pyrroles, synthesis and evaluation for cytotoxicity and antiviral activity, structure–activity relationships

Distamycin A (I), a basic oligopeptide antibiotic isolated from the fermentation medium of *Streptomyces distallicus* (1), has interesting antibacterial (2) and antiviral activities. As an antiviral drug, distamycin A inhibits the multiplication of DNA viruses and certain retroviruses (3–7). The mechanism of its antiviral activity is believed to be related to its ability to bind to single- and double-stranded DNA molecules, with a particularly high affinity for adenine–thymine-rich DNA sequences. Subsequent formation of a DNA–distamycin A complex destroys the DNA molecule, which serves as a template for the enzyme DNA polymerase (3–7). Distamycin A has been used clinically in cases of herpes virus infections (8).

Distamycin A belongs to a group of compounds known as pyrrole amidine antiviral antibiotics. Another member of this group is congocidine (netropsin, II) (6, 7). This

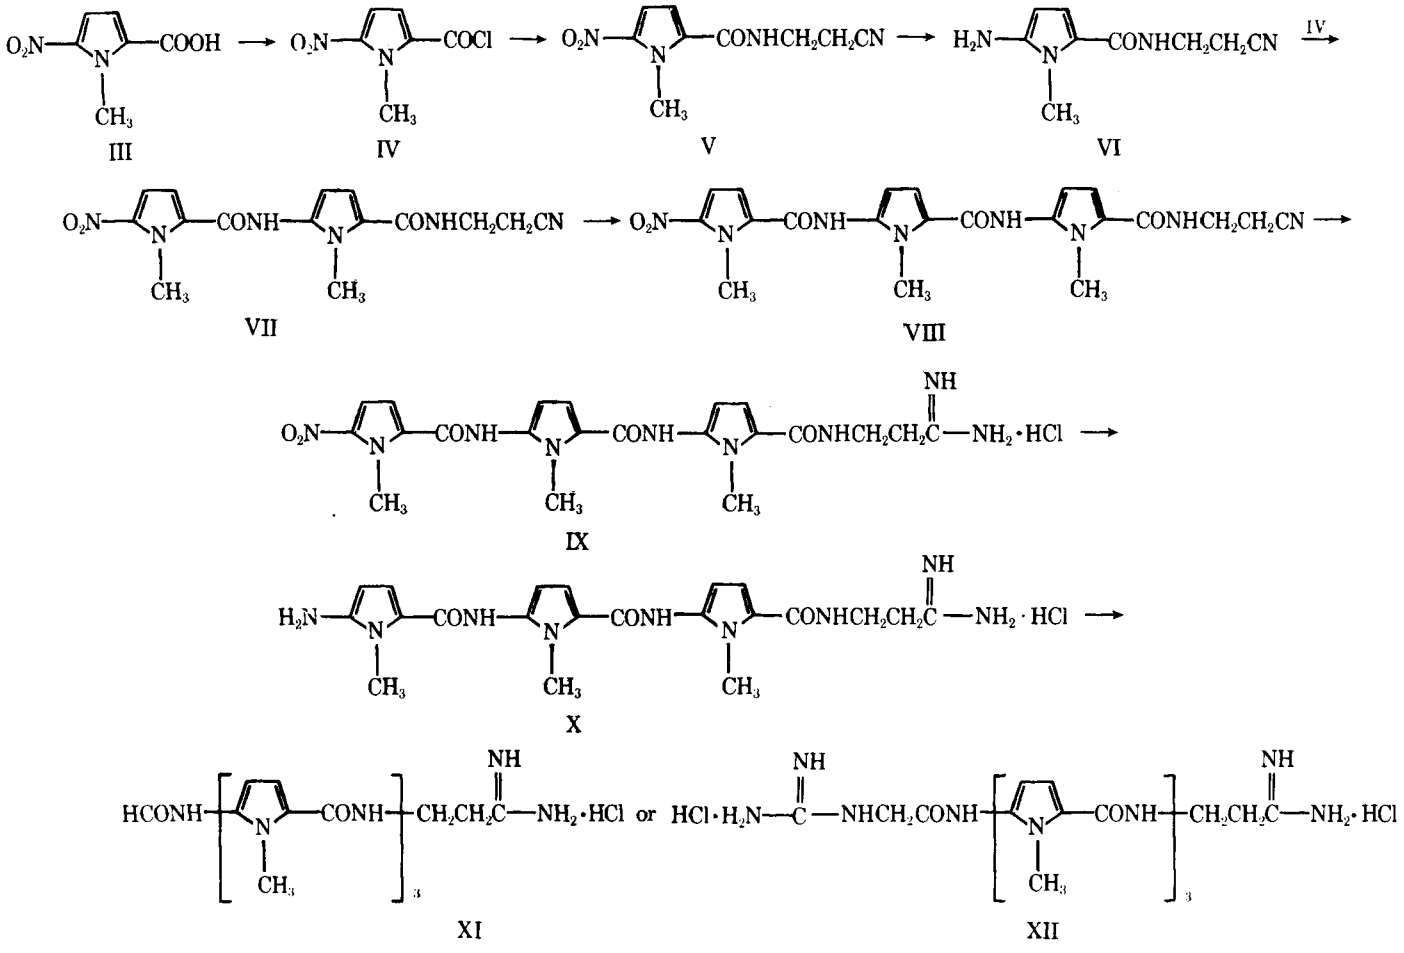
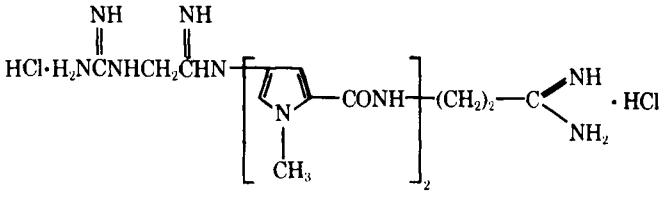


Scheme I

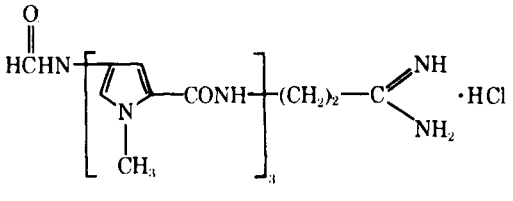
compound has biological activities similar to those of distamycin A.

DISCUSSION

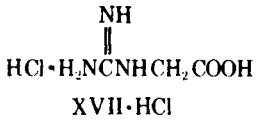
Little information is available on the structural requirements for the antiviral activity of distamycin A (9–17) and congocidine (18, 19). Due to the lack of clinically useful antiviral drugs, a thorough investigation into the structure–activity relationships of the known antiviral compounds is of importance. In continuation of previous research on the structure–activity relationships of pyrrole amidine antiviral antibiotics (13, 16), the present study concerned the synthesis of novel distamycin and congocidine analogs and evaluation of their antiviral activity.



II·2HCl



I·HCl

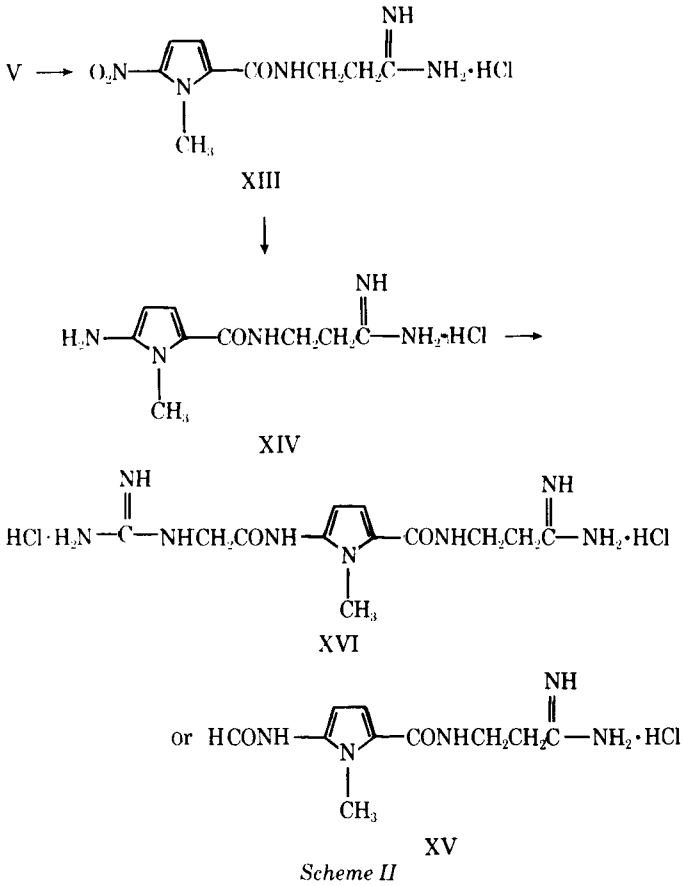


XVII·HCl

In all of the previous work (9–20), the peptide bonds were between positions 2 and 4 of the pyrrole ring. Thus, it was decided to determine if the location of the peptide in the pyrrole ring was critical for the antiviral activity of this series. Accordingly, isomers and homologs of distamycin A (I) and congocidine (II) in which the peptide bonds were moved to positions 2 and 5 of the pyrrole ring were synthesized.

Chemistry—The synthetic route is outlined in Scheme I and is similar to the first total synthesis of distamycin A (21). The starting material was *N*-methyl-5-nitropyrrole-2-carboxylic acid (III) (22). Compound III was prepared and purified similarly to its 4-nitro isomer. The acid (III) was converted to its acyl chloride (IV), which was condensed with β-aminopropionitrile to give the nitro nitrile (V). Compound V was reduced catalytically to the amine (VI) which, without further purification, was condensed with *N*-methyl-5-nitropyrrole-2-carboxyl chloride (IV) to give the dipeptide (VII).

The reduction–condensation process was repeated, leading to the intermediate nitro nitrile (VIII). Compound VIII was converted to the nitroamidine compound (IX) by the standard reaction with hydrochloric acid followed by ammonia (23). Compound IX served as a precursor for the synthesis of the distamycin and the tripyrrole congocidine isomers. Reduction of IX yielded the amino amidine compound (X), which, due to its sensitivity and instability, was condensed directly with formic acid in the presence of dicyclohexylcarbodiimide (24) to give the distamycin isomer (XI) or with glycocyamine hydrochloride (XVII) (25) to give the congocidine analog (XII). The total yield in this synthesis was lower than the yield obtained in the synthesis of analogs containing peptide bonds between positions 2 and 4 (21, 22). This result can be explained by the instability and minor chemical reactivity of α-amino pyrrole derivatives during condensation (26). Chemical reactions not requiring condensation of an α-amino pyrrole, such as in the preparation of V and IX, showed



Scheme II

similar yields as the analogs with peptide bonds between positions 2 and 4 (21, 22).

In comparing the UV data of IX and XI to those of analogous compounds in the distamycin series, a bathochromic shift of 30 nm was noted. In the NMR spectra of IV, V, VII, and VIII, the pyrrolic *N*-methyl group that was closest to the aliphatic side chain appeared at 4.1–4.2 ppm, and the aromatic hydrogens showed an *AB* system with J = 4 Hz.

Compound V served as a starting material for the preparation of 2,5-disubstituted monopyrrole derivatives of distamycin and congocidine (Scheme II). It was converted to the nitroamidine (XIII) by the standard reaction with hydrochloric acid followed by ammonia (23). Compound XIII was reduced catalytically to give the amino compound (XIV), which, without isolation, was condensed with formic acetic anhydride (21) or glycocyamine hydrochloride in the presence of dicyclohexylcarbodiimide to give XV or XVI, respectively. The IR, NMR, and mass spectra of the monopyrrole compounds (V, XIII, XV, and XVI) were similar to those of tripyrroles.

Virology—Selected compounds of this series were tested for their cytotoxicity and ability to inhibit Herpes simplex Type 1 viral replication in cultured cells. The details of these techniques were given previously (17).

EXPERIMENTAL

Unless otherwise stated, the following procedures were followed. UV measurements were made for solutions in ethanol or dimethylformamide[1]. IR[2] spectra were taken in potassium bromide pellets. PMR[3] data were determined in dimethyl sulfoxide-d_6 as the solvent with sodium 3′-(trimethylsilyl)tetradeuteropropionate as the external standard. TLC was performed on 0.3-mm silica gel plates, which were developed with Ehrlich's reagent [2% *N,N*-(dimethylamino)benzaldehyde in 6 *N* HCl] or by irradiation at 254 nm. Mass spectra[4] were obtained by direct inlet at 80 ev; in several cases, the technique of field desorption was used.

***N*-Methyl-5-nitropyrrole-2-carboxylic Acid (III)**—*N*-Methyl-5-nitropyrrole-2-carboxylic acid methyl ester (22) (5 g, 27.1 mmoles) was dissolved in ethanol (50 ml), and a solution of sodium hydroxide (1.9 g in 125 ml of water) was added. The reaction mixture was stirred overnight at room temperature, and the ethanol was evaporated. The solution was cooled and acidified with 6 *N* HCl.

The precipitate formed was filtered off and crystallized from ethanol–water to give III, 4 g (87%), mp[5] 198°; NMR: δ 4.22 (s, 3H, *N*-CH_3), 6.82, and 7.08 (d, 2H, J = 4 Hz, aromatic H); UV (ethanol): λ_{max} 225 (ϵ 11,000) and 392 (15,500) nm; IR: ν_{max} 3100, 2600–2900, 1680, 1450, 1350, 1290, and 1250 cm^{-1}; mass spectrum: m/e 170 (M^+, 100%), 152 (17), 122 (65), and 109 (48).

Anal.—Calc. for $C_6H_4N_2O_4$: C, 42.4, H, 3.53; N, 16.5. Found: C, 42.5; H, 3.37; N, 16.1.

***N*-Methyl-5-nitropyrrole-2-carboxamido-β-propionitrile (V)**—Compound III (3 g, 18.2 mmoles) was dissolved in thionyl chloride and boiled under reflux for 1 hr. The remaining thionyl chloride was evaporated. The residue (IV) was dissolved in benzene (30 ml) and added gradually to a solution of β-aminopropionitrile[6] (1.23 g, 176 mmoles) and sodium bicarbonate (2.1 g) in water (25 ml). The reaction mixture was stirred at room temperature and filtered.

The precipitate formed was crystallized from methanol–water to give V, 3.3 g (84%), mp 117–119°; NMR: δ 2.79 (t, 2H, J = 4.8 Hz, *C*-CH_2), 3.52 (t, 2H, J = 4.8 Hz, *N*-CH_2), 4.12 (s, 3H, *N*-CH_3), 6.78, and 7.02 (d, 2H, J = 3.6 Hz, aromatic H); UV (ethanol): λ_{max} 271 (ϵ 10,700) and 345 (14,200) nm; IR: ν_{max} 3270, 3110, 2960, 2250, 1640, 1530, 1460, 1490, 1160, and 1070 cm^{-1}; mass spectrum: m/e 222 (M^+, 32%), 205 (5), 192 (32), 182 (5), 174 (6), and 153 (100).

Anal.—Calc. for $C_9H_{10}N_4O_3$: C, 48.65; H, 4.54; N, 25.22. Found: C, 48.58; H, 4.69; N, 24.78.

***N*-Methyl-5-(*N*-methyl-5-nitropyrrole -2 -carboxamido)pyrrole-2-carboxamido-β-propionitrile (VII)**—Compound V (4 g, 18 mmoles) was dissolved in dimethylformamide (30 ml) and reduced at atmospheric pressure with 10% palladium-on-charcoal (1.2 g) to give VI. Water (90 ml) was added, and the catalyst was filtered off. Sodium bicarbonate (2.25 g) was introduced into the filtrate, followed by a solution of IV (3.06 g, 18 mmoles) in benzene (15 ml). The mixture was stirred overnight. The precipitate formed was filtered off and washed with 5% $NaHCO_3$ and water.

The residue was crystallized from ethanol to give VII, 1.1 g (18%), mp 241–245°; NMR: δ 2.74 (t, 2H, J = 5 Hz, *C*-CH_2), 3.44 (t, 2H, J = 5 Hz, *N*-CH_2), 4.12 (s, 6H, *N*-CH_3), 6.02 (d, 1H, J = 3 Hz), 6.76 (d, 1H, J = 3 Hz), 6.98 (d, 1H, J = 4.8 Hz), 7.2 (d, 1H, J = 4.8 Hz, aromatic H), 8.16 (t, 1H, aliphatic amide H), and 10.2 (s, 1H, aromatic amide H); UV (ethanol): λ_{max} 271 (ϵ 17,000) and 345 (14,200) nm; IR: ν_{max} 3320, 3230, 1670, 1640, 1540, 1460, 1370, 1350, 1290, and 1240 cm^{-1}; mass spectrum: m/e 344 (M^+, 100%), 328 (3.5), 312 (14), and 275 (8).

Anal.—Calc. for $C_{15}H_{16}N_6O_4 \cdot H_2O$: C, 49.72; H, 4.97; N, 23.20. Found: C, 50.11; H, 5.01; N, 23.30.

***N*-Methyl-5-[*N*-methyl-5-(*N*-methyl-5-nitropyrrole-2-carboxamido)pyrrole-2-carboxamido]pyrrole -2 -carboxamido-β -propionitrile (VIII)**—Compound VII (1 g, 3.2 mmoles) was dissolved in dimethylformamide (10 ml). The reduction procedure followed was that described for obtaining VII from V. Sodium bicarbonate (330 mg) was introduced into the filtrate, followed by a solution of IV (620 mg, 36 mmoles) in benzene (8 ml). The mixture was stirred overnight. The precipitate formed was filtered off and washed with 5% $NaHCO_3$ and water.

The precipitate obtained was crystallized from methanol to give VIII, 700 mg (47%), mp 270°; NMR: δ 2.80 (t, 2H, J = 5 Hz, *C*-CH_2), 3.41 (t, 2H, J = 5 Hz, *N*-CH_2), 3.80, 3.81, 4.28 (s, 9H, *N*-CH_3), 6.02 (d, 1H, J = 4 Hz), 6.12 (d, 1H, J = 4 Hz), 6.83 (d, 1H, J = 4 Hz), 7.1 (d, 1H, J = 2 Hz), 7.16 (d, 1H, J = 2 Hz), 7.32 (d, 1H, J = 4 Hz, aromatic H), 8.25, 9.7, and 10.3 (amide H); UV (dimethylformamide): λ_{max} 298 (ϵ 15,200) and 348 (12,900) nm; IR: ν_{max} 3250, 3060, 2960, 2250, 1640, 1540, 1470, 1360, 1230, and 1040 cm^{-1}; mass spectrum: m/e 466 (M^+, 10%), 370 (2), 369 (2), 344 (24), 340 (38), 314 (10), 299 (24), and 275 (100).

Anal.—Calc. for $C_{21}H_{22}N_8O_5 \cdot H_2O$: C, 52.66; H, 4.96; N, 23.14. Found: C, 52.76; H, 5.18; N, 23.11.

***N*-Methyl-5-[*N*-methyl-5-(*N*-methyl-5-nitropyrrole-2-carboxamido)pyrrole-2-carboxamido]pyrrole -2 -carboxamido-β -propionamidine Hydrochloride (IX)**—Compound VIII (700 mg, 1.5 mmoles) was dissolved in absolute ethanol (20 ml). The solution was cooled to 0° and stirred, and dry hydrochloric acid was bubbled through it for 1 hr.

Table I—Toxicity and Plaque Inhibition by Distamycin and Congocidine Derivatives

Compound	Maximal Nontoxic Concentration, μg/ml[a]	Inhibition of Virus Progeny[b], %
I	25	99.7
IX	>200[c]	98.45
XI	>200	96.3
XIII	>200	99.12
XVI	>200	76.4

[a] Toxic effect is regarded as cell death within 2 days of incubation of cultured cells with the drug at 37°. The maximal nontoxic concentration is defined as the nontoxic drug concentration whose twofold increase causes toxicity. [b] The titer of virus progeny produced in untreated infected cells and in cells treated with each distamycin derivative was determined by plaque assay on BSC-1 cells. The virus progeny yielded by infected cells was taken as 100%, and the yield of virus from infected treated cells was related to the yield from untreated infected cells. All compounds were tested at a concentration of 200 μg/ml except for I, which was tested at 25 μg/ml. [c] The designation >200 indicates that the drug was nontoxic at 400 μg/ml.

The solution was kept at 0° for an additional 12 hr, the ethanol was evaporated, and the dry residue was washed with ether. Then the residue was dissolved in absolute ethanol (15 ml). The solution was cooled to 0° and stirred, and dry ammonia was bubbled through it for 1 hr.

After the bubbling was stopped, the solution was stirred at room temperature for 12 hr. The ethanol was evaporated, and the residue was crystallized from methanol to give IX, 520 mg (67%), mp 192–198°; NMR: δ 2.89 (d, 2H, *C*-CH_2), 3.6 (d, 2H, *N*-CH_2), 3.78, 3.81, 4.29 (s, 9H, *N*-CH_3), 6.02 (d, 1H, J = 4 Hz), 6.18 (d, 1H, J = 4 Hz), 6.94 (d, 1H, J = 3.84 Hz), 7.21, 7.36 (d, 2H, J = 4 Hz, aromatic H), 8.26, 9.66 (amide H), and 8.74 (amidine H); UV (ethanol): λ_{max} 261 (ε 8800) and 295 (10,000) nm; IR: ν_{max} 3100–3300, 1640, 1540, 1450, 1300, and 1260 cm^{-1}; mass spectrum (field desorption): m/e 466 (M − NH_3), 412, 344, 248, and 218.

***N*-Methyl-5-[*N*-methyl-5-(*N*-methyl-5-(formylamido)pyrrole-2-carboxamido)pyrrole -2-carboxamido]pyrrole-2-carboxamido-β-propionamidine Hydrochloride (XI)**—Compound IX (400 mg, 0.77 mmole) was dissolved in dimethylformamide (7 ml) and reduced at atmospheric pressure with 10% palladium-on-charcoal (120 mg). The mixture was filtered. The intermediate amine (X) presumably obtained was not purified due to instability. Formic acid (53 mg, 1.15 mmoles) in dimethylformamide (10 ml) was gradually added under nitrogen to a solution of X and kept at 0° for 1 hr.

The reaction mixture was stirred at room temperature overnight and filtered, and the filtrate was evaporated. The residue was crystallized from ethanol–ethyl acetate to give XI, 20 mg (5%), mp 182–190°; UV (ethanol): λ_{max} 324 (ε 24,400) nm; IR: ν_{max} 3000–3440, 2440, 2860, 1680, 1640, 1520, 1450, 1370, 1330, 1250, and 1100 cm^{-1}; mass spectrum: m/e 421 (1%), 382 (2), 340 (40), 314 (10), 220 (12), and 218 (100).

***N*-Methyl-5-[*N*-methyl-5-(*N*-methyl-5-(guanidinoacetamido)-pyrrole-2-carboxamido)pyrrole -2- carboxamido]pyrrole-2-carboxamido-β-propionamidine Dihydrochloride (XII)**—Compound XII was obtained from IX as described for XI. The only difference was that the intermediate amine (X) was condensed with glycocyamine hydrochloride[7] (XVII) (1.18 mg, 0.77 mmole), 2 mg (2%); UV (ethanol): λ_{max} 237 (ε 17,100) and 298 (11,200) nm; IR: ν_{max} 2980–3440, 1680, 1640, 1490, 1280, and 1230 cm^{-1}; mass spectrum: m/e 344 (9%), 340 (7), 314 (5), 289 (8), 220 (100), and 218 (26).

***N*-Methyl-5-nitropyrrole -2 -carboxamido -β- propionamidine Hydrochloride (XIII)**—Compound XIII was obtained from the nitrile (V) (2 g, 9 mmoles). The reaction procedure followed was the same as that described for obtaining IX from VIII, 1.5 g (73%), mp 189°; UV (ethanol): λ_{max} 240 (ε 8100) and 344 (9800) nm; IR: ν_{max} 3340, 3240, 3080, 1670, 1540, 1470, 1290, 1250, 1200, and 1150 cm^{-1}; NMR: δ 2.81 (t, 2H, J = 6 Hz, *C*-CH_2), 3.79 (t, 2H, J = 6 Hz, *N*-CH_2), 4.24 (s, 3H, *N*-CH_3), 6.94, 7.27 (d, 2H, J = 4 Hz, aromatic H), and 8.94 (amidine H); mass spectrum: m/e 222 (M − NH_3, 80%), 209 (100), 192 (75), and 153 (65).

Anal.—Calc. for $C_9H_{13}N_5O_3$·HCl: C, 39.20; H, 5.12; Cl, 12.9; N, 25.6. Found: C, 39.31; H, 5.42; Cl, 12.63; N, 25.53.

***N*-Methyl-5-formylamidopyrrole-2-carboxamido -β- propionamidine Hydrochloride (XV)**—The nitropyrrole derivative (XIII) (1.5 g, 5.4 mmoles) was dissolved in 80% methanol (30 ml) and reduced at atmospheric pressure with 10% palladium-on-charcoal (0.4 g). The mixture was filtered and evaporated. The intermediate amine (XIV) presumably obtained was not purified due to its instability. Formic acetic anhydride (21), freshly prepared, was gradually added to the cooled residue. The reaction mixture was stirred at room temperature for 1 hr and then was poured into ether (50 ml).

A white precipitate formed and was washed with ether. The crude precipitate was purified by chromatography on a silica gel column (90 g); the eluent was chloroform–ethanol–water (100:50:4). Compound XV (230 mg, 16%) was obtained; UV (ethanol): λ_{max} 280 (ε 20,900) nm; IR: ν_{max} 3000–3500, 1760, 1620, 1500, 1380, 1330, 1270, and 1150 cm^{-1}; NMR: δ 2.81 (t, 2H, *C*-CH_2), 3.79 (t, 2H, *N*-CH_2), 3.91 (s, 3H, *N*-CH_3), 6.16, 6.94 (d, 2H, J = 5 Hz, aromatic H), 8.14 (amide H), 8.84, 9.30 (amidine H), and 10.34 (formyl H).

***N*-Methyl-5-(guanidinoacetamido)pyrrole -2- carboxamido -β-propionamidine Dihydrochloride (XVI)**—Compound XVI was obtained from XIII following the procedure described for the preparation of XII from IX (2% yield), mp 190–195°; UV (ethanol): λ_{max} 235 (ε 21,100) nm; IR: ν_{max} 3370, 3180, 2940, 2780, 2700, 1650, 1500, 1280, and 1120 cm^{-1}; NMR: δ 3.39 (t, 2H, *N*-CH_2), 3.74 (s, 3H, *N*-CH_3), 6.7, and 7.8 (d, 2H, aromatic H); mass spectrum: m/e 232 (53%), 219 (30), 193 (8), 181 (100), and 169 (65).

Virology—The details for the virological experiment were given previously (17).

RESULTS

The four compounds tested were nontoxic at 400 μg/ml (Table I). The most marked inhibition was shown by XIII. Isomer XI showed lower inhibition than its precursor (IX) and most of the other tripyrrole derivatives of distamycin and congocidine (17, 20).

The tripyrrole compounds tested showed less antiviral activity than distamycin A and the tripyrrole derivatives of congocidine (17, 20). Apparently, the peptide bond at positions 2 and 4 of the pyrrole rings is critical for the antiviral activity in the distamycin or congocidine series. The greatest antiviral activity in the 2,5-disubstituted pyrrole series was demonstrated by XIII, which was less toxic and had almost the same antiviral activity as distamycin A. Compound XIII is more antivirally active than similar monopyrrole homologs of distamycin A or congocidine (13, 20).

NOTES

Pharmacological Disposition of Negatively Charged Phospholipid Vesicles in Rats

YIN J. KAO and TI LI LOO ×

Received January 21, 1980, from the *Department of Developmental Therapeutics, University of Texas System Cancer Center M. D. Anderson Hospital and Tumor Institute, Houston, TX 77030.* Accepted for publication May 9, 1980.

Abstract □ The pharmacological disposition of four negatively charged phospholipid vesicles with radioactive cholesteryl oleate as a tracer was investigated in rats. The acidic phospholipids included phosphatidylserine, phosphatidylglycerol, phosphatidylinositol, and diphosphatidylglycerol (cardiolipin). The blood half-life of phosphatidylserine vesicles was the shortest (<2 min), while that of phosphatidylinositol was the longest (90 min). Cardiolipin and phosphatidylglycerol vesicles had intermediate blood half-lives (7 and 18 min, respectively). The distribution of these vesicles in six major organs (liver, spleen, heart, kidneys, lungs, and brain) varied greatly. Contrary to the long-held belief, it was possible to prepare negatively charged phospholipid vesicles with long blood half-lives. Furthermore, tissue disposition of these negatively charged vesicles could be manipulated partially by judicious selection of their components.

Keyphrases □ Phospholipid vesicles, negatively charged—tissue distribution in rats □ Drug delivery systems—negatively charged phospholipid vesicles, tissue distribution in rats

Phospholipid vesicles, or liposomes when in combination with several similar preparations, are small (20–50 nm in diameter), single-bilayered, aqueous dispersions of phospholipids (1). The solutes entrapped in the closed interior aqueous compartment of phospholipid vesicles are protected from reacting with exterior chemicals. This property makes phospholipid vesicles an ideal pharmaceutical system for the *in vivo* delivery of biologically active material to target cells (2–5).

BACKGROUND

The interaction between cells and phospholipid vesicles consists of two known mechanisms (6), endocytosis and membrane fusion. Cells can take up phospholipid vesicles *via* endocytosis, producing intracellular vesicles that subsequently are degraded through fusion with lysosomes. Alternatively, phospholipid vesicles can fuse directly with the cell membrane, and the contents become incorporated into the cytoplasm. In terms of therapeutic efficacy, membrane fusion offers certain pharmacological advantages. For example, in enzyme replacement therapy in the treatment of storage disease, vesicle-entrapped enzymes retain their activity if they do not encounter the catalytic proteases in lysosomes (4).

Negatively charged phospholipids are involved in cell membrane fusion (7, 8). Vesicles prepared with negatively charged phospholipids have been used successfully to deliver biologically active chemicals to cells in culture (9). However, difficulties frequently are encountered in the *in vivo* application of negatively charged phospholipid vesicles. In plasma (or any calcium-containing medium), negatively charged liposomes sometimes aggregate to form larger particles, which are removed rapidly from circulation by the reticuloendothelial system (10). In addition, various blood proteins interact with phospholipid vesicles, and phospholipid molecules from blood lipoproteins are apt to exchange with those of the phospholipid vesicles (11, 12). These complicated interactions are expected to influence the pharmacological fate of circulating phospholipid vesicles.

These considerations prompted an investigation of the pharmacokinetics of four negatively charged phospholipid vesicles in rats, particularly since negatively charged liposomes with long blood half-lives may have enhanced bioavailability to the target tissue.

EXPERIMENTAL

Chemicals—Phosphatidylserine[1] (bovine brain), phosphatidylglycerol[1], phosphatidylinositol[1], cardiolipin[1], cholesterol[2] (chromatographically pure), cholesteryl [1-^{14}C]oleate[3] (20 mCi/mmole), and ethylenediaminetetraacetic acid disodium salt[4] were used as received. All solvents were glass distilled[5].

Liposome Preparation—Well-characterized single-bilayer vesicles were prepared by the simple method of Batzri and Korn (13). A solution of 3.75 mg of the phospholipid, 1 mg of cholesterol, and 0.05 μmole of cholesteryl [1-^{14}C]oleate (1 μCi) in 0.5 ml of chloroform was dried first under a nitrogen stream at room temperature and then in a vacuum desiccator for 2 hr at 10^{-5} torr. This procedure was essential to obtain a consistent liposome preparation.

The lipid mixtures were dissolved in 100 μl of ethanol at 37°. The ethanolic lipid solution was added as a fine stream with a 100-μl gastight

microsyringe[6] to 2 ml of isotonic saline containing 10 m*M* ethylenediaminetetraacetic acid (pH 7.4) while being vortexed at 37°. Vesicles thus prepared were transparent and remained so for at least 10 hr at room temperature. However, in these experiments, liposomes always were prepared fresh on the day of use.

Pharmacokinetic Studies—Male Sprague–Dawley rats, 200–300 g, were used. Laboratory rat chow and water were provided freely. While the rat was under pentobarbital anesthesia, a 0.5-ml vesicle preparation was administered intravenously *via* the lateral tail vein. Blood samples of 100 μl were collected by clipping the tail at various intervals and then were combusted in a sample oxidizer[7]. The radioactive carbon dioxide was absorbed in 6 ml of a high-capacity carbon dioxide-absorbing solution[8], and this solution was diluted with an equal volume of xylene-based counting fluid[9]. The radioactivity of the samples was determined with a scintillation spectrometer[10]. Quenching was determined and corrected automatically with an external standard; the counting efficiency for carbon 14 was 95%.

After 90 min, the rat was killed by decapitation. The blood was drained, and the internal organs were removed, rinsed with deionized water, blotted with tissue paper, and weighed. Tissue samples were processed in the same manner as the blood except that 11 ml each of the carbon dioxide-absorbing solution and the counting fluid was used. In the phosphatidylserine study, three rats were killed at 20 min because of the short plasma half-life of the vesicles. The tissue disposition patterns were similar to those from rats killed at 90 min.

RESULTS AND DISCUSSION

The disappearance of the four negatively charged liposomes from the blood after a single intravenous administration is depicted in Fig. 1. Phosphatidylserine liposomes were eliminated quickly from the circulation; 4 min after liposome administration, the blood radioactivity decreased almost 10-fold, with the half-life estimated to be 1.2 min by nonlinear regression analysis. In contrast, phosphatidylinositol liposomes persisted much longer (half-life of 90 min); phosphatidylglycerol and cardiolipin liposomes showed half-lives of 18 and 7 min, respectively.

Table I summarizes the normalized percent distribution of radioactivity in six major organs 90 min after intravenous administration of the four liposomes. These results must be considered in light of the fraction of the administered dose recovered in these organs: 45% of phosphatidylserine, 70% of cardiolipin, 40% of phosphatidylglycerol, and 20% of phosphatidylinositol. Clearly, in all of the studies, the liver took up almost all of the radioactivity. However, although it was still high, the hepatic radioactivity of phosphatidylinositol was the lowest (87.4%) of the four liposomes. Since the recovery of the administered phosphatidylinositol also was the lowest (20%), the smallest amount of this liposome persisted in the liver 90 min after its administration.

As a major component of the reticuloendothelial system, the liver undoubtedly plays a critical role in the elimination of liposomes from the blood. Compared with the other three liposomes, phosphatidylinositol liposomes were taken up to the least extent by the liver. Consequently, their elimination from the blood is expected to be much slower than the elimination of the other liposomes. This finding is consistent with the observation that phosphatidylinositol showed the longest half-life in the blood *in vivo*.

The comparative distribution of liposomal radioactivity in the six organs is shown in Fig. 2, with the hepatic radioactivities normalized to 100%. Of the total administered radioactivity recovered, more phosphatidylinositol liposomes than any other liposomes were found in all organs except the spleen. This finding is attributed to the more protracted exposure of the organs to phosphatidylinositol liposomes due to the relatively long blood half-life of these liposomes.

The optimal application of liposomes to drug delivery depends on the mechanism of liposomal internalization. For encapsulated, biologically active chemicals that are resistant to liposomal enzyme catalysis, endocytosis may not be detrimental. However, for other drugs, particularly enzymes for replacement therapy, endocytosis may lead to their degradation by lysosomes. In contrast, fusion of the plasma membrane with liposomes can result in the release of encapsulated materials directly into the cytoplasm. Accordingly, membrane fusion would be preferred for liposomal delivery of drugs.

Negatively charged phospholipids are believed to be essential in the fusion process (8, 14). Tissue membranes that actively participate in fusion are high in negatively charged phospholipids, particularly in neural tissues in which exocytosis contributes significantly in neurotransmission (15). Liposomes recently were used as a model biomembrane system (16–18). The fusion of liposomes under defined conditions provides information on the nature of this process. Generally, the chemical properties of the phospholipid and the cation are critical to fusion. Of the

negatively charged phospholipids, phosphatidylserine fuses at the lowest cation concentration. Furthermore, among divalent cations, calcium is the most effective in inducing fusion. The free calcium concentration in plasma is ~1 m*M*. At this calcium concentration, phosphatidylserine vesicles alone, but not other negatively charged phospholipid vesicles, precipitate and cause disorganization of the membrane and leakage of the contents. This finding is consistent with the observation that the phosphatidylserine liposome blood half-life is <2 min, indicating that phosphatidylserine vesicles are not useful for drug delivery.

The various components in plasma may interact with liposomes. Some phospholipids exchange with blood lipoproteins and vesicles, and various apolipoproteins may bind to liposomes. These interactions must be quantified before a serious application of negatively charged liposomes to drug delivery can be attempted. The interactions between blood components and phosphatidylglycerol and cardiolipin liposomes probably account for their relatively short blood half-life. Although the pharmacological experiments were not designed to identify these interactions, the results suggested their existence.

Phosphatidylinositol liposomes were comparatively stable in the bloodstream since their half-life *in vivo* was the longest. Dapergolas *et al.* (19) showed that insulin encapsulated with phosphatidylinositol liposomes had hypoglycemic activity in rats when given orally. It is inferred that phosphatidylinositol liposomes can maintain their integrity in an extreme chemical environment. Because inositol, a carbohydrate, is highly hydrated in aqueous media, the bonded water molecules surrounding a phosphatidylinositol liposome may contribute to its low reactivity and thus sustain its long blood half-life.

In conclusion, based on pharmacokinetic observations of four negatively charged phospholipid vesicles in the rat, phosphatidylinositol vesicles clearly deserve further studies; they have a very long circulation half-life and a relative high uptake by organs in which the reticuloendothelial system plays a minor role.

High-Pressure Liquid Chromatographic Determination of Lidocaine and Its Active Deethylated Metabolites

JÉRÉMY HILL *, **ANDRÉ ROUSSIN** ‡, **JACQUES LELORIER** *‡x, and **GILLES CAILLE** *

Received January 22, 1980, from the *Department of Pharmacology, Faculty of Medicine, University of Montreal, Montreal, Quebec, Canada, and the ‡Department of Medicine, Hôtel-Dieu Hospital, Montreal, Quebec, Canada. Accepted for publication May 2, 1980.

Abstract □ A simple, specific, high-pressure liquid chromatographic method for lidocaine and its active dealkylated metabolites, monoethylglycinexylidide (I) and glycinexylidide (II), is described. Recoveries were 94% for lidocaine, 98% for I, 77% for II, and 99% for the internal standard, ethylmethylglycinexylidide (III). The sensitivity of the assay is 0.04 μg/ml. Coefficients of variation for day-to-day replicate analyses of lidocaine and the metabolites were <7%.

Keyphrases □ Lidocaine—high-pressure liquid chromatographic analysis, human plasma □ High-pressure liquid chromatography—analysis, lidocaine and active dealkylated metabolites, human plasma □ Antiarrhythmics—lidocaine, high-pressure liquid chromatographic analysis, human plasma

Lidocaine, a widely used antiarrhythmic drug, undergoes extensive metabolism in the liver. Two of its principal metabolites, monoethylglycinexylidide (I) and glycinexylidide (II), often are found in significant concentrations in plasma and both possess pharmacological and toxicological properties (1–4). The pharmacokinetic parameters of lidocaine are affected by disease states (5–7) as well as by the duration of the infusion (6, 8, 9). The elimination of I was shown to be reduced in heart failure (6, 10), and that of II was reduced in both renal (11) and heart (6) failure.

The wide interpatient variability of plasma lidocaine, I, and II levels (5, 10, 12), the narrow margin between therapeutic and toxic plasma lidocaine levels, and the possible contribution of I and II to the therapeutic and toxic effects of lidocaine warrant routine monitoring of plasma lidocaine, I, and II levels in patients receiving lidocaine infusions.

A simple, rapid, accurate, and specific analytical method for quantitating lidocaine, I, and II in plasma by high-pressure liquid chromatography (HPLC) is presented.

EXPERIMENTAL

Materials—The amounts and concentrations of lidocaine[1], I[1], II[1], and ethylmethylglycinexylidide[1] (III) are expressed as the free base. Hydrochloric acid[2] was ultrex grade. Phosphoric acid[3], monobasic potassium phosphate[3], and methylene chloride[3] were reagent grade. Acetonitrile[3] was HPLC grade.

Apparatus—The analyses were performed on a liquid chromatograph equipped with a variable-wavelength UV detector[4]. Separation was carried out on an RP-8 10-μm column[5]. The instrumental conditions included a mobile phase of 18% acetonitrile in 0.1 *M* phosphate buffer adjusted to pH 3.2 at a flow rate of 2 ml/min, and the detector was set at 195 nm.

Procedure—To 2 ml of plasma contained in a culture tube were added 0.1 ml of 0.5 *N* NaOH and 50 μl of the internal standard (III, 5 μg/100 μl). The solution was vortexed for 30 sec. Following the addition of 2.5 ml of methylene chloride, the mixture was shaken for 10 min on a reciprocating shaker and then centrifuged at 3500 rpm. The aqueous phase was discarded; the organic phase was dried over anhydrous sodium sulfate and transferred to a second culture tube, to which was added 0.5 ml of 0.01 *N* HCl. The mixture was shaken for 60 min on a reciprocating shaker and centrifuged, and 150 μl of the aqueous phase was injected into the chromatograph.

Standard samples were prepared by spiking human plasma with increasing concentrations of lidocaine (0.1, 0.4, 0.8, 2, 3, 4, and 5 μg/ml) and the metabolites (0.04, 0.16, 0.32, 0.8, 1.2, 1.6, and 2 μg/ml). Calibration curves, which were identical whether prepared in plasma or in water, were constructed by plotting the ratios of the peak heights of lidocaine, I, and II to the peak height of the internal standard against the concentrations of lidocaine, I, and II.

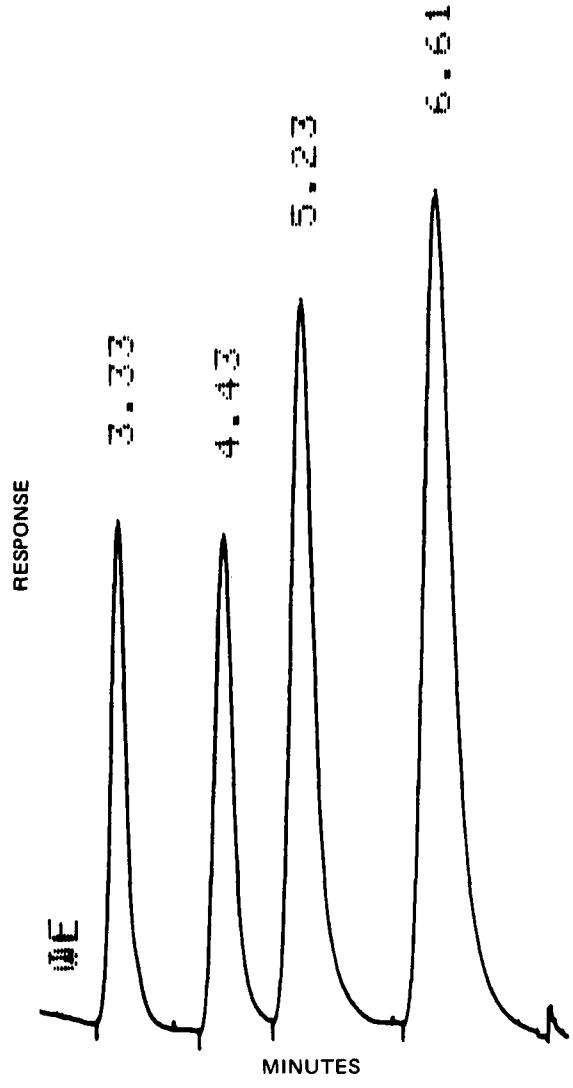

Figure 1—*Typical chromatogram. The retention times were 3.33 min for I (0.53 μg/ml), 4.43 min for II (0.60 μg/ml), 5.23 min for III, and 6.61 min for lidocaine (2.35 μg/ml).*

Table I—Day-to-Day Reproducibility

Compound	Plasma Concentration, μg/ml	n	CV, %
Lidocaine	2.0	22	4.8
	0.8	11	3.0
I	0.8	22	2.2
	0.32	11	4.1
II	0.8	21	3.5
	0.32	10	6.8

Analytical recovery of lidocaine and I–III was determined by comparing the peak areas obtained by direct injection of standard aqueous solutions with those obtained from the injection of the same standard solutions after running them through the extraction procedure. Three samples were run at each of the seven different concentrations.

Blood samples were obtained from 75 patients receiving lidocaine for therapeutic or prophylactic indications and were analyzed by both the presently described method and by a GLC method (13).

RESULTS AND DISCUSSION

The standard curves were linear throughout the ranges studied (r^2 = 0.998, 0.999, and 0.998 for lidocaine, I, and II, respectively). The average ($\pm SD$) analytical recoveries were 94.3 ± 3.4% for lidocaine, 98.4 ± 4.1% for I, 77.2 ± 2.7% for II, and 99.7 ± 2.1% for III. The retention times were 3.33, 4.43, 5.23, and 7.01 min for II, I, III, and lidocaine, respectively. The day-to-day reproducibility of replicate analyses of standard plasma samples containing different concentrations of lidocaine, I, and II is presented in Table I. A typical chromatogram is shown in Fig. 1.

Concomitantly administered drugs included digoxin, propranolol, procainamide, nitroglycerin, carbamazepine, diazepam, flurazepam, isosorbide dinitrate, chlorpropamide, dipyridamole, allopurinol, methyldopa, furosemide, spironolactone, sulfinpyrazone, hydrochlorothiazide, hydralazine, morphine, aspirin, and oxazepam. None interfered with the assay. The sensitivity of the assay is 0.04 μg/ml, and a concentration as low as 0.01 μg/ml can be detected in the plasma.

The least-squares regression analysis of the data for the GLC method (X) *versus* the presently described method (Y) gave the following results: Y intercept, 0.08; slope, 0.99; r^2, 0.99; and S_Y, 0.57. These results suggest that the HPLC method is relatively free of significant systematic errors (14).

Plasma levels of II in one patient whose myocardial infarction was complicated by severe heart failure rose progressively, attaining 3.2 μg/ml on the 5th day of continuous lidocaine therapy. The corresponding lidocaine and I levels were 2.4 and 0.5 μg/ml, respectively. The infusion rate was 20 μg/kg/min, and there were no signs of lidocaine toxicity. The relatively low lidocaine concentration in this patient was surprising since previous work in this (9) and other (6) laboratories indicated that both heart failure and prolonged infusions should produce plasma lidocaine concentrations of 4 μg/ml at an infusion rate of 20 μg/kg/min.

The highest level of I (1.5 μg/ml) recorded was in another myocardial infarction patient with heart failure after 19 hr of continuous lidocaine infusion (35 μg/kg/min). In this patient, the plasma lidocaine concentration was 5.2 μg/ml and the concentration of II was 0.70 μg/ml. Immediately after the sample was taken, the infusion was ceased, and samples were taken hourly (Fig. 2). The lidocaine concentration fell exponentially to 0.16 μg/ml after 12 hr ($t_{1/2}$, 141 min), and the concentration of I also appeared to decline exponentially, reaching 0.23 μg/ml after 12 hr. The concentration of II was still 0.59 μg/ml 12 hr later. The half-lives cannot be determined for the metabolites from the slopes of their plasma disappearance curves since they are both synthesized from lidocaine and eliminated during the sampling period. This patient recently had suffered a stroke, rendering evaluation of possible neurological toxic effects difficult.

The elevated levels of metabolites in heart failure were reported by other investigators. Prescott *et al.* (6) reported progressively rising I and II levels in patients in whom the myocardial infarction was complicated by heart failure. Halkin *et al.* (10) found higher I levels in patients with heart failure but did not measure II levels. Narang *et al.* (15) described one patient with mild congestive heart failure whose I level was 183% of that of lidocaine (lidocaine, 1.38 μg/ml; I, 2.53 μg/ml), thus contributing more than unchanged lidocaine to the antiarrhythmic effect.

Few conclusions can be drawn concerning the relative contributions of I and II to the pharmacological and toxic effects of lidocaine therapy because their concentrations have been measured in only a limited number of patients. The availability of this method, as well as other HPLC and GLC methods (15–19) that simultaneously measure lidocaine, I, and II, should result in further studies of lidocaine and its active metabolites.

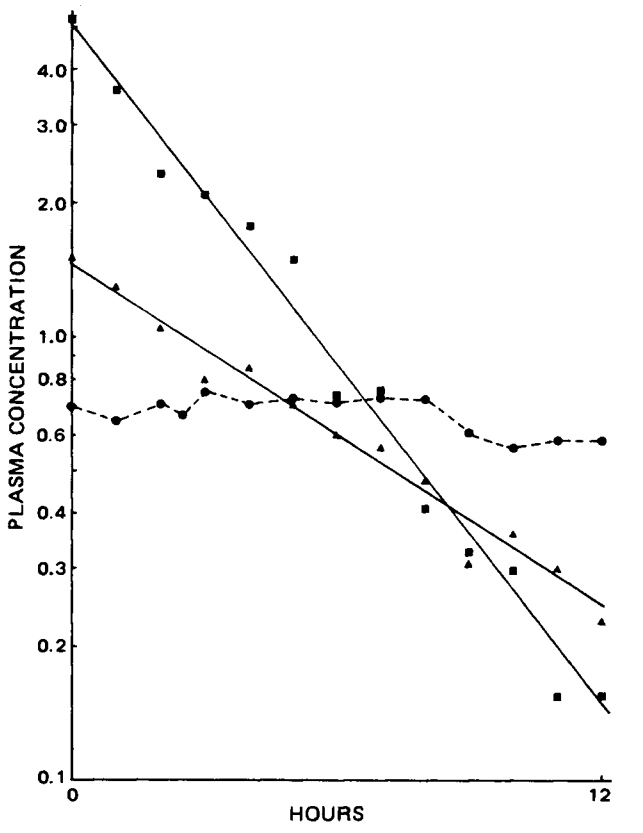

Figure 2—*Plasma concentrations of lidocaine (■), II (▲), and I (●) over the 12-hr period immediately following cessation of the lidocaine infusion.*

Synthesis and Structure–Activity Relationship of a Pyrimido[4,5-*d*]pyrimidine Derivative with Antidepressant Activity

J. L. BERNIER *x, J. P. HENICHART *, V. WARIN ‡, and F. BAERT ‡

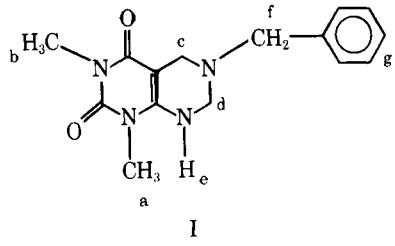
Received April 10, 1979, from **INSERM U16, Place de Verdun, 59045 Lille Cedex, France*, and the ‡*Laboratoire de Dynamique des cristaux moléculaires associé au CNRS (ERA 465), Bât. P.5, Université des Sciences et Techniques de Lille, 59650 Villeneuve d'Ascq, France.* Accepted for publication May 2, 1980.

Abstract □ The synthesis and antidepressant properties of a new pyrimido[4,5-*d*]pyrimidine are described. Spectral data determined in solution and in the solid state allowed establishment of the relationship between the activity and the conformation of the molecule. The spatial structure seems to be in accordance with a possible binding at the presynaptic α-receptor sites.

Keyphrases □ Pyrimido[4,5-*d*]pyrimidines—synthesis and evaluation for antidepressant activity, binding at presynaptic α-receptor sites, structure–activity relationships □ Structure–activity relationships—pyrimido[4,5-*d*]pyrimidines, synthesis and evaluation for antidepressant activity, binding at presynaptic α-receptor sites □ Antidepressant activity—pyrimido[4,5-*d*]pyrimidines, synthesis and evaluation for antidepressant activity, binding at presynaptic α-receptor sites, structure–activity relationships

The basic assumptions in the analysis of a structure–activity relationship are that the drug and the receptor exhibit mutual complementarity and that the study of drug conformation yields information relevant to the geometry of the binding sites of the receptors. As a continuation of studies on 1,3-dimethyl-2,4-dioxo-6-substituted octahydropyrimido[4,5-*d*]pyrimidines (1), the particular behavior of the 6-benzyl derivative (I) was evaluated. This compound appears to possess significant antidepressant activity. Antidepressant drugs containing the pyrimido[4,5-*d*]pyrimidine ring system have not been described. In addition, the apparent importance of the benzyl moiety[1] in inducing such properties prompted the establishment of relationships between three-dimensional molecular structure and pharmacological response.

The mechanism of action of antidepressant drugs has been studied recently (2). It is generally accepted that the therapeutic effect of antidepressant agents may be a consequence of an increased availability of norepinephrine at postsynaptic sites. A 3-week administration of tricyclic antidepressant drugs gradually decreased the sensitivity of the presynaptic α-receptor (3), which would explain the delay in the onset of the clinical effect. On the other hand,



I

the feedback inhibition of brain norepinephrine neurons by tricyclic antidepressants was due to an α-receptor mediation (4). This finding would explain the increase of the availability of norepinephrine at postsynaptic receptor sites after an antidepressant treatment. A correlation may be postulated between antidepressant activity and the action of the drug at the α-adrenergic receptors.

EXPERIMENTAL[2]

1,3-Dimethyl-2,4-dioxo-6-benzyl-1,2,3,4,5,6,7,8-octahydropyrimido[4,5-*d*]pyrimidine (I)—To an ethanolic solution of 9 g (0.06 mole) of 1,3-dimethyl-6-aminouracil were added successively 8.5 g (0.08 mole) of benzylamine and 12 ml of 35% aqueous formaldehyde (0.12 mole) solution. The mixture was stirred and heated under reflux for 2 hr and then concentrated *in vacuo* to dryness. The residual solid was washed with acetone and recrystallized from ethanol to give 14 g (81%) of white crystals. Further recrystallization from ethanol gave an analytical sample, mp 160°; IR(KBr pellets): 1630 and 1690 (C=O), 3150 (NH), and 2750 and 2810 (CH_2) cm^{-1}; PMR (dimethyl sulfoxide-d_6): δ 3.23 (s, 3H, CH_3a), 3.36 (s, 3H, CH_3b), 3.75 (s, 2H, CH_2c), 4.15 (d, 2H, CH_2d), 7.48 (t, 1H, J_{d-e} = 3 Hz, NHe), 3.56 (s, 2H, CH_2f), and 7.56 (s, 5H, phenyl g) ppm.

tinuously over 6 hr. Lethality and delayed effects were noted 24 hr after drug administration.

Tests for Neurological Deficit—*Activity Chambers (6)*—Sedative activity was measured in groups of 10 mice housed singly in photobeam cages. The number of beam interruptions occurring during the 60-min periods immediately prior to and after dosing was recorded.

Traction Test (7)—The percentage of mice unable to climb onto a wire and balance themselves within 5 sec after being suspended by the forepaws was determined 60 min after administration of the test compound.

Forced Motor Activity (8)—This activity was evaluated by the use of a rod revolving at 14 rpm. The number of mice remaining on the rod for >1 min was used as the measure.

Anticonvulsant Activity—*Convulsions from Pentylenetetrazol (9)*—Pentylenetetrazol was administered in a convulsifying dose (125 mg/kg ip) to groups of 10 mice pretreated for 1 hr with the test compound. Animals that did not have any tonic–clonic attack for 30 min after the pentylenetetrazol were considered to be protected.

Convulsions from Electroshock (10)—The effect of the compound on the maximal electroshock seizure was investigated in mice after intraperitoneal administration. The stimulation was carried out by means of corneal electrodes at 30 mamp for 0.2 sec. The percentage of mice protected from the tonic phase of the seizure was recorded.

Antipsychotic Activity (11)—The ability to reverse a conflict of motivation between exploration and punishment was assessed. The floor of the cage was divided into four plates. When a mouse went from one plate to another, it was subjected to an electrical shock.

Prevention of Prochlorperazine-Induced Catalepsy (12)—This measurement was used as an index of antidepressant activity. Groups of five rats were pretreated with prochlorperazine (10 mg/kg sc); 5.5 hr later, they were treated with the test compound having anticataleptic activity. The test compound was given again 0.5, 1.5, and 2.5 hr thereafter.

***d*-Amphetamine-Induced Lethality (13)**—*d*-Amphetamine-induced lethality was used to evaluate antipsychotic activity. Mice were medicated orally with test drugs 0.5 hr before intraperitoneal injection of *d*-amphetamine (20 mg of the free base/kg). Deaths were recorded during the following 4 hr.

RESULTS

The Irwin test (5) showed that I was not toxic up to 300 mg/kg po. No peculiar symptomatology was observed. Compound I had no effect on the motor activity for mice at a dose of 100 mg/kg (6). At the same dose,

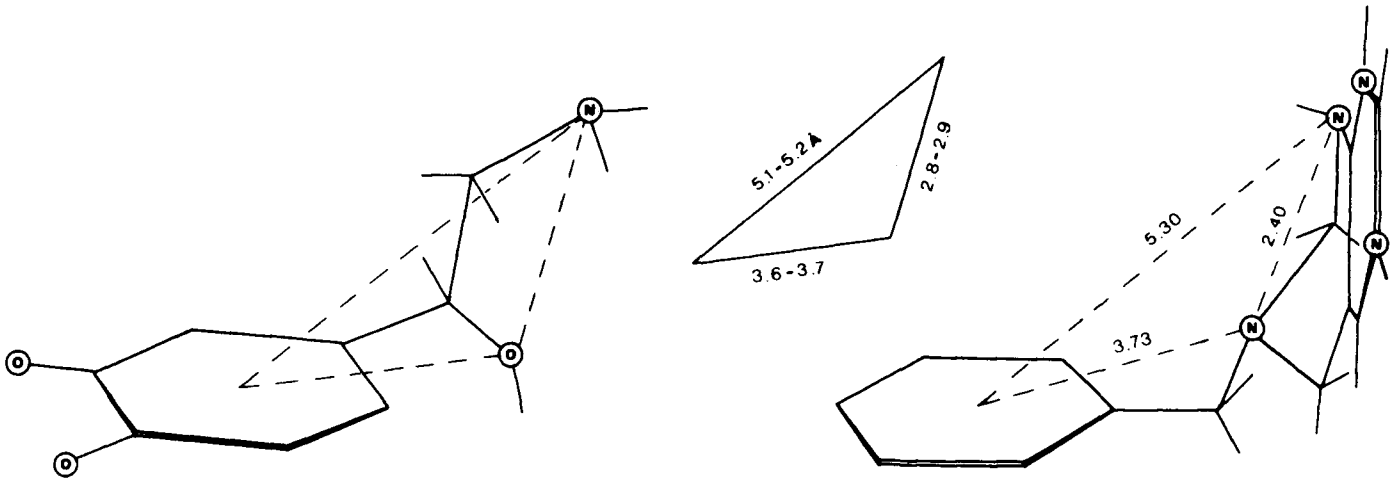

Figure 3—*Proposed binding mode at α-adrenergic receptor sites for norepinephrine and I.*

traction (7) and equilibration (8) reflexes were not changed, and pentylenetetrazol- or electroshock-induced convulsive effects (9, 10) were not antagonized. No anxiolytic activity was observed until 30 mg/kg was administered (11). No central anticholinergic action was noted at 100 mg/kg by the classical antipilocarpine test in rats (14).

Prochlorperazine-induced catalepsy (13) was inhibited at the ED_{50} value of 30 mg/kg ($p \leq 0.05$, Student t test). The amphetaminic group toxicity effect was potentiated at 50 mg/kg (13). Thus, the results reported here suggest that I may be a significant and selective antidepressant compound.

Structural Determinations—The crystal data were: space group P2/C; a = 7.109(3), b = 12.766(3), and c = 16.110(4) Å; β = 97.52(5); V = 1395.2 Å^3; Z = 4; D_c = 1.33; and R = 0.052.

The distances between the center of the phenyl ring and N-6 and N-8 atoms are 3.73 and 5.30 Å, respectively (Fig. 1). The interatomic distance[3] between N-6 and N-8 is 2.40 Å.

PMR Spectrographic Results—The shifts (expressed in δ parts per million using deuterated dimethyl sulfoxide as the solvent) (Fig. 2) corresponding to the methylene protons (c and d) of I were designed unambiguously and compared to shifts reported previously for other compounds (II and III) (1).

The chemical shifts of protons c and d unequivocally indicate that the anisotropic cone of the phenyl ring is closed to proton d (deshielding effect) and that, in solution, I exhibits a privileged conformation in accordance with that observed in the solid state.

DISCUSSION

A number of binding sites at the receptor are known to be important for α-adrenergic activity: the catechol moiety, the β-hydroxyl group, and the ammonium function (Fig. 3). The extended Hückel theory (16) and the perturbative configuration interaction using localized orbitals (17, 18) calculations have permitted postulation of the distance between the center of the aryl ring and the oxygen atom (3.6–3.7 Å), the center of the ring and the nitrogen atom (5.1–5.2 Å), and the nitrogen–oxygen distance (2.8–2.9 Å) as the main characteristics of the molecule binding the α-adrenergic receptor sites.

The spatial configuration of I fits this proposed model.

It can be concluded that I displays structural features making it suitable for binding the presynaptic receptor sites. Nevertheless, I cannot activate them; the bulky group attached to the nitrogen atom accounts for this inhibition. As such, when it partially occupies the site, it hinders the feedback inhibition of norepinephrine, increasing its release in the synaptic cleft. This effect could account for its pharmacological properties and provides information on the activity of certain antidepressant drugs.

[3] Full details concerning the crystallographic data (interatomic distances, angles, and coordinates) are available (15).

Effect of Sodium Oleate on Salicylic Acid Binding to Human Serum Albumin

PETER A. SCHWARTZ, DOUGLAS S. GREENE, and C. T. RHODES ˣ

Received January 3, 1980, from the *Department of Pharmacy, College of Pharmacy, University of Rhode Island, Kingston, RI 02881.* Accepted for publication May 19, 1980.

Abstract □ The pharmacological activity of salicylates is related to the nonprotein-bound fraction of drug in the plasma. Free fatty acids have been shown to displace bound drug and to increase the serum levels of salicylates. Continuous ultrafiltration was used to measure unbound salicylic acid at 37°. A nonlinear analysis of the ultrafiltration data using whole number values for the number of binding sites indicates that sodium oleate displaces the salicylic acid competitively at both binding sites. Increased concentrations of fatty acids due to disease or the infusion of fatty acid emulsions perhaps may produce toxic levels of salicylic acid.

Keyphrases □ Sodium oleate—effect on binding of salicylic acid to human serum albumin □ Salicylic acid—binding to human serum albumin, effect of sodium oleate □ Protein binding—effect of sodium oleate on binding of salicylic acid to human serum albumin

Since the pharmacological activity of many drugs is related to the non-protein-bound fraction of the drug in plasma (1–3), any decrease in the fraction of protein-bound drug may be expected to result in an increased pharmacological effect. Free fatty acids bind rapidly to albumin at more than one site (4–6), have a higher affinity for albumin than do most drugs (7, 8), and increase the concentration of unbound drug *in vivo* by displacement of

traction (7) and equilibration (8) reflexes were not changed, and pentylenetetrazol- or electroshock-induced convulsive effects (9, 10) were not antagonized. No anxiolytic activity was observed until 30 mg/kg was administered (11). No central anticholinergic action was noted at 100 mg/kg by the classical antipilocarpine test in rats (14).

Prochlorperazine-induced catalepsy (13) was inhibited at the ED_{50} value of 30 mg/kg ($p \leq 0.05$, Student t test). The amphetaminic group toxicity effect was potentiated at 50 mg/kg (13). Thus, the results reported here suggest that I may be a significant and selective antidepressant compound.

Structural Determinations—The crystal data were: space group P2/C; a = 7.109(3), b = 12.766(3), and c = 16.110(4) Å; β = 97.52(5); V = 1395.2 Å^3; Z = 4; D_c = 1.33; and R = 0.052.

The distances between the center of the phenyl ring and N-6 and N-8 atoms are 3.73 and 5.30 Å, respectively (Fig. 1). The interatomic distance[3] between N-6 and N-8 is 2.40 Å.

PMR Spectrographic Results—The shifts (expressed in δ parts per million using deuterated dimethyl sulfoxide as the solvent) (Fig. 2) corresponding to the methylene protons (c and d) of I were designed unambiguously and compared to shifts reported previously for other compounds (II and III) (1).

The chemical shifts of protons c and d unequivocally indicate that the anisotropic cone of the phenyl ring is closed to proton d (deshielding effect) and that, in solution, I exhibits a privileged conformation in accordance with that observed in the solid state.

DISCUSSION

A number of binding sites at the receptor are known to be important for α-adrenergic activity: the catechol moiety, the β-hydroxyl group, and the ammonium function (Fig. 3). The extended Hückel theory (16) and the perturbative configuration interaction using localized orbitals (17, 18) calculations have permitted postulation of the distance between the center of the aryl ring and the oxygen atom (3.6–3.7 Å), the center of the ring and the nitrogen atom (5.1–5.2 Å), and the nitrogen–oxygen distance (2.8–2.9 Å) as the main characteristics of the molecule binding the α-adrenergic receptor sites.

The spatial configuration of I fits this proposed model.

It can be concluded that I displays structural features making it suitable for binding the presynaptic receptor sites. Nevertheless, I cannot activate them; the bulky group attached to the nitrogen atom accounts for this inhibition. As such, when it partially occupies the site, it hinders the feedback inhibition of norepinephrine, increasing its release in the synaptic cleft. This effect could account for its pharmacological properties and provides information on the activity of certain antidepressant drugs.

[3] Full details concerning the crystallographic data (interatomic distances, angles, and coordinates) are available (15).

Effect of Sodium Oleate on Salicylic Acid Binding to Human Serum Albumin

PETER A. SCHWARTZ, DOUGLAS S. GREENE, and C. T. RHODES ˣ

Received January 3, 1980, from the *Department of Pharmacy, College of Pharmacy, University of Rhode Island, Kingston, RI 02881.* Accepted for publication May 19, 1980.

Abstract □ The pharmacological activity of salicylates is related to the nonprotein-bound fraction of drug in the plasma. Free fatty acids have been shown to displace bound drug and to increase the serum levels of salicylates. Continuous ultrafiltration was used to measure unbound salicylic acid at 37°. A nonlinear analysis of the ultrafiltration data using whole number values for the number of binding sites indicates that sodium oleate displaces the salicylic acid competitively at both binding sites. Increased concentrations of fatty acids due to disease or the infusion of fatty acid emulsions perhaps may produce toxic levels of salicylic acid.

Keyphrases □ Sodium oleate—effect on binding of salicylic acid to human serum albumin □ Salicylic acid—binding to human serum albumin, effect of sodium oleate □ Protein binding—effect of sodium oleate on binding of salicylic acid to human serum albumin

Since the pharmacological activity of many drugs is related to the non-protein-bound fraction of the drug in plasma (1–3), any decrease in the fraction of protein-bound drug may be expected to result in an increased pharmacological effect. Free fatty acids bind rapidly to albumin at more than one site (4–6), have a higher affinity for albumin than do most drugs (7, 8), and increase the concentration of unbound drug *in vivo* by displacement of

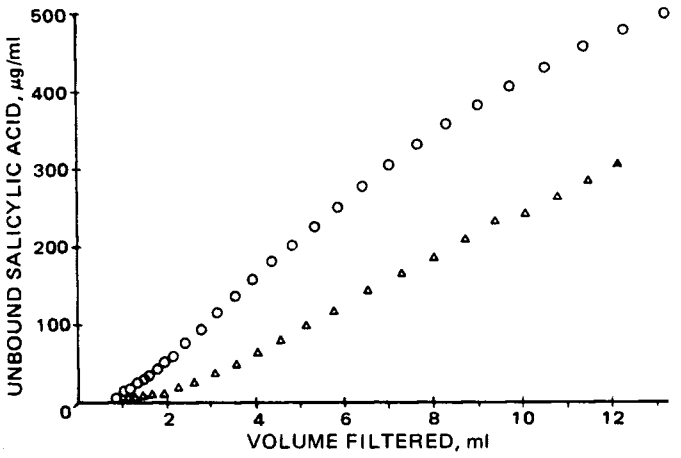

Figure 1—*Relationship between unbound salicylic acid and ultrafiltration volume for salicylic acid alone (△) and salicylic acid with 2.0 mEq of sodium oleate (○).*

bound drug (9, 10). Since salicylates can be relatively highly protein bound at certain concentrations (11–14), drug displacement due to elevated free fatty acid concentrations may have significant clinical implications (15).

Palmitic, oleic, and linoleic acids are the major free fatty acids present in serum (16, 17). Elevated concentrations of free fatty acids, *i.e.*, above the normal range of 0.3–0.8 mEq/liter, have been reported in renal disease (18), diabetes (19), hyperthyroidism (20), stress and exercise (21–23), myocardial infarction (24), and infection (25). Because free fatty acid increases are common in clinical practice and may result in significant drug displacement, the changes in salicylic acid binding in the presence of varying free fatty acid concentrations were investigated *in vitro* using human serum albumin at 37°.

EXPERIMENTAL

Human serum albumin[1] was prepared in pH 7.4 phosphate buffer at a physiological concentration of 4 g/100 ml. Salicylic acid[2] solutions were prepared in pH 7.4 phosphate buffer at concentrations between 700 and 800 μg/ml. Sodium oleate[3] was added to the human serum albumin to yield concentrations of 0.5, 1.0, 1.5, and 2.0 mEq/liter.

The bound fraction of drug was determined using continuous ultrafiltration (26). The salicylic acid solution was placed in the reservoir above the 25-mm ultrafiltration cell, equipped with a membrane having a 10,000 Dalton molecular weight cutoff[4]. The cell then was filled with either human serum albumin or a human serum albumin–sodium oleate mixture. The contents of the cell and reservoir were kept at 37° in a water bath.

The ultrafiltrate was collected under nitrogen (<20 psi) in tared, glass-stoppered test tubes at a flow rate of ~10 ml/hr. After an initial collection of 1 ml (to allow for the void volume), samples were collected and the collected filtrate volumes were determined by reweighing the tubes and converting weights to volumes, assuming a solution density of one (filtrate volumes varied between 0.1 and 0.7 ml).

Salicylate concentrations were determined spectrophotometrically at the absorption maximum of 295 nm from suitably diluted filtrate samples. A regression line of absorbance as a function of salicylate concentration was linear up to 40 μg/ml ($r = 0.999$, $n = 8$). A control study performed without protein showed no evidence of drug binding by the membrane or other parts of the cell.

The method of Greene and Nightingale (27) was used to calculate the number of binding sites and the affinity constants for each site. The raw data, *i.e.*, the filtrate concentration, C_f, as a nonlinear function of the volume filtered, V, were fitted using a computer[5] and the NONLIN program (28):

$$\frac{dC_f}{dV} = \frac{(C_r - C_f)/V_c}{1 + \frac{n_1K_1P}{(1 + K_1C_f)^2} + \frac{n_2K_2P}{(1 + K_2C_f)^2}} \quad \text{(Eq. 1)}$$

where C_r, V_c, and P are the reservoir concentration, ultrafiltration cell volume, and moles of protein, respectively.

All calculations were corrected by subtraction of the void volume from the total volume filtered (26). The void volume, V', was calculated using the NONLIN program to fit the following equation iteratively (27):

$$C_f = C_r - C_re^{\left(\frac{-V+V'}{V_c}\right)} \quad \text{(Eq. 2)}$$

Initial estimates of binding constants were obtained from the computer program MAP (28), which calculates the map of the sum of squares surface. All fits were obtained for a two-site model either with four parameters, *i.e.*, n_1, K_1, n_2, and K_2, or with two parameters, *i.e.*, K_1 and K_2, with whole numbers assigned to n_1 and n_2.

RESULTS AND DISCUSSION

The salicylic acid concentration in the ultrafiltrate is a nonlinear function of the volume filtered (Fig. 1). From these data, a Scatchard plot (Fig. 2) can be constructed using a mass balance analysis of the cell (29). Examination of the intercept on the r axis in Fig. 2 for salicylic acid alone and in the presence of 2.0 mEq of sodium oleate/liter suggests at least four salicylate binding sites on human serum albumin distributed between

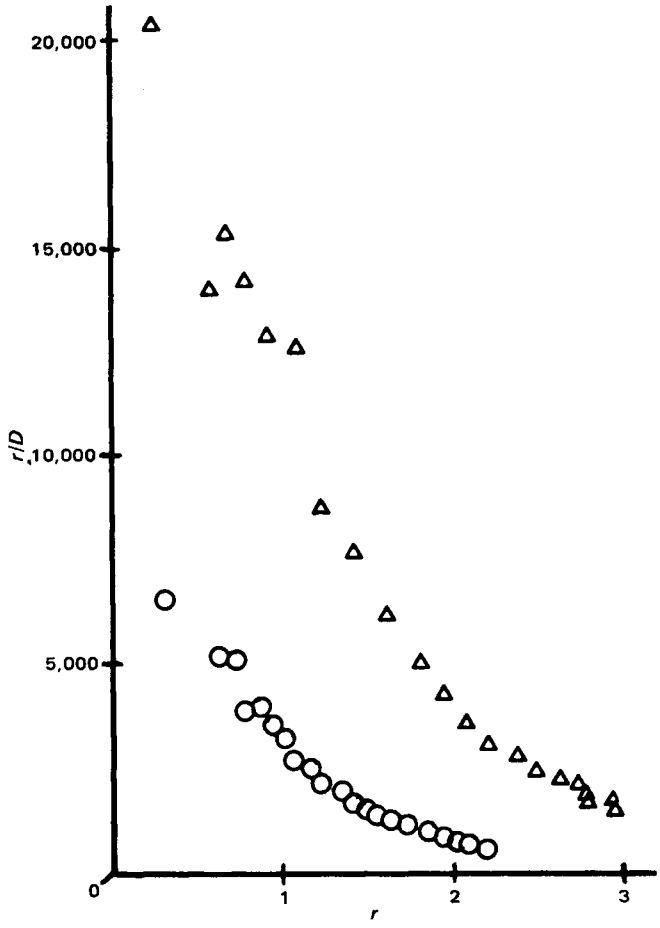

Figure 2—*Scatchard plot of salicylic acid binding. Key: △, salicylic acid alone; and ○, salicylic acid with 2.0 mEq of sodium oleate; r is the moles of salicylic acid bound per mole of human serum albumin and D equals moles of unbound salicylic acid.*

Table I—Scatchard Parameters for Salicylic Acid Binding to 4% Human Serum Albumin at 37°

Model	n_1	K_1, liters/mole	n_2	K_2, liters/mole
Unconstrained	1.33 (0.22)[a]	18,750 (10,600)	2.48 (0.21)	840 (310)
Constrained	2	7440 (2460)	2	430 (48)

[a] The standard deviation is given in parentheses.

two classes of sites. The data are quite clear for the systems that did not contain sodium oleate but are not unequivocal for the systems containing sodium oleate.

Table I lists the Scatchard parameters of a two-class binding model that were obtained by fitting the filtrate data as a function of volume to Eq. 1 using the NONLIN program. The estimates for these parameters are in reasonable agreement with those of other investigations at 37° (30, 31).

The NONLIN program can be modified to constrain the number of binding sites to whole numbers (32). The most likely combination of whole numbers of a two-class binding model, *i.e.*, n_1 and n_2, appears to be one of the following constrained systems: 1, 3; 1, 4; 1, 5; 2, 2; 2, 3; and 2, 4. The best-fit constrained model for the two binding sites (n_1 and n_2) using the criteria of smaller sums of squares was 2, 2. This result differs from a similar analysis of a Scatchard plot of salicylic acid binding to 0.3% human serum albumin at 25°, in which 1, 4 was reported for n_1 and n_2, respectively (32). The 2, 2 model also appeared to describe adequately the salicylic acid binding in the presence of 0.5–2.0 mEq of sodium oleate/liter.

Figure 3 demonstrates that the apparent dissociation constants for both classes of binding sites decreased apparently linearly with increasing oleate concentration. Decreased affinity for binding without a change in the number of binding sites also was shown for diazepam in the presence of oleic acid (10).

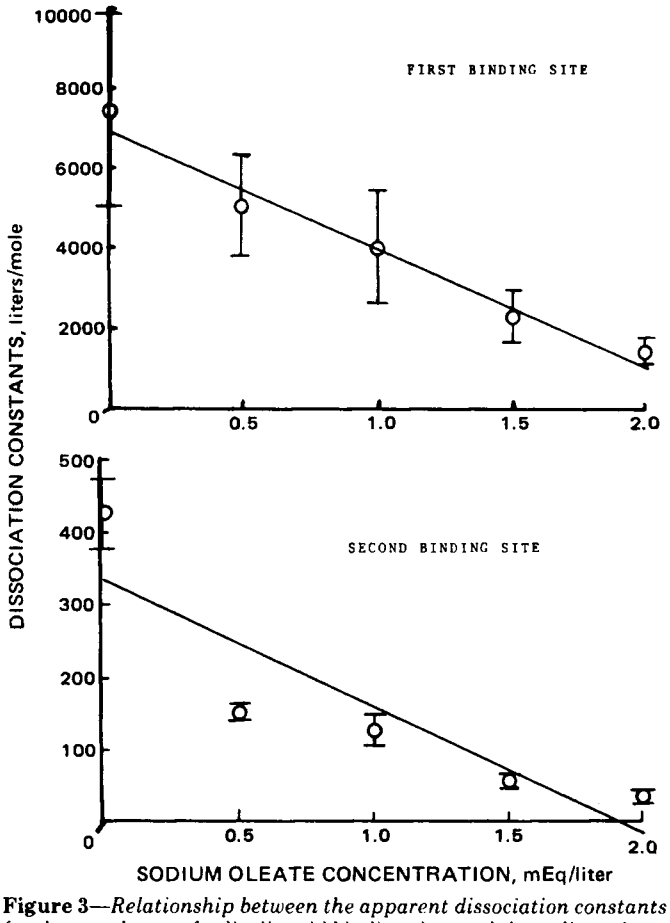

Figure 3—*Relationship between the apparent dissociation constants for the two classes of salicylic acid binding sites and the sodium oleate concentration.*

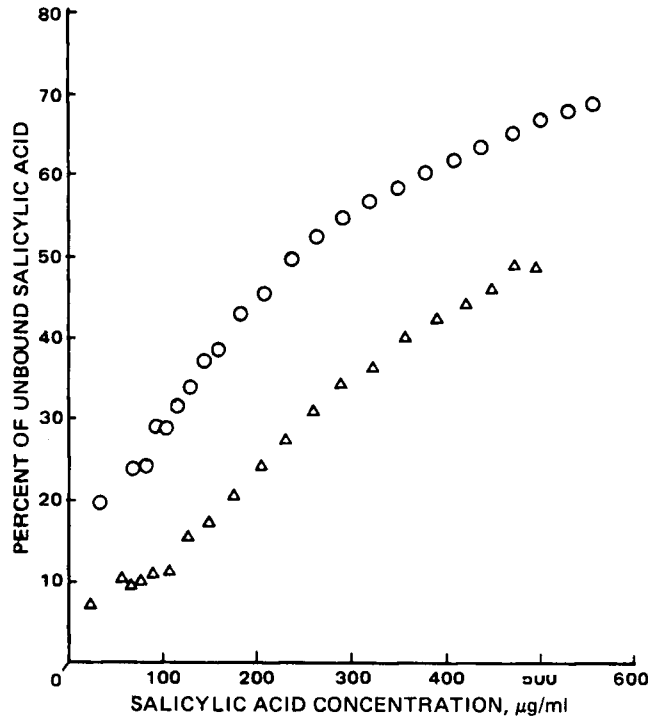

Figure 4—*Relationship between the percent of unbound salicylic acid and the total drug concentration. Key: △, salicylic acid alone; and ○, salicylic acid with 2.0 mEq of sodium oleate.*

Oleic acid appears to alter the binding affinity for salicylic acid to human serum albumin without affecting the number of binding sites. Similar competitive effects of free fatty acids on the binding of salicylic acid and other drugs have been attributed to allosteric conformational changes of protein molecules (32).

The unbound percent of salicylic acid as a function of total drug concentration calculated from the mass balance of cell contents is shown in Fig. 4. A twofold increase in the percent unbound salicylic acid, *i.e.*, from ~20 to 40%, occurred at oleic acid levels of 2.0 mEq/liter, as compared to normal free fatty acid levels of ~0.5 mEq/liter.

This investigation was purely *in vitro* in nature, and there always is an uncertainty in any attempt to extrapolate *in vitro* data to *in vivo* clinical situations. However, it is known that the toxic effects of salicylic acid are related to its unbound concentration, the dose-related volume of distribution, and the clinical status of the patient, *e.g.*, acidosis (15). Since salicylic acid binding can be reduced considerably by elevation of the free fatty acid level, any substantial increase in free fatty acids due to disease or the use of fatty acid emulsion infusions may perhaps be potentially clinically relevant. Since salicylic acid has a quite high therapeutic ratio, the effect may not be hazardous; however, it would be desirable to study the effects of the free fatty acid concentration on several strongly bound drugs with low therapeutic indexes.

Novel Potential Anticancer Agents Derived from Benzimidazole

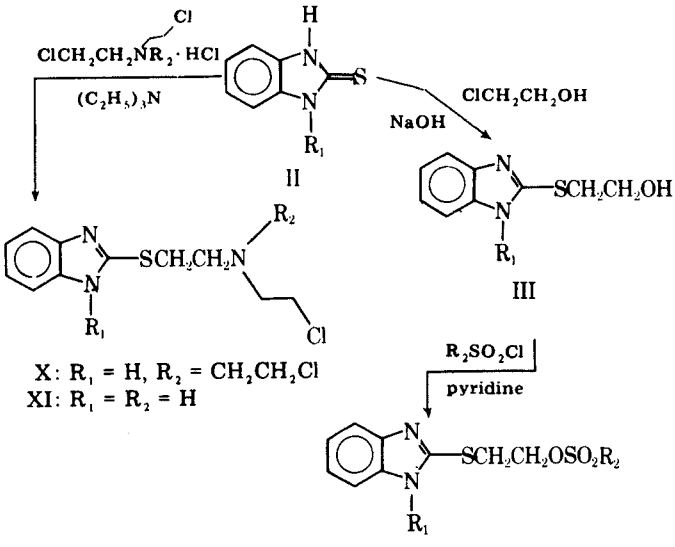
EL-SEBAII A. IBRAHIM, A.-MOHSEN M. E. OMAR ˣ, and M. A. KHALIL

Received March 4, 1980, from the *Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.* Accepted for publication May 20, 1980.

Abstract □ Two novel series of benzimidazole derivatives bearing structural modifications of certain drugs were prepared for evaluation for potential anticancer activity. The first series was a group of alkylating agents, and the second series was a variety of 4-substituted-1-thioacetyl-3-thiosemicarbazides. The tests of some representative products for antileukemic activity against P-388 lymphocytic leukemia indicated no significant effects.

Keyphrases □ Antineoplastic agents, potential—benzimidazole sulfonic esters and nitrogen mustards, synthesis and evaluation for antileukemic activity □ Benzimidazole derivatives—sulfonic esters and nitrogen mustards, synthesis and evaluation for anticancer activity

Among the benzimidazole alkylating agents whose syntheses have been described (1–5), only 2-[bis(2-chloroethyl)aminoethyl]benzimidazole (benzimidazole mustard NSC 23891, I) has shown pronounced anticancer activity (6, 7). Interest in the effect of structural modification on the anticancer activity of such compounds prompted the synthesis of benzimidazole sulfonic esters (IV–IX) and nitrogen mustards (X and XI) (Scheme I), in which the thioethyl chain replaced the methylenic group in I. In addition, 4-substituted-1-(2-mercaptoacetylbenzimidazole)-3-thiosemicarbazides (XIV–XX) (Scheme II) were prepared to compare their anticancer properties with those reported for some heterocyclic α-formylthiosemicarbazone derivatives (8–11).



Scheme I

RESULTS AND DISCUSSION

Chemistry—The sulfonic esters (IV–IX) were prepared starting with *S*-alkylation of benzimidazole-2-thione or the 1-substituted derivatives (II) with ethylene chlorohydrin in the presence of potassium hydroxide, followed by treatment of the resulting alcohols (III) with methanesulfonyl chloride or *p*-toluenesulfonyl chloride and pyridine (12) (Scheme I). When the 1-position in the alcohols (III) was vacant, the reactions proceeded with the production of the disulfonated products (VIII and IX) (Table I). The bi- and monofunctional nitrogen mustards (X and XI) were synthesized by reacting benzimidazole-2-thione with a mixture of tris(2-chloroethyl)amine hydrochloride or bis(2-chloroethyl)amine hydrochloride and triethylamine in absolute ethanol.

Treatment of benzimidazole-2-thione (II) with ethyl bromoacetate gave

the corresponding *S*-alkyl ester (XII) (13), which, on reaction with hydrazine hydrate in ice, yielded benzimidazole-2-mercaptoacetohydrazide (XIII) (13). Heating this acid hydrazide with the equivalent amount of alkyl-, aryl-, or aralkylisothiocyanates in refluxing ethanol (14) produced the required 4-substituted-1-(2-mercaptoacetylbenzimidazole)-3-thiosemicarbazides (XIV–XX) (Scheme II and Table II). The new products were identified by microanalysis and IR spectra and, for some representative compounds, by PMR and mass spectra.

Anticancer Screening—Compounds IV–VIII, X, XI, XIV–XVI, and XX were evaluated against P-388 lymphocytic leukemia in mice[1]. The activities were measured as the ratio of the mean survival time of the test animals to that of the control animals expressed as a percentage (% T/C). All compounds tested were inactive since their % T/C values were <125.

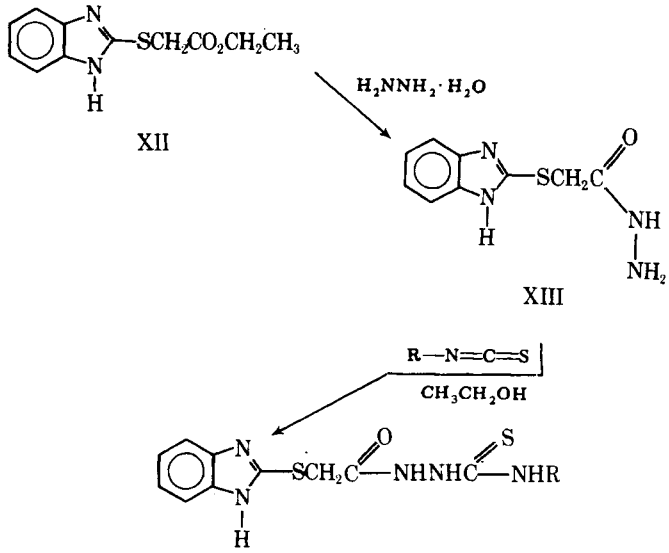
The inactivity of the synthesized alkylating agents was assumed to be due to the presence of sulfur in the thioethyl chain separating the alkylating function from the benzimidazole ring. This assumption is supported by the fact that no loss in carcinostatic activity or therapeutic index was observed when the methyl group in methylbis(2-chloroethyl)amine (HN_2 NSC 762) was replaced by a longer or more complex substituent (7). On the other hand, the lack of anticancer activity of the thiosemicarbazides (XIV–XX) was attributed to their inability to form the tridentate ligands (15) with the iron required by ribonucleoside diphosphate reductase; as a result, they cannot block DNA synthesis.

EXPERIMENTAL[2]

2-(2-Hydroxyethyl)thiobenzimidazole and Corresponding 1-Methyl- and 1-Benzyl Derivatives (III)—Ethylene chlorohydrin (7 g, 0.1 mole) was added dropwise to an ice-cold solution of benzimidazole-2-thione (II) (0.1 mole) in 12% KOH (40 ml). The mixture was stirred for 3 hr and set aside overnight at room temperature. The separated products were crystallized from ethanol or aqueous ethanol, identified by their IR spectra, and used for the preparation of the sulfonic esters; IR (mineral oil): 3175 (associated OH and NH), 1620 (C=N), 1510 (δ NH), 1265 (OH, out of plane bending), and 1065 (C–O) cm^{-1}.

