Figure 1 shows a plot of the budesonide content relative to a budesonide working standard *versus* the number of purification step. The content increased with purification to a constant value. The substance obtained in the ethanol–water recrystallization (Step 6) could not be purified further and, therefore, was defined as the primary standard. Reversed-phase HPLC with System 2 revealed a few traces of foreign steroids, and no further impurities were detected by normal-phase HPLC. Traces of methanol and water were detected by GLC and coulometric Karl Fischer titration, but no other chemicals used in purification could be traced. These results are summarized in Table I.

Known detector response factors are necessary for a correct evaluation of foreign steroids and epimer distribution. Such factors are listed in Table II. They were used for all of the reported content determinations of the four impurities and the two epimers. These factors are close to one since the molar absorptivities of the impurities and of Epimers A and B are similar to that of budesonide. This result is due to the fact that the UV absorption originates from ring A in the steroid nucleus. This structure probably is common to each of the four impurities.

The HPLC assay for budesonide using System 1 was tested by a standard addition procedure (Table III). Known samples containing 92–100% of the budesonide primary standard were assayed with a mean recovery of 100.3% and a standard deviation of 0.16. In the same experiment, the four impurities were evaluated analytically (Table III). In the range of 0.05–0.2% of individual foreign steroids, recoveries of 78–102% were obtained. The corresponding standard deviations were 7.6–9.8. For samples with individual impurities between 0.2 and 2%, the recoveries were 92–102% with standard deviations of 1.1–4.6.

Even in the low impurity range (0.05–0.2%), quantification gives fairly good accuracy and precision. This result is possible since the detection limit, 0.005%, is below this range and since the chromatographic system works linearly and is stable down to the highest sensitivity, *i.e.*, 0.005 absorbance unit full scale. For Impurity 4, the analytical evaluation depends on its concentration; in the range of 0.05–0.25%, the impurity could not be separated chromatographically from the budesonide Epimer B. Therefore, the impurity peak is added to the budesonide peaks. This addition results in a slightly higher recovery for budesonide. However, if Impurity 4 has to be determined in the range of 0.05–0.25%, System 2 can be used since it results in larger retention times and, thus, in higher separation efficiency.

Mixtures with a known content of Epimers A and B were investigated with ethanol–water in ratios of 43:57 (v/v) (System 2) and 48:52 (v/v) (System 1) as the mobile phases. For the control of the epimer distribution of budesonide batches, System 2 was used since it was optimal with respect to the epimer separation. The effect of increasing the water content in the mobile phase to improve the epimer separation was due to increased retention and to an increase in the separation factor (7).

Figures 2 and 3 show chromatographic separations of the impurities and the epimers of budesonide using Systems 1 and 2. The resolution was improved significantly by increasing the mobile phase water content from 52 to 57%. This change in resolution had little effect on the quantification of the epimers. Although no baseline separation was obtained, System

Table IV—Recovery for Individual Epimers of Budesonide in HPLC Analysis

Sample	Percent of Epimer A in Standard Mixtures of Epimers A and B[a]		
	Added	Found[b]	Found[c]
1	62.41	62.16	62.41
2	55.46	55.30	55.72
3	49.90	49.62	49.95
4	44.34	44.20	44.58
5	37.50	37.56	37.75
Recovery, %		99.7	100.3
SD		0.27	0.29

[a] Since the standard mixtures contained only Epimers A and B, the percentage of Epimer B was obtained from 100% − % of Epimer A. [b] Mobile Phase System 1 was ethanol–water in a ratio of 48:52 (v/v). [c] Mobile Phase System 2 was ethanol–water in a ratio of 43:57 (v/v).

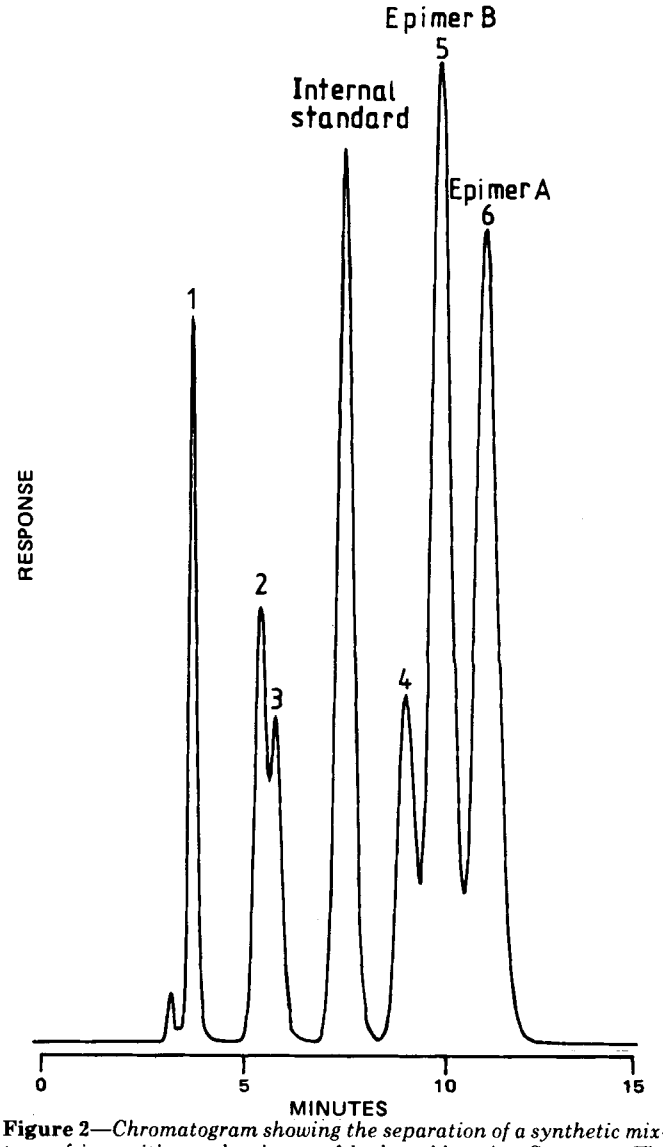

Figure 2—*Chromatogram showing the separation of a synthetic mixture of impurities and epimers of budesonide using System 1. The support was μBondapak C_{18}, the mobile phase was ethanol–water (48:52 v/v), and the flow rate was 1.0 ml/min. Key: 1, Impurity 1 (16α-hydroxyprednisolone); 2, Impurity 2 (homolog of budesonide; see text); 3, Impurity 3 (unknown); 4, Impurity 4 (unknown); 5, Epimer B of budesonide; and 6, Epimer A of budesonide.*

Total sum[a], %	99.3	99.8	100.7	100.0	100.0	100.0	99.9	99.8

[a] Mean of total sum is 99.9%. Standard deviation of total sum is 0.39.

1 gave similar accuracy in the epimer distribution determination to that of System 2 (Table IV). This result must be a consequence of the ideal behavior of the chromatographic system; *i.e.*, symmetrical peaks were obtained. As for the epimeric resolution, the separation of impurities was improved by changing from System 1 to System 2. Several tests showed that even the quantification of individual foreign steroids was not significantly affected by the differences in resolution.

The ratio between the peak area of budesonide and the peak area of the flucloronide internal standard was plotted *versus* the concentration of budesonide between 0 and 0.6 mg/ml. The result was a straight line with an intercept of 0.096, a slope of 6.01 ml/mg, and a correlation coefficient of 0.999989. The data indicate that the chromatographic system behaves properly and that the detector responds with high linearity. The use of an internal standard is necessary to minimize the injection error. Repeated injections gave a relative standard deviation of ~0.1% for the peak area ratio. Furthermore, the internal standard must not interfere with budesonide or impurity peaks. This condition is satisfied by flucloronide (Fig. 2).

In all budesonide batches analyzed, Impurities 1–4 represented ~75% of the total foreign steroids found by reversed-phase liquid chromatography. The remaining content (*i.e.*, traces of other impurities in budesonide) was quantified by calculation of the area under the chromatographic peaks since the detector response factors are unknown. The same procedure was used for traces of several nonpolar impurities, which could not be eluted by reversed-phase chromatography but were eluted and detected by normal-phase chromatography on μBondapak NH_2. In general, impurities that eluted before budesonide in the reversed-phase system eluted after the drug substance in the normal-phase system, as illustrated for the four impurities in Fig. 4. Figure 4 also shows the separation of the two epimers of Impurity 2, in contrast to the reversed-phase systems where they were not separated (Figs. 2 and 3).

Analytical results from eight small-scale production batches of budesonide (Table V) gave a mean for the sum of budesonide and impurities of 99.9% with a standard deviation of 0.39. This result suggests that the detector response factors are similar for budesonide and for all unknown impurities.

The results show that the necessary prerequisites for an accurate evaluation of budesonide substance by HPLC are fullfilled. The proposed analysis method is highly selective, linear, precise, and sensitive. Another advantage of the method is its high analytical capacity. The budesonide content, the impurity content, and the epimer distribution can be evaluated accurately by one chromatographic system. Comparison of retention times in sample and standard chromatograms may serve as an identity test for budesonide. The proposed HPLC method meets the main points in monographs for steroid substances and seems analytically superior to the usual procedures suggested in pharmacopeias.

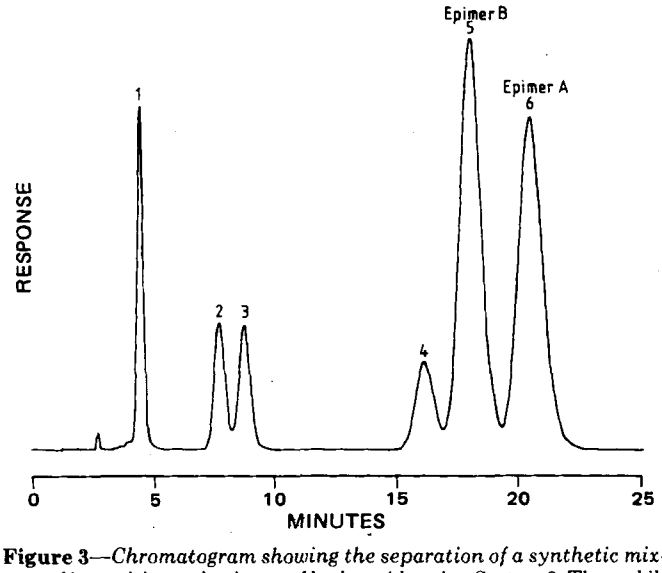

Figure 3—*Chromatogram showing the separation of a synthetic mixture of impurities and epimers of budesonide using System 2. The mobile phase was ethanol–water (43:57 v/v). The other conditions were the same as those described for Fig. 2.*