1-Substituted-2-(alkyl or arylsulfonoxyethyl)thiobenzimidazoles (IV–IX)—Methanesulfonyl chloride or *p*-toluenesulfonyl chloride (0.3 mole) was added to a well-stirred and cooled (ice–salt bath) solution of the 2-(2-hydroxyethyl)thiobenzimidazoles (III) in dry pyridine (10 ml). Stirring was continued for 3 hr, and the mixture was left in the refrigerator overnight. Sufficient ice-cold water was added with vigorous stirring. The separated products were filtered, washed well with water, and crystallized from a benzene–light petroleum mixture. The yields and physical constants of the products are given in Table I; IR (KBr): 1355 and 1170 (asymmetric and symmetric SO_2) cm^{-1}; PMR for V (deuterochloroform): δ 2.29 (s, 3H, aromatic CH_3), 3.89 (s, 3H, *N*-CH_3), 4.38–4.62 (m, distorted, 2H, *S*-CH_2), 4.80–5.25 (m, distorted, 2H, CH_2OSO_2), and 6.89–7.81 (m, 8H, aromatic H) ppm.

2-[2-[Bis(2-chloroethyl)amino]ethyl]thiobenzimidazole Hydrochloride (X)—A mixture of benzimidazole-2-thione (0.45 g, 0.003 mole), tris(2-chloroethyl)amine hydrochloride (0.72 g, 0.003 mole), and triethylamine (0.3 g) in absolute ethanol (20 ml) was heated under reflux for 6 hr. The separated product was filtered and crystallized from absolute ethanol as white crystals, 0.55 g (72%), mp 223–225°; TLC: R_f 0.53



XIV: R = *n*-C_4H_9

Scheme II

[1] Assays were performed in accordance with the protocol of the Drug Evaluation Branch, National Cancer Institute, Bethesda, MD 20014. The compounds, dissolved or suspended in saline with Tween 80, were given as intraperitoneal injections 24 hr after tumor implantation in BDF_1 male and female mice. With a multiple-dose assay, the antileukemic activity of the products was evaluated on Day 30 after tumor implantation.

[2] All melting points are uncorrected. IR spectra were measured on a Beckman 4210 IR spectrophotometer. PMR and mass spectra were measured at Janssen Pharmaceutica Laboratories, Belgium.

Electron-Capture GLC Determination of Clobazam and Desmethylclobazam in Plasma

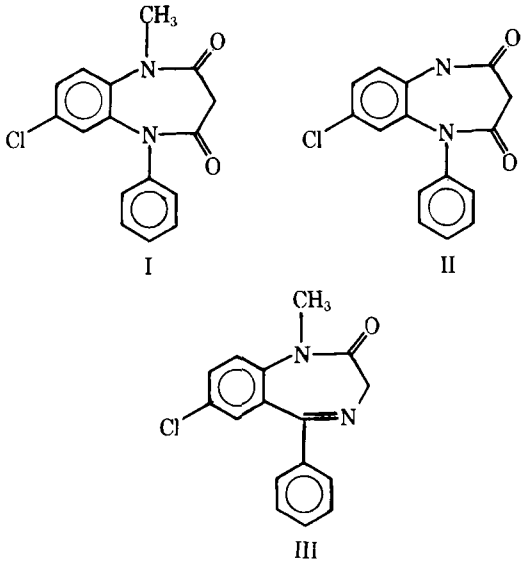
DAVID J. GREENBLATT

Received November 13, 1979, from the *Division of Clinical Pharmacology, Tufts-New England Medical Center, Boston, MA 02111.* Accepted for publication May 6, 1980.

Abstract □ Electron-capture GLC was utilized for simultaneous quantitation of clobazam, a 1,5-benzodiazepine derivative, and its active metabolite, desmethylclobazam, in human plasma and serum. After addition of diazepam as the internal standard, samples were extracted into benzene–isopentanol. The organic extracts were evaporated to dryness, reconstituted, and subjected to chromatographic analysis without derivatization or cleanup. All three compounds were resolved completely and had favorable chromatographic properties using an OV-101 liquid phase. The limits of detection are 3–5 ng/ml for clobazam and 5–10 ng/ml for desmethylclobazam. Relative standard deviations for identical samples do not exceed 6%. The application of the method to a clinical pharmacokinetic study is demonstrated.

Keyphrases □ Clobazam—electron-capture GLC analysis with desmethylclobazam, human plasma □ Desmethylclobazam—electron-capture GLC analysis with clobazam, human plasma □ GLC, electron capture—analyses, clobazam and desmethylclobazam, human plasma

Clobazam (I) is a 1,5-benzodiazepine derivative utilized as a sedative and antianxiety agent (1–3). The major metabolic pathway of clobazam in humans appears to involve hepatic *N*-demethylation, yielding desmethylclobazam (II) (4). This metabolite also has pharmacological activity (5). The present report describes a rapid and sensitive method for simultaneous quantitation of clobazam and desmethylclobazam in plasma following therapeutic doses of the parent compound.



EXPERIMENTAL

Apparatus and Chromatographic Conditions—The analytical instrument was a gas chromatograph[1] equipped with a 15-mCi ^{63}Ni-electron-capture detector and an electronic integrator. The column was coiled glass (122 cm long × 4 mm i.d.) packed with 10% OV-101 on 80–100-mesh Chromosorb WHP[2]. The carrier gas was argon–methane[3] (95:5) at a flow rate of 25 ml/min. The operating temperatures were: injection port, 310°; column, 265°; and detector, 320°. At the beginning of each workday, the column was primed by injection of 2–3 μl of a solution of azolectin[4] (1 mg/ml) in benzene.

Preparation of Stock Solutions—Clobazam[5] and desmethylclobazam[5] (10 mg) each were dissolved in 2–3 ml of absolute ethanol and diluted to 100 ml with benzene. The stock solution, containing 100 μg/ml, were stored in amber bottles at −4°. Freezing of the stock solutions is recommended because desmethylclobazam may deteriorate when stored unfrozen. Diazepam[6] (III) served as the internal standard in all analyses, and the stock solution of diazepam was prepared similarly.

Working standards, containing 1.0 μg of each compound/ml, were prepared daily by appropriate dilution with benzene or toluene.

Preparation of Samples—A constant amount (100 μl) of a 1-μg/ml working solution of the internal standard was added to round-bottom 13-ml glass culture tubes equipped with polytef-lined screw-top caps. The solutions were evaporated to dryness at 40–50° under mildly reduced pressure in a vacuum oven. Calibration standards were prepared by addition of known amounts of clobazam and desmethylclobazam, ranging from 25 to 300 ng, to some of these tubes. The solvents again were evaporated to dryness.

One milliliter of drug-free control plasma was added to each calibration tube, and 0.5–1 ml of unknown plasma was added to each tube that contained only the internal standard. The calibration standards were extracted and analyzed daily together with each set of unknowns. Samples found to contain clobazam or desmethylclobazam concentrations exceeding the limits of the standard curve were reextracted using a smaller aliquot of plasma.

Extraction—To each tube was added 3–5 ml of benzene (containing 1.5% isopentanol to minimize adherence to glassware). The tubes were agitated for 30 sec on a vortex-type mixer and then centrifuged at room temperature for 10 min at 400×*g*. An aliquot of the organic layer was transferred to another tube and evaporated to dryness at 40° under mildly reduced pressure. The residue was redissolved in 100–200 μl of toluene (containing 15% isopentanol), of which 1–6 μl was injected into the chromatograph.

Clinical Pharmacokinetic Study—A healthy 30-year-old male volunteer participated after giving informed consent. After an overnight fast, a single 20-mg dose of clobazam (two 10-mg tablets) was administered with 150 ml of water. Venous blood samples were drawn into heparinized tubes at multiple time points over the next 168 hr. Plasma was separated and frozen until it was assayed. Plasma concentrations of clobazam and desmethylclobazam were determined as described.

The apparent elimination half-life of clobazam during the terminal (β) phase of the plasma concentration curve was determined by least-squares regression analysis.

RESULTS

Evaluation of Method—Under the described chromatographic conditions, the approximate retention times were: diazepam, 5.5 min; clobazam, 7.4 min; and desmethylclobazam, 8.8 min (Fig. 1).

The relation between the plasma concentration of clobazam or desmethylclobazam and the peak area ratio[7] of each compound to the internal standard was linear through plasma concentrations of at least 300 ng/ml (Table I). The relative standard deviations (*RSD*) for replicate

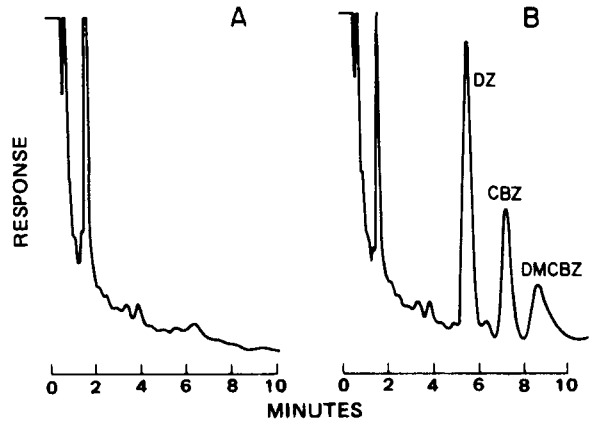

Figure 1—*Chromatogram of a drug-free control plasma extract (A) and chromatogram of the same plasma sample to which was added: diazepam (DZ), 100 ng/ml; clobazam (CBZ), 50 ng/ml; and desmethylclobazam (DMCBZ), 50 ng/ml (B). The chromatographic conditions are given in the text.*

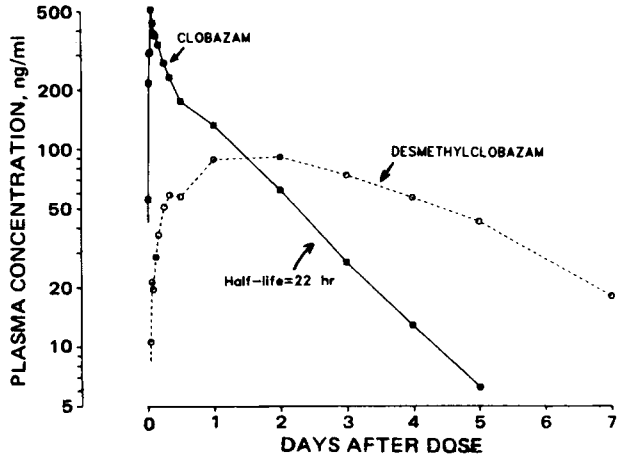

Figure 2—*Plasma concentrations of clobazam and desmethylclobazam over 168 hr after a single 20-mg oral dose of clobazam administered to a healthy male volunteer.*

samples (n = 10) containing 25 ng of clobazam and desmethylclobazam/ml were 1.8 and 5.4%, respectively. At 50 ng/ml, the *RSD* values were 2.5 and 2.9%. The approximate detection limits were 3–5 ng/ml of original sample for clobazam and 5–10 ng/ml of original sample for desmethylclobazam; below these limits, the *RSD* values exceeded 10%. Residue analysis indicated that recovery of clobazam, desmethylclobazam, and diazepam was >95% complete and independent of concentration.

Plasma samples from patients receiving clobazam are stable at room temperature for at least 24 hr. Freezing is recommended for prolonged storage. Plasma extracts also are stable at room temperature and can be stored frozen after reconstitution. Samples are not sensitive to ambient light or to temperatures of <40°.

Pharmacokinetic Study—A peak plasma clobazam concentration of 510 ng/ml was reached at 1.5 hr after dosage (Fig. 2). The elimination half-life during the terminal (β) phase of the curve was 22 hr. Disappearance of clobazam was mirrored by formation of its metabolic product. The highest desmethylclobazam concentration was 91 ng/ml, which was reached 48 hr after clobazam dosage.

DISCUSSION

The sensitivity and specificity of the electron-capture detector have facilitated development of quantitative assays for a number of benzodiazepines in human blood and plasma following therapeutic doses (6–10). The present report describes the application of this approach to the simultaneous quantitation of clobazam and its major pharmacologically active metabolite, desmethylclobazam. Preliminary studies in this laboratory suggested that phenyl methyl silicone liquid phases (such as OV-17) could be used for this purpose. However, chromatographic peaks for the desmethyl metabolite were asymmetric, thereby complicating reliable quantitation. Utilization of a less polar silicone phase (OV-101) substantially improves the chromatographic properties of desmethylclobazam but still allows complete resolution of clobazam and its metabolite from the internal standard and from endogenous plasma contaminants, provided a relatively high phase load (10%) is used.

The clinical pharmacokinetic study illustrates that the method is suitable for pharmacokinetic studies of clobazam and its metabolite following single therapeutic doses. Absorption of clobazam following oral dosage in the fasting state was rapid, with the peak plasma concentration attained 1.5 hr after administration. Clobazam elimination proceeded with a half-life of 22 hr and was mirrored by the formation of desmethylclobazam, which, in turn, was eliminated more slowly than the parent drug. Since both compounds have pharmacological activity, plasma concentrations of both compounds must be measured simultaneously and considered to elucidate the clinical implications of the kinetic properties of clobazam.

Table I—Representative Calibration Data

Concentration, ng/ml	Area Ratio	
	Clobazam	Desmethylclobazam

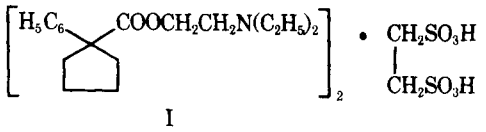
Use of Nitrogen-Specific Detector for GLC Determination of Caramiphen in Whole Blood

P. LEVANDOSKI ˣ **and T. FLANAGAN**

Received March 10, 1980, from *Smith Kline and French Laboratories, Philadelphia, PA 19101.* Accepted for publication May 27, 1980.

Abstract □ A sensitive GLC determination of caramiphen in whole blood was developed using a nitrogen-specific detector. The method permits the determination of levels of caramiphen as low as 2.5 ng/ml of blood and provides sufficient sensitivity and reproducibility for clinical use.

Keyphrases □ Caramiphen—analysis in whole blood by GLC with nitrogen-specific detector □ GLC—analysis, caramiphen, nitrogen-specific detector □ Antitussives—caramiphen, GLC analysis in whole blood with nitrogen-specific detector



I

Caramiphen ethanedisulfonate[1] (β-diethylaminoethyl 1-phenylcyclopentane-1-carboxylate ethanedisulfonate, I) is an antitussive used as an active ingredient in cough/cold preparations.

A sensitive determination of caramiphen in blood was developed to support clinical studies. The use of a nitrogen-specific detector was proven to be specific and sensitive for other nitrogen-containing compounds in this laboratory and in reported methods for imipramine and desipramine (1), pemoline (2), and bucainide (3).

EXPERIMENTAL

Reagents—Hexane[2] was nanograde, and methanol[3] and sodium hydroxide[4] were reagent grade. Diphenylpyraline hydrochloride[5] was used as the internal standard.

All glassware was washed with chromic acid, silanized with 5% dichlorodimethylsilane[6] in toluene, and rinsed with toluene and then methanol.

Instrumentation—The gas chromatograph[7] was equipped with a nitrogen–phosphorus flame-ionization detector and a 1-mv recorder. The chromatograph was fitted with a 183-cm × 4-mm i.d. coiled glass column packed with 3% OV-17 on 80–100-mesh Chromosorb WHP[6]. The column was conditioned overnight at 310° with a helium flow and several 25-μl injections of a silylating agent[8]. Normal operating temperatures were 270, 300, and 300° for the oven, injection port, and manifold, respectively. The recorder speed was 20 mm/min. Helium was used as the carrier gas at a flow rate of 60 ml/min. The air gauge was set at 3.5 kg/cm². The detector was run in the nitrogen mode at a setting of 710.

Preparation of Standards—Standard stock solutions of 10 mg/100 ml (as the free base) of caramiphen and the internal standard were pre-

pared in methanol. A working internal standard solution (0.5 μg/ml) was prepared by diluting 1 ml of the stock solution to 200 ml with distilled water. A working standard caramiphen solution (100 ng/0.1 ml) was prepared by diluting 1 ml of the stock solution to 100 ml with distilled water.

Extraction Procedure—Aliquots of 0, 12.5, 25, 50, 75, 100, 150, 200, 300, and 400 μl of the working standard solution of I were added to 5 ml of blank whole blood in 12-ml silanized test tubes. A 0.5-ml aliquot of the working internal standard solution was added to each tube. These samples were used to generate a standard curve. A 0.5-ml aliquot of the internal standard solution was added to all unknown samples (5-ml aliquots).

The pH was adjusted to 9.0 with 5% NaOH. A 1-ml aliquot of hexane was added, and the tubes were stoppered and shaken slowly (65 shakes/min) on an automatic shaker[9] for 30 min and centrifuged[10] for 10 min. The hexane layer was transferred to a second 12-ml silanized test tube, and the blood was extracted with another 1-ml aliquot of hexane with shaking for 30 min and centrifugation for 10 min. The second hexane extract was added to the first extract, and the combined solution was evaporated to dryness under a nitrogen stream. The residue was dissolved in 25 μl of methanol. Aliquots (2 μl) were injected into the gas chromatograph.

Calculations—A calibration curve was constructed by plotting the peak height ratio of caramiphen to the internal standard against the blood concentration of caramiphen on linear coordinate paper. Unknown values were read from the calibration curve.

RESULTS AND DISCUSSION

Figure 1 is a typical chromatogram of a spiked blood sample used for the standard curve. The peak at 1.6 min represents 20 ng of caramiphen/ml, and the peak at 2.7 min represents the internal standard (total of 250 ng added).

Spiked standards over the range of 2.5–40 ng/ml were analyzed. Table I shows the standard deviation and standard error obtained.

The assay sensitivity was <2.5 ng/ml of blood. Calibration curves were linear over the range of 2.5–80 ng of caramiphen/ml of blood.

Caramiphen is stable in frozen whole blood specimens for at least 1 week. Its stability was not studied beyond this period.

After overnight fasting, 11 subjects received 20 mg of caramiphen edisylate (plain drug in capsule) at 0, 4, and 8 hr daily for 4 consecutive days. On the 4th day, blood was drawn in heparinized syringes at 0, 1, 2, 4, 5, 6, 8, 9, 10, 13, 18, and 24 hr. The levels of caramiphen found are shown in Table II.

All 11 blood samples were screened before drug administration, and no interference peaks appeared in the area of caramiphen or its internal standard. These control bloods were spiked with the caramiphen standards and the internal standard. Based on these studies, the method was judged as specific for the determination of caramiphen in blood from controlled clinical studies when the subjects were free from other medication.

The sensitivity, reproducibility, and specificity make this method desirable for bioavailability and pharmacokinetic studies.

Comparative Plasma Salicylate and Urine Salicylurate Levels following Administration of Aspirin, Magnesium Salicylate, and Choline Magnesium Trisalicylate

WILLIAM D. MASON

Received April 25, 1980, from the *Pharmacokinetics Laboratory, Schools of Pharmacy and Medicine, University of Missouri-Kansas City, Kansas City, MO 64108.* Accepted for publication May 23, 1980.

Abstract □ Eighteen healthy volunteers were administered single doses of commercially available solid dosage forms of aspirin, magnesium salicylate (I), and choline magnesium trisalicylate (II), equivalent to ~500 mg of salicylic acid, in a randomized, complete crossover design. Plasma salicylate and urine salicylurate levels were measured by high-pressure liquid chromatography at frequent intervals following dosing; the resultant profiles, areas under the curve (*AUC*), and percentages of dose excreted as salicylurate were statistically analyzed by an analysis of variance. The plasma salicylate levels following the two dosage forms containing I and II were virtually identical when corrected for small differences in the dose. The plasma salicylic acid level following aspirin was ~10% lower during the 1.5–3.0-hr interval due to a portion of unhydrolyzed aspirin, but the dose-corrected *AUC* for the products tested did not differ significantly ($p < 0.05$). During the 24 hr following dosing, 66.5 ± 12.1, 68.4 ± 7.1, and 60.9 ± 14.1% of the salicylic acid were excreted as urine salicylurate for aspirin, I, and II, respectively, with no significant difference ($p < 0.05$). Based on this study, there are no significant differences in the rate and extent of absorption of salicylate following the three dosage forms tested, and the elimination kinetics of salicylic acid are not altered by these dosage forms.

Keyphrases □ Salicylate—comparison of plasma levels following administration of aspirin, magnesium salicylate, and choline magnesium trisalicylate □ Aspirin—plasma salicylate levels following administration of solid dosage form, comparison with magnesium salicylate and choline magnesium trisalicylate □ Magnesium salicylate—plasma salicylate levels following administration of solid dosage form, comparison with aspirin and choline magnesium trisalicylate □ Choline magnesium trisalicylate—plasma salicylate levels following administration of solid dosage form, comparison with aspirin and magnesium salicylate

Relatively high doses of salicylate, primarily as aspirin, frequently are indicated for prolonged periods in the treatment of rheumatoid arthritis. This intensive salicylate therapy commonly is associated with GI disturbances and acute blood loss (1). Recent reports (2–4) suggested that choline magnesium trisalicylate (II) can effectively deliver salicylate without the gastric irritation associated with aspirin. Magnesium salicylate (I) also was reported[1] to be less irritating to the gastric mucosa than aspirin.

If the two salts of salicylic acid are to be used as alternatives to aspirin, it is important to know the rate and extent of their absorption compared to aspirin. Furthermore, because the kinetics of metabolism and excretion of salicylate are complex and serum concentration dependent, the potential influence of the dosage form on elimination also should be evaluated. In the present study, plasma salicylate and urine salicylurate profiles following equivalent single doses of aspirin, I, and II were measured.

EXPERIMENT

Drug Products—Three commercially available products were chosen to provide aspirin[2], magnesium salicylate[3], and choline magnesium salicylate[4]. The salicylate content of each was determined and is reported with the results.

Clinical Protocol—Eighteen male volunteers underwent a comprehensive examination including urine analysis and hematological and blood chemistry determinations to ensure that they were in good health. Volunteers ranged in age from 18 to 24 years and in weight from 62 to 85 kg, and all were within ±20% of ideal body weight. No volunteer had a history of chronic drug use, and none had taken any medications, including salicylate, during the 14 days preceding the study. The three drugs were administered as single doses, equal to ~500 mg of salicylic acid, following a randomized, complete crossover design with a minimum of 3 days between doses.

Following an 8-hr fast, drugs were administered with 240 ml of water; no additional food or water was allowed until a standard meal was given following the 4-hr blood sample. Blood samples were taken *via* an indwelling catheter from a forearm vein, with heparin used to maintain the patency of the catheter. Vacutainer tubes[5] were chilled and samples were handled as described previously (5) to ensure stability. Blood (7 ml) was collected prior to dosing and at 15, 30, 45, and 60 min and 1.5, 2, 3, 4, 8, 12, and 16 hr after dosing. All urine voided was collected 6 hr prior to dosing and for the 0–12- and 12–24-hr intervals following dosing.

Plasma salicylate and urine salicylurate levels were determined by the previously described (5) high-pressure liquid chromatographic method with two modifications. Since the unhydrolyzed aspirin was not to be measured, the retention times of salicylic acid and urine salicylurate were decreased by increasing the amount of acetonitrile in the mobile phase to 22.5%. Only fluorescence detection was employed, with metaanisic acid as the internal standard. A comprehensive evaluation of the method proved its sensitivity, specificity, and reproducibility to be equal or better than published values (5). Samples were stored at −30° prior to analysis.

RESULTS AND DISCUSSION

Table I presents the mean plasma salicylic acid and urine salicylurate levels with the computed parameters and statistical analysis. Estimates of the area under the curves (*AUC*) up to the 16-hr sample [AUC_{0-16} in (micrograms times hours) per milliliter] were computed by the trapezoidal method, and the half-lives were calculated by linear regression of the natural logarithm of the plasma concentration *versus* time for the 4-, 8-, 12-, and 16-hr samples. The *AUC* to infinity [$AUC_{-\infty}$ in (micrograms times hours) per milliliter] was computed as $AUC_{0-16} + 1.44t_{1/2}C_{p16}$, while the maximum plasma concentration, $C_{p\max}$, and the time of $C_{p\max}$, $t_{\max}$, were read directly from the data for each volunteer. The urine salicylurate level is reported as the total milligrams excreted during the 0–12-, 12–24-, and 0–24-hr periods and as the percentage of the dose of salicylate excreted as salicylurate in 24 hr.

As expected, the analysis of variance showed no significant difference in the plasma salicylate level between I and II at any time, while the plasma salicylate level following aspirin was slightly lower during the 1.5–3.0-hr interval. This small difference in the plasma salicylate level probably was due to a portion of the aspirin being unhydrolyzed during the early part of the sampling period. Over the 16 hr, the hydrolysis of aspirin produced more salicylate, with the dose-corrected AUC_{∞},

[a] A common letter indicates no significant difference ($p < 0.05$) by an analysis of variance and the least-significant difference method (8). [b] Salicylurate excreted.

AUC_{∞}/D, being equivalent to the products containing salicylate salts. Furthermore, the absorption rate as indicated by the time to reach the maximum plasma concentration did not differ significantly among the three products tested.

The percentage of salicylate excreted as salicylurate agreed closely with previous observations (6, 7) and did not differ significantly ($p < 0.05$) among the three treatments. Moreover, the apparent elimination half-life of 2.0 hr was identical for the three treatments and was as expected for a single 500-mg dose. Although chronic administration should produce a longer half-life (6, 7), this result will not be dependent on the dosage form as long as the rate and extent of absorption do not differ substantially.

Based on the present study, the absorption and elimination kinetics and the resultant plasma concentration of salicylate following administration of the commercially available solid dosage forms of I and II are virtually identical. Furthermore, administration of commonly employed aspirin tablets provides a plasma salicylate level that is only slightly lower (10%) at the peak time due to some unhydrolyzed aspirin being present. Over a 16-hr period, and probably on chronic dosing, there would be no significant differences in the plasma salicylate level.

The possible therapeutic implications of these observations depend on the importance of unhydrolyzed aspirin in the body and the possible effects the different forms of salicylate may have on the GI mucosa over time. However, based solely on the plasma salicylate concentration produced, there is no reason to differentiate among the three sources of salicylate evaluated in the present study.

New Compounds: Synthesis of *para*-Substituted Nortropanyl Benzoates

J. L. WALLACE *, M. R. KIDD *x, S. E. CAUTHEN *, and J. D. WOODYARD ‡

Received January 28, 1980, from the **Department of Chemistry, Northeast Louisiana University, Monroe, LA 71201,* and the ‡*Department of Chemistry and Killgore Research Center, West Texas State University, Canyon, TX 79016.* Accepted for publication May 7, 1980.

Abstract □ The syntheses of the *p*-methyl-, *p*-*tert*-butyl-, *p*-chloro-, *p*-cyano-, *p*-amino-, and unsubstituted benzoate esters of nortropine are reported. These compounds were characterized by their NMR, IR, and mass spectra and analytical data.

Keyphrases □ Nortropanyl benzoate—*para*-substituted derivatives, synthesis, NMR, IR, and mass spectral characterization □ Tropanyl esters—demethylation to yield nortropanyl esters for comparison of kinetic data

To investigate the role of the tropanyl *N*-methyl group in the substrate specificity of rabbit serum atropin esterase, a series of nortropanyl benzoate esters was required. Specifically, the kinetic data will be compared to those obtained with the tropanyl benzoates (1). These compounds also will be useful in a continuing study of the anticholinergic properties of tropanyl benzoate (*endo*-8-azabicyclo[3.2.1]octan-3-yl benzoate) and its *para*-substituted methyl, methoxy, *tert*-butyl, chloro, cyano, and amino derivatives.

The most direct approach for producing the nortropanyl esters is demethylation of the corresponding tropanyl esters. Of the methods available for removal of *N*-methyl

[a] These assignments were determined upon addition of deuterium oxide.

groups, the use of 2,2,2-trichloroethyl chloroformate followed by reductive cleavage by zinc in acetic acid (Scheme I) appeared to be the best procedure since it preserves the ester linkage and avoids the benzoylation of a secondary amine alcohol. This method was reported by Woodward (2) and later used (3) to obtain nortropanyl acetate. The nortropanyl esters reported here were characterized by their NMR, IR, and mass spectra and analytical data.

EXPERIMENTAL[1]

The tropanyl benzoate was dissolved in 30 ml of benzene; if a cloudy solution was obtained, the benzene–water azeotrope was distilled until the solution was clear. Potassium carbonate and distilled 2,2,2-trichloroethyl chloroformate were added, and the mixture was refluxed for 4 days. A second portion of the chloroformate, equal to the first portion, was added after 2 days. The mixture was filtered, and the solvent was removed from the filtrate.

The clear residue was dissolved in a minimum amount of acetic acid. Zinc dust was added slowly over 2 hr, with sufficient cooling to maintain room temperature, until bubbling was no longer evident. The acetic acid was removed by evaporation, and 100 ml of water was added. The slurry was made basic with sodium hydroxide, which produced a copious white precipitate. This mixture was extracted with ethyl acetate. The extract was dried over magnesium sulfate, and the solvent was removed. The resulting free base was purified by recrystallization of its hydrochloride salt in ethanol. Analytical samples were sublimed (Table I).

[1] Mass spectra were obtained on a DuPont Dimaspec 321 gas chromatograph–mass spectrometer with a DuPont 320 data system using solid-probe introduction and ionization at 70 ev. NMR spectra were determined in deuterochloroform with a Varian Associates EM-390 NMR spectrometer using tetramethylsilane as the internal standard. IR spectra were recorded on a Beckman Acculab 6 spectrometer. Melting points were obtained using an Electrothermal apparatus and are corrected. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn. The 2,2,2-trichloroethyl chloroformate was obtained from Aldrich Chemical Co.

RESULTS AND DISCUSSION

All of the esters furnished the expected NMR spectra. They were comparable to those of the previously reported tropanyl benzoates except that the bridgehead protons appeared ~0.4 ppm downfield. The mass spectra base peak for all of the compounds was *m/e* 110, corresponding to the nortropanyl ion. In all spectra, there were peaks at *m/e* 68, 80, and 126. The substituted benzoyl and phenyl fragments were detected in all cases except for the *p-tert*-butyl compound. The molecular ion peaks were observed and were of low relative intensity compared to the tropanyl benzoates (1). A summary of these data appears in Table II.

Acetylation of Sulfisoxazole by Isolated Perfused Rat Kidney

Keyphrases □ Sulfisoxazole—renal metabolism to N^4-acetyl metabolite using the isolated perfused rat kidney □ Metabolism, renal—sulfisoxazole, acetylation by the isolated perfused rat kidney

To the Editor:

Although the kidneys contain many metabolizing enzymes of the liver (1), renal drug metabolism has received limited attention, due partially to the relegation of the kidneys to organs of excretion. The isolated perfused kidney is a useful technique for studies of the renal disposition of drugs. In many cases, experiments with the isolated perfused kidney give results that are consistent with data obtained from *in vivo* studies and more clearly define the role of the kidneys in the overall disposition of a drug. In our laboratory, the isolated perfused kidney has been used in renal clearance studies of several compounds (2, 3) as well as in studies of renal metabolism and interconversion of salicylic and salicyluric acids (4).

Since sulfisoxazole (I) is eliminated largely by renal excretion, it can be influenced by protein binding, urinary pH, and the urine flow rate (5, 6). Studies in our laboratory on the renal clearance of sulfisoxazole by the isolated perfused kidney indicated that rat kidneys metabolize this drug to its N^4-acetyl metabolite (II).

Male Sprague–Dawley rats, 350–375 g, were used in the isolated perfused kidney experiments. The surgical technique and experimental details were reported previously (2–4). Sulfisoxazole (6.5 mg) was administered to attain an initial concentration of ~100 μg/ml, and perfusion was continued for 90 min. The experimental time was divided into nine 10-min urine collection periods. Urine samples were assayed for sulfisoxazole and N^4-acetylsulfisoxazole by a modified high-performance liquid chromatographic assay (7).

The mean urinary excretion rates for N^4-acetylsulfisoxazole and sulfisoxazole from five perfusion experiments are presented in Table I. Although the amounts of N^4-acetylsulfisoxazole excreted in the urine were low, they accounted for 5–7% of the total drug excreted as sulfisoxazole plus N^4-acetylsulfisoxazole during the 90-min experiment. Previous *in vivo* experiments on elimination of sulfisoxazole in the rat indicated that, of the total drug excreted in the urine, 12% is excreted as the N-acetyl metabolite (8). The present results thus indicate that half of the excreted N-acetyl metabolite is due to renal metabolism and that, in the rat, the kidneys contribute significantly to the metabolic disposition of sulfisoxazole.

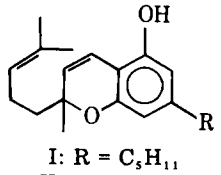
Anti-Inflammatory Activity of Cannabichromene Homologs

Keyphrases □ Anti-inflammatory activity—evaluation of cannabichromene homologs □ Cannabichromene homologs—evaluation for anti-inflammatory activity

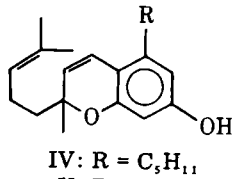
To the Editor:

As part of our continuing study of the cannabinoids, we recently reported that cannabichromene has anti-inflammatory activity. The two tests used to show this activity were the carrageenan-induced rat paw edema test and the red cell stabilization assay (1). To determine the effect of changing the length and position of the side chain of cannabichromene on its anti-inflammatory activity, four homologs were prepared and tested.

Cannabichromene-C_5 (I), cannabichromene-C_1 (II), and cannabichromene-C_0 (III) were prepared following the procedure outlined previously (2), starting from olivetol, orcinol, and resorcinol, respectively. The yield of I was



I: R = C_5H_{11}
II: R = CH_3
III: R = H



IV: R = C_5H_{11}
V: R = H

Table I—Effectiveness of Cannabichromene and Its C_1 Homolog in Inhibiting Carrageenan-Induced Rat Paw Edema [a]

Compound	Dose, mg/kg	Inhibition, %	Mean Difference[b]	SEM	n	p[c]
Vehicle control	—	—	0.340	0.560	24	—
I	120	70	0.102	0.049	8	0.01
	240	86	0.048	0.020	8	0.001
	480	100	0.002	0.058	8	0.001
II	60	53	0.160	0.037	8	0.01
	120	63	0.126	0.031	8	0.001
	240	92	0.027	0.038	7	0.001
Phenylbutazone	60	52	0.163	0.023	8	0.01
	120	76	0.082	0.046	8	0.01

[a] Rats received intraperitoneal injections of test compounds 30 min prior to injection of carrageenan, and postinjection measurements were taken after 3 hr. [b] Preinjection volume − postinjection volume. [c] Each test group was compared to the vehicle control group using the Student t test.

~60% (molar conversion) and that of III was 48.3%, while the yield of II was only 10.8%. Although only trace amounts of the *iso*-compounds were formed from the C_5 and C_1 homologs, almost equal quantities of II and isocannabichromene-C_0 (V) were formed under the same conditions. Thus, the same reaction was used to prepare II and V. Similar yields of II and V were formed when the same reaction was carried out in pyridine. However, isocannabichromene-C_5 (IV) was prepared by refluxing olivetol with citral in pyridine at 110° for 7 hr following literature procedures (3, 4). Purification was carried out in all cases by column chromatography on silica gel with benzene–chloroform (1:1) as the solvent system.

Because cannabinoids often have been misidentified, all natural and synthetic cannabinoids were subjected to GLC and GLC–mass spectrometric analysis using electron voltage–mass fragment intensity graphs for positive identification. Trimethylsilyl derivatives were used when needed. All analyses were conducted in accordance with published protocols (5, 6).

Compounds I–V were tested using the red cell stabilization assay, and I and II also were tested using the rat paw edema assay. All testing was conducted using previously described methods (1). All of the test compounds and phenylbutazone (used as a positive control) were tested in the red cell stabilization assay at a final concentration of 1×10^{-4} *M*. Compounds I and II and phenylbutazone were tested in the rat paw edema assay at the intraperitoneal doses indicated in Table I. The intraperitoneal route was chosen because our previous work showed that cannabichromene is more effective by the intraperitoneal route than by the conventional oral route. Positive and negative controls were tested to ensure that the effects observed were true anti-inflammatory effects rather than the result of counterirritation.

Table II—Effectiveness of Cannabichromene Homologs on the Red Cell Stabilization Assay (n = 3) [a]

Compound	Inhibition, %	Mean[b]	SEM
Vehicle control	—	13.43	0.13
I	94	0.76	0.05
II	86	1.86	0.13
Phenylbutazone	66	4.59	0.11
Vehicle control	—	17.21	0.52
I	79	3.66	0.52
IV	75	4.27	0.25
III	69	5.34	0.75
V	43	9.86	0.53
Phenylbutazone	54	7.86	0.70

[a] All compounds were tested at a final concentration of 1×10^{-4} *M*. [b] Mean of three replicates of blood taken from the same dog. Compounds I and II were tested using blood from one dog, and I and III–V were tested using blood from a second dog. Vehicle positive controls from both tests are given.

Cannabichromene and its derivatives stabilized red cell membranes, as indicated by the inhibition of heat-induced hemolysis (Table II). They inhibited hemolysis more effectively than did phenylbutazone at equimolar concentrations, except for V. Both I and II inhibited carrageenan-induced rat paw edema at all doses tested. The percent inhibition produced by I and II was roughly equivalent to the inhibition produced by phenylbutazone when all were tested at 120 mg/kg. Phenylbutazone was not tested at 240 and 480 mg/kg since it is lethal at those doses.

The length and position of the side chain on the cannabichromene moiety appear to have little or no effect on its potency, with the possible exception of V. This indication is of interest since Hollister (7) found that the psychological effects of another *Cannabis* compound, (−)-*trans*-Δ^9-tetrahydrocannabinol, were diminished as the length of the side chain was reduced. For example, the C-3 side-chain homolog of (−)-*trans*-Δ^9-tetrahydrocannabinol was only ~25% as active as (−)-*trans*-Δ^9-tetrahydrocannabinol itself.

Further experiments on the anti-inflammatory effects of cannabichromene are in progress, and the results will be reported.

REVIEWS

Principles of Pharmaceutical Accounting. By FRANCIS A. MARINO, EDWARD J. ZABLOSKI, and COLMAN M. HERMAN. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 1980. xi + 241 pp. 18 × 26 cm. Price $19.50.

Undergraduate pharmacy students and practicing pharmacists are the intended audience for this book on accounting principles. The major advantage of this book is that it was designed specifically for this audience. It ignores the concepts relevant primarily to multinational manufacturing conglomerates which are found in standard accounting texts, while including topics such as reconciliation of bank statements and determining prescription dispensing costs.

Most of the book is devoted to financial accounting (bookkeeping or the accumulation and summarization of financial data) rather than managerial accounting (the use of financial data to make management decisions). This reviewer recognizes that it is difficult for students to learn to use data properly without some background in how the data were generated.

While tables and figures are abundant, the amount of actual textual material is sparse. Terms tend not to be defined. It is assumed that the reader knows what gross profit is or will figure it out from its use. Examples tend to be used in place of definitions ("Cash includes . . . ." "Inventory consists of items such as . . . ."). It is 150 pages after "cash" is introduced that the reader learns that a certificate of deposit is an investment, not cash. The reader never is told that a bottle of aspirin for resale to a patient is inventory, while if the aspirin is consumed in the pharmacy by employees with a headache, it is a supplies expense.

Conspicuously absent in the book is any mention of UCAS (Uniform Cost Accounting System for Pharmacy). Also lacking is any guidance on what the pharmacy owner should look for in selecting an accountant or what services can be provided by an accountant.

The review questions and exercises at the end of each chapter are helpful aids in reinforcing the concepts presented.

It is not a compliment to say that this book is long overdue. It reflects a concept of the pharmacist keeping his or her own books and being his or her own accountant rather than managing a practice in which annual sales may be in excess of a half-million dollars.

As the only text of its kind in print, individual faculty members should review this book for possible use by students. Managers of community pharmacy practice are more likely to find that, although it is considerably more expensive, UCAS will more effectively satisfy their needs.

Activated Charcoal: Antidotal and Other Medical Uses. By DAVID O. COONEY. (Drugs and the Pharmaceutical Sciences, Vol. 9.) Dekker, 270 Madison Ave., New York, NY 10016. 1980. 160 pp. 15 × 23 cm. Price $23.50.

This book provides a much needed review of the literature concerning the use of activated charcoal for the treatment of acute drug overdose or poison ingestion. The first chapter emphasizes the advantages of orally administered activated charcoal for the treatment of acute poison ingestion relative to other common emergency measures, such as induced emesis and gastric lavage. Chapter 2 points out the historical highlights of charcoal, indicating that the use of medicinal charcoal was recorded in an Egyptian papyrus in 1500 B.C., that a great variety of starting materials were used in its manufacture, and that the process of activation (which greatly increases the adsorbent capacity of charcoal) was not introduced until 1900.

Chapter 3 describes the manufacture, physicochemical properties, and adsorptive process of activated charcoal. Such knowledge is important for understanding the differences among various charcoal preparations and why a certain charcoal may be more effective than other charcoals for adsorption of a specific chemical. Chapter 4 is devoted to a discussion of the five classical papers of A. H. Anderson, which were published between 1946 and 1948. These publications are important because they summarized many earlier studies on activated charcoal and reported the definitive studies of Anderson, which served as the basis for subsequent work by many investigators.

Chapter 5 discusses the antidotal aspects of activated charcoal, with commentaries on characteristics to be considered in the selection of the most suitable charcoal preparation for oral antidotal uses (*e.g.*, acid-washed charcoal, pore-size distribution predominantly in the 20-Å range, high internal surface areas, and a fine powder as opposed to granules or tablets), dosages, effects of delayed administration, stability of the charcoal–drug complex in the GI tract, storage stability of activated charcoal suspension, safety of activated charcoal, fallacies and dangers of the so-called universal antidote, and the development of palatable formulations of activated charcoal suspension.

Chapter 6 reviews the results of *in vitro* and *in vivo* studies of the binding and antidotal potentials of activated charcoal. A great amount of previously published data is included. Chapter 7 describes investigations of other possible medical or diagnostic applications of activated charcoal. Most of these works were published in the 1930s and are mainly of historical interest, *e.g.*, intravenous injection of activated charcoal for treatment of systemic infections. However, use of activated charcoal to bind bacterial toxins in certain GI infections appears rational, and the use of activated charcoal for hemoperfusion appears to be effective.

A few errors were obvious to the reviewer. On page 40, it is stated that the adsorption isotherm for strychnine nitrate (based on *in vitro* studies in human gastric contents) is presented in Fig. 4.8, but this figure is concerned with diethylbarbituric acid. On page 41, a statement is made in reference to Fig. 4.8 that a change in pH from 8.4 to 5.0 decreases charcoal adsorption of diethylbarbituric acid, whereas the reverse is shown in the figures. Also, the data presented in Fig. 4.3 and Table 5.7 are credited to the wrong authors. However, these errors do not detract from the usefulness of the book.

Probably very few references have escaped citation in this small volume. This book is a convenient source of information concerning the antidotal application of activated charcoal for management of drug overdose or poison ingestion and should be a useful reference for health professionals involved in the treatment of poisoning cases, poison control information centers, and people engaged in research.

Prescription Drugs in Short Supply. By MICHAEL A. SCHWARTZ. (Drugs and the Pharmaceutical Sciences, Vol. 8.) Dekker, 270 Madison Ave., New York, NY 10016. 1980. 130 pp. 15 × 23 cm. Price $17.50.

This interesting book documents, by case histories, the shortage of some vital drugs that occurred between 1973 and 1976. Among the major sources of documented information are Senatorial hearings, reports to the Drug Enforcement Administration, various symposia, and the *Federal Register*.

Shortages of five substances are discussed in detail: opium, quinidine, heparin, two injectable penicillins, and some large- and small-volume parenterals. Although no deaths are known to have resulted from the shortages, it is highly likely that there were cases in which optimum patient care was not possible because substitute drugs had to be used.

The shortages were caused by a number of factors which were different in most instances for each substance. The demand for codeine increased significantly, which contributed to the shortage of opium. This increased demand was attributed to: (*a*) increases in population, (*b*) aging of the population, (*c*) an increase in third-party payments for medication, and

It is assumed that the reader knows what gross profit is or will figure it out from its use. Examples tend to be used in place of definitions ("Cash includes . . . ." "Inventory consists of items such as . . . ."). It is 150 pages after "cash" is introduced that the reader learns that a certificate of deposit is an investment, not cash. The reader never is told that a bottle of aspirin for resale to a patient is inventory, while if the aspirin is consumed in the pharmacy by employees with a headache, it is a supplies expense.

Conspicuously absent in the book is any mention of UCAS (Uniform Cost Accounting System for Pharmacy). Also lacking is any guidance on what the pharmacy owner should look for in selecting an accountant or what services can be provided by an accountant.

The review questions and exercises at the end of each chapter are helpful aids in reinforcing the concepts presented.

It is not a compliment to say that this book is long overdue. It reflects a concept of the pharmacist keeping his or her own books and being his or her own accountant rather than managing a practice in which annual sales may be in excess of a half-million dollars.

As the only text of its kind in print, individual faculty members should review this book for possible use by students. Managers of community pharmacy practice are more likely to find that, although it is considerably more expensive, UCAS will more effectively satisfy their needs.

Activated Charcoal: Antidotal and Other Medical Uses. By DAVID O. COONEY. (Drugs and the Pharmaceutical Sciences, Vol. 9.) Dekker, 270 Madison Ave., New York, NY 10016. 1980. 160 pp. 15 × 23 cm. Price $23.50.

This book provides a much needed review of the literature concerning the use of activated charcoal for the treatment of acute drug overdose or poison ingestion. The first chapter emphasizes the advantages of orally administered activated charcoal for the treatment of acute poison ingestion relative to other common emergency measures, such as induced emesis and gastric lavage. Chapter 2 points out the historical highlights of charcoal, indicating that the use of medicinal charcoal was recorded in an Egyptian papyrus in 1500 B.C., that a great variety of starting materials were used in its manufacture, and that the process of activation (which greatly increases the adsorbent capacity of charcoal) was not introduced until 1900.

Chapter 3 describes the manufacture, physicochemical properties, and adsorptive process of activated charcoal. Such knowledge is important for understanding the differences among various charcoal preparations and why a certain charcoal may be more effective than other charcoals for adsorption of a specific chemical. Chapter 4 is devoted to a discussion of the five classical papers of A. H. Anderson, which were published between 1946 and 1948. These publications are important because they summarized many earlier studies on activated charcoal and reported the definitive studies of Anderson, which served as the basis for subsequent work by many investigators.

Chapter 5 discusses the antidotal aspects of activated charcoal, with commentaries on characteristics to be considered in the selection of the most suitable charcoal preparation for oral antidotal uses (*e.g.*, acid-washed charcoal, pore-size distribution predominantly in the 20-Å range, high internal surface areas, and a fine powder as opposed to granules or tablets), dosages, effects of delayed administration, stability of the charcoal–drug complex in the GI tract, storage stability of activated charcoal suspension, safety of activated charcoal, fallacies and dangers of the so-called universal antidote, and the development of palatable formulations of activated charcoal suspension.

Chapter 6 reviews the results of *in vitro* and *in vivo* studies of the binding and antidotal potentials of activated charcoal. A great amount of previously published data is included. Chapter 7 describes investigations of other possible medical or diagnostic applications of activated charcoal. Most of these works were published in the 1930s and are mainly of historical interest, *e.g.*, intravenous injection of activated charcoal for treatment of systemic infections. However, use of activated charcoal to bind bacterial toxins in certain GI infections appears rational, and the use of activated charcoal for hemoperfusion appears to be effective.

A few errors were obvious to the reviewer. On page 40, it is stated that the adsorption isotherm for strychnine nitrate (based on *in vitro* studies in human gastric contents) is presented in Fig. 4.8, but this figure is concerned with diethylbarbituric acid. On page 41, a statement is made in reference to Fig. 4.8 that a change in pH from 8.4 to 5.0 decreases charcoal adsorption of diethylbarbituric acid, whereas the reverse is shown in the figures. Also, the data presented in Fig. 4.3 and Table 5.7 are credited to the wrong authors. However, these errors do not detract from the usefulness of the book.

Probably very few references have escaped citation in this small volume. This book is a convenient source of information concerning the antidotal application of activated charcoal for management of drug overdose or poison ingestion and should be a useful reference for health professionals involved in the treatment of poisoning cases, poison control information centers, and people engaged in research.

Prescription Drugs in Short Supply. By MICHAEL A. SCHWARTZ. (Drugs and the Pharmaceutical Sciences, Vol. 8.) Dekker, 270 Madison Ave., New York, NY 10016. 1980. 130 pp. 15 × 23 cm. Price $17.50.

This interesting book documents, by case histories, the shortage of some vital drugs that occurred between 1973 and 1976. Among the major sources of documented information are Senatorial hearings, reports to the Drug Enforcement Administration, various symposia, and the *Federal Register*.

Shortages of five substances are discussed in detail: opium, quinidine, heparin, two injectable penicillins, and some large- and small-volume parenterals. Although no deaths are known to have resulted from the shortages, it is highly likely that there were cases in which optimum patient care was not possible because substitute drugs had to be used.

The shortages were caused by a number of factors which were different in most instances for each substance. The demand for codeine increased significantly, which contributed to the shortage of opium. This increased demand was attributed to: (*a*) increases in population, (*b*) aging of the population, (*c*) an increase in third-party payments for medication, and

REVIEWS

Principles of Pharmaceutical Accounting. By FRANCIS A. MARINO, EDWARD J. ZABLOSKI, and COLMAN M. HERMAN. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 1980. xi + 241 pp. 18 × 26 cm. Price $19.50.

Undergraduate pharmacy students and practicing pharmacists are the intended audience for this book on accounting principles. The major advantage of this book is that it was designed specifically for this audience. It ignores the concepts relevant primarily to multinational manufacturing conglomerates which are found in standard accounting texts, while including topics such as reconciliation of bank statements and determining prescription dispensing costs.

Most of the book is devoted to financial accounting (bookkeeping or the accumulation and summarization of financial data) rather than managerial accounting (the use of financial data to make management decisions). This reviewer recognizes that it is difficult for students to learn to use data properly without some background in how the data were generated.

While tables and figures are abundant, the amount of actual textual material is sparse. Terms tend not to be defined. It is assumed that the reader knows what gross profit is or will figure it out from its use. Examples tend to be used in place of definitions ("Cash includes . . . ." "Inventory consists of items such as . . . ."). It is 150 pages after "cash" is introduced that the reader learns that a certificate of deposit is an investment, not cash. The reader never is told that a bottle of aspirin for resale to a patient is inventory, while if the aspirin is consumed in the pharmacy by employees with a headache, it is a supplies expense.

Prescription Drugs in Short Supply. By MICHAEL A. SCHWARTZ. (Drugs and the Pharmaceutical Sciences, Vol. 8.) Dekker, 270 Madison Ave., New York, NY 10016. 1980. 130 pp. 15 × 23 cm. Price $17.50.

This interesting book documents, by case histories, the shortage of some vital drugs that occurred between 1973 and 1976. Among the major sources of documented information are Senatorial hearings, reports to the Drug Enforcement Administration, various symposia, and the *Federal Register*.

Shortages of five substances are discussed in detail: opium, quinidine, heparin, two injectable penicillins, and some large- and small-volume parenterals. Although no deaths are known to have resulted from the shortages, it is highly likely that there were cases in which optimum patient care was not possible because substitute drugs had to be used.

The shortages were caused by a number of factors which were different in most instances for each substance. The demand for codeine increased significantly, which contributed to the shortage of opium. This increased demand was attributed to: (*a*) increases in population, (*b*) aging of the population, (*c*) an increase in third-party payments for medication, and

(*d*) increased prescribing of codeine. Other factors contributing to the opium shortage were the ban on opium growing in Turkey and reduced production in India due to unfavorable weather conditions.

A Dutch cartel succeeded in gaining control of a significant portion of the world's supply of quinidine, which resulted in alleged shortages of this drug and subsequent price increases.

The heparin shortage resulted from increased demand and also from a short supply of the major raw material, the intestinal mucosa of the hog. This shortage occurred when the number of hogs being slaughtered was reduced.

The penicillin shortage was attributed to an 11-month shutdown of a major manufacturer's facilities for making the product.

The author points out that there is a lack of information concerning drug shortages and that no agency has the authority and responsibility to gather and apply such information. Such an agency, along with a national advisory group with representatives from the pharmaceutical industry, the health professions, and government, is recommended by the author as a means to prevent shortages of essential drugs.

This book is interesting reading for anyone associated with the health professions or the pharmaceutical industry. Most of us are unaware that shortages of vital drugs have occurred and can occur in the future.

Nuclear Medicine: Review Syllabus. Edited by PETER T. KIRCHNER. Society of Nuclear Medicine, 475 Park Ave. S., New York, NY 10016. 1980. 619 pp. 15 × 23 cm. Price $30.00.

This book is a product of over 50 contributors. It is an update of the major scientific and clinical advances that have occurred in nuclear medicine since the early 1970s. This volume is not presented as a textbook of nuclear medicine nor as an exposition of basic knowledge. In the preface, the senior editor states his hope that this book "will achieve its goal of assisting physicians in their efforts to maintain or reach clinical competence in the specialty of nuclear medicine."

The book offers an overview of 12 major areas in nuclear medicine. Chapters are included on radiopharmacology, instrumentation, radiation effects and radiation protection, cardiovascular, the central nervous system, endocrinology, gastroenterology, the genitourinary system, hematology–oncology, pulmonary, radioassay, and the skeletal system. The majority of the material is presented in a descriptive manner, with illustrations and tables kept to a minimum. With few exceptions, the text is well written, clear, and easy to follow. Difficulty may be encountered in attempting to locate a reference in a bibliography that was cited within the text.

The text contains a great amount of pertinent information beneficial to nuclear medicine physicians. This book is an excellent source of information for nuclear pharmacy practitioners and educators as well. Although not useful as an entry level textbook, it is of value as a library reference source in institutions with active research and educational programs in nuclear medicine or nuclear pharmacy.

Catalog of Teratogenic Agents, 3rd Ed. Edited by THOMAS H. SHEPARD. Johns Hopkins University Press, Baltimore, MD 21218. 1980. 410 pp. 16 × 23.5 cm.

This reference text is essentially an alphabetized listing of known and suspected teratogenic agents that are believed to be involved in the development of congenital anomalies in experimental animals and humans. It is an updated version of previous editions, and the reader is made aware that yearly revisions probably will be forthcoming. Easy and quick revision is made possible by the fact that the material has been collected in the usual way and then transferred to computer cards and finally to tape for storage. New material can be inserted at the proper places without totally revising the previously written material. Both positive and negative results and full bibliographic references are included in the discussion of each agent. In addition, there are adequate subject and author indexes.

The stated purpose of the book is to help link the available information on experimental teratogenic agents with malformations occurring in humans. It is clearly pointed out in the introductory material that this task is not easy and that it often is impossible for a variety of reasons.

The most outstanding contribution to the literature provided by this book is the tables of comparative time periods of embryonic and fetal development in humans and experimental animals. One can determine easily what organ or tissue is developing at any time in gestation and consequently predict which tissues may be affected should a suspected teratogen be present at that particular time.

Many obviously important references have been left out, a deficiency that the author admits may be the case. To remedy this problem, the author states that anyone wishing to add material or provide corrections for future editions should do so on the address form provided in the last pages of the text. Unfortunately, this form is not present.

Because this catalog contains information concerning congenital defects due to pharmaceuticals, chemicals, environmental pollutants, food additives, household products, and viruses, it is recommended as a reference souce for anyone who has to answer questions concerning the teratogenic nature of the many agents included in these categories. Along with teratologists, obstetricians, pediatricians, geneticists, pharmacologists, and general practitioners would be particularly interested in this book.

British Pharmacopoeia 1980. Her Majesty's Stationery Office, Atlantic House, Holborn Viaduct, London EC1P 1BN, England. 1980. 1196 pp. 22 × 31.5 cm. Price £60.

The *1980 British Pharmacopoeia* provides standards for the quality of substances and preparations used in medicine and pharmacy which will become effective in the United Kingdom on December 1, 1980. The 1980 BP incorporates, in edited form, all of the relevant monographs and methods currently contained in the *European Pharmacopoeia*. It also presents, in updated form, a large number of monographs formerly contained in the *British Pharmaceutical Codex*.

The increase in the range of entries covered in the BP resulted in its expansion to two volumes. Volume I contains monographs of medicinal and pharmaceutical substances, including simple organic salts, complex synthetic chemicals, vegetable drugs, antibiotics, and hormones and vitamins. The standards are accompanied by information on their action, use, dose, solubility, storage, and labeling. Style changes in this edition include indication of the stereochemical configuration in structural formulas, where possible. SI units have been introduced where practicable, and an approximate equivalent in the more familiar cgs system is given in parentheses.

Volume II includes an extensive formulary section. It also features discussions of blood products, immunological products, radiopharmaceutical preparations, and surgical materials. The 24 appendixes in Volume II describe procedures and requirements that are necessary for interpretation of the standards. Among the subjects featured in the appendixes are reagents, spectroscopic and chromatographic analyses, determinations of physical properties, limit tests, disintegration tests for dosage forms, and biological and biochemical assays and tests for antibiotics, immunological products, hormones, blood and related products, and enzymes. Tests for sterility, microbial contamination, and efficacy of preservatives also are included. A 48-page index is provided at the end of Volume II.

The significant expansion of the *British Pharmacopoeia* since its previous (1973) edition enhances its value as a reference source.

Style changes in this edition include indication of the stereochemical configuration in structural formulas, where possible. SI units have been introduced where practicable, and an approximate equivalent in the more familiar cgs system is given in parentheses.

Volume II includes an extensive formulary section. It also features discussions of blood products, immunological products, radiopharmaceutical preparations, and surgical materials. The 24 appendixes in Volume II describe procedures and requirements that are necessary for interpretation of the standards. Among the subjects featured in the appendixes are reagents, spectroscopic and chromatographic analyses, determinations of physical properties, limit tests, disintegration tests for dosage forms, and biological and biochemical assays and tests for antibiotics, immunological products, hormones, blood and related products, and enzymes. Tests for sterility, microbial contamination, and efficacy of preservatives also are included. A 48-page index is provided at the end of Volume II.

The significant expansion of the *British Pharmacopoeia* since its previous (1973) edition enhances its value as a reference source.

Staff Review

(*d*) increased prescribing of codeine. Other factors contributing to the opium shortage were the ban on opium growing in Turkey and reduced production in India due to unfavorable weather conditions.

A Dutch cartel succeeded in gaining control of a significant portion of the world's supply of quinidine, which resulted in alleged shortages of this drug and subsequent price increases.

The heparin shortage resulted from increased demand and also from a short supply of the major raw material, the intestinal mucosa of the hog. This shortage occurred when the number of hogs being slaughtered was reduced.

The penicillin shortage was attributed to an 11-month shutdown of a major manufacturer's facilities for making the product.

The author points out that there is a lack of information concerning drug shortages and that no agency has the authority and responsibility to gather and apply such information. Such an agency, along with a national advisory group with representatives from the pharmaceutical industry, the health professions, and government, is recommended by the author as a means to prevent shortages of essential drugs.

This book is interesting reading for anyone associated with the health professions or the pharmaceutical industry. Most of us are unaware that shortages of vital drugs have occurred and can occur in the future.

Nuclear Medicine: Review Syllabus. Edited by PETER T. KIRCHNER. Society of Nuclear Medicine, 475 Park Ave. S., New York, NY 10016. 1980. 619 pp. 15 × 23 cm. Price $30.00.

This book is a product of over 50 contributors. It is an update of the major scientific and clinical advances that have occurred in nuclear medicine since the early 1970s. This volume is not presented as a textbook of nuclear medicine nor as an exposition of basic knowledge. In the preface, the senior editor states his hope that this book "will achieve its goal of assisting physicians in their efforts to maintain or reach clinical competence in the specialty of nuclear medicine."

The book offers an overview of 12 major areas in nuclear medicine. Chapters are included on radiopharmacology, instrumentation, radiation effects and radiation protection, cardiovascular, the central nervous system, endocrinology, gastroenterology, the genitourinary system, hematology–oncology, pulmonary, radioassay, and the skeletal system. The majority of the material is presented in a descriptive manner, with illustrations and tables kept to a minimum. With few exceptions, the text is well written, clear, and easy to follow. Difficulty may be encountered in attempting to locate a reference in a bibliography that was cited within the text.

The text contains a great amount of pertinent information beneficial to nuclear medicine physicians. This book is an excellent source of information for nuclear pharmacy practitioners and educators as well. Although not useful as an entry level textbook, it is of value as a library reference source in institutions with active research and educational programs in nuclear medicine or nuclear pharmacy.

Catalog of Teratogenic Agents, 3rd Ed. Edited by THOMAS H. SHEPARD. Johns Hopkins University Press, Baltimore, MD 21218. 1980. 410 pp. 16 × 23.5 cm.

This reference text is essentially an alphabetized listing of known and suspected teratogenic agents that are believed to be involved in the development of congenital anomalies in experimental animals and humans. It is an updated version of previous editions, and the reader is made aware that yearly revisions probably will be forthcoming. Easy and quick revision is made possible by the fact that the material has been collected in the usual way and then transferred to computer cards and finally to tape for storage. New material can be inserted at the proper places without totally revising the previously written material. Both positive and negative results and full bibliographic references are included in the discussion of each agent. In addition, there are adequate subject and author indexes.

The stated purpose of the book is to help link the available information on experimental teratogenic agents with malformations occurring in humans. It is clearly pointed out in the introductory material that this task is not easy and that it often is impossible for a variety of reasons.

The most outstanding contribution to the literature provided by this book is the tables of comparative time periods of embryonic and fetal development in humans and experimental animals. One can determine easily what organ or tissue is developing at any time in gestation and consequently predict which tissues may be affected should a suspected teratogen be present at that particular time.

Many obviously important references have been left out, a deficiency that the author admits may be the case. To remedy this problem, the author states that anyone wishing to add material or provide corrections for future editions should do so on the address form provided in the last pages of the text. Unfortunately, this form is not present.

Because this catalog contains information concerning congenital defects due to pharmaceuticals, chemicals, environmental pollutants, food additives, household products, and viruses, it is recommended as a reference souce for anyone who has to answer questions concerning the teratogenic nature of the many agents included in these categories. Along with teratologists, obstetricians, pediatricians, geneticists, pharmacologists, and general practitioners would be particularly interested in this book.

British Pharmacopoeia 1980. Her Majesty's Stationery Office, Atlantic House, Holborn Viaduct, London EC1P 1BN, England. 1980. 1196 pp. 22 × 31.5 cm. Price £60.

The *1980 British Pharmacopoeia* provides standards for the quality of substances and preparations used in medicine and pharmacy which will become effective in the United Kingdom on December 1, 1980. The 1980 BP incorporates, in edited form, all of the relevant monographs and methods currently contained in the *European Pharmacopoeia*. It also presents, in updated form, a large number of monographs formerly contained in the *British Pharmaceutical Codex*.

The increase in the range of entries covered in the BP resulted in its expansion to two volumes. Volume I contains monographs of medicinal and pharmaceutical substances, including simple organic salts, complex synthetic chemicals, vegetable drugs, antibiotics, and hormones and vitamins. The standards are accompanied by information on their action, use, dose, solubility, storage, and labeling. Style changes in this edition include indication of the stereochemical configuration in structural formulas, where possible. SI units have been introduced where practicable, and an approximate equivalent in the more familiar cgs system is given in parentheses.

Volume II includes an extensive formulary section. It also features discussions of blood products, immunological products, radiopharmaceutical preparations, and surgical materials. The 24 appendixes in Volume II describe procedures and requirements that are necessary for interpretation of the standards. Among the subjects featured in the appendixes are reagents, spectroscopic and chromatographic analyses, determinations of physical properties, limit tests, disintegration tests for dosage forms, and biological and biochemical assays and tests for antibiotics, immunological products, hormones, blood and related products, and enzymes. Tests for sterility, microbial contamination, and efficacy of preservatives also are included. A 48-page index is provided at the end of Volume II.

The significant expansion of the *British Pharmacopoeia* since its previous (1973) edition enhances its value as a reference source.

ETHICAL CONSIDERATIONS IN RESEARCH PUBLICATION

Periodically, news reports in the public press and the broadcast media inform us about a new scandal rocking either Congress or some governmental agency. The scandal might be anything from taking bribes, to exerting improper influence, to improper moral behavior, to any other of a host of misdeeds.

Only relatively rarely, however, do we hear about comparable situations in the world of science and research.

In part, this may be because the people involved are more honorable or have a greater sense of ethics. It may also be because they are simply less likely to face the pressures and temptations that persons who are in positions of greater public prominence routinely encounter.

But we suspect that there is also another explanation. In short, most people in research, in science, and in the health professions are inclined to treat such matters with reserve, discretion, and perhaps even a sense of incredulity. It is almost as if they refuse to believe that such misdeeds occur or that their colleagues and associates could be guilty of the purported practices. For example, the general reluctance of physicians to testify against fellow physicians in malpractice cases is widely recognized within the legal profession.

The psychology underlying this behavior can be explained in a number of ways. But whatever the reason for it, there is no question but that it exists.

These observations are prompted by a detailed exposé of an alleged scientific fraud that was reported this past October in a two-part story appearing in *Science* magazine. Many of the central figures named read like a Who's Who of American medical science. The principal institutions involved are the revered Yale University School of Medicine, the Columbia College of Physicians and Surgeons, and the National Institutes of Health.

The articles in *Science* are entitled, respectively, "Imbroglio at Yale (I): Emergence of a Fraud" and "Imbroglio at Yale (II): A Top Job Lost." We shall not attempt to summarize the story because it is exceedingly complex and a brief summary might treat one or another of the parties unfairly. As a consequence, we recommend to our readers that they read the entire report as it is fully laid out in *Science*. The specific wrong-doing includes plagiarism, destruction of data, falsification of data, and efforts to conceal or down-play the problem. For the principal scientist involved, the episode became an "intellectual Watergate."

In reviewing the scenario, the account in *Science* reveals that initially the incident appeared of minor significance: *"The so-called plagiarism consisted of a few unimportant phrases containing, in total, some 60 words."* After first reviewing the case, the dean at Yale was inclined to dismiss it. However, over the next year, matters gradually snowballed and eventually led to the retraction of 11 papers published in prominent scientific journals, the forced resignation of the chairman of the department of medicine at Columbia, and a host of other sordid consequences.

With this background, we would particularly like to highlight a couple of key conclusions in the *Science* articles:

- *"The Yale part of the story is a case study in how a busy senior investigator lost touch with the laboratory of a junior associate. It raises serious questions about the career pressures that lead to coauthorship and about the health of team research in general."*
- *"The subtle effects of the Yale imbroglio might never be measured, but they will be there nonetheless. Senior researchers, for instance, may hesitate a bit in the future before signing a paper not carefully checked out."*
- *"The fabric of the reward system of coauthorship was torn. To the extent that there are [other researchers of similar bent] at large in the labs, doctoring data, the incident stands as a threat and a warning."*

All of this may appear to be very remote to the *Journal of Pharmaceutical Sciences* and its readers, authors, reviewers, and editors. At most, we might consider the Yale–Columbia incident to be of only casual and incidental interest.

Regrettably, however, over the past decade we have experienced several comparable and analogous situations. Fortunately, in most of these cases, the unethical behavior was uncovered before publication of the pertinent manuscripts; as a result, appropriate corrective action was taken to prevent soiling the published literature. In several other instances, the particular problem only came to light following the paper's publication and the opportunity thereby afforded an affected party to read the paper, to recognize the existence of a problem, and to bring that problem to the attention of the editors and other pertinent parties.

Because these instances of apparent fraud or unethical behavior are not widely publicized like those mentioned in the opening paragraph above, few of our readers, authors, or reviewers are ever aware of them. Nevertheless, they do result in a serious embarrassment and a permanent taint on the reputations of the scientist or scientists involved. Consequently, when it comes to research publication, we wish to counsel the utmost care and caution on the part of all those who would author or coauthor papers, as well as on the part of those who have the responsibility to review or otherwise pass judgment on such manuscripts for possible publication.

Improving Intestinal Absorption of Water-Insoluble Compounds: A Membrane Metabolism Strategy

G. L. AMIDON ˣ, G. D. LEESMAN, and R. L. ELLIOTT

Received February 27, 1980, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication June 11, 1980.

Abstract □ A strategy for improving the intestinal absorption of water-insoluble drugs was developed and tested. The strategy is based on making a soluble derivative of an insoluble compound which, in turn, is a substrate for enzymes in the surface coat of the brush border region of the microvillous membrane. Consequently, just prior to reaching the membrane, the physical properties of the diffusing species are changed from polar to nonpolar. The experimental test used two drug–drug derivative pairs, estrone–lysine estrone ester and *p*-nitroaniline–lysine *p*-nitroanilide. Wall permeabilities were determined using an external perfusion technique in the rat intestine and a laminar flow convective diffusion model for transport in the lumen. Analysis of the permeability results indicates that the derivatives have higher wall permeabilities than the parent compounds and that the microvillous surface coat may be a significant contributor to the intestinal wall resistance. Comparison of the absorption rates for estrone and the lysine estrone ester indicates that the absorption rate of the derivative could be up to five orders of magnitude greater than that for the parent compound.

Keyphrases □ Permeability—intestinal absorption of water-insoluble drugs, improved membrane permeability through synthesis of soluble derivative as prodrug □ Absorption, intestinal—water-insoluble drugs, improved membrane permeability through synthesis of soluble derivative as prodrug □ Models—intestinal absorption of water-insoluble drugs, improved membrane permeability through synthesis of soluble derivative as prodrug

Water-insoluble compounds frequently are absorbed slowly due to slow dissolution of the solid and/or a very low solution concentration, leading to a small diffusive driving force. Two approaches often are used in these cases to improve absorption: formulation and soluble derivative formation (1). The formulation approach uses physical methods such as micronization or dispersion in a soluble carrier to increase the dissolution rate of the drug product and, hence, the absorption rate. The soluble derivative (prodrug) approach attaches a solubilizing progroup (*e.g.*, phosphate or succinate) to the drug, taking advantage of the usually high solubility and dissolution rate of the derivative salt. Examples of the successful application of both approaches are available (1).

BACKGROUND

Each approach has its limitations. With the formulation approach, the maximal diffusive driving force still is limited by the low aqueous solubility of the drug. While it may be possible to maintain a supersaturated solution for a finite period of time, the supersaturation often is only a factor of two or less, which is not sufficient to ensure complete absorption for very insoluble compounds. The solubilizing progroup approach is limited by the fact that while the aqueous solubility may be increased by several orders of magnitude, the increase in solubility is coupled to a decrease in the membrane–water partition coefficient (2–4) and, consequently, results in a reduction in the membrane permeability. While the transport basis for this trade-off will be discussed in more detail, the significant point is that increased aqueous solubility usually is obtained at the expense of reduced membrane permeability. If, for oral dosage forms, the conversion back to the nonpolar drug occurs rapidly, chemically or biochemically, in the gut lumen, then the reduced membrane permeability of the drug derivative is of no consequence. However, as with the formulation approach, the diffusive transport of the drug again is limited by its low solubility.

This report discusses an approach that may avoid this compromise. The essential strategy is to make derivatives of insoluble compounds that are substrates for enzymes in the brush border region of the mucosal cells. In the next section, the biochemical background is reviewed briefly and the prodrug strategy is developed. Next, the transport processes involved are analyzed. The approach is tested experimentally using two drug–drug derivative pairs in an externally perfused rat intestine preparation. The results then are discussed in light of the transport models and the potential of this approach for improving oral absorption.

Protein Digestion and Absorption—Understanding of the digestion and absorption of proteins has increased over the past 20 years, as demonstrated by numerous reviews and symposium volumes (5–14). Prior to reaching the intestine, ingested protein is acted on by gastric and pancreatic enzymes. This process is intraluminal and reduces the protein to a mixture of free amino acids (<30%) and oligopeptides having two to six residues. This mixture is presented to the intestinal mucous membrane where an active, sodium-dependent carrier transports the free amino acids into the cell. Final hydrolysis of the remaining oligopeptides occurs along the mucous membrane and is complete so that, for practical purposes, only amino acids enter the portal circulation.

For many years, it was assumed that all of the protein was reduced to free amino acids prior to transport across the intestinal wall. Then, in a pioneering series of reports published between 1959 and 1962, Newey and Smyth (15–17) demonstrated that intraluminal hydrolysis accounted

for only a minor portion of the total protein hydrolyzed. In addition, they showed that small amounts of dipeptides could be absorbed into the enterocytes intact, a finding also reported by Prockop *et al.* (18). Matthews and coworkers (19, 20) made the important observation that dipeptides could be absorbed more rapidly than amino acids. This finding established that dipeptides could be transported by a mechanism independent of that used by amino acids. This result was supported by reports that patients with defective intestinal amino acid absorption, as in Hartnup's disease or cystinuria, are able to absorb dipeptides without difficulty (20, 21). Several schemes were proposed to account for the final stages of hydrolysis and absorption of oligopeptides (22–26), and these schemes include one or both of the following mechanisms (Fig. 1):

1. Hydrolysis of the small peptides by enzymes in the brush border region to amino acids. The amino acids then are transported into the cell by a unique carrier system.

2. The small peptides are reduced to (mostly) dipeptides and tripeptides by enzymes on the external surface of the cell, followed by uptake of the di- and tripeptides into the cell where the final hydrolysis takes place.

Membrane Metabolism Strategy—While the nature and specificity of the brush border region enzymes still are the subject of intensive research, the extensive enzymatic activity in the region is well established (6, 7, 11, 23). The significance of this fact, from the point of view of a prodrug strategy, is based on the solubility–partition coefficient trade-off. Increasing the membrane permeability by increasing the membrane–water partition coefficient usually results in reduced solubility, leading to an optimum partition coefficient. That is, the aqueous (luminal) phase and the nonpolar membrane phase have conflicting physical property requirements.

The basis for the prodrug solubilization strategy is as follows. If a (soluble) derivative of an insoluble (high membrane–water partition coefficient) compound can be made that is a substrate for the brush border enzymes located at the interface between the polar and nonpolar phases, then conversion back to the high partition coefficient (low aqueous solubility) compound would occur immediately adjacent to the nonpolar (membrane) sink. This, in turn, would preclude or minimize precipitation of the insoluble drug. In other words, the prodrug strategy involves the use of interfacial enzymes to convert a drug (derivative) that has desirable properties in the one phase (high solubility) to one having desirable properties in the other phase (high partition coefficient). A scheme for this approach is presented in Fig. 2.

THEORETICAL

Membrane Permeability—The transport of a solute through a composite planar membrane will be considered first. The rate of mass transport per unit area, J, is given by (using the film model) (2, 3):

$$J = P_{\text{eff}}\,\Delta C \qquad \text{(Eq. 1)}$$

$$P_{\text{eff}} = \frac{P_a P_m}{P_a + P_m} \qquad \text{(Eq. 2)}$$

$$P_a = D/\delta_a \qquad \text{(Eq. 3)}$$

$$P_m = PCD/\delta_m \qquad \text{(Eq. 4)}$$

where ΔC is the concentration difference between the two sides of the composite barrier, P_{eff} is the effective permeability coefficient, P_a is the aqueous permeability, P_m is the membrane permeability, δ_a and δ_m are the respective film thicknesses, and PC is the membrane–water partition coefficient. Equation 2 can be rewritten as:

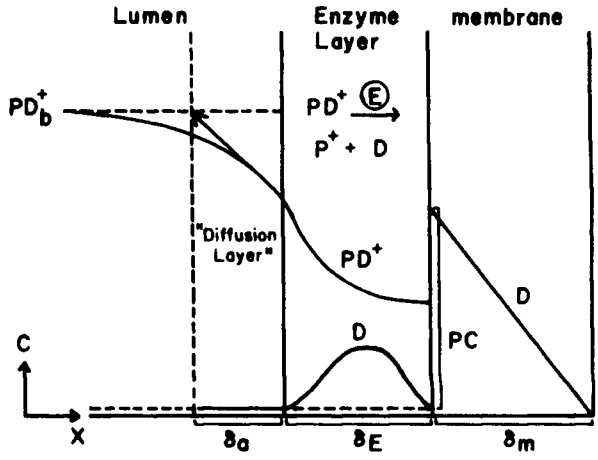

Figure 2—*Reaction diffusion model for absorption of soluble derivatives of insoluble compounds. Drug* (D) *may or may not build up in the enzyme layer. Key:* PD^+, *charged prodrug;* Ⓔ, *enzyme;* δ_a, *diffusion layer thickness;* δ_E, *enzyme layer thickness;* δ_m, *membrane thickness; and* PC, *membrane–enzyme layer partition coefficient.*

$$P_{\text{eff}} = \frac{D}{\delta_a + (\delta_m/PC)} \qquad \text{(Eq. 5)}$$

Under sink conditions, Eq. 1 becomes:

$$J = P_{\text{eff}} C_b \qquad \text{(Eq. 6)}$$

From Eq. 5, it is clear that as PC increases, P_{eff} increases and, hence, the absorption rate increases (Eq. 6). In the limit $PC \to \infty$, $P_{\text{eff}} = D/\delta_a$. However, as PC increases, a significant physical constraint must be considered: as PC increases, the aqueous solubility decreases and, as a result, C_b in Eq. 6 eventually must be replaced by C_s, the aqueous solubility:

$$J = P_{\text{eff}} C_s \qquad \text{(Eq. 7)}$$

Equation 7 represents the flux from suspensions. In this situation, increasing PC increases P_{eff} but decreases C_s to a greater extent. This trade-off leads to the existence of an optimum PC value (2, 3). Equations 5–7 are significant to a prodrug strategy since one can increase C_s but, in most cases, not without a corresponding decrease in P_{eff}[1]. However, given the preceding discussion of the interfacial (brush border) enzymatic activity, a prodrug strategy based on interfacial reconversion may be particularly effective. The transport basis for this approach is as follows. The model (Fig. 2) requires three layers with an enzymatic reaction occurring in the middle layer. The composite barrier is assumed to be planar[2], and the enzymatic reaction is assumed to be first order.

The solution for the three-layer model with a first-order reaction in the enzyme layer (rate constant = k) is:

$$J = P_R C_{A_0} \qquad \text{(Eq. 8)}$$

where P_R is a complex function of δ_w, δ_E, δ_m, K, k, and D (Fig. 2). However, a much simpler expression is obtained if it is assumed that the membrane layer is a sink for the drug and the membrane is impermeable to the (soluble) drug derivative (27). For this two-layer model, P_R from Eq. 8 becomes:

$$P_R = \frac{P_a P_E}{P_a + P_E} \qquad \text{(Eq. 9)}$$

with:

$$P_E = \alpha D \tanh(\alpha \delta_E) \qquad \text{(Eq. 10)}$$

$$\alpha^2 = k/D \qquad \text{(Eq. 11)}$$

[1] See Ref. 4 for examples where this is not the case.

[2] The error involved with this assumption for a cylinder having a radius of 0.2 cm is only 2–3% (27).

where k is the first-order reaction rate in the enzyme layer and P_a is D/δ_a. Note that:

$$\lim_{k\to 0} P_R = 0 \quad \text{and} \quad \lim_{k\to\infty} P_R = P_a$$

The most significant point regarding Eqs. 8–11 is that C_{A_0} is the concentration of the soluble drug derivative and that the membrane–aqueous solution partition coefficient does not enter into the equation. If the enzymatic reaction is fast (large k), the flux of the soluble drug derivative can be orders of magnitude greater than that of the insoluble drug.

Convective Diffusion Model—The experimental test system used a perfused rat intestine. Consequently, a model accounting for both convection and diffusion in a tube is required. The most appropriate model with the present experimental procedure is a laminar flow model (28). The solution to the convective diffusion problem for steady flow in a cylindrical tube with a permeable wall gives (27):

$$C_m/C_0 = \Sigma M_n \exp(-\beta_n^2 Gz) \qquad \text{(Eq. 12)}$$

where:

C_m = outlet (cup-mixing) concentration
C_0 = inlet concentration
$Gz = \pi DL/2Q$
D = aqueous diffusivity of the solute
L = length of the perfused intestine
Q = flow rate

and the M_n and β_n values are functions of the dimensionless (membrane) wall permeability, P_w^*, defined as:

$$P_w^* = \frac{P_w R}{D} \qquad \text{(Eq. 13)}$$

where R is the radius of the intestine.

The P_w value is defined by the boundary condition at the tube wall:

$$-D\left.\frac{\partial C}{\partial r}\right|_{r=R} = P_w C_w \qquad \text{(Eq. 14)}$$

where $C_w = C(R,z)$ is the wall concentration. The results in this study were analyzed using the laminar flow model, although other models could be applied to the data (28). It is important to note that P_w (or P_w^*) does not contain any contribution from the luminal diffusion of the drug. That is, there is no diffusion layer in the model; the luminal diffusion of the drug is accounted for by solution of the appropriate transport equation (27). For passively absorbed compounds, P_w^* is equal to P_m^* in Eq. 4; for the reactive compounds, P_w^* is equal to P_k^* of Eq. 10. Consequently, in interpreting the results, P_w^* must be interpreted appropriately.

The preceding analysis can be related to a pharmacokinetic analysis through a mass balance on the tube. This approach gives:

$$dm/dt = C_0(1 - C_m/C_0)Q \qquad \text{(Eq. 15)}$$

where dm/dt is the mass transported across the absorbing surface per unit time and can be computed directly from the perfusion results. A pharmacokinetic analysis would give $dm/dt = k_{abs}VC_0$, where V is the volume of the intestinal segment. Hence:

$$k_{abs} = (1 - C_m/C_0)Q/V \qquad \text{(Eq. 16)}$$

where C_m/C_0 is a function of the wall permeability (Eq. 12) and Q/V is the residence time of the fluid in the perfused segment. Equation 16 indicates that k_{abs} increases as Q/V increases. That is, the fluid stays in the intestinal segment longer and increases as C_m/C_0 decreases, *i.e.*, as P_w^* or Gz increases.

EXPERIMENTAL

Materials—The drug–prodrug pairs used were p-nitroaniline[3]–L-lysine p-nitroanilide[3] and [^{3}H]estrone[4]–[^{3}H]estrone-3′-L-lysine ester (I). [^{14}C]Polyethylene glycol[4] was used as a volume marker. [^{3}H]Estrone-3′-L-lysine ester was synthesized from [^{3}H]estrone and L-lysine. The synthesis and physicochemical properties of I will be the subject of a subsequent report (29).

Perfusion Experiments—Male Holtzman rats (300–350 g), fasted 12–18 hr, were anesthetized intramuscularly (gluteal muscle) with a 50% urethan solution (150 mg/100 g). A midline longitudinal incision was made in the abdomen, and a glass cannula was placed 2 and 10 cm distal to the ligament of Treitz. A pump[5] was used for perfusion at flow rates of 0.05–1.2 ml/min. Glass tubing was used throughout. [^{14}C]Polyethylene glycol was used as the volume marker. Volume changes rarely exceeded 3%.

An isotonic Sorensen phosphate buffer (pH 6.72) was used. The intestine was perfused first with buffer for 30 min and then for 30–60 min (until steady state) with drug solution. At the conclusion of the experiment, the animal was sacrificed. The intestine was excised and the length of the intestine from cannula to cannula was measured. The radius was calculated from the volume of the excised segment.

Assay—p-Nitroaniline and L-lysine p-nitroanilide were assayed spectrometrically at 375 and 315 nm, respectively. [^{3}H]Estrone, [^{3}H]lysine estrone ester, and [^{14}C]polyethylene glycol were assayed by liquid scintillation. In experiments with lysine p-nitroanilide, the effluent solution was analyzed for both lysine p-nitroanilide and p-nitroaniline. Measurable amounts of p-nitroaniline were not detected in any experiments with lysine p-nitroanilide.

Table I—Coefficients and Exponents for Eq. 19

3	0.03250	10.6734
4	0.01544	14.6712
5	0.00879	18.6699

RESULTS AND DISCUSSION

The experimental design was such that luminal reconversion (either biochemical or chemical) of the drug derivatives would not be significant, and none was observed. The conditions also maximized the possible attainment of laminar flow in the lumen (28). The results were analyzed using the method of Elliott *et al.*[6], interpreting the wall permeability appropriately (Eq. 4 or 10). The approximate wall permeability, ${}^0P_w^*$, was calculated from:

$$\frac{1}{{}^0P_w^*} = \frac{1}{P_{eff}^*} - \frac{1}{{}^0P_{aq}^*} \qquad \text{(Eq. 17)}$$

where:

$${}^0P_{aq}^* = \frac{\ln(C_m/C_0)\exp}{-4Gz} \qquad \text{(Eq. 18)}$$

and:

$${}^0P_{aq}^* = -\left[\sum_{n=1}^{5} {}^0M_n \exp(-{}^0\beta_n^2 Gz)\right] \Big/ 4Gz \qquad \text{(Eq. 19)}$$

The coefficient and exponents in Eq. 19 are given in Table I. This approach is equivalent to the diffusion layer approach but with the diffusion layer thickness calculated *a priori* (27). The exact expression for the diffusion layer thickness is:

$$\delta/R = \frac{1}{p_{aq}^*} = \frac{-4Gz}{\Sigma M_n \exp(-\beta_n^2 Gz)} - \frac{1}{P_w^*} \qquad \text{(Eq. 20)}$$

using the M_n and β_n values that are appropriate to the wall permeability, P_w^*. While P_w^* is unknown, analysis of the model shows that δ/R is only slightly dependent on P_w^*; hence, Eq. 19, which is appropriate for sink conditions [$P_w^* = \infty$ or $C(R,z) = 0$], provides a good estimate. A small correction then can be applied to the estimated ${}^0P_w^*$ from Eq. 17 to obtain P_w^* (27).

permeabilities are given in Tables II–V. Table VI presents a summary of the results, including the correction factors that are required to obtain an estimate of the (laminar flow) wall permeability. In analyzing the data in Tables II–V, the negative membrane permeabilities were omitted. In these cases, P^*_{eff} is greater than the calculated ${}^0P^*_{aq}$, predominantly with the reactive enzyme substrates having high P^*_w values. The possible reasons for this result are as follows. With the laminar flow model at any given Gz value, C_m/C_0 approaches a finite limit as $P^*_w \to \infty$. Since $P^*_{aq} \doteq 3$ as P^*_w increases above this value, the method loses sensitivity to P^*_w; that is, small changes in the experimentally determined C_m/C_0 values give rise to widely different P^*_w values. Experimental variation and error then can give rise to C_m/C_0 values that actually are lower than the values that the model can predict. In addition, the flow in the intestine in any given experiment may depart from laminar flow. Such mixing decreases C_m/C_0 below that expected by the model for very permeable compounds.

Since the variables of the flow rate and the length of the perfused intestine both are incorporated into the dimensionless variable Gz and since P^*_w should be independent of Gz[7] (27), regression analysis on ${}^0P^*_w$ *versus* Gz was performed. The results for estrone are shown in Fig. 3, and the regression equation is:

$${}^0P^*_w = 8.57 - 80.5Gz \qquad \text{(Eq. 21)}$$

$$n = 17 \quad s = 2.14 \quad r = 0.69$$

While there is considerable scatter and the variance does not appear to be constant, an increase in ${}^0P^*_w$ with decreasing Gz (increasing flow rate) is suggested by the data. A possible explanation might be that increasing the flow rate increases the diameter of the intestine. Since the Graetz number is independent of the radius[8] ($Gz = \pi DL/2Q$), the result is likely to be due to a change in the wall characteristics with the flow rate. For example, the surface coat on the microvillous membrane may become thinner as the radius increases, and, hence, the resistance would be lower.