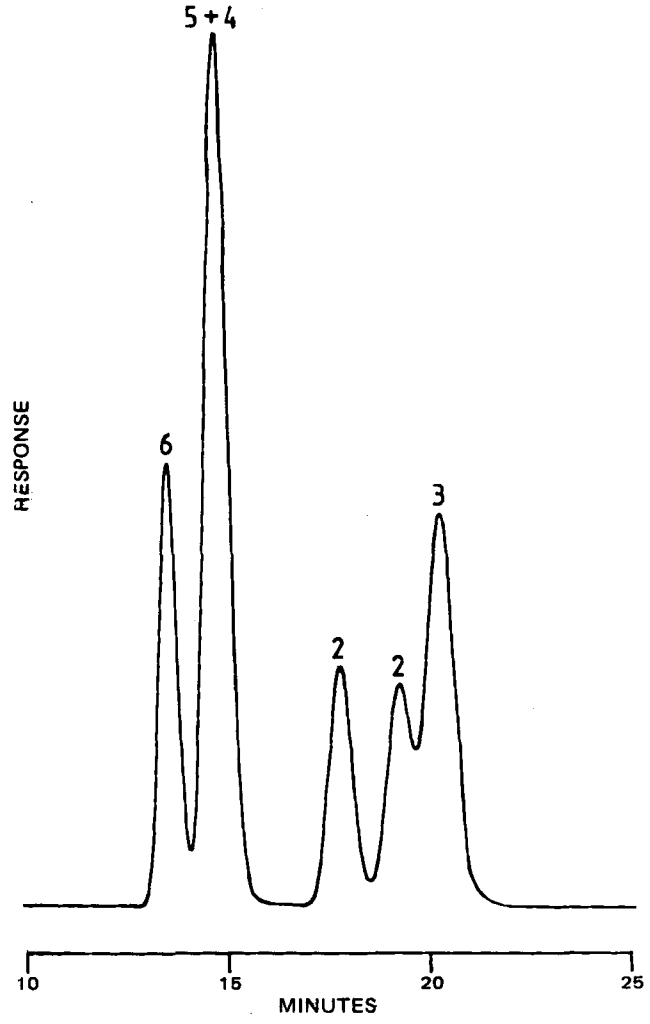

Figure 4—*Chromatogram showing the separation of a synthetic mixture of impurities and epimers of budesonide using a normal-phase system. The support was μBondapak NH_2, the mobile phase was heptane–ethanol (91:9 v/v), and the flow rate was 1.0 ml/min. The peak designations are the same as in Fig. 2. Impurity 2 (a mixture of two epimers; see text) appeared in this system as two peaks. Impurity 1 was not eluted.*

Physical Model Evaluation of Topical Prodrug Delivery—Simultaneous Transport and Bioconversion of Vidarabine-5′-valerate III: Permeability Differences of Vidarabine and *n*-Pentanol in Components of Hairless Mouse Skin

CHENG DER YU *, WILLIAM I. HIGUCHI ˣ, NORMAN F. H. HO, JEFFREY L. FOX, and GORDON L. FLYNN

Received August 2, 1979, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication December 13, 1979. *Present address: Syntex Research, Stanford Industrial Park, Palo Alto, CA 94304.

Abstract □ The permeation behavior of ^{3}H-vidarabine (^{3}H-9-β-D-arabinofuranosyladenine) and ^{14}C-*n*-pentanol through different strata of hairless mouse skin was studied using a diffusion cell at 37° under steady-state conditions. Partition coefficients for the skin components *versus* 0.9% aqueous NaCl solution also were obtained. Various skin preparations including full-thickness skin, cellophane-stripped skin, and dermis membranes of different thicknesses were employed. The dermis membranes were considered to be diffusionally homogeneous, and the product of the permeability coefficient and the thickness was taken as the apparent diffusivity. The apparent diffusivities for both compounds investigated were independent of thickness. Therefore, it was concluded that the molecular diffusivity is constant throughout the dermis. Comparisons of permeability coefficients in various strata of the skin revealed that, while the stratum corneum is the major diffusional barrier, the epidermis appears to be significantly less permeable than the dermis.

Keyphrases □ Vidarabine valerate prodrug—topical dosage forms, permeability differences through various mouse skin strata □ Prodrugs, topical—based on simultaneous transport and bioconversion of vidarabine, permeability differences in various components of mouse skin □ Diffusivity—vidarabine and *n*-pentanol, effect of skin strata and thickness on diffusivity □ Models, physical—based on simultaneous transport and bioconversion, effect of homogeneous distribution on prodrug evaluation

The basic experimental methods for determining key parameters and evaluating the transport and metabolism of a prodrug of vidarabine (9-β-D-arabinofuranosyladenine, I) in hairless mouse skin were discussed previously (1). Among the parameters needed for the mechanistic quantification of the problem are the transport parameters, the permeability coefficients, and the diffusivities in the various components of the skin. These parameters and the metabolizing enzyme constants, k_1 and k_2, permit a quantitative analysis of the prodrug delivery behavior in the skin.

The barrier nature of the various skin components is not fully understood. Several studies concerned the possible differences between the diffusional resistances of the epidermis and the dermis (2, 3). The purposes of this investigation were to study mechanistically the barrier nature of the various components of the hairless mouse skin using membrane preparations of different strata of the skin and to investigate the possible variations in the diffusivity with respect to position in the dermis component.

Studies were conducted on the permeabilities of I in various membrane preparations of the hairless mouse skin

from which the permeability coefficients for the stratum corneum, the epidermis, and the dermis were calculated. Experiments with *n*-pentanol were included to determine any possible effects of molecular size.

EXPERIMENTAL

The experimental procedures for the permeation studies were described previously (1). The materials were the same as those used previously (1), except ^{14}C-*n*-pentanol[1] was diluted with saline to give a 1-μCi/μl solution. As described previously (1), full-thickness skin, cellophane[2]-stripped skin, and dermatome-planed dermis preparations were the membranes used.

RESULTS AND DISCUSSION

Figure 1 shows raw data obtained from a typical permeation experiment. The accumulation of I or *n*-pentanol in the receiver chamber increased linearly after a short lag time. The slopes gave the fluxes, F, for the permeants. The permeability coefficients, P, then were calculated from the slope and the concentration differential, ΔC, for each species from:

$$P = \frac{F}{\Delta C} = \frac{\left(\frac{V}{A}\right)\text{slope}}{\Delta C} \qquad \text{(Eq. 1)}$$

where V is the volume of the receiver solution and A is the diffusional area of the membrane. The permeability coefficients of I and *n*-pentanol for the full-thickness skin, stripped skin, and dermis membranes are shown in Tables I–IV. The apparent diffusivity[3], D, which is determined from the lag time, also is listed in Tables III and IV. Experimental reproducibility was satisfactory and consistent with previous experiments (1). Repeated permeation experiments showed an animal-to-animal variation of approximately a factor of two. Also, the stabilities of the various membrane preparations were satisfactory up to ~2–3 days.

Comparison of the permeability coefficients of I in the various membrane preparations (Table V) revealed that stripped skin was ~100 times more permeable than full-thickness skin, while the dermis was >1000 times more permeable. A similar relationship also existed for the permeation of *n*-pentanol, but the permeability differences were much smaller (Table V). This evidence suggests that, while the stratum corneum is the major diffusional barrier, the epidermis may be significantly less permeable than the dermis.

It was noted previously that the epidermis may be significantly less permeable than the dermis and that it may be a biopharmaceutically important barrier. Feldmann and Maibach (2) reported that both the stratum corneum and the Malpighian–basal layers serve as skin barriers for the penetration of hydrocortisone through normal human skin. The anatomy of the skin reveals a significant structural difference between the epidermis[4] and the dermis: the former consists of highly packed, well-aligned epithelial cells, whereas the latter is composed of cells loosely scattered throughout a gel-like interstitial matter. Therefore, epidermis may be less permeable than the dermis for some molecules having low overall skin permeabilities such as those that are simultaneously large and polar.

The diffusivities (both D_{app} and D) of I and *n*-pentanol were relatively constant with respect to position in the dermis membrane. The permeation data on the dermis membranes of different thicknesses (Tables III and IV) show a random scattering around a constant value when D_{app} is plotted *versus* the membrane thickness (Fig. 2).

Table VI presents the calculated permeability coefficients for the stratum corneum and the epidermis. The permeability coefficients for

Abstract □ A semiquantitative assessment of esterase and deaminase distributions in hairless mouse skin was performed *in vitro*. The enzyme activities were quantified using ^{3}H-vidarabine and its 5′-valerate as the substrates. Full-thickness skin of the hairless mouse was cut into two halves, and each half was homogenized in pH 7.4 buffer. Both the supernate and the residue of the homogenate were assayed for esterase and deaminase activities. Results show that the outer half-thickness of the skin contained more esterase but slightly less deaminase than the other half. The characteristics of the esterase and the deaminase reactions also were studied employing the crude enzyme extract; these reactions were essentially irreversible. The deaminase reaction was in the linear region of Michaelis–Menten kinetics for substrate concentrations up to 4.5×10^{-5} *M*.

Keyphrases □ Vidarabine valerate prodrug—topical dosage forms, distribution of adenosine deaminase and esterase enzymes in various mouse skin strata □ Prodrugs, topical—simultaneous transport and bioconversion of vidarabine, distribution of adenosine deaminase and esterase enzymes in mouse skin, pharmacokinetics □ Enzyme distribution studies—location and nature of adenosine deaminase and esterase in mouse skin, pharmacokinetic parameters of deaminase and esterase □ Models, physical—based on simultaneous transport and metabolism, effect of nonhomogeneous distribution on prodrug evaluation

A physical model for the evaluation of a topical prodrug of vidarabine (9-β-D-arabinofuranosyladenine, I) was presented previously (1). The activity of the esterase that converts vidarabine-5′-valerate (III) to I and the activity of the deaminase that converts I to 9-β-D-arabinofuranosylhypoxanthine (II) were potentially capable of influencing the efficacy of the prodrug according to the model. For mathematical simplicity, the model assumed that the enzyme reactions were irreversible and within the linear range of Michaelis–Menten kinetics and that the distributions of both enzymes were homogeneous throughout the viable cutaneous tissue.

Subsequent experiments and data analysis using the model revealed some inconsistencies. Experiments conducted under two different boundary conditions yielded significantly different *in situ* enzyme rate constants. This result raised questions concerning the validity of the homogeneous enzyme distribution assumption employed in the calculations and the need for a more detailed study of the enzyme distribution in the membrane. Thus, the purpose of the present investigation was to study the distributions of the two enzymes in hairless mouse skin as well as the nature of the enzyme reactions.