Parent Compound Permeabilities—The wall permeabilities, P^*_w, for *p*-nitroaniline and estrone are interpreted following Eq. 4 as:

$$P^*_w = P^*_m = \frac{P_m R}{D} = PCR/\delta_m \qquad \text{(Eq. 22)}$$

Thus, a direct proportionality of P^*_w with the partition coefficient is expected. The octanol–water partition coefficients are ~25 and 600, respectively (30, 31). Hence, the wall permeabilities (P^*_w) of 6 and 3 are in the correct order, *i.e.*, estrone > *p*-nitroaniline. Since the aqueous resistance has been accounted for, the fact that the wall permeability ratio of estrone $[P^*_w(E_1)]$ to *p*-nitroaniline $[P^*_w(\text{pNA})]$ is 2 while the partition coefficient ratio is 25, combined with the model:

$$\frac{P^*_w(E_1)}{P^*_w(\text{pNA})} = \frac{P_w(E_1)}{P_w(\text{pNA})} = \frac{PC(E_1)}{PC(\text{pNA})} \qquad \text{(Eq. 23)}$$

clearly suggests that the model for the wall permeability must be improved. Some factors to be considered include: (*a*) the octanol–water partition coefficient does not reflect the physiological situation, (*b*) the aqueous phase and the membrane phase diffusivities differ greatly, and (*c*) the wall resistance term is composed of more than just a term for the nonpolar phase. The first factor undoubtedly is true, but it certainly is not the only (or perhaps major) reason. The effect of differing membrane diffusivities is analyzed as follows. The convective mass transport model used for analysis of the data was solved subject to the first-order boundary condition:

$$-\left.\frac{\partial C}{\partial r}\right|_{r=R} = \frac{P_w R}{D} C_w = P^*_w C_w \qquad \text{(Eq. 24)}$$

[7] The analysis is based on ${}^0P^*_w$ rather than P^*_w since the variation of the correction factor with Gz is small.

[8] The Gz value does not depend on R because the R dependence of the residence time cancels the R dependence of the radial penetration time when the flow rate is held constant.

Table VI—Wall Permeability Values for Compounds Studied

Compound	${}^0P^*_w$ [a]	γ [b]	P^*_w [c]
Estrone	6.3	0.92	6
Estrone-3′-L-lysine ester	34	0.87	30
p-Nitroanilide	3.3	0.93	3
L-Lysine *p*-nitroanilide	26	0.87	23

[a] Approximate (dimensionless) wall permeability (Eq. 17). [b] Correction factor (27). [c] Estimated wall permeability, $P^*_w = \gamma {}^0P^*_w$, for laminar flow model (Eqs. 12 and 13).

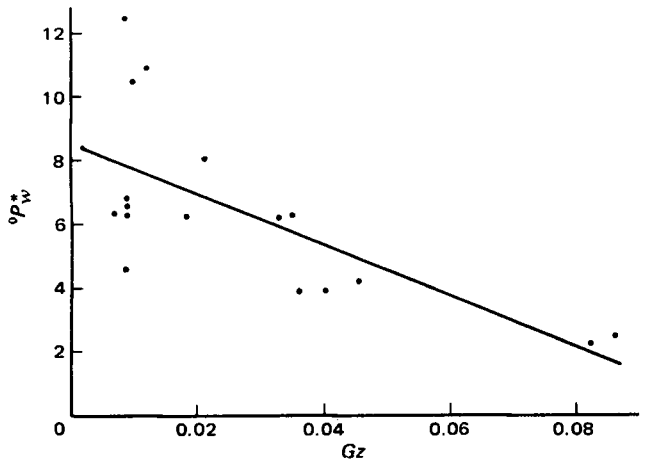

Figure 3—*Plot of the wall permeability,* $^0P^*_w$, *for estrone as a function of the Graetz number* (Gz).

or:

$$-D\left.\frac{\partial C}{\partial r}\right|_{r=R} = P_w C_w = J_w \qquad \text{(Eq. 25)}$$

where J_w is the flux at the wall, P_w is the permeability of the wall, and D is the aqueous diffusivity. A membrane model for the wall would give:

$$J_w = \frac{PCD_m C_w}{\delta_m} \qquad \text{(Eq. 26)}$$

where D_m and δ_m are the membrane parameters. Hence:

$$P_w = \frac{PCD_m}{\delta_m} \qquad \text{(Eq. 27)}$$

and:

$$P^*_w = \frac{PCD_m R}{D\delta_m} \qquad \text{(Eq. 28)}$$

Thus, the ratio of wall permeabilities is:

$$\frac{P^*_w(E_1)}{P^*_w(\text{pNA})} = \frac{PC(E_1)}{PC(\text{pNA})} = \frac{D_m(E_1)}{D_m(\text{pNA})} \qquad \text{(Eq. 29)}$$

assuming equal aqueous diffusivities for estrone and *p*-nitroaniline but not equal membrane permeabilities. Thus, the small ratio of dimensionless wall permeabilities may be due in part to a significantly lower D_m for estrone.

The third factor, an additional wall resistance term, is suggested by the presence of a surface coat on the microvillous membrane (32). If this glycoprotein layer is the major contributor to the membrane resistance, then the simple membrane model again would give Eq. 4, but, in this case, the partitioning would be into a more polar environment and the diffusivities of estrone and *p*-nitroaniline could be substantially different in the glycoprotein layer. Hence, both factors may reduce the permeability ratio.

Reactive Solute Permeabilities—For the reactive solutes, lysine estrone and lysine *p*-nitroanilide, the wall permeability may be interpreted following Eq. 10. Two limits are of interest: high reactivity, where $\alpha\delta_E > 1$ ($\tanh \alpha\delta_E \doteq 1$), for which:

$$P_w = \alpha D \qquad \text{(Eq. 30)}$$

or:

$$P^*_w = \alpha R \qquad \text{(Eq. 31)}$$

and low reactivity, where $\alpha\delta_E \ll 1$ ($\tanh \alpha\delta_E \doteq \alpha\delta_E$), for which:

$$P_w = \alpha^2 D\delta_E \qquad \text{(Eq. 32)}$$

or:

$$P^*_w = \alpha^2\delta^R_E \qquad \text{(Eq. 33)}$$

The lysine estrone–lysine *p*-nitroanilide permeability ratio $[P^*_w(\text{LE}_1)/P^*_w(\text{LpNA})]$ becomes:

$$\frac{P^*_w(\text{LE}_1)}{P^*_w(\text{LpNA})} = \frac{k_{\text{LE}_1}}{k_{\text{LpNA}}} \qquad \alpha\delta_E > 1 \qquad \text{(Eq. 34)}$$

and:

$$\frac{P^*_w(\text{LE}_1)}{P^*_w(\text{LpNA})} = \left(\frac{k_{\text{LE}_1}}{k_{\text{LpNA}}}\right)^2 \qquad \alpha\delta_E \ll 1 \qquad \text{(Eq. 35)}$$

While the membrane enzymes involved in the hydrolysis reactions are not well characterized, kinetic results for trypsin have shown amides to be much poorer substrates than the corresponding esters (33). Consequently, the similar permeability values for LE_1 and LpNA are not likely to be explained in this manner.

As with the passively absorbed compounds, it may be that the surface coat on the microvillous membrane serves as an additional resistance. In this case, the enzymes at the interface (and perhaps to some extent in the surface coat) would provide the effective sink rather than the partitioning into the membrane. Although the scatter in the data is considerably larger for the reactive substrates, the results clearly indicate that the effective wall permeability of the reactive substrates is higher than the corresponding passively absorbed compounds by a factor of five to 10. Based on the suggested interpretation, the reason could be that the effective thickness of the surface coat is smaller for the reactive substrates.

While the interpretation of the permeability values clearly requires more experimental work, the most important point to be obtained from these results is that the derivatives have permeabilities at least as great as those of the parent compounds. Consequently, they are absorbed very efficiently, even though the compounds have smaller diffusivities and much higher polarity (lower partition coefficients) due to the protonated α- and ϵ-amino groups. Thus, an equal or greater effective permeability has been achieved along with much higher aqueous solubility. Since absorption of the intact derivatives is unlikely, hydrolysis at the membrane interface apparently is very effective.

The results also imply that the interfacial reaction is as fast or faster than aqueous diffusion or diffusion through the surface coat since the results approach (and exceed) the value that would be obtained if sink conditions ($P^*_w = \infty$) prevail. Furthermore, lysine *p*-nitroanilide is relatively stable in solution and yet is absorbed very efficiently. This finding suggests that the hydrolysis of amides is at least as fast as luminal diffusion. Consequently, amide derivatives of amines, which otherwise are too stable for chemical reconversion to be effective, may be effective using this strategy.

Absorption Rate—To illustrate further the potential of this approach, the results of the estrone and lysine estrone experiments are graphed in Fig. 4 following Eq. 15 in the form:

$$\log dm/dt = \log[(1 - C_m/C_0)Q] + \log C_0 \qquad \text{(Eq. 36)}$$

A single line is drawn through the estrone and lysine estrone data since their effective permeabilities are nearly the same. That is, at the same flow rate, the fraction absorbed $(1 - C_m/C_0)$ is the same, provided that C_0 is below the saturation concentration. When saturation is reached, $C_0 = C_s$ and the amount absorbed per unit time levels off at a constant value.

On the other hand, for lysine estrone, the mass transfer per unit time increases until the solubility of 0.3 *M* is reached (29). The result is that the amount of lysine estrone absorbed per unit time could be about five orders of magnitude greater than that for estrone (note that Fig. 4 is a log–log plot).

Clearly, many questions remain to be investigated, both with respect

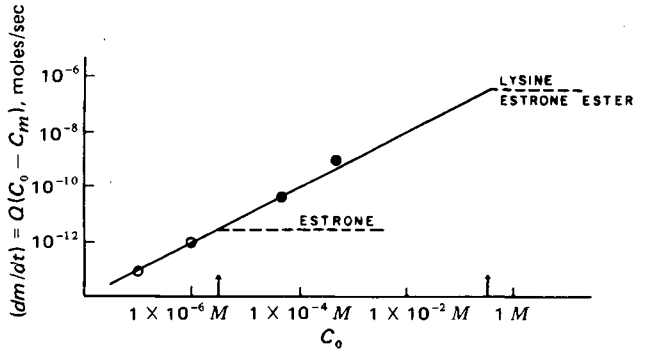

Figure 4—*Amount of drug absorbed per unit time* (dm/dt) *as a function of the initial perfusing concentration* (C_0) *for estrone and lysine estrone. Key:* ○, *estrone;* ●, *lysine estrone;* ↑, *solubilities; and* – –, *theoretical limits.*

to the absorption mechanism and to the actual effectiveness of the strategy in normal physiological situations. However, the results obtained to date strongly suggest that the biochemical strategy offers a new approach with great potential for improving drug product efficacy.

CONCLUSION

A biochemical strategy for improving the absorption of water-insoluble drugs has been tested and shown to have potential for increasing the absorption rates of insoluble compounds by several orders of magnitude. The strategy is based on the use of the enzymes in the interfacial brush border region of the mucosal cells to effect a conversion of the soluble derivative back to the insoluble, high partition coefficient parent compound. Since the aqueous luminal fluid and nonpolar membrane phases have conflicting physical property requirements, the interfacial reaction is, in effect, being used to change the physical properties of a compound from one having desirable aqueous (luminal) properties to one having desirable membrane permeation properties.

Results on two drug–drug derivative pairs, estrone–lysine estrone and *p*-nitroaniline–lysine *p*-nitroanilide, show that the effective intestinal membrane permeability of the derivatives is actually five to 10 times greater than that of the parent compounds. Since the derivatives are significantly more polar than the parent compound, the results indicate that the effective permeability associated with the interfacial enzymatic reaction is not a determining resistance. Thus, the usual physical property compromise necessary to obtain efficient drug absorption by other strategies is avoided. Analysis of the permeability data for both the parent compounds and derivatives suggests that the surface coat on the microvillous membrane may be an important resistance in the absorption process. The apparent residual dependence of the wall permeability on Gz also may be due to a thinning of this coat as *Gz* decreases. In addition, the higher wall permeabilities of the derivatives compared to the parent compounds may be due in part to hydrolysis partially occurring in this layer, reducing its effective thickness.

Analysis of the data in terms of the absorption rate (mass transport per unit time) indicates that an improvement of several orders of magnitude is possible. For lysine estrone–estrone, a two to three order of magnitude increase has been demonstrated, with a four or five order of magnitude increase possible. Given the high solubility, dissolution rate, and permeability of lysine estrone, the biochemical strategy appears to be capable of significantly improving the absorption of water-insoluble drugs.

Analysis of Models for Determining Intestinal Wall Permeabilities

G. L. AMIDON *x, J. KOU *, R. L. ELLIOTT *, and E. N. LIGHTFOOT ‡

Received February 27, 1980, from the *School of Pharmacy and the ‡Department of Chemical Engineering, University of Wisconsin, Madison, WI 53706. Accepted for publication June 11, 1980.

Abstract □ In determining intestinal wall permeabilities, several mass transport models may be applied to analyze the results from external perfusion experiments. The appropriateness of any given model depends on the applicability of the model assumptions to the experimental system. This report compares several mass transport models with respect to their assumptions and applicability to a particular experimental design. The models are shown to differ in their assumptions regarding convection and diffusion in the perfusing fluid. However, since the wall permeability is an unknown parameter in each model and is estimated from the data, all of the models fit the mass transfer results reasonably well, despite fundamentally different assumptions. However, the determined permeabilities differ. Residence time distribution analysis of the experimental system is more sensitive to the model assumptions. It is shown that, in a particular experimental system, laminar flow in a cylindrical tube is the most appropriate model. The model also has the advantage of implicitly accounting for the convection–diffusion problem in the perfusing fluid. Hence, the diffusion layer thickness is not estimated from the data. With the hydrodynamics defined, the relative permeabilities resulting from the application of the several models to the data can be interpreted. The wall permeability determined in the suggested manner provides an estimate of the limiting assistance under perfect mixing conditions.

Keyphrases □ Permeability—mass transport models of intestinal wall permeability □ Models, hydrodynamic—mass transport models of intestinal wall permeability □ Diffusion—mass transport models of intestinal wall permeability

In determining the permeability of the intestinal wall by external perfusion techniques, several models have been proposed (1–5). In each model, assumptions must be made regarding the convection and diffusion conditions in the experimental system. These assumptions, in turn, affect the interpretation of the resulting permeabilities. In addition, the appropriateness of the assumptions in the models to the actual experimental situation must be determined. Often, good agreement between the predicted (theoretical) result and the experimental result is used to support the validity of the model. However, in many cases, several models may be equally satisfactory, particularly when significant variation occurs from experiment to experiment. In this situation, independent experiments that are more sensitive to the assumptions in the models are needed to substantiate their validity.

This report shows that several reasonable models for mass transfer in external perfusion experiments can account for the data reasonably well because the actual wall permeability is unknown. That is, if the permeability is treated as a parameter and is estimated from the data, all of the models can describe the data relatively well.

However, the resulting permeabilities differ, and their interpretation rests on the validity of the assumptions. Consequently, residence time distribution analysis is used to obtain more direct insight into the convection and diffusion assumptions of the mass transfer models. Since the laminar flow model discussed previously (5) has the advantage of providing a direct measure of the wall permeability, the experimental system used was one that maximizes the possible attainment of these conditions.

EXPERIMENTAL

[^{14}C]Polyethylene glycol[1] was used for the residence time studies. Assays were conducted by liquid scintillation. For the residence time perfusion experiments, male Holtzman rats (250–350 kg) were fasted for 12–18 hr and anesthetized with an intramuscular (gluteal muscle) dose of 150 mg/100 g with a 50% urethan solution. A midline abdominal incision was made, and the intestine was cannulated 2 and 10 cm distal to the ligament of Treitz. The entrance tubing was connected to a three-way stopcock such that the test solution would flow straight through the stopcock. The buffer solution, isotonic Sorensen's buffer at pH 7.3, was perfused through the remaining stopcock arm for 20–30 min.

The experiment was initiated by turning the stopcock to the test solution (polyethylene glycol–Sorensen's buffer) at time zero. Samples were collected at 15-sec intervals for ~2 min ($2\bar{t}$) and then at 30-sec intervals for up to ~6 min ($6\bar{t}$). From the collected samples, 0.1 ml was transferred by micropipet to the counting vial. For the step change in concentration, the test solution was perfused throughout the experiment. For the (finite) pulse change, the stopcock was switched from the buffer to the test solution and back to the buffer over about a 2-sec interval. The flow rate was 0.5 ml/min for all experiments.

At the conclusion of the experiment, the animal was sacrificed and the cannulated intestine was excised. The length and volume of the excised intestine were measured to estimate the residence time in the perfused segment. The mass transfer studies used [^{3}H]estrone[1] and followed a procedure described previously (6).

RESULTS AND DISCUSSION

Mass Transfer Models—Four models will be described that differ in their convection and diffusion assumptions (Fig. 1). These models include the laminar flow, plug flow, and complete radial mixing (diffusion layer) models for convective mass transport in a tube and the perfect mixing tank model. It is convenient to begin with the solute transport equation in cylindrical coordinates (5, 7):

$$v_z \frac{\partial C}{\partial z} = D \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial C}{\partial r}\right) \qquad \text{(Eq. 1)}$$

where:

v_z = axial velocity distribution
D = solute diffusivity in the solvent
C = concentration of A in B
z = axial coordinate
r = radial coordinate

Introduction of the dimensionless variables:

$z^* = z/L$
$r^* = r/R$
$v_z^* = v_z/V_m$
$Gz = DL/V_mR^2 = \pi DL/2Q$
R = radius of the tube
L = length of the tube
V_m = maximum velocity
Q = perfusion flow rate

gives:

Table I—Summary of Various Models

Model	Equation	Variables	Comments
Laminar flow	$C_m/C_0 = \Sigma M_n \exp(-\beta_n^2 Gz)$	P_w^* and Gz	M_n and β_n are functions of P_w^* (Ref. 5)
Plug flow	$C_m/C_0 = \Sigma M'_n \exp(-\beta_n'^2 Gz)$	$P_w'^*$ and Gz	M'_n and β'_n are functions of $P_w'^*$ (Ref. 8)
Complete radial mixing	$C_m/C_0 = \exp(-4P_{eff}^* Gz)$	P_{eff}^* and Gz	$P_{eff}^* = \frac{P_a^* P_w^*}{P_a^* + P_w^*}$
Mixing tank	$C_m/C_0 = (1 + 4P_{eff}'^* Gz)^{-1}$	$P_{eff}'^*$ and Gz	$P_{eff}'^* = \frac{P_a'^* P_w^*}{P_a'^* + P_w^*}$

$$v_z^* \frac{\partial C}{\partial z^*} = Gz \left(\frac{1}{r^*} \frac{\partial}{\partial r^*} r^* \frac{\partial C}{\partial r^*} \right) \quad \text{(Eq. 2)}$$

This relationship is subject to the first-order boundary condition at the wall:

$$\left. \frac{\partial C}{\partial r^*} \right|_{r^*=1} = -P_w^* C_w \quad \text{(Eq. 3)}$$

where $P_w^* = P_w R/D$ = the dimensionless wall permeability.

The main assumptions in arriving at Eqs. 1 and 2 are: (*a*) the diffusivity and density are constant; (*b*) the solution is dilute so that the solvent convection is unperturbed by the solute; (*c*) the system is at steady state ($\partial C/\partial t = 0$); (*d*) the solvent flows only in the axial (z) direction; (*e*) the tube radius, R, is independent of Gz; and (*f*) axial diffusion is small compared to axial convection (7). The boundary condition (Eq. 3) is true for many models having a tube wall but does not describe a carrier transport or Michaelis–Menten process at the wall, except at low solute concentrations. Rewriting Eqs. 2 and 3[2] gives:

$$v_z^* \frac{\partial C}{\partial z} = Gz \left(\frac{1}{r} \frac{\partial}{\partial r} r \frac{\partial C}{\partial r} \right) \quad \text{(Eq. 4)}$$

$$\left. \frac{\partial C}{\partial r} \right|_{r=1} = -P_w^* C_w \quad \text{(Eq. 5)}$$

It is clear that the solution is $C = C(r, z, Gz, P_w^*)$. That is, Gz and P_w^* are the two fundamental independent (dimensionless) variables. Since the measured exit concentration is generally a velocity-averaged concentration (cup-mixing concentration), averaging over r gives:

$$C_m(Gz, P_w^*) = \frac{\int_0^{2\pi} \int_0^1 v_z C r \, dr \, d\theta}{\int_0^{2\pi} \int_0^1 v_z r \, dr \, d\theta} \quad \text{(Eq. 6)}$$

where z (dimensionless) is set equal to 1 (*i.e.*, the concentration is measured at the end of the tube). For the several models discussed here, the given solution refers to the cup-mixing concentration, and Gz and P_w^* are the only fundamental independent variables. However, the P_w^* value will have different interpretations within the context of the different models.

Laminar Flow Model—In the laminar flow model, the velocity profile is taken to be that for a Newtonian fluid in a tube:

$$v_z^* = v_z/V_m = 1 - r^2 \quad \text{(Eq. 7)}$$

where $V_m = 2\langle v \rangle$ and $\langle v \rangle$ is the average flow velocity; *i.e.*, $Q = \langle v \rangle \pi R^2$. With this velocity profile, Eq. 4 is separable and with the boundary condition in Eq. 5 has the solution (5):

$$C_m/C_0 = \sum_n M_n \exp(-\beta_n^2 Gz) \quad \text{(Eq. 8)}$$

where C_m is the exit cup-mixing concentration at length L and C_0 is the inlet concentration (constant). The laminar flow model will be discussed in detail in a report[3] that also contains tabulated values of the M_n and β_n values as a function of P_w^*.

Plug Flow Model—In the plug flow model, the velocity profile is considered to be independent of both r and z. That is, $v_z = Q/\pi R^2$ and is constant; hence, $V_z = V_m$ and $V_z^* = 1$. The solution to Eqs. 4 and 5 is (8):

$$C_m/C_0 = \Sigma M'_n \exp(-\beta_n'^2 Gz) \quad \text{(Eq. 9)}$$

where $M'_n = -4P_w'^*/(\beta_n'^4 + \beta_n'^2 P_w'^{*2})$ and the β'_n values are the roots of the equation:

$$\beta' J_1(\beta') - P_w'^* J_0(\beta) = 0 \quad \text{(Eq. 10)}$$

with J_1 and J_0 being zero-order bessel functions of the first and second kinds. The roots of Eq. 10 are tabulated in Refs. 8 and 9.

With this model, the assumption that V_z is constant is one of perfect slip at the wall. That is, V_z is constant throughout the fluid while the velocity of the wall is zero. However, there is radial diffusion as well as a corresponding concentration gradient toward the wall. The $P_w'^*$ value is the true wall permeability if the actual hydrodynamics are of this type. For a given wall permeability, the plug flow model predicts greater absorption of the solute compared to the laminar flow model due to greater convection near the wall.

Complete Radial Mixing Model—For this model, the velocity profile is assumed to be constant as with the plug flow model. In addition, the concentration is assumed to be constant radially but not axially. That is, there is complete radial, but not axial, mixing to give uniform radial velocity and concentration profiles. With these assumptions, Eq. 4 and

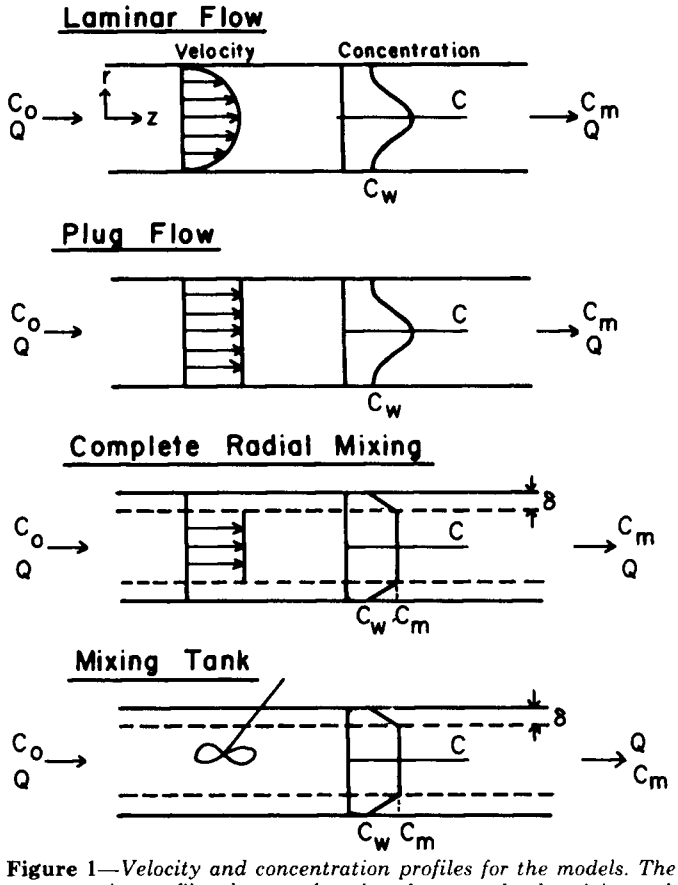

Figure 1—*Velocity and concentration profiles for the models. The concentration profiles also are a function of z except for the mixing tank model.*

[2] Hereafter, all equations will be in dimensionless form but the asterisk will be deleted from the r and z symbols except where the context clearly indicated otherwise.

[3] See R. L. Elliott, G. L. Amidon, and E. N. Lightfoot, *J. Theor. Biol.*, in press.

the boundary condition (Eq. 5) have the solution (5):

$$C_m/C_0 = \exp(-4P^*_{eff}Gz) \quad \text{(Eq. 11)}$$

where P^*_{eff} replaces P^*_w. Since no aqueous resistance is included directly in the model, the wall resistance usually is augmented with a film or diffusion layer resistance. That is, complete radial mixing occurs up to a thin region or film adjacent to the membrane. The aqueous (luminal) resistance is confined, within this model, entirely to this region in series with the membrane. Hence, the wall permeability includes an aqueous or luminal resistance term and can be written as:

$$P^*_{eff} = \frac{P^*_w P^*_a}{P^*_w + P^*_a} \quad \text{(Eq. 12)}$$

where P^*_w is the true wall permeability and P^*_a is the effective aqueous permeability (1–3, 5).

The aqueous permeability often is written as:

$$P_a = D/\delta \quad \text{(Eq. 13)}$$

or:

$$P^*_a = R/\delta \quad \text{(Eq. 14)}$$

where δ is the film thickness and represents an additional parameter that needs to be determined from the data to obtain P^*_w. Since the assumed hydrodynamic conditions probably are not realistic at the low Reynolds numbers for typical experiments, P^*_a or δ/R is an empirical parameter.

The complete radial mixing model also can be derived from a differential mass balance approach (1) and often is referred to as the diffusion layer model. A comparison of the laminar flow and complete radial mixing models will be reported later[3].

Mixing Tank Model—This model takes the next step and assumes that both radial and axial mixing are complete. The aqueous resistance again is thought to be confined to a region (film) next to the membrane where only molecular diffusion occurs, whereas the rest of the contents are well mixed (perfect mixer). This model is described most easily by a mass balance on the system:

$$(\text{mass/time})_{inlet} - (\text{mass/time})_{outlet} = (\text{mass/time})_{absorbed} \quad \text{(Eq. 15a)}$$

or:

$$QC_0 - QC_m = (2\pi RL)(P'_{eff})C_m \quad \text{(Eq. 15b)}$$

where $2\pi RL$ is the area of the mass transfer surface (cylinder) of length L and radius R, P'_{eff} is the permeability or mass transfer coefficient of the surface, and C_m is the concentration in the tube (which is constant and equal to the outlet concentration by the perfect mixing assumption). From Eq. 15b is obtained:

$$\frac{C_0 - C_m}{C_m} = P'_{eff}\frac{2\pi RL}{Q} \quad \text{(Eq. 16)}$$

or:

$$C_0/C_m = 1 + 4P'^*_{eff}Gz \quad \text{(Eq. 17)}$$

As with the complete radial mixing model, P'^*_{eff} contains the additional parameter $P'^*_a = R/\delta'$ that must be estimated from the data. The P'^*_a and P'^*_{eff} values for the mixing tank model differ from those for the complete radial mixing model by nature of the different hydrodynamic assumptions. While this model probably is not appropriate to most perfusion experiments, it will be useful to compare its ability to correlate mass transfer data with the other models.

Model Comparison and Summary—Table I summarizes the models with respect to the predicted mass transfer. If the true wall permeability, P^*_w, were known, then each model could be tested against the data to determine its ability to reproduce the data. Since this is not the case, the appropriate P^*_w or P^*_{eff} value must be determined from the data. A test of the model then is to determine its ability to correlate the data, given a value for the permeability (estimated from the data). That is, the equations in Table I correlate the observed C_m/C_0 as a function of the Gz value, with the permeability being used as a variable parameter.

Mass Transfer Results—Figure 2 presents the results using the simple mixing tank model (Eq. 17). The best-fit line (with zero intercept) is:

$$(C_0/C_m) - 1 = 6.97Gz \quad \text{(Eq. 18)}$$

with $n = 17$, $s = 0.064$, and $p < 0.0005$. The standard error of the slope is 0.43. The P'^*_{eff} calculated from Eq. 17 is 1.7. Given the simplicity of the model, it accounts for the data reasonably well. However, from the graph, it is clear that systematic deviations occur from the best-fit line. If the two data points at the highest Gz value were removed from the data set, the model would do quite well.

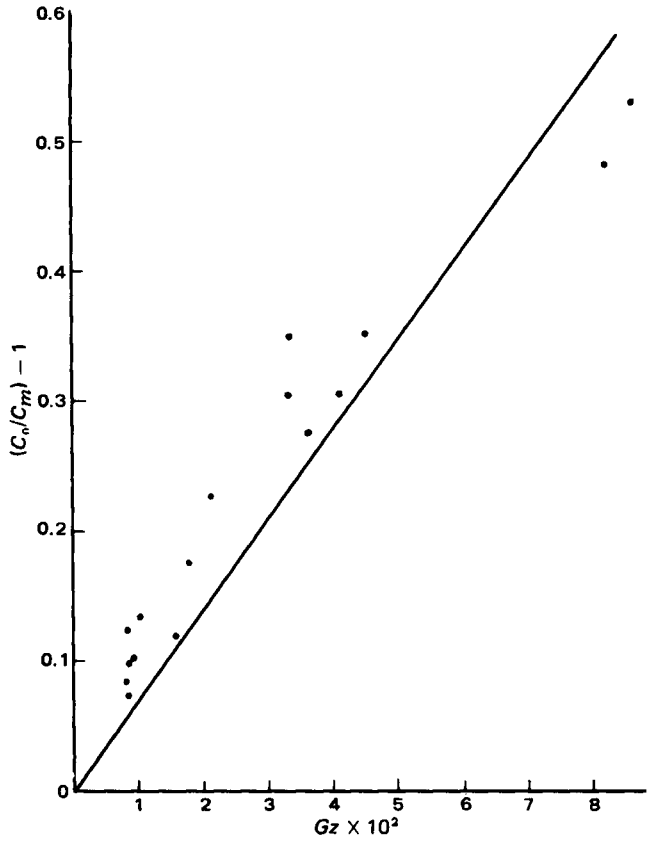

Figure 2—*Graph of* $(C_0/C_m) - 1$ versus Gz *following the mixing tank model* (—) *and the experimental data* (●) *for estrone.*

Figure 3 presents the data as well as the best-fit lines for all four models. The permeabilities were estimated *via* linear regression following Eqs. 11 and 17 and by nonlinear regression following Eqs. 8 and 9 for the respective models. The resulting permeabilities are given in Table II. From Fig. 3, it is clear that it is not possible to choose from among the models on the basis of the mass transfer data if the permeability itself is estimated from the data. The permeabilities differ for the various models. Interpretation of the respective permeabilities requires knowledge as to which model most closely reflects the actual experimental situation.

Residence Time Distribution Analysis—To interpret the mass transfer results and the associated permeabilities, it is necessary to establish the actual hydrodynamics. Since, as noted, the mass transfer data are not sensitive to the model if the wall permeability is known, an independent method that is more sensitive to the hydrodynamics is required. In any given situation, the hydrodynamics implied (assumed) by one or another of the mass transfer models may be the most appropriate. The experimental design used for this study maximized the possible attainment of laminar flow.

Residence time distribution analysis provides one method for determining flow characteristics (10–12). A step or pulse change in the inlet concentration of a completely inert tracer is made, and the resulting appearance of the tracer in the outlet stream is monitored. The appear-

Table II—Permeability Values Estimated from the Data for the Various Models

Model	Permeability[a]
Mixing tank	1.7 (±0.9)
Complete radial mixing	2.0 (±0.3)
Plug flow	3.1 (±0.5)
Laminar flow	5.7 (±1.3)

[a] Dimensionless permeability. Values in parentheses represent the approximate 95% confidence intervals.

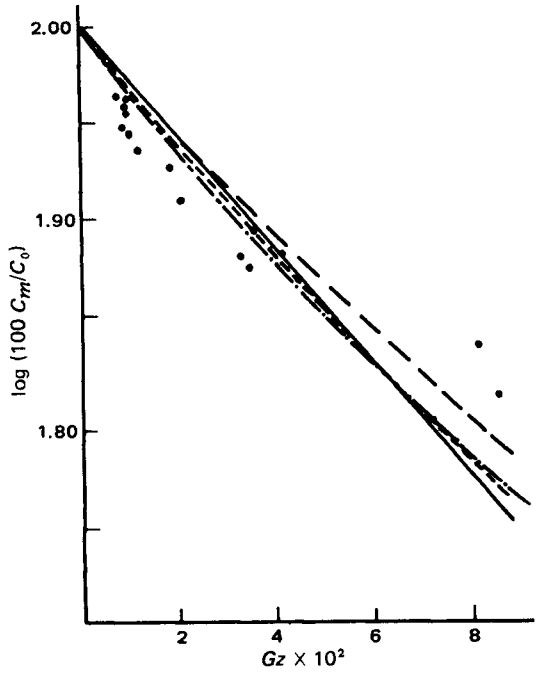

Figure 3—*Graph of log(100*C_m/C_0*) versus Gz for the several models and the experimental data (●) for estrone. Key: – –, mixing tank model; —, complete radial mixing model; - - -, plug flow model; and · – ·, laminar flow model.*

ance of tracer in the outlet stream is a function of the flow (hydrodynamic) conditions since these conditions, in turn, determine the length of time a given fluid element entering the inlet stays in the apparatus. In dealing with potentially very simple hydrodynamics, three simple models are appropriate: mixing tank, plug flow, and laminar tube flow. The step change in concentration, $C = 0$ at $t < 0$ and $C = C_0$ at $t > t_0$, at the inlet gives the F curve, while a finite pulse change (12) gives the E curve. The F curve is defined as:

$$F = \langle C \rangle / C_0 \qquad \text{(Eq. 19)}$$

where $\langle C \rangle$ is the exit cup-mixing concentration and C_0 is the inlet concentration.

The E curve is defined by:

$$E = dF/dt \qquad \text{(Eq. 20)}$$

For a pulse change in concentration at the inlet with a total mass, M, of tracer injected:

$$M = \int_0^\infty \langle C \rangle \, dt \qquad \text{(Eq. 21)}$$

and the E curve is obtained from:

$$E = \frac{\langle C \rangle}{M} \qquad \text{(Eq. 22)}$$

The (experimental) mean residence time, $\bar{t}$, in the apparatus is obtained from:

$$\bar{t} = \int_0^\infty \bar{t} E \, dt \qquad \text{(Eq. 23)}$$

for the pulse change and from:

$$\bar{t} = \int_0^\infty (1 - F) \, dt \qquad \text{(Eq. 24)}$$

for the step change. The corresponding F and E functions for the plug flow model are:

$$F = 0 \qquad t < \bar{t} \qquad \text{(Eq. 25a)}$$

$$F = 1 \qquad t > \bar{t} \qquad \text{(Eq. 25b)}$$

$$E = 0 \qquad t \neq \bar{t} \qquad \text{(Eq. 25c)}$$

$$E = \text{input function} \qquad t = \bar{t} \qquad \text{(Eq. 25d)}$$

For the perfect mixer model, they are:

$$F = 1 - e^{-t/\bar{t}} \qquad \text{(Eq. 26a)}$$

$$E = \frac{1}{\bar{t}} e^{-t/\bar{t}} \qquad \text{(Eq. 26b)}$$

For the laminar flow model, they are:

$$F = 1 - \left(\frac{\bar{t}}{2t}\right)^2 \qquad t > \bar{t}/2 \qquad \text{(Eq. 27a)}$$

$$E = \frac{\bar{t}^2}{2} \frac{1}{t^3} \qquad t > \bar{t}/2 \qquad \text{(Eq. 27b)}$$

The theoretical E and F curves for these models using $\theta = t/\bar{t}$ as dimensionless time are shown in Fig. 4. These models contain only one parameter, $\bar{t}$.

More complex, two- (or more) parameter models, *e.g.*, tanks in series or a dispersion model, could be fitted to the data. However, given the simplicity of the flow situation, this is unnecessary.

The experimental results from the intestinal perfusion studies also are shown in Fig. 4. Since the plug flow model clearly is inappropriate, it will not be analyzed further.

Table III presents the mean residence times estimated by the following three methods: (*a*) the volume measurement of the intestine at $\bar{t} = V/Q$,

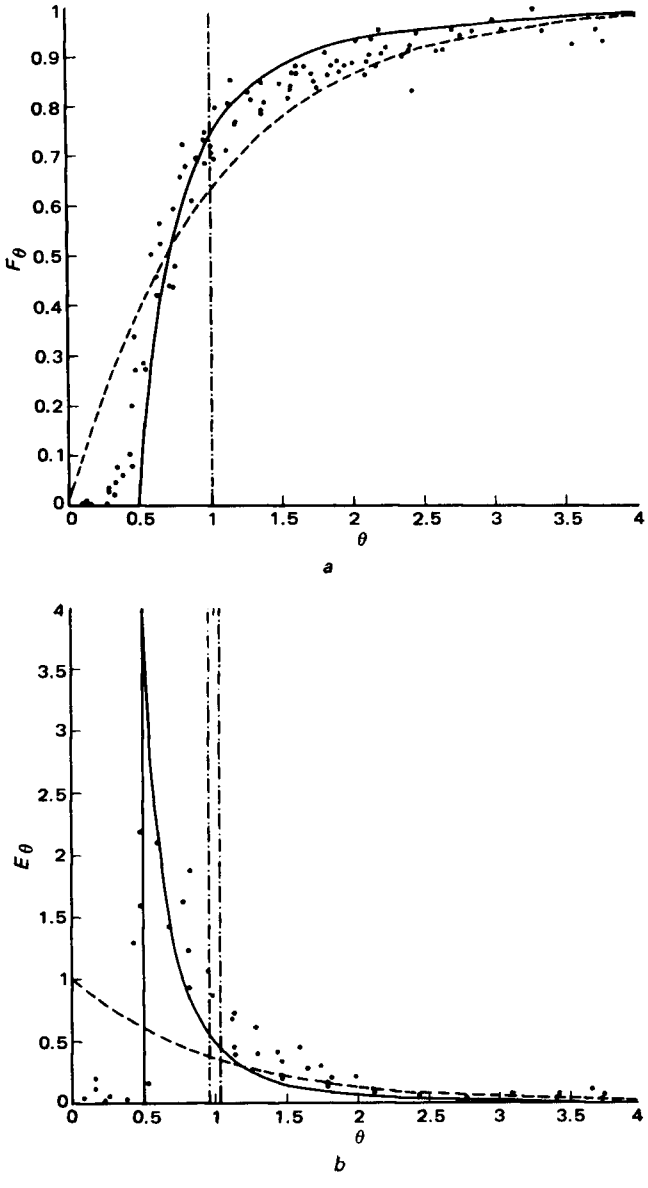

Figure 4—*Curves for perfusion experiments,* F versus θ = t/$\bar{t}$ (a) *and* E versus θ (b). *Key: - - -, mixing tank model; —, laminar flow model; - · -, plug flow model; and ●, experimental results.*

Table III—Estimated Mean Residence Times

Experiment[a]	$\bar{t}\left(\frac{V}{Q}\right)$	$\bar{t}$ (Area)	Mixing Tank $\bar{t}$ (regression)[b]	Laminar Flow $\bar{t}$ (regression)[b]
1	65	60.6	63.9 (13)	60.8 (5)
2	65	51.5	52.4 (8)	57.8 (5)
3	65	52.6	53.0 (11)	56.8 (4)
4	97	70.1	67.5 (13)	76.1 (9)
5	97	86.2	82.7 (23)	79.4 (5)
6	97	82.3	74.8 (11)	77.2 (13)
7	78	65.5	55.8 (11)	55.7 (5)
8	78	71.5	68.7 (16)	65.0 (2)
9	78	81.2	75.8 (14)	76.2 (10)
10	43	46.0	73.6 (75)	37.4 (2)
11	43	46.2	70.6 (63)	34.6 (3)
12	85	86.6	230.3 (300)	89.9 (8)
13	85	99.2	237.0 (310)	74.9 (1)

[a] Experiments 1–9 represent step changes in inlet concentration, and Experiments 10–13 represent pulse changes in concentration. [b] Numbers in parentheses represent approximate 95% confidence intervals.

(*b*) integration following Eq. 23 or 24, and (*c*) nonlinear regression fitting of the mixing tank and laminar flow models to the data using the mean residence time, $\bar{t}$, as the only parameter.

The results in Fig. 4 and Table II clearly suggest that the laminar flow model is the most appropriate of the three simple models. However, the data suggest that some mixing or dispersion is occurring in the system since the tracer appears at the outlet somewhat faster than laminar flow would predict.

Interpretation of Mass Transfer Data—Given the results of the residence time studies, the permeabilities are interpreted most appropriately on the basis of laminar flow hydrodynamics. The estrone permeability value of 6, determined under the assumption of laminar flow, represents an estimate of the true wall permeability. The luminal diffusive component, P^*_{aq}, is not included in the wall permeability. In fact, if the flow is laminar, P^*_{aq} can be calculated from the model (5).

Assuming that the laminar flow permeability measures the wall permeability, the permeabilities resulting from application of the other models can be interpreted. The plug flow value of 3 is lower than the laminar flow result since a larger membrane resistance is needed to compensate for the lower estimate of the aqueous resistance. That is, the larger amount of convection near the wall in the plug flow model leads to a larger P^*_{aq} than actually is the case. Consequently, the membrane permeability must be lower to account for the observed result.

The permeability value for the complete radial mixing model of 2 is lower than the plug flow (and laminar flow) model since this model assumes radial mixing, which leads to still lower estimated luminal (aqueous) resistance values and a higher estimated membrane resistance (lower permeability value). However, the usual interpretation of the complete radial mixing model recognizes that the permeability value includes an aqueous (film) resistance.

The mixing tank model takes the final step in assuming both radial and axial mixing. The permeability value for this model is the lowest of all of the models. Again, this result is due to the low luminal resistance implied by the model. As with the complete radial mixing model, a film resistance usually is included in the wall permeability to account for the presence of an aqueous resistance.

If, as suggested, the complete radial mixing permeability includes a film (diffusion layer) aqueous resistance, the permeability value should be that obtained from the laminar flow model augmented by a P^*_{aq} value following Eq. 12. However, P^*_{aq} is a function of both P^*_w and Gz and, hence, must be calculated at every flow rate (Gz value) using the known P^*_w value. However, an estimate of P^*_{aq} can be made that is not greatly in error by using the ${}^0P^*_{aq}$ value for sink conditions at the wall and an average Gz value (5). This approach gives ${}^0P^*_{aq} = 3.7$. The predicted permeability for the complete radial mixing model thus is 2.2, which is in good agreement with the estimated value of 2.0. A more detailed discussion of the basis for this calculation was given previously (5, 6).

This discussion illustrates one major advantage of the laminar flow approach. The diffusion layer thickness is not a parameter in the model, and the wall permeability can be calculated directly. In the complete radial mixing model, the P^*_{aq} (equal to R/δ) value enters the model to account for the unknown hydrodynamics and, hence, must be estimated from the data as well. The residence time distribution analysis indicates that laminar flow can be established to a reasonable approximation in external perfusion experiments. Consequently, there is no need to introduce a new parameter.

With respect to the normal physiological situation, the hydrodynamics clearly are much more complex. However, the wall permeability is of intrinsic interest since it represents the limiting (controlling) resistance under perfect mixing conditions. Consequently, the wall permeability can be used to quantitate the absorption characteristics of drugs as well as for an experimental approach to the study of the nature of the wall resistance.

CONCLUSION

Four mass transport models that can be applied to intestinal perfusion studies were developed and compared. The models differ with respect to the assumptions regarding convection and diffusion in the perfusing fluid. If the wall permeability is estimated from the experimental results, all of the models work reasonably well. The wall permeabilities fall in the order mixing tank < complete radial mixing (diffusion layer) < plug flow < laminar flow.

Residence time distribution analysis was employed as a more sensitive measure of the validity of the underlying model assumptions. In the experimental system employed, laminar flow in a circular duct is the most appropriate model. This model provides the most direct measure of the intrinsic wall (membrane) permeability. The permeabilities for the various models are in the expected order for the test system, with the wall permeability decreasing in direct proportion to the extent to which the models overestimate the aqueous permeability.

It is concluded that laminar flow in an externally perfused intestine is attainable experimentally and provides the most direct measure of the intrinsic wall permeability. The wall permeability, in turn, represents the limiting permeability under perfect mixing conditions.

Received September 7, 1979, from the *Product Development Laboratories, Sankyo Company, Ltd., 1-2-58, Hiromachi, Shinagawa, Tokyo, Japan.* Accepted for publication February 21, 1980.

Abstract □ The relationship between the dose of levodopa and its pharmacokinetic behavior following intravenous and oral administration was investigated in dogs and parkinsonian patients. Six beagle dogs received single doses of 2.4, 4.8, and 9.6 mg of levodopa/kg iv and single doses of 4.8, 9.6, and 19.2 mg of levodopa/kg po in a crossover fashion on separate occasions. Three parkinsonian patients received single oral doses of ~3.8, 7.7, and 15.4 mg of levodopa/kg in a crossover test. Plasma samples were analyzed for intact levodopa and total dopamine. The relationship between the area under the plasma concentration–time curve (*AUC*) of levodopa and the intravenous dose to dogs was linear. However, in both dogs and patients, the relationship after oral dosing was nonlinear, with the relative *AUC* increasing with increasing dose. Therefore, the pharmacokinetic behavior of levodopa after oral administration to dogs and patients was dose dependent.

Keyphrases □ Levodopa—pharmacokinetics, effect of dose, dogs and parkinsonian patients □ Pharmacokinetics—levodopa, effect of dose, dogs and parkinsonian patients □ Bioavailability—levodopa, effect of dose, dogs and parkinsonian patients

It was shown previously (1, 2) that the bioavailability of intact levodopa after oral administration was ~35% in both dogs and parkinsonian patients but that the total amount absorbed, including levodopa metabolites, was 80–90% of the administered dose, probably due to extensive metabolism of levodopa during absorption (2). On the other hand, Cotzias *et al.* (3) succeeded in treating parkinsonian patients with high doses of levodopa, and other investigators reported the effectiveness of high doses and the ineffectiveness of low doses in levodopa therapy (4–7).

The first-pass metabolism and clinical facts described indicate the need for an investigation of the absolute bioavailability of levodopa at different doses after intravenous and oral administration in beagle dogs and in patients.

EXPERIMENTAL

Intravenous Dose Studies of Levodopa in Dogs—Six healthy male beagle dogs, 10.3–13.3 kg, were fasted for ~16 hr and divided into three groups of two dogs each. Levodopa injection solution[1] was injected intravenously, over 30 sec, at 2.4 mg/kg to the first group, at 4.8 mg/kg to the second group, and at 9.6 mg/kg to the third group. Crossover experiments were carried out at 1-week intervals.

Blood samples were withdrawn with a heparinized syringe from the contralateral brachial vein. Sampling times were 0, 2, 5, 15, and 30 min and 1, 1.5, 2, 3, 4, and 6 hr postdosing. Urine was collected before the dose and over 48 hr after intravenous administration. The blood and urine specimens were processed as described previously (1, 2).

Oral Dose Studies of Levodopa in Dogs—The same six beagle dogs that were used in the intravenous dose studies were fasted for ~16 hr and divided into three groups of two dogs each. Levodopa in capsule form[2] was administered forcefully orally at 4.8 mg/kg to the first group, at 9.6 mg/kg to the second group, and at 19.2 mg/kg to the third group with 10 ml of warm water. Emesis was prevented by keeping the mouth closed by hand. Crossover experiments were carried out at 1-week intervals.

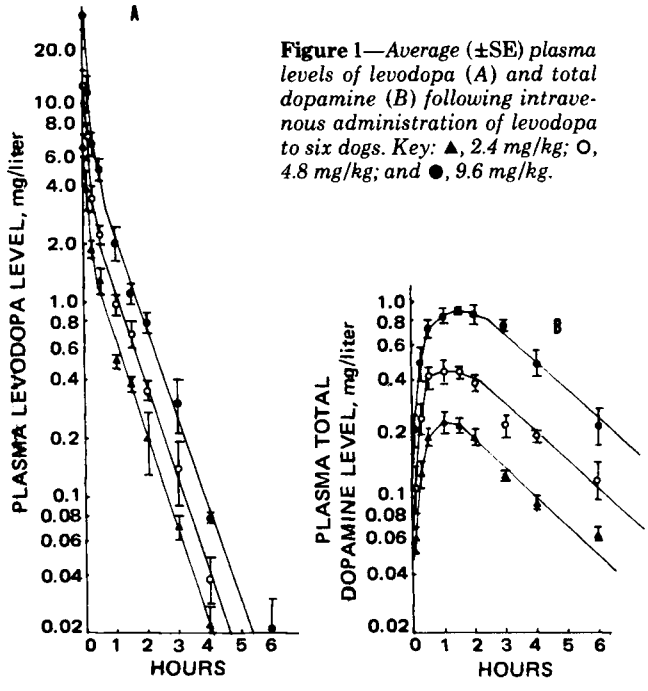

Figure 1—*Average (±SE) plasma levels of levodopa (A) and total dopamine (B) following intravenous administration of levodopa to six dogs. Key: ▲, 2.4 mg/kg; ○, 4.8 mg/kg; and ●, 9.6 mg/kg.*

Blood samples were withdrawn with a heparinized syringe before and at 0.5, 1, 2, 3, 4, and 6 hr after oral administration. Urine also was collected before the dose and over 48 hr. The blood and urine samples were processed as described previously (1, 2).

Oral Dose Studies of Levodopa in Parkinsonian Patients—Three parkinsonian patients, 26–63 years old, participated in this study. Three days prior to the experiments, all levodopa preparations and other drugs administered for the treatment of Parkinson's disease were withdrawn. Levodopa capsules[3] were administered orally at ~3.8 mg/kg together with a cup of water at ~9 am to the first subject, at ~7.7 mg/kg to the second subject, and at ~15.4 mg/kg to the third subject in the same manner. Crossover experiments were carried out at 1-week intervals.

On the day of the experiment, the patients ate breakfast at ~7:00 am, lunch at about noon, and dinner at ~5:30 pm. Blood was withdrawn with a heparinized syringe before dosing and at 0.5, 1, 2, 3, 4, and 6 hr after oral administration. The blood sample processing was carried out as described previously (1, 2). During the 3 days between the experiments of the crossover test, to prevent the appearance of parkinsonian syndrome, 500-mg doses of levodopa capsules were administered three times per day ~30 min after each meal instead of withdrawing the drug.

Assay of Levodopa and Its Metabolites in Plasma and Urine—Levodopa and its metabolites in plasma and urine were assayed according to the method reported previously (1).

Ratio of *AUC* for total dopamine to levodopa	0.52 ± 0.04	0.58 ± 0.04	0.56 ± 0.05

Pharmacokinetic Analysis—The plasma levodopa concentration curves following intravenous administration to dogs were analyzed using the program of Hanano *et al.* (8). The plasma levodopa concentration curves following oral administration to dogs and patients were analyzed using the BMDP-3R nonlinear regression program (9) with a one-compartment open model.

RESULTS

Intravenous Dose Studies of Levodopa in Dogs—The average plasma levels of levodopa and total dopamine[4] following intravenous administration of 2.4-, 4.8-, and 9.6-mg/kg doses of levodopa to six dogs are shown in Fig. 1. Plasma levels of levodopa and total dopamine increased proportionally with the dose of levodopa administered. The linear relationship between the dose and the *AUC* of levodopa is shown in Fig. 2. Pharmacokinetic parameters of the disposition of intravenously administered levodopa were estimated for each dog by fitting the data to the two-compartment open model, assuming linear kinetics. The resultant parameter estimates are summarized in Table I. The *AUC* values of levodopa and total dopamine corrected for body weight also are shown in Table I, as is the ratio of the *AUC* values of total dopamine to levodopa. This ratio, as well as the parameter estimates, is essentially constant and independent of the dose of levodopa administered.

The average urinary excretion of levodopa and its metabolites over 48 hr after intravenous administration of 2.4, 4.8, and 9.6 mg of levodopa/kg to six dogs is shown in Fig. 3. These results show that the total amount excreted in the urine following intravenous administration of 2.4, 4.8, and 9.6 mg of levodopa/kg was similar, indicating 60–65% of the administered dose. The patterns of urinary levodopa and its metabolites were essentially constant, independent of the levodopa dose among the doses administered.

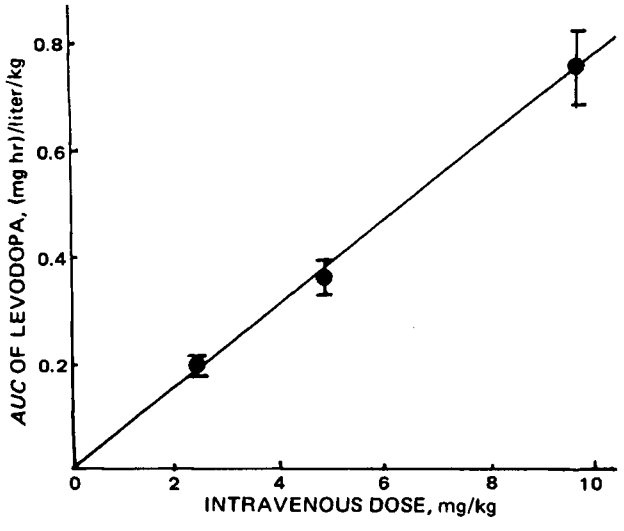

Figure 2—*Relationship between the intravenous dose and the observed* AUC *of levodopa corrected for body weight in dogs (average ± SE).*

[4] Total dopamine = conjugated dopamine + unconjugated dopamine.

Oral Administration of Levodopa in Dogs—The average plasma levels of levodopa and total dopamine following oral administration of 4.8, 9.6, and 19.2 mg of levodopa/kg to six dogs are shown in Fig. 4. As the levodopa dose administered increased, plasma levels of levodopa appeared to be disproportionally high. However, total dopamine, one of its metabolites, revealed an inverse situation; as the dose increased, the relative plasma levels of total dopamine were progressively lower. The average dose-normalized peak concentrations for levodopa were 0.11 ± 0.01, 0.14 ± 0.02, and 0.18 ± 0.01 kg/liter. While the differences do not appear to be statistically significant in most cases, they reflect a trend. The relationship between the levodopa dose administered and the ob-

Table III—Average Urinary Excretion of Levodopa and Its Metabolites as Percentage of Administered Dose following Oral Administration of 4.8, 9.6, and 19.2 mg of Levodopa/kg to Six Dogs

Dose, mg/kg	Percent Dose Excreted in 0–48-hr Urine (Average ± *SE*): Total Levodopa[a]	Total Dopamine	Total 3,4-Dihydroxyphenylacetic Acid[b]	Total Homovanillic Acid[c]	Total[d]
4.8	0.45 ± 0.04 [e]	10.2 ± 1.0	10.1 ± 1.1	31.5 ± 3.1	52.5 ± 4.9
9.6	0.54 ± 0.05 [e]	12.8 ± 1.1	12.3 ± 1.2	29.5 ± 3.0	55.1 ± 5.1
19.2	0.64 ± 0.06 [e] [f]	12.5 ± 1.2	12.9 ± 1.4	24.5 ± 2.1	50.6 ± 4.5

[a] Total levodopa = unconjugated levodopa + conjugated levodopa. [b] Total 3,4-dihydroxyphenylacetic acid = unconjugated 3,4-dihydroxyphenylacetic acid + conjugated 3,4-dihydroxyphenylacetic acid. [c] Total homovanillic acid = unconjugated homovanillic acid + conjugated homovanillic acid. [d] Sum of total levodopa, total dopamine, total 3,4-dihydroxyphenylacetic acid, and total homovanillic acid. [e] Not significant ($p > 0.05$). [f] Significant ($p < 0.05$).

served *AUC* of levodopa is shown in Fig. 5. As the dose increased, the *AUC* increased disproportionately.

Elimination rate constants of levodopa after oral administration to dogs were calculated for each dog by fitting the data to the one-compartment open model. These values are summarized in Table II, along with the *AUC* of levodopa and total dopamine corrected for body weight and the ratio of the *AUC* of total dopamine to that of levodopa. The estimated elimination half-lives were essentially constant, independent of the levodopa dose, but the ratio of the *AUC* decreased with an incease in the dose. On the other hand, the average urinary excretion of levodopa and its metabolites over 48 hr after oral administration of 4.8, 9.6, and 19.2 mg of levodopa/kg to six dogs is shown in Table III. The total amount excreted in the urine following oral administration of the three different doses was similar, but the total levodopa excreted in the urine appeared to increase as the dose increased; only the differences between the 4.8- and 19.2-mg/kg doses were statistically significant ($p < 0.05$).

The absolute bioavailability and the total amount absorbed from the GI tract, including levodopa and its metabolites, following oral administration of 4.8, 9.6, and 19.2 mg of levodopa/kg to six dogs were calculated, based on the assumed linear kinetics, using the respective *AUC* or urinary excretion from intravenous doses of 4.8 and 9.6 mg/kg and also using the dose-corrected *AUC* or urinary excretion from an intravenous 19.2-mg/kg dose (Table IV). The absolute bioavailability of oral levodopa in dogs was dose dependent, while the total amount absorbed was essentially constant, independent of the dose administered.

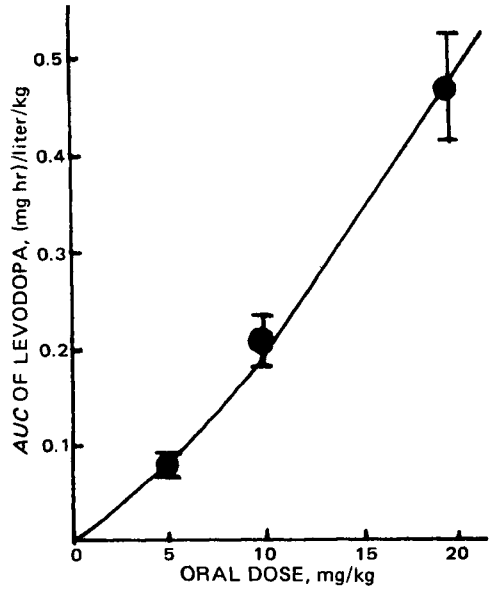

Figure 5—*Relationship between the oral dose and the observed* AUC *of levodopa corrected for body weight in dogs (average ± SE).*

Oral Dose Studies of Levodopa in Parkinsonian Patients—The average plasma levels of levodopa and total dopamine following oral administration of 3.8, 7.7, and 15.4 mg of levodopa/kg to three patients are shown in Fig. 6. The relationship between the dose administered and the plasma levels of levodopa and total dopamine was not directly proportional to the dose. As the dose increased, the relative plasma levels of levodopa were progressively higher but the relative plasma levels of total dopamine were progressively lower: *i.e.*, the dose-normalized plasma levels of levodopa increased with the dose while that of total dopamine decreased with the dose. The relationship between the levodopa dose and the *AUC* of levodopa is shown in Fig. 7. As found with the dogs, the *AUC* value of levodopa showed a nonlinear relationship as the dose increased.

The elimination rate constant of levodopa after oral administration to patients was calculated for each patient by fitting the data to a one-compartment open model. In addition, the ratio of the *AUC* of total dopamine to that of levodopa was calculated (Table V). The *AUC* values of levodopa and total dopamine corrected for body weight also are shown. The *AUC* of levodopa was constant and independent of the levodopa dose, but the *AUC* of total dopamine decreased with an increase in the dose.

The absolute bioavailability of doses of ~3.8, 7.7, and 15.4 mg of levodopa/kg after oral administration to three patients was evaluated on the assumptions that levodopa in the body obeys linear kinetics and that it is appropriate to compare the two different population groups, using the dose-corrected *AUC* from the intravenous dose reported previously (2). This result is listed in Table VI. The absolute bioavailability of oral levodopa in three different doses in patients was dose dependent in the same way as in dogs.

DISCUSSION

To evaluate the influence of the dose of levodopa on the pharmacoki-

15.4	31.2 ± 3.9

[a] Based on the assumed linear kinetics using the dose-corrected *AUC* from the intravenous dose.

netic behavior and bioavailability of the drug, plasma levodopa and total dopamine, one of its main metabolites, and urinary excretion following intravenous and oral administration to dogs and parkinsonian patients were determined. These results indicated that the pharmacokinetic behavior of levodopa and its total urinary excretion, including its metabolites, following intravenous administration to dogs was essentially constant within the dose range tested. Although the total urinary excretion was constant within the dose range after oral administration to dogs, the bioavailability of oral levodopa was dose dependent in both dogs and patients, and the urinary total dopamine also appeared to be dose dependent in dogs.

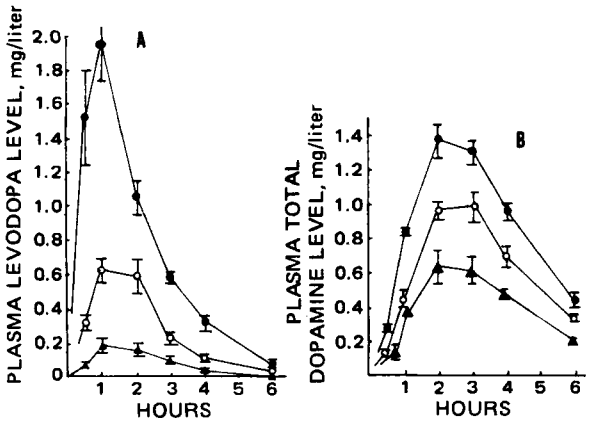

Figure 6—*Average* (±SE) *plasma levels of levodopa* (*A*) *and total dopamine* (*B*) *following oral administration of levodopa to three patients. Key:* ▲, *3.8 mg/kg;* O, *7.7 mg/kg; and* ●, *15.4 mg/kg.*

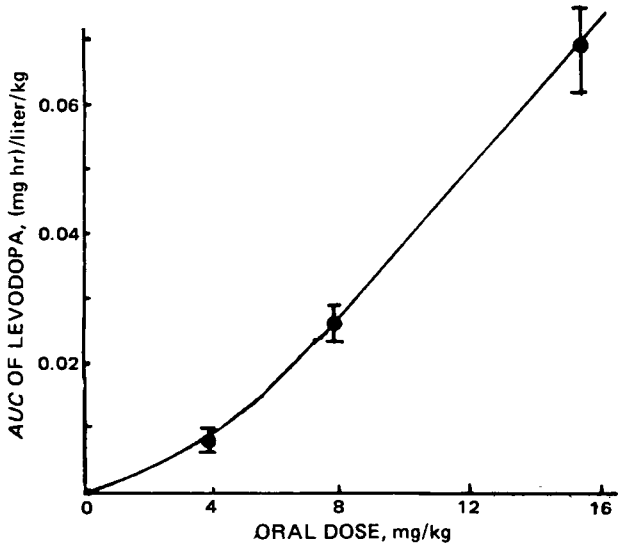

Figure 7—*Relationship between oral doses and observed* AUC *of levodopa in patients* (*average* ± SE).

The absolute bioavailability of oral levodopa must be calculated based on the assumption that levodopa in the body obeys linear kinetics. To test this assumption, an experiment is needed in which radiolabeled levodopa is given intravenously and unlabeled levodopa is given orally to the same subject at the same time. However, this assumption might be true since the clearance of levodopa in the plasma following intravenous administration proved to be constant, independent of the dose, and the elimination rate constant of levodopa in the plasma after oral administration was unchanged within the dose range tested, with nearly the same value found after intravenous administration. Furthermore, the change in total levodopa excreted in the urine after oral administration was proportional to the increase in the fraction of oral levodopa absorbed.

Bioavailability of the drug following oral administration is controlled by at least two factors: the rate and extent of uptake of levodopa in the gut and first-pass metabolism as a function of the dose. If active transport is the main process controlling the bioavailability of levodopa, then the total amount excreted in the urine can be expected to decrease as the dose increases. The observed results are contrary to this expectation. Therefore, if the active transport of levodopa in the GI tract occurs within the dose range tested, it does not play a significant role in affecting bioavailability. The elimination rate constant of levodopa in the plasma was observed to be constant, independent of the oral levodopa dose. This finding suggests the absence of saturation in the systemic elimination as the levodopa dose increased. In addition, the ratio of the *AUC* of total dopamine to that of levodopa after oral administration was small as the dose increased. This ratio reflects the extent of presystemic metabolism when compared to the ratio after intravenous administration (2).

These data support the contention that the dose-dependent bioavailability of levodopa is due to saturable first-pass metabolism during absorption. As the oral dose of levodopa is increased, the fraction of the dose metabolized to dopamine is reduced, and a larger fraction of the oral dose reaches the systemic circulation as intact, pharmacologically active drug. This phenomenon seems to be the most important factor in new dosage form design for improvement of the bioavailability of levodopa.

These results are interesting when they are related to the clinical use of levodopa. Hornykiewicz's assertion (10) that Parkinson's disease could be improved by offsetting the cerebral dopamine deficiency in parkinsonian patients with the administration of levodopa was not achieved at low doses of the drug. However, the high-dose therapy administered in 1967 by Cotzias *et al.* (11) led to the first successful treatment of Parkinson's disease and several subsequent studies (6, 12–14) supported their findings. The results in this report help explain these results.

Simultaneous Determination of Cephalexin and Lysine in Their Salt Using High-Performance Liquid Chromatography of Derivatives

J. L. FABREGAS ˣ and J. E. BENEYTO

Received November 2, 1979, from the *Analytical Department, Laboratorios Almirall, C/Cardoner, 68-74, Barcelona 24, Spain.* Accepted for publication February 29, 1980.

Abstract □ A sensitive and useful high-performance liquid chromatographic method using derivatization was developed for the simultaneous determination of intact cephalexin and lysine in their salt. This method is rapid and reliable, and its inherent specificity makes it an improvement over the common wet chemical methods for stability studies.

Keyphrases □ Cephalexin—simultaneous high-performance liquid chromatographic determination with lysine in their salt using derivatization □ Lysine—simultaneous high-performance liquid chromatographic determination with cephalexin in their salt using derivatization □ High-performance liquid chromatography—analysis, cephalexin and lysine in their salt, derivatization

The sodium salt of cephalexin is absorbed poorly after intramuscular injection (1, 2). Similar observations were made with a related compound, cephradine (3). Investigations with other soluble salts of cephalexin showed that some basic amino acids increased the absorption and bioavailability of cephalexin (4). The extensive use of the lysine salt of cephalexin necessitated the development of methods for the simultaneous determination of both components in this salt. Alkalimetric determination of carboxylic groups and nonaqueous titration of α-amino groups cannot be used because these two groups are present in both components. For the same reason, the Folin reaction with sodium β-naphthoquinone-4-sulfonate or hypobromite and α-naphthol (5) and the Saxena method (6) for microtitration of amino acid mixtures are unsatisfactory, and the selective titration of the ϵ-amino group of lysine in aqueous media with sulfuric acid is insufficiently accurate.

A recent report described the intramolecular aminolysis of some cephalosporins, caused by the nucleophilic attack of an α-amino group in the C-7 side chain in the β-lactam nucleus, which yields piperazine-2,5-dione derivatives (7). Estimation of the rate of disappearance of free amino groups was carried out by the 2,4,6-trinitrobenzenesulfonic acid (I) assay of Satake *et al.* (8) in a modified form. Applications of this technique to cephalexin lysinate was not possible due to interference by lysine.

A high-performance liquid chromatographic (HPLC) procedure for the analysis of lysine and cephalexin trinitrophenyl derivatives (II and III, respectively) is presented here. It is a rapid, sensitive, and specific method for the simultaneous determination of these two substances.

EXPERIMENTAL

Apparatus—Absorption spectra were obtained with a double-beam spectrophotometer[1] with a 1.0-cm cell. HPLC assays were performed with a liquid chromatograph[2] equipped with a variable-wavelength detector[3] and a 1-μl loop injection valve[4]. A stainless steel column (25 × 0.46 cm) loaded with alkylamine[5] (13 μm) was used.

Reagents—Cephalexin monohydrate[6], lysine hydrochloride[7], the lysine salt of cephalexin[8], and trinitrobenzenesulfonic acid[9] were used. The buffer solutions of pH values up to 7.6 were McIlvaine's buffers (9), the pH 7.6 buffer was prepared according to the method of Bundgaard (7), and the buffer solutions of higher pH were those of Clark and Lubs (10). All other reagents were analytical reagent grade.

General HPLC Procedure—An aqueous solution containing the lysine salt of cephalexin (2.0 ml) (5×10^{-4}–2×10^{-3} *M*) was mixed in a 100-ml volumetric flask with buffer solution (pH 10, 2.0 ml) and I (0.4% in water, 5.0 ml). The mixture was shaken and kept in the dark for 1 hr. Acetate buffer (pH 4.8, 20.0 ml) and aqueous 0.1% *o*-nitrophenol (2.0 ml as the internal standard) were added, and the solution was brought to volume with water.

A sample of this solution (1 μl) was injected into the liquid chromatograph and developed using an eluent system of 1% citric acid in a methanol–water mixture (5:40 v/v) with an isocratic flow rate of 0.75

ml/min and detection at 425 nm. Good chromatographic performance was achieved only when the column temperature was 50°.

Any significant degradation products were detected by TLC after the initial reaction at pH 10.

Procedure in Basic Degradation Study—Solutions ($\sim 10^{-3}$ *M*) of cephalexin and lysine in 0.5 *N* NaOH were prepared. The assay was carried out on samples taken after standing for 20 and 60 min, respectively, at room temperature. The pH was adjusted to pH 4.8 with 2 *N* HCl, and HPLC of II and III was carried out as described.

Procedure in Acid Degradation Study—Solutions of cephalexin and lysine ($\sim 10^{-3}$ *M*) in 1 *N* HCl were maintained at 60° for 1 hr. These solutions were brought to pH 4.8 with 1 *N* NaOH, and HPLC of II and III was carried out as described.

RESULTS AND DISCUSSION

The simple spectrophotometric method of Bundgaard (7) could not be used for the simultaneous analysis of lysine and cephalexin because both derivatives show identical absorption maxima (425 nm). The velocity constants of the reaction of I with the primary amino compounds is known to be related exponentially to the pH of the reaction medium (11). Consequently, a study was made to find conditions for the direct spectrophotometric assay of cephalexin and lysine in mixtures of these two components. Cephalexin and lysine do not react with I at an appreciable rate below pH 6. Both II and III are stable over long periods and, at other pH values, the reaction obeys pseudo-first-order kinetics, except the reaction of lysine and I at pH 7.6, which is linear with time (Fig. 1).

The different reaction rates of the α- and ϵ-amino groups of lysine with

Table II—Parameters of Calibration Curves

Equation[a]	Compound	a_0, mg/ml	Correlation Coefficient	*n*
$c(\text{mg/ml}) = a_0 + a_1 \frac{h}{h_s}$	II	0.0477	0.9909	8
	III	0.7501	0.9873	8
$c(\text{mg/ml}) = a_0 + a_1 h(\text{mm})$	II	0.0177	0.9916	15
	III	0.0833	0.9977	15

[a] h and h_s are the heights of the sample and internal standard chromatographic peaks, respectively.

I are apparent from a change in the slope of the rate curve (Fig. 2). The slope of the absorbance–time curve for lysine at pH 7.6 is proportional to the concentration of lysine and is linear over the concentration range of 0.5–1.3 × 10^{-3} *M*. By measuring the change of absorbance with time at pH 7.6, it is possible to measure the concentration of both cephalexin and lysine, but there are only small changes in the slope of the line with large changes in the lysine concentration, leading to low sensitivity.

For these reasons, the liquid chromatography of derivatives of I was selected since these derivatives are stable (12), they behave well on alkylamine columns (13), and lysine does not absorb appreciably in the visible or UV regions.

Quantitative formation of II and III occurred most rapidly when the reaction medium was at pH 10 (Fig. 1). However, Amino Sil-X-I columns are not stable at this pH, and the pH of the medium after formation of these derivatives was reduced to pH 4.8. The cephalexin derivative is stable for up to 20 hr at this pH and the lysine derivative is stable for 2 hr, after which it slowly decomposes. The retention times of II and III using different eluents are shown in Table I.

Lysine and especially cephalexin (14) are degraded in both alkaline and acidic solutions. Many of the degradation products contain primary amino groups and are a potential source of interference in the specific analysis of lysine and cephalexin, particularly in pharmaceutical products undergoing stability studies.

Pure solutions of lysine and cephalexin were degraded under acidic and alkaline conditions for different times, and the chromatograms of II and III were studied. Under alkaline conditions, the original peaks of unchanged lysine and cephalexin derivatives (retention times of 3.9 and 11.6 min, respectively) disappeared, and well-defined peaks of degradation products appeared (at 8.8 min from II and at 1.8, 2.4, and 9.4 min from III). However, none of these peaks interfered with the main peaks

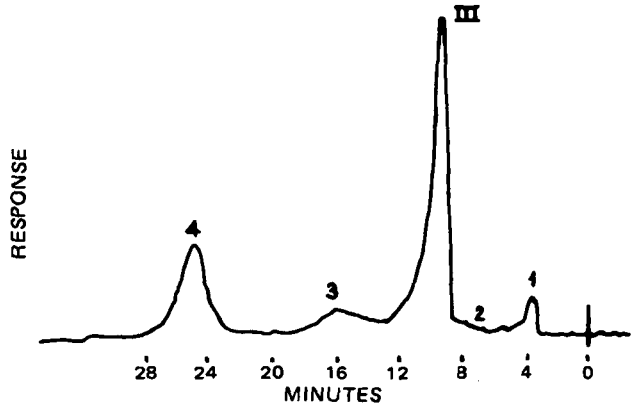

Figure 3—*Chromatogram of III and acid-degraded cephalexin derivative mixture.*

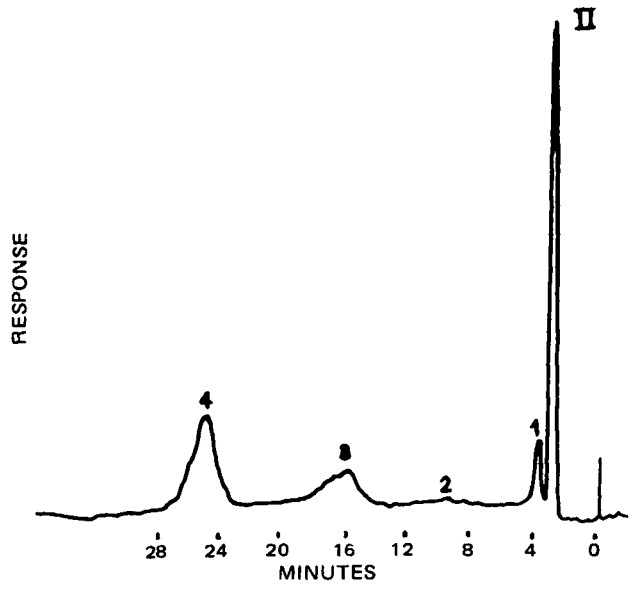

Figure 4—*Chromatogram of II and acid-degraded cephalexin derivative mixture.*

used in the assay of lysine and cephalexin. Cephalexin solutions stored under acidic conditions at 60° yielded four secondary peaks (retention times of 4.1, 11.0, 15.2, and 27.2 min), which could interfere with the chromatographic assay. Trinitrophenyl derivatives were prepared from mixtures containing 50% of acid-hydrolyzed cephalexin solutions and 50% of a pure cephalexin or pure lysine solution (Figs. 3 and 4), respectively. It is apparent that the peak of II was not affected by the acid decomposition products of cephalexin and that the peak of III was affected only minimally. The chromatogram of II after acid hydrolysis (1 hr) showed only two small additional peaks at 16.4 and 26.0 min.

The calibration factors used for the quantitative analysis of cephalexin and lysine are given in Table II. The low values of the intercept at the origin (a_0), when operating with the loop-injection technique but without the internal standard, allow use of this technique. Table II shows that similar calibration parameters were obtained by both techniques (with and without an internal standard), corresponding to the listed straight-line equations. The average response factors for II and III were 110.94 and 36.92 mm/mg with standard deviations of 0.76 and 1.05, respectively, for a set of 45 chromatograms. Sensitivity was three times higher for lysine than for cephalexin, but the sensitivity of the instrument allows lower detection limits of 0.1 and 0.3 μg/ml for lysine and cephalexin, respectively.

The high reproducibility and sensitivity of the HPLC method described here recommend it as a suitable procedure for the simultaneous analysis of cephalexin and lysine in mixtures of these two products for quality control and stability studies of pharmaceutical formulations containing cephalexin lysinate.

Determination of Dextromethorphan Hydrobromide by High-Performance Liquid Chromatography Using Ion-Pair Formation

E. J. KUBIAK and J. W. MUNSON ˣ

Received February 25, 1980, from *Quality Control, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication April 9, 1980.

Abstract □ The chromatographic retention behavior of dextromethorphan hydrobromide on an octadecylsilane column was investigated as a function of the pairing ion and the mobile phase composition. Dramatic increases in the capacity factor were observed with pairing ions containing more than eight carbons and with decreasing organic modifier (acetonitrile) concentration. Several pharmaceutically important amines exhibited similar behavior with respect to acetonitrile concentration. An analytical method was developed for dextromethorphan hydrobromide bulk drug and syrups and was applied to commercial preparations.

Keyphrases □ Dextromethorphan hydrobromide—high-performance liquid chromatographic analysis using ion-pair formation □ High-performance liquid chromatography—analysis, dextromethorphan hydrobromide, ion-pair formation □ Antitussives—dextromethorphan hydrobromide, high-performance liquid chromatographic analysis using ion-pair formation

Dextromethorphan hydrobromide [(+)-3-methoxy-17-methyl-9α,13α,14α-morphinan hydrobromide, I] is a centrally active antitussive which, unlike codeine, is devoid of analgesic properties and exhibits little or no depression of the central nervous system. Because of its lack of addiction potential, it is widely used in nonprescription

I

cough–cold preparations. The bulk drug and a syrup are described in USP XX (1). This drug is present in over 50 nonprescription antitussive preparations (2).

For USP XX, bulk I is analyzed by titration with acetous perchloric acid (1). The official method for the syrup employs extraction into hexane from a basic aqueous phase, back-extraction into dilute hydrochloric acid, and spectrophotometric quantitation. An automated system was developed which employs formation of an ion-pair with bromcresol green at pH 5.3, extraction of the ion-pair into chloroform, and measurement at 420 nm (3). This method has been used for the analysis of I in mixtures with guaifenesin and phenylpropanolamine in cough syrups. GLC after isolation by extraction into chloroform also has been employed (4). Reversed-phase high-pressure liquid chromatography (HPLC) has been used to measure I in syrups containing I and chlorpheniramine maleate (5). Ion-pair HPLC recently was employed to measure I in syrups along with pseudoephedrine hydrochloride and brompheniramine maleate (6). This report discussed a method that used a microparticulate octadecylsilane column with an acetonitrile–water mobile phase containing the sodium salt of octanesulfonic acid as the pairing ion.

A comprehensive study was made recently on the effects of the carbon chain length of the anionic ion-pairing reagents on the retention behavior of codeine, morphine, and

[a] The placebo syrup contained 100 mg of guaifenesin/5 ml and 4.75% alcohol.

ethylmorphine (7). In that study, dioctyl sodium sulfosuccinate was an effective ion-pairing reagent for the analysis of codeine in syrups. Utilizing the conditions developed for codeine as a starting point, a systematic study was undertaken to test the applicability of the method for dextromethorphan in syrups. This paper reports the results of this study and describes a reversed-phase ion-pair HPLC method for I in syrups and as the bulk drug. The chromatographic behavior of several pharmaceutically important amines also was examined using the conditions employed for the analysis of I.

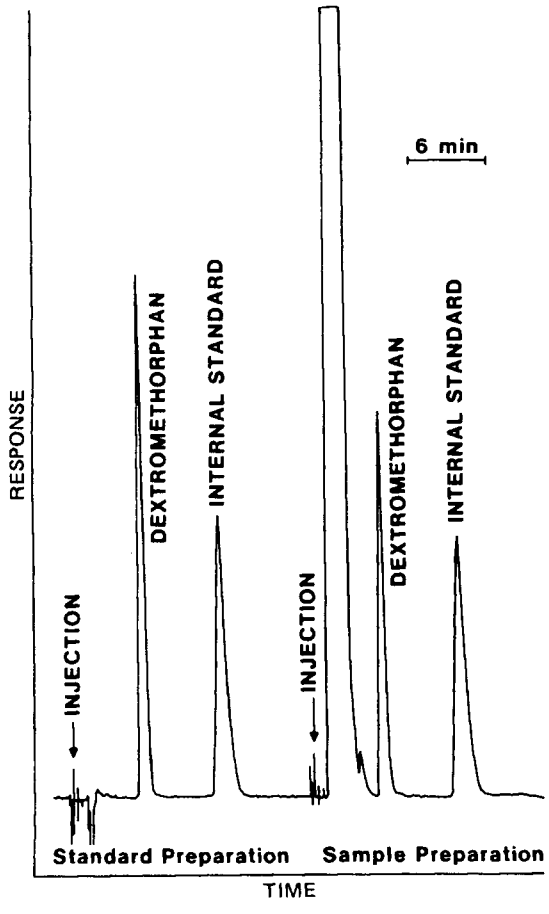

Figure 3—*Typical chromatographic tracings of a standard preparation and a sample preparation. The internal standard was testosterone propionate. The mobile phase was 55% (v/v) acetonitrile in water and contained 0.01 M ammonium nitrate and 0.005 M sodium dioctylsulfosuccinate. The pH of the mobile phase was adjusted to 3.3 with acetic acid. The flow rate was 2.0 ml/min.*

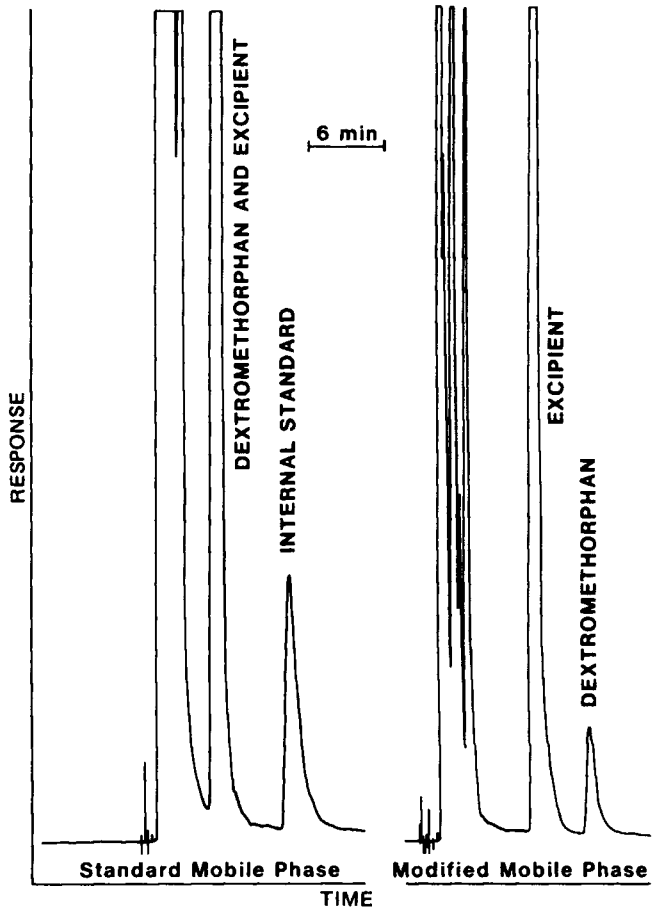

Figure 4—*Chromatographic tracings of a sample syrup preparation containing a large excipient interference. The standard mobile phase was the same as described in Fig. 3. The modified mobile phase was the same, except that the acetonitrile content was lowered from 55 to 45%. The flow rate was 2.0 ml/min.*

EXPERIMENTAL

Materials—Ethanesulfonic acid[1], sodium butanesulfonate[1], sodium hexanesulfonate[1], sodium octanesulfonate[1], sodium decylsulfate[1], sodium dodecylsulfate[1], sodium tetradecylsulfate[1], and sodium dioctylsulfosuccinate[2] were used as received. Dextromethorphan hydrobromide, codeine phosphate, methoxyphenamine hydrochloride, tetracaine hydrochloride, diazepam, ephedrine sulfate, cocaine hydrochloride, naloxone hydrochloride, morphine sulfate, scopolamine hydrobromide, lidocaine hydrochloride, hydralazine hydrochloride, meperidine hydrochloride, methadone hydrochloride, methylphenidate hydrochloride, and quinine sulfate were USP or NF quality.

The internal standard, testosterone propionate, was used as received[3]. Distilled-in-glass acetonitrile[4] and deionized water were used for all mobile phase preparations. All other chemicals were reagent grade. Samples of syrups containing dextromethorphan hydrobromide were obtained from a local wholesale drug distributor.

[a] Two individual assays. [b] Contained 100 mg of guaifenesin/5 ml and 1.4% alcohol. [c] Contained 100 mg of guaifenesin and 12.5 mg of phenylpropanolamine hydrochloride/5 ml and 4.75% alcohol. [d] Contained 100 mg of guaifenesin/5 ml and 5% alcohol. [e] Contained 50 mg of guaifenesin and 12.5 mg of phenylpropanolamine hydrochloride/5 ml and 10% alcohol. [f] Contained 25 mg of guaifenesin/5 ml and 200 mg of sodium citrate/5 ml and 5% alcohol.

consisting of a reciprocating piston pump equipped with a pulse dampener[5], an automated loop injector[6], a UV detector[7] (254 nm), and a recorder[8] was used for all measurements. For quantitative measurements, data were collected and processed by a digital computer[9].

Mobile Phase—All mobile phases contained 0.005 *M* pairing ion and 0.01 *M* ammonium nitrate in acetonitrile–water. After mixing, the mobile phases were adjusted to pH 3.3 with acetic acid and filtered through a 5-μm filter. A mobile phase containing acetonitrile and water in a 55:45 ratio (v/v) was used for the final analysis of I.

Columns—A microparticulate octadecylsilane column[10] (10-μm particles, 30 cm × 4 mm) was obtained from commercial sources. When not in use, the column was flushed with acetonitrile–water (80:20 v/v) and stored in the same solvent. Flow rates of 2–3 ml/min gave adequate resolution with reasonable analysis times.

Quantitation of Dextromethorphan Hydrobromide in Syrup—Exactly 5.0 ml of the syrup was transferred quantitatively to a 125-ml erlenmeyer flask containing 40.0 ml of the internal standard solution (15 mg of testosterone propionate in 1 liter of the mobile phase) and mixed well. In some cases, 20.0 ml of the internal standard solution was used. When a clear solution did not form upon mixing, 5 ml of water was added to the mixture. Aliquots (25 μl) of the samples were chromatographed at a detector setting of 0.032 aufs. Concentrations were determined by comparison of peak height ratios from sample preparations to those from a standard preparation.