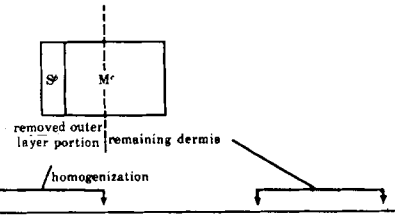
Table I—Distributions of the Esterase and the Deaminase in Hairless Mouse Skin [a]



Enzyme	Extract	Residue	Extract	Residue
Deaminase	1.95×10^{-2}	0.10×10^{-2}	3.59×10^{-2}	0.18×10^{-2}
Esterase[d]	21.7×10^{-3}	7.93×10^{-3}	6.46×10^{-3}	0

[a] Values are in reciprocal seconds. [b] S is the stratum corneum. [c] M is the cutaneous tissue. [d] Raw data are shown in Figs. 1 and 2.

for a 0.01 *M* 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid[1] buffer solution (adjusted with 10 *N* NaOH to pH 7.4).

Enzyme Distribution Studies—Although extraction of enzymes from tissue homogenates may not reach 100%, useful data for comparing the relative enzyme content of tissue of the same mass may be obtained. Full-thickness skin may be planed into two halves, and each half may be extracted for its enzyme content. A comparison of enzyme activities in the extracts then may provide some measure of the relative enzyme distribution in the whole skin.

Hairless mice were sacrificed by snapping the neck. After sacrifice, the abdominal skin was planed with a dermatome[2] to remove a top layer (including the stratum corneum, the epidermis, and part of the dermis) about 150–200 μm thick. The remaining dermis then was excised from the animal. The two pieces, after weighing, were homogenized separately in a centrifuge-type tissue grinder[3] with 1 ml each of the buffer. The tissue grinder was immersed in an ice–water mixture during the grinding.

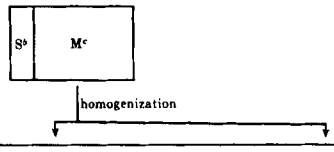
Table II—Esterase and Deaminase Activities in Tissue Homogenate of Hairless Mouse Skin [a]



Enzyme	Extract	Residue
Deaminase	2.28×10^{-2}	0.15×10^{-2}
Esterase	5.78×10^{-3}	1.9×10^{-3}

[a] Values are in reciprocal seconds. [b] S is the stratum corneum. [c] M is the cutaneous tissue.

For each homogenate, the supernate was separated from the residue by centrifugation at 3000 rpm for 5 min. A 0.5-ml aliquot of the supernate then was divided into two aliquots. One aliquot was incubated with 5 μCi (specific activity of 41.7 μCi/μg) of ^{3}H-2-I and the other with ^{3}H-2-III at 37°. The residues were redispersed in 1 ml of buffer after washing several times by redispersion and centrifugation. The redispersed residues were divided into aliquots and incubated with ^{3}H-2-I and ^{3}H-2-III, as were the supernates. Samples were analyzed by TLC and scintillation counting as described previously (2). The initial rates were obtained from the substrate concentration–time curve.

Studies of Irreversible Nature of Enzyme Reactions—Two methods were employed to study the irreversibility of the esterase and deaminase enzyme reactions. One method involved the crude extracts; the other was based on the in-and-out method with intact full-thickness skin. The procedure for the in-and-out experiments was described previously (2), and the homogenization procedure for obtaining the enzyme extracts was the same as that given under *Enzyme Distribution Studies*, except that full-thickness abdominal skin (0.334 g) was homogenized without dermatome planing.

Determination of Linear Region of Enzyme Reaction—The spectrophotometric assay of Kalckar (3–5) for adenosine deaminase was employed. The skin homogenate (1.6 g from three mice of the same age in 5 ml of buffer) was obtained as described. After centrifugation, 0.05 ml of the supernate was diluted to 20 ml with buffer. A different enzyme concentration was prepared by diluting 0.5 ml of the supernate to 40 ml with the buffer.

To determine the reaction rate for a given substrate concentration, 2 ml of one enzyme solution was transferred into a cell of which 50 μl then was replaced with the appropriate solution of I at zero time. The change in absorbance at 265 μm (ΔA_{265}) was measured with a spectrophotometer[4] for 1 hr at 5-min intervals. A background reading was taken before

introduction of the substrate, and the zero-time reading was taken 20 sec after the substrate was mixed well with enzyme solution in the cell.

RESULTS AND DISCUSSION

Esterase and Deaminase Distributions in Hairless Mouse Skin—Figures 1 and 2 show the esterase activities in the supernate and the residues of the homogenates prepared from the outer layer of skin and from the remaining dermis. The initial rates of the esterase and deaminase reactions obtained from these substrate concentration–time curves are tabulated in Table I. The esterase activity was much higher in the outer layer half than in the other half of the skin, whereas the deaminase distribution was in the reverse order but with less difference between the two halves. Table II shows the results of similar studies with a whole skin sample. These results have significant consequences in the physical model analysis of the transport and metabolism problem.