Bulk drug samples were prepared by adding accurately weighed samples (~10 mg) to 40.0 ml of the internal standard solution to produce the sample preparation.

RESULTS AND DISCUSSION

Dextromethorphan hydrobromide exhibited retention behavior similar to that of codeine under the conditions described previously (7). Figure 1 shows a plot of the log of the capacity factor for I as a function of the carbon chain length of the pairing ion. A dramatic increase in the capacity factor was observed with pairing ions containing more than eight carbons. When sodium dioctylsulfosuccinate (II) was used, a capacity factor of about 100 was obtained. This finding clearly represents a retention time far greater than that required for a reasonable retention time. Since I lacks the 4,5-ether linkage and the 6-hydroxyl group of codeine, the ion-pair resulting from I and II would be predicted to be considerably less polar than that resulting from codeine and II. Consequently, a reduction in the polarity of the mobile phase should reduce the capacity factor for I.

This idea was tested by measuring capacity factors of I as a function of the acetonitrile content in the mobile phase while keeping the pairing ion (II) and the pH constant. The results of this study are shown in Fig. 2. Below 60% (v/v) acetonitrile, the concentration of the organic modifier had a dramatic effect on the capacity factor. As a compromise between a short analysis time and resolution of I from syrup excipients, 55% acetonitrile was chosen for the analytical development. To test the generality of the observed relationship of the capacity factor and the acetonitrile concentration, several amines were studied using acetonitrile and water in ratios of 55:45 (v/v) and 37:63 (v/v) (II as the pairing ion). The results

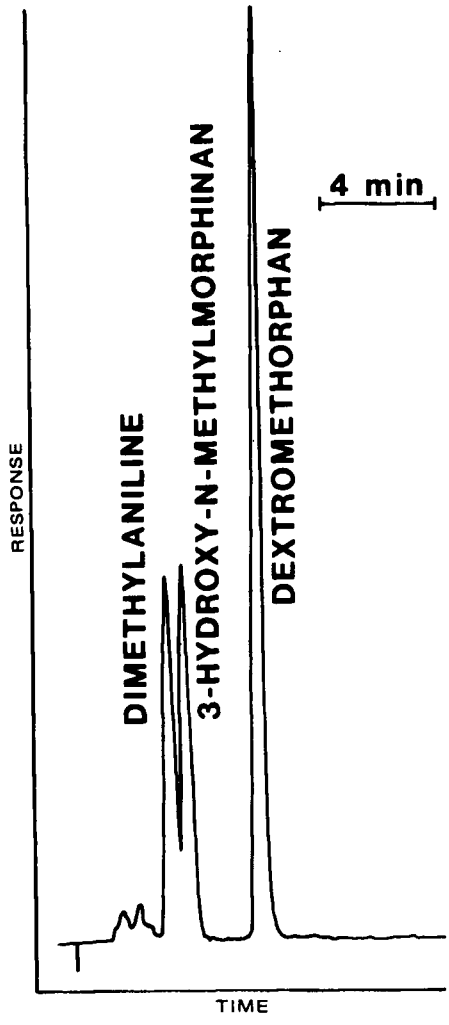

Figure 5—*Chromatographic tracing of a synthetic mixture of dimethylaniline, 3-hydroxy-N-methylmorphinan, and dextromethorphan. See Fig. 3 for the mobile phase composition and flow rate.*

are shown in Table I. With the exception of methadone and quinine, a seven- to 22-fold increase in the capacity factor was observed in going to the 37:63 acetonitrile–water mobile phase [this mobile phase has been used for the analysis of codeine (7)].

tions are shown in Fig. 3. Total analysis time was ~15 min. Spiked samples of a placebo syrup were analyzed by this method, giving quantitative recovery from 2.0 to 14.0 mg/5 ml (Table II). Replicate analyses of a single lot of syrup (n = 6) on 2 days gave precision (expressed as the relative standard deviation) of 0.3% (Table II).

Other commercially available syrups containing I were obtained and analyzed by this method. The results are summarized in Table III. Excellent agreement with the labeled contents was obtained. One syrup tested showed a rather large excipient peak that was not resolved from the I peak. To solve this problem, the percentage of acetonitrile in the mobile phase was reduced to 45% (v/v). Under these conditions, the excipient peak was resolved completely from the I peak (Fig. 4) but the internal standard peak did not elute in a reasonable time. Using peak height measurements, a value of 9.4 mg/5 ml (label claim was 10.0 mg/5 ml) was obtained for this syrup. This approach demonstrates that the acetonitrile content, as well as the carbon chain length of the pairing ion, can be manipulated to produce resolution of the I peak from interfering components in the mixture.

The method also was applied to the analysis of bulk drug samples. In this case, consideration must be given to the resolution of I and potential impurities arising from the synthetic process. Compound I is synthesized by the methylation of (+)-3-hydroxy-17-methyl-9α,13α,14α-morphinan (III) with phenyltrimethylammonium bromide. The by-product of the reaction is dimethylaniline. Compendial assays for I include tests for dimethylaniline and phenolic compounds (*e.g.*, III). Since dimethylaniline and III both are amines, trace amounts would be expected to be carried over in any acid–base extraction of I used for purification. A chromatographic tracing of a mixture of I, III, and dimethylaniline is shown in Fig. 5. The two potential impurities are well resolved from I. The results of the analyses of bulk I are shown in Table IV. Quantitative recovery and excellent precision are observed.

High-Performance Liquid Chromatographic Assay for Benzocaine and *p*-Aminobenzoic Acid Including Preliminary Stability Data

P. K. NARANG, G. BIRD, and W. G. CROUTHAMEL *x

Received February 19, 1980, from the *Department of Pharmacy, School of Pharmacy, University of Maryland, Baltimore, MD 21201.* Accepted for publication May 29, 1980.

*Present address: Department of Pharmacokinetics and Biopharmaceutics, Hoffmann–La Roche Inc., Nutley, NJ 07110.

Abstract □ A high-performance liquid chromatographic assay was developed that separates and quantitates benzocaine and its primary degradation product, *p*-aminobenzoic acid. This method is rapid, sensitive, and specific. Preliminary stability data obtained with this method demonstrate its utility for this purpose.

Keyphrases □ Benzocaine—high-performance liquid chromatographic analysis with *p*-aminobenzoic acid, effects of pH, temperature, and phosphate ion on benzocaine stability □ *p*-Aminobenzoic acid—degradation product of benzocaine, high-performance liquid chromatographic analysis with benzocaine □ High-performance liquid chromatography—analysis, benzocaine and *p*-aminobenzoic acid, stability studies of benzocaine □ Degradation—benzocaine, effect of pH, temperature, and phosphate ion

In spite of the long history of benzocaine as a therapeutic agent, little information has appeared regarding its stability. It has been reported to be relatively unstable under certain conditions, and attempts have been made to decrease its degradation through the use of complexing agents (1) and surfactants (2). Benzocaine also may be unstable in the presence of pharmaceutical excipients such as citric acid, glucose, and cherry flavoring (3). This lack of information is due in part to the absence of a rapid, specific, stability-indicating assay for benzocaine in the presence of its degradation products.

Over the years, benzocaine has been assayed quantitatively by titration (4), diazotization (5), colorimetry (6), potentiometry (7), and crystal formation (8), all of which take advantage of the basic and aromatic character imparted by the aryl amino group. Some initial benzocaine stability work was undertaken by Higuchi and Lachman (1) using a partition spectroscopic method of analysis. GLC was used later for the analysis of benzocaine (9–11). However, recent data (12, 13) showed interference by *p*-hydroxybenzoates in the UV, GLC, and column chromatographic methods for benzocaine, thereby raising questions about the specificity of these commonly employed methods.

A recently developed high-performance liquid chromatographic (HPLC) assay was reported which measures intact benzocaine (14), but the report did not mention the separation or identification of the primary degradation product of benzocaine, *p*-aminobenzoic acid. This paper describes a rapid, precise, and sensitive method for the simultaneous analysis of benzocaine and *p*-aminobenzoic

acid and reports preliminary stability data using this assay method.

EXPERIMENTAL

Apparatus—A high-performance liquid chromatograph equipped with a multiwavelength detector[1] was employed in conjunction with a microparticulate C_{18} column[2] for separation.

Reagents—All chemicals and reagents were analytical grade unless otherwise indicated. Benzocaine[3], *p*-aminobenzoic acid[4], monobasic potassium phosphate[5], and glass-distilled methanol[6] were used as received. Glass-distilled water was used throughout the study.

Analytical Procedure—All standard solutions of benzocaine and *p*-aminobenzoic acid were prepared in water. The concentrations of benzocaine and *p*-aminobenzoic acid were determined directly from their respective peak heights by comparison to a standard curve. The mobile phase was methanol–acetic acid–water (33:4:63). At ambient temperature and a solvent flow rate of 2 ml/min, the retention times for *p*-aminobenzoic acid and benzocaine were 2 min 28 sec and 7 min 10 sec, respectively.

The sensitivity of *p*-aminobenzoic acid and benzocaine at an injection volume of 10 μl was 0.3 and 0.7 μg/ml, respectively, which was equivalent to 3 and 7 ng injected on column. The assay sensitivity can be increased by increasing the injection volume or decreasing the dilution. Similarly, the assay sensitivity can be increased about fourfold by using 294 nm rather than the more conventional 254 nm as the detector wavelength, although this capability may not be available in all laboratories. Injections of benzocaine and *p*-aminobenzoic acid solutions prepared in nonbuffered and buffered solutions of pH 2, 7, and 11 are chromatographically similar. The solutions to be chromatographed are primarily aqueous, and there is little risk of evaporation at room temperature. Adequate reproducibility can be obtained without the use of an internal standard.

Stability Studies—*Effect of pH and Phosphate Ion*—A methanolic stock solution of benzocaine (5 mg/ml) was diluted to ~40 μg/ml with water and adjusted to pH 2, 7, or 11 with 0.1 *N* NaOH or 0.1 *N* HCl. These solutions were placed in glass vessels at room temperature (25 ± 2°). Each experiment was conducted in duplicate. Aliquots (10 μl) were withdrawn periodically and assayed for benzocaine and *p*-aminobenzoic acid.

In a similar experiment, phosphate (adjusted to 0.1 *M*) was used in place of sodium hydroxide or hydrochloric acid to adjust the solution pH. Only phosphate-ion-containing salts and their corresponding acids were used in preparing these solutions, as calculated by the Henderson–Hasselbach equation (15).

Effect of Temperature—Benzocaine solutions prepared in phosphate buffer (pH 7.0) were placed in sealed glass containers at 40, 60, and 70 ± 1.0°. Aliquots (10 μl) were assayed periodically for benzocaine and *p*-aminobenzoic acid over a 24-hr period.

Treatment of Data—Semilogarithmic plots of the benzocaine concentration as a function of time were constructed to evaluate the order and rate of benzocaine degradation. All plots were consistent with first-order kinetics, *i.e.*, plots of log benzocaine concentration *versus* time were linear. An Arrhenius plot (15) was constructed from the data obtained for the experiment on the effect of temperature. The line of best fit was determined by linear regression.

RESULTS

A typical chromatogram for benzocaine and *p*-aminobenzoic acid is shown in Fig. 1. Retention times varied slightly from day to day, but no interfering peaks were encountered. Standard curves for both benzocaine and *p*-aminobenzoic acid were linear over the concentration range of 0–100 mg/liter, using peak height or peak area as a function of concen-

tration. The correlation coefficient for the standard curves over the concentration range used in this study, 0–100 mg/liter, was ≥0.99 (n = 8) in all cases. Standard solutions assayed repetitively over 15 weeks showed a coefficient of variation of 2% for benzocaine and 1.5% for *p*-aminobenzoic acid. No significant differences were observed (p = 0.05) between the mean peak height obtained from repeated injections (n = 10) on 2 days. The coefficient of variation in the slope obtained from eight standard curves over a 2-month period for benzocaine and *p*-aminobenzoic acid was <3%. The pH of the injected solutions did not affect the retention times.

Table I shows the percent of benzocaine remaining and the percent of *p*-aminobenzoic acid formed (based on the total amount available for formation) at three pH values. Benzocaine degradation was most rapid at pH 11, intermediate at pH 2, and slowest at pH 7. Good agreement was found between the amount of benzocaine lost and the amount of *p*-aminobenzoic acid formed, suggesting that *p*-aminobenzoic acid is the only major degradation product of benzocaine under these conditions. This conclusion is supported by the fact that no other peaks are seen in the chromatograms of degraded benzocaine solutions. A plot of log benzocaine concentration as a function of time for various pH values is shown in Fig. 2. The apparent first-order half-lives determined from these data were 2.2 hr at pH 11, 15.5 hr at pH 2, and 139 hr at pH 7.

Table II shows the disappearance of benzocaine and the appearance of *p*-aminobenzoic acid in solutions containing 0.1 *M* phosphate buffer. As was observed in water, benzocaine degradation was most rapid at pH 11 and slowest at pH 7; good agreement existed between benzocaine loss

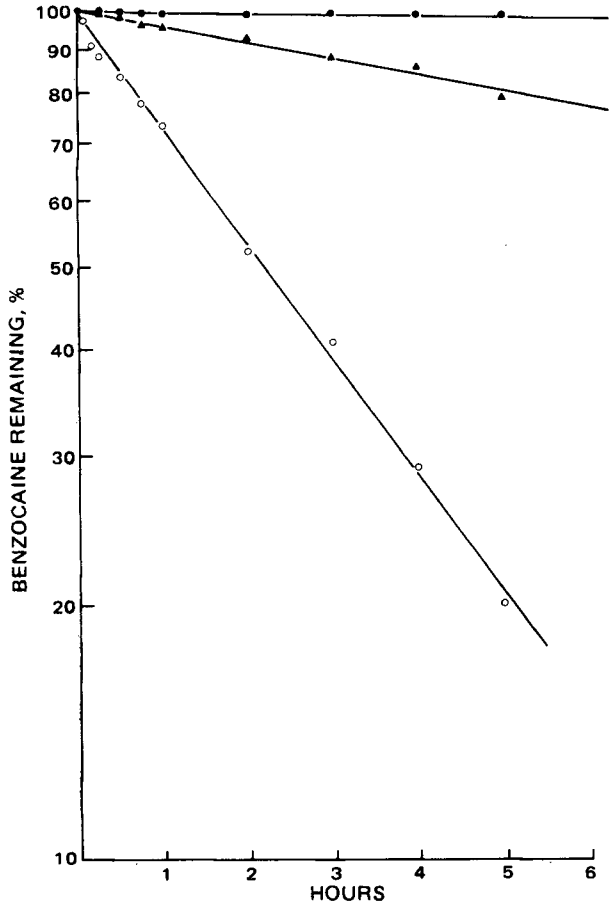

Figure 2—*Benzocaine degradation in aqueous solutions of three pH values at 25°. Key: ●, pH 7, ▲, pH 2; and ○, pH 11.*

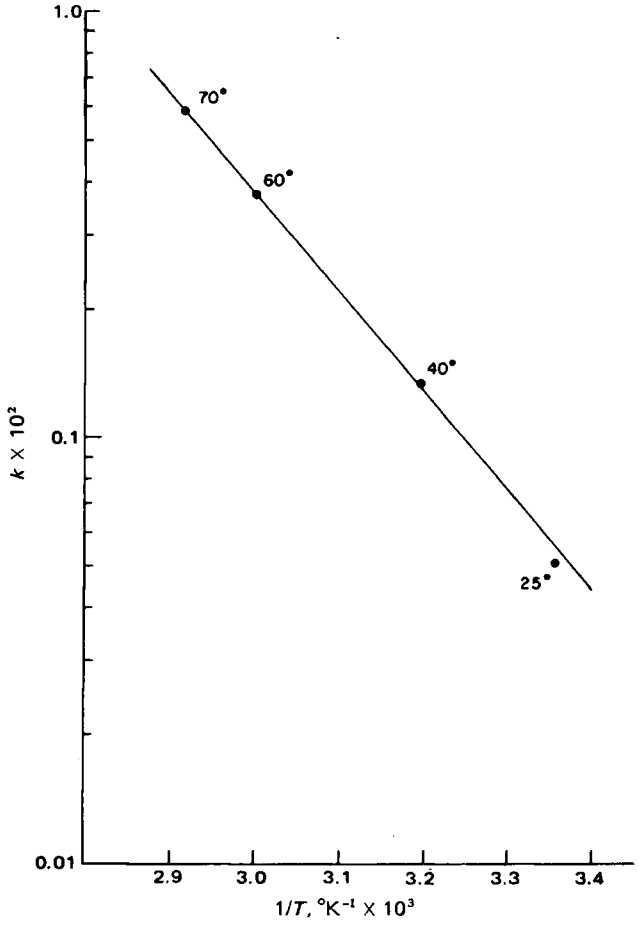

Figure 3—*Arrhenius plot of benzocaine stability in 0.1* M *phosphate buffer (pH 7).*

Table IV—Observed and Predicted Values for Benzocaine Stability at pH 7 in 0.1 *M* Phosphate Buffer [a]

Temperature (t), °C	$1/T$, °K^{-1} × 10^3	k, hr^{-1}	log k	Time for 10% Degradation, hr	Time for 50% Degradation, hr
40	3.195	0.0136	−1.866	7.75	50.96
60	3.003	0.0376	−1.425	2.80	18.44
70	2.915	0.0586	−1.232	1.80	11.82
25	3.356	0.0051	−3.295	20.78	136.70
25		0.0057[b]	−2.444[b]	18.49[b]	121.60[b]

[a] Frequency factor (A) = 2.35 × 10^7 hr^{-1}. Activation energy (E_a) = 5.217 kcal/mole. [b] From Arrhenius plot, based on data at 40, 60, and 70°C.

and *p*-aminobenzoic acid appearance. However, at all three pH values, the degradation rate was slower in phosphate buffer than in water. Half-lives for the loss of benzocaine in the presence of 0.1 *M* phosphate were 17.7 hr at pH 11, 115 hr at pH 2, and 180 hr at pH 7. Thus, benzocaine was approximately 1.3 (pH 7), 7.3 (pH 2), and 8.0 (pH 11) times more stable in phosphate buffer than in nonbuffered solutions of equivalent pH (Table III). The reason for the protective effect of phosphate ion is unknown. However, increasing the phosphate buffer concentration from 0.1 to 0.5 *M* while maintaining a constant ionic strength with sodium chloride did not alter the degradation rate at room temperature and pH 7.

Benzocaine stability was studied at 25, 40, 60, and 70°C in 0.1 *M* phosphate buffer at pH 7.0. An Arrhenius plot (15) constructed by plotting the apparent first-order rate constants obtained as a function of the inverse of temperature (°K) is shown in Fig. 3. Extrapolation of the elevated temperature data to room temperature (25°C) results in a predicted first-order rate constant of 0.0057 hr^{-1}, which compares favorably with the rate constant of 0.0051 hr^{-1} observed at room temperature (Table IV).

DISCUSSION

Various analytical methods were employed in previous stability studies of benzocaine. These methods suffer from several deficiencies, including the inability to quantitate or separate the primary degradation product of benzocaine and the lack of a chromatographic step to separate benzocaine from other potentially interfering materials. The potential interference of *p*-aminobenzoic acid in the methods used in some previous stability studies (1, 11) has been discussed (13). The official assay (16) employs a diazotization titration and hence may not be specific for benzocaine alone. The assay described here is rapid and precise and allows simultaneous quantitation of benzocaine and its primary degradation product, *p*-aminobenzoic acid. This capability allows for the continuous monitoring of mass balance during stability studies and precludes nonspecific losses such as loss into packaging materials.

The new assay has been used to study several stability characteristics of benzocaine, including the effects of pH, temperature, and phosphate ion. Benzocaine degradation is both acid and base catalyzed but is much slower in the presence of phosphate ion. First-order kinetics are observed in all cases. Studies at elevated temperatures indicate that benzocaine obeys the Arrhenius equation. Degradation rates at room temperature agree with those predicted from elevated temperature studies.

Essentially all of the benzocaine lost due to degradation can be accounted for by the appearance of *p*-aminobenzoic acid; hence, *p*-aminobenzoic acid appears to be the only significant degradation product under the study conditions used.

The sensitivity of this assay is ~0.7 μg/ml for benzocaine and ~0.3 μg/ml for *p*-aminobenzoic acid. The sensitivity can be enhanced fourfold if a multiple-wavelength detector is used at 294 nm or if the injection volume is increased.

The method described here suffers from no known interference and is applicable for the content uniformity and quality control of products containing benzocaine. This rapid assay is good for the evaluation of raw materials and employs basic equipment found in most analytical laboratories.

Preparation of Enteric-Coated Microcapsules for Tableting by Spray-Drying Technique and *In Vitro* Simulation of Drug Release from the Tablet in GI Tract

H. TAKENAKA, Y. KAWASHIMA ˣ, and SHAN-YANG LIN

Received March 27, 1980, from the *Gifu College of Pharmacy, Mitahora, Gifu 502, Japan.* Accepted for publication May 29, 1980.

Abstract □ Improved methods were developed for the preparation of enteric-coated microcapsules for tableting by a spray-drying technique, and the drug release behavior from the tableted microcapsules was investigated using a disintegration apparatus and a new *in vitro* method of simulating the GI tract. As a model system, ammonium solutions of sulfamethoxazole and cellulose acetate phthalate were spray dried using a centrifugal wheel atomizer at 140°. Additives such as colloidal silica, montmorillonite clay, and talc were included in the formulations for spray drying. The influence of the additives on the particle diameter, density, packing properties, and compressibility of the product and on the release characteristics of the resultant tablet *in vitro* were investigated. The additives in the formulations greatly improved the flow properties of the spray-dried products, which could be tableted easily. Products from the nonadditive formulations could not be tableted due to their poor flowability. The hardness and disintegration rate of the tablet increased with increasing concentration of additives in the formulations. X-ray analysis and IR spectroscopy confirmed that the crystals of sulfamethoxazole in the spray-dried microcapsules with cellulose acetate phthalate were converted from Form I to Form II. *In vitro* release characteristics of the tablets were studied using a disintegrator (JP) in buffer solutions (pH 1.2 and 7.5) and distilled water. Enteric action of the spray-dried products was proved by comparison with the original nontreated powders. The additives in the tablet increased the release rate at the initial stage in all dissolution media used. A new *in vitro* release simulator was devised consisting of a flow-type dissolution container in which the pH of the medium was changed continuously from 1.2 to 7.0 to simulate the pH change of tablets exposed to the GI tract.

Keyphrases □ Microcapsules—preparation of enteric-coated microcapsules for tableting by a spray-drying technique, drug release from tableted microcapsules □ Tablets—preparation of enteric-coated microcapsules for tableting, drug release from tableted microcapsules □ Dissolution—tableted enteric-coated microcapsules

Spray-drying techniques have been used widely for drying heat-sensitive foods, pharmaceuticals, and other substances because of the rapid evaporation of the solvent from the droplets. Interest has been renewed in this technique for the preparation of agglomerates or microcapsules of pharmaceuticals. Speiser *et al.* (1) prepared microcapsules of barbituric acid employing a spray polycondensation method. Kawashima and Takenaka (2) produced sustained-action antacid tablets by compressing spray-dried microcapsules of magnesium carbonate. The successful results from these studies encouraged further development of this technique for preparation of a new dosage form.

One objective of the present study was to prepare enteric-coated microcapsules of sulfamethoxazole efficiently by a spray-drying technique instead of by a phase separation method (3). Proper formulation and spray-drying conditions were sought for producing microcapsules with enteric action that meet the requirement for tableting. Another objective was to devise a new *in vitro* simulator for the GI tract to evaluate the enteric action of the tablet prepared by compressing the spray-dried products.

EXPERIMENTAL

Spray-Drying Technique—Sulfamethoxazole[1] was used as received as a model pharmaceutical for microencapsulation or agglomeration. Sulfamethoxazole and cellulose acetate phthalate[2] (50 g each) were dissolved in 1 liter of 5% NH_4OH. To this solution were added 0, 30, and 50 g of colloidal silica[3], montmorillonite clay[4], and talc[5]. Formulations without cellulose acetate phthalate also were prepared as a reference for testing the enteric action.

The slurries or solutions were atomized into a drying chamber by a centrifugal wheel atomizer at 40,000 rpm. The drying chamber was maintained at 140 ± 10°. The dried products were collected by a cyclone collector.

Measurement of Physicochemical Properties—The particle size of the spray-dried products was measured by a photographic counting method using a particle-size analyzer[6]. Packing properties and particle density were measured by a tapping powder method and with a helium–air comparison pycnometer[7], respectively. The surface topography of the spray-dried particles coated with gold was investigated with a scanning electron microscope[8]. To analyze the crystalline form of sulfamethoxazole in the spray-dried products, X-ray diffraction patterns[9] and IR spectra[10] were obtained.

Dissolution Test of Tablets Prepared from Spray-Dried Products—Spray-dried products with additives and the mixtures with microcrystalline cellulose[11] (1:1) were tableted using a single-punch tablet machine. The dimensions and weights of 10 tablets were measured. The hardness of the tablets was measured by a moving platen-type hardness tester[12]. Tablet hardness is presented as average values.

The dissolution test of a tablet was undertaken using the JP IX disintegration apparatus and the specified disintegration test solutions (pH 1.2 and 7.5) and distilled water at 37°. Tests also were conducted with a new *in vitro* release simulator (Fig. 1) with a flow-type dissolution container in which the pH of the medium was changed continuously to simulate the pH change on the surface of the tablets exposed in the GI tract.

The test was carried out by placing a tablet in the basket specified in the USP dissolution apparatus, which was modified by attaching a four-blade propeller. This basket was set 1.0 ± 0.2 cm from the bottom of the container and was rotated at 94 rpm. The pH 1.2 medium (300 ml) was introduced into the dissolution apparatus, followed by the addition of the alkaline medium (pH 7.5) at a rate of 1.27 ml/min. Simultaneously, the agitated dissolution medium was removed at the same rate to a reservoir using a rotating-type pump[13]. With this technique, the volume of medium in the container was held to 300 ml and the pH of the medium was changed continuously from 1.2 to 7.0. This pH change corresponds to that of the GI tract. The pH change in the dissolution medium was monitored by a pH meter placed in the dissolution medium.

Aliquots of 2 ml of the dissolution medium in the apparatus and the reservoir were sampled at prescribed intervals through a pipet plugged with cotton and were filtered through a Millipore filter (0.3 μm). Aliquots of distilled water (same volume and temperature) were added immediately to the dissolution apparatus to keep the volume of the dissolution medium in the container constant during the test. The concentration of dissolved sulfamethoxazole in the medium was determined spectrophotometrically at a suitable UV region using a double-beam spectrophotometer[14].

RESULTS AND DISCUSSION

Physicochemical Properties of Spray-Dried Products—The size distribution of the spray-dried particles was described in log-normal form. The geometric mean diameter ranged from 3.6 to 22.0 μm. The formulations including cellulose acetate phthalate and the additives yielded smaller products than the formulations without the additives. The products prepared from the formulations with the additives alone became smaller compared to the others (Table I).

Scanning electron microscopic photographs of the spray-dried products are shown in Fig. 2. The surfaces of the products prepared from the nonadditive formulations were covered with flake-like crusts (Fig. 2A). When the additives were added to the formulations, no flakes appeared, and the surface had an orange peel texture (Fig. 2B). Figure 2C shows an

image of the product with the additives alone, which seems to be an agglomerate composed of lobes. Many sulfamethoxazole crystals apparently are adsorbed onto the surface.

The characteristic bulkiness of the spray-dried product from the formulations with cellulose acetate phthalate alone (Fig. 2A) suggests that their particle density and packing property differ from those of the other formulations. It was assumed that these products might be lighter than those with the additives. This assumption was proved by the particle density data given in Table I. The products including the additives alone had a higher particle density. The packing process of the spray-dried products in a tapped graduated cylinder was represented by (4):

$$n/c = 1/ab + n/a \quad \text{(Eq. 1)}$$

$$c = (V_0 - V_n)/V_n \quad \text{(Eq. 2)}$$

where b is a constant, n is the number of taps, V_0 is the volume of powder in a measuring cylinder at the loosest packing, and V_n is the volume after the nth tapping. The parameter a in Eq. 1 for the products without additives was found to be larger than that of the particles with montmorillonite clay and colloidal silica. This finding indicates that the particles with the additives might be packed more easily since a corresponds to the proportion of consolidation at the closest packing attained.

Tablets could not be made directly by compressing the products without the additives due to their poor flowabilities. The products including the additives were tableted easily. Compressibility of the spray-dried products including the additives was improved with increasing amounts of the additives, as indicated by their greater hardness and smaller porosity. This trend clearly appeared with the tablets containing colloidal silica and montmorillonite clay (Table I).

The crystalline forms of the spray-dried products were investigated by X-ray diffraction analysis and IR spectroscopy. The IR spectra and X-ray diffraction patterns of the untreated original sulfamethoxazole used in the present study identified the crystals as Form I, as defined previously (5). The peaks in the X-ray diffraction patterns of the spray-dried products were less intense than those of the original crystals (Fig. 3). This finding indicated that some sulfamethoxazole crystals were converted to a disordered form due to rapid crystallization.

In the patterns of the products with cellulose acetate phthalate, regardless of whether the additives were included, fairly characteristic peaks of Form II appeared. Form II was prepared as a reference by recrystallization in water at dry ice–acetone temperature (Fig. 3). The X-ray diffraction patterns of the products with colloidal silica and montmorillonite clay proved that they were Form I. The patterns of the products with talc exhibited peaks of both Forms I and II, indicating that they were a mixture.

The polymorphic forms of the spray-dried products also were confirmed by their IR spectra (Fig. 4). The spray-dried products with cellulose acetate phthalate exhibited the characteristic bands of Form II at 3080, 2990, and 1640 cm^{-1}, which did not appear in the spectrum of Form I. Differences in the spectra from Form I also were found at 1395, 1330, 1150, and 750 cm^{-1}. When cellulose acetate phthalate was excluded from the formulations, the spectra of the spray-dried products changed to those of Form I. Spectra of the products with talc exhibited the intense bands at 3300 and 3150 cm^{-1} and several characteristic bands of Form II. This result suggests that the products with talc contain Forms I and II.

It has been suggested that polymorphism in sulfonamides may be

brought about due to the intermolecular hydrogen bonding (6, 7). Hydrogen bonding in the alkaline solutions used might be attained mainly by the interaction between the hydrogen of the *p*-amino group and the oxygen of the S–O group in the sulfamethoxazole molecule. Furthermore, cellulose acetate phthalate molecules might influence the way in which the sulfamethoxazole molecules associate in the solution. This effect was confirmed by the fact that the products from the simple formulations without cellulose acetate phthalate or the additives exhibited Form I but not Form II. Such a polymorphism might make the drug metastable, but it could improve solubility.

Dissolution Behavior of Tablets in Disintegration Apparatus—Dissolution patterns of the tablets of the spray-dried products with colloidal silica and cellulose acetate phthalate in the disintegration test solutions (pH 1.2 and 7.5) and distilled water were determined using a disintegration apparatus (Fig. 5). The dissolution curves in the alkaline solution were distinguished by their much faster release rate from those in the other media used due to the enteric-coating action of the cellulose acetate phthalate contained in the tablet. Although the initial release rate in the acidic solution was faster than in distilled water, the slope of the release curve became almost identical at the later stage. In the alkaline solution, the tablets were gradually disintegrated to fine particles and a few small pieces; in the acidic media, disintegration did not occur, and only the size of the tablet slowly decreased during the dissolution process.

The dissolution behavior of the tablets prepared from the formulations with colloidal silica but without cellulose acetate phthalate is shown in Fig. 6. There was less variation in the rate in the three dissolution media used. The colloidal silica may have acted as a disintegrating agent due to its wettability, which might have resulted in an increased release rate. However, when the concentration of colloidal silica in the tablet was increased, the release rate was decreased significantly, which might have been due to a matrix-like structure of the tablet binding strongly with colloidal silica.

These differences in the release behavior of the tablets were explained by plotting the data on a semisquare root graph (Fig. 7). In the acidic solution and distilled water, all release patterns of the tablets, regardless of the formulation, became fairly straight lines after enhanced dissolution periods. This finding indicates that the release process at the later stage obeys the Higuchi model (8) represented by:

$$Q = [D(2A - C_s)C_s t]^{1/2} \quad \text{(Eq. 3)}$$

where Q is the amount dissolved per unit area of exposure at time t, A is the total amount of drug present in the matrix per unit volume, C_s is the solubility of the drug in the external phase of the matrix, and D is the diffusion constant. When $C_s \ll A$, Eq. 3 can be transformed to a more convenient form to exhibit the release patterns described in Fig. 7 (9):

$$C_r = 100[S_v(2DC_s t/A)^{1/2}] \quad \text{(Eq. 4)}$$

where C_r is the percent of the drug dissolved and S_v is the specific surface area. In alkaline solution, the release patterns of the tablets with and without cellulose acetate phthalate exhibited sigmoid curves and straight lines, respectively.

When microcrystalline celluloses were mixed into the spray-dried products in a 1:1 ratio, tablets could be made even if the products without the additives were used. However, the hardness of the tablet was insufficient for practical use compared with the tablets containing the additives. The dissolution rate of the tablets containing microcrystalline cellulose became faster than that of the tablets without it in all dissolution media due to their rapid disintegration. The distinct discrepancies of the release patterns depended on the type of dissolution medium used (Fig. 8). The prolonged release in the acidic medium was clearly evident when compared to the mixtures of microcrystalline cellulose and original sulfamethoxazole. Thus, the effectiveness of the enteric coating of the spray-dried products containing cellulose acetate phthalate is proved in Figs. 7 and 8.

In the alkaline medium and in distilled water, the dissolution rate was delayed when the additives were included in the formulations. In the acidic solution, the release rate of the tablet with the additives was faster than for those without them. This result might have been due to the fact that the additives included in the discrete microcapsules could promote penetration of the solvent.

Dissolution Behavior of Tablet Containing Various Additives in a Flow-Type Simulator—Gastric contents do not become alkaline merely as a result of passing through the pylorus. The upper small intestine is more likely to be slightly acidic. Thus, to simulate *in vivo* action, it may be desirable to conduct the enteric test in a dissolution medium whose pH is changed continuously from 1.2 to 7.0 rather than in a medium fixed at pH 7.0 or above. Release patterns of tablets prepared from the mixtures of microcrystalline cellulose and the spray-dried products containing various additives exposed to a medium whose pH changed continuously from 1.2 to 7.0 are shown in Figs. 9 and 10. The pH change of the medium with residence time followed a sigmoid curve which varied slightly from batch to batch, although the patterns were almost identical.

The release rate of the tablets with cellulose acetate phthalate was relatively fast at the initial stage, followed by a stage with a decreased rate. After the residence time of 70–90 min at pH 3.5–5.5, the release rate increased rapidly again, which caused an inflection on the release curve. It is reasonable to assume that this point corresponds to the starting point of the enteric action. By increasing the concentration of colloidal silica, the release rate at the initial stage (pH values of <3.5–4.0) increased due to enhancement of the solvent penetrating action by colloidal silica (Fig. 9).

The release patterns of the tablets without cellulose acetate phthalate were characterized by a smooth convex curve without an inflection point. With talc and montmorillonite clay, similar enteric action of the tablets containing cellulose acetate phthalate was observed; however, some solvent penetration appeared at the lower concentrations of these additives. At the later stage (pH > 5.0), the release rate was more delayed compared to that of the additive-free tablets. This result might have been due to the fact that the drug was adsorbed firmly in the pores of the additives, forming a matrix-like structure.

From these results, it is concluded that the enteric-coating behavior of the tablets was more clearly demonstrated by using the flow-type simulator and a medium whose pH changed continuously than by studying dissolution and disintegration at constant pH values. By this technique, it also was possible to detect the pH above which the enteric action was overcome.

Potential of Organic Cation-Saturated Montmorillonite as Treatment for Poisoning by Weak Bases

JEFFREY E. BROWNE *, JOSEPH R. FELDKAMP ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received March 13, 1980, from the *Industrial and Physical Pharmacy Department and the ‡Department of Agronomy, Purdue University, West Lafayette, IN 47907. Accepted for publication May 21, 1980.

Abstract □ The preferential adsorption of the protonated form of weak bases by montmorillonite causes an increase in the pK_{eff} of atrazine. The effect on the acid–base equilibrium of atrazine is related to the exchangeable cation on the surface of montmorillonite. The greatest effect was produced by the presence of 3-hydroxypropylammonium-saturated montmorillonite, which caused the pK_{eff} of atrazine to increase 5.3 units to 6.9. This shift in pK_{eff} causes the protonated form of atrazine to be the predominate species in the pH range encountered in the GI tract and should result in a high degree of adsorption of atrazine. Fraction-bound studies confirmed this hypothesis by demonstrating virtually complete adsorption of atrazine by 3-hydroxypropylammonium-saturated montmorillonite up to pH 6. The fraction-bound studies also verified that protonated atrazine is adsorbed more completely by 3-hydroxypropylammonium-saturated montmorillonite than by bentonite USP or sodium-saturated montmorillonite. It is believed that saturation of the clay surface by an organic cation alters the surface environment of the clay, which results in enhanced adsorption of the protonated form of atrazine. The potential utility of montmorillonite saturated with an organic cation as an adsorbent for the emergency treatment of poisoning by weak bases is suggested.

Keyphrases □ Montmorillonite—saturation with organic cations for potential treatment of poisoning by weak bases □ Adsorbents—montmorillonite saturated with organic cations, potential treatment of poisoning by weak bases □ Poisoning—weak bases, potential treatment with organic cation-saturated montmorillonite

A major limitation in the use of clays as adsorbents in the treatment of poisoning is that their strongest adsorption mechanism is chemisorption of cations due to the negative charge of clays arising from isomorphous substitution (1). Clays such as montmorillonite have a high adsorptive capacity for cations but do not interact strongly with neutral molecules (2). Thus, weak bases, which constitute a large chemical class of potential poisons, are well adsorbed by montmorillonite if the pK is high so that the protonated form of the weak base is present in the pH range encountered in the GI tract. However, montmorillonite is a less effective adsorbent if the pK of the weak base is low since these weak bases then exist as neutral molecules in the GI tract.

It was observed recently that the first acid–base equilibrium of tetracycline was displaced in the presence of montmorillonite while the second and third acid–base equilibria were not altered (3). The presence of montmorillonite thus caused the protonated form of tetracycline to be present in a montmorillonite suspension over a wider pH range than occurs in an aqueous solution. As a result, adsorption of tetracycline by montmorillonite occurred over a wider pH range than was expected based on solution pK values. The nature of the exchangeable cation influenced the magnitude of the shift in the first acid–base equilibrium of tetracycline (4). For example, sodium-saturated montmorillonite caused a greater shift than did calcium-saturated montmorillonite.

It was hypothesized that montmorillonite that was specially treated to replace the naturally occurring inorganic cations with an organic exchangeable cation might have a desirable effect on the acid–base equilibrium of weak bases. 3-Hydroxypropylammonium hydrochloride was chosen as the organic cation because it is a cation in the pH range of interest and is relatively small.

Atrazine (2-chloro-4-ethylamino-6-isopropylamine-*s*-triazine) was chosen as a model weak base because it was expected to be neutral in the pH range of the GI tract due to its pK of 1.64 (5).

EXPERIMENTAL

Materials—Atrazine[1] and bentonite USP[2] were obtained commercially. Montmorillonite (Wyoming bentonite) was a reference standard[3]. The presence of organic matter in the bentonite USP sample was established by the peroxide method (6). Thirty milliliters of 30% H_2O_2 was added to 15 ml of a 1% clay suspension and heated in a steam bath for 15 min. The treated clay was centrifuged along with an untreated reference suspension. The presence of organic matter was indicated when the color of the sample sediment was significantly lighter than the reference sediment.

Metal-ion analysis by atomic absorption spectrometry[4] was used to identify the exchangeable cations in the bentonite USP, and X-ray diffraction[5] was used to identify the nonclay components.

Sodium-saturated montmorillonite was prepared by washing a 2% montmorillonite suspension with 1 *M* NaCl. The washing procedure was repeated five times, and excess salt was removed by repeated washing with water until the addition of silver nitrate to the supernate gave a negative chloride test.

Calcium-saturated montmorillonite was prepared in the same manner using 1 *M* $CaCl_2$ as the exchanging solution.

3-Hydroxypropylammonium-saturated montmorillonite was prepared similarly using a 1 *M* 3-hydroxypropylammonium hydrochloride solution as the exchanging solution.

To confirm that 3-hydroxypropylammonium was the exchangeable cation after the washing procedure, the following comparison was made. Since ammonium washing is commonly used to remove calcium from montmorillonite (7), the amount of calcium exchanged by washing calcium-saturated montmorillonite with 1 *M* ammonium acetate was compared to the amount of calcium replaced by washing an identical aliquot of calcium-saturated montmorillonite with 1 *M* 3-hydroxypropylammonium chloride. Two aliquots of a 2% calcium-saturated montmorillonite suspension were washed five times with either 1 *M* ammonium acetate or 1 *M* 3-hydroxypropylammonium chloride. Following centrifugation, the calcium content of the pooled supernate from all five washings was determined by atomic absorption spectrometry[4]. Complete exchange of calcium by 3-hydroxypropylammonium chloride was indicated by the recovery from three individually tested clay samples of 72.9 ± 2.5 mEq of Ca^{2+}/100 g following ammonium acetate washing and 69.8

± 3.1 mEq of Ca^{2+}/100 g following 3-hydroxypropylammonium chloride treatment.

UV Spectroscopic Titrations—Displacement of the pK of atrazine in clay suspensions was determined by spectroscopic titration. The pK_{eff} and the partial molar Gibbs free energy change upon addition of the clay, $\Delta\overline{G}_i$, for atrazine and atrazine–H^+ were calculated from the spectroscopic titration curve using the procedure of Feldkamp and White (8).

The UV spectra of the protonated and neutral forms of atrazine show the greatest difference in absorbance at 223 nm. Thus, titration curves were constructed by preparing a series of atrazine–clay suspensions containing 5 mg of atrazine and 200 mg of clay/liter at different pH^b (bulk pH) conditions and determining the absorbance at 223 nm.

Titration of atrazine in aqueous solution was done using the same procedure except that the clay was omitted.

Adsorption Studies—The fraction of atrazine bound by the clay at different pH^b conditions was determined using the samples from the spectroscopic titration experiment. A sample of each suspension was centrifuged, and 15 ml of supernate was collected. Sufficient hydrochloric acid was added to ensure that all of the atrazine was in the protonated form (pH^b = 0.5). The absorbance was measured at 223 nm.

The fraction of atrazine bound, f, was calculated from:

$$f = \frac{A_0 - (A_s - A_r)}{A_0} \qquad \text{(Eq. 1)}$$

where A_0 is the absorbance of an atrazine solution (5 mg/liter) containing only the protonated form of atrazine, A_s is the absorbance of the sample supernate, and A_r is the absorbance of the reference supernate.

RESULTS AND DISCUSSION

The effect of bentonite USP, sodium-saturated montmorillonite, and 3-hydroxypropylammonium-saturated montmorillonite on the acid–base equilibrium of atrazine is shown in Fig. 1. In aqueous solution, the pK of atrazine was found to be 1.64, which agrees with previously reported values (5).

In general, pK_{eff} and $\Delta\overline{G}_i$ depend on the composition of the system, *i.e.*, pH, ionic strength, temperature, pressure, other solutes, and concentration. Therefore, the reported values for pK_{eff} and $\Delta\overline{G}_i$ represent average values over the pH range of interest.

The presence of bentonite USP caused the titration curve of atrazine to shift to higher pH values, indicating that the protonated form of atrazine interacts with the clay to a greater extent than does the neutral form of atrazine. This interaction caused a shift in the apparent dissociation constant, pK_{eff}, of atrazine. The magnitude of the interaction of each species of atrazine with the clay can be characterized by $\Delta\overline{G}_i$ (8).

As seen in Table I, the apparent dissociation constant of atrazine increased from 1.64 to 2.80 in the presence of bentonite USP. The change in the partial molar Gibbs free energy of the protonated form of atrazine was −1.46 kcal/mole, indicating that this species of atrazine interacted with the clay. In contrast, virtually no interaction occurred between the neutral atrazine molecule and the clay since $\Delta\overline{G}_B$ was approximately zero.

Table I—Effect of Bentonite USP, Sodium-Saturated Montmorillonite, and 3-Hydroxypropylammonium-Saturated Montmorillonite on the Acid–Base Equilibrium of Atrazine

Sample	pK_{eff}	$\Delta\overline{G}_{BH^+}$, kcal/mole	$\Delta\overline{G}_B$, kcal/mole
Aqueous solution	1.64	—	—
Bentonite USP suspension	2.80	−1.46	~0
Sodium-saturated montmorillonite suspension	4.40	−3.61	~0
3-Hydroxypropylammonium-saturated montmorillonite	6.90	−7.21	~0

The acid–base equilibrium of atrazine was affected more strongly by sodium-saturated montmorillonite. The value of pK_{eff} increased by almost 3 units, reflecting the increased interaction of the protonated form of atrazine with the sodium-saturated montmorillonite (Table I).

Although bentonite USP is predominantly a sodium-saturated montmorillonite (9, 10), the effect of bentonite USP on the acid–base equilibrium of atrazine was not as great as that produced by sodium-saturated montmorillonite. The sample of bentonite USP contained sodium as the major exchangeable cation, although 7.1 and 2.7% of the exchange capacity was satisfied by calcium and magnesium ions, respectively. In addition, X-ray diffraction showed the presence of quartz, gypsum, and calcite, while the peroxide test indicated the presence of organic material.

Thus, the smaller effect of bentonite USP on the acid–base equilibrium of atrazine may be due to the screening effect of the divalent exchangeable

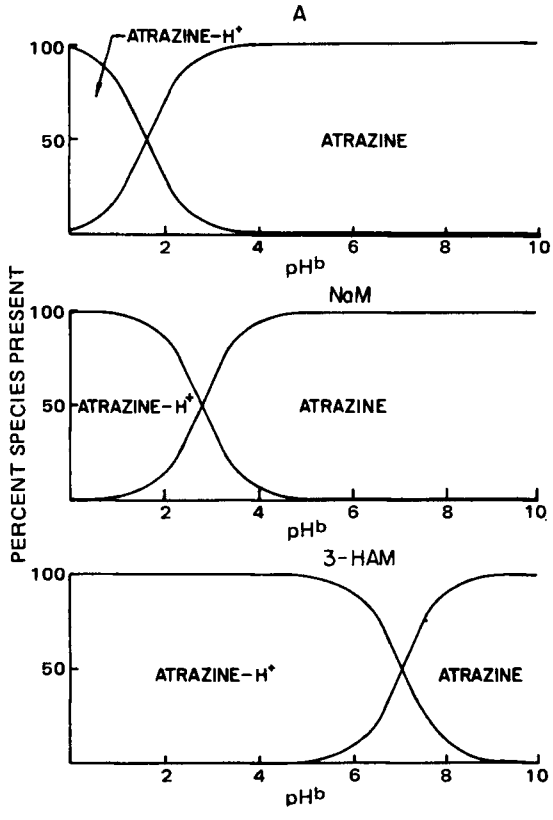

Figure 2—*Distribution of ionic species of atrazine in clay suspensions based on pK_{eff}. Key: A, aqueous solution; NaM, bentonite USP suspension; and 3-HAM, 3-hydroxypropylammonium-saturated montmorillonite.*

cations. It also is possible that the organic material in bentonite USP reduces the protonated atrazine–clay interaction. Similar findings were reported by Feldkamp (11), who observed a reduced ability of charged sites to interact with the protonated form of bases in soils containing organic matter.

The presence of 3-hydroxypropylammonium-saturated montmorillonite produced the greatest effect on the acid–base equilibrium of atrazine. The pK_{eff} of atrazine in a 3-hydroxypropylammonium-saturated montmorillonite suspension was 6.9, an increase of more than 5 units in comparison to the pK of atrazine. This shift was caused by the strong interaction of the protonated form of atrazine with the 3-hydroxylpropylammonium-saturated montmorillonite, as evidenced by the magnitude of $\Delta\bar{G}_{BH^+}$ and the virtual absence of any interaction of atrazine with the specially treated clay (Table I).

The interaction of atrazine with the clay surfaces caused a substantial shift in pK_{eff}, which resulted in an altered distribution of the protonated and neutral forms of atrazine. Figure 2 demonstrates the dramatic shift in the pH region in which the protonated form of atrazine predominated due to the presence of 3-hydroxypropylammonium-saturated montmorillonite.

The changes in the acid–base equilibrium of atrazine in the presence of bentonite USP, sodium-saturated montmorillonite, or 3-hydroxypropylammonium-saturated montmorillonite resulted in dramatic changes in the adsorption profile of atrazine (Fig. 3). Bentonite USP and sodium-saturated montmorillonite both adsorbed ~60% of the atrazine, although the maximum adsorption occurred at a higher pH^b (2.6) for sodium-saturated montmorillonite than for bentonite USP (2.0). The fraction of atrazine bound by 3-hydroxypropylammonium-saturated montmorillonite approached 100% at pH^b values up to 5.

The pH^b of maximum adsorption of atrazine reflects the pK_{eff} of atrazine in the presence of each clay. At low pH^b conditions, both protons and protonated atrazine cations compete for the negatively charged sites on the clay surface. The pH^b of maximum adsorption occurs when the interaction of protonated atrazine with the clay surface predominates. At pH^b conditions favoring the formulation of the neutral atrazine species based on pK_{eff}, the fraction bound curves decreased. Virtually no adsorption occurred at higher pH^b conditions, where the unionized atrazine would predominate. This observation confirms that $\Delta\bar{G}_B$ is virtually zero as reported in Table I.

The fraction-bound study also suggests that saturation of montmorillonite with an organic cation such as 3-hydroxypropylammonium increases the interaction between the protonated form of atrazine and the clay. It is believed that the 3-hydroxypropylammonium cation induced a highly diffuse, electrical double layer at the surface of montmorillonite. Thus, 3-hydroxypropylammonium was less effective than sodium in countering the negative surface charge of montmorillonite.

A number of factors may be responsible for this effect. The distribution of the electrostatic charge on the organic cation might render it less effective than sodium in satisfying the surface charge. Geometric considerations also may prevent effective balancing of the surface charge by the organic cation.

It is not surprising that the protonated form of atrazine was able to replace the exchangeable cations in montmorillonite since large organic cations are adsorbed by van der Waals forces in addition to electrostatic forces (1). Hendricks (12) reported that large organic cations adsorbed by montmorillonite were nearly impossible to replace by smaller cations.

In addition to the formation of a highly diffuse, electrical double layer, the strong interaction of atrazine with 3-hydroxypropylammonium-saturated montmorillonite may be enhanced by a surface environment that is highly compatible with protonated atrazine. This is possible if the exchangeable organic cation induces a structured environment at the clay surface in which the polarity of the surface phase is similar to the polarity of protonated atrazine. As a consequence, protonated atrazine will exhibit a greater preference for the clay phase than for the solution phase.

Surface modification of montmorillonite through organic cation saturation may have an important therapeutic application in the treatment of poisoning. For weak bases with low pK values, the uncharged base should exist throughout the small intestine where systemic absorption is most likely. Conventional clay adsorbents such as bentonite USP do not strongly interact with neutral molecules and, therefore, are not effective in treating poisoning by weak bases. However, when montmorillonite is saturated with an organic cation such as 3-hydroxypropylammonium, the fraction of weak base bound and the pH^b range over which adsorption takes place should be greatly increased. Evaluation of the toxicity of small organic cations that may serve as exchangeable cations in montmorillonite may lead to the development of organic cation-saturated montmorillonite, which may prove valuable in the treatment of poisoning by weak bases.

Comparison of Two High-Pressure Liquid Chromatographic Assays for Carboprost, a Synthetic Prostaglandin

LEO W. BROWN and BRUCE E. CARPENTER ˣ

Received January 17, 1980, from *Control Research and Development, The Upjohn Company, Kalamazoo, MI 49002.* Accepted for publication June 25, 1980.

Abstract □ A high-pressure liquid chromatographic assay for carboprost tromethamine as the bulk drug and in a sterile solution formulation is described. The procedure involves derivatization of the prostaglandin to form the UV-absorbing naphthacyl ester, which then is chromatographed on a silica gel column using methylene chloride–1,3-butanediol–water (496:4:0.25) as the mobile phase. This procedure is compared with a nonderivatization procedure with refractive index detection. Both procedures separate the 15*R*-epimer of carboprost from carboprost, but only the derivatization procedure separates the 5-*trans*-isomer of carboprost. Possible reasons for the better separation using the derivatization procedure are discussed. Both procedures gave a coefficient of variation of ~1% for carboprost. The derivatization procedure gave a coefficient of variation of ~7% for the 15*R*-epimer and 5-*trans*-isomer when present at 2% of the carboprost level.

Keyphrases □ Carboprost—comparison of high-pressure liquid chromatographic assays with and without derivatization □ High-pressure liquid chromatography—analysis, carboprost, comparison of procedures with and without derivatization □ Prostaglandins—carboprost, high-pressure liquid chromatographic analysis, comparison of procedures with and without derivatization

Several reviews of prostaglandins have been published. Oesterling *et al.* (1) reviewed the nomenclature, chemistry, stability, analytical methods, metabolism, and biology of many prostaglandins. Analytical methods have been developed for the assay of prostaglandins in biological matrixes using GLC, radioimmunoassay, and GLC–mass spectrometry. Liquid chromatography has been used to separate prostaglandins of similar structures (2–4).

The high-pressure liquid chromatographic (HPLC) assays presented here were developed for carboprost [(15*S*)-15-methyldinoprost, I] and its possible impurities or degradation products in bulk drug and pharmaceutical formulations. A similar prostaglandin, dinoprost (II), was used as the internal standard in the nonderivatization procedure.

Carboprost and dinoprost are present initially as their tromethamine salts. The free acids are formed during extraction.

EXPERIMENTAL

Nonderivatization Assay—*HPLC Conditions*—A high-pressure liquid chromatograph[1] was used with a differential refractometer detector[2]. Two 3.9-mm × 30-cm microparticulate silica gel columns[3] were used in series. The flow rate of the mobile phase was maintained at 1 ml/min, and a 25-μl injection volume was used with a loop injector[4]. The chart speed was 0.64 cm/min, and attenuation of the refractive index detector was set at 9.6×10^{-5} unit full scale. The mobile phase was acetonitrile–methanol–acetic acid (96:3:1).

Internal Standard Solution—An aqueous solution containing ~3.4 mg of dinoprost tromethamine/ml was prepared.

Bulk Drug Carboprost Tromethamine Reference Preparation—To a separator were added ~3.3 mg of carboprost tromethamine reference standard, accurately weighed, 1.0 ml of the internal standard solution, and 0.5 g of boric acid. The mixture was swirled to dissolve the boric acid partially, and the carboprost free acid and the internal standard were extracted from the aqueous layer using two 5-ml portions of chloroform. The chloroform extracts were combined and evaporated to dryness with a nitrogen stream.

Carboprost Tromethamine Sterile Solution Reference Preparation—Ten milliliters of 0.9% benzyl alcohol[5] in water was added to a separator, followed by the same additions as used for the reference preparation of bulk drug carboprost tromethamine.

Bulk Drug Sample Preparation—The same procedure as that for the reference preparation was used, substituting the bulk drug sample for the carboprost tromethamine reference.

Carboprost Tromethamine Sterile Solution Sample Preparation—Ten milliliters of sterile solution (0.25 mg carboprost equivalents/ml) was added to a separator, followed by 0.5 g of boric acid and 1.0 ml of the internal standard solution. Carboprost and the internal standard were extracted from the aqueous layer using two 5-ml portions of chloroform. The extracts were combined and evaporated to dryness with a nitrogen stream.

Procedure—To the residues of both the reference and the sample was added 0.5 ml of the mobile phase. The vials were swirled to dissolve the residue and chromatographed using the described HPLC conditions.

Derivatization Assay—*HPLC Conditions*—A high-pressure liquid chromatograph[1] was used with a UV detector[6] at 254 nm. A single 3.9-mm × 30-cm microparticulate silica gel column[3] was used. The flow rate was maintained at ~1.8 ml/min, and a 10-μl injection volume was used with a loop injector[4]. The recorder chart speed was 0.64 cm/min, and attenuation on the UV detector was set at 0.08 aufs. The mobile phase was methylene chloride–1,3-butanediol–water (496:3.5:0.25).

Internal Standard Solution—A mobile phase solution containing ~3 or 7 mg of guaifenesin/ml was prepared for the assay of carboprost sterile solution (0.25 mg/ml) or the bulk drug, respectively.

Derivatization Reagents—An acetonitrile solution containing 20 mg of α-bromo-2-acetonaphthone[7] or 10 μl of diisopropylethylamine[8]/ml was used.

Bulk Drug Reference Preparation—Approximately 5.0 mg of carboprost tromethamine reference was weighed accurately and transferred to a stoppered 35-ml centrifuge tube.

Sterile Solution Reference Preparation—A solution containing ~0.332 mg of carboprost tromethamine reference/ml in water and 9 mg of benzyl alcohol[5]/ml was accurately prepared.

Bulk Drug Sample Preparation—Approximately 5 mg of the carboprost tromethamine sample was weighed accurately and transferred to a 35-ml centrifuge tube.

Sterile Solution Sample Preparation—The solution (0.25 mg of carboprost equivalent/ml) was used without dilution.

Procedure—For bulk drug, 20.0 ml of methylene chloride and 2.0 ml of citrate buffer (0.5 *M*, pH 4.0) were added to the sample and reference tubes. After the tubes were shaken for 10 min and centrifuged, the top aqueous layer was discarded. A 4.0-ml aliquot of the methylene chloride layer was transferred to a small vial and evaporated to dryness. Eighty microliters of the α-bromo-2-acetonaphthone solution was added, followed by 60 μl of the diisopropylethylamine solution. The vials were swirled to dissolve the residue and allowed to stand for 1 hr or heated at 30–35° for 15 min. Then the solutions were evaporated to dryness, and 2.0 ml of the internal standard was added. After mixing, the solutions

I: R = CH_3
II: R = H

were chromatographed within 24 hr of derivatization using the described HPLC conditions. The standard and sample preparations were protected from light, because light was shown to cause degradation of the naphthacyl ester of carboprost.

For the sterile solution, 2.0 ml of the sample solution and 2.0 ml of the reference solution were added to separate stoppered 35-ml centrifuge tubes. To each tube were added 20.0 ml of methylene chloride and 1.0 ml of citrate buffer. The tubes were shaken for 10 min and centrifuged. The top aqueous layer was discarded, and an 8.0-ml aliquot of the methylene chloride layer was transferred to a small vial and evaporated using a nitrogen stream (complete evaporation was not obtained due to the presence of benzyl alcohol extracted from the aqueous solution). Forty microliters of α-bromo-2-acetonaphthone solution was added, followed by 30 μl of diisopropylethylamine solution. After swirling to mix and dissolve the residue, the solution was allowed to stand for 1 hr or heated at 30–35° for 15 min. The acetonitrile then was evaporated, and 1.0 ml of the internal standard solution was added. After mixing, the solutions were chromatographed within 24 hr of derivatization using the described HPLC conditions. Standard and sample preparations were protected from light, because light was shown to cause degradation of the naphthacyl ester of carboprost.

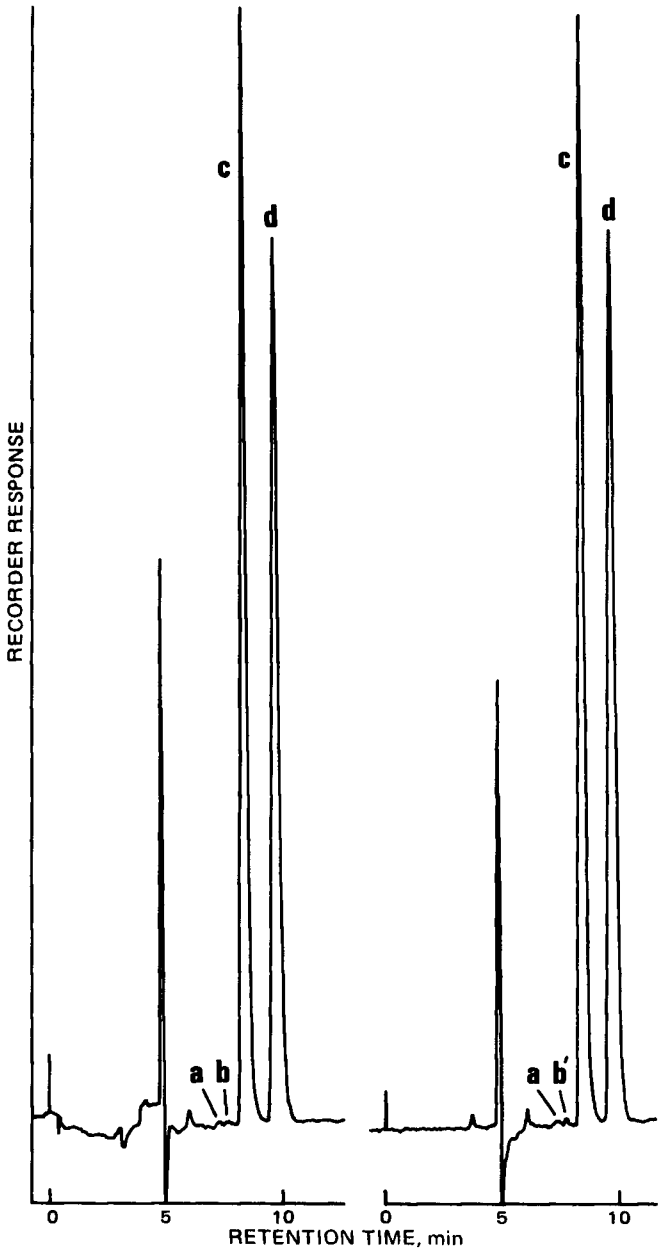

Figure 1—*Chromatograms of the 15R-epimer of dinoprost (a), the 15R-epimer of carboprost at 0.5% (b), the 15R-epimer of carboprost at 1.0% (b′), carboprost (c), and dinoprost (internal standard) (d) using the nonderivatization HPLC procedure with refractive index detection.*

Calculations—For the bulk drug:

$$\% \text{ purity of carboprost tromethamine} = \frac{R_s}{R_{ref}} \times \frac{W_{ref}}{W_s} \times P \quad \text{(Eq. 1)}$$

where R_s is the peak height ratio of the carboprost peak to the internal standard peak in the sample preparation; R_{ref} is the peak height ratio of the carboprost peak to the internal standard peak in the reference preparation; W_{ref} is the weight, in milligrams, of carboprost tromethamine

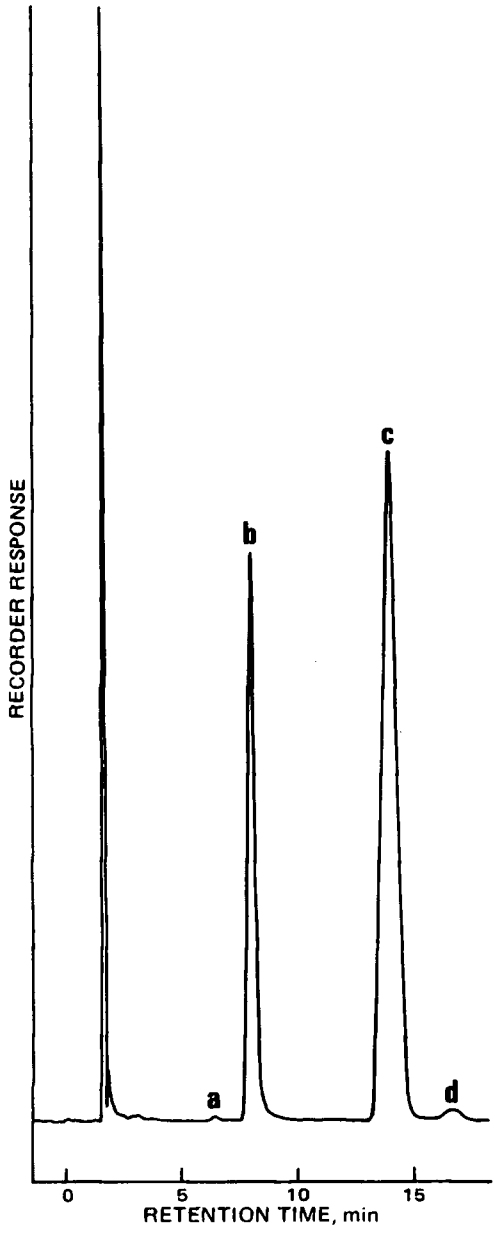

Figure 2—*Chromatogram of guaifenesin impurity (a), guaifenesin (internal standard) (b), 2-naphthacyl carboprost (c), and the 2-naphthacyl 5-*trans*-isomer of carboprost (d) using the derivatization procedure with UV detection.*

amine reference standard; W_s is the weight, in milligrams, of sample; and P is the purity of the carboprost tromethamine reference expressed in percent.

For the sterile solution:

$$\text{mg of carboprost/ml of sterile solution} = \frac{R_s}{R_{\text{ref}}} \times \frac{W_{\text{ref}}}{V_s} \times F_c \times P \qquad \text{(Eq. 2)}$$

where R_s is the peak height ratio of the carboprost peak to the internal standard peak in the sample preparation; R_{ref} is the peak height ratio of the carboprost peak to the internal standard peak in the reference preparation; W_{ref} is the weight, in milligrams, of carboprost tromethamine reference standard used in the procedure; V_s is the volume, in milliliters, of sample; F_c is the factor to convert carboprost tromethamine (mol. wt. 489.65) to carboprost (mol. wt. 368.50) = 0.7526; and P is the purity of the carboprost tromethamine reference expressed as a decimal.

For the impurities:

$$\% \text{ impurity} = \frac{A_a \text{ or } A_c}{A_a + A_b + A_c} \times 100 \qquad \text{(Eq. 3)}$$

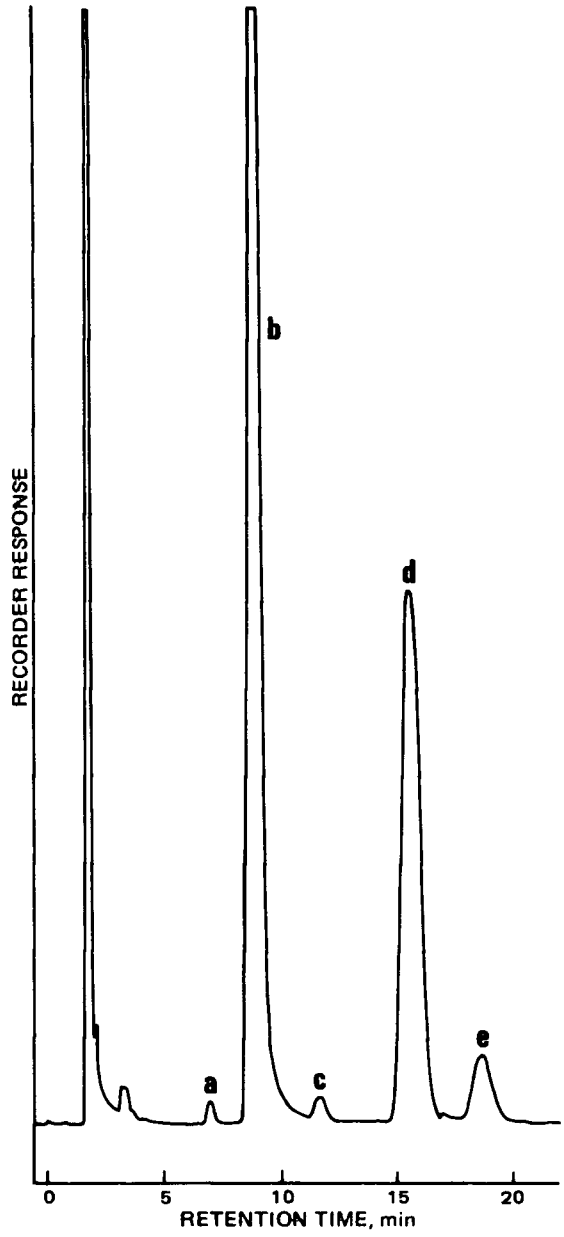

Figure 3—*Chromatogram of a guaifenesin impurity (a), guaifenesin (internal standard) (b), 2-naphthacyl 15*R*-epimer of carboprost at 0.5% (c), 2-naphthacyl carboprost at an attenuation four times that of the other peaks (d), and 2-naphthacyl 5-*trans*-isomer of carboprost at 2.3% (e) using the derivatization procedure with UV detection.*

or:

$$\% \text{ impurity} = \frac{F_aH_a \text{ or } F_cH_c}{F_aH_a + H_b + F_cH_c} \times 100 \qquad \text{(Eq. 4)}$$

where A_a is the area of the 15*R*-epimer peak, A_b is the area of the carboprost peak, A_c is the area of the 5-*trans*-isomer peak, F_a is the factor to normalize the 15*R*-epimer peak height (0.78), F_c is the factor to normalize the 5-*trans*-isomer peak height (1.12), H_a is the peak height of the 15*R*-epimer peak, H_b is the height of the carboprost peak, and H_c is the height of the 5-*trans*-isomer peak.

RESULTS AND DISCUSSION

Both assay procedures (derivatization and nonderivatization) involve extraction of the prostaglandin as the free acid from an acidified aqueous solvent into an organic solvent. This extraction is tailored for the assay of dilute sterile solutions of the prostaglandin in which a concentration step is necessary when using the nonderivatization procedure. Furthermore, the derivatization reaction proceeds much more rapidly with the

	1.7	2.4
Average	1.7	2.4
CV, %	7.1	7.4

free acid than with the tromethamine salt (Table I). After 1 hr, the tromethamine salt samples exhibit a low mean ratio and a high variation between samples, while the free acid samples exhibit a high mean ratio and little variation between samples. The derivatization reaction for the free acid is essentially complete after 1 hr (Table II).

Recovery studies showed that the extraction procedure produced nearly complete recovery (~96%) of the prostaglandin. To eliminate possible bias, the reference is carried through the complete procedure along with the sample to be assayed. Replicate samples assayed by either method gave a relative standard deviation of <1% (Table III).

Chromatograms of carboprost (nonderivatization procedure) are shown in Fig. 1; authentic samples of the 15*R*-epimer of carboprost had been added at concentrations of ~0.5 and 1.0% of the carboprost concentration. The epimer peak is baseline separated from the carboprost peak, making the assay satisfactory for stability studies (carboprost degrades to the 15*R*-epimer under acidic conditions). The small peak on the front side of the 15*R*-epimer is the 15*R*-epimer of dinoprost, which was used as the internal standard.

To obtain greater sensitivity for the assay of the 15*R*-epimer in carboprost samples, the derivatization procedure was developed. Formation of the 2-naphthacyl ester has been used for fatty acids (5) and is similar to *p*-nitrophenacyl derivatization of prostaglandins (4). The 2-naphthacyl ester of carboprost was found to exhibit greater absorptivity than the *p*-nitrophenacyl ester at 254 nm with the UV detector. A chromatogram of 2-naphthacyl carboprost using guaifenesin as the internal standard is shown in Fig. 2.

In comparing the nonderivatization and derivatization methods, it is evident that derivatization produced better chromatography. The 15*R*-epimer is better separated, and another impurity, the 5-*trans*-isomer of carboprost, is baseline separated from carboprost. Although the nonderivatization procedure is less time consuming because of the absence of a derivatization step, it is not satisfactory if the 5-*trans*-isomer is present in the carboprost sample. Although several mobile phases were tried, the 5-*trans*-isomer could not be separated from carboprost using the nonderivatization procedure, even with two silica columns in series. With the derivatization procedure, greater separation than is shown in Fig. 2 can be achieved by decreasing the relative concentration of 1,3-butanediol in the mobile phase. This is a definite advantage of the derivatization procedure.

Increased liquid chromatographic separation of the 15-position epimers of carboprost is observed with the derivatization procedure, probably because of the reduced polarity of the carboxyl group by naphthacyl ester formation. The presence of the highly polar carboxyl group masks subtle polarity differences due to the position of the hydroxyl groups in the isomers. Thus, the blocking of the carboxyl group maximizes the effect of the hydroxyl groups, and the polarity differences between the 15-position epimers become more significant.

Figure 3 shows a chromatogram (derivatization procedure) of carboprost with the 15*R*-epimer added. In the absence of reference samples to quantitate the impurities by peak height percent, the 15*R*-epimer and 5-*trans*-isomer peak heights must be multiplied by response factors of 0.78 and 1.12, respectively. The response factors were required to normalize peak height differences due to retention times. These factors were determined using authentic samples. Since the UV chromophore in each compound is the naphthacyl ester, carboprost and the two impurities should have the same absorptivity. By measuring peak area instead of peak height, response factors were not needed. Results by peak area percent showed good agreement with carboprost samples spiked with impurities at known concentrations. Assay results of replicate samples of the 15*R*-epimer at a concentration of 1.7% and of the 5-*trans*-isomer at a concentration of 2.3% in carboprost bulk drug are shown in Table IV. A coefficient of variation of ~7% was obtained for both impurities by peak area percent at 2% of the carboprost concentration.

Light caused degradation of the naphthacyl ester of carboprost. When derivatized samples were placed near a light source, a noticeable increase in the peak corresponding to the 5-*trans*-isomer was observed. No significant change was observed in derivatized samples protected from light for 24 hr. The peak height ratios of carboprost to the internal standard and of the 5-*trans*-isomer to carboprost showed no significant changes. The degradation in light may be due to the chromophore. Acetophenone and several similar compounds have been shown to act as photosensitizers for *cis–trans*-isomerization (6).

Comparative Pharmacokinetics of Quinidine and Its *O*-Desmethyl Metabolite in Rabbits

CLARENCE T. UEDA [x] **and JEANNETTA G. NICKOLS**

Received March 4, 1980, from the *Department of Pharmaceutics, College of Pharmacy, and the Cardiovascular Center, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication June 9, 1980.

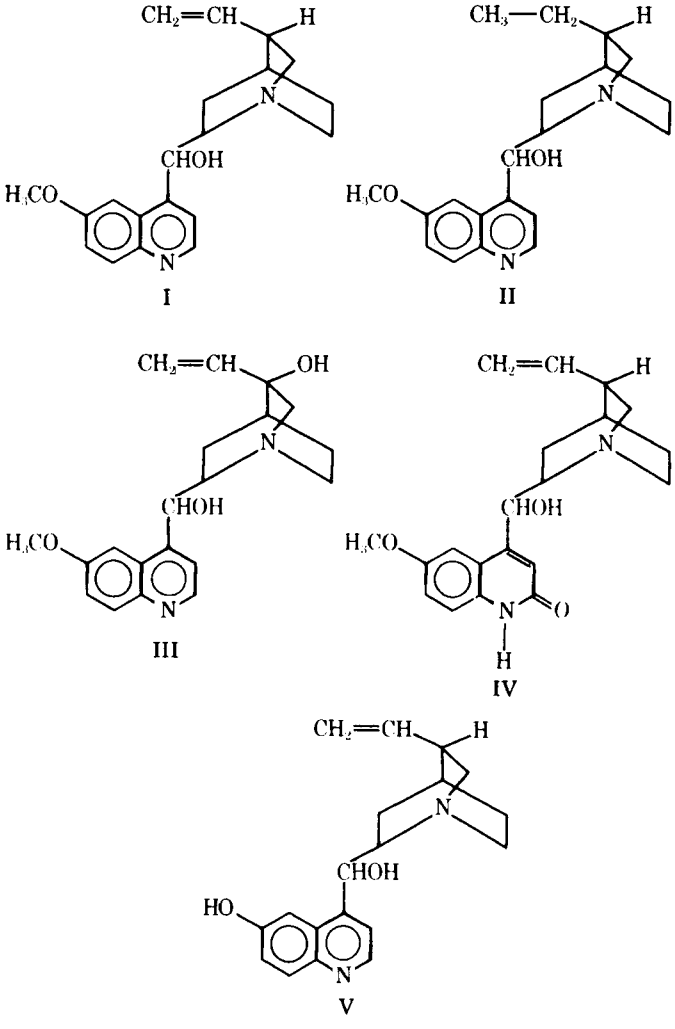
Abstract □ The pharmacokinetics of quinidine and the *O*-desmethyl metabolite 6′-hydroxycinchonine were studied in rabbits. After intravenous bolus injections of equimolar doses, the blood concentration–time curves of each agent declined biexponentially, which was characteristic of a two-compartment open model. A significant difference between quinidine and 6′-hydroxycinchonine was observed for the following parameters: $t_{1/2\alpha}$, β, $t_{1/2\beta}$, k_{12}, Vd_β, and the intercompartmental distribution ratio, k_{12}/k_{21}. The results showed that the distribution of the metabolite was slower than quinidine and suggested that it *also* was less extensive. The Vd_β value for 6′-hydroxycinchonine was approximately one-half of the value observed for quinidine, and its k_{12}/k_{21} ratio was about one-fourth of the quinidine value. The terminal half-lives for quinidine and the metabolite were 132.4 ± 27.1 and 65.4 ± 34.4 min, respectively. Total body clearance was similar for both compounds. The findings of this study could be explained by the greater polarity or greater water solubility of 6′-hydroxycinchonine. The limited data in humans coupled with the results of this investigation suggest that, although it is intrinsically active, the *O*-demethylated metabolite probably contributes little to the antiarrhythmic effects seen after quinidine administration in humans.

Keyphrases □ Quinidine—and its *O*-desmethyl metabolite, comparison of pharmacokinetics in rabbits □ Pharmacokinetics—comparison of quinidine and its *O*-desmethyl metabolite, rabbits □ Antiarrhythmic agents—quinidine and its *O*-desmethyl metabolite, pharmacokinetics, rabbits

6′-Hydroxycinchonine (*O*-desmethylquinidine, V) is a newly reported metabolite of quinidine (I) (1, 2). Nwangwu *et al.* (3, 4) reported that the antiarrhythmic potency of V was equivalent to that of I when tested against aconitine-induced arrhythmias in mice. They also suggested that V was less toxic than I. Drayer *et al.* (1, 2) showed that V possessed ~60% of the antiarrhythmic activity exhibited by quinidine using a chloroform- and hypoxia-induced ventricular fibrillation animal model.

Quinidine metabolites such as 2′-oxoquinidinone (IV), 3-hydroxyquinidine (III), and V are believed to contribute to the antiarrhythmic effects seen after the administration of I in humans[1] (5), but they have not been tested directly for such activity.

The purpose of this study was to investigate the comparative pharmacokinetics of I and V in rabbits. This information could provide important insight into the behavior of this metabolite relative to quinidine in humans.



EXPERIMENTAL

Materials—Restrained, male New Zealand White rabbits[2], 4–5 kg, were used.

Quinidine base, free of the dihydro analog (II), was obtained as described previously (6) and was used to prepare a parenteral solution of quinidine sulfate containing 20 mg (0.062 mmole) of quinidine base/ml of solution. An injectable solution containing 19.14 mg (0.062 mmole) of V[3]/ml was prepared fresh from the dihydrochloride salt just before individual experiments. Chromatographic analysis of V revealed 8% of a substance that was presumed to be its dihydro derivative since this material also was prepared from commercial quinidine sulfate powder[4]. Because it did not interfere with the assay for V, no attempt was made to remove this minor impurity.

Methods—To give the intravenous bolus injections and to withdraw blood samples for drug and metabolite analysis, a 25-gauge vein infusion set with a winged adapter[5] was placed in a marginal ear vein and secured to the external ear with adhesive tape. After a control blood specimen was obtained, 1 ml of drug solution was given as an intravenous bolus dose. Complete administration of each dose was achieved by flushing the contents of the infusion set with ~0.8 ml of heparinized normal saline (5 units/ml). Blood specimens of 0.5 ml for the analysis of I and V were collected in heparinized tubes[6] at 5, 10, 15, 30, 45, and 60 min and thereafter at 0.5-hr intervals for up to 3–4 hr after the dose. The blood samples were stored at −20° until they were assayed.

Blood concentrations of V were determined by the following high-

performance liquid chromatographic procedure. After the previously frozen samples were thawed, 0.5 ml of whole blood was diluted in a 15-ml culture tube with 0.5 ml of distilled water and 0.5 ml of 0.2 *M* phosphate buffer (pH 7.4), containing 40 ng of dihydroquinidine (II) as the internal standard. Following the addition of 100 μl of 95% ethanol to this mixture, the sample was vortexed[7] and extracted with 4 ml of benzene by shaking for 2 hr on a reciprocating shaker[8] at room temperature.

The benzene extract was separated by centrifugation, and the upper organic layer was carefully removed by pipet and transferred to a 5-ml conical tube. The benzene extract, to which was added 100 μl of absolute alcohol, then was evaporated to dryness at room temperature under a nitrogen stream. The residue was reconstituted with 25 μl of the mobile phase, and an aliquot was injected into a preconditioned liquid chromatograph.

The concentrations of V in the unknown samples were determined from standard calibration curves prepared with the experimental specimens. In the concentration range of 0.5–10 μg/ml for V, the peak height ratio of V to the internal standard was linearly related to the metabolite concentration. The best-fitting equations for the standard curves were obtained by linear regression analysis.

The liquid chromatograph[9] was equipped with a loop injector[10], a μBondapak C_{18} reversed-phase column[11] (30 cm × 3.9 mm i.d.), and a fluorescence detector[12]. The mobile phase, which was filtered and degassed before use, consisted of 15% (v/v) acetonitrile[13] in a 2.5% (v/v) solution of acetic acid and was pumped at a flow rate of 2 ml/min (about 1800 psi). The column eluate was monitored with an excitation wavelength of 315 nm and a KV 418 emission cutoff filter. The detector sensitivity setting was 0.5–1.0 μamp full scale with a time constant set at 4 sec and a chart speed[14] of 0.5 cm/min.

As shown in Fig. 1, with the chromatographic conditions used, V and the internal standard (II) were readily separable with elution times of ~2 and 4 min, respectively. The minor impurity, presumed to be the dihydro analog of V, eluted about midway between the metabolite and internal standard peaks. Peak c in Fig. 1 was an unknown benzene-extractable substance in rabbit blood.

Blood quinidine concentrations were determined with the TLC–fluorometric procedure described previously (7).

After the quinidine and V bolus doses, the blood concentration–time curves for both agents declined biexponentially (Fig. 2). Therefore, the data were fitted using the least-squares computer program NONLIN (8) and a digital computer to:

$$C_b = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where C_b is the concentration of alkaloid in the blood at time t, A and B are ordinate intercept constants, and α and β are first-order disposition rate constants. Each value was weighted by the reciprocal of the concentration squared. Initial parameter estimates were obtained with the CSTRIP computer program (9).

Equation 1 describes the two-compartment open model shown in Scheme I. This model was used to characterize the disposition of I and V in rabbits. The pharmacokinetic parameters were derived as reported previously (10, 11). The Student t test was used to evaluate the significance of the observed difference.

RESULTS AND DISCUSSION

As shown in Fig. 2 for a representative animal, the blood concentration–time curves for I and V declined biexponentially after intravenous injection of equimolar doses of the two agents. The pharmacokinetic constants derived for each compound are presented in Table I. Three rabbits were given both I and V. The remaining animals received only one agent.

A significant difference between quinidine and the *O*-demethylated metabolite was observed for the following parameters: $t_{1/2\alpha}$, β, $t_{1/2\beta}$, k_{12} (the first-order rate constant for movement of the drug from the central to the peripheral compartment), $V_d\beta$ (the apparent volume of distribution), and k_{12}/k_{21} (the intercompartmental distribution ratio). No difference was observed in the remaining parameters between the two

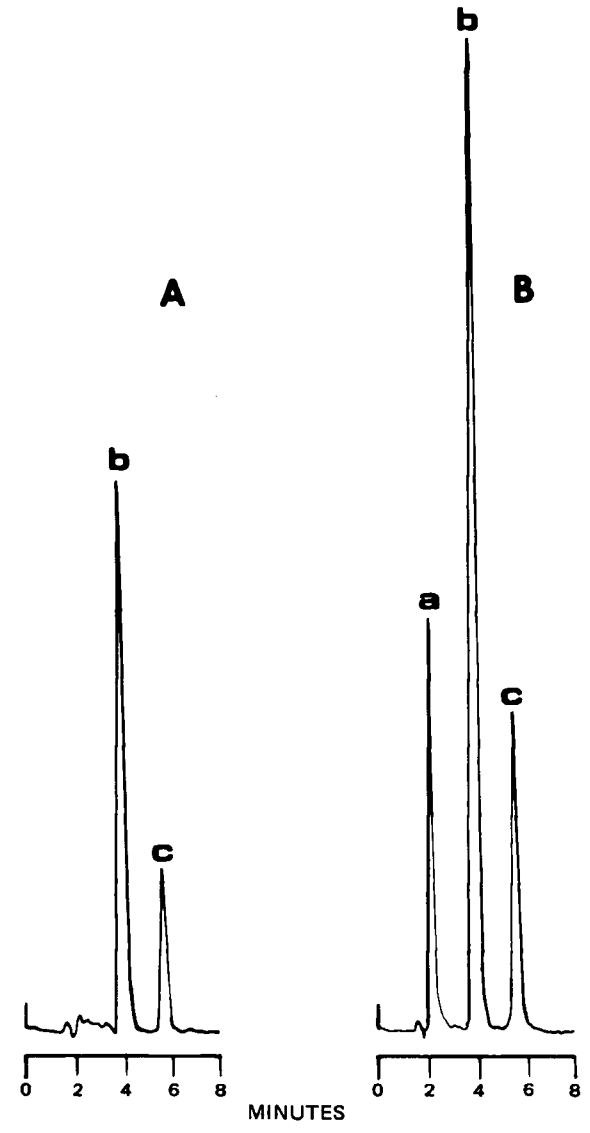

Figure 1—*Liquid chromatograms of blank blood (A) containing the internal standard (II) (b) and a blood sample (B) containing V (a) and II (b). Peak c is an unknown element extracted from rabbit blood.*

compounds; I and V exhibited similar total body clearance rates.

Compared to quinidine, the α or distribution half-life for the metabolite was longer (2.9 *versus* 1.7 min), indicating that it distributed more slowly in the body. The smaller k_{12} value for V (0.134 *versus* 0.226 min^{-1}) agreed with this finding. Furthermore, the distribution of V did not appear to be as extensive as I. The apparent volume of distribution of V of 1.56 ± 0.92 liters/kg was about one-half of the distribution volume for I, which was 3.26 ± 1.11 liters/kg. However, the central compartment volumes for both compounds were of similar size. Thus, the volume of the peripheral or tissue compartment was smaller for the metabolite.

The observed k_{12}/k_{21} ratio, an intercompartmental distribution coefficient, was substantially smaller for the *O*-demethylated metabolite compared to quinidine (4.65 *versus* 17.08). Since the blood flow between the two compartments probably was the same for both agents, the dif-

ferences in the k_{12}/k_{21} ratio between I and V as well as the observed differences in $t_{1/2\alpha}$, k_{12}, and $V_d\beta$ most likely were the results of the greater lipid solubility of I.

The terminal half-life values of 65.4 ± 34.4 and 132.4 ± 27.1 min for V and I, respectively, showed that the metabolite was eliminated more rapidly than the parent drug. This observation is in agreement with the greater polarity or greater water solubility of the *O*-demethylated molecule and indicates that the metabolite would accumulate to a lesser extent than I on repeated dosing of the parent drug (12).

On the basis of its greater polarity, it was anticipated that V would be cleared at a faster rate than I. Therefore, the similarity in total body clearance for V and I was unexpected. Nevertheless, this finding is explained by the following reason. It is widely recognized that metabolism alters the physicochemical properties (*e.g.*, lipid solubility) of a drug molecule, which then leads to changes in its disposition characteristics. For drugs that are converted to more polar metabolites, these biotransformation products would be expected to have smaller volumes of distribution because their ability to cross lipid membranes by diffusion would be diminished. Furthermore, it is reasonable to expect that they would be eliminated more rapidly (*i.e.*, larger β) since they are more water soluble. From the relationship for total body clearance, $Cl = V_d\beta$, it can be seen that a decrease in V_d and an increase in β tend to offset each other and, thus, minimize the anticipated changes in Cl from situations where V_d or β changes alone.