Because of the nonhomogeneous distribution of these enzymes, the analytical solutions describing the simultaneous diffusion and metabolism (1) based on the homogeneous enzyme distribution assumption may serve only as a first approximation in the evaluation of a prodrug. A more rigorous analysis that considers the effects of nonhomogeneous enzyme distributions may be carried out with a numerical computational procedure. A computer program for handling any possible enzyme distri-

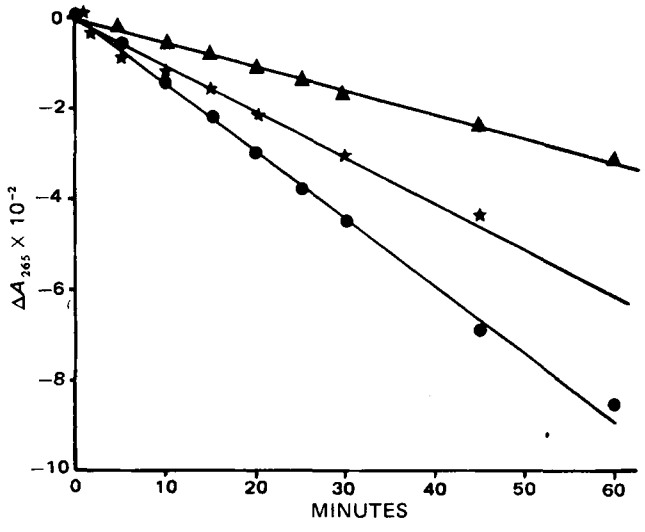

Figure 6—*Time curves showing the decrease in absorbance (ΔA_{265}) resulting from incubation of various concentrations of I with a crude extract of skin deaminase. Key: ▲, 3.1 μg/ml; ★, 6.5 μg/ml; and ●, 12.0 μg/ml.*

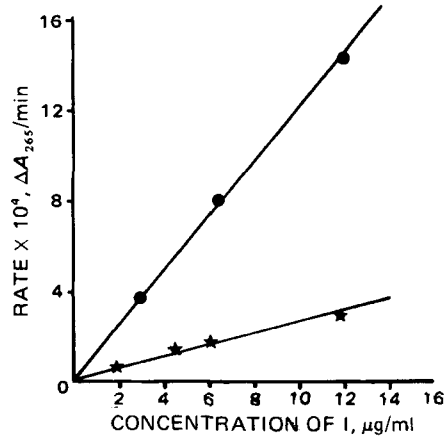

Figure 7—*Linear range of the deaminase activity, showing that the first-order enzyme kinetics hold up to a substrate concentration of 12 μg/ml (or 4.5 × 10^{-5} M). Key: ●, high enzyme concentration; and ★, low enzyme concentration.*

bution was developed by Fox *et al.* (6), and the rigorous evaluation of III as a potential prodrug using this approach will be presented later.

Irreversibility of Enzyme Reactions—Figure 3 shows the conversion of I to II by the deaminase in the supernate of a skin homogenate. The reaction is essentially complete in 20 min. Thus, the reaction is essentially irreversible from a practical standpoint. Similar results were obtained for the deaminase reaction in the intact skin with the in-and-out experiment. Figure 4 shows that the conversion of I to II by the deaminase in the intact skin experiment was almost complete in 6 hr. In the in-and-out experiment involving an intact skin incubated with ^{3}H-2-III, a typical A → B → C reaction pattern was observed (Fig. 5).

Linear Region of Michaelis–Menten Kinetics for Deaminase Reaction—Figure 6 shows the ΔA_{265} *versus* time curve for three different concentrations of I incubated at room temperature with the enzyme solution. The initial rates obtained from the slopes were plotted *versus* the substrate concentration (Fig. 7). Results of similar experiments with a different enzyme concentration also were plotted (Fig. 7). The deaminase enzyme reaction was in the linear region of Michaelis–Menten kinetics for substrate concentrations up to 12 μg/ml or 4.5 × 10^{-5} *M* for I. This result is in good agreement with reported K_m values (7–9) for purified adenosine deaminase (using I as the substrate) obtained from calf intestine mucosa, which range from 7 to 14 × 10^{-5} *M*.

Abstract □ The mathematical problem of simultaneous transport and metabolism in the case of nonuniform enzyme distributions in the skin was solved, and the solutions were used for analyzing experimental data. Experimental data were obtained from permeation experiments with ^{3}H-vidarabine and its 5′-valerate using cellophane tape-stripped hairless mouse skin. Results of the analyses revealed that the esterase activity was four to nine times higher in the epidermis than in the dermis, whereas the deaminase activity was about the same in the two strata. These results were in good agreement with independent experiments using tissue homogenates. The enzyme distributions and the previously reported diffusivities were employed in generating concentration profiles for the prodrug and the drug in the skin. These results may be used in predicting the possible therapeutic effect of the prodrug when it is topically applied.

Keyphrases □ Vidarabine valerate prodrug—topical dosage forms, physical models employing homogeneous and nonhomogeneous enzyme distributions, various mouse skin strata, mathematical analysis □ Prodrugs, topical—simultaneous transport and bioconversion of vidarabine valerate, effect of enzyme distribution and diffusivities on bioavailability, various mouse skin strata, mathematical analysis □ Models, physical—homogeneous and nonhomogeneous enzyme distributions, various mouse skin strata, vidarabine valerate prodrug, topical dosage forms, mathematical analysis

A physicochemical method was developed to determine the *in situ* enzyme rate constants in hairless mouse skin (1, 2). Because of the lack of specific information, preliminary analyses of the experimental data were conducted based on the assumptions of uniform enzyme distribution and constant membrane diffusivities for the substrate and metabolite. It was believed then that when appropriate data became available, a more comprehensive analysis should be conducted based on the possible nonuniform enzyme distributions and the possible variations in diffusivity with respect to position in the membrane.