When metabolism involves the conversion to less polar metabolites, a similar situation would be in effect wherein the volumes of distribution and first-order elimination rate constants of the metabolites would increase and decrease, respectively. This situation was observed recently (13) for diethyldithiocarbamate (a metabolite of disulfiram) and its metabolite, methyl diethyldithiocarbamate in dogs. Diethyldithiocarbamate, with a V_d value of 0.16 liter/kg and a β value of 0.205 min^{-1}, is readily soluble in water. Methyl diethyldithiocarbamate (V_d = 2.53 liters/kg and β = 0.014 min^{-1}) is virtually insoluble in water (highly lipid soluble). The observed total body clearances for the respective drug species were 33.1 and 31.9 ml/min/kg.

In this study, the clearance of V and I from the central compartment ($k_{10} \times V_c$) also was similar (16 *versus* 17 ml/min/kg).

In humans, quinidine is eliminated essentially by metabolism (14, 15). The fate of V is not known. Drayer *et al.* (2) detected conjugated and unconjugated V in the urine of four patients receiving quinidine and estimated that both forms accounted for ~1–2% of the quinidine dose. Preliminary findings in this laboratory also suggest that the *O*-demethylation pathway is a minor route for quinidine elimination in humans. These observations, coupled with the results of this study on the disposition and accumulation characteristics of V in rabbits, suggest that, although the *O*-demethylated metabolite possesses intrinsic antiarrhythmic activity (1–4), it probably contributes little to the antiarrhythmic effects seen after the administration of quinidine in humans.

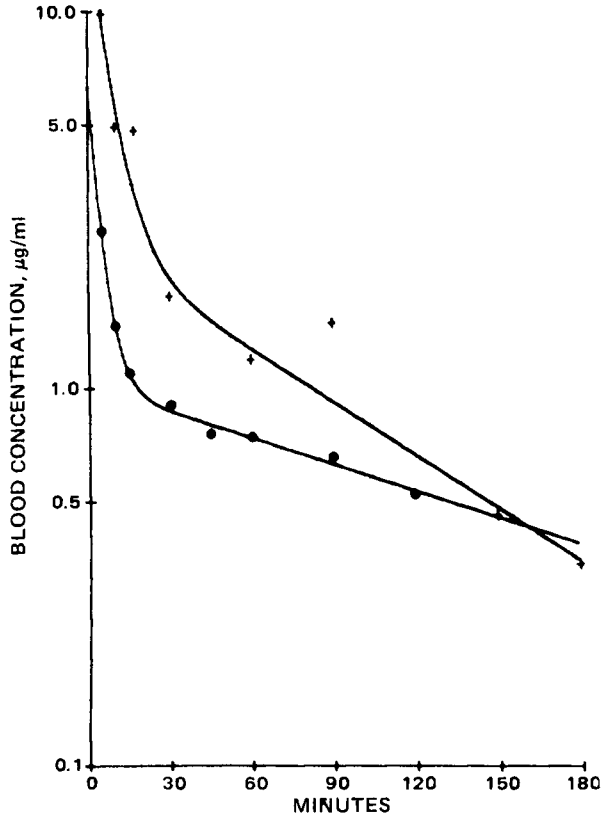

Figure 2—*Computer-simulated curves and experimental data points following intravenous bolus injections of 20 mg of I (●) and 19 mg of V (+) in a single rabbit.*

Interaction of Povidone with Aromatic Compounds I: Evaluation of Complex Formation by Factorial Analysis

J. A. PLAIZIER-VERCAMMEN ˣ **and R. E. De NÈVE**

Received January 28, 1980, from the *Faculteit Geneeskunde en Farmacie, Vrije Universiteit Brussel, Laarbeeklaan 103, B-1090, Brussel, Belgium.* Accepted for publication June 2, 1980.

Abstract □ In a study of complex formation between macromolecules and small ligands such as drugs, it appeared that the association constants must be calculated with more care (*i.e.*, after a thorough investigation of the influencing parameters such as buffer composition, ionic strength, and temperature) to allow meaningful interpretations of the phenomena. For this purpose, factorial analysis seems to be the method of choice; it offers the advantage of evaluating the influence of several variables and their interactions at the same time with a minimum of experiments. The method was applied to the association of povidone with two ligands, salicylic acid and benzoic acid. Parameters such as buffer composition and ionic strength, which affect binding, could be distinguished. Especially at pH 7.00, a great positive influence of buffer ions (phosphate buffer) and a relative positive interaction between temperature and ionic strength were noted. Knowledge of the influences of these parameters allowed comparison of the effects of the functional groups attached to the ligand molecules, as well as their degree of dissociation, on adsorption to permit more meaningful interpretation of thermodynamic constants.

Keyphrases □ Salicylic acid—binding to povidone, effects of temperature, buffer composition, and ionic strength □ Benzoic acid—binding to povidone, effects of temperature, buffer composition, and ionic strength □ Povidone—complex formation with salicylic acid and benzoic acid, effects of temperature, buffer composition, and ionic strength □ Complexation—povidone with salicylic acid and benzoic acid, effects of temperature, buffer composition, and ionic strength

The binding of various drugs with macromolecules in aqueous solution has been reviewed (1–3). Vallner (3) showed the discrepancies among the results obtained by several investigators and cited the need for the calculation of the association constants in a more meaningful manner. These discrepancies often are due to the uncontrolled influence of variables such as buffer composition, pH, ionic strength, and temperature. There have been few reports concerning the influence of buffer ions on the binding onto macromolecules (4, 5). The parameters usually are studied in the classical manner, *i.e.*, by successively changing one parameter at a time. However, as demonstrated previously (6), an accurate interpretation of the individual effects of the variables or their interactions is not possible with that approach.

Factorial analysis offers the possibility of evaluating the influence of individual variables and their interactions at the same time with a minimum of experiments. This method seems to be a first step for a thorough study of complex formation. Once the influence of these parameters is known, comparison of the effects of the functional groups attached to the ligands and their degree of dissociation on adsorption is possible, and the association constants can be interpreted more meaningfully. The application of factorial analysis to the binding of two simple ligands, benzoic acid and salicylic acid, onto povidone demonstrates the advantages and possibilities of this method in the study of complex formation.

EXPERIMENTAL

Reagents—Povidone[1] with a molecular weight of 700,000 was used as the macromolecule and was oven dried at 50° until a constant weight was reached. Salicylic acid[2] (p.a.) and benzoic acid[3] (p.a.) were used without further purification.

Buffer solutions were used at pH 7.00 (phosphate buffer) and at pH values equal to the pKa value of the two cosolutes (McIllvaine buffers) plus and minus 0.80; the solutions were brought to a determined ionic strength with sodium chloride. To control the influence of buffer ions, two kinds of buffer solutions were used; the normal buffers are denoted by 1 and those with half of the normal capacity are indicated as 0.5. The pH of the solutions at 25 and 50° was controlled with a potentiometric pH measurement[4] and adjusted if necessary.

Methods—The solutions containing the ligand and povidone were prepared in the respective buffers and allowed to stand overnight to attain equilibrium. Ultrafiltration[5] was performed, using a membrane of regenerated cellulose with a claimed cutoff value of ~10,000 mol. wt. units. Compressed nitrogen (4 kg/cm^2) was used, and the filtration was performed under continuous stirring of the sample solution to avoid accumulation of the macromolecule at the membrane–solution interface (7).

The concentration of unbound ligand in the filtrate was assayed spectrophotometrically. Corrections were made for membrane adsorption effects, and the concentration of bound ligand was calculated. The spectrophotometric measurements were performed with a double-beam spectrophotometer[6] at 296 nm for salicylic acid and at 224 nm for benzoic acid.

Calculations—Complex formation can be studied as a function of either macromolecule concentration or ligand concentration. In the first method, the relative tendencies of several ligands to form complexes are expressed as the ratio of the total ligand concentration, T, to the con-

Table I—Binding of Salicylic Acid (1.00×10^{-2} *M*) to Povidone (6.00%) at pH 2.20

Ionic Strength	Buffer	Temperature	Percentage of Ligand Bound		Difference
		Influence of Temperature[a]	25°	50°	
Low	Low	—	56.9	54.0	−2.9
Low	High	—	57.1	55.0	−2.1
High	Low	—	62.9	62.2	−0.7
High	High	—	62.8	62.4	−0.4
		Influence of Ionic Strength[b]	μ = 0.15	μ = 1.00	
—	Low	Low	56.9	62.9	+6.0
—	Low	High	54.0	62.2	+8.2
—	High	Low	57.1	62.8	+5.7
—	High	High	55.0	62.4	+7.4
		Influence of Buffer Ions[c]	0.5 Buffer	1 Buffer	
Low	—	Low	56.9	57.1	+0.2
Low	—	High	54.0	55.0	+1.0
High	—	Low	62.9	62.8	−0.1
High	—	High	62.2	62.4	+0.2

[a] Factor A = temperature; low level = 25° and high level = 50°. [b] Factor B = ionic strength (μ); low level = 0.15 and high level = 1.00. [c] Factor C = buffer ions; low level = 0.5 and high level = 1.

centration of the free form, *F*, as a function of the percentage of povidone (8–10):

$$Q = \frac{T}{F} = \frac{r}{F}[\text{PVP}] + 1 \qquad \text{(Eq. 1)}$$

where *r* is the number of moles of ligand bound per mole of macromolecule and [PVP] is the molar concentration of povidone in the solution. If *r*/*F* is constant (*i.e.*, if the same type of binding is taking place with increasing povidone concentration), a linear relationship is obtained (11) between *T*/*F* and [PVP].

The second method permits the calculation of equilibrium constants and the maximum number of binding sites on the macromolecule. The basic theory of the calculation of ligand–macromolecule equilibria was described previously (12–15). If no interaction phenomena take place, then reversible binding can be described by:

$$r = \frac{nkF}{1 + kF} \qquad \text{(Eq. 2)}$$

where *n* represents the total number of sites available and *k* is the intrinsic binding constant. The relationship between the intrinsic binding constant, *k*, and the constants for the individual equilibrium reactions, k_i, is given by (16):

$$k_i = \left[\frac{n - (i-1)}{i}\right]k \qquad \text{(Eq. 3)}$$

where *n* is the total number of available sites and *i* is the number of possible combinations of *n* binding sites taken exactly *i* at a time.

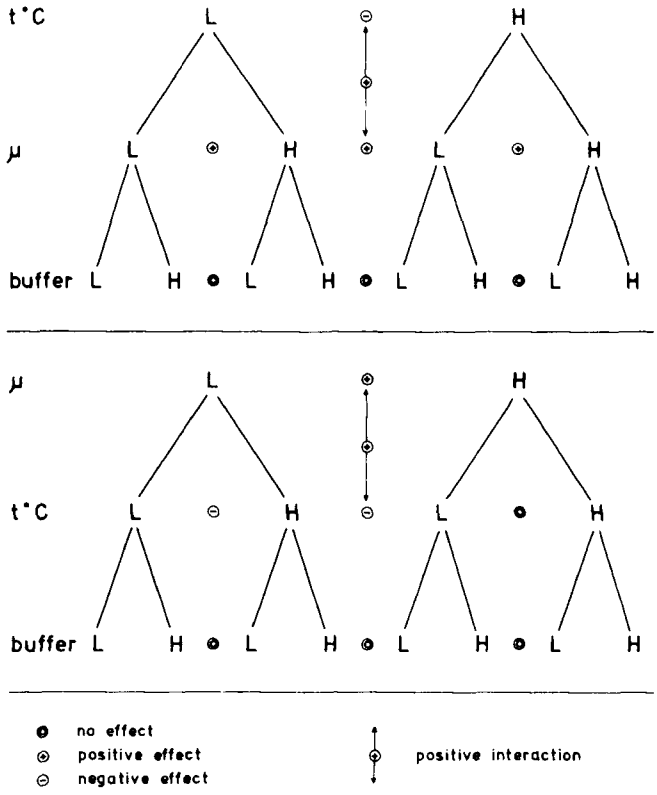

Figure 1—*Influence of parameters on the complexing of salicylic acid (1.00×10^{-2} M) with povidone (6.00%) at pH 2.20.*

The hyperbolic graph of *r versus F* (Eq. 2) can be converted into linear form. The approach of Klotz *et al.* (12) usually is used:

$$\frac{1}{r} = \frac{1}{n} + \frac{1}{nkF} \qquad \text{(Eq. 4)}$$

The Scatchard equation (15) is:

$$\frac{r}{F} = kn - kr \qquad \text{(Eq. 5)}$$

Consequently, graphical representations of $1/r$ *versus* $1/F$ or r/F *versus* *r* are used to obtain *n* (the number of binding sites) and *k* (the intrinsic binding constant). Curvature of such plots usually indicates the existence of more than one class of sites (17).

Factorial Analysis—The overall objective of factorial analysis is to obtain a general picture of how the results are affected by changing the parameters or factors. The theory and practice of factorial analysis were given by Philippe (6) and Chatfield (18). In complex formation, the principal parameters or factors to be considered are ionic strength, buffer

ions, and temperature. In the present experiment, all of these factors were investigated at two levels. For simplicity, a letter was written when the corresponding factor was in the high level and not written when it was in the low level. When all of the factors were in the low level, a number one was written. Generally, with n factors at two levels, 2^n treatment combinations were possible. To obtain an estimation of the experimental error, each factor was determined in duplicate. The sum of the duplicates was analyzed using the Yates method (19), which is a systematic method for estimating the individual effects and performing the analysis of variance.

RESULTS AND DISCUSSION

To determine the influence of the dissociation of the ligand molecules on their binding to povidone, each ligand was investigated at two pH values: at pH = pKa − 0.80 and at pKa + 0.80. At these pH values, the drugs are 86.3% in the undissociated and dissociated state, respectively. Salicylic acid also was investigated at pH 7.00, where the drug is fully dissociated.

Salicylic Acid (pKa 3.0)—Salicylic acid was investigated at pH 2.20 and 3.80. Table I summarizes the factors and their respective levels at pH 2.20. To demonstrate the difficulties in interpreting the results, they are represented in Table I by changing one parameter from the low to the high level, with the other variables being either at a low or high level. For instance, by observing the ionic strength at the low and the high levels, the positive influence of this variable can be seen since the results change from ~56 to 62% of the ligand bound. However, the results obtained by changing the temperature from 25 to 50° are not so easy to interpret. The influence seems to be negative and is greater at low than at high ionic strength, probably due to an interaction of the temperature and the ionic strength. An accurate interpretation is impossible.

With factorial analysis, the parameter effects and interaction phenomena can be interpreted easily and accurately. In Table II, the results given in Table I are analyzed according to Yates (19). In the first column, all of the treatment combinations are listed in a systematic way; the results are determined in duplicate for each factor and are expressed as the percentage of ligand bound (column 2); their sum is listed in column 3.

According to Yates, with three factors, three columns have to be calculated (columns 4–6). Each column is generated from the preceding column in the same way. The first 2^{n-1} values in a column are the sums of successive pairs of numbers in the preceding column. The next 2^{n-1} values are the differences of the successive pairs. In this way, the final column gives the total effect corresponding to the particular treatment combinations. With these estimates, an analysis of variance is performed. This analysis consists of splitting a total sum of squares into sums of squares for the factors considered. The total effect of each factor is squared (column 8) and divided by the number of observations ($2^3 \times 2$), with each factor possessing one degree of freedom. The estimate of the residual variation, *i.e.*, the variance of the experimental error, is calculated by the sum of squares of the variations between the duplicates, divided by 2×8.

With an F test, the significance of the observed effects is tested (column 10). Table II shows that the ionic strength has an overall positive influence; however, increasing the temperature reduces the adsorption, and buffer ions have no influence at all. Moreover, a relative positive interaction is noted between ionic strength and temperature (factor AB).

By splitting up the results at low and high temperatures, more infor-

mation about the influence of the ionic strength can be obtained; by considering the results at low and high ionic strengths, the influence of temperature can be analyzed more specifically. The results obtained by splitting at the different levels together with their analysis of variance are given in Table III. Considering the results at the different levels (Table III), the overall positive influence of ionic strength is maintained for the two temperatures, while the negative influence of temperature is observed at low ionic strength.

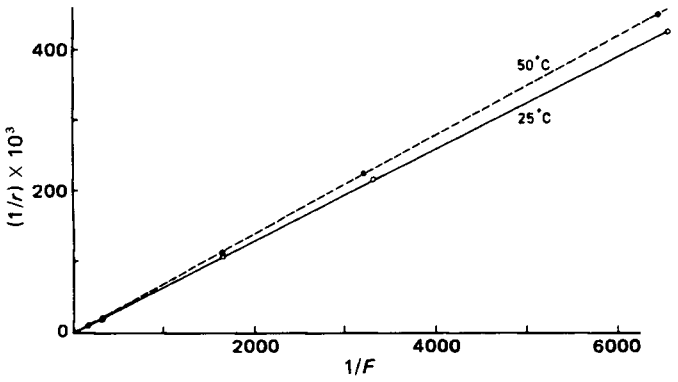

Figure 2—*Influence of temperature on the complexing of salicylic acid with povidone at pH 2.20. The salicylic acid concentration was 5.00 × 10^{-4}–1.00 × 10^{-2} M, the povidone concentration was 6.00% (8.57 × 10^{-5} M), the ionic strength was 0.15, and the buffer ions were 1.*

In Fig. 1, the influence of the different variables investigated before and after splitting the results at the different levels is represented. This figure also offers a good idea of how much information can be obtained from factorial analysis. In the middle of the graph, the overall effects are indicated; on the side, the results after splitting the results are represented.

By lowering the high level of the ionic strength from 1.0 to 0.40 and maintaining the other factors at their original levels, the percentage of ligand bound is determined by ultrafiltration, and a factorial analysis is carried out again. From these results (Table IV), it is noted that ionic strength no longer has an effect on the binding at these levels whereas temperature and buffer ions behave as indicated in Table I.

For salicylic acid at pH 3.80, where the drug is mainly dissociated, the same factors as are given in Table I were investigated. The levels used and the corresponding results are summarized in Table V. In contrast with the phenomena observed at pH 2.20, ionic strength no longer influenced the binding of salicylic acid to povidone while increasing the temperature also diminished the adsorption. The observations remained after splitting the results at the different levels of ionic strength and temperature.

The adsorption of salicylic acid in the dissociated state onto povidone was investigated at pH 7.00 using a phosphate buffer. Factorial analysis was carried out with three factors at two levels (Table VI). Increasing the temperature and the ionic strength had a negative and no influence, respectively, on the binding of salicylic acid. At pH 7.00, in contrast to pH 2.20 and 3.80, the buffer ions enhanced complex formation (from 49.6 to 56.9% of the ligand was bound). At the two lower pH values, the buffer ions were mainly monovalent phosphate and citrate ions. At pH 7.00, the phosphate ions were present as dibasic phosphate ions at 38%, indicating the great influence of these ions on complex formation. However, dibasic phosphate ions do not always enhance complex formation. Thus, no influence was found for the binding of methyl orange to povidone at pH 7.00 (20). On the other hand, dibasic phosphate ions increased binding for chlorpromazine with carboxymethylcellulose sodium (21), as well as citrate ions, by complex formation of local anesthetics and polyvinyl alcohol (22).

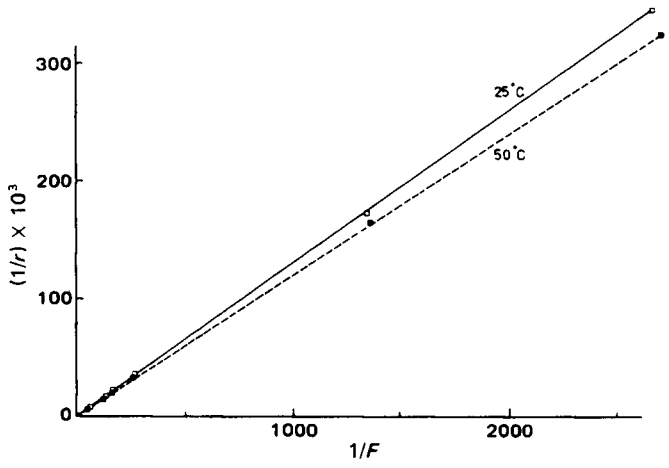

Figure 4—*Influence of temperature on the complexing of benzoic acid with povidone at pH 3.40. The benzoic acid concentration was 1.00 × 10^{-4}–1.00 × 10^{-2} M, the povidone concentration was 6.00% (8.57 × 10^{-5} M), the ionic strength was 0.25, and the buffer ions were 1.*

It is concluded that binding depends not only on the kind of buffer ions present but also on the structure of the macromolecule and the ligand. A second important conclusion is evident; without knowledge of the influence of buffer ions, the binding tendency of the undissociated and dissociated forms of salicylic acid cannot be compared.

Benzoic Acid (pKa 4.2)—For benzoic acid, the same factors and levels were investigated as for salicylic acid. However, the buffers used were McIllvaine buffers at pH 3.40 and 5.00. The ionic strength was maintained at 0.25 and 0.50. At pH 3.40 and 5.00, the ionic strength and buffer ions had no influence on the binding of benzoic acid to povidone (Tables VII and VIII). At pH 3.40, where benzoic acid is mainly undissociated, the adsorption was enhanced by increasing the temperature; at pH 5.00, the binding was diminished.

Isotherms and Thermodynamic Calculations—Isotherms were obtained at 25 and 50°; they are represented graphically using the Klotz isotherm (Eq. 4) in Figs. 2 and 3 for salicylic acid and in Figs. 4 and 5 for benzoic acid.

For the two derivatives, a linear relationship was observed, with the two lines nearly going through the origin. From Eq. 2, it is seen that this finding implies that $kF \ll 1$; from Eq. 4, it is shown that $1/n$ equals zero or n is infinite, indicating a nearly infinitely large number of adsorption sites. The fraction of the ligand bound to the macromolecule does not vary significantly with the ligand concentration, and the binding process ap-

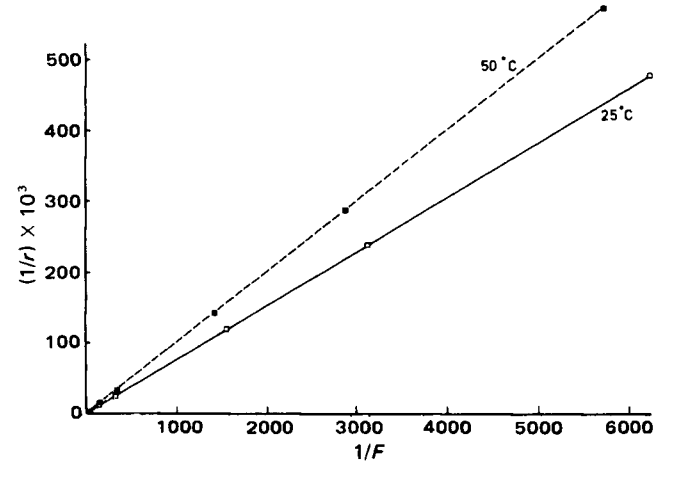

Figure 3—*Influence of temperature on the complexing of salicylic acid with povidone at pH 3.80. The salicylic acid concentration was 5.00 × 10^{-4}–1.00 × 10^{-2} M, the povidone concentration was 6.00% (8.57 × 10^{-5} M), the ionic strength was 0.15, and the buffer ions were 1.*

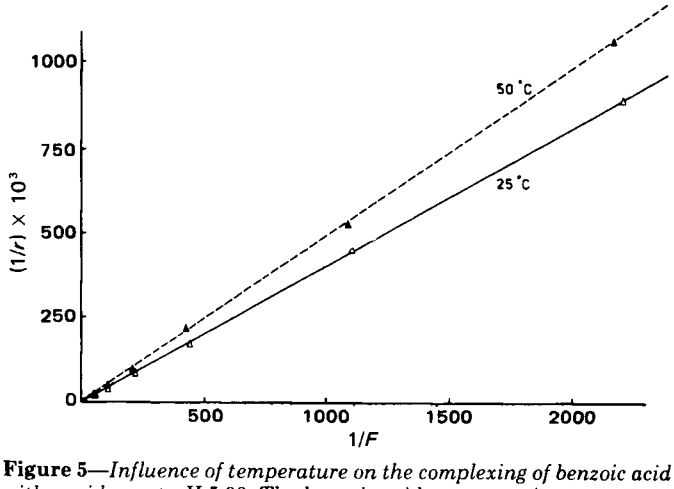

Figure 5—*Influence of temperature on the complexing of benzoic acid with povidone at pH 5.00. The benzoic acid concentration was 1.00 × 10^{-4}–1.00 × 10^{-2} M, the povidone concentration was 6.00% (8.57 × 10^{-5} M), the ionic strength was 0.25, and the buffer ions were 1.*

Table IX—Thermodynamic Data for the Binding of Salicylic Acid and Benzoic Acid to Povidone

Cosolute	pH	nk ($\times 10^{-3}$) at 298 °K, liters/mole	nk ($\times 10^{-3}$) at 323 °K, liters/mole	$\Delta F°$ (323 °K), kcal/mole	$\Delta H°$, kcal/mole	$\Delta S°$, kcal/mole degree
Salicylic acid	2.20	16.2	15.4	−6.2	−0.4	+18.0
	3.80	13.1	9.3	−5.9	−2.1	+11.8
Benzoic acid	3.40	7.8	8.5	−5.8	+0.7	+20.1
	5.00	2.5	2.0	−4.9	−1.5	+10.4

pears to be unsaturable. The same finding was made by Higuchi and Kuramoto (23) in a study of complex formation between benzoic acid and povidone[7] in aqueous solution. Values for nk are deduced from the slopes. According to Scholtan (20), the value of n can be determined only with much uncertainty, so it has little physical meaning. In this case, it is better to use the value of $nk = k_1$, which is a measure for the strength of the binding, while n is indicative of the binding capacity.

The thermodynamic functions calculated from k_1 do not necessarily refer to a single site on the macromolecule. However, the values are useful in considering the nature of the binding, in comparing the binding of different ligands with the same macromolecule, and in analyzing the effects of parameters such as pH and ionic strength (14). The standard free energy, $\Delta F°$, for complex formation is calculated from:

$$\Delta F° = -RT \ln nk \qquad \text{(Eq. 6)}$$

With the assumption that there is no significant temperature dependence of the enthalpy change within the temperature range used, the standard enthalpy change, $\Delta H°$, for the association of 1 mole of ligand with 1 mole of macromolecule is given by:

$$\ln \frac{nk_{25\,°C}}{nk_{50\,°C}} = -\frac{\Delta H°}{R}\left(\frac{1}{298} - \frac{1}{323}\right) \qquad \text{(Eq. 7)}$$

and the entropy change, $\Delta S°$, is obtained by substituting $\Delta H°$ and $\Delta F°$ in the Gibbs–Helmholtz equation:

$$\left(\frac{\delta \Delta F°}{\delta T}\right)_p = -\Delta S° = \frac{\Delta F° - \Delta H°}{T} \qquad \text{(Eq. 8)}$$

Thermodynamic data for the association reactions are reported in Table IX. The negative sign for $\Delta F°$ means that the binding process occurs spontaneously. The high positive entropy and small negative enthalpy values are characteristic for hydrophobic binding (24–26). The positive entropies are associated with many reactions involving the binding of ligands to macromolecules as well as proteins (27–30) and to macromolecules such as polymethacrylic acid (31), polyvinyl alcohol (32), methylcellulose (33), hydroxyethyl cellulose (33), and povidone (34–36). With the knowledge that the buffer composition and ionic strength have no influence on the adsorbing tendency of the two derivatives studied, the thermodynamic constants calculated from the isotherms are due entirely to the binding of the ligand to the macromolecule. Thus, comparison of the thermodynamic constants and the effect of the substituted groups as well as the effect of their degree of dissociation on the binding tendency is possible now.

For salicylic acid (Table IX), the binding strength was lowered by increasing temperature, both for the undissociated and dissociated forms; at the two temperatures, binding was highest for the undissociated form. The same findings can be noted for benzoic acid, except for the undissociated form, where the binding strength was highest at 323 °K. Substitution of a hydroxyl function in the *ortho*-position of the carboxyl function increased the binding strength at 298 °K by a factor of 2.1 for the undissociated form and by a factor of 5.3 for the dissociated form; at 323 °K, it increased by factors of 1.8 and 4.6, respectively. The observations indicate that hydrogen binding also may play an important role in the binding. The application of factorial analysis is under investigation in the study of complex formation between povidone and a series of benzene and pyridine derivatives.

Suppression of Endogenous Hydrocortisone with Dexamethasone

THOMAS J. GOEHL *x, GLORIA M. SUNDARESAN *, JOHN P. HUNT *, VADLAMANI K. PRASAD *, ROGER D. TOOTHAKER ‡, and PETER G. WELLING ‡

Received March 17, 1980, from the *Biopharmaceutics Laboratory Branch, Division of Biopharmaceutics, Food and Drug Administration, Washington, DC 20204, and the ‡School of Pharmacy, University of Wisconsin, Madison, WI 53706. Accepted for publication June 12, 1980.

Abstract □ A newly developed high-pressure liquid chromatographic method was used to study the optimum dosage regimen needed to suppress endogenous hydrocortisone. Nine volunteers were randomly placed in three groups. Each group received 1 mg of dexamethasone at 11 pm (Treatment A), 2 mg of dexamethasone at 11 pm (Treatment B), or 1 mg at 11 pm and an additional 1 mg at 6 am the following day (Treatment C). Analysis of multiple blood samples obtained the day before and the day after drug administration showed suppression in all three groups. Although the duration and extent of this suppression varied, adequate suppression to permit bioavailability studies was observed for Treatments B and C.

Keyphrases □ Hydrocortisone—suppression of endogenous hydrocortisone with dexamethasone □ Dexamethasone—suppression of endogenous hydrocortisone

The principal natural glucocorticoid in humans is hydrocortisone (1). Although numerous synthetic glucocorticoids have been prepared, hydrocortisone remains an important agent in modern adrenocorticosteroid therapy, and many generic formulations have appeared on the market. However, the bioequivalence of these products has not been established. To conduct bioequivalence studies, assay methodology must be available with the required sensitivity, specificity, accuracy, and precision. A number of apparently adequate high-pressure liquid chromatographic (HPLC) methods have been reported recently (2–9).

BACKGROUND

Hydrocortisone production follows a circadian rhythm, so suppression of hydrocortisone production is necessary to simplify the interpretation of bioavailability data. Therefore, in addition to an appropriate analytical procedure, a method that will adequately suppress the endogenous hydrocortisone levels is needed. Without this suppression, it is not possible to quantitate the bioavailability of the administered hydrocortisone dosage forms. One way to achieve this suppression is to administer dexamethasone. This procedure was used in studies on prednisone (10, 11) and prednisolone (12, 13). In these cases, dexamethasone administration was necessary since endogenous steroids cross react with the antiserums used in these radioimmunoassays.

Dexamethasone is thought to act by blocking the release of endogenous ACTH (14). However, no extended detailed quantitative study has been performed to determine the amount of dexamethasone required to suppress endogenous steroids. The duration of such suppression also is not clearly established.

In one study (15), hydrocortisone levels were determined at 2 and 4 hr after administration of 1 mg of dexamethasone. During this period, hydrocortisone levels dropped to 14% of their basal values. In another study (16), the degree of suppression of endogenous hydrocortisone was related to the time of day the dexamethasone was administered. In a third study (17), 8 mg of dexamethasone was given for 2 days. The mean plasma hydrocortisone level for the subjects was 6.8 ng/ml; the blood sampling time was not given.

The present paper explores the extent and duration of dexamethasone suppression of circulating endogenous hydrocortisone using a newly developed, highly sensitive and specific HPLC assay.

EXPERIMENTAL

The nine normal male volunteers (22–45 years old) involved in this study had normal vital signs and selected laboratory parameters. The subjects, 63–80 kg, were randomly assigned to three groups of three each (Table I). Group A received 1 mg of dexamethasone, Group B received 2 mg of dexamethasone, and Group C received 2 mg of dexamethasone in two 1-mg divided doses administered 7 hr apart. Dexamethasone was given as an oral elixir[1] (0.5 mg/5 ml) in all cases.

Table I—Subject Data

Identification	Group	Height, cm	Weight, kg	Age, years
1	A	185	73	28
2	A	180	80	22
3	A	170	63	25
4	B	168	74	37
5	B	170	77	31
6	B	178	66	28
7	C	185	75	39
8	C	180	75	22
9	C	178	64	45

Basal values for plasma hydrocortisone levels were determined from heparinized blood samples (8 ml each) obtained at 8 am, 10 am, 12 noon, 2 pm, 4 pm, 6 pm, and 8 pm on Day 1 of the study. Prior to receiving the evening dexamethasone dose, the subjects were required to fast after 8 pm and to maintain that fast until noon the following day. At 11 pm on the same evening, dexamethasone (Groups A and C, 1 mg; and Group B, 2 mg) was administered to all volunteers followed by 180 ml of water. The following morning (Day 2), subjects in Group C received an additional 1 mg of dexamethasone followed by 180 ml of water at 6 am. Heparinized blood samples then were taken from all volunteers beginning at 8 am and continuing at 10 am, 12 noon, 2 pm, 4 pm, 6 pm, and 8 pm. All samples were collected, and the plasma was separated and frozen until it was assayed for hydrocortisone.

All plasma samples were assayed using a previously reported HPLC method (9) with minor modifications. An internal standard (4-pregnene-17α, 20α,21-triol-3,11-dione) was added to the plasma, which then was extracted with methylene dichloride–ether (60:40). After separation and evaporation of the organic phase, derivatization was carried out with dansylhydrazine. Upon completion of the reaction, the excess dansylhydrazine was reacted with pyruvic acid and a second extraction was performed.

The samples were placed in a water bath at room temperature and were evaporated just to dryness under a gentle nitrogen stream. The residue was immediately taken up in 200 μl of the HPLC mobile phase. Five microliters of this solution was injected[2] later onto a well-conditioned microparticulate silica column[3]. Elution[4] was carried out with an ethylene dichloride–butanol–water (93:6.6:0.4) mobile phase (1.5 ml/min). Conditioning of the column was achieved by pumping the mobile phase through the column for 1–2 days. The effluent was monitored with a fluorescence detector[5] [excitation, 240 nm; emission, 470 nm (cutoff filter)]. A linear calibration curve was found for hydrocortisone concentrations from 3 to 1000 ng/ml.

A special glassware cleaning procedure was adopted to eliminate extraneous chromatographic peaks that sometimes were observed. The procedure consisted of rinsing the glassware with distilled water (no soap was used), placing it into a commercial oven[6], which then was carried through a self-cleaning cycle, and rinsing all of the items with distilled water and methanol.

The hydrocortisone levels present in the clinical plasma samples were

determined from standard curves prepared by plotting the peak height ratios of the dansylhydrazones of hydrocortisone and the internal standard *versus* the concentrations of the known standards. To correct the standard curve for endogenous levels of hydrocortisone present in the control plasma, the peak height ratio of the control plasma was subtracted from all data points used in the standard curve.

RESULTS AND DISCUSSION

To establish the regimen for dexamethasone administration that would sufficiently suppress endogenous hydrocortisone production, three dexamethasone regimens were evaluated. The basal plasma levels of hydrocortisone in all nine subjects on Day 1 are recorded in Table II. There was a general trend, but not a smooth progression, of decreasing plasma levels from morning to evening. This trend agrees with the observation that plasma hydrocortisone levels follow a circadian rhythm.

The plasma levels of hydrocortisone on Day 2 are given in Table III. Substantial suppression was seen in all subjects. The plasma levels in subjects on Treatment C did not exceed 16 ng/ml from 8 am to 6 pm. Volunteers receiving Treatment B had plasma levels below 11 ng/ml throughout the same period. The plasma levels achieved with both Treatments B and C were quite stable. Suppression of endogenous hydrocortisone was not as complete in the subjects receiving Treatment A and showed greater variations. All three volunteers in Group A had plasma levels of at least 36 ng/ml by 6 pm on Day 2.

Since stress is known to affect the plasma levels of endogenous hydrocortisone (18), concern existed about the possibility of endogenous hydrocortisone levels fluctuating after suppression had been achieved with dexamethasone administration. In this study, the plasma level fluctuations seen during the control period were virtually absent in the postadministration period. This finding is important since any significant variations in the suppressed plasma hydrocortisone levels would seriously hinder the interpretation of bioavailability data of hydrocortisone dosage forms.

A profile analysis (19) using an F test for the average treatment effects, time effects, treatment with time effects, and subject effects was performed on the basal and suppressed plasma hydrocortisone levels. The data were analyzed by comparing Treatment A with Treatments B and C as well as Treatment B with Treatment C. The statistical analysis of basal plasma levels indicated that there were no significant differences due to what were evaluated as treatment effects ($p = 0.52$ and 0.90) and no significant differences due to treatment with time effects ($p = 0.29$ and 0.56). However, there were significant differences due to time ($p = 0.0001$) and intersubject variability ($p = 0.0001$), which could be expected. For the suppressed plasma hydrocortisone levels, the analysis indicated Treatment A was significantly different from Treatments B and C ($p = 0.007$). Treatments B and C were not significantly different ($p = 0.97$). A test of the treatment with time effects likewise indicated that Treatment A was significantly different from Treatments B and C ($p = 0.0001$) but that Treatments B and C were not ($p = 0.98$).

As shown in the preceding analysis, the extent and duration of the suppression of endogenous plasma hydrocortisone were similar with Treatments B and C. Therefore, selection of either regimen for subsequent bioavailability studies would be reasonable. However, since Treatment C requires an evening and a morning dose, Treatment B is more convenient. In addition, the possibility cannot be ruled out that an early morning dose of dexamethasone may affect the kinetics of orally administered hydrocortisone.

A study is underway to investigate the kinetics of hydrocortisone following a single oral dose; Treatment B administration of dexamethasone is being used.

Nasal Absorption of Propranolol from Different Dosage Forms by Rats and Dogs

ANWAR HUSSAIN ˣ, SHINICHIRO HIRAI, and RIMA BAWARSHI

Received October 22, 1979, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication June 9, 1980.

Abstract □ The blood levels of propranolol in rats and dogs were compared after the administration of nasal, intravenous, and oral solutions. The results indicate that the blood drug levels after nasal and intravenous administration were identical, but the oral administration resulted in considerably lower blood levels. Sustained-release formulations of the drug also were administered nasally and resulted in low initial but prolonged blood levels. The bioavailability of the sustained-release formulation was identical to that of the intravenous administration.

Keyphrases □ Propranolol—nasal absorption from different dosage forms, rats and dogs □ Bioavailability—propranolol, comparison of sustained-release nasal formulation with intravenous administration, rats and dogs □ Absorption, nasal—propranolol from different dosage forms, rats and dogs

The oral administration of propranolol in human subjects resulted in considerable variation in plasma drug levels. Peak plasma levels in five subjects given 80-mg oral doses varied sevenfold, while 10-mg doses given intravenously to the same subjects varied only twofold (1). Furthermore, the bioavailability of an 80-mg oral dose in several subjects varied from 16 to 60% of that of a 10-mg iv dose. The variations in blood levels as well as the low bioavailability from oral doses have been attributed to extensive drug metabolism during absorption and first passage through the liver (1–3). A previous report (4) indicated that the blood levels of propranolol after intravenous and nasal administration of 1-mg doses in rats were identical but that oral administration of the same dose resulted in considerably lower blood levels.

This report presents the results on the nasal absorption of propranolol in rats and dogs after its administration in a solution and a sustained-release formulation.

Table I—Composition of Sustained-Release Dosage Forms of Propranolol Used in Rat Studies

Ingredient	Formulation		
	SR-A	SR-B	SR-C
Propranolol hydrochloride, mg	1	—	—
Propranolol (base), mg	—	0.88[a]	—
Propranolol stearate, mg	—	—	1.84[a]
Methylcellulose, mg	3	3	3
Saline, ml	0.1	0.1	0.1

[a] One milligram as propranolol hydrochloride.

Table II—Composition of Dosage Forms of Propranolol Used in Dog Studies

Ingredient	Intravenous	Oral	Nasal

Methylcellulose, mg	—	—	—	—	15
Saline, ml	1	50	0.2	0.5	0.5

[a] Twenty milligrams as propranolol hydrochloride.

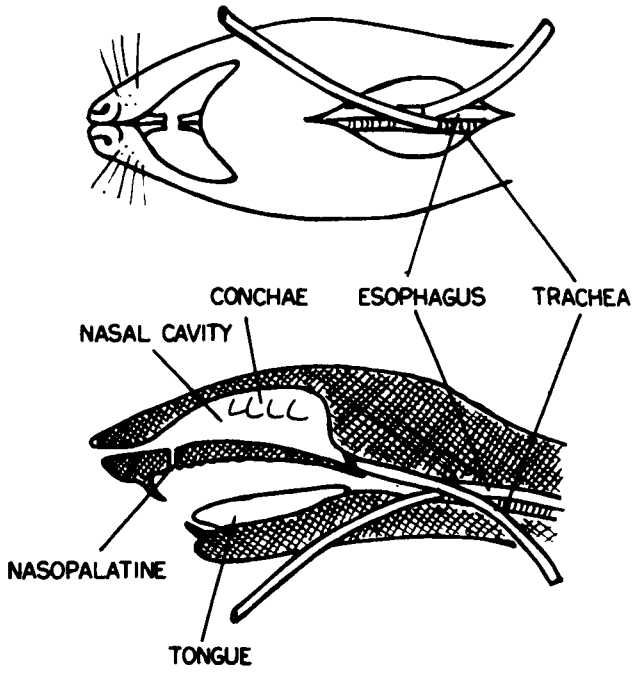

Figure 1—*Diagram of the surgical procedure of nasal absorption in the rat.*

EXPERIMENTAL

Materials—Propranolol hydrochloride USP[1], propranolol free base, and propranolol stearate were used. Propranolol free base and propranolol stearate were prepared from propranolol hydrochloride.

Composition of Formulations—The formulations used in the rat and dog studies are listed in Tables I and II, respectively.

***In Vitro* Dissolution**—The dissolution study was carried out using the USP rotating-basket method; 0.2 g of Formulation SR-A, SR-B, or SR-C was placed in the basket, which was lined from the inside with filter paper. (The filter paper was used as a barrier for the diffusion of methylcellulose.) The dissolution medium consisted of 500 ml of pH 7.4 isotonic buffer at 37°. The basket was rotated at 100 rpm. A 0.5-ml volume of the medium was withdrawn periodically, added to 0.2 ml of 0.1 *N* HCl, and assayed later.

Animal Studies—*Rats*—Male Sprague–Dawley rats, ~270 g, were anesthetized with pentobarbital (50 mg/kg). The surgical operation carried out on the rats was that described by Hirai *et al.*[2] (Fig. 1). An incision was made in the neck, and the trachea was cannulated with a polyethylene tube[3]. Another tube was inserted from the esophagus to the posterior part of the nasal cavity. The nasopalatine was closed with an adhesive agent[4] to prevent drainage of the drug from the nasal cavity to the mouth. The sustained-release preparation (equivalent to 1 mg of propranolol hydrochloride) was administered to the nasal cavity through the tube by means of a syringe. Blood (0.1–0.2 ml) was sampled from the femoral aorta periodically and analyzed later.

Dogs—Three beagle dogs, ~10 kg, were used in this crossover study.

Table IV—Peak Plasma Level (C_{max}), Time to Peak (T_{max}), and Area under Curve (AUC) after Intravenous, Oral, and Nasal Administration of Propranolol in Dogs

Route	C_{max}, ng/ml[a]	T_{max}, min	$AUC_{0-\infty}$, (ng hr)/ml[a]	$\frac{AUC_{oral,nasal}}{AUC_{iv}}$
Intravenous	—	—	1892.1 ± 102.1	—
Oral	42.5 ± 7.2	50	130.1 ± 8.2	0.068
Nasal				
Solution	1539.2 ± 70.9	5	1942.1 ± 64.2	1.026
SR-D	236.6 ± 24.3	80	1902.3 ± 66.4	1.005
SR-E[b]	64.3 ± 5.6	180	—	—

[a] Mean ± SE (n = 3). [b] Not enough points to calculate $AUC_{0-\infty}$.

For the intravenous administration, the dogs were anesthetized with the intravenous injection of 30 mg of pentobarbital sodium/kg. The administered solution (20 mg of propranolol hydrochloride) was injected through the cubital vein. For the oral administration, the dogs were not anesthetized and the drug was administered by a stomach tube. For the nasal administration, the dogs were anesthetized and both the solution and the sustained-release preparation were administered to the nasal cavity through the nostrils with a micropipet and a syringe, respectively. Blood was sampled periodically from the cubital vein. After centrifugation, 0.5 ml of plasma was separated and analyzed later.

Analytical Method—Blood and plasma levels of propranolol were assayed spectrophotofluorometrically by a minor modification of the method of Shand *et al.* (1). Distilled water (0.5 ml) was added to 0.1–0.5 ml of blood or plasma. The mixture then was made alkaline with 0.5 ml of 1 *N* NaOH and extracted into 10 ml of heptane. After shaking and centrifugation, 8 ml of the heptane layer was extracted into 1.5 ml of 0.1 *N* HCl; the fluorescence of the acid layer was determined by a spectrophotofluorometer[5] (maximum excitation at 295 nm and maximum emission at 360 nm). The minimum detectable concentration was 3 ng/ml; pentobarbital did not interfere with the assay. Corrections were made for the blank.

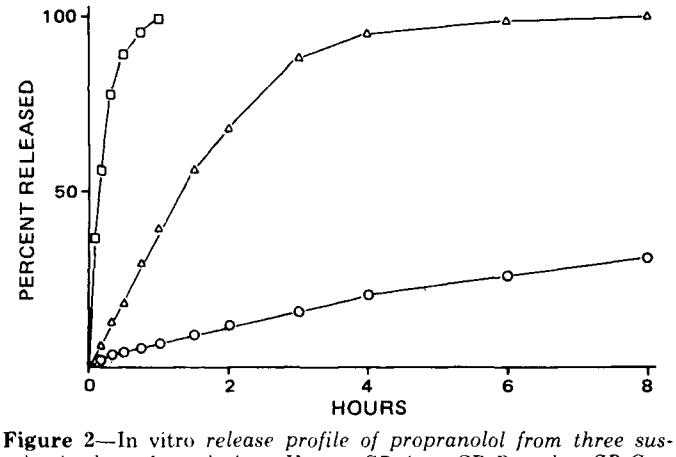

Figure 2—In vitro *release profile of propranolol from three sustained-release formulations. Key:* □, *SR-A;* △, *SR-B; and* ○, *SR-C.*

The samples of the *in vitro* dissolution study also were analyzed spectrophotofluorometrically.

RESULTS

Figure 2 shows the *in vitro* release profile of propranolol from three sustained-release formulations (SR-A, SR-B, and SR-C) administered nasally to rats.

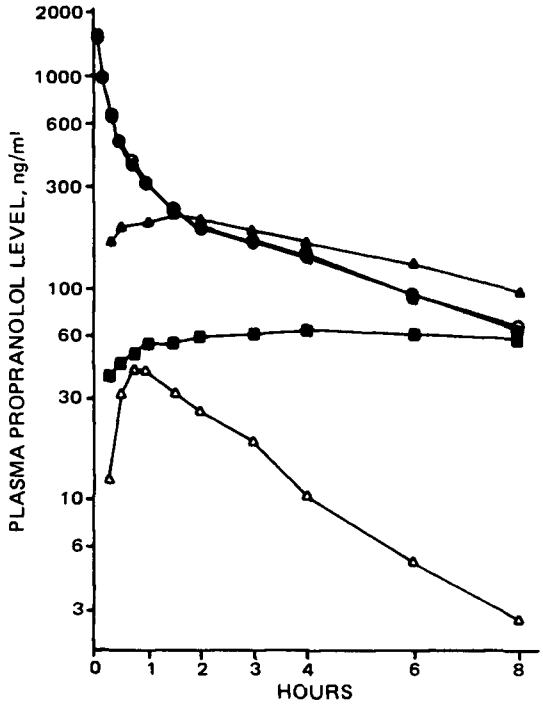

Figure 4—*Mean blood levels of propranolol in dogs* (n = *3*). *Key:* ○, *intravenous;* △, *oral;* ●, *nasal solution;* ▲, *nasal SR-D; and* ■, *nasal SR-E.*

Figure 3 shows the mean blood propranolol levels in rats after the nasal administration of the sustained-release formulations as compared to those obtained previously (4) after intravenous, oral, and nasal administration of an isotonic solution of the drug.

The pharmacokinetic parameters calculated for the different formulations and for the different administration routes are shown in Table III.

Figure 4 shows the mean plasma level in dogs after the nasal administration of the solution and two sustained-release formulations as well as the intravenous and oral solutions. Table IV shows the pharmacokinetic parameters in dogs calculated for the different formulations and for the different administration routes.

DISCUSSION

The oral administration of propranolol to human subjects resulted in low and variable plasma drug levels compared to intravenous administration (1). Similar results were obtained in rats and dogs after the oral administration of propranolol solution (Figs. 3 and 4). However, the data in Figs. 3 and 4 clearly show that the nasal administration of the drug solution in both rats and dogs resulted in plasma drug levels similar to those of an intravenous administration. The data in Figs. 3 and 4 show that the sustained-release formulations resulted in lower initial blood levels of the drug. However, the drug level in the blood was maintained longer. Furthermore, the blood drug profile from the sustained-release formulations administered to rats correlated with the *in vitro* (Fig. 2) release of the drug from these formulations.

The pharmacokinetic parameters for the different formulations and different administration routes obtained for both rats and dogs are shown in Tables III and IV, respectively. The maximum blood levels of the drug observed after administration of the sustained-release formulations were much lower than those observed after administration of the nasal solutions. However, the bioavailability calculated from the area under the blood level curves was identical.

The results of this study strongly suggest that the nasal administration of propranolol is superior to the oral route and as effective as the intravenous route. A study is underway on the bioavailability of propranolol from nasal dosage forms in humans.

Pharmacokinetics of Phenylbutazone in Healthy Subjects after Oral Administration of Single and Multiple Doses

A. SIOUFI *x, D. COLUSSI *, F. CAUDAL *, J. P. SCHOELLER ‡, and P. MASSIAS §

Received December 10, 1979, from the **Biopharmaceutical Research Center and the* ‡*Medical Department, Ciba-Geigy, Rueil-Malmaison, France,* and the §*Department of Rheumatic Diseases, Antoine Béclère Hospital, Clamart, France.* Accepted for publication June 23, 1980.

Abstract □ Plasma concentration profiles were studied after single oral doses of phenylbutazone of 100, 300, and 600 mg in cachets to six healthy volunteers. The pharmacokinetics of phenylbutazone can be described by a two-compartment open model. The drug is absorbed rapidly and distributed partially into an extravascular compartment; about one-third remains in the plasma. The mean elimination half-life was 77 hr (54–99 hr), and there was a linear relationship between the dose and the area under the plasma concentration curve. In a multiple-dose study, six healthy volunteers received 150 mg of phenylbutazone in cachets twice daily every 11–13 hr for 17 days. A steady state was reached after ~200 hr of chronic treatment. The resultant steady-state plasma concentrations were about four times higher than the peak concentration produced by a single 150-mg dose. The half-lives corresponding to the apparent elimination rate constant for the first and last administrations did not differ in each subject. The theoretical minimum concentrations are higher than the pseudosteady state reached during chronic treatment.

Keyphrases □ Phenylbutazone—pharmacokinetics after single and multiple oral doses □ Pharmacokinetics—phenylbutazone, single and multiple oral doses □ Anti-inflammatory agents—phenylbutazone, pharmacokinetics after single and multiple oral doses

Phenylbutazone has been used as an anti-inflammatory agent for about 25 years. After oral administration, it is completely and rapidly (1) absorbed and almost completely metabolized (1–3). Its half-life in plasma ranges from 1 to 3 days (1, 2, 4–6) and shows large interindividual differences. Phenylbutazone is highly protein bound (~99%) (1). The drug is eliminated mainly in the urine (60–70%) (1, 2).

The single-dose kinetics of phenylbutazone have been studied (1, 7, 8), and two-compartment model was proposed for it (8). There is an almost linear relationship between the dose and the area under the plasma concentration curve (*AUC*) (9).

No precise information is available on multiple-dose kinetics. The steady-state plasma levels of phenylbutazone were measured by several investigators (1, 10–14) and were predicted by Orme *et al.* (12) from knowledge of the half-lives of antipyrine in individual subjects but not from the single-dose kinetics of phenylbutazone. The discrepancy between predicted and measured steady-state plasma levels of phenylbutazone has been discussed, and it was suggested that an increase in the volume of distribution occurs after multiple dosing (14).

Recent advances in analytical methodology (15) have made possible the investigation of the pharmacokinetics of phenylbutazone in humans in greater detail. This report describes the plasma concentration profiles obtained after the oral administration of phenylbutazone in single doses of 100, 300, and 600 mg and after repeated administration of 150 mg twice daily for 17 days.

EXPERIMENTAL

Subjects—Six healthy volunteers were instructed to take no drugs of any kind for at least 1 week prior to the study and no drugs other than phenylbutazone during the experiment.

Five males and one female, 23–29 years and 58–95 kg, participated in the single-dose study. Subjects 2, 3, and 5 took part in the later multiple-dose study together with three additional volunteers. The subjects in this group of four males and two females were 22–29 years old and 59–80 kg.

Procedure—Phenylbutazone was given as the pure active ingredient in cachets without any excipient.

Single-Dose Study—Each subject received 100, 300, and 600 mg at 4-week intervals according to the crossover design. The doses were given to the fasting subjects with 100 ml of water at ~8 am, 2 hr before a light standardized breakfast. A standard lunch was given 4 hr later.

Blood samples (5 ml) were collected in heparinized tubes before and 0.5, 1, 2, 3, 4, 6, 8, 24, 48, 72, 96, and 168 hr after drug administration. The 48-hr sample was omitted after the 600-mg single dose, but additional samples were collected after 240 and 336 hr. Plasma was separated by centrifugation and kept at −20° until analysis.

Multiple-Dose Study—Each subject received one 150-mg dose on the 1st and 22nd days and 150 mg twice daily from the 5th day until the 21st day. The interval after the first dose was allowed so that the total plasma concentration curve of the first dose could be plotted over 96 hr. Morning doses were taken at ~9 am during breakfast. Evening doses were taken during the meal at ~8 pm.

Blood samples were collected in heparinized tubes at various times after the first and last administrations and just before each morning dose during chronic treatment. Plasma was obtained by centrifugation and kept at −20° until the time of analysis.

Drug Assay—Phenylbutazone was assayed in plasma samples from the single-dose study by a GLC method using a flame-ionization detector that measured concentrations as low as 250 ng/ml of plasma. All samples were assayed in duplicate.

In the meantime, a new GLC method (15) was developed using an electron-capture detector capable of determining concentrations down to 10 ng/ml of plasma with the same extraction procedure as used in the flame-ionization technique. Plasma samples from the multiple-dose study were analyzed for phenylbutazone by the electron-capture GLC method. All samples were assayed in duplicate.

Both methods yielded similar results for the same set of samples. Two spiked plasma solutions were prepared (250 and 2500 ng of phenylbutazone/ml of plasma) and analyzed six times by the flame-ionization method and six times by the electron-capture method for each concentration. The results were 250.8 ± 3.6 (*CV*%, n = 6) and 2473.3 ± 4.3 with flame-ionization detection and 249.8 ± 5.0 and 2483.0 ± 5.3 with electron-capture detection.

Moreover, the three unconjugated metabolites of phenylbutazone in plasma (15) were tested by the flame-ionization and electron-capture methods. None of these metabolites interfered with phenylbutazone chromatography.

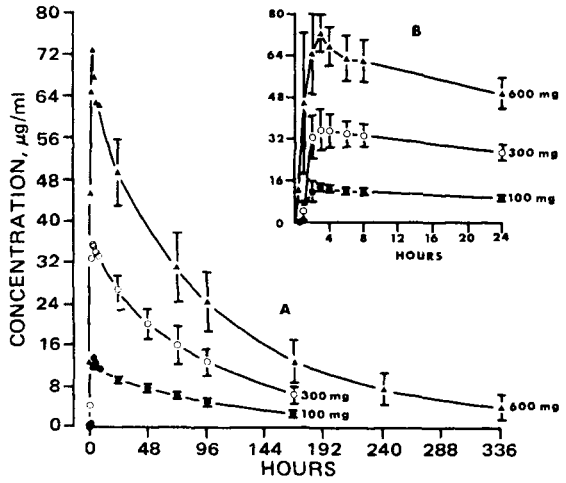

Figure 1—*Mean plasma phenylbutazone concentrations* (±SD) *in six healthy volunteers for doses of 100* (●), *300* (○), *and 600* (▲) *mg. Curve A shows concentrations up to 168 hr for 100 and 300 mg and up to 336 hr for 600 mg. Curve B shows concentrations up to 24 hr.*

[a] C_{max}, T_{max}, and k_E values were calculated from the multiexponential equation giving the best fit to the experimental results. The $T_{1/2}$ values were derived from k_E, and the AUC values were extrapolated to time infinity according to the $T_{1/2}$ values.

Mathematical Methods—The calculations, curve fitting, and statistical analysis were carried out with the aid of a computer[1] equipped with a plotter[2].

RESULTS

Single-Dose Study—*Plasma Concentration–Time Curves*—The curves were obtained by using a multiexponential computer program that selects the equation giving the best fit to the experimental results. The individual curves, as well as the average curves (Fig. 1), exhibited a two-phase decline of the plasma concentration as a function of time. This finding indicates a distribution phase that is sufficiently slow, as compared to the absorption phase, to be visible after absorption is almost completed.

The pharmacokinetics of phenylbutazone, therefore, can be described by a two-compartment open model. With the assumption that all transfer processes, including absorption, are first order, such a model corresponds to a three-term exponential equation. In fact, 16 of the 18 individual curves fitted such an equation.

The equations of the average curves are as follows. For the 100-mg dose:

$$C = -88.00e^{-1.651t} + 12.22e^{-0.5606t} + 10.74e^{-0.0093t} \quad \text{(Eq. 1)}$$

For the 300-mg dose:

$$C = -180.00e^{-1.802t} + 4.87e^{-0.0920t} + 30.78e^{-0.0101t} \quad \text{(Eq. 2)}$$

For the 600-mg dose:

$$C = -152.38e^{-0.994t} + 5.94e^{-0.4005t} + 55.67e^{-0.0092t} \quad \text{(Eq. 3)}$$

The individual equations permitted the calculation of the pharmacokinetic parameters shown in Table I.

Absorption—Phenylbutazone was absorbed rapidly, with the maximum concentration being reached ~3 hr after administration. Nevertheless, the individual values of T_{max} were scattered, and there was a variable delay in some subjects before absorption started (lag time).

In six of 18 cases, the rate of absorption appeared to be slow initially and then increased gradually. This finding indicates that drug absorption was fast enough to have little, if any, effect on the other two phases, *i.e.*, distribution and elimination.

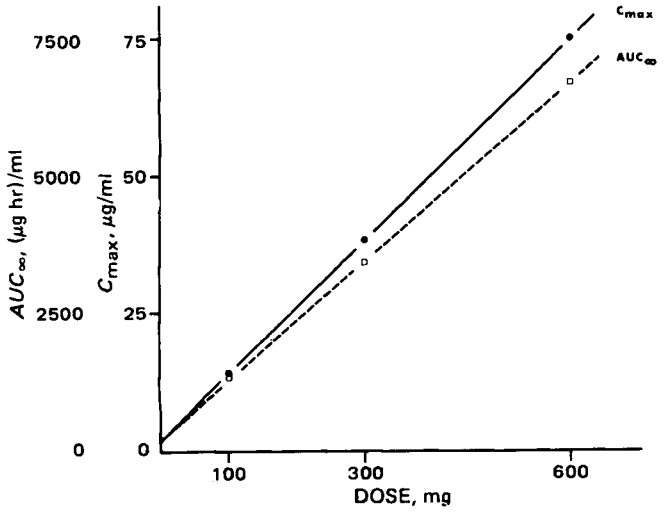

Figure 2—*Relationship between dose and* C_{max} (●) *and between dose and* AUC_∞ (□) *for phenylbutazone in a single-dose study.*

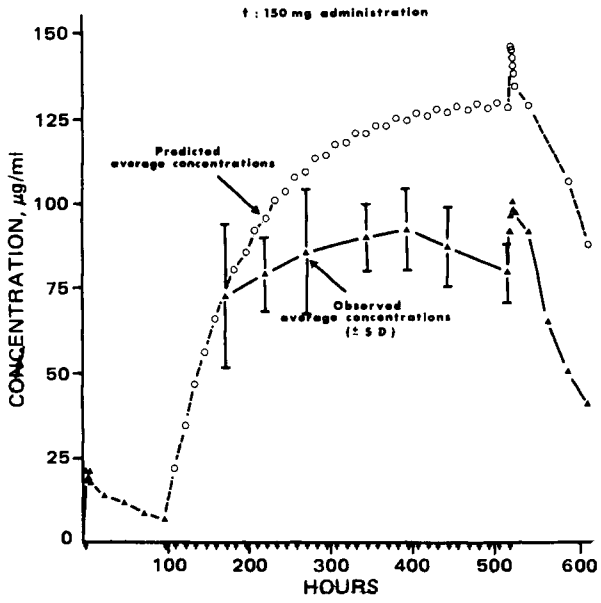

Figure 3—*Predicted* (○) *and observed* (▲) *average plasma concentrations of phenylbutazone during chronic treatment.*

Distribution—The apparent volume of distribution can be estimated from the area under the plasma concentration curve (AUC) and the elimination rate constant (k_E):

$$V_{area} = \frac{F \text{ dose}}{k_E AUC} \qquad \text{(Eq. 4)}$$

where F is the fraction of the dose absorbed.

The average value of the apparent volume of distribution (V_{area}) for all doses was 10.2 liters, assuming that $F = 1$. The volume of plasma (calculated on the basis of 41 ml/kg of body weight) was 2.9 liters. Since F is ≤ 1, ~30% of the administered phenylbutazone remained in the plasma.

Elimination—The overall elimination rate constant, k_E (Table I), clearly was independent of the dose. The mean elimination half-life for all doses was 77 hr, but the individual values varied from 54 to 99 hr. The intrasubject variation was less but was not negligible.

Dose Dependency of Pharmacokinetic Parameters—As shown in Fig. 2, there was a satisfactory linear relationship between the dose and C_{max} and between the dose and AUC_∞ (AUC extrapolated to infinity).

Multiple-Dose Study—Phenylbutazone elimination half-lives ($T_{1/2}$) estimated from the slope of the terminal linear segment of log–linear plots of the plasma concentration were similar at the beginning and end of the chronic treatment. Mean values (±SD) were 65.5 (±8.9) and 66.8 (±12.0) hr, respectively. The areas under the concentration profiles following administration of the first dose were measured by the trapezoidal rule and extrapolated to time infinity using the $T_{1/2}$ values. Their mean value (±SD) was 1697 (±231) (μg hr)/ml, which was in good agreement with the value calculated from the single-dose study [1706 (μg hr)/ml].

The AUC values after single doses were larger than those for a dose interval after multiple dosing; the mean values for the six subjects were 1697 (μg hr)/ml for AUC_0^∞ after a single dose and 1140 (μg hr)/ml for AUC_{504}^{516} after multiple doses. (Plasma levels after 516 hr were estimated roughly by interpolation from the 512- and 528-hr values.) The ratio of these two mean AUC values is similar to the ratio of the measured (~90 μg/ml) to the predicted (~130 μg/ml) steady-state plasma levels (~0.7).

As chronic treatment proceeded, the plasma phenylbutazone concentration measured just before the morning dose increased progressively up to values about four times higher than the peak concentration following the administration of the first dose of the treatment (mean value ± SD, 24.7 ± 6.2 μg/ml). Theoretical phenylbutazone concentrations just before the morning dose were obtained by the superposition technique and were distinctly higher than the corresponding experimental values (Fig. 3).

DISCUSSION

The pharmacokinetics of single doses of phenylbutazone can be described by a two-compartment open model. The drug was absorbed rapidly after oral administration in a single dose. It was distributed partially to an extravascular compartment, but at least one-third of the absorbed drug remained in the plasma. This finding is in agreement with the data reported by Burns *et al.* (1). The mean elimination half-life of phenylbutazone was ~77 hr, with individual values varying from 54 to 99 hr, which are within the reported range (1, 2, 4–6). There was a satisfactory linear relationship between the dose and the AUC. This finding is in agreement with the results reported by Lukas *et al.* (9); the fourfold increase of the dose did not cause a qualitative change in the elimination kinetics of phenylbutazone.

Single doses showed a linear relationship of AUC, C_{max}, and dose up to 600 mg, whereas upon multiple dosing, the plasma levels were lower than would be expected from a linear superposition of single-dose kinetics.

The differences found between single-dose predictions and actual steady-state concentrations cannot be correlated to the fact that two analytical procedures were used for the two phases of the study. Both methods yielded similar results for the same samples, and there was no interference between phenylbutazone and its three metabolites in the two methods.

In the multiple-dose study, the half-lives corresponding to the apparent elimination rate constant in each subject did not differ greatly for the first and last administrations. The theoretical minimum concentrations were much higher than the pseudosteady-state concentrations reached during chronic treatment in healthy volunteers.

The same effects were noticed by Edström (8) in patients with ankylosing spondylitis and by Orme and coworkers (12, 13) in patients with rheumatoid arthritis.

Burns *et al.* (1) showed that, after multiple dosing, increases in the dosage of phenylbutazone did not produce a proportional increase in plasma levels, which tended to reach a limiting concentration. Moreover, when phenylbutazone was administered intravenously to a subject whose plasma level was at this limiting concentration, the drug disappeared rapidly from the plasma until the level declined to the limiting value; after this level was reached, the concentration decreased at a much slower rate. Burns *et al.* (1) assumed that this phenomenon was due to a greatly increased rate of metabolism at higher dosages. The present results are not in agreement with this assumption; the half-life is at least as long at the end of chronic treatment as at the beginning.

On the condition that absorption is complete after multiple dosing, the present data show an increase in drug clearance from the plasma, since the steady-state levels are lower than predicted. However, since the elimination half-life is unchanged, the volume of distribution probably is increased. This is reasonable since phenylbutazone has a low extraction ratio and is highly protein bound. An increase in the free fraction at high concentrations (12, 13) would explain the increase in the clearance and the volume of distribution with no change in the half-life.

Bioavailability and Pharmacokinetics of a New, Slow-Release Potassium Chloride Capsule

J. ARNOLD *x, J. T. JACOB ‡, and B. RILEY ‡

Received November 20, 1979, from **Quincy Research Center, Kansas City, MO 64127*, and ‡*Berlex Laboratories Inc., Cedar Knolls, NJ 07927.* Accepted for publication June 26, 1980.

Abstract □ The bioavailability of a new, slow-release potassium chloride product consisting of coated beads in a hard gelatin capsule was compared with the bioavailability of two marketed products, an elixir and a slow-release tablet, by determining the urinary excretion of potassium. Twelve healthy male volunteers were dosed with a total of 80 mEq of potassium, in a single dose for the capsule and tablet and in three 26.6-mEq doses at 6-hr intervals for the elixir. Mean recoveries in 24-hr urine potassium levels from all three dosage forms after subtracting normal urine potassium excretion levels were 50.8% from the capsule, 53.9% from the elixir, and 63.1% from the tablet. Maximum excretion rates were reached at 2.0 hr for the elixir, 6.8 hr for the capsule, and 4.0 hr for the tablet. Fewer side effects were reported with the capsule than with the elixir and tablet.

Keyphrases □ Potassium chloride—bioavailability and pharmacokinetics of slow-release capsule □ Bioavailability—potassium chloride in slow-release capsule □ Pharmacokinetics—potassium chloride in slow-release capsule

Potassium chloride is indicated for the treatment of hypokalemic alkalosis associated with various cardiovascular disorders. Aqueous solutions of potassium chloride are effective potassium supplements when taken as prescribed; however, because of an unpleasant taste due to the chloride ion, patient compliance during long-term therapy has been a problem. More palatable forms of potassium salts, such as the gluconate or mixtures of bicarbonate, citrate, and acetate, are available, but the chloride ion has been shown to be a prerequisite for effective treatment (1).

BACKGROUND

A new, slow-release potassium chloride preparation containing 600 mg (8 mEq) of potassium chloride[1] in the form of small, nearly spherical beads enclosed in a hard gelatin capsule was developed to avoid or minimize a high localized concentration of potassium within the GI tract. The potassium chloride crystals are specially coated to permit a uniform, controlled *in vivo* release over 8–10 hr. Extensive toxicity testing in animals was carried out to compare the new capsule preparation with a marketed wax-matrix tablet[2]. The results indicated a marked difference in the ulcerogenic potential of the tablet and capsule dosage forms (2). Based on the animal toxicity data, it was concluded that the new capsule dosage form is not likely to cause local irritation of the GI mucosa.

Certain pharmacokinetic characteristics of potassium make accurate determination of bioavailability difficult. Up to 98% of the physiological potassium in humans is distributed within the intracellular space. The major elimination pathway of potassium is *via* urinary excretion; the secondary elimination pathway is *via* the feces and perspiration. Bioavailability estimates derived from serum potassium levels are inaccurate because of the homeostatic mechanisms that maintain serum potassium levels within a relatively narrow range (3).

Attempts to determine the bioavailability of potassium preparations by measuring urinary potassium levels have been reported (4–6). To achieve any success, the bioavailability study must be conducted where there can be careful control of the diet, fluid intake, physical activity, and urine collection. Fixed menus with a known potassium content should be given throughout the study. Strenuous exercises that might cause

[a] After correcting for control values for each urine collection period.

excessive perspiration, and thus loss of electrolytes, should be avoided.

The following three-way crossover study was designed to determine the bioavailability and pharmacokinetics of potassium chloride sustained-release capsules by urinary potassium excretion in volunteers maintained in a cloistered environment.

EXPERIMENTAL

Twelve healthy male volunteers, 19–55 years (mean 31 years) and weighing within ±10% of the ideal weight for their height and frame (7), participated in the study. Informed consent was obtained. The subjects were examined and found to have no hepatic, renal, or cardiovascular disease or history of GI disorders due to peptic or duodenal ulcer. Routine laboratory determinations, 12-lead ECGs, and physical examinations were conducted before admission to the study center[3].

The subjects remained in the study center under the supervision of the medical and nursing staff throughout the 15-day study. To avoid salt and water loss through perspiration, the subjects stayed indoors in air-conditioned rooms from 9:00 am to 4:30 pm every day and did not engage in strenuous exercise.

The first 3 days after admission (Days −3, −2, and −1) were diet-adaptation days. Day 0 was the control day for the treatment on Day 1. After two rest days (Days 2 and 3), a second control day (Day 4) was observed and then was followed by the second treatment on Day 5. Days 6 and 7 were rest days, followed by the third control day (Day 8) and the final treatment on Day 9. On Day 12, 3 days after the final treatment, the subjects were released from the center.

The three potassium chloride products, capsules[4], elixir[5], and tablets[6], were administered in a randomly assigned fashion in an open-label, three-way crossover treatment. The total dose of elixir, equivalent to 80 mEq of potassium, was divided into three 26.6-mEq doses administered at 6-hr intervals. The capsules and tablets were administered as single doses, each consisting of 80 mEq of potassium (10 capsules and 10 tablets, respectively). On the three treatment days (Days 1, 5, and 9), each subject received one of the three treatments after an 8-hr fast.

All urine voided on Days −3–+11 was collected. On the control days (Days 0, 4, and 8) and treatment days (Days 1, 5, and 9), urine was collected hourly for 16 hr beginning at 6:00 am. On the other days, urine was collected every 4 hr for 16 hr. A 16–24-hr collection was made on the control days as well as on the treatment days. The volume of each collection was recorded, and a sample was analyzed for its potassium and creatinine concentration. Urine potassium was determined by flame photometry (8). The assay sensitivity was ±0.1 mEq/liter. Creatinine was determined by the alkaline picrate method (9). Stool guaiac tests were performed on all feces to determine any loss of blood.

The subjects were required to drink 5200 ml of fluid each day. They received a uniform diet containing an average of 100 mEq of potassium, 340 mEq of sodium, and 4920 cal/day. No additional food or snacks were permitted. Meals were served at 7:00 am, 12:30 pm, 5:00 pm, and 10:00 pm. Drugs were administered, and the effects of the treatments were monitored by the attending staff physician.

All subjects received the constant attention of the nursing staff and were encouraged to report any untoward effect, however trivial it might appear to them. During morning, afternoon, and evening rounds, drug effects and general health problems were discussed with every subject.

RESULTS AND DISCUSSION

Changes in the urine potassium levels for each collection were determined by first averaging the urine potassium levels for the three predosing control days for each subject and then subtracting these values from the corresponding urine potassium levels of the treatment day. Each subject's cumulative urine levels for 24 hr on the control days and treatment days are listed in Table I. The mean control value for 12 subjects was 59.0 mEq. The mean increase in the 24-hr potassium level was 43.1 mEq for the elixir, 40.6 mEq for the capsule, and 50.5 mEq for the tablet. These values correspond to 53.9% recovery from the 80-mEq dose administered for the elixir, 50.8% for the potassium chloride sustained-release capsule, and 63.1% for the tablet.

The 24-hr urine collection data were divided into three fractions to determine the potassium elimination patterns of the capsule and tablet in comparison to the elixir. The results (Table II) indicate that the elixir, which was administered every 6 hr, showed eliminations of 11.1 mEq in 0–6 hr, 12.6 mEq from 6 to 12 hr, and 19.3 mEq from 12 to 24 hr. The corresponding figures for the capsule were 13.6, 18.3, and 8.7 mEq, respectively, indicating slow and sustained release of potassium. In contrast, the tablet showed eliminations of 30.1 mEq in 0–6 hr, 13.2 mEq from 6 to 12 hr, and 7.2 mEq from 12 to 24 hr. Sixty percent of the total potassium eliminated from the tablet was eliminated in the first 6 hr, compared to 33.5% for the capsule.

The mean maximum excretion rate and the time for the maximum excretion rate were calculated for each dosage form. The excretion rate maximum was 6.1 mEq/hr (average of three doses) for the elixir, 8.1 mEq/hr for the capsule, and 10.1 mEq/hr for the tablet (Table III). The mean time for the maximum excretion rate was 2.0 hr for the elixir (average of three doses), 6.8 hr for the capsule, and 4.0 hr for the tablet. The capsule showed a slow excretion rate, characteristic for a sustained-release

Table III—Potassium Excretion Kinetics

	Elixir First Dose	Elixir Second Dose	Elixir Third Dose	Capsule	Tablet
Mean maximum excretion rate ± *SD*, mEq/hr	6.2 ± 2.9	5.1 ± 1.9	6.9 ± 3.1	8.1 ± 4.0	10.1 ± 3.0
Mean time of maximum excretion rate ± *SD*, hr	1.8 ± 1.1	1.9 ± 1.1	2.3 ± 0.8	6.8 ± 3.0	4.0 ± 2.5

[a] Excretion rate (mEq/hr) = [urine potassium (mEq) − mean control urine potassium (mEq) for urine collection period]/urine collection period (hr).

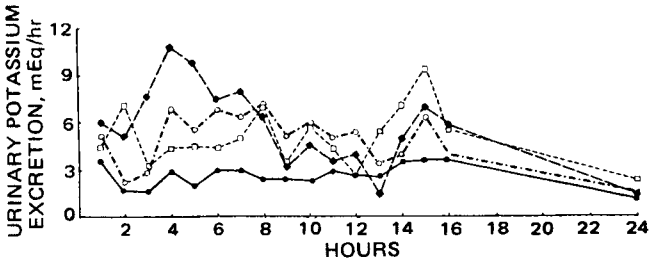

Figure 1—*Mean urinary potassium excretion rate before and after administration of 80-mEq oral doses of potassium chloride as slow-release capsules, elixir, and tablets in 12 subjects. Data for dosage forms were corrected for the mean potassium excretion during each collection period on the control days. Key: – • – O • –, capsules; - - □ - -, elixir; – – ■ – –, tablets; and —●—, control (mean of 3 control days).*

product, and reached a maximum much later than the immediately available elixir dosage form. The tablet also showed delayed release; however, the time for the maximum excretion rate was considerably shorter than for the capsule. The excretion rate curve of each product is shown in Fig. 1. Urine creatinine values for all subjects were within the normal range. Stool guaiac tests were negative for all subjects.

A Friedman two-way analysis of variance nonparametric, K-sample, related-measures test was significant at the 0.05 level, and differences in potassium excretion between the various formulations for each time interval were analyzed further using Wilcoxon's matched-pairs signed-ranks procedure (one tailed) (Table IV). For the mean 24-hr cumulative potassium recovery, both the elixir and the capsule were significantly lower than the tablet but were not significantly different from each other. This also was true for the early period of potassium excretion (0–6 hr), where the mean potassium level from the tablet was almost triple that of the other two formulations. During the 6–12-hr period, both the elixir and tablet means were significantly lower than the capsule mean; in the 12–24-hr period, both the capsule and the tablet gave significantly lower values than the elixir.

There also were significant differences between the mean potassium excretion between the time intervals for each formulation. For tablets, the greatest excretion occurred during the first 6 hr, and each succeeding interval featured significantly less excretion than its predecessor. For capsules and the elixir, the 12–24-hr period was significantly different from the two earlier periods.

Because of the complexity of potassium distribution and elimination kinetics in humans, the comparatively low recoveries seen in this study are not surprising. In another well-controlled crossover study with strict management of the diet, exercise, and fluid intake, only 27.4% of the potassium was recovered from the tablet[2] compared to 59.7% from a 10% solution of potassium chloride (4).

In a study of subjects receiving an effervescent tablet form of potassium chloride, only 46.4% of the potassium was recovered from the urine (5). Higher recoveries of potassium from urine have been reported (10, 11). However, these results are questionable because the controls seemed to be inadequate.

Despite the fact that 10 potassium chloride sustained-release capsules were administered as a single dose, there were no serious adverse reactions in any of the 12 subjects. Subject 1 complained of diarrhea from 2 to 10 hr after receiving the dose. A similar dose of the tablets elicited complaints of stomach pains starting 20 min after the dose and lasting for ~1 hr in Subjects 1, 3, and 9. Abdominal cramps and nausea lasting ~1 hr were reported by Subject 7 who received the tablets. The elixir produced nausea in Subject 10 30 min after the second dose of 26.6 mEq, and Subject 1 vomited 45 min after the second dose. Thus, of the seven complaints, four were related to the tablet, two to the elixir, and one to the capsule.

Table IV—Differences in Cumulative Potassium Excretion for Three Formulations

Formulation	Interval			
	0–6 hr	6–12 hr	12–24 hr	0–24 hr
Elixir – capsule	NS[a]	0.05	0.05	NS
Elixir – tablet	0.05	NS	0.05	0.05
Capsule – tablet	0.05	0.05	NS	0.05

[a] Not significant.

CONCLUSION

The results of this study show that the new potassium chloride slow-release capsule dosage form is equal in bioavailability to a 10% solution of potassium chloride. When tested in a three-way crossover study in 12 normal, healthy male volunteers, the rate of elimination, and thereby the rate of absorption, of potassium chloride sustained-release capsules were slower and more uniform than for the tablets or the elixir. The two slow-release products produced prolonged potassium levels after administration of a single dose. The potassium chloride sustained-release capsule was well tolerated, even though the subjects were given an unusually high single dose of 10 capsules, equivalent to 80 mEq of potassium.

Radioimmunoassay for Terfenadine in Human Plasma

C. E. COOK *x, DAVID L. WILLIAMS *, MARY MYERS *, C. RAY TALLENT *, G. A. LEESON ‡, R. A. OKERHOLM ‡, and G. J. WRIGHT ‡§

Received February 25, 1980, from the *Research Triangle Institute, Research Triangle Park, NC 27709, and the ‡Merrell Research Center, Cincinnati, OH 45215. Accepted for publication June 24, 1980. §Present address: A. H. Robins Company, Richmond, VA 23220.

Abstract □ A radioimmunoassay procedure was developed for the antihistamine terfenadine {α-[4-(1,1-dimethylethyl)phenyl]-4-(hydroxydiphenylmethyl)-1-piperidinebutanol}. The keto analog of terfenadine was converted to its *O*-carboxymethyloxime derivative, which was conjugated to bovine thyroglobulin by a mixed anhydride technique. Rabbits were immunized with the resulting conjugate, and antiserums capable of binding radiolabeled terfenadine were obtained. Tritium-labeled terfenadine was prepared by a combination of exchange and reduction with platinum oxide in the presence of tritium gas, and the procedure yielded a specific activity of 48 Ci/mmole. Plasma containing terfenadine was diluted with sodium carbonate solution and extracted with hexane, and the hexane extracts were evaporated and analyzed. The between-assay coefficient of variation on control samples ranged from 8% at 10 ng/ml to 14% at 1 ng/ml. The lower practical sensitivity limit was at least as low as 0.25 ng/ml (25 pg measured). Two metabolites of terfenadine cross-reacted 16–30% with the antiserum used. However, extraction eliminated essentially all of these compounds. Analysis of plasma samples from human subjects given terfenadine showed marked intersubject variability and low plasma levels.

Keyphrases □ Radioimmunoassay—terfenadine, human plasma □ Terfenadine—radioimmunoassay, human plasma □ Antihistaminics—terfenadine, radioimmunoassay, human plasma

A new antihistamine, terfenadine (I*a*), is under clinical study[1]. Metabolism studies in animals[2] indicated that plasma levels of the parent drug could be expected to be in the low nanogram per milliliter range. Therefore, for bioavailability studies, a sensitive analytical procedure was needed. Radioimmunoassay was chosen because of its sensitivity, specificity, and simplicity.

This report describes the synthesis of an immunogen containing a haptenic moiety corresponding to terfenadine, the production of antiserum in rabbits, the synthesis of tritium-labeled terfenadine as a radioligand for competitive binding studies, and the development of a radioimmunoassay procedure for terfenadine which was applied to human studies.

EXPERIMENTAL[3]

α-[4-(1,1-Dimethylethyl)phenyl]-4-(hydroxydiphenylmethyl)-1-piperidinebutanone *O*-Carboxymethyloxime (V)—Reaction of 1.00 g of α-[4-(1,1-dimethylethyl)phenyl]-4-(hydroxydiphenylmethyl)-1-piperidinebutanone (II) under nitrogen with 300 mg of carboxymethoxylamine hemihydrochloride in a refluxing mixture of 50 ml of methanol and 6 ml of 1 *M* sodium acetate in water for 16 hr yielded, after workup and recrystallization (chloroform–carbon tetrachloride), 719 mg (67% yield) of the oxime acid (V) as a white solid, mp (uncorrected) 138–145° (capillary), 138–142° (hot-stage microscope); UV (0.1 *N* NaOH): λ_{max} 256 (ε 12,790) nm; PMR (100 MHz, pyridine-d_5): δ 1.11 [s, $C(CH_3)_3$], 2.03 (m, CH_2), 2.50 (t, *J* = 7 Hz, $CH_2C{=}N$), 3.05 (br t, *N*-CH_2), and 5.07 (s, OCH_2CO); PMR (60 MHz, chloroform-d_3): δ 1.25 [s, $C(CH_3)_3$], 4.52 (s, OCH_2CO), and 6.8–7.8 (m, aromatic H).

Anal.—Calc. for $C_{33}H_{42}N_2O_4$: C, 75.24; H, 7.80; N, 5.16. Found: C, 74.95; H, 7.60; N, 4.76.

Conjugation Reaction—The oxime acid (V) (16.25 mg, 0.03 mmole) in 4 ml of dioxane, on reaction with tributylamine (7.4 μl) and isobutyl chloroformate (39.5 μl) under nitrogen for 20 min at 14–15°, yielded a solution of the mixed anhydride (VI). To this solution was added a solution (pH 11.2, 15°) of 82.2 mg (1.25×10^{-4} mmole) of bovine thyroglobulin[4] and 86 μl of 1 *N* NaOH in 4 ml of water. The thyroglobulin flask was rinsed with ~1 ml of aqueous sodium hydroxide (pH 11.2), which also was added to the mixed anhydride.

The reaction mixture was stirred for 4.5 hr at 8° and then poured onto a 2.2 × 31.5-cm agarose gel[5] column in which the liquid phase was dioxane–water (1:1). The column was eluted with distilled dioxane–water (1:1). The eluate fraction from 25 to 60 ml was lyophilized to yield the conjugate (VII) (102 mg) as a fluffy white fluorescent solid. The molar ratio (hapten to protein) was calculated to be 141 by differential UV spectrophotometry (2) at 255 nm in 0.1 *N* NaOH[6].

Catalytic Formation of Tritiated Terfenadine—To 10 mg of II as the free base in 0.7 ml of dry 1,4-dioxane was added 5 mg of platinum oxide, and the mixture was stirred under tritium gas (5 Ci) for 2 days. It then was filtered through successive layers of diatomaceous earth, magnesium sulfate, molecular sieve, and cotton in a Pasteur pipet. Half of the filtrate was concentrated, brought up in 0.1 ml of ethyl acetate, and chromatographed on silica gel plates (0.1 mm thick) with toluene–diethylamine (9:1) as the mobile phase. The terfenadine bands were eluted with ethyl acetate. The ethyl acetate was evaporated almost to dryness, and the tritiated terfenadine (110 mCi) was brought to volume in a 50-ml volumetric flask with benzene–ethanol (9:1). Thin-layer radiochromatography (toluene–diethylamine 9:1) indicated pure tritiated terfenadine.

[3] PMR spectra were recorded on a Varian EM 360 spectrometer at 60 MHz or on a HA-100 spectrometer at 100 MHz with tetramethylsilane as the internal standard. IR spectra were obtained on a Perkin-Elmer 467 grating IR spectrophotometer. Analytical TLC on silica gel 60F-254 precoated TLC plates (0.25 mm thick) from EM Reagents, Elmsford, N.Y., was routinely used to monitor reactions. Elemental analyses were from Micro-Tech Laboratories, Skokie, Ill. Terfenadine (I*a*) and its analogs I*b*–I*d* were prepared at Merrell Research Center (1).

[4] Type I, Sigma Chemical Co., St. Louis, Mo.

[5] Bio-Gel A, Bio-Rad Laboratories, Richmond, Calif.

[6] The equation used was:

$$\text{molar ratio} = \frac{A_{conj}\ \text{mol. wt.}_{\text{thyroglobulin}} - \epsilon_{\text{thyroglobulin}} C_{conj}}{\epsilon_{\text{oxime acid}} C_{conj} - A_{conj}\ \text{mol. wt.}_{\text{hapten residue}}}$$

where *A* is the absorbance, *C* is the concentration in milligrams per milliliter, mol. $\text{wt.}_{\text{thyroglobulin}}$ = 670,000, mol. $\text{wt.}_{\text{hapten residue}}$ = 542 − 18 (loss of water in conjugation reaction) = 524, $\epsilon_{\text{oxime acid}}$ = 12,790 at 255 nm, and $\epsilon_{\text{thyroglobulin}}$ = 490,000 at 255 nm. This formula differs slightly from the calculation of Ref. 2, which ignores the weight of the hapten residue in calculating the absorbance due to the protein.