Subsequent studies were conducted to assess the possible variations in diffusivities and enzyme rate constants. Permeability coefficients of vidarabine (9-β-D-arabinofuranosyladenine, I) in various components of hairless mouse skin were factored out, and the dermis permeability of I was found to be constant throughout the whole stratum (3). Experiments using tissue homogenates revealed (4) that the outer half-thickness of the skin (*i.e.*, the stratum corneum, the epidermis, and part of the dermis) contained more esterase but slightly less deaminase than the remainder of the skin. These data now form the basis for a more comprehensive analysis.

The purposes of the present study were to solve the mathematical problem involved in the simultaneous diffusion and metabolism in the case of the nonuniform enzyme distributions and to analyze the experimental data using these mathematical solutions. The enzyme distributions together with the diffusivities then were employed to generate concentration profiles for the prodrug and the drug in the skin from which the behavior, including the efficacy, of the prodrug may be predicted.

THEORY

General Multilayer Model for Analysis of Simultaneous Diffusion and Metabolism of a Compound—A physical model derived previously (Fig. 2 in Ref. 1) was modified to involve a membrane consisting of N layers (Fig. 1) in which the ith layer has the following properties:

1. Thickness is given by $h_i = x_i - x_{i-1}$.
2. A first-order reaction occurs in this layer, which converts A to B with a rate constant, k_i.
3. Diffusivities of A and B are given by $D_{A,i}$ and $D_{B,i}$.
4. Partition coefficients of A and B are $K_{A,i}$ and $K_{B,i}$.

For generality, aqueous diffusional layers will be considered in a manner similar to the other layers.

Mathematical Solution to Simultaneous Diffusion and Metabolism Problem of Multiple-Layer Model—The differential equations for the steady-state concentrations of A and B in the ith layer are:

$$D_{A,i}\frac{d^2[A]}{dx^2} - k_i[A] = 0 \qquad \text{(Eq. 1)}$$

$$D_{B,i}\frac{d^2[B]}{dx^2} + k_i[A] = 0 \qquad \text{(Eq. 2)}$$

Some new variables may be defined:

$$U_A(x) = \frac{[A]}{K_{A,i}} \qquad \text{(Eq. 3)}$$

$$U_B(x) = \frac{[B]}{K_{B,i}} \qquad \text{(Eq. 4)}$$

$$F_A(x) = -D_{A,i}\frac{d[A]}{dx} \qquad \text{(Eq. 5)}$$

$$F_B(x) = -D_{B,i}\frac{d[B]}{dx} \qquad \text{(Eq. 6)}$$

where $F_A(x)$ and $F_B(x)$ are the fluxes of A and B at x.

Some new constants may be defined:

$$a_i = \sqrt{\frac{k_i}{D_{A,i}}} \qquad \text{(Eq. 7)}$$

$$P_{A,i} = (K_{A,i})(D_{A,i}) \qquad \text{(Eq. 8)}$$

$$P_{B,i} = (K_{B,i})(D_{B,i}) \qquad \text{(Eq. 9)}$$

$$\Delta x = x_i - x_{i-1} \qquad \text{(Eq. 10)}$$

where $P_{A,i}$ and $P_{B,i}$ are the permeability coefficients of A and B, respectively.

The solution of the system in terms of these new variables in the ith layer can be written in matrix form as:

$$\begin{bmatrix} U_A(x) \\ F_A(x) \\ U_B(x) \\ F_B(x) \end{bmatrix} = \begin{bmatrix} \cosh a_i\,\Delta x & \frac{-\sinh a_i\,\Delta x}{P_{A,i}a_i} & 0 & 0 \\ -P_{A,i}a_i \sinh a_i\,\Delta x & \cosh a_i\,\Delta x & 0 & 0 \\ \frac{P_{A,i}}{P_{B,i}}(1-\cosh a_i\,\Delta x) & \frac{\sinh a_i x - a_i\,\Delta x}{P_{B,i}a_i} & 1 & \frac{-\Delta x}{P_{B,i}} \\ P_{A,i}a_i \sinh a_i\,\Delta x & 1-\cosh a_i\,\Delta x & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} U_A(x_{i-1}) \\ F_A(x_{i-1}) \\ U_B(x_{i-1}) \\ F_B(x_{i-1}) \end{bmatrix} \qquad \text{(Eq. 11)}$$

Table III—Observed Fluxes in Go-Through Experiments with III Using a Stripped Skin [a]

Running Order[b]	Direction[c]	Flux/Initial Donor Concentration, × 10^6 cm/sec: Donor III	Donor I	Receiver III	Receiver I
First	Dermis → epidermis	—	44.6	0.60	0.80
Second	Epidermis → dermis	—	2.59	1.01	1.06

[a] From a 5-week-old mouse (G). [b] Indicates the first run or the second run with the given skin preparation. [c] Indicates the permeation direction, *i.e.*, from the donor side to the receiver side.

Table IV—Observed Fluxes in Go-Through Experiments with III Using a Stripped Skin [a]

Running Order[b]	Direction[c]	Flux/Initial Donor Concentration, × 10^6 cm/sec: Donor III	Donor I	Receiver III	Receiver I
First	Dermis → epidermis	—	41.7	1.64	2.73
Second	Dermis → epidermis	—	18.9	1.82	2.43
Third	Epidermis → dermis	—	2.68	1.50	2.30

[a] From a 5-week-old mouse (H). [b] Indicates the sequence of the runs with the given skin preparation. [c] Indicates the permeation direction, *i.e.*, from the donor side to the receiver side.