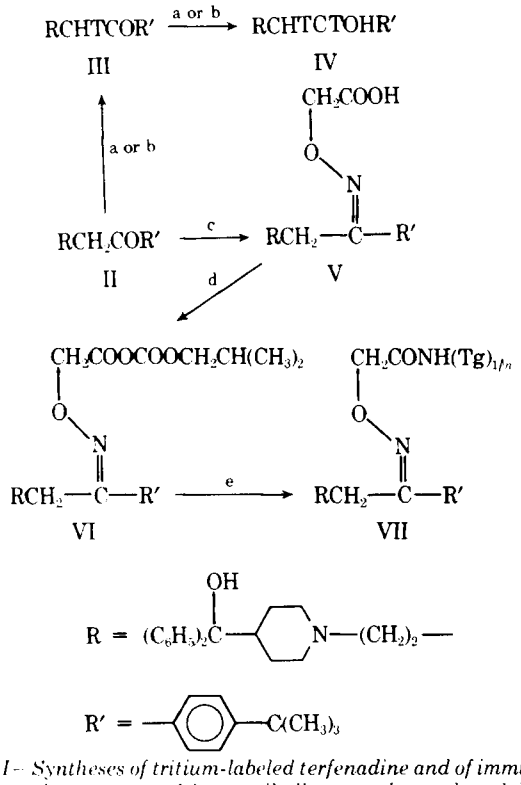

Scheme I—Syntheses of tritium-labeled terfenadine and of immunogen. Key to reaction steps: a, tritium, palladium-on-charcoal, and dioxane; b, tritium, platinum oxide, and dioxane; c, carboxymethoxylamine, sodium acetate, and methanol; d, isobutyl chloroformate, tributylamine, and dioxane (cf., *Ref. 9*); *and e, bovine thyroglobulin (Tg) and aqueous sodium hydroxide* (cf., *Ref. 9*).

The specific activity was determined by self-displacement in radioimmunoassay (3).

Development of Antiserum—The thyroglobulin conjugate was dissolved in 0.9% NaCl at a concentration of 0.2 mg/ml with adjustment of the pH (by addition of a few drops of dilute sodium bicarbonate) to achieve complete solution. Five milliliters of this solution was emulsified with Freund's complete adjuvant[7], and the emulsion was used to immunize four New Zealand White rabbits (two male and two female) intradermally (about 20 sites) with 2 ml of the mixture (4). After 4 weeks, a 0.1-mg/ml solution was emulsified with an equal volume of Freund's incomplete adjuvant[7] and injected intradermally as described (2 ml/rabbit). Rabbits were bled 12 days later (ear vein, 30 ml).

Four weeks after the first booster injection, each rabbit was injected subcutaneously with 1 ml of a solution of the conjugate (0.1 mg/ml) in 0.9% NaCl, and subsequent booster injections were given at 4-week intervals (total of seven subcutaneous booster injections). Rabbits were bled ~12 days after each booster injection. Serums were stored at −20°.

Analytical Procedures—The buffer was 0.1 *M* phosphate-buffered saline (pH 6.8, prepared from 5.38 g of monobasic sodium phosphate monohydrate, 16.35 g of dibasic sodium phosphate heptahydrate, and 9.0 g of sodium chloride/liter) containing 0.1% NaN_3 and 0.1% bovine serum albumin[8].

Standard solutions were prepared from human male drug-free plasma[9] (citrate as anticoagulant). A 50-ng/ml solution of terfenadine in plasma was made by adding an ethanol solution (20 μg/ml) to plasma. Further dilutions in plasma yielded standards containing 0.5, 0.75, 1, 2, 3, 5, 8, and 12 ng/ml. Control samples containing 1, 3, 5, and 10 ng/ml were made up separately to check the reproducibility of the assay and standard preparation. Standard and control solutions were aliquoted into 3.7-ml vials and stored at −20°.

Plasma (0.5 ml) (blank, standard, control, or unknown) was placed in a 20-ml scintillation vial. To the vial was added 0.5 ml of 0.1 *M* Na_2CO_3. The mixture was shaken, and 4.0 ml of hexane was added. The vials were capped, placed in an upright position in a reciprocating shaker, and shaken overnight at ~80 cycles/min. The vials were immersed in dry ice–acetone to freeze the aqueous layer, and the hexane was decanted. Aliquots (0.8 ml) of the hexane were then transferred to individual 12 × 75-mm glass culture tubes, and the hexane was evaporated in a centrifuge-type vacuum evaporator[10]. To the residue were added 10 μl of aqueous ethanol (1:1), 10 μl of an aqueous ethanolic (1:1) solution of tritium-labeled terfenadine (~16,000 cpm), 0.6 ml of buffer, and 0.1 ml of diluted antiserum. For direct measurement of metabolite cross-reactions, terfenadine and metabolites were added in 10 μl of aqueous ethanol.

The contents were vortexed and incubated overnight at 4°. A 0.5-ml aliquot of a 1.5% suspension of charcoal[11] (washed to remove fine particles) in buffer was added. Tubes were agitated on a vortex mixer and allowed to stand for 20 min at 4°. They were then centrifuged for 15 min at 733×*g* and 4°. The supernate was decanted into liquid scintillation vials, each containing 10 ml of scintillation cocktail (5). Radioactivity was measured in a liquid scintillation spectrometer. Samples were counted to a precision of 2% (2σ) or for 5 min, whichever came first, for three separate cycles.

Data Treatment—The counts per minute for each vial from the three cycles were averaged. In some earlier work and to determine the cross-reactions of metabolites, standard curves were determined and calculations were made by the logit–log procedure (6); however, all of the plasma analyses were performed by means of a four-parameter logistic procedure (7, 8).

Clinical Procedure—The clinical portion of this study[12] involved six male volunteers from whom informed consent was obtained. The subjects were randomly placed in three groups of two. Group 1 took 60 mg as a single tablet, Group 2 took two 60-mg tablets, and Group 3 took three 60-mg tablets after an overnight fast. Venous blood samples (10 ml) were drawn in tubes[13] containing solid ethylenediaminetetraacetic acid as the anticoagulant just before dosing (0 hr) and at 0.5, 1, 1.5, 2, 3, 4, 6, 8, 12, 18, and 24 hr after dosing. The blood samples were centrifuged and the plasma was separated, labeled with a code number, and frozen. The plasma samples were kept frozen until they were assayed, and the code was not broken until the assays were completed.

RESULTS

Synthesis of Immunogen and Radioligand—Reaction of the ketone analog (II) of terfenadine with *O*-carboxymethylhydroxylamine led in reasonable yield to the desired *O*-carboxymethyloxime (V, Scheme I). The presence in the PMR spectrum of a singlet at δ 5.07 (pyridine-d_5) or 4.52 (chloroform-d_3) was indicative of OCH_2CO. The presence of only one peak in this region indicated that only one isomer was isolated. For steric reasons, this isomer was assigned the *E*-stereochemistry shown in V. Compound V was converted to a mixed anhydride (9) and conjugated to bovine thyroglobulin, presumably by reaction with the ε-aminolysine groups of the protein. Differential UV determination indicated that 141 terfenadine moieties were incorporated per molecule of the thyroglobulin.

Tritium-labeled terfenadine (48 Ci/mmole) was obtained by treatment of the ketone (II) with platinum oxide and tritium gas.

Development of Assay—Initial studies showed that when terfenadine was added in aqueous ethanol solution, binding equilibrium was reached by 0.5 hr. However, for plasma analysis, overnight incubation was necessary. Bovine serum albumin was preferable to gelatin as a buffer protein because it markedly reduced nonspecific binding (radioactivity not adsorbed to charcoal). Nonspecific counts per minute values were <2.5% of the total counts per minute at final charcoal concentrations above 0.4%, and net binding was constant over the range of 0.4–0.8% charcoal but decreased sharply at concentrations above 1.2%. The nonspecific counts per minute values remained constant after a 10-min exposure to charcoal; after 20 min, net binding decreased <0.5%/min.

The titer of all antiserums was measured with 7.5-Ci/mmole radiolabeled terfenadine obtained by the reduction of II with tritium gas over palladium-on-charcoal[14]. Titer was defined as the dilution that bound 50% of ~16,000 cpm of labeled terfenadine when 0.1 ml was used in an incubation and thus is partially a function of the specific activity of the

Table I—Cross-Reactions with Terfenadine Antiserum [a]

Antiserum [b]	Test Compound	Cross-Reaction, %
R5-2	Ib	70
	Ic	42
	Id	3
	II	38
R7-2	Ib	21
	Ic	17
	Id	0.9
	II	19
R7-5	Ib	29
	Ic	21
	Id	0.8
	II	29

[a] Radioligand specific activity was 48 Ci/mmole [b] The first number refers to the rabbit; the second number refers to the bleeding. See *Experimental* for details of immunization. Rabbit 5 was a male; Rabbit 7 was a female.

radioligand. Antiserums from one female and one male rabbit did not exhibit any titer greater than 1:500. The titer and percent displacement of the radioligand by 500 pg of terfenadine at the antiserum titer that initially bound 50% of the radioligand are shown in Fig. 1 for antiserums from the other two rabbits. Antiserum R5-2 gave the highest titer at 1:1325, but R7-5 exhibited the greatest sensitivity. When radiolabeled terfenadine with a specific activity of 48 Ci/mmole was used, the 50% titer of R5-2 was increased from 1:1325 to 1:9500 and that of R7-5 was increased from 1:500 to 1:5000. The sensitivity of the assay was such that 25 pg of terfenadine caused 10% displacement of bound radioligand.

When plasma (0.5 ml) containing 1 and 10 ng of tritiated terfenadine/ml was diluted 1:1 with 0.1 *M* Na_2CO_3 and extracted three times (shaking for 30 min) with 2 ml of hexane, the average total recovery was 71.5 ± 2.9% (*SD*) for the 1-ng/ml solution and 72.5 ± 3.7% for the 10-ng/ml samples (triplicate samples). Extraction in 20-ml liquid scintillation vials containing 0.5 ml of plasma, 0.5 ml of 0.1 *M* Na_2CO_3, and hexane (2 or 4 ml) shaken[15] gently (80 cycles/min) overnight in a vertical position gave excellent recoveries (80% using 2 ml of hexane and 90% using 4 ml).

The cross-reaction of Metabolites Ib[16] and Ic[16] and common fragment Id[16] as well as the ketone (II) was measured by comparison of the amount required to displace 50% of bound radioligand (5) (Table I). Although pure samples of the metabolites cross-reacted with the terfenadine antiserums, the specificity of the overall assay is dependent on the extent

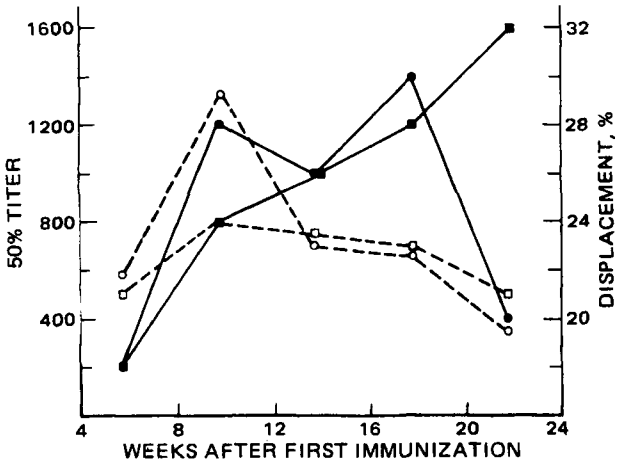

Figure 1—*Antiserum titer (dotted lines) and sensitivity (solid lines) as a function of time after the first immunization. The radioligand was [^3H]terfenadine with a specific activity of 7.5 Ci/mmole. Sensitivity was measured by percent displacement of the radioligand from antiserum by 500 pg of unlabeled terfenadine when the antiserum initially bound 50% of the radioligand. [a] Metabolites were added to plasma, which then was diluted with sodium carbonate solution and extracted with hexane. The hexane extracts were analyzed for terfenadine equivalents. (See *Experimental* for details of extraction and analysis.) Experiments A and B were run at separate times. Antiserum R7-5 was used. [b] Not done.

to which the metabolites were extracted from plasma by the hexane. Therefore, solutions of terfenadine and Ib and Ic were prepared in plasma and analyzed. Metabolites were calculated as the nanogram equivalents of terfenadine per milliliter based on the terfenadine standard curve. Table II shows that the carboxylic acid metabolite (Ic) at 100 ng/ml cross-reacted to the extent of only 0.3 ng equivalent of terfenadine/ml and that the alcohol (Ib) at the 100-ng/ml level was measured as 1.4 ng equivalents/ml.

Validation of Assay—Table III shows the mean values obtained for control samples in 10 consecutive assays as well as calculations of between-assay and within-assay variability. These calculations were carried out according to the procedure of Rodbard (10). One assay included a blank plasma pool and 38 blind samples[17]. The sample code was not broken until after the assay results were reported. Acceptable agreement was achieved between added and found values (Table IV). The regression equation was y (found) = 0.93x (added) + 0.40 ng/ml (r = 0.9792, n = 39).

Plasma Levels in Humans—Plasma levels in the six subjects studied were low and highly variable between subjects (Fig. 2). One subject who was given 180 mg exhibited the maximum concentration recorded (5.8

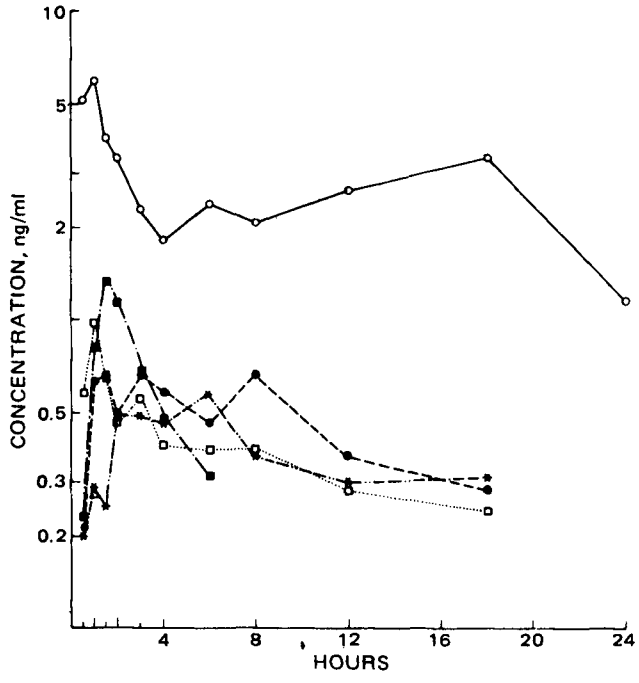

Figure 2—*Plasma levels of terfenadine in human males given a single oral dose of terfenadine. Levels were measured by the radioimmunoassay procedure described. Samples were analyzed at 0.5, 1, 1.5, 2, 3, 4, 6, 8, 12, 18, and 24 hr, but data points below 0.2 ng/ml were below assay sensitivity and are not shown. Key: ■ and *, 60-mg dose; ● and △, 120-mg dose; and ○ and □, 180-mg dose.*

[17] The samples were prepared at Merrell-National Laboratories and shipped to the Research Triangle Institute.

Table III—Results from Analysis of Control Samples from 10 Consecutive Assays [a]

Statistical Variable	Blank	Concentration, ng/ml 1	3	5	10
Average	0.12	0.99	2.95	5.00	10.57
SD (between assays)	0.07	0.14	0.35	0.63	0.89
CV, % (between assays)	58	14.0	11.9	12.6	8.4
SD (within assay, single extract)	—	0.09	0.31	0.51	0.69
CV, % (within assay, single extract)	—	9.2	10.5	10.1	6.5
SD (within assay, three extracts)	—	0.053	0.18	0.29	0.40
CV, % (within assay, three extracts)	—	5.3	6.0	5.8	3.8

[a] Triplicate samples were extracted and duplicate aliquots of each extract were analyzed. Calculations were done according to the method of Rodbard (10).

ng/ml 1 hr after dosage). In contrast, the corresponding value for one subject given 120 mg was only 0.28 ng/ml, and the second highest plasma level (1.3 ng/ml) was achieved by a subject given a 60-mg dose.

DISCUSSION

Since terfenadine is a small molecule, the development of antibodies capable of binding it required the synthesis of a protein conjugate that incorporated the terfenadine moiety. To minimize the cross-reaction of terfenadine metabolites, those portions of the molceule that are principally involved in metabolic reactions should be left free to influence antibody selectivity. Two known metabolites are the alcohol (I*b*) and the carboxylic acid (I*c*). Other metabolites having hydroxylation on an aromatic ring apparently also are present[1]. However, the ketone (II) resulting from oxidation of the secondary benzylic hydroxyl group of terfenadine apparently is not a metabolite. Therefore, the carboxymethyloxime analog (V) of terfenadine (derived from II) was chosen as the hapten. Compound V lacks the asymmetric center of terfenadine, which should minimize the possibility that the antiserum developed would be selective for only one optical isomer of terfenadine.

Several coupling experiments were carried out to achieve maximum incorporation of the drug moiety into thyroglobulin while retaining reasonable solubility properties of the thyroglobulin. An agarose gel (suitable for use with organic or aqueous–organic solvent mixtures) allowed separation of the conjugate and unreacted acid with a good yield of the desired conjugate, and the ratios of the reactants given under *Experimental* resulted in the best combination of hapten incorporation and solubility of the conjugate.

Although a radioligand with a specific acitivity of 0.86 Ci/mmole was obtained readily by reduction of II with sodium borotritide, material of a higher specific activity was required for best sensitivity. A combination of catalytic exchange (11) and catalytic reduction of the keto group with tritium gas was chosen. Palladium-on-carbon initially was used as the catalyst, but it yielded terfenadine with a specific activity of only 7.5 Ci/mmole. Platinum oxide has been reported to give high yields in the reduction of acetophenone to 1-phenylethanol (12). Reduction of platinum oxide with tritium gas would lead to the formation of tritiated water, which should undergo exchange reactions with the enolic form of the ketone (II). Reduction of the keto group with excess tritium gas in the presence of the platinum catalyst would yield the desired alcohol. In fact, these conditions resulted in terfenadine with a specific activity of ~48 Ci/mmole.

Since the metabolites are more polar than terfenadine, extraction of plasma with a relatively nonpolar solvent should significantly reduce the amounts of metabolites in the final analytical sample. The polarity of the carboxylic acid and phenolic metabolites also could be enhanced by making the plasma samples basic with sodium carbonate solution. Hexane extraction of alkalinized plasma markedly improved the assay specificity since very large amounts of the metabolites were required to make a significant contribution to the assay results. Little interference from the carboxylic acid (I*c*) would be expected at levels 50 times those of terfenadine or from the alcohol metabolite (I*b*) at 10 times the terfenadine levels. Thus, the assay should measure terfenadine itself with little contribution from its metabolites. In view of the structure of the immunogen, the relatively low cross-reactivity of the ketone (II) is noteworthy. Use of terfenadine as a radioligand apparently selects the antibody population with stronger affinity for the secondary alcohol structure.

Table IV—Blind Analysis of Terfenadine Plasma Samples

Added, ng/ml	Number of Samples	Found, mean ± *SD*
0.0	3	0
1.02	6	1.22 ± 0.03
2.04	2	2.22 ± 0.05
3.06	2	3.33 ± 0.13
4.07	6	4.44 ± 0.09
5.09	3	5.19 ± 0.42
6.11	5	6.32 ± 0.41
7.13	3	6.36 ± 1.48
8.14	1	8.28
10.2	8	9.73 ± 1.03

When the assay was run several times, the reproducibility and accuracy of the measurement of control samples were acceptable (Table III). The between-assay coefficient of variation ranged from 14% at 1 ng/ml to 8% at 10 ng/ml. The coefficient of variation within assays based on the extraction of samples in triplicate and assay of each extract in duplicate was ≤6%. Indeed, calculations show that duplicate plasma extracts analyzed in duplicate would be acceptable, with a coefficient of variation of <8%. Acceptable accuracy and precision also were obtained with blind spiked samples.

As expected from the metabolism studies in animals, low levels of terfenadine were observed in the plasma of human subjects administered the drug. The variability between subjects was marked (Fig. 2), but such variability has been observed with other drugs (13, 14). There was no apparent correlation between the dose administered and the maximum plasma level observed. However, since this was not a crossover study, individual variation could account for the apparent discrepancy. In addition to the initial absorption peak at ~1 hr, at least one secondary peak in the plasma concentration was seen for some subjects[18] (Fig. 2). The low plasma levels achieved with relatively high doses, the large variation in plasma levels (not highly dose correlated), and the secondary maxima observed in the plasma levels strongly indicate that a significant first-pass effect and enterohepatic circulation as well as other factors influence the plasma levels of terfenadine in humans. These questions will be addressed in a future study.

Prodrugs of Etilefrine: Synthesis and Evaluation of 3′-(*O*-Acyl) Derivatives

JOSEF WAGNER *ˣ, HELMUT GRILL *, and DIETRICH HENSCHLER ‡

Received March 10, 1980, from the **Department of Chemical Research, Klinge Pharma, Munich, West Germany,* and the ‡*Institute of Pharmacology and Toxicology, University of Würzburg, Würzburg, West Germany.* Accepted for publication June 27, 1980.

Abstract □ A series of 3′-(*O*-acyl) derivatives of etilefrine {α-[(ethylamino)methyl]-3′-hydroxybenzyl alcohol} was synthesized. Correlations between structure and solubility, pKa value, lipophilicity, and esterase-catalyzed hydrolysis were demonstrated. Of special interest is the 3′-(*O*-pivaloyl) derivative, which shows, in addition to favorable solubility and improved lipophilicity, marked stability against enzymatic cleavage in blood along with a high rate of hydrolysis in the liver.

Keyphrases □ Etilefrine—synthesis and evaluation of 3′-(*O*-acyl) derivatives as prodrugs □ Prodrugs—etilefrine, synthesis and evaluation of 3′-(*O*-acyl) derivatives as prodrugs

The uncertain activity of orally administered phenolethanolamines is partly assumed to result from metabolic processes during absorption. Phenolethanolamines with a free hydroxyl group in the *meta*-position are primarily subject to this gut wall first-pass metabolism. As they pass the intestinal wall, they are conjugated to inactive compounds. For example, in the intestinal wall, 80% of orally administered isoproterenol is converted to sulfate (1, 2) in the *meta*-position. During the gut wall passage, a similar conjugation was found for orciprenaline (metaproterenol) (3), terbutaline (4), norfenefrine (5), and etilefrine (6). Due to this early metabolic reaction, the bioavailability of compounds, even those with a high rate of absorption, is frequently reduced (7).

To avoid the attack of conjugating enzymes at the 3′- or 5′-hydroxy group, it was masked by acylation, thus converting the phenolethanolamines into prodrugs. *O*-Acyl derivatives of this type are known for phenylephrine (8, 9), etilefrine (8, 9), norepinephrine (10), *meta*-norepinephrine (10), epinephrine (8, 9), *meta*-epinephrine (8, 9), isoproterenol (10), orciprenaline (10), *N*-*tert*-butylnorepinephrine (11), and terbutaline (12). These *O*-acyl derivatives differ from their parent drug significantly in their solubility, dissociation constants, and lipophilicity. In addition to these properties that affect the absorption rate, enzymatic cleavage is influenced by the structure of the acyl radicals (8, 9, 13).

Since enzymatic hydrolysis also is dependent on the number and position of the acyl radicals, it was of interest to test *O*-acyl derivatives of one phenolethanolamine that only differed by the acyl radical. By taking into account all properties essential for bioavailability, a search has been centered on a prodrug applicable for therapeutic use. Therefore, the model compound selected was etilefrine {α-[(ethylamino)methyl]-3′-hydroxybenzyl alcohol}, which is used in the treatment of circulatory diseases. Its systemic bioavailability as unmetabolized etilefrine is ~50% (6, 7), although it is completely absorbed.

A series of 3′-(*O*-acyl) derivatives of etilefrine was synthesized according to various methods (Table I). Their physical properties and hydrolysis rates are listed in Table II.

RESULTS AND DISCUSSION

Starting from 3′-hydroxy-2-(benzylethylamino)acetophenone (I), which was prepared according to known procedures for the synthesis of hydroxy-2-(benzylalkylamino)acetophenones (14, 15), acylation was carried out according to Methods A–E (Scheme I). The esters (II) obtained were debenzylated with hydrogen in the presence of palladium-on-carbon to give intermediates (III), which were reduced to the corresponding alcohols (IV), usually without interrupting the reaction (Method F). In cases where the substituents at the nucleus were sensitive to hydrogenolysis (IV*r*), the keto group was reduced with sodium borohydride (Method G). In one case (IV*f*), isolation of the levorotatory form (IV*g*) was achieved by reaction with (+)-dibenzoyltartaric acid (Method H).

The compounds thus obtained had characteristic IR, PMR, and mass spectra, consistent with the structures indicated. All IR spectra exhibited strong, sometimes broad absorptions at 3340–3160 cm^{-1} (OH), bands between 2500 and 2360 cm^{-1} with several splits (NH_2^+), and intensive absorptions at ~1760–1730 cm^{-1} (C=O) (Table III).

Common to all PMR spectra were CH_3 signals from NCH_2CH_3 as a triplet at ~1.3–1.4 ppm, both CH_2 absorptions due to CH_2NHCH_2 as a multiplet at 2.9–3.1 ppm, a multiplet between 5.0 and 5.5 ppm due to the CH proton from CHOH, and broad absorptions centered in the regions of 5.7–5.8 ppm (OH) and 9.0–9.2 ppm (NH). The latter absorptions disappeared on treatment with deuterium oxide. The absorptions of the *m*-disubstituted phenyl-ring protons and those due to the R group are summarized in Table III.

The mass spectra of IV*a*–IV*s* contained the molecular ions of the free amines and peaks at M − 18 (H_2O) with low intensity. In addition, diagnostic fragments appeared in all cases at *m/e* 162[1] (M − H_2O − RCO) and 134[2] (M − H_2O − RCO − CO). The dominant ions at *m/e* 58

($CH_2NHC_2H_5$, mostly base peak) and *m/e* 30 (CH_2NH_2) were due to characteristic amine fragmentations. Furthermore, all mass spectra, with the exception of IV*h* and IV*q*, showed typical fragment ions (R, RCO, or RCOH) from ester cleavage (Table III).

Table II illustrates that the high water solubility of the etilefrine hydrochloride was hardly influenced by introducing short aliphatic acyl radicals (IV*a*–IV*e*). Surprisingly, water solubility was reduced markedly whenever the acyl radical was highly branched (IV*f* and IV*g*). While araliphatic acyl radicals still led to sufficient solubility in water (IV*j*, IV*l*, and IV*m*), this was no longer the case either with very long aliphatic acyl radicals (IV*h*) or with aromatic acyl radicals that carry some substituents (IV*p*–IV*r*) at the nucleus.

Phenolethanolamines in solution represent a mixture of the uncharged form and ionic species (cation, anion, and zwitterion) (16). At half-neutralization, these components are in a specific equilibrium, which is represented by an apparent average pKa value. The pKa value is dependent on the substituent at the amino nitrogen and is increased from 8.67 (norfenefrine) (17) to 8.89 (phenylephrine) (17) or 9.0 (etilefrine) (18) for the 3′-hydroxyphenylethanolamines when introducing a methyl or ethyl radical into the amino group. The same value also was obtained for etilefrine in 1.5×10^{-3} *M* aqueous solution (Table II).

When the phenolic hydroxyl group is lost, the participating components of the dissociation equilibrium are reduced to the uncharged form and the ammonium compound. This results in a change of the pKa value (17). As shown by the pKa values of the acyl derivatives (IV*a*–IV*f*) in aqueous solution, the same effect can be observed when the phenolic hydroxyl group is masked with an acyl radical. However, in methanolic solution, the pKa values decreased from 9.4 (water) to 8.7 (90.7% methanol). The pKa values of IV*g*–IV*s* could not be ascertained because of insufficient solubility, although some of these compounds, being hydrochlorides, would be easily water soluble (IV*j*, IV*l*, and IV*m*). However, considering that all acyl derivatives in water–methanol (9.3:90.7) showed identical pKa values, it is assumed that the pKa value of 9.4 found for IV*a*–IV*f* in water would be the same for IV*g*–IV*s*.

As suggested by the pKa values, 2.45% of the etilefrine and 0.99% of the acyl derivatives (IV*a*–IV*s*) are present in aqueous solution of pH 7.4 in the uncharged form. Judging by the partition coefficient, 2.1% of etilefrine was present in the lipophilic phase. This value closely corresponds

Table II—Physical Properties and Hydrolysis Rates of Etilefrine 3′-(*O*-Acyl) Derivatives

Compound (as Hydrochloride)	Solubility[a]		pKa[b]		log *P* in *n*-Octanol–Buffer[c]	Hydrolysis Rates[d], μl of CO_2		
	Percent	*M*	Water[e]	Water–Methanol[f] (9.3:90.7)		Human Blood[g]	Rat Blood[g]	Rat Liver[h]
Etilefrine	75	3.4	9.0	8.9	−1.66			
IV*a*	60	2.3	9.4	8.7	−1.57	57.5	44	182

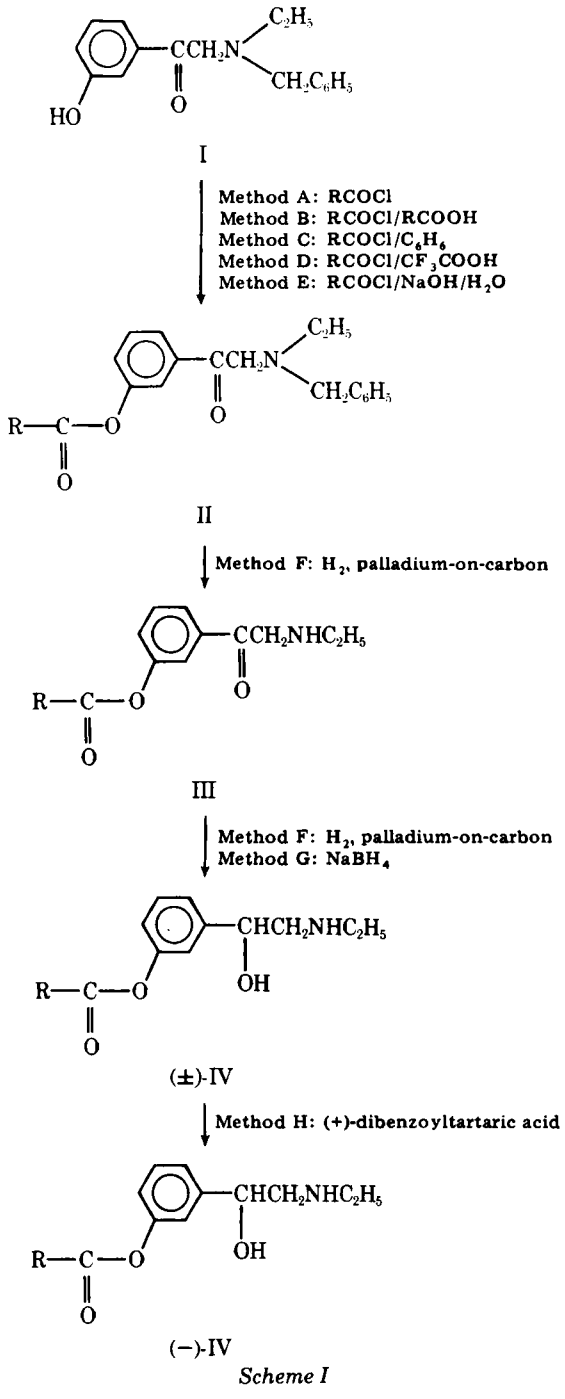
[a] In water; accuracy of ±5%. [b] Accuracy of ±0.05 pK unit. [c] Phosphate buffer, pH 7.4, 0.15 *M*; initial concentrations = 1.0×10^{3}–1.8×10^{3} *M*. [d] Substrate concentration of 10^{-2} *M*. [e] $c = 1.5 \times 10^{-2}$ *M*. [f] $c = 2 \times 10^{-2}$ *M*. [g] Blood (30 μl) and substrate (30 μmoles) in 2.5×10^{-2} *M* $NaHCO_3$ (2970 μl). [h] A suspension of a liver homogenate (60 μl) and substrate (30 μmoles) in 2.5×10^{-2} *M* $NaHCO_3$ (2940 μl). [i] Not determinable because of poor solubility of the base.



Scheme I

to the existing amount of the uncharged form of etilefrine. A similar lipophilicity was shown by IV*a*, although the addition of an acetyl radical in the molecule would suggest an increase. However, since IV*a* has a higher pKa value than etilefrine itself, its normally higher lipophilicity is reduced because of the higher dissociation at pH 7.4. With increasing lipophilicity of the acyl moiety (IV*b*–IV*s*), the amount of ionized acyl etilefrine in the lipophilic phase is augmented.

The experimentally determined Δ log P values of homologs are in most cases in reasonable agreement with the reported π values (19–23). However, in some cases (IV*a*/IV*b*, IV*c*/IV*e*, and IV*j*/IV*k*), considerable discrepancies were observed. This finding is attributed to the fact that the Hansch π value system will falter whenever aliphatic groups are near a very polar moiety such as the carbonyl function.

On the basis of log P values found through experimentation, it is evident that the lipophilicity increases with the chain length (IV*b* < IV*c* < IV*e* < IV*h*). However, the lipophilicity of the *n*-acyl derivatives is not necessarily higher than that of the *iso*-acyl compounds (IV*c* < IV*d*). A similar inconsistency was observed for the 5′-(*O*-acyl) derivatives of 9-β-D-arabinofuranosyladenine (24). The levorotatory form of the pivaloyl derivative (IV*g*) showed no difference compared to the racemate (IV*f*). Even the change of position of a methyl substituent in the benzoyl radical (IV*n* and IV*o*) did not alter the lipophilicity.

After absorption through the gut wall, orally administered substances are transported by the blood into the liver by way of mesentery veins and the vena portae. Through this passage, the 3′-(*O*-acyl) derivatives of etilefrine are protected from attacking conjugating enzymes, provided they do not become subject to esterase-catalyzed hydrolysis. To obtain better insight into the cleavage, tests were conducted with these esters in diluted rat and human blood and in rat liver homogenate.

The rate of enzymatic hydrolysis of the aliphatic acyl radicals decreased in human blood with increasing alkyl chain length (IV*a* > IV*b* > IV*c* > IV*e*) or when the radical was highly branched (IV*c* > IV*f* = IV*g*) (Table II). In most cases, rat blood was slightly less active in hydrolyzing acyl radicals than was human blood, but the deviations in general were rather low. However, there was one exception. The phenyl acetyl derivative (IV*j*) was hydrolyzed extremely rapidly by rat blood, probably due to a specific esterase in this species. The hydrolysis carried out by the enzymes of the rat liver was much faster and was nearly the same with the aliphatic acyl radicals, whereas compounds with araliphatic or aromatic acyl radicals were split up according to their steric hindrance in the blood as well as in the liver. Thus, the hydrolysis rate was decreased as the size of the aromatic system of the araliphatic acyl derivatives was enlarged (IV*j* > IV*m*) or the length of the alkyl radical grew (IV*j* > IV*k* > IV*l*). For the aromatic acyl radicals, the splitting rate was reduced considerably if substituents were introduced at position 2 or positions 2 and 6 (IV*n* > IV*o* > IV*q*). Due to insufficient solubility in 2.5×10^{-2} *M* $NaHCO_3$, hydrolysis rates of IV*h*, IV*p*, IV*r*, and IV*s* could not be ascertained enzymatically.

As the data in Table II illustrate, the 3′-(*O*-acyl) derivatives of etilefrine can differ by over 100-fold with respect to solubility, lipophilicity, and enzymatic cleavage. In selecting a prodrug with improved bioavailability after oral administration, the following criteria are decisive: (*a*) sufficient solubility and enhanced lipophilicity for accelerated absorption; (*b*) very reduced enzymatic hydrolysis during absorption, thus giving improved protection against conjugation; and (*c*) extensive enzymatic hydrolysis while passing through the liver, resulting in the fast release of drug activity.

Judging by the cleavage through hepatic enzymes, the aliphatic acyl derivatives (IV*a*–IV*g*) are superior to IV*h*[3]–IV*s*. Of these compounds, IV*e*–IV*g* promise more accelerated absorption than etilefrine due to their 70 times greater lipophilicity. Since the pivaloyl derivative (IV*f*) exhibits a hydrolysis rate in the blood of less than one-fifth of that of IV*e* and possesses a solubility six times higher than that of IV*g*, IV*f* was preferred. Comparative absorption studies with dogs[4] and humans[5] confirmed the superiority of this compound to etilefrine. As shown with tritium-labeled material, the absorption rate was increased with dogs[4] and humans[5] when a pivaloyl radical was introduced, and bioavailability was increased by 46%[5].

Investigations of the pharmacological properties of etilefrine pivalate will be discussed elsewhere.

EXPERIMENTAL[6]

Chemical Methods—*Method A/F: Etilefrine 3′-Pivalate (IVf) Hydrochloride*—A mixture of I·HCl (30.6 g, 0.1 mole) in pivaloyl chloride (60.3 g, 0.5 mole) was stirred and heated slowly to 106° with an increasing rate of hydrogen chloride evolution. The suspension was maintained at

[3] After completion of these studies, results of comparative pharmacokinetic investigations on etilefrine and its stearoyl derivative (IV*h*) were published (25). It was shown that introduction of the stearoyl radical reduced the bioavailability of etilefrine by 49%.

[6] All melting points were obtained using a Mettler FP 1 melting-point apparatus and are uncorrected. Microanalyses were carried out at the Analytical Laboratories, 5279 Gummersbach, West Germany. Purity of intermediates not subjected to elemental analysis was ascertained by TLC performed on Merck silica gel 60 F_{254}. Spots were located under UV light or with iodine vapor. Solvent mixtures used for TLC were chloroform–methanol–water (59:33:8) (Solvent A), chloroform–methanol–water (90:9:1) (Solvent B), and chloroform–methanol (98:2) (Solvent C).

UV absorption curves were recorded on a Beckman ACT A III UV–visible spectrophotometer. IR spectra were run on a Perkin-Elmer model 257 spectrophotometer, and PMR spectra were determined on a Varian EM 360 spectrometer. Mass spectra were obtained from a Varian MAT 112 S spectrometer using a direct-sample insertion system and ionization by electron impact (70 ev). Optical rotations were measured with a Schmidt-Haensch (model Polartronic I) electronic polarimeter. The pH values were obtained using a Metrohm A 603 pH meter.

Table III—Spectral Data for Etilefrine 3′-(*O*-Acyl) Derivatives

Compound (as Hydrochloride)	IR[a], $\nu_{C=O}$	PMR[b] Solvent	PMR[b] δ for $RCOOC_6H_4$—	Mass Fragmentations, *m/e* (relative intensity, %)
IV*a*	1760	A	1.38 (t, 3H, CH_3) and 6.73–7.53 (m, 4H, aromatic H)	223 (M^+, 0.1) and 43 (8)

[a] IR spectra were run in potassium bromide, and absorption values are in reciprocal centimeters. [b] PMR spectra were run at 60 MHz in deuterochloroform (A), methanol-d_4 (B), or dimethyl sulfoxide-d_6 (C), and chemical shifts (δ) are given in parts per million relative to tetramethylsilane as the internal standard. Multiplicities of the peaks are expressed as singlet (s), doublet (d), triplet (t), quartet (q), and multiplet (m).

this temperature until the starting material went into solution; the temperature then was raised to 110° and maintained there until cessation of gas evolution (~2 hr). After evaporation of the remaining pivaloyl chloride, the residue was dissolved in methanol (30 ml) and poured into petroleum ether (700 ml). The precipitate, R_f 0.8 on TLC (Solvent B), was filtered, dissolved in isopropanol–water (330 ml), and hydrogenated in the presence of 10% palladium-on-carbon (3.3 g) at room temperature and normal pressure until the calculated amount of hydrogen had reacted (about 3 hr). After removal of the catalyst and then the solvent by vacuum evaporation, the residue was crystallized from isopropanol to give 19.6 g (65%) of IV*f*·HCl, mp 209.4°, R_f 0.4 (Solvent A).

Anal.—Calc. for $C_{15}H_{23}NO_3$·HCl: C, 59.69; H, 8.01; N, 4.64. Found: C, 59.69; H, 7.91; N, 4.39.

*Method B/F: Etilefrine 3′-(2-Methylpropionate) (IV*d*) Hydrochloride*—A suspension of I·HCl (30.6 g, 0.1 mole) in 2-methylpropionyl chloride (85.2 g, 0.8 mole) and 2-methylpropionic acid (85 ml) was stirred and heated slowly until the starting material went into solution; then the mixture was refluxed for 0.5 hr. After evaporation to dryness, the residue, R_f 0.8 on TLC (Solvent B), was reprecipitated and hydrogenated under the same conditions as described for the preparation of IV*f*·HCl to give 16.4 g (57%) of IV*d*·HCl after crystallization from isopropanol, mp 159.8°, R_f 0.4 (Solvent A).

Anal.—Calc. for $C_{14}H_{21}NO_3$·HCl: C, 58.43; H, 7.71; N, 4.87. Found: C, 58.48; H, 7.59; N, 4.85.

*Method C/F: Etilefrine 3′-(2,4,6-Trimethylbenzoate) (IV*p*) Hydrochloride*—A mixture of I·HCl (30.6 g, 0.1 mole) in 2,4,6-trimethylbenzoyl chloride (36.5 g, 0.2 mole) and benzene (20 ml) was refluxed for 1.5 hr. The mixture was extracted at room temperature with petroleum ether. The bottom layer was separated and evaporated under reduced pressure. The residue, R_f 0.8 on TLC (Solvent B), was dissolved in isopropanol–water (450 ml) and hydrogenated in the presence of 10% palladium-on-carbon (11.0 g) in the same manner as described for the preparation of IV*f*·HCl to give 28.0 g (77%) of IV*p*·HCl after recrystallization from methanol–ether, mp 180.1°, R_f 0.4 (Solvent A).

Anal.—Calc. for $C_{20}H_{25}NO_3$·HCl: C, 66.01; H, 7.20; N, 3.85. Found: C, 65.96; H, 7.10; N, 3.81.

*Method D/F: Etilefrine 3′-(4-Methylbenzoate) (IV*n*) Hydrochloride*—To a suspension of I·HCl (30.6 g, 0.1 mole) in trifluoroacetic acid (39.9 g, 0.35 mole) was added 4-methylbenzoyl chloride (30.9 g, 0.2 mole) over 0.5 hr with vigorous evolution of hydrogen chloride. The mixture was refluxed for 1.5 hr. The volatile portion was distilled off under vacuum, and the residue was stirred in ether. The precipitate was poured into a mixture of ether (500 ml) and water (100 ml). After cooling, the two-phase system was adjusted to pH 9 with cold ammonium hydroxide. The organic layer was separated and washed twice with cold 1 *N* NaOH (400 ml) and water (400 ml). After removal of the solvent under vacuum, the residue, R_f 0.8 on TLC (Solvent B), was dissolved in isopropanol–water (300 ml), acidified to pH 2 with hydrochloric acid, and hydrogenated in the presence of 10% palladium-on-carbon (6.5 g) in the same manner as described for the preparation of IV*f*·HCl to give 13.8 g (41%) of IV*n*·HCl after recrystallization from methanol–ether, mp 190.1°, R_f 0.4 (Solvent A).

Anal.—Calc. for $C_{18}H_{21}NO_3$·HCl: C, 64.38; H, 6.60; N, 4.17. Found: C, 64.43; H, 6.56; N, 4.17.

*Method D/F/G: Etilefrine 3′-(2,6-Dichlorobenzoate) (IV*r*) Hydrochloride*—A mixture of I·HCl (30.6 g, 0.1 mole) and 2,6-dichlorobenzoyl chloride (42.0 g, 0.2 mole) in trifluoroacetic acid (114.0 g, 1 mole) was stirred and heated slowly to 80° with an increasing rate of hydrogen chloride evolution. Then the mixture was refluxed for 1.5 hr. After evaporation of the volatile portion, the oily residue was poured into a mixture of ice and ammonium hydroxide and extracted twice with ether (500 ml). The organic layer was separated and washed with cold 1 *N* NaOH and water. The solvent was evaporated to give 23.0 g (52%) of 3′-hydroxy-2-(benzylethylamino)acetophenone 3′-(2,6-dichlorobenzoate) (II*r*) as an oil, R_f 0.9 (Solvent B).

A solution of II *r* (23.0 g, 0.052 mole) in methanol–water (9:1, 300 ml) was adjusted to pH 2 with hydrochloric acid and then hydrogenated in the presence of 10% palladium-on-carbon (2.3 g) at room temperature and atmospheric pressure until 1 equivalent of hydrogen had reacted. After the catalyst and then the solvent were removed by vacuum evaporation, the residue was crystallized from methanol–isopropanol to give 12.0 g (60%) (31% referenced to I·HCl) of 3′-hydroxy-2-(ethylamino)-acetophenone 3′-(2,6-dichlorobenzoate) (III*r*) hydrochloride, mp 170° dec., R_f 0.85 (Solvent A). The PMR and IR spectral data supported the assigned structure.

Sodium borohydride (4.0 g) was added in portions to a mixture of III*r*·HCl (12.0 g, 0.031 mole) in dry methanol (200 ml) over 1 hr while the temperature of the reaction was kept below 5°. Excess sodium borohydride was destroyed by the addition of acetic acid. After evaporation to dryness, the residue was suspended in diluted ammonium hydroxide (200 ml) and extracted with ether. The organic layer was separated, washed with water, and evaporated to dryness. The residue was dissolved in isopropanol–water (9:1, 400 ml), acidified to pH 2 with hydrochloric acid, and concentrated. The solid residue was crystallized with methanol–ether to give 10.5 g (87%) (27% referenced to I·HCl) of IV*r*·HCl, mp 190.2°, R_f 0.4 (Solvent A).

Anal.—Calc. for $C_{17}H_{17}Cl_2NO_3$·HCl: C, 52.26; H, 4.64; N, 3.59. Found: C, 52.35; H, 4.63; N, 3.58.

Method E/F: Etilefrine 3′-Stearate (IVh) Hydrochloride—A mixture of I·HCl (30.6 g, 0.1 mole) and stearoyl chloride (33.3 g, 0.11 mole) in 1 *N* NaOH (250 ml) was stirred at ambient temperature for 1 hr. The mixture was extracted with ether, and the organic layer was washed with 1 *N* NaOH and water.

After removal of the solvent under reduced pressure, the waxy residue, R_f 0.8 on TLC (Solvent C), was taken up in methanol (1 liter) and adjusted to pH 2 with hydrochloric acid. The mixture was hydrogenated in the presence of 10% palladium-on-carbon (10.0 g) at 40° and atmospheric pressure until the calculated amount of hydrogen had reacted. After the catalyst and solvent were removed by vacuum evaporation, the residue was crystallized from methanol–ether to give 29.1 g (60%) of IV*h*·HCl, mp 117.4°, R_f 0.5 (Solvent A).

Anal.—Calc. for $C_{28}H_{49}NO_3$·HCl: C, 69.46; H, 10.41; N, 2.89. Found: C, 69.82; H, 10.27; N, 2.77.

Method H: (−)-Etilefrine 3′-Pivalate (IVg) Hydrochloride—To a mixture of IV*f*·HCl (301.8 g, 1 mole) in water (2.7 liters) and (+)-*O,O*-dibenzoyltartaric acid monohydrate (188.0 g, 0.5 mole) in methanol (2.7 liters) was added sodium bicarbonate (42.0 g, 0.5 mole) at room temperature. The solution was cooled slowly to 2° and maintained at this temperature for 5 days. The white crystalline precipitate was filtered off and washed with cold methanol–water (1:1). This product was recrystallized (13 times) from methanol–water (55:45) until the optical rotation remained constant. The yield was 39.1 g of (−)-etilefrine 3′-pivalate (+)-*O,O*-dibenzoylhydrogentartrate, mp 163.5° dec., $[\alpha]_D^{20}$ +55.3° (*c*, 1 in methanol).

This product was dissolved in methanol–water (9:1, 200 ml), acidified to pH 2 with hydrochloric acid, and concentrated. The residue was crystallized with methanol–ether to give 18.1 g of IV*g*·HCl (6%) referenced to IV*f*·HCl, mp 225°, R_f 0.4 (Solvent A), $[\alpha]_D^{20}$ −36.7° (*c*, 1 in methanol).

Anal.—Calc. for $C_{15}H_{23}NO_3$·HCl: C, 59.69; H, 8.01; N, 4.64. Found: C, 59.72; H, 7.98; N, 4.58.

Determination of Solubility—An excess of each compound (100–1000 mg weighed accurately) was stirred in a portion of water at room temperature for 1 hr. Additional portions of water were added at 1-hr intervals until the entire sample was dissolved under stirring. The percentage solubility, *S*, was calculated according to:

$$S(\%) = \frac{\text{weight}_{\text{sample}}}{\text{weight}_{\text{solution}}} \times 100 \qquad \text{(Eq. 1)}$$

Measurement of pKa Values—The pKa values listed in Table II were determined by measuring the pH of a solution containing equivalent concentrations of the amine and its salt. These solutions were obtained by adding to a solution of the salt the calculated amount of aqueous 0.1 *N* NaOH for half-neutralization. The concentrations of the compound were 1.5×10^{-3} *M* in water and 2×10^{-2} *M* in water–methanol. For IV*g*–IV*s*, which were insufficiently soluble in water at the point of half-neutralization, aqueous solutions were made up to contain 90.7% methanol at half-neutralization. The pH values were measured using a pH meter with a digital scale at room temperature. The results were estimated to be accurate to ±0.05 pK unit.

The percentage of the protonated form, $[BH]^+$, at pH 7.4 is expressed by:

$$[BH]^+(\%) = \frac{100}{1 + \text{antilog}\,(7.4 - \text{pKa})} \qquad \text{(Eq. 2)}$$

Measurement of Partition Coefficients—For the partitioning, pure *n*-octanol saturated with 0.15 *M* phosphate buffer (pH 7.4) and phosphate buffer saturated with *n*-octanol were used. Normally, 20–40-mg samples were dissolved in the buffer solution (50 ml) and shaken with the *n*-octanol solution (50–600 ml) at room temperature for 0.5 hr. After centrifugation, an aliquot of the bottom layer was removed and diluted to give an absorbance range of 0.2–0.7, measured at the absorption maximum of the compounds (206–223 nm) using a 1-cm cell. A standard curve of at least four points was used for each sample to determine the concentration in the bottom layer. Multiple analyses showed the data in Table II to be reproducible. The partition coefficient, *P*, was calculated from:

$$P = \frac{V_{\text{buffer}}}{V_{n\text{-octanol}}} \left(\frac{C_{\text{buffer},\,i}}{C_{\text{buffer},\,f}} - 1 \right) \qquad \text{(Eq. 3)}$$

The first factor in Eq. 3 is the ratio of the volumes of the buffer and *n*-octanol used for partitioning of the sample. The second factor contains the ratio of the initial to the final concentration in the buffer layer, as determined by readings of the absorbance in the UV region.

Determination of Enzymatic Ester Cleavage—The Warburg manometric technique was used as described by Ammon (26). Blood was obtained from one healthy female volunteer and from rats (female Wistar, 180 g). One part of rat liver (female Wistar, 180 g) was homogenized in one part of buffer (2.5×10^{-2} *M* $NaHCO_3$).

Heparinized blood (30 μl) or rat liver homogenate (60 μl) diluted with buffer to 300 μl was pipetted into the side arm, and the solution of the respective ester substrate in the buffer (30 μmoles/2700 μl) was put into the main trough of the calibrated reaction vessels. After equilibration for 10 min with a stream of nitrogen and carbon dioxide (95:5), the vessels were closed, and the reaction was started by mixing the enzyme preparation with the substrate–buffer solution. Readings were taken at 5-min intervals for up to 1 hr, corrected for volume and actual atmospheric pressure, transformed into volume units, and plotted as microliters of carbon dioxide against time. The plotted curves were idealized graphically and adjusted for spontaneous hydrolysis as determined in the control vessels without the addition of enzymes. With some sparingly water-soluble substrates, stock solutions were obtained with pure ethanol. With final ethanol concentrations not exceeding 5%, no inhibition of esterase activities was recorded.

Pharmacokinetics of Oral and Intravenous Fluorouracil in Humans

THOMAS A. PHILLIPS *§, ANTHONY HOWELL ‡, ROBERT J. GRIEVE ‡, and PETER G. WELLING *§x

Received April 16, 1980, from the *Departments of *Clinical Pharmacology and ‡Medicine, School of Medicine, University of Birmingham, Birmingham, England.* Accepted for publication June 25, 1980. §Present address: School of Pharmacy, University of Wisconsin, Madison, WI 53706.

Abstract □ The pharmacokinetics of fluorouracil were examined after single 250-mg iv doses and 500-mg oral doses to female patients with breast cancer. In five patients who received intravenous fluorouracil, the mean peak plasma level of unchanged drug was 13.4 μg/ml, the elimination half-life was 6.3 min, and the plasma clearance was 1410 ml/min. The last value is similar to the hepatic blood flow. In six patients who received oral fluorouracil, the mean peak value of unchanged drug in plasma, which occurred within 20 min of dosing, was 8.3 μg/ml, and the fluorouracil elimination half-life was 7.2 min. The overall bioavailability of oral fluorouracil as unchanged drug was 28%, and the variation in plasma drug levels between individuals was similar following oral and intravenous doses. The data provide additional evidence of saturable hepatic metabolism of fluorouracil during the first pass.

Keyphrases □ Fluorouracil—comparison of oral and intravenous doses pharmacokinetics, human plasma □ Pharmacokinetics—fluorouracil levels in human plasma following intravenous and oral doses □ Antineoplastic activity—fluorouracil, pharmacokinetics, human plasma

The pharmacokinetics of fluorouracil following intravenous administration to humans have been characterized (1–4). The drug distributes into an apparent body volume equivalent to 25% of the body weight and is cleared rapidly from the circulation, principally due to metabolism, with a half-life of 5–15 min. The high plasma clearance of fluorouracil suggests that considerable first-pass metabolism occurs following oral administration (5).

Reports on the availability of orally dosed fluorouracil to the general circulation are conflicting. Cohen *et al.* (1) reported 50 and 80% absorption in two patients, while other investigators reported much lower absorption (6). A recent study suggested that the availability of fluorouracil increases with increasing dose (2), which may be due to saturation of the initial degradative metabolic step in the liver (7).

The circulating levels of fluorouracil in patients receiving relatively low single doses of fluorouracil by the intravenous and oral routes were examined. The description of these data and comparisons with previous reports are the subjects of this paper.

EXPERIMENTAL

Subjects and Protocols—The subjects were 11 female patients undergoing therapy for breast carcinoma, postmastectomy, as outpatients at the Selly Oak Hospital, Birmingham, England. Characteristics of the subjects and diagnostic information are given in Table I. The subjects were ambulatory and were taking solid food. They were being treated under the conditions of a multicenter trial to examine the benefits of cyclic adjuvant chemotherapy in both node-positive and node-negative operable breast cancer. Node-positive patients received fluorouracil by intravenous injection; node-negative patients were dosed orally.

The medication received by the two groups of subjects is summarized in Table II. Since each subject received either oral or intravenous fluorouracil, it was not possible to examine fluorouracil kinetics after oral and intravenous doses in the same person.

All fluorouracil doses were administered at the hospital in the presence of the attending physician. Intravenous doses of 250 mg of fluorouracil were administered in 5 ml of water for injection into a forearm vein over 30 sec. Oral doses of 500 mg of fluorouracil were administered in 10 ml of water for injection followed immediately by 90 ml of orange juice. No dietary restrictions were applied. Since subjects had to travel from their homes to the hospital to receive the fluorouracil doses, an interval of at least 1 hr elapsed between eating and dosing.

Blood samples (10 ml) were taken from a forearm vein in the arm, not used for drug administration in the intravenous study, and were placed in heparinized tubes. Plasma was promptly separated and stored at −20° until it was assayed.

Assay—Fluorouracil was extracted from plasma by the method described previously (3). The high-pressure liquid chromatographic (HPLC) system consisted of a 25-cm × 4-mm (10-μm particle size) column[1] preceded by a 5-cm × 4-mm (10-μm particle size) guard column[2], a constant-volume pump[3], and a variable-wavelength detector[4] set at 265 nm. The solvent was 10^{-2} *M* phosphate buffer (pH 5.5) at a flow rate of 2 ml/min.

Uridine was used as the internal standard since it had a shorter retention time in this system than thymidine (3). Dried residues from extracted plasma were redissolved in 200 μl of 5% methanol in water, and 50 μl of this solution was injected into the chromatograph. Fluorouracil was measured by the peak height ratio method against uridine. Using this procedure, the retention volumes for fluorouracil and uridine were 11 and 21 ml, respectively, and the time required to analyze each sample was reduced from 30 (3) to 11 min. The method had similar sensitivity and reproducibility for fluorouracil to those reported previously (3). The lower limit of detection was 0.1 μg/ml, and neither commonly occurring nucleosides nor drugs other than fluorouracil being taken by the subjects interfered with the chromatographic peaks of fluorouracil or uridine.

All pharmacokinetic parameters were obtained by standard graphical procedures (9). All rate constants were calculated by linear regression of the natural logarithm of the fluorouracil concentration against time. In the intravenous studies, the value of C_0 was corrected for the 30-sec fluorouracil injection time. In the oral studies, it was not possible to obtain a value for the absorption rate constant for Patient MD because of the absence of data during the absorption phase of the plasma fluorouracil profile.

Fluorouracil standard[5] and uridine[6] were used as received. All other chemicals and reagents were of the highest grade available and were used as received.

RESULTS

Individual plasma levels of fluorouracil obtained from the intravenous and oral doses are given in Table III, and the mean values from the two dosage forms are summarized in Fig. 1. The results of the pharmacokinetic analysis are described in Table IV.

Following intravenous dosing, plasma fluorouracil levels at the 5-min sampling varied from 6.4 to 29.5 μg/ml with a mean value of 13.4 μg/ml. Drug levels declined monoexponentially between 5 and 45 min and had returned to baseline values by 60 min. The mean half-life of fluorouracil in plasma was 6.3 min, the mean distribution volume was 0.2 liter/kg, and the plasma clearance was 1410 ml/min.

Following oral dosing, peak plasma levels of fluorouracil ranged from 4.4 to 14.3 μg/ml with a mean value of 8.3 μg/ml and occurred 10–20 min postdosing. The mean half-life of drug elimination was 7.2 min, statis-

tically indistinguishable from the equivalent value after intravenous dosing, while the absorption half-time was 3.4 min. This value was obtained by conventional curve-stripping procedures assuming first-order absorption and elimination (9) and indicates fast absorption of fluorouracil under the conditions employed in this study. The absorption phase was essentially complete within 20 min of dosing.

The ratio of the mean areas under the plasma fluorouracil curves from the oral and intravenous doses, corrected for the individual elimination rate constants (Table IV), provides a measure of the efficiency with which fluorouracil is absorbed from the oral dose as unchanged drug (10). The

[a] The notations are: k_a, first-order rate constant for drug absorption; $t_{1/2a}$, half-time for absorption; k_{el}, first-order rate constant for drug elimination; $t_{1/2el}$, half-life of elimination; C_0, concentration at time zero obtained by extrapolation of plasma fluorouracil levels after intravenous dosing; C_{max}, maximum concentration of fluorouracil in plasma after oral dosing; t_{max}, time at which C_{max} occurs; AUC, area under fluorouracil concentration *versus* time curve in plasma calculated by the trapezoidal rule; $AUCk_{el}$, area corrected for variance in k_{el}; V, apparent distribution volume of fluorouracil in the body obtained from V = dose/C_0; and Vk_{el}, plasma clearance of fluorouracil. [b] Not determined.

mean corrected area from the oral dose of 500 mg is 15 μg/ml, while that from the intravenous dose is 27 μg/ml. Correction for dose size yields a ratio of 0.28, indicating an average fluorouracil availability of 28% from the oral dose.

DISCUSSION

The plasma levels of fluorouracil obtained from the intravenous dose in this study are comparable to those obtained previously (1–3). The mean distribution volume for fluorouracil of 0.2 liter/kg and the plasma clearance of 1410 ml/min are consistent with previously reported values of 0.35 liter/kg and 1441 ml/min obtained in three patients (2) and of 0.25 liter/kg and 1265 ml/min obtained in eight patients (3).

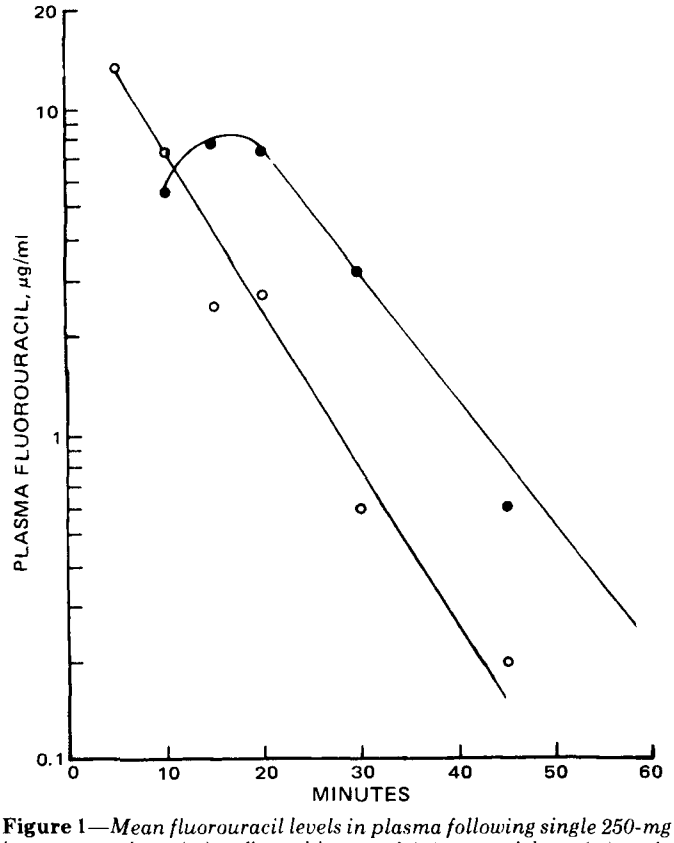

Figure 1—*Mean fluorouracil levels in plasma following single 250-mg intravenous doses (○) to five subjects and 500-mg oral doses (●) to six subjects.*

Although the overnight methotrexate infusion in these patients was terminated 1 hr before the fluorouracil dose, circulating levels of methotrexate still would be present at the time of fluorouracil dosing and could have affected the circulating levels of fluorouracil. However, due to the relatively low dose of methotrexate and the low binding of both compounds to plasma proteins (2, 11), direct interaction between these drugs in plasma, which might influence fluorouracil distribution, is unlikely.

Previous reports suggested that absorption of fluorouracil from oral dosage forms is extremely variable (6, 7). Clarkson *et al.* (12) reported a two- to 10-fold reduction in the initial plasma fluorouracil levels in patients after oral doses compared to equivalent intravenous doses. Finn and Sadée (13) also obtained variable plasma levels of fluorouracil after oral administration to three patients with colon cancer, with peak drug levels varying between 0.8 and 60 μg/ml. However, in two patients, the circulating levels of fluorouracil were prolonged relative to those after intravenous dosing. Other studies demonstrated efficient absorption of oral fluorouracil (1, 14), which has been associated with high and prolonged drug levels in plasma and bile. High fluorouracil levels in bile after oral doses may be particularly advantageous in treating hepatic metastases and tumors of the biliary tree (14).

Cohen *et al.* (1) suggested that the nature of fluorouracil absorption may depend on the vehicle with which the drug is administered but also may be influenced by the degree of hepatic involvement. Their data suggested that patients with hepatic tumor or metastases achieve lower but more prolonged circulating levels of fluorouracil than patients with no hepatic involvement. This theory was supported partially by Finn and Sadée (13), who obtained prolonged plasma levels of fluorouracil in patients with hepatic involvement, and by Garrett *et al.* (2), who obtained a similar disappearance rate for fluorouracil from plasma after oral and intravenous doses to patients with relatively normal liver function. In the latter study, fluorouracil absorption as unchanged drug was more efficient from a 1000-mg oral dose than from a 500-mg dose in two individuals, suggesting saturable metabolism of fluorouracil during the first pass (5).

The results obtained in the present study are consistent with the hypotheses (1, 2). Absorption of fluorouracil from the oral doses to subjects who had no discernible hepatic involvement was efficient and rapid. Although the clinical protocol prevented intravenous and oral doses being given to the same subjects, thus preventing direct comparisons within an individual, the plasma data nevertheless indicate that the oral dose was ~28% available as unchanged drug. This value is intermediate between the values of 1–15% reported by Garrett *et al.* (2) and of 50–80% reported by Cohen *et al.* (1) and provides further evidence that hepatic clearance of fluorouracil, which is similar to hepatic blood flow after parenteral doses (10), is highly saturable during the first pass.

Furthermore, the data obtained in this study indicate that circulating levels of oral fluorouracil may be as reproducible between individuals as

those obtained from intravenous doses. The apparent inconsistency between this observation and some earlier reports may be explained by the relatively homogeneous patient population used in this study and the heterogeneous (at least regarding the degree of hepatic involvement) patient group (1) or the very small numbers of subjects (2, 13) used previously. Considerable variability in circulating levels of fluorouracil also was reported following intravenous doses to male and female patients (4).

While it is recognized that the clinical effectiveness of fluorouracil is a complex function of the anabolic metabolism of fluorouracil and the biochemistry of cell death and cell resistance, the present results indicate that oral fluorouracil in this patient population is absorbed with reproducible efficiency, resulting in no greater variation in circulating drug levels than that following intravenous doses.

This observation may have important implications in fluorouracil treatment of patients with breast cancer, particularly in view of the relationship that exists between the patient response rate and circulating levels of fluorouracil (15).

NOTES

Structural Elucidation of Adducts Formed by Ninhydrin with Indoles and Thiourea by ^{13}C-NMR Spectroscopy

NITHIANANDA CHATTERJIE *[x], RALPH A. STEPHANI [‡], and CHARLES H. STROM [§]

Received January 28, 1980, from the **New York State Institute for Basic Research in Mental Retardation, Staten Island, NY 10314*, the [‡]*Department of Pharmaceutical Sciences, College of Pharmacy, St. John's University, Jamaica, NY 11439*, and the [§]*Department of Chemistry, New York University, New York, NY 10003.* Accepted for publication June 2, 1980.

Abstract □ Condensation products were prepared by the reaction of ninhydrin with indole and 2,5-dimethylindole. The structures of these 1:1 adducts were assigned as 3-(2-hydroxy-2-indane-1,3-dionyl)indole and 3-(2-hydroxy-2-indane-1,3-dionyl)-2,5-dimethylindole, respectively, on the basis of spectral data including ^{13}C-NMR evidence. ^{13}C-NMR also was used to confirm the structure of a thiourea–ninhydrin adduct as a substituted thioindeno[1,2-*d*]imidazole-2,8-dione.

Keyphrases □ Ninhydrin—condensation products with indoles and thiourea, structural elucidation by NMR spectroscopy □ Heterocyclic adducts—cyclic ureides, condensation products of ninhydrin with indoles and thiourea, structural elucidation by NMR spectroscopy □ NMR spectroscopy—structural elucidation of condensation products of ninhydrin with indoles and thiourea

Interest in the heterocyclic adducts formed between ninhydrin (triketohydrindene hydrate, I) and aromatic amines (1, 2) and enamines (3) led to the investigation of the reaction products of this reagent with certain aromatic compounds whose structure might contain an enamine moiety. The structures of indole and 1-naphthylamine could be visualized as such; the N-1, C-2, and C-3 positions of indole and the NH_2, C-1, and C-2 positions of 1-naphthylamine possess the enamine triad (4). It was found that 1-naphthylamine forms a stable pentacyclic adduct with I, whose mode of cyclization has not been definitely established (5).

BACKGROUND

The ready formation of a 1:1 adduct between I and indole was first reported by Tomita and Fukagawa (6). However, the structure assigned by these investigators involved attack of the C-2 position of indole at the masked, central carbonyl group of ninhydrin to give II. This is in contrast to the expected reactivity of the C-3 position in indole (7, 8).

The reaction between I and indole was repeated by Roth and Kok (9); a stable, yellow adduct (1:1) was obtained with the same melting point as reported previously (6). These investigators (9) reported this adduct

0022-3549/80/1200-1431$01.00/0

© 1980, American Pharmaceutical Association

those obtained from intravenous doses. The apparent inconsistency between this observation and some earlier reports may be explained by the relatively homogeneous patient population used in this study and the heterogeneous (at least regarding the degree of hepatic involvement) patient group (1) or the very small numbers of subjects (2, 13) used previously. Considerable variability in circulating levels of fluorouracil also was reported following intravenous doses to male and female patients (4).

While it is recognized that the clinical effectiveness of fluorouracil is a complex function of the anabolic metabolism of fluorouracil and the biochemistry of cell death and cell resistance, the present results indicate that oral fluorouracil in this patient population is absorbed with reproducible efficiency, resulting in no greater variation in circulating drug levels than that following intravenous doses.

This observation may have important implications in fluorouracil treatment of patients with breast cancer, particularly in view of the relationship that exists between the patient response rate and circulating levels of fluorouracil (15).

as having Structure III, based on the interpretation of the PMR spectrum. However, a warning concerning the assignment of C-2 or C-3 substitutions in indole indicates that the effects of concentration and solvent polarity should be considered (10) when structural interpretations based on PMR evidence are made. However, these considerations were not cited in the report of Roth and Kok (9).

To establish unambiguously the structures of III and the products derived from 2,5-dimethylindole, thiourea, and I, ^{13}C-NMR spectroscopy was employed in the present study. Interest in the latter adduct (11) stems from the cyclic ureide (V) formed between urea and I (2). The nucleophilicity of the sulfur in thiourea prompted determination of the mode of cyclization; this investigation sought to distinguish between IV and VI or its [1,2-*d*]-isomer.

EXPERIMENTAL[1]

Melting points are uncorrected. All carbon spectra were decoupled with a 1-kHz wide noise bandwidth. All spectra were obtained in deuterated dimethyl sulfoxide; chemical shifts are reported relative to tetramethylsilane as the internal standard. Mass spectra were obtained on a double-focusing instrument[2] equipped with an electron-impact (70 ev) source and a direct-sample introduction probe.

Synthesis of 3-(2-Hydroxy-2-indane-1,3-dionyl)-2,5-dimethylindole (VII)—2,5-Dimethylindole (14.5 g, 0.01 mole) was dissolved in hot methanol (50 ml). To this solution was added I (1.78 g, 0.01 mole) in methanol (30 ml). The reaction mixture was warmed for 1 hr (80°) with stirring and set aside overnight. A volume of water equal to approximately one-third of the solution volume was added, and the solution was warmed and set aside for 2.5 hr. The crystals were filtered, washed with hot water, and dried.

The product weighed 2.67 g (87.5%), mp 200–205° dec. Recrystallization from methanol–water gave golden-yellow crystals, mp 198–202° dec.; IR: 3375 (OH), 3275 (NH), 1700, and 1748 (C=O) cm^{-1}; PMR: δ 10.97 (s, 1H, NH), 8.05 (s, 4H, aromatic), 7.29–6.75 (m, 3H, indole), 6.54 (s, 1H, OH), 2.31 (s, 3H, CH_3), and 2.26 (s, 3H, CH_3) (upon addition of deuterated water, the signals at δ 10.97 and 6.54 were diminished); mass spectrum: *m/e* 305 (M^+, 80%).

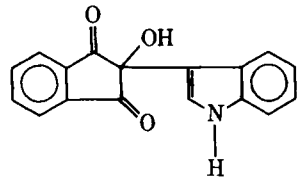
Anal.—Calc. for $C_{19}H_{15}NO_3$: C, 74.72; H, 4.95; N, 4.58. Found: C, 74.63; H, 4.92; N, 4.60.

Synthesis of 1,3,3a,8a-Tetrahydro-3a,8a-hydroxy-2-thioindeno[1,2-*d*]imidazole-2,8-dione (IV)—To 10 g of I (0.056 mole) in ~400 ml of hot water was added thiourea (4.25 g, 0.056 mole) dissolved in a minimum volume of water. The reaction mixture was stirred for 1 hr at 80°, cooled, and filtered. White crystals (12.0 g, 91%) were obtained, mp 236–240°. Recrystallization from water gave crystals with a melting point of 240–242°; IR: 3350–3100 (OH and NH) and 1715 (C=O) cm^{-1}; mass spectrum: *m/e* 236 (M^+, 100%).

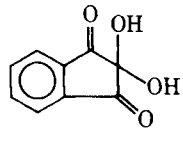
Anal.—Calc. for $C_{10}H_8N_2O_3S$: C, 50.85; H, 3.38; N, 11.86; S, 13.55. Found: C, 50.94; H, 3.44; N, 11.82; S, 13.66.

RESULTS AND DISCUSSION

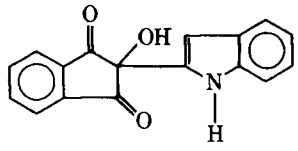
The carbon 13 chemical shifts of the carbon atoms of the adducts and some appropriate model compounds are shown in Tables I and II. Of critical significance are the peaks at 124.8 and 110.2 ppm, assigned to C-2′ and C-3′[3], respectively, of adduct III. This assignment is based on analogy



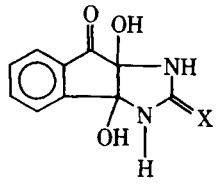
III



I



II



IV: X = S
V: X = O

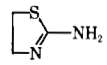
VIII: X = S	183.4
	


IX	159.0
V	158.3
IV	178.4

to the carbon 13 shifts assigned to simple C-2 and C-3 methylindoles shown in Table I. Such substituted carbons are shifted downfield by ~10 ppm. The data clearly indicate that this adduct is the 3-substituted indole (III). Similarly, the 2,5-dimethylindole–ninhydrin adduct was assigned Structure VII (Table I). In this case, the C-3′ position of the indole moiety absorbs at 110.0 ppm. The pertinent chemical shifts such as those of C-2′ are in agreement with those of the model compounds. This result also is consistent with the expected chemistry for a 2-substituted indole. In addition, the chemical shifts of the carbons in the indanedione moiety as shown in Table II support the structural assignments of adducts III and VII.

The reaction of I with thiourea in neutral aqueous solution gave a product that was assigned Structure IV. The C=S group previously has been difficult to identify positively by IR spectra (14). Moreover, the superior nucleophilicity of the thiocarbonyl sulfur over that of the nitrogen atom in this ambident nucleophile is well known (15, 16). Thus, the thiazoline structure (VI) could not be excluded since the PMR spectrum of the adduct in dimethyl sulfoxide-d_6 showed two exchangeable one-proton singlets at 9.70 and 9.48, a four-proton aromatic multiplet centered at 7.85, and a two-proton broad exchangeable singlet at 6.88, attributable to a primary amino group, as in VI, or two separate NH absorbances, as in IV (which have the same chemical shift).

These considerations necessitated examination of the ^{13}C-NMR data of this adduct along with closely related model compounds (Table III). Since the thiocarbonyl group in ethylenethiourea (VIII) absorbs at 183.4 ppm, and the corresponding carbon of 2-amino-2-thioazoline (IX) absorbs at 159.0, and the adduct in question absorbs at 178.4 (C=S), one concludes that this adduct has a thioureide structure (IV). In addition, a change from ureidocarbonyl to thiocarbonyl produces a downfield shift of ~18–20 ppm. This result is in accord with the differences in the chemical shift of C-2 (thiocarbonyl *versus* carbonyl) in uracil (17), V *versus* IV, and ethyleneurea (X) *versus* ethylenethiourea (VIII) in Table III.

Khellin Determination in Human Serum and Urine by High-Performance Liquid Chromatography

ADNAN EL-YAZIGI [x] **and SOBHI A. SAID** *

Received March 27, 1980, from the *Department of Pharmaceutics, College of Pharmacy, University of Riyad, Riyad, Saudi Arabia.* Accepted for publication June 2, 1980. *On leave from Cairo University, Cairo, Egypt.

Abstract □ A rapid, sensitive, and specific high-performance liquid chromatographic method was developed for the determination of khellin in serum and urine using theophylline as the internal standard. Chromatography was performed on a reversed-phase C_{18} column with 65% (v/v) methanol as the mobile phase. The assay is capable of measuring khellin concentrations down to 100 ng/ml with a total procedure time of <20 min. Oral administration of 60 mg of khellin tablets to two healthy human males was carried out, and the serum samples were analyzed by the described method. Serum concentration–time profiles are presented.

Keyphrases □ Khellin—high-performance liquid chromatographic analysis in human serum and urine □ High-performance liquid chromatography—analysis, khellin in human serum and urine □ Vasodilators—khellin, high-performance liquid chromatographic analysis in human serum and urine

Khellin (4,9-dimethoxy-7-methyl-5*H*-furo[3,2-*g*][1]-benzopyran-5-one, I), the active ingredient of *Ammi visnaga*, is used mainly as a vasodilator in the treatment of renal colic and renal stones.

Gravimetry (1), colorimetry (2, 3), and TLC–colorimetry (4) are used for the determination of I in formulations and *A. visnaga* extracts. The gravimetric assay is tedious and lacks the desired sensitivity (5), while the colorimetric methods suffer from color instability and inefficiency (4). An analytical method for the determination of this drug in biological fluids has not been available, and no information has been presented on its elimination and distribution patterns in humans.

This report describes a rapid, specific, accurate, and sensitive high-performance liquid chromatographic (HPLC) method for the determination of I in serum and urine. The procedure involves a simple, one-step solvent extraction followed by HPLC using theophylline (II) as an internal standard.

EXPERIMENTAL

Reagents and Solvents—Khellin[1] (I) was recrystallized from isopropanol[1]. Theophylline[2] (II) was used as supplied. Chloroform[3] and methanol[3] were analytical reagent grade and were used without further purification. Double-distilled water was employed in the mobile phase.

Apparatus and Operating Conditions—The analysis was performed using a high-performance liquid chromatograph[4] with a 254-nm UV detector[5], an injection system[6], and a 30-cm × 4-mm i.d. reversed-phase, high-efficiency C_{18} column[7]. The mobile phase was methanol–water (65:35), which was filtered twice through a 0.45-μm pore filter[8] and degassed before use. The flow rate was 0.8 ml/min but occasionally varied between 0.6 and 1 ml/min.

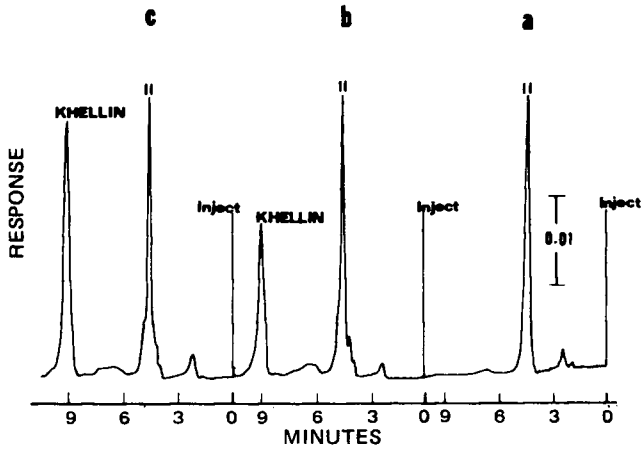

Figure 1—*Chromatograms of 1-ml human serum samples containing 5 μg of theophylline (internal standard). Key: a, taken prior to khellin administration; b, taken 6.5 hr after oral administration of 60-mg khellin tablets; and c, spiked with 1 μg of khellin. The mobile phase was 65% (v/v) methanol at a flow rate of 0.8 ml/min, and the chart speed was 0.5 cm/min.*

Extraction—A 1-ml portion of water, serum, or urine was transferred to a 13-ml centrifuge tube, and 5 or 20 μg of II and 7 ml of chloroform were added. The tube was vortexed for 60 sec and centrifuged for 8 min at 2000 rpm. After the aqueous creamy phase was aspirated and discarded, 5 ml of the organic phase was transferred to a glass tube and evaporated in a water bath at 60°. The residue was reconstituted with 0.2 ml of the mobile phase by shaking it for 30 sec on a vortex mixer, and 15–25 μl was injected onto the column.

Standard Curves—Calculations were carried out using standard curves constructed by analyzing 1-ml samples of the respective fluid spiked with 5 or 20 μg of II and known amounts of I and plotting the peak height ratio (I/II) *versus* the corresponding concentration of I. The standard curve data were subjected to least-squares linear regression analysis, and the resulting equation was utilized for the calculation of the drug concentration in the unknown samples.

Serum Level Study in Humans—Two healthy human males were given three 20-mg tablets of khellin[9] after fasting for 12 hr. Blood samples (5 ml) were removed from the median cubital vein at the indicated time intervals and placed in centrifuge tubes. After allowing the blood to clot, serum was cultivated and stored frozen until analysis. The assay was performed in duplicate.

Urine Collection—Urine was collected from one subject at various intervals after drug administration, and the volume was recorded. Samples (1 ml) were transferred into stoppered centrifuge tubes and stored frozen until assay. Urine collection was stopped 11 hr after drug administration.

RESULTS

Figure 1 shows typical chromatograms of a blank serum sample with a sample spiked with 1 μg of khellin (I) and another sample obtained from a healthy human volunteer 6.5 hr after oral administration of 60 mg of I. All three samples contained 5 μg of theophylline (the internal standard, II). The specificity of this method is clearly demonstrated by the absence of interfering peaks. With 65% methanol in water as the eluent at a flow rate of 0.8 ml/min, the retention times for I and II were 9 and 4.4 min, respectively.

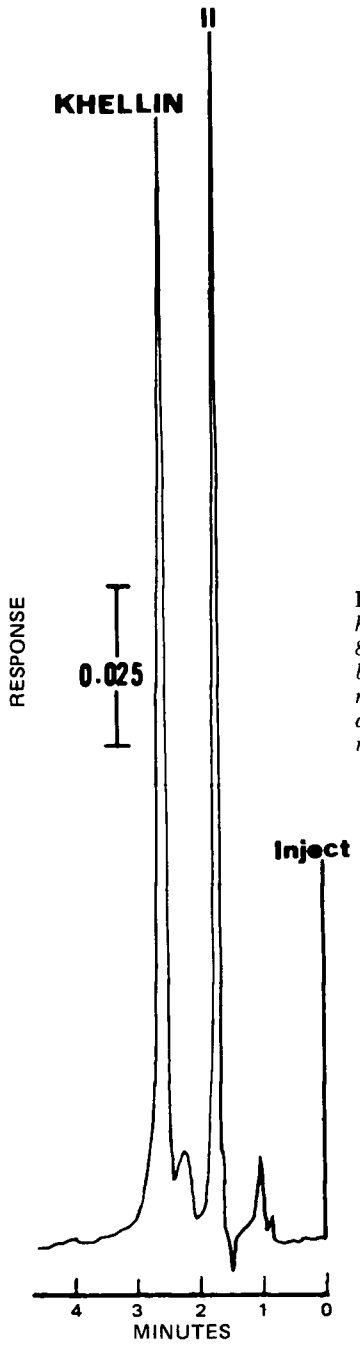

Figure 2—*Chromatogram of 1-ml human serum sample spiked with 8 μg of I and 20 μg of II. The mobile phase was 70% (v/v) methanol at a flow rate of 1.0 ml/min, and the chart speed was 0.5 cm/min.*

Figure 2 represents a chromatogram of a urine sample spiked with 8 and 20 μg of I and II, respectively. The retention times for I and II were 5 and 3.3 min, respectively, using 70% methanol as the mobile phase at a flow rate of 1.0 ml/min. The small peak preceding the drug peak was due to an impurity, which appeared to be adequately separated from the drug. Complete resolution was obtained by decreasing the flow rate and the methanol content of the mobile phase.

Recovery—The described procedure for the extraction of I from serum and urine is simple, rapid, and efficient. There was no back-extraction involved, and the extraction was carried out in <10 min. The relative serum to water recovery of I as measured by the ratio of the slopes of the standard curves of the peak height ratio *versus* concentration obtained for I in serum and water, respectively, was 0.88. Addition of 0.1 ml of 0.1 *N* NaOH to the samples did not increase the relative recovery. There was excellent linearity between the peak height ratios and khellin concentrations in serum and urine ($r > 0.999$ for both) in the concentration range employed, *i.e.*, 0.1–5 μg/ml for serum and 1–20 μg/ml for urine.

Accuracy—Table I shows the amounts found and the actual amounts with which 1-ml blank serum samples were spiked and analyzed according to the described method. The experiment was performed in duplicate, and the percent error for each unknown sample was calculated according to (6):

Table I—Accuracy of HPLC Assay for Khellin in Serum

Amount Added, μg	Experiment 1 Amount Found, μg	Experiment 1 Percent Error	Experiment 2 Amount Found, μg	Experiment 2 Percent Error
1.0	1.04	4	1.03	3
2.0	1.90	5	1.86	7
4.0	3.96	1	4.12	3
8.0	8.04	0.5	7.82	2.25
10.0	9.98	0.2	9.28	7.2

$$\% \text{ error} = \frac{\text{amount added} - \text{amount found}}{\text{amount added}} \times 100 \qquad \text{(Eq. 1)}$$

As can be seen in Table I, the percent error was ~0.2–5%. In no case did it exceed 7.5%, indicating the excellent accuracy and reproducibility of the described method.

Reliability—Since no other method is available for the determination of I in serum and urine, comparison of this HPLC assay with another method was impossible. However, the accuracy demonstrated for this method indicates that it is reliable for assaying I in these biological fluids.

Serum Levels and Urine Collection Data—The serum khellin concentration–time profiles are shown in Fig. 3. The total amount of the unchanged drug excreted through the urine in 11 hr was only 48.1 μg.

DISCUSSION

The lack of an analytical method for the determination of khellin (I) in biological fluids has precluded its clinical monitoring in patients. Indeed, since the therapeutic serum index for this drug has not been established, dosing is quite arbitrary. The daily dose of I ranges from 20 to 100 mg, and dosing frequency varies from once to three times daily. Furthermore, no information is available on the half-life and other pharmacokinetic parameters for this drug.

To the knowledge of the present investigators, this report is the first to deal with the determination of khellin in biological fluids and the first to give data on the oral absorption of this drug in humans. As shown in Fig. 3, the serum khellin levels following the administration of 60 mg of khellin tablets ranged from 0.100 to 1.7 μg/ml, and the half-life, as determined from the semilogarithmic plot of the three terminal data points assuming rapid absorption, was ~1.5–5.6 hr. The fraction of the dose excreted unchanged through the urine in 11 hr was only 0.8%. Therefore, it appears that the elimination of I occurs principally by metabolism, and, hence, analysis of the unchanged drug in the urine may be of little interest.

Further investigation to extend this preliminary information on the

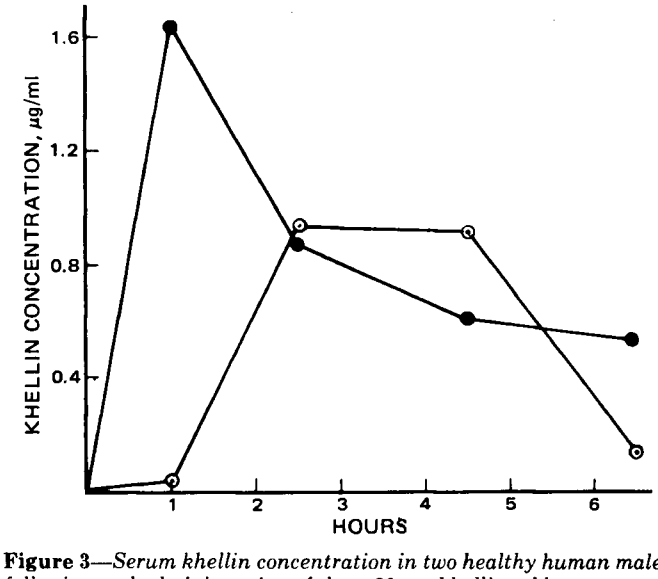

Figure 3—*Serum khellin concentration in two healthy human males following oral administration of three 20-mg khellin tablets.*

pharmacokinetics of I in humans is underway, and the results will be reported later.

Differential Pulse Polarographic Determination of Colchicine

WALTER HOLAK ˣ **and WILLIAM M. PLANK**

Received December 4, 1979, from the *Food and Drug Administration, Department of Health, Education, and Welfare, 850 Third Avenue, Brooklyn, NY 11232.* Accepted for publication June 4, 1980.

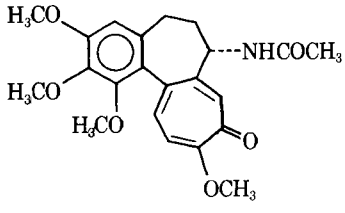
Abstract □ A differential pulse polarographic method for the analysis of colchicine-containing dosage forms is described. The reduction of the tropolone carbonyl is useful for quantitative analysis in that the relationship of the colchicine concentration to the current is linear over the concentration range of 0 to ~50 μg/ml, with a slight negative deviation at higher concentration. The procedure involves no preliminary treatment, is simple and specific, and is applicable to the assay of composite tablets, individual tablets, and injectable solutions. Polarography is conducted on a solution of colchicine in pH 1.81 Britton–Robinson buffer with 0.01% alkylphenoxy polyethoxyethanol. The quantitative analysis is achieved using the method of standard addition. A relative standard deviation of 3.2% was obtained for tablets. The results agree with those obtained using the USP XIX method.

Keyphrases □ Colchicine—analysis by differential pulse polarography □ Polarography, differential pulse—analysis of colchicine

Colchicine (I), an alkaloid obtained from various species of *Colchicum*, is used for the suppression of gout. The USP XIX assay for colchicine tablets involves extraction with chloroform followed by a spectrophotometric determination. The quantity of the drug specified to be taken for the assay is 3 mg. Since the usual tablet strength is 0.5 mg, this amount is equivalent to six tablets. For a content uniformity test, the method needs to be scaled down sixfold to accommodate a single tablet. As a result, the aqueous phase volume, as well as the organic volumes used for extractions, becomes less than optimum, so that difficulties with the procedure may be encountered.

Colchicine has a tropolone ring which bears a reducible carbonyl group, similar to an aromatic aldehyde that was determined by classical direct-current polarography in Britton–Robinson or McIlvane buffer (1–3). Reduction of colchicine at a dropping mercury electrode was studied at various pH levels by Sartori and Guadiano (4). These investigators reported that below pH 8, two reduction waves are obtained; the potential of the first wave becomes more negative with increasing pH and reaches that of the second wave at pH ~8. Above pH 8, there is only one wave, whose potential does not vary with pH and corresponds to the formation of a secondary alcohol. This reduction is irreversible (4).

However, the sensitivity of direct-current polarography is limited due to the large capacitance current contribution to the Faradaic current. This difficulty is reduced in differential pulse polarography. This paper describes the application of differential pulse polarography to the determination of colchicine in dosage forms with the goal of developing a general method applicable to the assay of composite tablets as well as individual tablets and injection solutions.



I

EXPERIMENTAL

Apparatus and Polarographic Conditions—A polarographic analyzer[1] equipped with a drop timer[2] in conjunction with a three-electrode system was used for polarographic determinations. The electrodes were a dropping mercury electrode, a saturated calomel electrode, and a platinum wire auxiliary electrode. The drop timer was set at 1 sec, and the height of the mercury column was 70 cm. Other conditions were: current range, 2–5 μamp; pulse amplitude, 50 mv; and scan rate, 5 mg/sec. The potential range scan was from −0.7 to −1.2 v. All polarograms were recorded on an *x–y* recorder[3].

Reagents and Chemicals—All chemicals were reagent grade unless otherwise specified. The standard was colchicine USP[4].

Supporting Electrolyte Solution—One liter of solution was prepared to contain 0.04 *M* acetic acid, 0.04 *M* phosphoric acid, and 0.04 *M* boric acid in water (pH 1.81). Different pH buffers were prepared for the pH *versus* polarographic behavior study by mixing 100 ml of the supporting electrolyte solution with the required volumes of 0.2 *M* NaOH and checking with the pH meter[5].

Standard Colchicine Solution—Colchicine standard, 25 mg, was accurately weighed and dissolved with supporting electrolyte solution in a 25-ml volumetric flask and then diluted to volume with the same solvent.

Surfactant Solution—The surfactant solution was 0.5% alkylphenoxy polyethoxyethanol in water[6].

Table I—Composite Tablet Assay of Commercial Samples by the Differential Pulse Polarographic Method and by the USP XIX Method

Colchicine Dosage Form	Amount Declared	Differential Pulse Polarography[a] Amount Found	Differential Pulse Polarography[a] Percent of Claim	USP XIX[a] Amount Found	USP XIX[a] Percent of Claim
Tablets	0.60 mg/tablet	0.59 mg/tablet	99.3	0.60 mg/tablet	100.0
Tablets	0.50 mg/tablet	0.50 mg/tablet[b]	100.0	0.49 mg/tablet	98.0
Injection	1 mg/2 ml	1.04 mg/2 ml	104.0	1.04 mg/2 ml	104.0
Tablets	0.648 mg/tablet	0.590 mg/tablet	91.0	0.582 mg/tablet	89.8

[a] Single determinations. [b] Mean value of six determinations; *RSD* = 3.2%.

Procedure—*Composite Tablet Assay*—Twenty tablets were weighed accurately, and the average weight per tablet was determined. The tablets were ground thoroughly in a mortar, and a portion of the powder containing ~0.5 mg of colchicine was weighed and transferred to a 50-ml volumetric flask. About 20 ml of supporting electrolyte solution was added, and the flask was stoppered and shaken for ~5 min. Then 1 ml of surfactant solution was added, and the solution was diluted to volume with supporting electrolyte solution and mixed.

Content Uniformity—The same procedure was used as for the composite tablet assay, except that an intact tablet was used as the sample.

Polarographic Procedure—Ten milliliters of the solution to be assayed was pipetted into the dry polarographic cell, and the solution was deaerated for 5 min with nitrogen and then polarographed under the described conditions. With a micropipet, 100 μl of the standard solution was added, and the solution was deaerated for 1 min and polarographed exactly as before. Peak heights were measured that occurred at ~−0.88 v *versus* a saturated calomel electrode. The milligrams of colchicine in the sample was calculated from:

$$\text{mg/tablet or mg/ml of injection solution} = \frac{A}{(B \times 1.01) - A} \times 0.1 \times \frac{50}{10} \times \frac{1}{C} \quad \text{(Eq. 1)}$$

where A is the peak height of the sample, B is the peak height of the sample plus the standard, 1.01 is the concentration factor for the dilution,

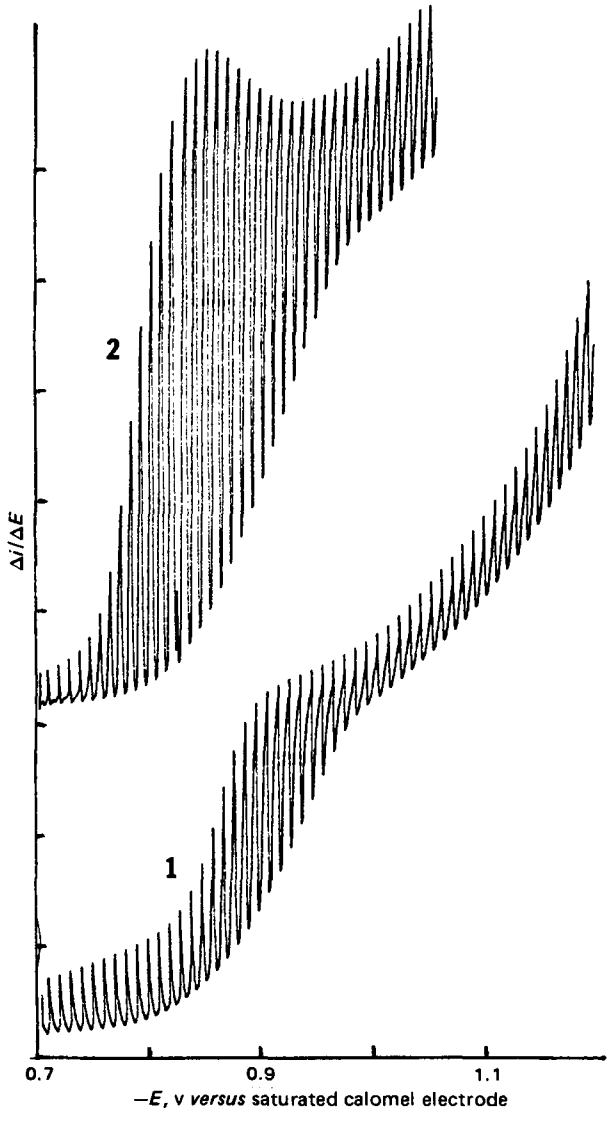

Figure 1—*Direct-current polarograms of colchicine in Britton–Robinson buffer (pH 1.81). Key: 1, 10 μg/ml; and 2, 20 μg/ml.*

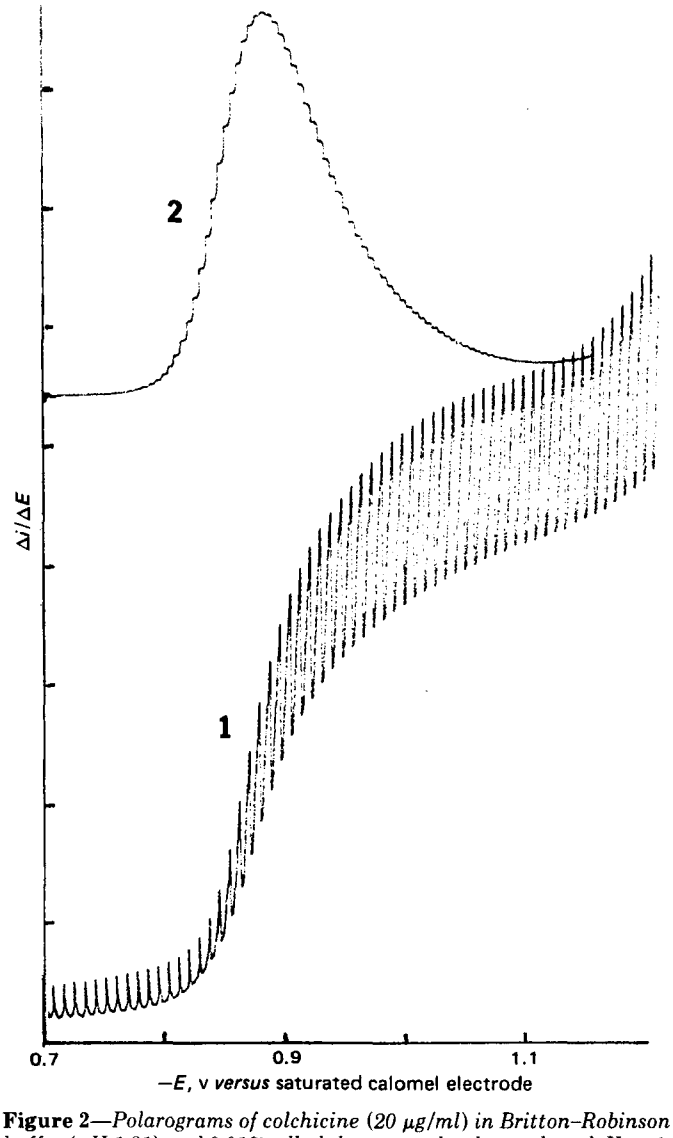

Figure 2—*Polarograms of colchicine (20 μg/ml) in Britton–Robinson buffer (pH 1.81) and 0.01% alkylphenoxy polyethoxyethanol. Key: 1, direct-current mode; and 2, differential pulse polarographic mode.*

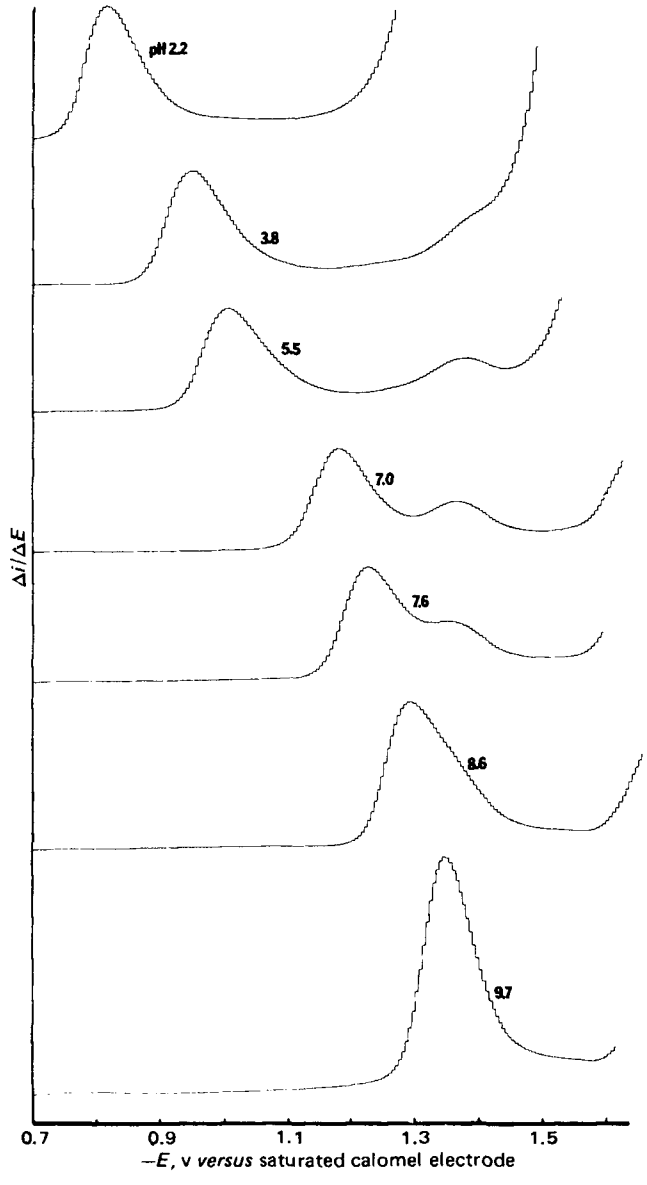

Figure 3—*Differential pulse polarographic behavior of colchicine (20 μg/ml) as a function of pH.*

and C is the number of tablets or milliliters of injection solution. In the composite tablet assay, C is the weight of the sample divided by the average weight per tablet; in the individual tablet assay, $C = 1$.

RESULTS AND DISCUSSION

When the initial differential pulse polarograms in Britton–Robinson buffer (pH 1.81) at colchicine concentrations of 10–50 μg/ml were recorded, there was a pronounced concentration-related peak potential shift in the anodic direction. The effect of adsorption was suspected and then was confirmed by running polarograms in the direct-current mode and observing the presence of a maximum (Fig. 1). Addition of 0.01% alkylphenoxy polyethoxyethanol (Fig. 2) to the test solution eliminated the maximum and almost all of the peak potential shift.

The general polarographic behavior of colchicine is similar to that of aromatic aldehydes. For example, the data for benzaldehyde (5) indicate that the mechanism for its reduction involves the formation of a free radical followed by dimerization (first wave) and the production of benzyl alcohol (second wave). A similar mechanism may be operative during the reduction of colchicine. The differential pulse polarographic behavior of colchicine as a function of pH is shown in Fig. 3.

Table II—Content Uniformity Analysis of 0.5-mg Colchicine Tablets by Differential Pulse Polarography

Tablet	Amount Found, mg/tablet
1	0.50
2	0.50
3	0.54
4	0.50
5	0.50
6	0.50
7	0.48
8	0.49
9	0.47
10	0.50
Average	0.50

The electrochemical properties of colchicine are useful for its quantitative measurement in pharmaceutical dosage forms. Quantitation is achieved by a method of standard addition to compensate for differences in sample matrixes.

A linear relationship between colchicine concentration and electrochemical behavior ($\Delta i/\Delta E$) was established from the following data points (micrograms per milliliter *versus* microamperes): 11.2, 1.08; 22.4, 2.23; 33.6, 3.29; and 44.8, 4.35. The line showed an intercept of 0.020 μamp, a slope of 0.0971 (μamp ml)/μg, and a correlation coefficient of 0.9998. The line showed a slight negative deviation from linearity at higher concentrations.

Four commercial preparations were analyzed using the proposed method and the USP XIX procedure (6). The results are given in Table I. An estimate of the precision of the differential pulse polarographic method obtained by analyzing one sample six times gave a relative standard deviation of 3.2%. Ten individual tablet assay results for 0.5-mg tablets ranged from 0.47 to 0.54 mg/tablet (Table II), with an average of 0.50 mg/tablet. The same value was obtained for the composite tablet assay.

The differential pulse polarographic assay presented here is rapid and sensitive and is specific for analyzing colchicine-containing preparations. Moreover, the same procedure is applicable for the assay of individual tablets. The results of the differential pulse polarographic method are in excellent agreement with those obtained using the more involved USP XIX assay.

Analysis of Procainamide Hydrochloride and Acecainide Hydrochloride in Rat Feed

JAMES E. CARTER *x, JOHN S. DUTCHER ‡, DANIEL P. CARNEY *, LAWRENCE R. KLEIN *, LAWRENCE A. BLACK *, and PAUL W. ERHARDT *

Received December 5, 1979, from the *Research and Development Department, American Critical Care, McGaw Park, IL 60085, and the ‡Molecular Toxicology Section, Clinical Pharmacology Branch, Division of Cancer Treatment, National Cancer Institute, Bethesda, MD 20205. Accepted for publication June 9, 1980.

Abstract □ An extraction and GLC assay procedure was developed for quantitation of procainamide hydrochloride and acecainide hydrochloride in rat feed. 4-Amino-*N*-[2-(dipropylamino)ethyl]benzamide hydrochloride was synthesized and utilized as an internal standard. The assay has good precision and accuracy and was used to establish the stability of acecainide hydrochloride and procainamide hydrochloride in rat feed.

Keyphrases □ Procainamide hydrochloride—GLC analysis in rat feed □ Acecainide hydrochloride—GLC analysis in rat feed □ GLC—analysis, procainamide hydrochloride and acecainide hydrochloride in rat feed

The identification of acecainide (*N*-acetylprocainamide) as the major metabolite of procainamide in humans (1, 2) generated interest in acecainide as an antiarrhythmic agent and has required development of an assay for the simultaneous determination of these two drugs (3). Although sensitive spectrophotometric methods have been employed (4, 5), they do not exhibit the specificity of GLC (6, 7) and high-performance liquid chromatographic (8–11) assays reported for the analysis of these compounds in plasma and urine.

In accord with present regulatory trends, there also is a need to monitor accurately and ensure precise drug levels in chronic toxicity studies. Such studies are conducted at therapeutic and subtoxic drug concentrations and, thus, require at least two widely varying levels of drug determination.

The present study established a GLC procedure for accurately determining procainamide hydrochloride and acecainide hydrochloride concentrations in rat feed. A structural analog of procainamide, 4-amino-*N*-[2-(dipropylamino)ethyl]benzamide hydrochloride, is utilized as an internal standard to minimize extraction and assay variability.

EXPERIMENTAL

Materials—Procainamide hydrochloride[1] and acecainide hydrochloride[2] were not <98% pure by nonaqueous titration. Elemental analysis and melting-point data also indicated the purity of the raw material. Diethyl ether was reagent grade. The rats were given a commercial rat food *ad libitum*[3].

The internal standard, 4-amino-*N*-[2-(di-*n*-propylamino)ethyl]-benzamide hydrochloride, was obtained through a synthetic scheme analogous to that employed for the synthesis of procainamide (12, 13). Recrystallization of the final product was effected from ethanol to provide white crystals in a 33% overall yield, mp 185–187°; chemical-ionization mass spectrum: M + 1, 264.

Anal.—Calc. for $C_{15}H_{26}ClN_3O$: C, 60.11; H, 8.68; N, 14.02. Found: C, 59.96; H, 8.74; N, 13.82.

Instrumentation—Assays were performed with a gas–liquid chromatograph[4] equipped with a flame-ionization detector. A 1.2-m × 2-mm i.d. glass column, packed with 3% OV-17 on 100–120-mesh Chromosorb W-HP, was maintained at 245 or 270° for procainamide or acecainide, respectively. The column inlet was maintained at 275°, while the detector temperature was 300°. The carrier gas was helium at a flow rate of 20 ml/min.

Analysis of Rat Feed—Standard solutions of procainamide hydrochloride and acecainide hydrochloride were prepared in water at 10.0 mg/ml. The internal standard solution was prepared in water at 4.0 mg/ml.

A 2.0-g homogeneous aliquot of rat feed containing drug was accurately weighed and added to 1.0 ml of the internal standard and 19 ml of water (pH 2) in a centrifuge tube. The contents were extracted and centrifuged. The water layer containing the drug and internal standard was transferred to a second tube. The solution was made basic (pH 12) with sodium hydroxide, sodium chloride (2 g) and ether (20 ml) were added, and the drugs were extracted into the ether layer. The contents were centrifuged, and the ether layer was drawn off for concentration and/or injection into the gas–liquid chromatograph (normally 2.0 μl).

Standard curves were constructed by spiking the drug-free rat feed with appropriate volumes of procainamide hydrochloride or acecainide hydrochloride standard solutions and following the procedure outlined. Peak area ratios of the drug to the internal standard were plotted against milligrams of drug per gram of feed.

RESULTS AND DISCUSSION

In the analysis of acecainide and procainamide from rat feed, it was desirable to sample a representative quantity of drug in feed and to utilize an internal standard that would have physical properties similar to those of the test substances. Sampling of <1 g of feed could result in considerable assay variability caused by drug–feed mixing variability. Extraction of more than a few grams of feed requires large extraction vessels and considerable quantities of solvents and the internal standard. Extraction of samples and addition of the internal standard to an aliquot introduces assay variability caused by extraction differences.

The described procedure yielded small representative samples and permitted the use of a true internal standard. The use of the di-*n*-propyl derivative provided an internal standard with partitioning and chromatographic properties similar to those of acecainide and procainamide. The internal standard has a retention time between those of procainamide and acecainide and does not overlap with either test substance.

In the procainamide assay (column temperature 245°), procainamide has a retention time of ~2.8 min while the internal standard elutes at 4.0 min. With the acecainide analysis, the column temperature is 270°. Procainamide elutes with the solvent, the internal standard elutes at 1.8 min, and acecainide emerges at 3.5 min. This procedure is specific for acecainide and procainamide, with no interfering peaks present in the chromatogram.

The analysis of acecainide hydrochloride in rat feed was linear over a wide concentration range. Standards were determined in quadruplicate at 1.0, 2.0, 5.0, and 10.0 mg of drug/g of feed. The resulting plot had a correlation coefficient of 0.9990, an intercept of −0.004, and a slope of 0.115. The analytical range was extended by varying the concentration of the internal standard and the final volume of ether. Standards determined in duplicate at 10.0, 20.0, 30.0, and 40.0 mg of acecainide hydrochloride/g of feed gave a correlation coefficient of 1.000, an intercept of −0.142, and a slope of 0.145. In this example, 3.0 ml of the internal standard at 4.0 mg/ml was added to the feed, and the ether extract con-

taining the drugs did not require concentration. The coefficients of variation for the standard curves at the low and high concentrations were 3.89 and <1%, respectively. The analysis of acecainide in rat feed is linear, precise, and accurate over the needed concentration range. The construction of a standard curve spanning the desired concentration range on each day of analysis assures good quantitation of drug in the feed.

Procainamide hydrochloride was analyzed from 0.50 to 50.0 mg/g of feed. Standards were determined in quadruplicate at 0.5, 1.0, 2.0, and 5.0 mg/g of feed. Over this concentration range, the linear regression exhibited a correlation coefficient of 0.9997, an intercept of −0.067, and a slope of 0.872. Increasing the concentration of the internal standard again allowed extension of the analytical range. Standards determined in quadruplicate at 5.0, 10.0, 20.0, and 50.0 mg/g of feed exhibited a correlation coefficient of 0.9998, an intercept of 0.027, and a slope of 0.063. The coefficient of variation for both standard curves was <1%. The assay of procainamide hydrochloride from rat feed is linear, precise, and accurate over the desired concentration range.

Acecainide hydrochloride in rat feed was tested and shown to be stable (85–115% of the theoretical amount) for up to 5 months at ambient temperature. Procainamide hydrochloride exhibited some instability over the same period, but the cause or result of this instability was not determined.

Acecainide and procainamide may be mixed with rat feed and accurately analyzed with this procedure. The drugs were stable in rat feed if kept at or below room temperature and utilized within a few months.

Analysis of 4′-Demethylepipodophyllotoxin-9-(4,6-*O*-ethylidene-β-D-glucopyranoside) by High-Pressure Liquid Chromatography

LARRY M. ALLEN

Received December 14, 1979, from the *Departments of Oncology and Pharmacology R-71, School of Medicine, University of Miami, Miami, FL 33101.* Accepted for publication June 12, 1980.

Abstract □ A rapid and specific high-pressure liquid chromatographic assay is described for the quantitative analysis of 4′-demethylepipodophyllotoxin-9-(4,6-*O*-ethylidene-β-D-glucopyranoside) (I) in plasma. After chloroform extraction, I was analyzed by reversed-phase chromatography and UV detection (252 nm). The maximum sensitivity was 0.1 μg/ml. Quantitation was by relative response factor calibration using an integrating microcomputer. Over the concentration range of 0.5–90 μg/ml, the average recovery of I from plasma was 95.4 ± 3.8% (*SD*).

Keyphrases □ 4-Demethylepipodophyllotoxin -9- (4,6-*O*-ethylidene-β-D-glucopyranoside)—high pressure liquid chromatographic analysis □ High-pressure liquid chromatography—analysis, 4-demethylepipodophyllotoxin-9-(4,6-*O*-ethylidene-β-D-glucopyranoside) □ Antitumor activity—4-demethylepipodophyllotoxin -9- (4,6 -*O*- ethylidene-β-D-glucopyranoside), high-pressure liquid chromatographic analysis

The semisynthetic epipodophyllotoxin analog 4′-demethylepipodophyllotoxin-9-(4,6-*O*-ethylidene-β-D-glucopyranoside) (I) has shown activity against a variety of human tumors (1). Since I is undergoing advanced clinical investigation, it is desirable to monitor plasma drug concentrations from different dosage regimens and from drug interaction studies. Analysis of I previously was carried out by radioisotopic techniques (2–4). This report discusses a high-pressure liquid chromatographic (HPLC) method developed for the quantitation of I in plasma.

EXPERIMENTAL

Apparatus—The analyses of I were conducted using a liquid chromatograph[1] operated at ambient temperature and equipped with a variable-wavelength detector (252 nm). Separations were performed on a 250 × 3.0-mm i.d. reversed-phase column[2]. Samples were introduced onto the column through a septumless injector (10 μl) coupled to an automatic sampler injection system[1]. The chromatograms were traced on a strip-chart recorder with the peak area integration performed by a microcomputing data system[1].

Reagents and Solvents—Compound I was obtained as a gift[3]. All chemical reagents were analytical grade except for methanol and dioxane, which were pesticide residue or HPLC quality[4].

Chromatographic Conditions—The mobile phase was a 50:50 mixture of 5 m*M* KH_2PO_4–NaOH buffer (pH 7.8) and methanol with the flow rate adjusted to 40 ml/hr (~1000 psi). A precolumn[2] was used to minimize the effect of extraneous plasma-extracted material on the performance of the reversed-phase column.

Extraction Procedure—Aliquots (2.0 ml) of plasma were transferred to 15-ml thick-wall centrifuge tubes[5], diluted with 2 ml of water, and extracted with 4 ml of chloroform. The mixture was vortexed vigorously for 30 sec, and the phases were separated by centrifugation (15 min at 10,000×*g*). The lower organic layer was removed by a Pasteur pipet (24

taining the drugs did not require concentration. The coefficients of variation for the standard curves at the low and high concentrations were 3.89 and <1%, respectively. The analysis of acecainide in rat feed is linear, precise, and accurate over the needed concentration range. The construction of a standard curve spanning the desired concentration range on each day of analysis assures good quantitation of drug in the feed.

Procainamide hydrochloride was analyzed from 0.50 to 50.0 mg/g of feed. Standards were determined in quadruplicate at 0.5, 1.0, 2.0, and 5.0 mg/g of feed. Over this concentration range, the linear regression exhibited a correlation coefficient of 0.9997, an intercept of −0.067, and a slope of 0.872. Increasing the concentration of the internal standard again allowed extension of the analytical range. Standards determined in quadruplicate at 5.0, 10.0, 20.0, and 50.0 mg/g of feed exhibited a correlation coefficient of 0.9998, an intercept of 0.027, and a slope of 0.063. The coefficient of variation for both standard curves was <1%. The assay of procainamide hydrochloride from rat feed is linear, precise, and accurate over the desired concentration range.

Acecainide hydrochloride in rat feed was tested and shown to be stable (85–115% of the theoretical amount) for up to 5 months at ambient temperature. Procainamide hydrochloride exhibited some instability over the same period, but the cause or result of this instability was not determined.

Acecainide and procainamide may be mixed with rat feed and accurately analyzed with this procedure. The drugs were stable in rat feed if kept at or below room temperature and utilized within a few months.

The occasional shoulder on I is associated with impurities from dioxane.*

cm) and transferred to either 15-ml ground-glass conical centrifuge tubes or to all-glass evaporator cups[6]. A second and third extraction were performed similarly.

The pooled chloroform layers from each sample were dried under reduced pressure either in a water bath (45°) using a rotary evaporator or at 45° in a sample concentrator[6]. To the dried chloroform extracts was added 2 ml of chloroform, and the samples were redried. This step was repeated two times with 1 and 0.5 ml of chloroform, respectively. The final residues were transferred in 0.2 ml of dioxane to microsample vials, capped, and prepared for HPLC analysis.

Extraction Efficiency—Plasma from a local blood bank was used along with tritium-labeled and unlabeled I. The efficiency of extracting I from plasma was established using the following procedure. Known amounts of I and 0.01 μCi of radiolabeled I (14 μCi/μmole) were added to drug-free plasma (10 ml each) to achieve concentrations of I from 0.1 to 100 μg/ml. Aliquots (2.0 ml) of each plasma sample were transferred to thick-wall centrifuge tubes and stored frozen (−20°) until they were extracted. Samples ($n \geq 6$) at each concentration were analyzed in duplicate. Quantitation of I was accomplished by the relative response factors calculated from analysis of standards of I of known concentration. The linearity of the calibration curve for I was established over the concentration range of 0.1–100 μg/ml. Specificity for I was established using drug-free plasma.

Clinical Specimens—Written informed consent was obtained from two patients who participated in the institutionally approved I protocol. This protocol called for administration of I at 10 mg/m^2 by intravenous push followed immediately by a continuous infusion of I for 24 hr. Venous blood (5 ml) was collected in heparinized tubes at specified times and centrifuged for 2 min at 1000×*g*, and the plasma was removed and stored frozen until it was analyzed for I.

RESULTS AND DISCUSSION[7]

Figure 1A shows the elution profile of I (largest peak) directly injected into the high-pressure liquid chromatograph. The shoulder on the peak of I was observed with different batches of dioxane and was independent

[6] Brinkmann Instruments, Westbury, N.Y.

[7] The PROPHET computer system is sponsored by the Division of Research Resources of the National Institutes of Health (5).

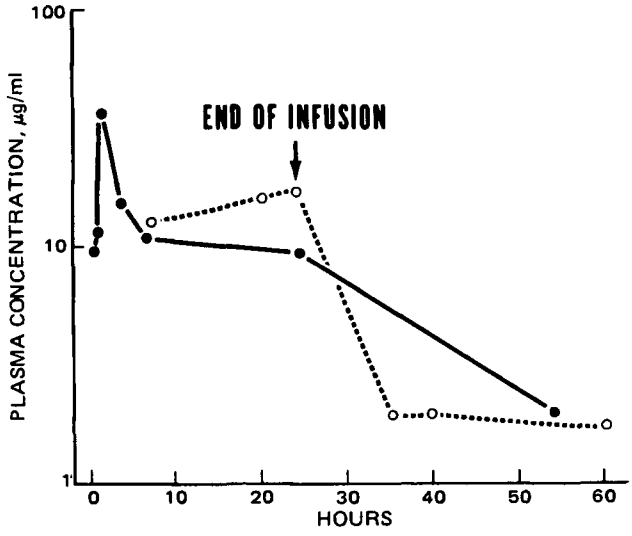

Figure 2—*Plasma levels of I. According to the protocol (written informed consent was obtained from the patients with an institutionally approved protocol), I was administered by a 24-hr continuous infusion at 180 (○) and 340 (●) mg/m^2 immediately after a 10-mg/m^2 short intravenous infusion (30 min).*

of the peak height of I. Figure 1B also shows a typical elution pattern of I (largest peak) derived from spiked plasma. To date, no interfering peaks from plasma have created a problem in the quantitation of I. The retention time of I in this system was 6.63 ± 0.04 min. A standard curve for I as a function of the peak area *versus* drug concentration (0.1–100 μg/ml) was linear with a correlation coefficient of >0.99 for six runs. The extraction efficiency for I over the concentration range of 0.5–90 μg/ml was 95.4 ± 3.8%, and this percentage was used in all recovery calculations. This range of drug concentrations is suitable for most clinical doses of the drug (>100 mg/m^2) and for measurements of I up to 48 hr or longer after drug administration.

Figure 2 shows two plasma curves for I as determined by this HPLC method. The more common wavelength detector (254 nm) can be used with somewhat reduced sensitivity for I (maximum sensitivity of 0.8 μg/ml). By increasing the proportion of methanol in the mobile phase to 75%, an analog of I, 4′-demethylepipodophyllotoxin-9-(4,6-*O*-thenylidene-β-D-glucopyranoside), can be quantitated in plasma by this method.

Turbidimetric Determination of Blood Aminoglycoside Levels by Growth Curve Analysis

STEPHEN C. EDBERG *x **and ABRAHAM MISKIN** ‡

Received February 19, 1980, from the *Division of Microbiology and Immunology, Department of Pathology, Montefiore Hospital and Medical Center, New York, NY 10467, and the ‡Department of Microbiology, Kaplan Hospital, Rehovot, Israel. Accepted for publication June 3, 1980.

Abstract □ A procedure to assay rapidly blood aminoglycoside levels was developed based on growth curve analysis of continuous absorbance measurements of a bacterial test strain. Of the means available for monitoring bacterial growth quantitatively, turbidimetric measurement was selected because it can be used to perform a clinical assay in <4 hr. Continuous turbidimetric measurements provide information as soon as the antimicrobial agent affects growth, which often occurs within 60 min of the start of an assay. Several bacterial isolates were evaluated before *Staphylococcus aureus* (MHMC 386) was chosen as the test microorganism. This isolate was quite sensitive to the aminoglycoside antibiotics, permitted the rapid measurement of blood levels of amikacin, gentamicin, kanamycin, and tobramycin, and exhibited a linear dose–response relationship of turbidity over a wide range of antibiotic concentrations.

Keyphrases □ Antibiotics, aminoglycoside—amikacin, gentamicin, kanamycin, and tobramycin, effect on bacterial growth, turbidimetric measurement of blood levels □ Antibacterials—amikacin, gentamicin, kanamycin, and tobramycin, effect on bacterial growth, turbidimetric measurement of blood levels □ Spectrophotometry—turbidimetric determination of blood levels of amikacin, gentamicin, kanamycin, and tobramycin, effect on bacterial growth

The concentration at which aminoglycoside antibiotics injure animal cells is only two to four times greater than the concentration required to inhibit most common bacterial pathogens. In addition, distribution of the drug to the various body compartments is not the same in all individuals. Accordingly, a rapid assay is required for the optimal usage of aminoglycosides.

BACKGROUND

There is a direct relationship between bacterial growth measured turbidimetrically and the increase in bacterial numbers, collective mass, and cell volume. During the period when cells are dividing with a constant doubling time, the number of cells increases exponentially. If t_0 is the starting time and t_2 is the time required for the average bacterium to become two, then the number of bacteria (N_2) at t_2 can be calculated from:

$$\log N_2 = N_0\, 10^{t_0/t_2} \qquad \text{(Eq. 1)}$$

where N_0 is the number of bacteria at the starting time. The Rayleigh–Debye theory can be used to interrelate turbidity and cell mass if turbidity can be measured as a function of the ratio of the particle size to the wavelength at maximum turbidity and if the refractive indexes of the solvent and the particle are not significantly different. The concentration of bacteria per unit volume of suspending medium can be calculated from:

$$NVD = \frac{R_\theta 3\lambda D \sin^3(\theta/2)}{(\Delta\mu)(M-1)\mu x} \qquad \text{(Eq. 2)}$$

where θ is the modification of the light intensity due to the finite size of the particle, V is the volume of the particle, N is the number of particles per milliliter, R_θ is the reduced intensity for unpolarized light scattered at an angle θ from an incident beam, D is the density of the particle, λ is the wavelength of the light, M is the ratio of the refractive indexes of the particle and the medium, and μ is the refractive index function (1).

Equation 2 indicates that at 0°, light-scattering turbidity is related directly to the number or mass of bacteria (1–3). Based on this theory, spectrophotometric techniques were developed to assay antimicrobial agents. These systems have been used primarily in industry, where relatively high concentrations of antibiotics are measured. The development of clinical turbidimetric assays has suffered from a lack of sensitive equipment and the labor-intensive nature of this assay.

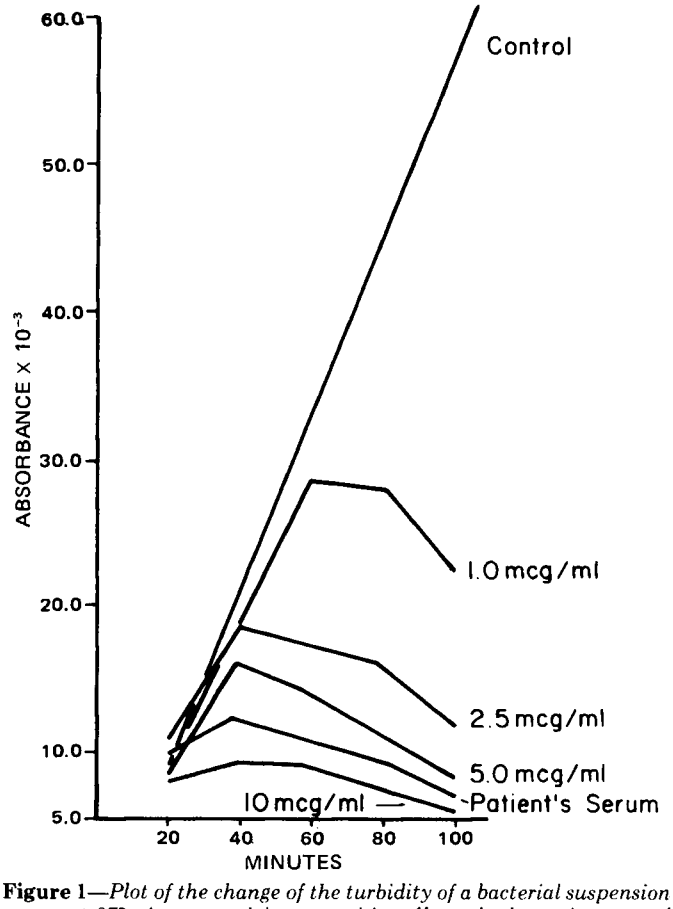

Figure 1—*Plot of the change of the turbidity of a bacterial suspension grown at 37°. As gentamicin exerted its effect, the bacteria stopped growing and the absorbance decreased.*

EXPERIMENTAL

A sensitive, low-noise spectrophotometer[1] was developed recently that automatically determines the bacterial density every 5 min under temperature-controlled conditions (4). This instrument currently is sold for antibiotic susceptibility tests. Because of its availability and ability to yield continuous printouts of absorbance measurements without manipulation of the cell, it seemed a likely candidate for the clinical assay of aminoglycosides.

A unique feature of this instrument is the design of the cell. The cell consists of two physically separated compartments: an upper compartment, which accepts the bacterial test strain and allows growth to occur to the log phase; and a lower compartment, which is divided into discrete, 1-cm³ chambers, with each chamber able to receive one antibiotic test specimen. A technique to determine the concentration of blood amino-

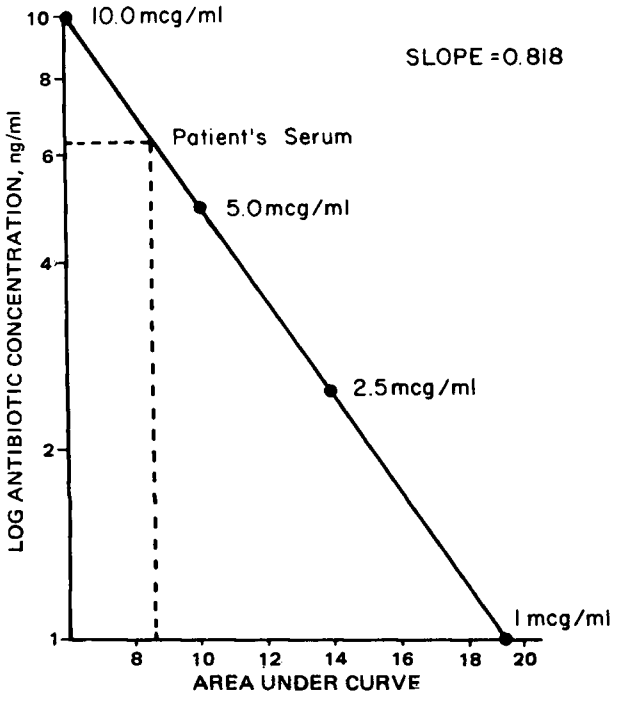

Figure 2—*Plot of area under the curve produced from a graph of absorbance* versus *time (Fig. 1) calculated for each antibiotic concentration, the control (no antibiotic), and the patient's serum. The area under the curve was proportional to the antibiotic concentration in the patient's serum. The amount of antibiotic in a patient's serum can be calculated by direct interpolation from a plot of log antibiotic concentration* versus *area under the curve. The patient's serum concentration was 6.8 μg/ml.*

glycoside levels using growth curve analysis from turbidimetric measurements supplied by this instrument was developed.

The selected strain of *Staphylococcus aureus* (MHMC 386) was sensitive to the aminoglycoside antibiotics and did not clump when grown in broth. *S. aureus* MHMC 386 was resistant to penicillin and sensitive to amikacin, cephalothin, chloramphenicol, clindamycin, erythromycin, gentamicin, kanamycin, oxacillin, tetracycline, tobramycin, and vancomycin. Antibiotic medium No. 5[2] was prepared according to directions from the manufacturer and adjusted to pH 7.4. A 17-ml volume of this medium was added to a sterile test tube. All antibiotics were obtained in powder form of known potency[3]. Aminoglycosides were prepared in standard solutions of 100 μg/ml in 0.1 *M* phosphate buffer (pH 7.9) (5). Stock solutions were frozen at −20° and stored for no longer than 90 days.

Human serum was obtained from normal blood bank donors and was heated to 56° for 30 min and filter sterilized (porosity 0.45 μm). For the measurement of serum antibiotic concentrations, the following dilutions in serum at pH 7.4 were made: amikacin, 25, 15, 10, and 5 μg/ml; gentamicin, 10, 5, 2.5, and 1 μg/ml; kanamycin, 25, 15, 10, and 5 μg/ml; and tobramycin, 10, 5, 2.5, and 1 μg/ml.

Forceps sterilized by alcohol and flaming were used to place filter paper disks[4] on a sterile petri plate, and 25 μl of each standard was added to individual disks. Twenty-five microliters of the patient's serum was added to each of two other disks. If the patient was receiving a β-lactam antibiotic, 0.25 ml of a broad-spectrum β-lactamase was added to 2 ml of the patient's serum prior to addition to the disks, and an appropriate correlation computation was made for this dilution. Each disk was placed in a separate compartment in the multichambered cell. Although the disks were used within 2 hr of preparation, the stability of aminoglycosides on the disks for long periods is not known.

Table I—Comparison of Blood Antibiotic Levels by Bioassay and Turbidity

Antibiotic	Number of Specimens	Discrepancy between Methods[a] 0–5%	5–10%	10–15%	15–25%	>25%
Gentamicin	112	20	38	28	13	2
Kanamycin	22	27	27	32	14	0
Tobramycin	26	15	42	36	3	4
Amikacin	11	9	45	36	9	0

[a] Percentages are rounded to the nearest whole number.

A suspension of *S. aureus* at 0.5 MacFarland's turbidity was made in 0.9% NaCl, and 0.1 ml of this suspension was added to 17 ml of antibiotic broth No. 5. Fifteen milliliters was added to the upper growth chamber of the cell, and the cell was placed in the spectrophotometer, which was temperature controlled at 35°. The bacterial suspension was physically separated from the antibiotics and the patient's serum until log-phase growth was entered as monitored by continuous turbidimetric reading. Utilizing a suction device built into the instrument, the bacterial suspension was drawn into compartments containing the disks. Incubation and continuous readings at 470 nm continued until the compartment with the smallest concentration of standard antibiotic had exerted its effect.

RESULTS AND DISCUSSION

Figure 1 represents a typical determination. The area under the curve for each standard and the area under the curve of the patient's specimen were calculated by the least-squares method. The areas under the curve for the two individual patient serum compartments were averaged. Log antibiotic concentration was plotted *versus* the area under the curve (Fig. 2), and the amount of antibiotic in the patient's specimen was determined by direct interpolation from this graph.

Table I presents a comparison of results obtained by a standard bioassay method (5, 6) with those obtained by the turbidimetric assay. The bioassay and turbidimetric assays agreed, on the average, within 10% for the 161 blood specimens tested. The turbidimetric assay could determine 10 μg of gentamicin/ml within 160 min of the start of an assay, a period comparable to the radioimmunoassay method. As little as 1 μg of gentamicin/ml could be determined within 4 hr. The ability to determine physiological concentrations of the other aminoglycoside antibiotics was equally rapid.

CONCLUSION

Under carefully controlled conditions, turbidimetric assay of antibiotics can be applied to clinical specimens. Because turbidimetric assays are amenable to automation and can be monitored continuously without human intervention, the data can be produced and interpreted with almost no expenditure of the technician's time. Currently, blood antibiotic level measurements are generally restricted to large medical institutions. With automated spectrophotometric systems, all medical facilities could determine blood antibiotic concentrations rapidly when potentially toxic antimicrobial agents are administered.

Impurities in Drugs V: Meprobamate

R. C. LAWRENCE, E. G. LOVERING ˣ, M. A. POIRIER, and J. R. WATSON

Received April 8, 1980, from the *Drug Research Laboratories, Health Protection Branch, Tunney's Pasture, Ottawa, Ontario, K1A 0L2 Canada.* Accepted for publication May 27, 1980.

Abstract □ One lot of meprobamate raw material and 28 lots of tablets were examined for impurities by TLC. All lots contained di-(2-methyl-2-propyl-3-carbamoyloxypropyl) carbonate (V) at levels that ranged between 0.1 and 1.0% of the total drug content. Nine lots also contained low levels of a second impurity (~0.1%), and one of these lots contained a third impurity (~0.1%), neither of which was identified. Estimates of the unidentified impurities were based on the assumption of a TLC response with furfural–hydrochloric acid spray equivalent to that of meprobamate. Compound V was identified by mass spectrometry and PMR and IR spectroscopy and by comparison of the TLC R_f value to that of a synthesized sample of V.

Keyphrases □ Meprobamate—identification of impurities in tablets □ Drug impurities—meprobamate, identification in tablets

The origins of organic impurities in drugs and some consequences of their presence were outlined previously (1). The present paper reports the occurrence of impurities in 28 lots of meprobamate tablets.

Meprobamate (I) can be synthesized (2, 3) by reduction of methylpropylpropanedioic acid diethyl ester (II) with lithium aluminum hydride to the corresponding 2-methyl-2-propyl-1,3-propanediol (III). Reaction of III with phosgene affords the dichlorocarbonate (IV), which, upon treatment with ammonia, yields I.

USP XX (4) and BP 1973 (5) contain specifications for meprobamate raw material and tablets. The BP includes a specification of 1% for related substances (not specified), with the test to be done by TLC. There are no USP specifications for impurities in meprobamate.

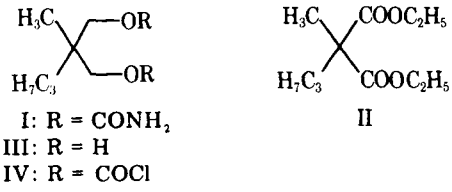
EXPERIMENTAL

Materials—All drugs and formulations were obtained directly from the manufacturer. Ammonia[1], 2-methyl-2-propyl-1,3-propanediol[2], ethyl chlorocarbonate[3], diethyl carbonate[3], furfural[4], pyridine[4], sodium methoxide[4], hydrochloric acid[5], and anhydrous sodium sulfate[5] were obtained commercially. All solvents[6] were analytical grade. Precoated silica gel GF-60 (20-cm × 20-cm × 0.25-mm) TLC plates[7] and silica gel powder[5] (60–200 mesh) were used. All PMR spectra were obtained in deuterochloroform[8] on an 80-MHz instrument[9] with tetramethylsilane as the internal standard. Mass spectral[10] samples were introduced *via* the direct probe and were recorded at an ionizing potential of 70 ev.

Standard Solutions—The standard solutions consisted of 100 mg of I/ml and 1.0 mg of V/ml in acetone.

TLC System—The chloroform–ethanol (90:10) developing solution was allowed to equilibrate in filter paper-lined chromatographic tanks for 20 min prior to use. Spots were visualized by spraying the plates sequentially with furfural and concentrated hydrochloric acid. The R_f values and the lower limits of detection of I and related compounds were established by the serial dilution of stock solutions.

Sample Preparation—To prepare the raw material samples, ~400 mg of I, accurately weighed, was dissolved in 4 ml of acetone. To prepare the tablet samples, an amount of powdered tablet equivalent to 400 mg of I was weighed into a 10-ml screw-capped tube, extracted by shaking for 15 min with 4 ml of acetone, centrifuged, and filtered.



I: R = $CONH_2$
III: R = H
IV: R = COCl

II

Screening for Impurities—Aliquots (10 μl) of the tablet extracts in acetone were applied to the TLC plates. Decomposition on the plate was checked for by two-dimensional TLC but was not found. The concentration of impurities was estimated by comparison of the spot diameters and intensities with the corresponding spots from the standard solutions, with the assumption that the response of the unidentified impurities to the spray was the same as that of I.

Isolation of Impurities—An amount of formulation equivalent to 2 g of I was shaken with two 40-ml portions of acetone for 15 min and filtered. The combined fractions were evaporated to dryness, and the residue was dissolved in 200 ml of ether. The ether solution was partitioned three times with 0.05 *N* NaOH to remove any fatty acids present as excipients, evaporated to dryness, redissolved in ~10 ml of the TLC solvent system, and poured onto the top of a slurry-packed silica gel[5] glass column prepared from 50 g of silica gel and 200 ml of the TLC solvent. After ~70 ml of the TLC solvent system had flowed through the column, 45 fractions of 3 ml each were collected.

The location of the various compounds was established by spotting a 15-μl aliquot of every other fraction on a TLC plate. The plate was developed and the spots were visualized with the furfural–hydrochloric acid spray. The fractions containing the impurity to be identified were combined, evaporated to dryness, and subjected to mass spectral, NMR, and IR[11] analyses.

Syntheses—The syntheses are illustrated in Scheme I.

2-Methyl-2-propyl-3-hydroxypropylcarbamate (VI)—Compound VI was prepared in a 40% yield from the dioxanone (VIII) using the method described by Ludwig and coworkers (2, 3), mp 51–52°; IR (KBr): 3380 (OH), 3240, 3200 (NH), 1690 (C=O), 1620 (C–N), 1075, and 1040

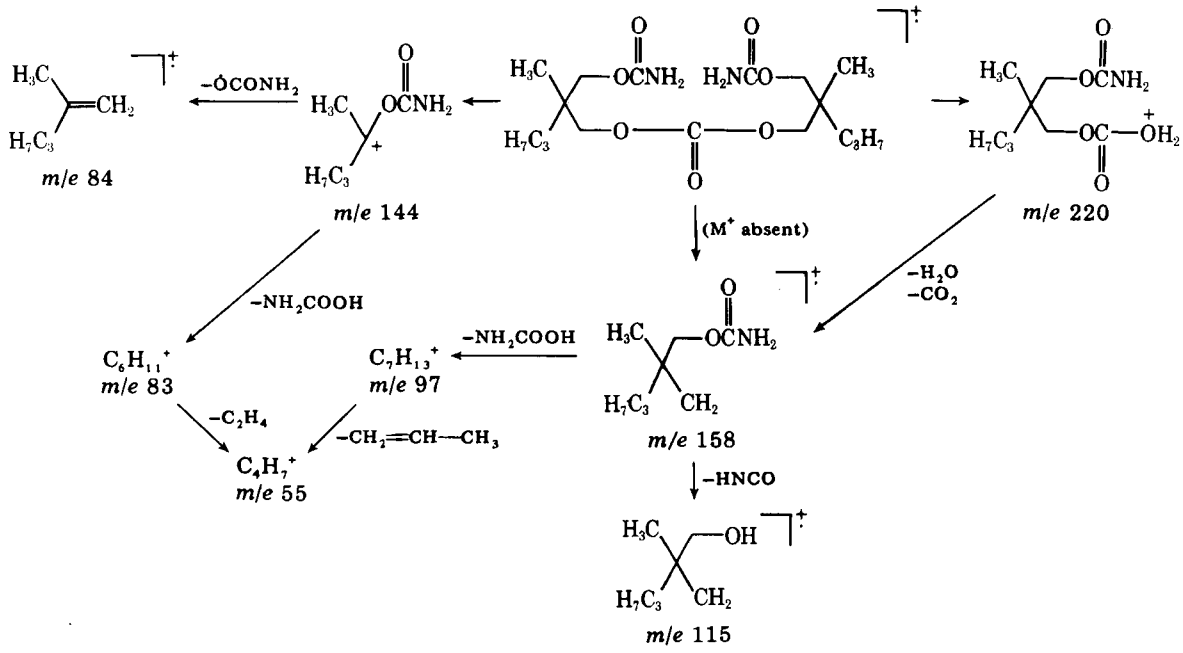

Scheme II

(C–O) cm^{-1}; PMR ($CDCl_3$): δ 5.16 (broad, 2H, NH_2), 3.90 (s, 2H, CH_2O), 3.28 [s, 2H, CH_2OH (disappears with D_2O exchange)], 3.03 (broad, 1H, OH), 1.22, and 0.90 (m, 10H, alkyl protons) ppm; mass spectrum (70 ev, 45°): M^+ absent, *m/e* 101 (31.0%), 96 (18), 84 (100), 83 (95), 75 (88), 62 (87), and 55 (96).

(2-Methyl-2-propyl-3-carbamoyloxypropyl)ethyl Carbonate (VII) (*2, 3*)—To 4 ml of chloroform in which 118 mg (1.5 mmoles) of pyridine had been dissolved were added 52 mg (0.3 mmole) of VI and 33 mg (0.3 mmole) of ethyl chlorocarbonate dissolved in ~2 ml of chloroform. The reaction mixture was refluxed for 1 hr and then poured into cold water. The chloroform layer was washed with 10% hydrochloric acid, washed again with water, dried over anhydrous sodium sulfate, and filtered. Evaporation of the filtrate yielded 69 mg (95%) of oily VII; IR (film): 3470, 3360 (NH), 1730 (C=O), 1600 (C–N), 1060, and 1005 (C–O) cm^{-1}; PMR ($CDCl_3$): δ 4.62 (broad, 2H, NH_2), 4.20 (q, 2H, OCH_2CH_3), 3.94 (s, 2H, CH_2O), 3.90 (s, 2H, CH_2O), 1.28, and 0.90 (m, 13H, alkyl protons) ppm; mass spectrum (70 ev, 25°): M^+ absent, *m/e* 173 (28%), 144 (26), 114 (50), 101 (42), 96 (95), 84 (96), 83 (100), 75 (55), 62 (88), and 55 (96).

Di-(2-methyl-2-propyl-3-carbamoyloxypropyl) Carbonate (V) (*2, 3*)—Compound VI, 18 mg, and 25 mg of VII were dissolved in 5 ml of chloroform and refluxed in the presence of ~1 mg of sodium methoxide for 3 hr. The mixture was cooled, diluted with chloroform, washed with water, and dried over anhydrous sodium sulfate. Evaporation to dryness yielded V (45%), mp 88–90°; IR (film): 3490, 3380 (NH), 1730 (C=O), 1610 (C–N), 1260, and 1070 (C–O) cm^{-1}; PMR ($CDCl_3$): δ 4.70 (broad, 4H, NH_2), 3.97 (s, 4H, OCH_2), 3.93 (s, 4H, OCH_2), 1.26, and 0.93 (m, 20H, alkyl protons) ppm; mass spectrum (70 ev, 115°): M^+ absent, *m/e* 220 (33%), 158 (90), 144 (16), 115 (24), 97 (100), 84 (45), 83 (57), and 55 (63).

RESULTS AND DISCUSSION

The TLC R_f values and the limits of detection of I, VI, VII, and the impurities in tablet formulations are given in Table I.

Twenty-eight lots of meprobamate tablets and one lot of drug raw material were screened for impurities by TLC. All lots contained V at levels ranging from 0.1 to 1.0%. Nine lots also contained a second impurity, designated as IX, and one of these lots contained a third impurity, X. The levels of IX and X were estimated by TLC to be ~0.1%, with the assumption of a response identical to that of meprobamate. They were not investigated further. The identity of V was established by IR, PMR, and mass spectral analyses and by comparison of the TLC R_f value with that of a synthesized specimen.

Table I—TLC Characteristics of Meprobamate and Related Compounds

Compound	R_f Absolute	R_f Relative	Limit of Detection, μg
I	0.26	1.00	1
VI	0.27	1.04	2
VII	0.56	2.15	2
V	0.42	1.61	1
IX	0.35	1.35	—
X	0.65	2.50	—

The structure postulated for V is supported by the mass spectral and PMR data. The molecular ion is absent from the electron-impact mass spectrum, but the chemical-ionization spectrum obtained with methane shows a weak peak at *m/e* 377 (3%), attributable to MH^+, and a strong fragment at *m/e* 158 (100%), also present in the electron-impact spectrum, corresponding to breakage of the carbonate bond. The ion at *m/e* 115 is formed by the loss of isocyanic acid from the *m/e* 158 fragment, and the base peak, *m/e* 97, is attributable to a loss of water from *m/e* 115. Mechanisms for the formation of fragments in the mass spectrum of V are proposed in Scheme II (6, 7). The PMR spectrum shows the NH_2 protons at 4.70 ppm and two singlets for the two sets of $-CH_2-$, with each singlet integrating for four protons. The aliphatic part of the spectrum is similar to that of meprobamate because of the symmetry of the molecule.

Compound V may form during the synthesis of meprobamate by the reaction of IV with the semichlorinated derivative of III, which, upon treatment with ammonia, would yield V. It is unlikely that V is a degradation product of meprobamate.

Major Skin-Irritant Principle from *Synadenium grantii*

A. DOUGLAS KINGHORN

Received April 7, 1980, from the *Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication May 29, 1980.

Abstract □ The latex of *Synadenium grantii* Hook. f. (Euphorbiaceae) yielded a novel skin irritant, 12-*O*-tigloyl-4-deoxyphorbol-13-isobutyrate (I). The identity of the diterpene parent alcohol and the relative positions of the esterifying groups were established by spectral analysis and experiments leading to the hydrolysis and acetylation of I. Compound I is the first phorbol derivative to be reported from the genus *Synadenium*.

Keyphrases □ 12-*O*-Tigloyl-4-deoxyphorbol-13-isobutyrate—isolation as skin irritant from *Synadenium grantii* and identification □ Euphorbiaceae—isolation of phorbol ester derivative as skin irritant from *Synadenium grantii* □ Diterpene esters—isolation as skin irritant from *Synadenium grantii*

Synadenium grantii is a member of a small genus of 15 species indigenous to East Africa (1). The shrub is grown in Europe and North America as an ornamental plant (2). A previous clinical report described symptoms from contact with the latex of this plant, which included burning and blistering of the face and neck (3).

This study was initiated to determine whether the toxicological effects of *S. grantii* latex are due to phorbol ester constituents since many representatives of this class of irritant and tumor-promoting diterpenoids have been found in the related genus Euphorbia (4). A previous phytochemical study of *S. grantii* enabled the detection of euphol, tirucallol, euphorbol, and an isomer of lanosterol (5), although these phytosterols do not produce a skin-irritant effect (6).

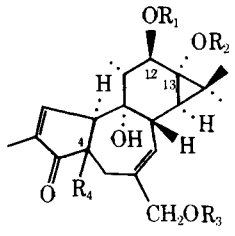
In the present work, fractionation of *S. grantii* latex resulted in the isolation of a novel irritant natural product, 12-*O*-tigloyl-4-deoxyphorbol-13-isobutyrate (I). Esters of 4-deoxyphorbol were isolated before from only two plant species (7–9).

EXPERIMENTAL

Plant Material—*Synadenium grantii* Hook. f. (Euphorbiaceae), propagated from a cutting[1], was used as the source of latex[2].

Extraction and Fractionation—Dried latex (19.9 g) was extracted at room temperature with six 100-ml portions of acetone. After drying, the residue (6.1 g) was partitioned between 60 ml of hexane and two 20-ml portions of methanol–water (9:1). Mouse ear-irritant activity (10) was traced to the methanol–water layer (1.1 g), which was subjected to low-pressure column chromatography on octadecylsilyl silica gel[3] with water–acetonitrile–methanol (3:2:2) as the eluting solvent. Irritant fractions were concentrated into 200 mg of the original column charge. The major active[4] principle, I, was purified by preparative TLC on silica gel G[3] in chloroform–benzene–ether–ethyl acetate (1:3:3:1) (R_f 0.22) and methylene chloride–ether–acetone (3:1:1) (R_f 0.55), as well as on diethylene glycol-impregnated kieselguhr G[3] (8) in cyclohexane–methyl ethyl ketone (9:1) (double development) (R_f 0.32).

Characterization of I—Resinous 12-*O*-tigloyl-4-deoxyphorbol-13-isobutyrate (I) (10 mg, 0.05%) exhibited major absorbance maxima in the IR spectrum[5] at ν_{max} 3430 (broad), 1710, 1650, 1625, and 1250 cm^{-1} and



I: R_1 = OCC(CH_3)=$CHCH_3$, R_2 = $OCCH(CH_3)_2$, R_3 = H, R_4 = βH
II: R_1 = OCC(CH_3)=$CHCH_3$, R_2 = R_3 = H, R_4 = αH
III: R_1 = R_2 = R_3 = $OCCH_3$, R_4 = αH

in the UV spectrum[6] at λ_{max} 220 (log ε 4.37) nm. The NMR spectrum[7] showed signals at δ 0.91 (d, 1H, J = 6 Hz, 14-H), 0.95 (d, 3H, J = 6Hz, 18-CH_3), 1.10–1.26 (m, 12H, 16-CH_3, 17-CH_3, and two isobutyl CH_3), 1.74 [m, 6H, 19-CH_3 and =$CH(CH_3)$], 1.85 (s, 3H, 2′-CH_3), 2.25–2.61 (m, 3H), 2.92 (m, 1H, OH, exchangeable with D_2O), 3.24 (m, 1H, 10-H), 3.99 (s, 2H, 20-H_2), 5.51 (d, 1H, J = 9.5 Hz, 12-H), 5.54 (m, 1H, 7-H), 5.82 (m, 1H, OH, exchangeable with D_2O), 6.91 [m, 1H, =$CH(CH_3)$], and 7.55 (m, 1H, 1-H). Its mass spectrum[8] exhibited principal fragment ions at *m/e* 500 (M^+, 4%), 482 (3), 457 (3; found, 457.2221; calc. for $C_{26}H_{33}O_7$, 457.2225), 412 (10), 401 (8), 312 (16; found, 312.1727; calc. for $C_{20}H_{24}O_3$, 312.1725), 294 (18), 83 (100), 71 (30), and 43 (52).

Hydrolysis, Epimerization, and Acetylation of I—Hydrolysis and epimerization of I (6 mg) in 0.02 *M* KOH in methanol for 15 min at room temperature (8) led to the formation of a more polar compound, 12-*O*-tigloyl-4-deoxy-4α-phorbol (II) (4 mg), which was purified by preparative TLC on silica gel[3] in methylene chloride–acetone–hexane (3:1:1) (triple development) (R_f 0.10). The major absorbances in the IR spectrum[5] of II were observed at ν_{max} 3400 (broad), 1690, 1640, and 1625 cm^{-1}, and in the UV spectrum[6] at λ_{max} 220 (log ε 3.82) nm. In the NMR spectrum[7] of II, an upfield shift for the C-1 proton to δ 7.10 was evident, as well as a downfield shift for the C-10 proton to δ 3.42, suggesting an epimerization of the C-4 proton on hydrolysis (7, 8). There were no signals in the NMR spectrum of II assignable to an isobutyrate moiety, although all of the tigliate signals observed in the NMR spectrum of I were present. Other assignable signals were observed at δ 0.95 (d, 3H, J = 8.8 Hz, 18-CH_3), 1.17 (s, 6H, 16-CH_3 and 17-CH_3), 1.79 (m, 3H, 19-CH_3), 3.92 (s, 2H, 20-H_2), and 4.91 (d, 1H, J = 12 Hz, 12-H). Although the molecular ion of II was not apparent in the mass spectrum, fragment ions were observed at *m/e* 394 (3%), 330 (2), 312 (16), 294 (14), 91 (27), 83 (100), 69 (24), and 55 (55).

Compound II (2 mg) was hydrolyzed further with 0.05 *M* KOH in methanol at ambient temperature for 45 min. The product was partitioned and acetylated by a standard procedure (8). The resulting compound, 4-deoxy-4α-phorbol-12,13,20-triacetate (III) (2 mg), was identical to an authentic sample (co-TLC, mass spectral, and NMR analyses) (8).

DISCUSSION

The parent diterpene alcohol of the major skin-irritant factor (I) in *S. grantii* latex was shown to be 4-deoxyphorbol by hydrolysis (with simultaneous epimerization) (7), acetylation, and direct comparison to 4-deoxy-4α-phorbol-12,13,20-triacetate (III). The two esterifying groups in I were positioned at C-12 and C-13 since the NMR resonance at δ 3.99

is typical of other 4-deoxyphorbol diesters with a primary hydroxyl group at C-20 (7–9). Mass spectral and NMR observations permitted the assignment of these ester functions as tiglic and isobutyric acids (9, 11). The tiglic group was assigned to C-12 because a fragment ion in the mass spectrum of I at *m/e* 401 indicated the loss of an acyloxy radical rather than a whole acid substituent from the molecular ion, an effect that was noted previously in phorbol 12,13-diesters (12). In contrast, as indicated by the fragment ion at *m/e* 412, the C-13 isobutyric substituent left the molecule of I as an acid (12). Confirmation of these assignments was achieved using a selective hydrolysis procedure in which the C-12 substituent of I was less susceptible to hydrolysis than the C-13 substituent (8). This procedure resulted in the formation of II, in which the tiglyl substituent was detected by NMR and mass spectral analyses.

Esters of 4-deoxyphorbol appear to be rare in the plant kingdom, having been described previously in *Euphorbia tirucalli* (7, 8) and *E. biglandulosa* (9). The irritant principle I in *S. grantii* is the first representative in this series to be esterified with two short-chain acids.

N-Demethylation of Dextromethorphan

NORTON P. PEET

Received March 5, 1980, from the *Pharmaceutical Research and Development–Medicinal Chemistry Department, Dow Chemical Company, Indianapolis, IN 46268.* Accepted for publication June 3, 1980.

Abstract □ In addition to providing an efficient synthesis of 3-methoxymorphinan hydrochloride, the use of 2,2,2-trichloroethyl chloroformate in the *N*-demethylation of dextromethorphan led to the isolation of two novel zinc salts of 3-methoxymorphinan.

Keyphrases □ Dextromethorphan—*N*-demethylation to yield 3-methoxymorphinan hydrochloride and two novel zinc salts of 3-methoxymorphinan □ Antitussives—dextromethorphan, *N*-demethylation to yield 3-methoxymorphinan hydrochloride and two novel zinc salts of 3-methoxymorphinan □ 3-Methoxymorphinan—synthesis by *N*-demethylation of dextromethorphan

A sample of 3-methoxymorphinan (V) recently was required in these laboratories for pharmacological evaluation. Compound V is one of the three known metabolites of dextromethorphan (3-methoxy-*N*-methylmorphinan, I) (1, 2), a clinically useful antitussive agent. This report describes a new synthesis of V from I and the isolation of novel zinc salts of V.

EXPERIMENTAL[1]

Synthesis of 1,3,4,9,10,10a-Hexahydro-6-methoxy-2*H*-10,4a-(iminoethano)phenanthrene-11-carboxylic Acid 2,2,2-Trichloroethyl Ester (II)—Dextromethorphan hydrobromide monohydrate[2] (27.8 g, 75.0 mmoles) was partitioned between chloroform and a solution of 5.7 g of potassium hydroxide in water. The organic layer was separated, dried (sodium sulfate), and concentrated to leave a viscous oil, which solidified upon standing to yield 20.4 g (100%) of I, mp 107–110°; IR (mineral oil): 1610 cm^{-1}. TLC on silica gel with chloroform–methanol (9:1) gave a single spot at $R_f \simeq 0.1$.

To a solution of I (8.14 g, 30.0 mmoles) in 100 ml of benzene was added 2,2,2-trichloroethyl chloroformate[3] (6.99 g, 33.0 mmoles). After refluxing for 1 hr, the solution was concentrated to leave 14.6 g of crude II as a viscous oil; IR (mineral oil): 1710 (C=O) cm^{-1}; NMR (deuterochloroform): δ 4.70 (s, 2H, OCH_2); mass spectrum (70 ev, electron impact): *m/e* 431 (molecular ion). TLC on silica gel with chloroform–methanol (9:1) gave a single spot at $R_f \simeq 0.8$.

Synthesis of 3-Methoxymorphinan Tetrachlorozincate (IV)—To a solution of II (12.7 g, 29.3 mmoles) in 100 ml of 90% acetic acid was added 5 g of powered zinc. An exotherm followed. After 20 min, TLC indicated completeness of the reaction, and the mixture was filtered. The filtrate was concentrated to a white solid, which was triturated with ether and collected to yield 3-methoxymorphinan tetraacetatozincate (III), mp 157–167° (glass); NMR (deuterochloroform and dimethyl sulfoxide-d_6): δ 7.20–7.00 (m, 1H, aromatic), 6.87–6.68 (m, 2H, aromatic), 3.80 (s, 3H, OCH_3), 3.30–3.00 (m, 3H, $CHNHCH_2$), and 2.06 (s, ~6H, acetate ions); mass spectrum (70 ev, electron impact): *m/e* 257 (molecular ion). TLC on silica gel with chloroform–methanol (9:1) gave a single spot at $R_f \simeq 0.15$.

Crude III (10.0 g) was dissolved in 2000 ml of chloroform, and dry hydrogen chloride gas was bubbled through the solution for 10 min. The solution was concentrated, and the resulting oil partially crystallized upon standing under ether. Trituration with a small volume of isopropanol

[1] Melting points are uncorrected. IR spectra were recorded with a Perkin-Elmer model 727B spectrophotometer. NMR spectra were obtained with a Varian EM360A spectrometer. Mass spectra were recorded with a Finnigan model 4023 gas chromatograph–mass spectrometer (electron impact and chemical ionization) at 70 ev. Combustion analyses for carbon, hydrogen, nitrogen, chlorine, and zinc were performed by Dow Analytical Laboratories and Galbraith Laboratories, Knoxville, Tenn.

is typical of other 4-deoxyphorbol diesters with a primary hydroxyl group at C-20 (7–9). Mass spectral and NMR observations permitted the assignment of these ester functions as tiglic and isobutyric acids (9, 11). The tiglic group was assigned to C-12 because a fragment ion in the mass spectrum of I at *m/e* 401 indicated the loss of an acyloxy radical rather than a whole acid substituent from the molecular ion, an effect that was noted previously in phorbol 12,13-diesters (12). In contrast, as indicated by the fragment ion at *m/e* 412, the C-13 isobutyric substituent left the molecule of I as an acid (12). Confirmation of these assignments was achieved using a selective hydrolysis procedure in which the C-12 substituent of I was less susceptible to hydrolysis than the C-13 substituent (8). This procedure resulted in the formation of II, in which the tiglyl substituent was detected by NMR and mass spectral analyses.

Esters of 4-deoxyphorbol appear to be rare in the plant kingdom, having been described previously in *Euphorbia tirucalli* (7, 8) and *E. biglandulosa* (9). The irritant principle I in *S. grantii* is the first representative in this series to be esterified with two short-chain acids.

N-Demethylation of Dextromethorphan

NORTON P. PEET

Received March 5, 1980, from the *Pharmaceutical Research and Development–Medicinal Chemistry Department, Dow Chemical Company, Indianapolis, IN 46268.* Accepted for publication June 3, 1980.

Abstract □ In addition to providing an efficient synthesis of 3-methoxymorphinan hydrochloride, the use of 2,2,2-trichloroethyl chloroformate in the *N*-demethylation of dextromethorphan led to the isolation of two novel zinc salts of 3-methoxymorphinan.

Keyphrases □ Dextromethorphan—*N*-demethylation to yield 3-methoxymorphinan hydrochloride and two novel zinc salts of 3-methoxymorphinan □ Antitussives—dextromethorphan, *N*-demethylation to yield 3-methoxymorphinan hydrochloride and two novel zinc salts of 3-methoxymorphinan □ 3-Methoxymorphinan—synthesis by *N*-demethylation of dextromethorphan

A sample of 3-methoxymorphinan (V) recently was required in these laboratories for pharmacological evaluation. Compound V is one of the three known metabolites of dextromethorphan (3-methoxy-*N*-methylmorphinan, I) (1, 2), a clinically useful antitussive agent. This report describes a new synthesis of V from I and the isolation of novel zinc salts of V.

EXPERIMENTAL[1]

Synthesis of 1,3,4,9,10,10a-Hexahydro-6-methoxy-2*H*-10,4a-(iminoethano)phenanthrene-11-carboxylic Acid 2,2,2-Trichloroethyl Ester (II)—Dextromethorphan hydrobromide monohydrate[2] (27.8 g, 75.0 mmoles) was partitioned between chloroform and a solution of 5.7 g of potassium hydroxide in water. The organic layer was separated, dried (sodium sulfate), and concentrated to leave a viscous oil, which solidified upon standing to yield 20.4 g (100%) of I, mp 107–110°; IR (mineral oil): 1610 cm^{-1}. TLC on silica gel with chloroform–methanol (9:1) gave a single spot at $R_f \simeq 0.1$.

To a solution of I (8.14 g, 30.0 mmoles) in 100 ml of benzene was added 2,2,2-trichloroethyl chloroformate[3] (6.99 g, 33.0 mmoles). After refluxing for 1 hr, the solution was concentrated to leave 14.6 g of crude II as a viscous oil; IR (mineral oil): 1710 (C=O) cm^{-1}; NMR (deuterochloroform): δ 4.70 (s, 2H, OCH_2); mass spectrum (70 ev, electron impact): *m/e* 431 (molecular ion). TLC on silica gel with chloroform–methanol (9:1) gave a single spot at $R_f \simeq 0.8$.

Synthesis of 3-Methoxymorphinan Tetrachlorozincate (IV)—To a solution of II (12.7 g, 29.3 mmoles) in 100 ml of 90% acetic acid was added 5 g of powered zinc. An exotherm followed. After 20 min, TLC indicated completeness of the reaction, and the mixture was filtered. The filtrate was concentrated to a white solid, which was triturated with ether and collected to yield 3-methoxymorphinan tetraacetatozincate (III), mp 157–167° (glass); NMR (deuterochloroform and dimethyl sulfoxide-d_6): δ 7.20–7.00 (m, 1H, aromatic), 6.87–6.68 (m, 2H, aromatic), 3.80 (s, 3H, OCH_3), 3.30–3.00 (m, 3H, $CHNHCH_2$), and 2.06 (s, ~6H, acetate ions); mass spectrum (70 ev, electron impact): *m/e* 257 (molecular ion). TLC on silica gel with chloroform–methanol (9:1) gave a single spot at $R_f \simeq 0.15$.

Crude III (10.0 g) was dissolved in 2000 ml of chloroform, and dry hydrogen chloride gas was bubbled through the solution for 10 min. The solution was concentrated, and the resulting oil partially crystallized upon standing under ether. Trituration with a small volume of isopropanol

[1] Melting points are uncorrected. IR spectra were recorded with a Perkin-Elmer model 727B spectrophotometer. NMR spectra were obtained with a Varian EM360A spectrometer. Mass spectra were recorded with a Finnigan model 4023 gas chromatograph–mass spectrometer (electron impact and chemical ionization) at 70 ev. Combustion analyses for carbon, hydrogen, nitrogen, chlorine, and zinc were performed by Dow Analytical Laboratories and Galbraith Laboratories, Knoxville, Tenn.

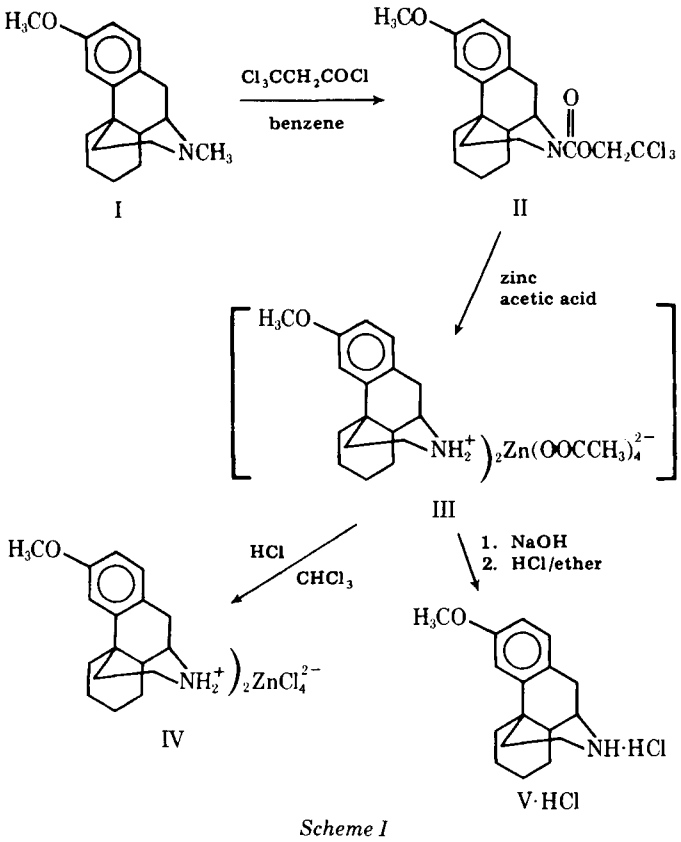

Scheme I

effected complete crystallization. Recrystallization of this material twice from isopropanol–ethyl acetate gave 2.19 g of IV, mp 191–192°; IR (mineral oil): 3200–2750 (NH_2^+), 1600, 1505, 1235, and 1030 cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 9.07 (broad s, 2H, NH_2^+, deuterium oxide exchangeable), 7.30–7.10 (m, 1H, aromatic), 6.96–6.77 (m, 2H, aromatic), and 3.78 (s, 3H, OCH_3). TLC on silica gel with chloroform–methanol (9:1) gave a single spot at $R_f \simeq 0.15$.

Anal.—Calc. for $C_{34}H_{48}Cl_4N_2O_4Zn$: C, 56.40; H, 6.68; Cl, 19.59; N, 3.87; Zn, 9.03. Found: C, 56.52; H, 6.54; Cl, 19.40; N, 3.70; Zn, 8.94.

Synthesis of 3-Methoxymorphinan (V) Hydrochloride—Crude III (21.8 g, 26.7 mmoles) was dissolved in chloroform and treated with 75 ml of 1 *N* NaOH. A flocculent white precipitate was removed by filtration. The organic phase of the filtrate was separated, dried (sodium sulfate), and concentrated to yield 10.5 g (77%) of V as a viscous oil; IR (neat): 1610, 1490, 1240, 1040, and 745 cm^{-1}; NMR (deuterochloroform): δ 7.15–6.95 (m, 1H, aromatic), 6.88–6.64 (m, 2H, aromatic), and 3.79 (s, 3H, OCH_3).

A solution of the free base (10.0 g, 38.8 mmoles) in ether–ethyl acetate was treated with ethereal hydrogen chloride until oiling no longer occurred. Scratching produced a white solid, which was collected, washed with ether, and air dried to yield 9.30 g (81%) of V, mp 249–250.5° (methanol–ether–ethyl acetate) [lit. (3) mp 253.5–255°]; IR (mineral oil): 3100–2400 (NH_2^+), 1610, 1510, 1245, 1040, and 900 cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 9.55 (broad s, 2H, NH_2^+, deuterium oxide exchangeable), 7.26–7.05 (m, 1H, aromatic), 6.95–6.73 (m, 2H, aromatic), and 3.75 (s, 3H, OCH_3).

RESULTS AND DISCUSSION

N-Demethylation of I was accomplished previously using phenyl chloroformate (followed by hydrolysis of the resulting carbamate) (3) or cyanogen bromide (4). 2,2,2-Trichloroethyl chloroformate was considered an attractive potential reagent for this *N*-demethylation since it is mild and was previously employed for the demethylation of tertiary methylamines. Yields are high for *N*-demethylation using this reagent; morphine was demethylated in 75% yield with 2,2,2-trichloroethyl chloroformate (5). Demethylation with 2,2,2-trichloroethyl chloroformate generally leads to fewer side reactions and a cleaner product than does demethylation with cyanogen bromide. The use of ethyl or phenyl chloroformate for demethylation requires a strong acid or strong base for hydrolysis of the intermediate carbamates, whereas 2,2,2-trichloroethyl chloroformate does not.

Accordingly, dextromethorphan (I) was treated with 2,2,2-trichloroethyl chloroformate to produce II. Treatment of an acetic acid solution of II with zinc dust produced a material that was partially characterized and assigned as the zinc tetraacetate salt of 3-methoxymorphinan (III). This remarkable salt (mol. wt. 818.30) was soluble in chloroform and displayed an elution position on a silica gel TLC plate using chloroform–methanol (9:1) as the eluent. Spectral data were in accord with the structural assignment for III (Scheme I). However, the structure of III was clearly indicated by its conversion to the zinc tetrachloride salt of 3-methoxymorphinan (IV).

Treatment of a chloroform solution of III with dry hydrogen chloride yielded a white solid, which, when recrystallized twice from isopropanol–ethyl acetate, displayed a sharp melting point at 191–192°. An aqueous solution of this material, when treated with aqueous silver nitrate, produced a voluminous, white precipitate. Spectral data for this material were in accord with Structure IV and were similar to those recorded for III. Elemental combustion analysis established the structure of the zinc salt as IV. Correct analyses for carbon, hydrogen, nitrogen, chlorine, and zinc were obtained. These analyses could be obtained only if the salt was dried under vacuum at 60°. Drying at 40 or 80° led to incorrect analyses, presumably due to insufficient removal of volatile substances and decomposition, respectively.

The tendency for 3-methoxymorphinan (V) to associate with zinc produced two salts (III and IV), whose identification was subordinate to the preparation of the desired metabolite (V). However, it is speculated that the ability of at least one metabolite of dextromethorphan to complex with zinc (and perhaps other trace metals) may be intimately associated with the pharmacology displayed by I.

Associated zinc was separated readily from III by partitioning between chloroform and aqueous base. The chloroform layer then contained noncomplexed V, which was isolated and treated with dry hydrogen chloride to produce 3-methoxymorphinan (V) hydrochloride. The overall yield of V·HCl from I was ~70%.

GLC Method for Assay of Forskolin, a Novel Positive Inotropic and Blood Pressure-Lowering Agent

P. K. INAMDAR ˣ, H. DORNAUER, and N. J. de SOUZA

Received April 15, 1980, from the *Research Centre, Hoechst Pharmaceuticals Ltd., Bombay 400 080, India.* Accepted for publication June 9, 1980.

Abstract □ A GLC method for the quantitative determination of forskolin, a novel positive inotropic and blood pressure-lowering agent, is described. This method is simple, rapid, and sensitive and is suitable for the routine assay of plant materials and pharmaceutical preparations containing forskolin.

Keyphrases □ Forskolin—GLC analysis in plant extracts and pharmaceutical preparations □ GLC—analysis, forskolin in plant extracts and pharmaceutical preparations □ Antihypertensive agents—forskolin, GLC analysis in plant extracts and pharmaceutical preparations

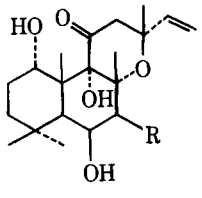
Forskolin (1α,6β,9α-trihydroxy-7β-acetoxy-8,13-epoxy-labd-14-en-11-one, Ia) is a novel positive inotropic and blood pressure-lowering agent isolated from the Indian plant *Coleus forskohlii* Briq. (Labiatae) (1, 2). Compound Ia currently is under preclinical development.

Different rapid, precise methods for the quantitative estimation of forskolin in plant materials and pharmaceutical preparations, as well as for application to pharmacokinetic studies, are under investigation in these laboratories. This report describes a GLC method for the assay of forskolin; it is applicable to forskolin in plant extracts and pharmaceutical preparations.

EXPERIMENTAL

Instrumentation—The gas–liquid chromatograph[1] was equipped with a flame-ionization detector and a 180-cm × 5-mm glass, coil-shaped column packed with 3% OV-1[2] on 100–120-mesh Gas Chrom Q[3]. Nitrogen was the carrier gas at a flow rate of 20 ml/min, and the air and hydrogen flow rates were set to maximize the detector response. A potentiometric continuous-line recorder[4] (2.5 mv) with a speed of 300 mm/hr was used. The temperatures were: injector, 250°; column oven, 220°; and manifold, 270°. A microsyringe[5] was used in the GLC analysis.

Reagents and Materials—Samples of forskolin (Ia), 7-deacetylforskolin (Ib), plant materials, and tablets of forskolin were obtained[6]. The solvents were analytical grade.



Ia: R = $OCOCH_3$
Ib: R = OH

[2] E. Merck, Darmstadt, West Germany.
[3] Supelco, Bellefonte, Pa.
[4] Kompensograph, 1288 × 288, type M-810-417, Siemens Aktiengesellschaft, Erlangen, West Germany.
[5] Hamilton 701N, Micromesure AG., 7402, Bonaduz, Switzerland.
[6] These samples were obtained from the research and development laboratories of Hoechst Pharmaceuticals Ltd. The plant materials were identified as *C. forskohlii* Briq. (No. HOE 141) and *C. spicatus* Benth. (No. HOE 142), both of the Labiatae family, by Miss Virbala Shah of Hoechst Pharmaceuticals Ltd. Voucher specimens are preserved at the Herbarium of the Research Centre, Hoechst Pharmaceuticals Ltd., Mulund, Bombay 400 080, India.

Standard Solutions and Calibration Curves—Forskolin (120 mg) was dissolved in chloroform (10 ml). The internal standard solution was prepared by dissolving Ib (80 mg) in chloroform (10 ml). Forskolin solutions were prepared in triplicate from these solutions to contain 1.2, 2.4, 3.6, 4.8, and 6 mg of forskolin/ml of chloroform, in which the concentration of the internal standard was 4 mg/ml.

Each solution (1 μl) was injected in triplicate onto the column. The peak area ratio of forskolin to the internal standard was plotted against the ratio of the weight of forskolin to the internal standard to yield a calibration curve.

Preparation of Semipurified Extracts of Plant Materials—The dried and finely divided plant material (15 g) was extracted with benzene (3 × 150 ml) at 40–50° for 5 hr, and the combined extracts were filtered and concentrated *in vacuo*. The residue was triturated with petroleum ether (bp 60–80°) (2 × 50 ml), and the petroleum ether layer was decanted. The petroleum ether-insoluble residue was treated further with methanol (2 × 50 ml), and the methanolic solution was separated and concentrated *in vacuo* to constant weight to provide the semipurified extract.

Assay of Plant Materials—The semipurified plant extract was dissolved, depending on its weight, in chloroform (0.125–3.0 ml). The solution always was adjusted to contain the internal standard at a concentration of 4 mg/ml. One microliter of the solution was injected onto the column. The mean peak area ratio of six injections was used for quantitation of the amount of forskolin in *C. forskohlii*.

Assay of Forskolin Tablets (5 mg/Tablet)—Ten tablets, each weighing an average of 125 mg, were powdered. A quantity equivalent to one tablet (125 mg) was transferred to a 25-ml centrifuge tube. Chloroform (10 ml) was added, and the suspension was centrifuged for 10 min; the procedure was repeated three times.

The pooled chloroform extracts left a residue upon evaporation of the chloroform *in vacuo*, and this residue was dissolved in chloroform (0.5 ml) and mixed with the internal standard solution (0.5 ml). One microliter of this solution was injected in quadruplicate onto the column.

Placebo tablets also were extracted in parallel with the sample. The placebo chromatogram was checked for interfering peaks at the retention times for forskolin and the internal standard.

RESULTS AND DISCUSSION

The gas chromatogram of forskolin and the internal standard is presented in Fig. 1. The retention times were 21.6 and 18.0 min, respectively. The GLC responses for forskolin and Ib were linear over a range of at least 1.2–6.0 μg of the drug and the internal standard injected separately. The minimum detectable level was 30 ng of forskolin. A calibration curve indicated that a linear relation existed in the 1.2–6.0-μg range between the peak area ratio of forskolin to the internal standard and the ratio of the weight of forskolin to the internal standard.

Typical chromatograms for a semipurified extract of *C. forskohlii* and the semipurified extract of *C. forskohlii* together with the internal standard (4 μg) are presented in Fig. 2. A GLC–mass spectrometric analysis of the semipurified extract of *C. forskohlii* revealed that the peak with the retention time of that for forskolin gave a mass spectrum identical to that of a standard forskolin sample. By referring to the calibration curve, the amount of forskolin present in *C. forskohlii* was calculated. In the different samples assayed, forskolin occurred in amounts ranging from ~0.05 to 0.1% of the dry weight of the plant material, depending on the part of the plant that was assayed as well as on the time and location of collection of the plant material. The results agreed well with amounts of forskolin isolated from bulk quantities of plant material (1). Therefore, the method is a rapid and sensitive technique for evaluating and controlling the quality of *C. forskohlii*.

To find alternative and, possibly, richer sources of forskolin than *C. forskohlii*, the method was applied to semipurified extracts of other

Anti-Inflammatory Activity of Diazomethyl Ketone and Chloromethyl Ketone Analogs Prepared from *N*-Tosyl Amino Acids

I. H. HALL ˣ, J. E. HALL, Jr., M. MOHSENI, and Z. SAJADI

Received January 7, 1980, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication June 9, 1980.

Abstract □ A series of diazomethyl ketone and chloromethyl ketone analogs prepared from *N*-tosyl amino acids was shown to have anti-inflammatory activity in mice at 20 mg/kg and in rats at 10 mg/kg. *N*-Tosyl-L-alanine and *N*-tosyl-β-alanine chloromethyl ketones demonstrated the most potent anti-inflammatory activity. The writhing reflex also was inhibited at 20 mg/kg in mice. In the tail flick test, *N*-tosyl-D,L-alanine and *N*-tosyl-D,L-isoleucine chloromethyl ketones demonstrated the highest increase in time. Toxicity studies indicated good therapeutic indexes for most of these agents.

Keyphrases □ Anti-inflammatory activity—diazomethyl ketone and chloromethyl ketone analogs prepared from *N*-tosyl amino acids, biological evaluation □ *N*-Tosyl amino acids—diazomethyl ketone and chloromethyl ketone analogs, evaluation for anti-inflammatory activity

A series of *N*-tosyl, *N*-benzoyl, *N*-acetyl, *N*-carbobenzyloxy, and *N*-cinnamyl cyanomethyl esters of amino acids was shown to have anti-inflammatory and immunosuppressive activities in mice (1). The standard proteolytic inhibitor tosylphenylalanyl chloromethyl ketone also was active as an anti-inflammatory agent. This report discusses a series of diazomethyl ketones and chloromethyl ketones of *N*-tosyl amino acids that demonstrated similar activity.

EXPERIMENTAL

The synthesis and physical data of this series of compounds were reported previously (2). The synthetic methods were essentially those outlined by Schoellman and Shaw (3). Male CF_1 mice (~30 g) or male Sprague–Dawley rats (~160 g) were administered the test drugs at 20 or 10 mg/kg ip, respectively, in 0.05% polysorbate 80, 3.5 hr prior to the injection of 1% carrageenan in 0.9% saline into the plantar surface of the right hindfoot. Isotonic saline was injected into the left hindfoot to obtain baseline data. After 3 hr, both feet were excised at the tibiotarsal (ankle) joint according to a modification of the method of Winter *et al.* (4, 5).

As an analgesic screen, the tail flick (6) method was employed with male CF_1 mice (~30 g) who received the test drugs at 20 mg/kg ip 5 min prior to the analgesic test. An apparatus was designed and implemented in these laboratories to measure the tail flick response time of mice (Fig. 1). A control box housed all of the timing, logic, and sensing circuitry and the feedback controls. A secondary box provided the self-contained heater (55 ± 0.5°), the temperature-sensing elements, and special custom-made optical sensors to detect the flick of the tail. The sense signals were coupled to the control box to regulate the surface temperature and to freeze the digital clock (accuracy of 0.001%) display at the time of the first tail flick.

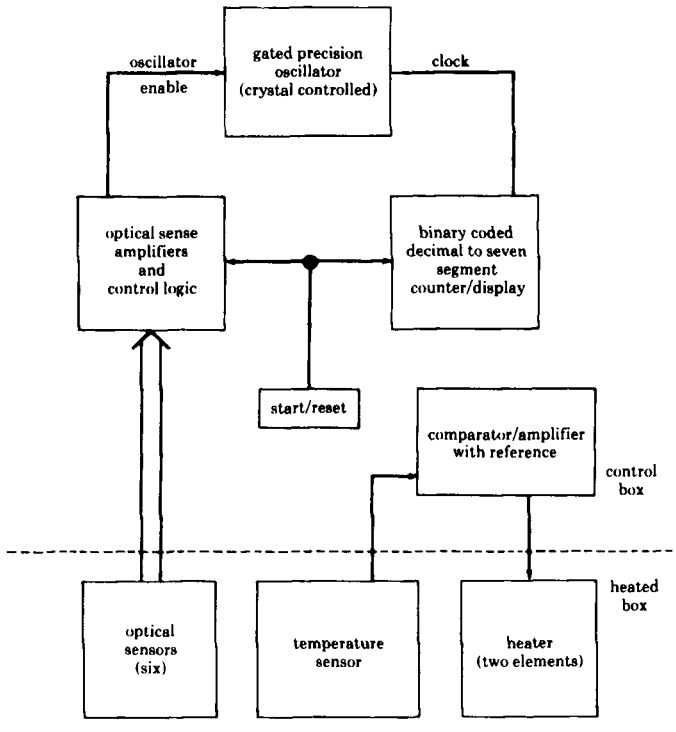

Figure 1—*Functional diagram of tail flick apparatus.*

The writhing reflex also was utilized as an analgesic test. Mice were administered the test drugs at 20 mg/kg ip 20 min prior to the administration of 0.5 ml of 0.6% acetic acid (7). After 5 min, the number of

0022-3549/80/1200-1451$01.00/0

six *Coleus* species other than *C. forskohlii* and the six *Plectranthus* species assayed was forskolin detected at levels as low as $\sim 1 \times 10^{-4}\%$ of the dry weight of the plant material (3).

Chromatograms from the assay of forskolin tablets are presented in Fig. 4. There was no interference due to peaks observed in the placebo samples. Assays were carried out in quadruplicate on five samples. The results indicated 5.12 mg of forskolin/tablet (label claim of 5.0 mg/tablet) with a range of 5.07–5.19 mg/tablet and a *RSD* of ±0.28%.

Anti-Inflammatory Activity of Diazomethyl Ketone and Chloromethyl Ketone Analogs Prepared from *N*-Tosyl Amino Acids

I. H. HALL ˣ, J. E. HALL, Jr., M. MOHSENI, and Z. SAJADI

Received January 7, 1980, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication June 9, 1980.

Abstract □ A series of diazomethyl ketone and chloromethyl ketone analogs prepared from *N*-tosyl amino acids was shown to have anti-inflammatory activity in mice at 20 mg/kg and in rats at 10 mg/kg. *N*-Tosyl-L-alanine and *N*-tosyl-β-alanine chloromethyl ketones demonstrated the most potent anti-inflammatory activity. The writhing reflex also was inhibited at 20 mg/kg in mice. In the tail flick test, *N*-tosyl-D,L-alanine and *N*-tosyl-D,L-isoleucine chloromethyl ketones demonstrated the highest increase in time. Toxicity studies indicated good therapeutic indexes for most of these agents.

Keyphrases □ Anti-inflammatory activity—diazomethyl ketone and chloromethyl ketone analogs prepared from *N*-tosyl amino acids, biological evaluation □ *N*-Tosyl amino acids—diazomethyl ketone and chloromethyl ketone analogs, evaluation for anti-inflammatory activity

A series of *N*-tosyl, *N*-benzoyl, *N*-acetyl, *N*-carbobenzyloxy, and *N*-cinnamyl cyanomethyl esters of amino acids was shown to have anti-inflammatory and immunosuppressive activities in mice (1). The standard proteolytic inhibitor tosylphenylalanyl chloromethyl ketone also was active as an anti-inflammatory agent. This report discusses a series of diazomethyl ketones and chloromethyl ketones of *N*-tosyl amino acids that demonstrated similar activity.

EXPERIMENTAL

The synthesis and physical data of this series of compounds were reported previously (2). The synthetic methods were essentially those outlined by Schoellman and Shaw (3). Male CF_1 mice (~30 g) or male Sprague–Dawley rats (~160 g) were administered the test drugs at 20 or 10 mg/kg ip, respectively, in 0.05% polysorbate 80, 3.5 hr prior to the injection of 1% carrageenan in 0.9% saline into the plantar surface of the right hindfoot. Isotonic saline was injected into the left hindfoot to obtain baseline data. After 3 hr, both feet were excised at the tibiotarsal (ankle) joint according to a modification of the method of Winter *et al.* (4, 5).

As an analgesic screen, the tail flick (6) method was employed with male CF_1 mice (~30 g) who received the test drugs at 20 mg/kg ip 5 min prior to the analgesic test. An apparatus was designed and implemented in these laboratories to measure the tail flick response time of mice (Fig. 1). A control box housed all of the timing, logic, and sensing circuitry and the feedback controls. A secondary box provided the self-contained heater (55 ± 0.5°), the temperature-sensing elements, and special custom-made optical sensors to detect the flick of the tail. The sense signals were coupled to the control box to regulate the surface temperature and to freeze the digital clock (accuracy of 0.001%) display at the time of the first tail flick.

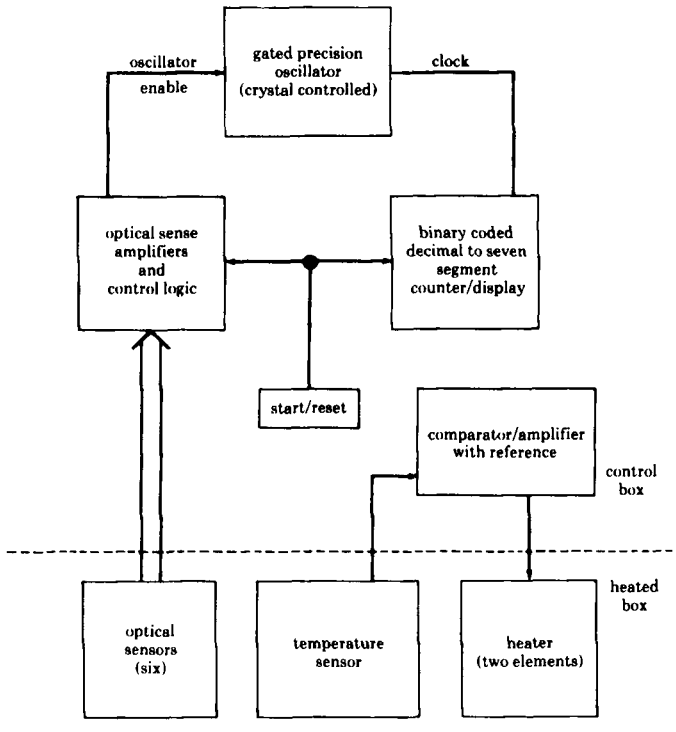

Figure 1—*Functional diagram of tail flick apparatus.*

The writhing reflex also was utilized as an analgesic test. Mice were administered the test drugs at 20 mg/kg ip 20 min prior to the administration of 0.5 ml of 0.6% acetic acid (7). After 5 min, the number of

stretches, characterized by repeated contractures, was counted for 10 min.

Toxicity studies were determined in male CF_1 mice (8).

RESULTS AND DISCUSSION

With the exception of VI, all of the diazomethyl ketone and chloromethyl ketone analogs of *N*-tosyl amino acids demonstrated significant anti-inflammatory activity in both mice and rats (Table I). Compounds VIII and X demonstrated the highest activity; at 20 mg/kg, they showed improved activity over phenylbutazone at 50 mg/kg in rats. In the writhing reflex, a test that mimics inflammation pain, V, VII–X, and XIV demonstrated potent activity, which was actually higher than that of indomethacin at a comparable dose. In the tail flick test, a narcotic analgesic test, the *N*-tosyl amino acid derivatives also were active and were comparable to morphine at 1 mg/kg. Although IX and XII demonstrated the best activity in the tail flick test, they did not possess the highest anti-inflammatory activity or the ability to inhibit the writhing reflex. Previous studies (2) indicated that these compounds were not toxic in mice when administered for 10 days at 20 mg/kg.

Toxicity studies in male mice indicated that I, II, IV, VI, and X–XII had an LD_{50} value of ≥400 mg/kg; VII, IX, XIII, and XIV had an LD_{50} value of >200 mg/kg. Compound V had an LD_{50} value of ≃100 mg/kg, while the value for VIII was 140 mg/kg. The solubility of the material and the limited amount of compounds curtailed further detailed studies of toxicity.

Comparison of Acidic and Enzymatic Hydrolysis Procedures for Identification of Natural Estrogens in Pharmaceutical Preparations

G. CARIGNAN ˣ **and B. A. LODGE**

Received December 13, 1979, from the *Drug Research Laboratories, Health Protection Branch, Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario, K1A 0L2 Canada.* Accepted for publication May 29, 1980.

Abstract □ The usefulness of a distinct enzyme-hydrolyzed preparation for the identification of conjugated and esterified estrogens USP was studied. No significant differences were found when the GLC identification test was performed on the acid-hydrolyzed assay preparation.

Keyphrases □ Estrogens—identification of conjugated and esterified estrogens in pharmaceutical preparations, comparison of acidic and enzymatic hydrolysis procedures for sample preparation □ Enzymatic hydrolysis—procedure for sample preparation for identification of conjugated and esterified estrogens in pharmaceutical preparations, comparison with acidic hydrolysis procedure □ GLC—identification of conjugated and esterified estrogens in pharmaceutical preparations, comparison of acidic and enzymatic hydrolyses for sample preparation

Conjugated and esterified estrogens are two types of natural estrogenic substances. Both groups are described in USP XIX (1) as a mixture of the sodium salts of the sulfate esters of the estrogenic substances, principally estrone and equilin for conjugated estrogens and estrone for esterified estrogens, that are of the type excreted by pregnant mares.

Since the publication of USP XIX, the colorimetric identification test has been replaced by a more specific GLC identification test (2) to show the presence of other complementary estrogens, in particular, α-estradiol, β-estradiol, 17α-dihydroequilin, 17β-dihydroequilin, 17α-dihydroequilenin, 17β-dihydroequilenin, 9-dehydroestrone, and equilenin. However, one major result of this test has been a substantial increase in analysis time.

This report discusses the possibility of reducing the analysis time and avoiding many of the required manipulations by using a single sample preparation for both identification and assay. The colorimetric assay described in USP requires a more purified extract than the GLC identification test. This extract is obtained by acidic hydrolysis and subsequent purification. The GLC identification test introduced recently involves a long enzymatic hydrolysis procedure (2.5 hr), resulting in an extract that is not pure enough for use in the assay.

The milder acidic hydrolysis procedure (3), developed in these laboratories to replace the USP XIX acidic hydrolysis procedure, and the USP XIX acidic hydrolysis procedure were compared to an enzymatic hydrolysis procedure (4), which was very similar to the procedure used in the USP XIX GLC identification test. Qualitative and quantitative results were obtained by the GLC procedure of McErlane and Curran (4).

[a] Average of five determinations. [b] Average of seven determinations.

EXPERIMENTAL

Apparatus—The gas chromatograph[1] was equipped with a U-shaped column and a flame-ionization detector. Peak retention times and areas were obtained using a reporting integrator[2].

Acidic Hydrolysis—The residue obtained from elution with dicyclohexylamine acetate solution was dissolved in 20 ml of methanol. A few antibumping granules were added as a boiling aid. A 6.0-ml portion of hydrochloric acid of a specified concentration was added. A water condenser was placed in the neck of the flask, and the flask was placed on a steam bath so that only the liquid was immersed. After the specified time, the flask was cooled in an ice bath. The hydrolysate was extracted and purified as in the USP procedure.

For milder acidic hydrolysis, 0.6 *N* HCl (1 in 20) was used for 12.0 min. For the USP acidic hydrolysis, 2 *N* HCl (1 in 6) was used for 10 min. The stronger acidic hydrolysis required 4 *N* HCl (1 in 3) for 12 min.

Enzyme Hydrolysis—An aliquot equivalent to ~1.5 mg of conjugated estrogens in a 50-ml centrifuge tube was shaken for 30 min with 15 ml of 0.02 *M* sodium acetate (pH 5.2) and then extracted twice with 10 ml of benzene (shaken for 20 min each time). The tube was centrifuged for 10 min, and the benzene was discarded. After all traces of residual benzene had been removed, 7500 units of sulfatase enzyme[3] was added, and the tube was incubated for 30 min at 45° with occasional shaking. The tube then was cooled to room temperature, 15 ml of chloroform was added, and the tube was shaken for 15 min. After centrifugation for 10 min, the chloroform layer was filtered through anhydrous sodium sulfate and stored in a well-closed container in the refrigerator until it was used for derivatization.

Sample Derivatization—Two portions of each hydrolysate equivalent to 300 μg of estrogens were transferred to separate 5-ml polytef-lined screw-capped conical vials. To one vial was added 50 μg of ethynyl estradiol[4] (internal standard). The samples were evaporated to dryness using low heat and a gentle nitrogen stream. To the vials containing the internal standard were added 0.2 ml of pyridine and 0.05 ml of silylating reagent[5]; the vial then was capped and heated for 15 min at 60°. To the other vial (no internal standard) was added 0.2 ml of a 2% solution of methoxamine in pyridine; this sample was heated for 3 hr at 60°. After

this time, 0.05 ml of silylating reagent was added, and the solution was heated at 60° for 10 min.

A 2–4-μl aliquot was injected into a 1.8-m × 0.63-cm o.d. (6 ft × 0.25 in.) glass U-shaped column packed with 3% methyl phenyl cyanopropyl silicone[6] (OV-225) on 100–120-mesh Chromosorb WHP[7]. The temperature was maintained at 225°, and the helium flow rate was 50 ml/min.

RESULTS AND DISCUSSION

Results from the milder acidic hydrolysis (assay preparation) and the enzymatic hydrolysis (test preparation) in the identification of a commercial conjugated estrogens formulation, which fully met requirements of the previous colorimetric identification test, are shown in Table I. Average amounts, standard deviations, and coefficients of variation (CV) are given for each component.

The distinctive estrone and equilin peaks and the prominent β-estradiol/17α-dihydroequilin peak[8] showed the same relative amounts, within experimental error, with both hydrolysis procedures. Moreover, the relative amounts of other additional minor peaks (α-estradiol, 17β-dihydroequilin, 17α-dihydroequilenin, 17β-dihydroequilenin, 9-dehydroestrone, and equilenin) were very similar to each other.

Reproducibility was good for the major peaks ($CV \leq 3.6\%$) but decreased in proportion to the concentration of the minor peaks.

The robustness of the acidic hydrolysis procedure was studied. Table II shows a comparison of the enzymatic hydrolysis and three different acidic hydrolyses where the acid concentration was varied (0.6, 2, and 4 N) for the identification of conjugated estrogens tablets that were bor-

Table III—Comparison of the Enzymatic Hydrolysis and the Milder Acidic Hydrolysis of a Commercial Esterified Estrogens Product

Steroid	Enzyme Hydrolysis[a], %	Acid Hydrolysis[b], %
α-Estradiol	1.6	1.2
β-Estradiol/17α-dihydroequilin	5.8	5.4
17β-Dihydroequilin	0.4	0.3
17α-Dihydroequilenin	0.8	0.6
17β-Dihydroequilenin	0.2	—[b]
Estrone	78.1	79.4
Equilin	11.8	12.1
9-Dehydroestrone	0.5	0.3
Equilenin	0.7	0.7
Assay, % of label claim	114.2	112.3

[a] Single determination. [b] Peak was present but had an area less than the area reject setting.

derline in the colorimetric identification test. No major differences were seen for all of the individual components among the enzymatic, milder acidic, and USP acidic hydrolyses. The only differences were a small increase of β-estradiol/17α-dihydroequilin and a small decrease of 17β-dihydroequilenin and 9-dehydroestrone in the acidic procedures.

The results in Table III show that the two hydrolysis procedures also are applicable to the identification of commercial esterified estrogens products. The small differences between the results obtained with the two procedures are not important and do not lead to any misinterpretations. Several other benefits are derived from the use of the acidic hydrolysis procedure. The assay preparation is a much cleaner extract than the enzymatic identification test preparation. The presence of equol (5) is no longer a problem; it is removed in the early chromatographic column step by benzene washing. Chromatograms exhibit less tailing, the detector background signal is reduced, and column lifetime is much longer.

In summary, the assay preparation obtained by the milder hydrolysis or by the USP acid hydrolysis gave identification test results for conjugated and esterified estrogens formulations comparable to the new enzyme-hydrolyzed identification test preparation. Since it is unnecessary to prepare the latter, the analysis time is shortened and the expense of enzyme reagents is avoided.

Comparative Pharmacokinetics of Butylated Hydroxyanisole and Butylated Hydroxytoluene in Rabbits

RAGAB EL-RASHIDY * **and SARFARAZ NIAZI** ˣ

Received November 19, 1979, from the *Department of Pharmacy, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60680.* Accepted for publication June 16, 1980. *Present address: G. D. Searle & Company, Skokie, IL 60076.

Abstract □ The widespread use of butylated hydroxyanisole (I) and butylated hydroxytoluene (II) as food antioxidants recently has been criticized by the Food and Drug Administration because of their pharmacological and toxicological effects. Interest also has arisen recently in the use of these compounds as anticancer agents. The purposes of this study were to evaluate the pharmacokinetics of I and II in rabbits and to compare their physicochemical properties with their disposition kinetics. It was found that I has a disposition half-life of ~1 hr, compared to 11 days for II. These differences are explained in terms of their lipid solubility and protein binding characteristics.

Keyphrases □ Butylated hydroxyanisole—pharmacokinetics, rabbits □ Butylated hydroxytoluene—pharmacokinetics, rabbits □ Antioxidants—butylated hydroxyanisole and butylated hydroxytoluene, pharmacokinetics, rabbits □ Pharmacokinetics—butylated hydroxyanisole and butylated hydroxytoluene, rabbits

Butylated hydroxyanisole (I) and butylated hydroxytoluene (II) are the most commonly used food antioxidants in the United States (1). Although I and II generally are regarded as safe, recent actions by the Food and Drug Administration have been directed toward restricting their use (2) because of their pharmacological and toxicological effects (3–7). Moreover, these compounds recently were reported to possess anticancer characteristics (8, 9). Although no specific biochemical pathways have been suggested for their action in inhibiting chemical carcinogenesis, these mechanisms may involve alteration of the metabolism of the chemical carcinogens (10) and blocking of hydrocarbon free radical–DNA complex formation (11).

Despite widespread interest in I and II, whose structures differ only by a *tert*-butyl group, there have been no reports of their pharmacokinetic properties based on blood levels and no reports of their effectiveness and toxicity. The purposes of this study were to monitor the disposition kinetics of I and II following single intravenous dosing in rabbits and to relate their pharmacokinetic parameters to their physicochemical properties.

EXPERIMENTAL

Materials and Equipment—Butylated hydroxyanisole[1] (I), butylated hydroxytoluene[1] (II), dibutylated hydroxyanisole[2], polyethylene glycol 400[3], an infusion set[4], a catheter placement unit[5] (20 gauge), sterile disposable syringes[6], an infusion pump[7], and a gas chromatograph[8] were used.

Formulations of Intravenous Dosage Form—Solutions of I and II (10 mg/ml) were prepared in polyethylene glycol 400–normal saline (1:1), which was sterilized by heating at 100° for ~1 hr over a hot plate.

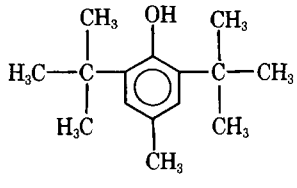
I



II

Animal Procedure—New Zealand White male rabbits, 2.9–3.2 kg, were used; food and water were withheld prior to and for 12 hr after drug administration. The marginal ear vein was cannulated using a 20-gauge catheter for sample collection. The I and II solutions were infused for <2 min at a constant rate of 2 ml/min to provide a total dose of 10 mg/kg. At the end of infusion, the cannula was flushed with 5 ml of heparinized sterile normal saline.

The blood samples (1.5 ml) were collected from the catheter placed in the other ear at 0, 0.085, 0.173, 0.33, 0.50, 0.75, 1, 1.5, 2.0, 3.0, 4.0, 6.0, and 12 hr and thereafter twice per day for 2 days and daily for 3 days. The zero time for sampling was assigned when the infusion was completed. A blank blood sample was obtained before the solution was infused to obtain the baseline on the gas chromatogram.

Blood Analysis—All blood samples were analyzed for their concentration of I and II using a highly sensitive and specific GLC method (12).

RESULTS AND DISCUSSION

The absorption of I and II was reported to vary significantly when given orally as a suspension in milk–olive oil and as a gelatin capsule to humans (13). Therefore, an intravenous dosage form was chosen to avoid complications due to absorption variability. The maximum allowable intake of I and II is 2 mg/kg/day, but there are indications that the per capita daily intake is >5 mg/kg (2). Thus, the dose of 10 mg/kg used in this study may represent the level of exposure for numerous people who consume many processed foods.

Pharmacokinetics of Butylated Hydroxyanisole (I)—The plasma concentrations obtained at different time intervals following a single intravenous dose (10 mg/kg) were plotted on a semilogarithmic scale, assigning time zero as the midpoint of infusion, and the data were fitted by a monoexponential model using a programmable calculator (14) (Fig. 1). This model suggests that the body behaves as a homogeneous compartment for I in terms of the equilibrium rates among various body tissues (15):

$$C_p = C_p^0 e^{-kt} \quad \text{(Eq. 1)}$$

It was reported that at low concentration (<100 μg/ml), the percent of

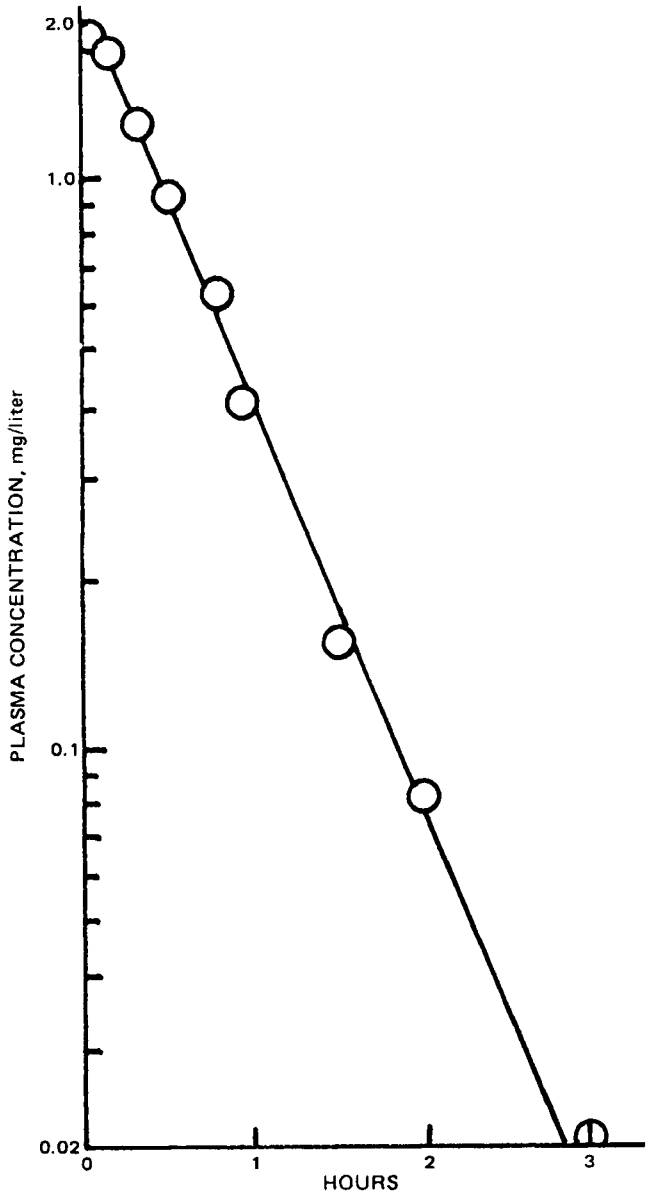

Figure 1—*Plasma concentration profile of I in a rabbit following intravenous administration of a 10-mg/kg dose.*

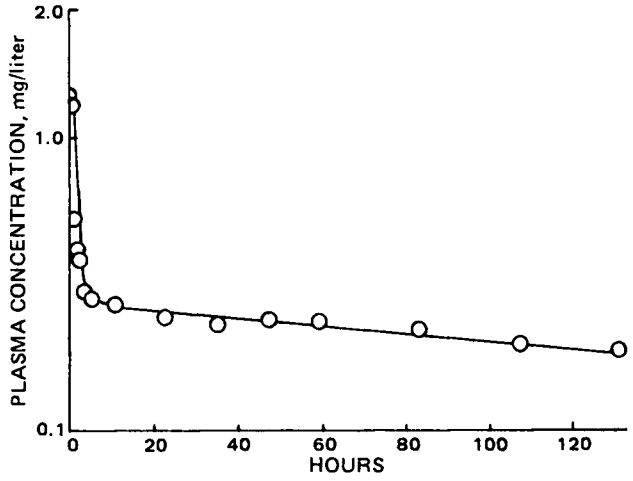

Figure 2—*Plasma concentration profile of II in a rabbit following intravenous administration of a 10-mg/kg dose.*

total I bound to human serum albumin was inversely proportional to the total concentration (16). Since >59% of the total exchangeable albumin is located in the extravascular compartments such as the skin and muscles (17), the human body can be conceived of as a large pool for I. In addition, the probable binding of I to other components of different tissues and fluids makes its distribution more extensive throughout the body, causing exposure of deep body tissues.

The estimates of C_p^0, $t_{1/2}$, V_d, and k_{el} reported in Table I were obtained from least-squares data fitting. In spite of the large volume of distribution (mean = 7.48 liters/kg), I disappears from the plasma very rapidly (mean $t_{1/2}$ = 1 hr). Thus, despite extensive distribution, fast clearance is achieved due to the highly reversible nature of its storage in the body tissues.

Pharmacokinetics of Butylated Hydroxytoluene (II) (Fig. 2)—The disposition of II in animals and in humans is complicated by the presence of two *tert*-butyl groups at *ortho*-positions of the phenolic group. More than 10 metabolites of II have been isolated (18, 19). Significant biliary excretion also has been reported in rats, rabbits, and dogs. Daniel *et al.* (5) recovered ~67% of an oral dose of [^{14}C]II in human urine samples collected over an 11-day period. They concluded that intact II and/or its metabolites first are stored in the tissues and then are slowly released after a pseudoequilibrium, which takes ~5 days, indicating extensive uptake by tissues (5).

The plasma concentration–time profiles of II were, unlike I, characterized by:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 2)}$$

where A and B are constants and α and β are complex rate constants. The estimation of A, B, α, and β was made using a programmable calculator (14). The pharmacokinetic parameters are reported in Table II. The fast disposition phase half-life of II was ~1 hr, and the slow disposition phase decayed with a half-life of >11 days. These data suggest rapid accumulation and slow clearance from the body, in agreement with earlier speculations for II (5).

A comparison of the disposition of I and II in rabbits clearly reveals large differences between their distribution and elimination characteristics. Whereas the accumulation of I does not appear to be a serious problem, II tends to be stored in body tissues upon multiple dosing, as encountered in daily life exposure to this compound. Based on the following equation, more than a 16-fold accumulation of II is possible on daily exposure whereas the accumulation is negligible for I:

$$\text{accumulation} = 1/1 - e^{-k\mathrm{T}} \qquad \text{(Eq. 3)}$$

where k is the terminal disposition rate constant and T is the frequency of exposure.

Such large differences in the *in vivo* kinetic properties of I and II occur because of the additional *tert*-butyl group in II. This structural change renders II more lipid soluble, explaining the approximately threefold increase in the final volume of distribution while the volume of the central compartment remains identical for both compounds. Since the volume of the central compartment does not change, an increase of over 100-fold in the total body clearance results from a change in the elimination rate constant from the central compartment (k_{el}).

The distribution characteristics of I and II also can be related to their plasma protein binding characteristics. The volumes of distribution often are inversely related to the extent of plasma protein binding (17), especially for compounds that have weaker association constants, such as I

Table II—Pharmacokinetic Parameters of II in Rabbits after a Single Intravenous 10-mg/kg Dose

Parameter[a]	Mean ± *SEM* (n = 4)
A, mg/liters	1.0402 ± 0.26
B, mg/liters	0.4535 ± 0.025
α, hr^{-1}	0.7841 ± 0.073
β, hr^{-1}	0.00258 ± 0.0008
k_{21}, hr^{-1}	0.2639 ± 0.06
k_{10}, hr^{-1}	0.00760 ± 0.0013
k_{12}, hr^{-1}	0.5152 ± 0.057
V_d, liters/kg	7.31 ± 1.18
TBC[b], liters/hr/kg	0.0551 ± 0.013
V_{deg}, liters/kg	21.13 ± 1.29
AUC[c], (mg hr)/liter/kg	208.9 ± 35.5

and II (16, 18). The binding constant for I reported from this laboratory was $2 \times 10^{-3} M^{-1}$ and that for II was $3 \times 10^{4} M^{-1}$. The number of binding sites was ~2.6 for I and 0.25 for II (20). Thus, increased lipid solubility of II results in its increased strength of interaction with albumin molecules, but the steric hindrance due to the additional *tert*-butyl group makes the extent of binding only about 10% of that observed for I. Thus, the total exchangeable albumin present in the extravascular compartments provides a large pool for possible storage of I but not for II, which probably is taken up by the body fatty tissues due to its higher lipid solubility (5).

Human Whole Blood and Parotid Saliva Concentrations of Oral and Intramuscular Promethazine

G. JOHN DiGREGORIO ˣ and EILEEN RUCH

Received February 13, 1980, from the *Department of Pharmacology, Hahnemann Medical College, Philadelphia, PA 19102.* Accepted for publication June 20, 1980.

Abstract □ Ten healthy male subjects received 25 mg of promethazine intramuscularly, followed within 3 weeks by oral administration of 25 mg. Whole blood and parotid saliva were collected over a 12-hr period after drug administration. Promethazine was quantitated by high-performance liquid chromatography. After intramuscular administration, the promethazine concentrations were 3.0–22.4 ng/ml in blood and 0.9–2.8 ng/ml in parotid saliva. After oral administration, the promethazine concentrations were 1.4–5.5 ng/ml in blood and 0.2–0.8 ng/ml in parotid saliva. The peak blood promethazine concentration after the intramuscular dose was four times higher than that following the oral dose, which indicates that promethazine possesses an extensive first-pass effect. The mean parotid saliva to whole blood ratio (S/B) was calculated to be 0.24 after the intramuscular route and 0.20 after the oral route over the 12-hr period. The calculated percentage of free drug in the blood was 20–24% of the whole blood concentration determined from the S/B ratio.

Keyphrases □ Promethazine—whole blood and parotid saliva concentrations following oral and intramuscular administration □ High-performance liquid chromatography—analysis, promethazine, whole blood and parotid saliva concentrations following oral and intramuscular administration □ Phenothiazines—promethazine, high-performance liquid chromatographic analysis in whole blood and parotid saliva following oral and intramuscular administration

Several investigators have reported analytical methods for the determination of phenothiazines, including colorimetric (1), spectrofluorometric (2), spectrophotometric (3), GLC (4, 5), and liquid chromatographic (6) procedures. However, little or no information is available on the quantitation of promethazine in therapeutic doses in human whole blood or parotid saliva.

This report presents a sensitive method for the detection and quantitation of promethazine in whole blood and parotid saliva after the administration of 25 mg of promethazine orally and intramuscularly in human volunteers. Parotid saliva to blood promethazine concentration ratios were calculated, and the bioavailability of promethazine was compared for the two routes of administration.

EXPERIMENTAL

Materials—Powdered promethazine[1] and promazine[1], the internal standard, were used without further purification as the analytical standards. Commercially available promethazine tablets[1] and injectable liquid[1] were obtained from a local pharmacy. All solvents and reagents were analytical reagent grade, except for methanol[2], which was high-performance liquid chromatographic (HPLC) grade. All glassware was coated with silicone[3] by the method described on the package insert.

Apparatus—The liquid chromatograph[4] was fitted with a loop injector and a fixed-wavelength UV detector (254 nm). A 1-mv recorder[5] was attached to the chromatograph. The detector was attenuated at 0.005 aufs.

Column—A prepacked, 300 × 3.9-mm i.d., μBondapak CN column[6] was run at ambient temperature.

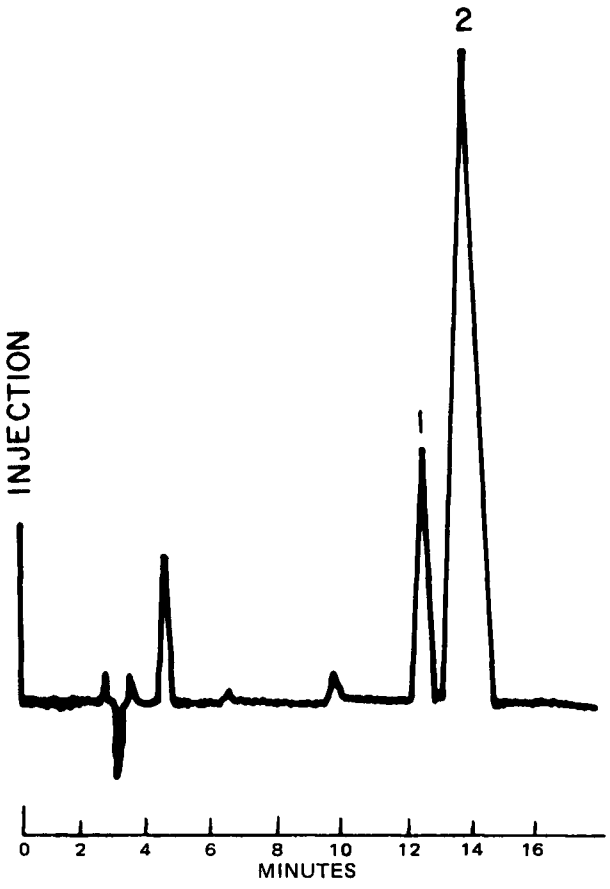

Figure 1—*Typical high-performance liquid chromatogram of (1) promethazine and the internal standard (2), promazine.*

Mobile Phase—A solution of 1% acetic acid in 0.005 *M* heptanesulfonic acid and methanol (50:50) was used. The mixture was pumped isocratically through the column at a flow rate of 2 ml/min.

Method—Ten healthy male volunteers, 25–57 years, participated in the crossover study. Complete histories and physical examinations, including blood and urine chemistries, were performed before and after the experiments. Each subject initially was given 25 mg of promethazine intramuscularly, followed in 3 weeks by 25 mg orally.

The subjects fasted for a minimum of 12 hr prior to each experiment. Baseline parotid saliva and blood samples were taken before each experiment. Parotid saliva samples were collected by means of a modified double-lumen parotid cup (7). Orange-flavored lozenges[7] served as a reflex stimulus to induce salivation, and the resultant parotid secretions were collected in silicone-coated graduated test tubes. At least 5 ml of parotid saliva was collected over a period not exceeding 10 min. Blood samples (10 ml) were collected in silicone-coated vacuum tubes[8] containing 143 IU of heparin sodium.

After intramuscular administration of 25 mg of promethazine, venous blood and parotid saliva samples were taken at 0.5, 1, 2, 4, 6, 8, and 12 hr. To make certain that the subjects returned to baseline levels, 3 weeks was allowed between experiments. At that time, the same 10 subjects were given 25 mg of promethazine orally; blood and parotid saliva samples were collected at the same time intervals.

Whole blood (5 ml) or parotid saliva (5 ml) was added to 1 ml of 1 *N* NaOH. Promazine, which was chosen as the internal standard because of the similarity of its structure and chemical properties to promethazine, was dissolved in the mobile phase, and 25 ng was added to the whole blood or parotid saliva sample before extraction. The sample then was shaken with 25 ml of heptane for 10 min and centrifuged for 5 min.

The heptane layer was removed by aspiration with a siliconized Pasteur pipet and allowed to evaporate under a steady stream of air at 55°. The residue was redissolved in 50 μl of the mobile phase, and 10 μl was injected into the liquid chromatograph. Quantitation was performed using the method of internal standards by measuring the peak heights and comparing the peak height ratios to a calibration curve. The sensitivity of the method was tested by the extraction of various concentrations of promethazine in blood and saliva and determination of the smallest detectable peak on the liquid chromatograph.

12	0.9 ± 0.40	3.0 ± 0.84

[a] Mean concentration (±*SE*) of promethazine in 10 human volunteers after the intramuscular administration of 25 mg.

RESULTS AND DISCUSSION

The separation and identification of promethazine by HPLC are illustrated in Fig. 1. The retention time for promethazine was 12.6 min; the internal standard, promazine, had a retention time of 13.8 min. The separation was reproducible and sensitive in both extracted whole blood and parotid saliva. The sensitivity of promethazine was 0.2 ng on-column by this procedure. Standard concentration curves for spiked whole blood and parotid saliva were linear between 2.5 and 50 ng/ml (blood) and between 0.5 and 10 ng/ml (parotid saliva).

The mean (±*SE*) whole blood and parotid saliva promethazine concentrations in the 10 subjects receiving 25 mg intramuscularly are presented in Table I. The range of promethazine concentrations determined in whole blood and parotid saliva was 0.9–22.4 ng/ml over the 12-hr period. The blood promethazine concentration peaked within 4 hr (22.4 ± 5.90 ng/ml) but fell rapidly over the next 2 hr to 8.3 ± 0.91 ng/ml and then declined slowly over the next 6 hr to 3.0 ± 0.84 ng/ml. The parotid saliva concentrations peaked within 2 hr (2.8 ± 0.52 ng/ml) and declined more slowly than the plasma to 0.9 ± 0.40 ng/ml over the next 10 hr. The calculated saliva to blood (*S/B*) ratio ranged between 0.10 and 0.30, with a mean of 0.24, over the 12-hr period.

The mean (±*SE*) whole blood and parotid saliva promethazine concentrations in the 10 subjects receiving 25 mg orally are listed in Table II. The range of promethazine concentrations determined in whole blood and parotid saliva was 0.2–5.5 ng/ml over the 12 hr. The blood promethazine concentrations peaked within 2 hr (5.5 ± 1.4 ng/ml) and declined to 1.4 ± 0.2 ng/ml within the next 6 hr. The parotid saliva concentration was elevated consistently between 1 and 6 hr after drug administration. Only at the 8-hr period did it fall from 0.8 to 0.2 ng/ml. The calculated saliva to blood ratio ranged between 0.13 and 0.29, with a mean of 0.20, over the 8-hr period.

The results indicate that the bioavailability of orally or intramuscularly administered promethazine in therapeutic doses can be determined by HPLC. This analytical method was sensitive enough to detect and quantitate parotid saliva concentrations of promethazine during the corresponding times in which whole blood concentrations were determined. The sensitivity of the assay was suitable for detection of pro-

Table II—Whole Blood and Parotid Saliva Concentrations of Promethazine Administered Orally

Hours	Saliva[a], ng/ml	Blood[a], ng/ml
0.5	0.4 ± 0.2	2.5 ± 0.5
1	0.8 ± 0.2	2.9 ± 0.5
2	0.7 ± 0.1	5.5 ± 1.4
4	0.8 ± 0.2	3.8 ± 0.7
6	0.8 ± 0.2	2.8 ± 0.8
8	0.2 ± 0.1[b]	1.4 ± 0.2[b]
12	0	0

[a] Mean concentration (±*SE*) of promethazine in 10 human volunteers after the oral administration of 25 mg. [b] Estimated values from standard concentration curves.

methazine concentrations as low as 0.2 ng/ml of saliva or blood, a 50-fold increase in sensitivity over that reported previously for a GLC procedure (5).

After the administration of equal doses of promethazine (25 mg), the peak blood concentrations were significantly different after oral and intramuscular administration. The peak whole blood concentration (22.4 ng/ml) after intramuscular administration was approximately four times higher than that (5.5 ng/ml) after oral administration. The results indicate that promethazine possesses a significant first-pass effect through the liver. Other investigators have demonstrated that promethazine has an extensive first-pass effect, accounting for lower blood levels after oral administration compared to parenteral administration (5). After oral administration of 25 mg, the elimination half-life of promethazine was 3.3 hr as determined from plasma levels measured over the 8-hr period.

The present results indicate that the mean parotid saliva to whole blood promethazine ratios after oral (0.20) and intramuscular (0.24) administration did not significantly differ from each other. Previous studies involving saliva to blood ratios of other drugs consistently showed that saliva drug concentrations correlated with the blood free drug concentrations and that percentages of free drug in blood could be determined from the calculated saliva to blood ratios (7–9). In this study, the ratios of 0.20 and 0.24 indicate that the free form of promethazine in blood ranged between 20 and 24%, meaning that it was bound 80 and 76% to whole blood.

High-Performance Liquid Chromatographic Determination of Metaraminol Bitartrate in the Presence of Parabens

C. J. MARTIN ˣ and S. J. SAXENA

Received May 15, 1980, from *McGaw Laboratories, Irvine, CA 92714.* Accepted for publication June 20, 1980.

Abstract □ A high-performance liquid chromatographic (HPLC) procedure was developed for the determination of metaraminol bitartrate in the presence of methylparaben and propylparaben. Reversed-phase ion-pair chromatography was employed using dioctyl sodium sulfosuccinate as the counterion. The current official USP procedure for the determination of metaraminol requires dilution, extraction, and measurement of UV absorption. The HPLC procedure is rapid and precise and correlates well with the USP XX procedure. It can be used for metaraminol injectables as well as the raw material.

Keyphrases □ Metaraminol bitartrate—high-performance liquid chromatographic analysis in the presence of methylparaben and propylparaben □ High-performance liquid chromatography—analysis, metaraminol bitartrate in the presence of methylparaben and propylparaben □ Methylparaben—high-performance liquid chromatographic analysis with metaraminol bitartrate and propylparaben □ Propylparaben—high-performance liquid chromatographic analysis with metaraminol bitartrate and propylparaben

Metaraminol bitartrate, an adrenergic vasopressor drug, may be administered intravenously or intramuscularly to raise the blood pressure in acute hypotensive states and shock. Some commercially available injectables contain both methylparaben and propylparaben as preservatives. Spectrophotometric (1) and spectrophotofluorometric (2) analyses are currently used for the analysis of metaraminol bitartrate injectables. The USP XX spectrophotometric procedure requires extraction before analysis to remove parabens. While the spectrophotofluorometric procedure needs no extraction, it requires reaction with *O*-phthalaldehyde for 1 hr (60 ± 1 min) before analysis. For both procedures, a separate GLC (3) procedure must be used for the determination of parabens. This GLC procedure for parabens involves extraction and derivatization before analysis.

This paper describes the parameters for the simultaneous qualitative and quantitative determination of metaraminol, methylparaben, and propylparaben by high-performance liquid chromatography (HPLC). The HPLC procedure involves the formation of an ion-pair with dioctyl sodium sulfosuccinate on an octadecylsilane column. The use of this counterion previously was reported for the HPLC determination of some other basic organic drug molecules (4, 5) and was successful for the separation of metaraminol, methylparaben, and propylparaben. The total analysis time to run standards and a sample is ~1 hr. This method is simple, accurate, and precise and compares favorably with the USP XX procedure.

EXPERIMENTAL

Reagents and Chemicals—USP reference standards were used for standard solutions of metaraminol, methylparaben, and propylparaben. Powdered samples of metaraminol bitartrate[1], methylparaben[2], propylparaben[2], and butylparaben[3] were used in the analytical procedure. HPLC grade methanol and reagent grade acetic acid and dioctyl sodium sulfosuccinate[4] were used in the mobile phase.

Mobile Phase—The mobile phase was prepared by mixing 600 ml of methanol with 2.2 g of dioctyl sodium sulfosuccinate. After dissolution, 400 ml of deionized, distilled water and 10 ml of acetic acid were added (pH 4.0). The mobile phase was degassed by vacuum filtration through

methazine concentrations as low as 0.2 ng/ml of saliva or blood, a 50-fold increase in sensitivity over that reported previously for a GLC procedure (5).

After the administration of equal doses of promethazine (25 mg), the peak blood concentrations were significantly different after oral and intramuscular administration. The peak whole blood concentration (22.4 ng/ml) after intramuscular administration was approximately four times higher than that (5.5 ng/ml) after oral administration. The results indicate that promethazine possesses a significant first-pass effect through the liver. Other investigators have demonstrated that promethazine has an extensive first-pass effect, accounting for lower blood levels after oral administration compared to parenteral administration (5). After oral administration of 25 mg, the elimination half-life of promethazine was 3.3 hr as determined from plasma levels measured over the 8-hr period.

The present results indicate that the mean parotid saliva to whole blood promethazine ratios after oral (0.20) and intramuscular (0.24) administration did not significantly differ from each other. Previous studies involving saliva to blood ratios of other drugs consistently showed that saliva drug concentrations correlated with the blood free drug concentrations and that percentages of free drug in blood could be determined from the calculated saliva to blood ratios (7–9). In this study, the ratios of 0.20 and 0.24 indicate that the free form of promethazine in blood ranged between 20 and 24%, meaning that it was bound 80 and 76% to whole blood.

High-Performance Liquid Chromatographic Determination of Metaraminol Bitartrate in the Presence of Parabens

C. J. MARTIN ˣ and S. J. SAXENA

Received May 15, 1980, from *McGaw Laboratories, Irvine, CA 92714.* Accepted for publication June 20, 1980.

Abstract □ A high-performance liquid chromatographic (HPLC) procedure was developed for the determination of metaraminol bitartrate in the presence of methylparaben and propylparaben. Reversed-phase ion-pair chromatography was employed using dioctyl sodium sulfosuccinate as the counterion. The current official USP procedure for the determination of metaraminol requires dilution, extraction, and measurement of UV absorption. The HPLC procedure is rapid and precise and correlates well with the USP XX procedure. It can be used for metaraminol injectables as well as the raw material.

Keyphrases □ Metaraminol bitartrate—high-performance liquid chromatographic analysis in the presence of methylparaben and propylparaben □ High-performance liquid chromatography—analysis, metaraminol bitartrate in the presence of methylparaben and propylparaben □ Methylparaben—high-performance liquid chromatographic analysis with metaraminol bitartrate and propylparaben □ Propylparaben—high-performance liquid chromatographic analysis with metaraminol bitartrate and propylparaben

Metaraminol bitartrate, an adrenergic vasopressor drug, may be administered intravenously or intramuscularly to raise the blood pressure in acute hypotensive states and shock. Some commercially available injectables contain both methylparaben and propylparaben as preservatives. Spectrophotometric (1) and spectrophotofluorometric (2) analyses are currently used for the analysis of metaraminol bitartrate injectables. The USP XX spectrophotometric procedure requires extraction before analysis to remove parabens. While the spectrophotofluorometric procedure needs no extraction, it requires reaction with *O*-phthalaldehyde for 1 hr (60 ± 1 min) before analysis. For both procedures, a separate GLC (3) procedure must be used for the determination of parabens. This GLC procedure for parabens involves extraction and derivatization before analysis.

This paper describes the parameters for the simultaneous qualitative and quantitative determination of metaraminol, methylparaben, and propylparaben by high-performance liquid chromatography (HPLC). The HPLC procedure involves the formation of an ion-pair with dioctyl sodium sulfosuccinate on an octadecylsilane column. The use of this counterion previously was reported for the HPLC determination of some other basic organic drug molecules (4, 5) and was successful for the separation of metaraminol, methylparaben, and propylparaben. The total analysis time to run standards and a sample is ~1 hr. This method is simple, accurate, and precise and compares favorably with the USP XX procedure.

EXPERIMENTAL

Reagents and Chemicals—USP reference standards were used for standard solutions of metaraminol, methylparaben, and propylparaben. Powdered samples of metaraminol bitartrate[1], methylparaben[2], propylparaben[2], and butylparaben[3] were used in the analytical procedure. HPLC grade methanol and reagent grade acetic acid and dioctyl sodium sulfosuccinate[4] were used in the mobile phase.

Mobile Phase—The mobile phase was prepared by mixing 600 ml of methanol with 2.2 g of dioctyl sodium sulfosuccinate. After dissolution, 400 ml of deionized, distilled water and 10 ml of acetic acid were added (pH 4.0). The mobile phase was degassed by vacuum filtration through

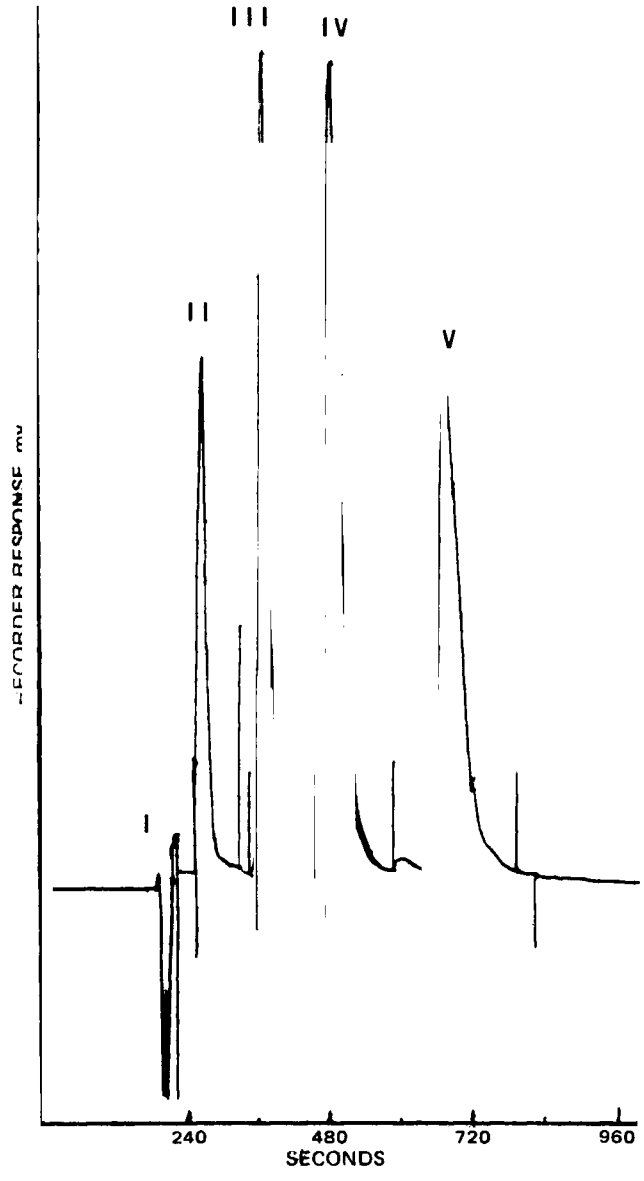

Figure 1—*Typical chromatogram of metaraminol bitartrate using a reversed-phase C_{18} column (room temperature) at a flow rate of 1.0 ml/min. The mobile phase was methanol–distilled water (60:40) with 0.005 M dioctyl sodium sulfosuccinate and 10 ml of acetic acid/liter. Key: I, solvent front; II, methylparaben (attenuation 256); III, propylparaben (attenuation 16); IV, butylparaben (attenuation 16); and V, metaraminol (attenuation 16).*

a polycarbonate membrane filter[5] (0.4-μm pore size, 47-mm diameter).

Internal Standard Solution—A 0.1-mg/ml solution of butylparaben was prepared by dissolving 50 mg in methanol and diluting the solution with water to 500 ml.

Working Standard Solution—A methylparaben stock solution was prepared by dissolving 15 mg of methylparaben USP reference standard in 5 ml of methanol in a 10-ml volumetric flask and diluting to volume with distilled water. A propylparaben stock solution was prepared by dissolving 10 mg of propylparaben USP reference standard in 5 ml of methanol in a 50-ml volumetric flask and diluting to volume with distilled water.

The working standard solution was prepared by dissolving 40 mg of metaraminol bitartrate USP reference standard in 50 ml of distilled water in a 100-ml volumetric flask. Then 2 ml of the methylparaben stock solution, 2 ml of the propylparaben stock solution, and 5 ml of the internal standard solution were added to the 100-ml volumetric flask, and the solution was diluted to volume with distilled water.

Sample Stock Solution—A sample stock solution was prepared by dissolving 75 mg of methylparaben and 10 mg of propylparaben in 10 ml of methanol in a 50-ml volumetric flask. Then 950 mg of metaraminol bitartrate was added to the 50-ml volumetric flask and dissolved in 30 ml of distilled water. The solution then was diluted to 50 ml with distilled water.

Sample Solutions for Linearity, Recovery, and Precision—Seven solutions were prepared from the sample stock solution. Portions of 0.5, 1, 2, 3, 4, and 5 ml of stock solution were added to separate 100-ml volumetric flasks, in which 5 ml of the internal standard solution had been placed. Each solution was diluted to 100 ml with distilled water. These six solutions were used for testing the linearity of the HPLC method. A solution of known concentration was used for determination of recovery and precision.

Determination of Purity of Metaraminol Bitartrate Raw Materials—Three stock solutions of different metaraminol bitartrate raw materials were prepared similar to the sample stock solution used for the linearity study. Then 2 ml of each stock solution was added to separate 100-ml volumetric flasks in which 5 ml of the internal standard solution had been placed. The solutions were diluted to 100 ml with distilled water. These three solutions were run against a USP working standard on the chromatograph to determine the assay values.

The USP XX procedure for metaraminol bitartrate injectables also was performed on these three solutions to show correlation between the USP XX method and the HPLC procedure. The three metaraminol bitartrate raw materials also were assayed by the USP XX procedure for the purity of metaraminol bitartrate raw material.

Conditions for Chromatographic Quantification—The liquid chromatograph[6] was equipped with a variable-wavelength detector[7] and

Table III—Purity of Metaraminol Bitartrate Raw Materials by HPLC and USP Methods

Sample[a]	Initial Concentration of Metaraminol, % w/v	Observed Results, % w/v		Purity of Metaraminol Bitartrate Raw Material, %	
		HPLC[b]	USP	HPLC	USP[c]
Raw material 1	1.065	1.037 ± 0.010	1.038	97.4	97.5
Raw material 2	1.019	0.994 ± 0.010	1.014	97.5	99.5
Raw material 3	1.001	0.980 ± 0.009	0.980	98.0	98.0

[a] The same solution of each raw material was used for both methods. [b] Result is based on two replicate injections. The value given is the mean ± *SD*. [c] The purity of each raw material also was determined by the USP XX procedure for metaraminol bitartrate raw material. The results for the three raw materials were 100.2, 100.5, and 99.6%, respectively.

an octadecylsilane column[8]. The degassed mobile phase [methanol–water (60:40) with 0.005 *M* dioctyl sodium sulfosuccinate and 10 ml of acetic acid/liter] was pumped through the column at a flow rate of 1.0 ml/min at ambient temperature until a stable baseline was obtained. Replicate 20-μl injections of the sample and standard solutions were made. The peaks were detected at 254 nm.

RESULTS AND DISCUSSION

Studies on metaraminol bitartrate preserved with methylparaben and propylparaben showed that these three drug components can be separated by HPLC and determined by UV absorption at 254 nm within 15 min. When injected into the chromatograph, methylparaben was eluted first, followed by propylparaben, butylparaben (the internal standard), and metaraminol at retention times of ~4.5, 6.3, 8.2, and 11.4 min, respectively (Fig. 1).

Standard solutions of metaraminol bitartrate, methylparaben, and propylparaben were chromatographed using the reversed-phase C_{18} column. The concentration of each component was determined by a programmable integrator[9]. A linear regression analysis of the data for six concentrations of metaraminol bitartrate, methylparaben, and propylparaben is shown in Table I. The data obtained show that metaraminol bitartrate, methylparaben, and propylparaben are linear to at least 25, 3.8, and 0.53 μg, respectively. A separate solution was run to determine the recovery and precision of the HPLC method. These data are shown in Table II.

The purity of three metaraminol bitartrate raw materials was determined by the HPLC method and the USP XX procedure as shown in Table III. The utility of HPLC in the analysis of metaraminol bitartrate is clearly demonstrated, and the results agree favorably with those obtained by the USP method.

High-Pressure Liquid Chromatographic Assay of Quinestrol Tablets

DIMITRI C. TSILIFONIS and LESTER CHAFETZ ˣ

Received April 30, 1980, from the *Analytical Research Laboratories, Pharmaceutical Research Division, Warner-Lambert Company, Morris Plains, NJ 07950.* Accepted for publication June 19, 1980.

Abstract □ A specific assay for quinestrol was developed using high-pressure liquid chromatography. The estrogen was separated from tablet excipients on a chemically bonded hydrocarbon column utilizing acetonitrile–water as the mobile phase. Linearity studies were carried out using peak height measurements, and the detector response to the concentration of the steroid was confirmed. This procedure was rapid, accurate, precise, and specific for the assay of the synthetic estrogen in the presence of formulation excipients and structurally similar estrogens.

Keyphrases □ Quinestrol—high-pressure liquid chromatographic analysis, tablets □ High-pressure liquid chromatography—analysis, quinestrol tablets

The pink chromophore resulting from the reaction of quinestrol with methanolic sulfuric acid was shown to afford an accurate, precise, and selective colorimetric assay for quinestrol in pharmaceutical dosage forms (1). This method correlated with the GLC assay (2), which proved useful as a reference method but had disadvantages in speed and convenience. High-pressure liquid chromatography (HPLC) affords a simple alternative with advantages in speed, interlaboratory precision, and productivity.

Roos (3) described an HPLC method for ethinyl estradiol, estrone, estradiol, and estradiol esters as their dansyl

derivatives, using UV detection at 254 nm or fluorescence detection. The HPLC method reported here uses detection of the estrogen at 281 nm without derivatization. Adequate sensitivity and excellent precision and recovery were obtained.

EXPERIMENTAL

Apparatus—The liquid chromatograph included a pump[1], an automatic injector[2] with a fixed-volume 50-μl loop, a stainless steel 4.6-mm × 25-cm column packed with bonded octadecylsilane on silica[3] (5–6-μm particles), a variable-wavelength detector[4] set at 281 nm, and a strip-chart recorder[5].

Mobile Phase—UV grade acetonitrile[6] was passed through a membrane[7]. Distilled water was passed through a membrane filter[8], and the filtered acetonitrile and water were mixed (80:20) and degassed.

Standard Preparation—About 10 mg of quinestrol USP reference standard was weighed accurately, transferred to a 50-ml volumetric flask, and dissolved in acetonitrile. The solution was diluted to volume, and 5.0 ml of this solution was diluted to 50 ml with the mobile phase in a volumetric flask to obtain a concentration of ~20 μg/ml.

Assay Preparation—Not less than 20 tablets were weighed and pulverized. A portion of the powder equivalent to ~100 μg of quinestrol was weighed, transferred to a 5-ml volumetric flask, suspended in 1 ml of water, and heated at steam bath temperature for ~5 min. The solution was diluted to volume with acetonitrile and mixed on a vibrating device[9] for ~2 min.

Procedure—The mobile phase was pumped through the column at a flow rate of 2 ml/min until a stable baseline was obtained. Fifty microliters of the assay preparation was injected by means of a precise loop injector, and the chromatogram was allowed to develop for 15 min. The procedure was repeated using the standard preparation. The peak corresponding to quinestrol eluted at ~8.5 min. The quantity of quinestrol was calculated from $5C(H_U/H_S)$, where C is the exact concentration (micrograms per milliliter) of the standard preparation and H_U and H_S are the peak heights in the chromatograms from the assay preparation and the standard preparation, respectively.

System Suitability—The relative standard deviation of the peak heights obtained after six successive injections of the standard preparation should not exceed ±1.0%. The number of theoretical plates should be no less than 5000, and the retention times for quinestrol and ethinyl estradiol should be ~8.5 and 2.0 min, respectively.

RESULTS AND DISCUSSION

Linearity—A straight line intercepting the origin was obtained by plotting the peak height against concentration (Table I).

Sensitivity—The quinestrol peak was ~0.35 full scale with a recorder sensitivity of 0.02 aufs and was adequate for quinestrol dosage forms. Sensitivity could be quadrupled using detection at 225 nm; however, at low wavelengths, detector sensitivity appeared to be more dependent on the light source age and detector cell cleanliness than at the wavelength chosen.

Recovery—The recovery of quinestrol was determined by adding known amounts of the estrogen to placebo tablets and assaying by the described procedure. Duplicate trials at levels representing 80, 100, and 120% of the claim for 100-μg tablets gave recoveries of 100.9, 101.8, and 99.8%, respectively. Six duplicate recovery experiments at 100.0% of the label claim by the same procedure gave recoveries of 98.8, 101.2, 100.0, 102.5, 102.5, and 99.4% of the added amounts, with an average of 100.7% and a relative standard deviation of ±1.6%.

Criteria for System Suitability—It is useful to establish criteria for system suitability on HPLC methods since the performance of any particular instrumental assembly may change over time and several different instruments may be employed. Excellent precision has been obtained in these laboratories using a loop injector, obviating the need to select an internal standard that could interfere with detection and estimation of a synthesis precursor, process contaminant, or degradation product. The actual precision of six replicate injections of the standard preparation was ±0.57%. The number of theoretical plates calculated for the column was 7530; this column gave satisfactory separations for the drug and related compounds. The requirement of not less than 5000 theoretical plates for system suitability was derived from a policy of setting this value at 70% of that obtained during method development.

Separation of Quinestrol from Other Estrogens—A chromatogram was run under the described conditions using 25 μg/ml of ethinyl estradiol, estrone, estrone 3-cyclopentyl ether, and quinestrol in the mobile

phase. Estrone, the starting material in the synthesis of quinestrol, and ethinyl estradiol, a possible process contaminant, were not resolved from each other and had a retention time of 2 min. Estrone 3-cyclopentyl ether, the penultimate intermediate in quinestrol synthesis, eluted at 10.8 min and was well separated from the quinestrol peak at 8.5 min (Fig. 1).

Selectivity of Assay in Presence of Decomposition Products—A 1-g sample of quinestrol was heated in an open vial at 125° for 96 hr. This procedure was shown previously to produce a similar TLC pattern to that obtained with quinestrol tablets that had been exposed to air for several months. (Quinestrol in open containers is susceptible to autoxidation, which involved an induction period of over 1 year at room temperature. None of the decomposition products has the same mobility as the synthesis precursors and process contaminants. One of the two major decomposition products isolated by preparative TLC had an NMR spectrum consistent with the structure of 6β-hydroxyquinestrol[10].) The brown material was pulverized, and a 50-mg portion was dissolved in acetonitrile and diluted to 50.0 ml with that solvent. A 5-ml aliquot was diluted further to 50.0 ml with the mobile phase and subjected to chromatography as described. The chromatogram (Fig. 2) exhibited unidentified peaks with retention times of ~1.7, 2.2, 2.4, 4.0, 5.7, 6.3, and 8.0 min, along with the peak for undegraded quinestrol at 8.5 min. The quantity of undegraded quinestrol was estimated as 57.7% by this HPLC method and 58.9% by the colorimetric method (1).

Further evidence of the validity of the HPLC method and the colorimetric method as stability-indicating methods was obtained by dissolving the degraded quinestrol in the mobile phase to obtain a concentration of ~10 mg/ml, injecting 50 μl into the liquid chromatograph, and collecting the eluates corresponding to the decomposition products. These eluates were evaporated to dryness on the steam bath with a nitrogen stream, and the residue was dissolved in 2.0 ml of methanol. A 1-ml portion, corresponding to >100 μg of quinestrol degradation products, was tested by the colorimetric method (1) and gave no color with the methanol–sulfuric acid chromogenic reagent.

Human Plasma Levels of Propranolol: Fluorometric Measurement in a Hydrosolvatic System

Keyphrases □ Propranolol—fluorometric measurement of human plasma levels □ Spectrofluorometry—analysis, propranolol, human plasma □ Antiarrhythmic agents—propranolol, fluorometric analysis, human plasma

To the Editor:

We have developed a rapid, sensitive, fluorometric technique for directly measuring human plasma concentrations of total propranolol. As little as 0.3 ml of plasma is required. The plasma sample is diluted 1:1 with a hydrosolvatic solution, such as dimethyl sulfoxide–water (1:2), and the fluorescence is measured with no further sample workup. Plasma concentrations of propranolol free base also may be determined, but a larger sample volume and an additional extraction step are needed. The limiting concentration that can be detected is 10 ng/ml, and the standard curve in plasma is linear from 10 to 10,000 ng/ml in each case. The principal aromatic metabolite of propranolol, 4-hydroxypropranolol, does not interfere with the procedure since it emits at much longer wavelengths than the parent compound.

The technique may be used for plasma, aqueous protein solutions, or purely aqueous systems that do not contain chemicals or drugs emitting UV radiation at the same wavelength as propranolol, such as metoprolol, timolol, oxprenolol, and nadolol. However, this limitation does not apply to many commonly and concurrently administered cardiovascular drugs. For example, triamterene, hydrochlorothiazide, clonidine, hydralazine, prazosin, digoxin, and quinidine either do not or should not interfere with the developed procedure (Table I).

Table I—Fluorescence Maxima of Some Commonly and Concurrently Administered Cardiovascular Drugs Compared to Those of Propranolol (λ_{ex} 317 nm)

Drug	Fluorescence Maximum, nm
Propranolol	337
4-Hydroxypropranolol[a]	420
Hydrochlorothiazide	380[b,c]
Triamterene	NI[d]
Clonidine	390[b,c]
Hydralazine	NF[e]
Prazosin	387[b,c]
Digoxin	NF[f]
Quinidine	450[g]

[a] Furnished by T. Walle, Department of Pharmacology, Medical University of South Carolina. [b] Determined in this laboratory. [c] These agents did not contribute to the emission intensity of propranolol (λ 340) in either plasma or buffer at concentrations 10^4 times the limiting detectable concentration of propranolol free base. [d] NI = no interference, absorption maximum at 356 nm ("The Merck Index," 9th ed., Merck & Co., Rahway, N.J., 1976, p. 1233) indicates that its fluorescence will not interfere with the assay. [e] NF = no fluorescence. Taken from Ref. 13. [f] NF from Ref. 14. [g] Taken from Ref. 14.

Propranolol[1], hydrochlorothiazide[2], clonidine[3], and prazosin[4] were obtained commercially. A buffer (μ = 0.005, pH 7.4) was prepared from analytical grade 0.1 *N* KH_2PO_4[5], 0.1 *N* K_2HPO_4[5], and distilled, deionized water. All solvents were analytical grade and contained no fluorescent impurities.

Table II—Fluorescence Excitation and Emission Characteristics of Human Plasma and Propranolol in Aqueous and Human Plasma Solution

Sample	Fluorescence Emission, λ_{em} 340					Fluorescence Excitation, λ_{ex} 317			
Human plasma	230	250	260	—	302[a]	—	—	—	—
Propranolol in plasma	230	250	260	—	—	317[a]	325	340[a]	350
Propranolol in aqueous solution	230	—	—	287[a]	—	317	325	340[a]	350

[a] Spectral maxima.

characteristics of propranolol in buffer and plasma. By exciting the propranolol sample in plasma at 317 nm (the maximum of the long wavelength vibrational feature) and monitoring its emission maximum at 340 nm, the background fluorescence of the plasma can be avoided completely. The absence of the shorter wavelength portion of the propranolol spectral band in plasma is probably due to the plasma absorbing all UV radiation below 310 nm. The spectra of plasma and plasma–propranolol solutions below this wavelength were virtually identical.

Initially, human plasma, 0.3 ml, was measured with a pipet[6] and transferred to a 0.2-mm path length, quartz, fluorescence semimicrocell[7] (1.4-ml capacity). Due to the shorter emission path length, use of this cell results in less light scatter from macromolecules in solution than when a conventional 10-mm path length cell is used. The fluorescence was measured immediately on a spectrofluorometer[8] (λ_{ex} 317, λ_{em} 340).

However, we must add several cautionary points. This simple procedure is usable only on clear plasma, usually obtained from fasted individuals, to a limiting concentration of 30 ng/ml. For cloudy plasma samples, usually obtained from recently fed individuals, the limiting detectable concentration was 60–70 ng/ml. To improve these detection limits, particularly in cloudy plasma samples, we examined the samples after dilution with water and several water–water-miscible solvent systems. The rationale for this approach was twofold:

1. *Dilution of the plasma sample should decrease light scatter caused by the higher concentration of lipoproteins, which will decrease the background noise and improve the signal-to-noise ratio.*

2. Propranolol and many other chemicals in some pure solvents demonstrate a greater fluorescence intensity than when in an equimolar aqueous solution (1). For example, in dimethyl sulfoxide, propranolol has a 1.25-fold greater intensity than when in buffer.

We examined propranolol-spiked plasma samples diluted 1:1, 1:2, and 1:3 with water and with dimethyl sulfoxide–water, acetonitrile–water, and dioxane–water solutions having solvent to water ratios of 1:1, 1:2, 1:3, and 1:4. A plasma sample diluted 1:1 with dimethyl sulfoxide–water (1:2 v/v) had the best signal-to-noise characteristics and limiting detectable concentrations of 10 ng/ml for clear samples and 20 ng/ml for cloudy samples. These values represent a threefold increase in sensitivity over those observed for the undiluted plasma samples. The 1:1 dilution caused a 15% loss of fluorescence intensity relative to an undiluted sample. A similar dilution with water caused a 25% loss accompanied by some, but not threefold, improvement in the signal-to-noise ratio. These results seem to indicate that the increased sensitivity caused by addition of the hydrosolvatic solution is due both to a decrease in scattered light and a specific solvent effect that enhances the emission intensity of propranolol.

Figure 1 shows the blood level curves for total plasma propranolol (propranolol and its metabolites) and propranolol obtained after oral administration of propranolol hydrochloride (one 20-mg dose and one 40-mg dose). The times of its peak concentration are similar to those reported elsewhere (2–4). Other pharmacokinetic characteristics were not compared due to the reported sevenfold differences in systemic blood levels between individuals (5).

Analytical specificity for free plasma propranolol can be achieved by modifying a recently published extraction procedure (6). The latter has been shown to extract propranolol free base specifically and quantitatively from alkalinized plasma. However, this procedure requires a larger sample volume than 0.3 ml. We found that the free base present in 1.0 ml of plasma could be extracted from the aqueous layer as follows. The plasma sample was diluted 1:1 with a dimethyl sulfoxide–aqueous buffer (pH

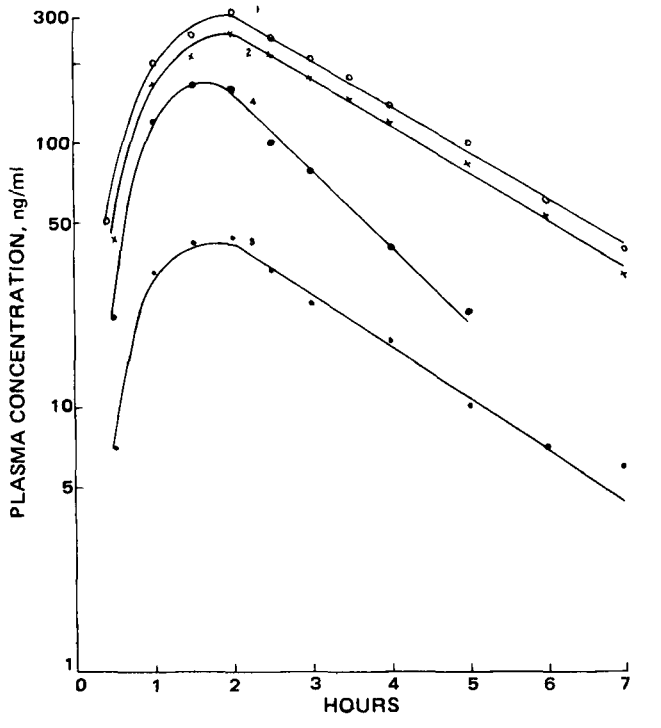

Figure 1—*Plasma concentration* versus *time for one normotensive volunteer after oral administration of a single dose of propranolol. Key: curve 1, total propranolol in plasma; curve 2, total propranolol minus propranolol free base; and curve 3, unmetabolized propranolol (curve 1 − curve 2). Curves 1–3 were obtained from one 40-mg oral dose, and curve 4 was obtained from one 20-mg dose.*

11, 1:2) and shaken vigorously with 10 ml of either ether or ethyl acetate for 10 min followed by centrifugation to separate the layers. The standard and control solutions were subjected to the same conditions. After removal of the propranolol, propranolol glucuronide (7) as well as the acidic metabolites of propranolol (6, 8, 9) remained in the aqueous layer. Therefore, the plasma propranolol concentration may be expressed as the difference in the fluorescence intensity of the aqueous layer before and after basic extraction (Fig. 1).

The concentration of propranolol free base extracted into each nonaqueous layer was verified at 1, 3, and 5 hr on curve 4 (Fig. 1) as follows. Five milliliters of ether was evaporated to dryness, and the fluorescence intensity of the residue taken up in methanol was compared to that of the standards prepared in methanol. For samples extracted with ethyl acetate, the fluorescence intensity of the latter was compared to that of the standards prepared immediately in this solvent.

The results in Fig. 1 corroborate recent reports that the plasma propranolol concentration is much less than that of its glucuronide and acidic metabolites (6–9).

This analytical method is two-to-20-fold less sensitive than established GLC, high-pressure liquid chromatographic (HPLC), and GLC–mass spectrometric procedures (3, 10–12). However, it is more rapid than either GLC or GLC–mass spectrometric procedures and comparable in speed to HPLC. The ready availability and relatively low cost of fluorescence instrumentation make it a useful alternative to chromatographic techniques.

A comparison of the reported fluorometric method with the one currently in use indicates an improvement in methodology since the sample volume and workup time are reduced (5). Excitation at 317 nm rather than at 287 nm eliminates fluorescence background from the plasma but reduces sensitivity due to the diminished intensity at the vibrational feature maximum, 317 nm. Therefore, the two procedures are comparable with regard to their limiting detectable concentrations.

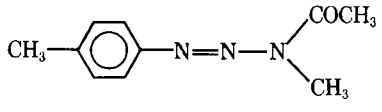
1-(*p*-Tolyl)-3-acetyl-3-methyltriazene: A Compound with Activity against African Trypanosomiasis

Keyphrases □ Antiprotozoal agents—1-(*p*-tolyl)-3-acetyl-3-methyltriazene, activity against African trypanosomiasis, mice □ 1-(*p*-Tolyl)-3-acetyl-3-methyltriazene—evaluation of activity against African trypanosomiasis, mice

To the Editor:

We wish to report our recent finding that 1-(*p*-tolyl)-3-acetyl-3-methyltriazene (I) is active against *Trypanosoma rhodesiense* and *T. rhodesiense* EATRO 1989 (mildly virulent strain) infection in the mouse. The triazene was synthesized according to the procedure of Dimroth (1). 1-(*p*-Tolyl)-3-methyltriazene was prepared from the diazocation of *p*-toluidine. The diazocation was treated with methylamine to give the monomethyltriazene. This compound was acetylated with acetic anhydride in pyridine. The yield of the triazene was 73% after recrystallization from hexane, mp 53° [lit. (1) mp 54–56°]; IR (KBr): 1716 cm^{-1}; mass spectrum (70 ev): *m/z* (relative intensity) 191 (8), 149 (5), 119 (8), 91 (100), and 43 (45).



I

Compound I was tested initially against *T. rhodesiense* (Wellcome CT strain) using a mouse model (2). Test and control mice (ICR/HA Swiss) were 6 weeks old and weighed 28–30 g. No differences in response between sexes have been reported. Each mouse was infected by intraperitoneal injection of 0.05 ml of a 1:50,000 dilution of heparinized heart blood drawn from donor mice infected 3 days earlier.

Drugs were administered subcutaneously or orally in peanut oil 2 hr after infection. Untreated mice died between 4.2 and 4.5 days postinfection. Surviving animals

Table I—Activity of I against *T. rhodesiense* (Wellcome CT Strain) Infection in Mice

Route of Administration	Dose, mg/kg					
	424	212	106	53	26.5	13.3

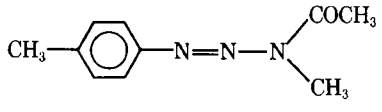
1-(*p*-Tolyl)-3-acetyl-3-methyltriazene: A Compound with Activity against African Trypanosomiasis

Keyphrases □ Antiprotozoal agents—1-(*p*-tolyl)-3-acetyl-3-methyltriazene, activity against African trypanosomiasis, mice □ 1-(*p*-Tolyl)-3-acetyl-3-methyltriazene—evaluation of activity against African trypanosomiasis, mice

To the Editor:

We wish to report our recent finding that 1-(*p*-tolyl)-3-acetyl-3-methyltriazene (I) is active against *Trypanosoma rhodesiense* and *T. rhodesiense* EATRO 1989 (mildly virulent strain) infection in the mouse. The triazene was synthesized according to the procedure of Dimroth (1). 1-(*p*-Tolyl)-3-methyltriazene was prepared from the diazocation of *p*-toluidine. The diazocation was treated with methylamine to give the monomethyltriazene. This compound was acetylated with acetic anhydride in pyridine. The yield of the triazene was 73% after recrystallization from hexane, mp 53° [lit. (1) mp 54–56°]; IR (KBr): 1716 cm^{-1}; mass spectrum (70 ev): *m/z* (relative intensity) 191 (8), 149 (5), 119 (8), 91 (100), and 43 (45).



I

Compound I was tested initially against *T. rhodesiense* (Wellcome CT strain) using a mouse model (2). Test and control mice (ICR/HA Swiss) were 6 weeks old and weighed 28–30 g. No differences in response between sexes have been reported. Each mouse was infected by intraperitoneal injection of 0.05 ml of a 1:50,000 dilution of heparinized heart blood drawn from donor mice infected 3 days earlier.

Drugs were administered subcutaneously or orally in peanut oil 2 hr after infection. Untreated mice died between 4.2 and 4.5 days postinfection. Surviving animals

Table I—Activity of I against *T. rhodesiense* (Wellcome CT Strain) Infection in Mice

Route of Administration	Dose, mg/kg					
	424	212	106	53	26.5	13.3
Subcutaneous	5/5[a]	—	0/5	—	0/5	—
Subcutaneous	5/5	3/5	0/5	0/5	0/5	0/5
Oral	5/5	2/5	0/5	0/5	0/5	0/5

[a] Number of mice cured/number of mice treated.

Table II—Activity of I against *T. rhodesiense* EATRO 1989 Infection in Mice

Dose[a], mg/kg ip	Days 5–6	7	8–9	10–12	19	30	39	50	60
1600	5/5[b]	4/5	0/5	0/5	0/2	0/2	0/2	0/1	0/1
800	5/5	4/5	0/5	0/4	0/3	0/3	0/3	0/3	0/3

50	5/5	5/5	5/5	5/5	5/5	5/5	5/5	4/4	1/1	Dead	
25	5/5	5/5	5/5	5/5	5/5	5/5	5/5	4/4	1/1	Dead	
Control (untreated)	5/5	5/5	5/5	2/2	2/2	2/2	1/1	Dead			

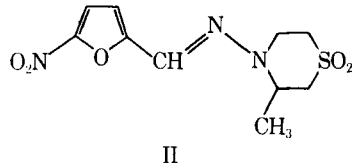
[a] The compound was dissolved in ethanol, and the mice were treated on Day 4 only. [b] Number of parasitemic mice/number of mice treated and still alive on various days.

were observed for 30 days. The mice surviving 30 days were considered cured. The test data are given in Table I.

To determine if I had activity against mildly virulent strains of the parasite, it was tested in a mouse model against *T. rhodesiense* EATRO 1989. Male albino mice were infected with the parasites on Day 0. The triazene was administered intraperitoneally as both ethanolic and methanolic solutions (total volume of 0.1 ml/injection) on Days 4 and 5, respectively. The mice then were observed until Day 60 postinfection; during the test period, the blood of the surviving mice was microscopically examined for parasites each day. The results of these tests are given in Tables II and III.

An examination of the data in Tables I–III indicates that I has activity against *T. rhodesiense* and its mildly virulent strain. The compound is curative when administered subcutaneously or orally at a dose of 424 mg/kg. Against the mildly virulent strain at a dose of 800 mg/kg in methanol, three of the five mice treated were alive and parasite free after 60 days; at 400 mg/kg, three survived and two were parasite free after 60 days.

Under the same conditions, (3-methyl-4,4′-nitrofurfurylidineamino)tetrahydro-4*H*-1,4-thiazene-1,1-dioxide



II

(II), a standard drug, only suppressed the parasite. At doses of ≥150 mg/kg ip, II cleared parasitemia for 9 days; when given orally at 400 mg/kg for 5 consecutive days, II cleared parasitemia temporarily from Days 6 to 9.

The results reported here indicate that I has sufficient activity to justify a thorough investigation of its chemical and pharmacological profiles using both drug-sensitive and drug-resistant strains. These studies are underway, and a more detailed report of the findings will follow.

We thank Dr. Tom Sweeney, Walter Reed Army Institute of Research, for obtaining the test data reported in Table I. Supported by the UNDP/World Bank/World Health Organization Special Program for Research and Training in Tropical Diseases.

In the article titled "Degradation Kinetics of a New Cephalosporin Derivative in Aqueous Solution" (1), the following corrections should be made:

On page 1373, column 1, Eq. 10 should read:

$$k_0 = k'_2 f_{HC} + k_6(OH^-)f_{C^-} \quad \text{(Eq. 10)}$$

On page 1373, column 1, Eq. 11 should read:

$$a_{H^+(min)} = [k_6 K_{w(exp)}/\gamma_\pm k'_2][1 + \sqrt{1 + (k'_2 K_a/k_6(K_{w(exp)}/\gamma_\pm))}] \quad \text{(Eq. 11)}$$

On page 1373, column 2, the first line should read: "from which $a_{H^+(min)} = 1.070 \times 10^{-6}$ and $pH_{min} = 5.97$ may be calculated."