Note that if $a_i = 0$, then:

$$-\frac{\sinh a_i\,\Delta x}{P_{A,i}a_i} = -\frac{\Delta x}{P_{A,i}} \qquad \text{(Eq. 12)}$$

and:

$$\frac{\sinh a_i\,\Delta x - a_i\,\Delta x}{P_{A,i}a_i} = 0 \qquad \text{(Eq. 13)}$$

Evaluation of the other terms is straightforward.

Since at $x = x_i$, $\Delta x = h_i$, by denoting the matrix evaluated for $\Delta x = h_i$ by M_i and $U_A(x_i)$ by $U_{A,i}$ and likewise for the other variables, the following is obtained:

$$\begin{bmatrix} U_{A,i} \\ F_{A,i} \\ U_{B,i} \\ F_{B,i} \end{bmatrix} = M_i \cdot \begin{bmatrix} U_{A,i-1} \\ F_{A,i-1} \\ U_{B,i-1} \\ F_{B,i-1} \end{bmatrix} \qquad \text{(Eq. 14)}$$

By applying this relationship repeatedly for $i = 1, \ldots, N$, it follows that:

$$\begin{bmatrix} U_{A,N} \\ F_{A,N} \\ U_{B,N} \\ F_{B,N} \end{bmatrix} = [M_N M_{N-1} \cdots M_2 M_1] \begin{bmatrix} U_{A,0} \\ F_{A,0} \\ U_{B,0} \\ F_{B,0} \end{bmatrix} \qquad \text{(Eq. 15)}$$

where the matrix, $M_N \cdots M_1$, can be shown to have the form:

$$m = \begin{bmatrix} m_{11} & m_{12} & 0 & 0 \\ m_{21} & m_{22} & 0 & 0 \\ m_{31} & m_{32} & m_{33} & m_{34} \\ m_{41} & m_{42} & m_{43} & m_{44} \end{bmatrix} \qquad \text{(Eq. 16)}$$

The solution now is straightforward. From the parameters for each layer, the matrixes, M_i, are evaluated and their product, m, is formed. This matrix then gives the relationship between the steady-state concentrations and fluxes at the two faces of the composite membrane. Determination of fluxes for the go-through and in-and-out experimental conditions is quite simple.

For the go-through experiment where $U_{A,0}$, $U_{A,N}$, $U_{B,0}$, and $U_{B,N}$ are given, it follows from Eqs. 15 and 16 that:

Σ dev.^{2}		—	2.24	2.23	0.03	0.03

[a] From Table IV. [b] The dermis diffusivity is 1.34×10^{-6} cm^2/sec; the thicknesses of the epidermis and the dermis are 10 and 190 μm, respectively; the aqueous permeability coefficient is 1.08×10^{-3} cm/sec; and the partition coefficient is 1.0. [c] D is the donor chamber and R is the receiver chamber. [d] Average value of the second and third runs from Fig. 2.

$$F_{A,0} = \frac{U_{A,N} - m_{11}U_{A,0}}{m_{12}} \quad \text{(Eq. 17)}$$

$$F_{A,N} = m_{21}U_{A,0} + m_{22}F_{A,0} \quad \text{(Eq. 18)}$$

$$F_{B,0} = \frac{U_{B,N} - m_{31}U_{A,0} - m_{32}F_{A,0} - m_{33}U_{B,0}}{m_{34}} \quad \text{(Eq. 19)}$$

$$F_{B,N} = m_{41}U_{A,0} + m_{42}F_{A,0} + m_{43}U_{B,0} + m_{44}F_{B,0} \quad \text{(Eq. 20)}$$

For the in-and-out experiment where $U_{A,0}$, $U_{B,0}$, $F_{A,N}$, and $F_{B,N}$ are given, it follows from Eqs. 15 and 16 that:

$$F_{A,0} = \frac{F_{A,N} - m_{21}U_{A,0}}{m_{22}} \quad \text{(Eq. 21)}$$

$$U_{A,N} = m_{11}U_{A,0} + m_{21}F_{A,0} \quad \text{(Eq. 22)}$$

$$F_{B,0} = \frac{F_{B,N} - m_{41}U_{A,0} - m_{42}F_{A,0} - m_{43}U_{B,0}}{m_{44}} \quad \text{(Eq. 23)}$$

$$U_{B,N} = m_{31}U_{A,0} + m_{32}F_{A,0} + m_{33}U_{B,0} + m_{34}F_{B,0} \quad \text{(Eq. 24)}$$

In both the go-through and in-and-out experiments, the boundary conditions require that several of the given quantities equal zero so that the equations are somewhat simpler. The matrixes, m, for the two situations are not identical because the go-through experiment has an aqueous diffusional layer on both sides as opposed to only one such layer for the in-and-out experiment.

EXPERIMENTAL

Stripped skin membranes were used for the go-through experiments, and full-thickness skin membranes were used for the in-and-out experiments. Procedures for preparing these skin specimens were described previously (2). The experimental arrangement and procedures for the go-through studies also were described previously (2). The materials were the same as those used previously. 2′-Deoxycoformycin (covidarabine) was used to inhibit the conversion of I to 9-β-D-arabinofuranosylhypoxanthine (II) by adenosine deaminase during the study of esterase activity.

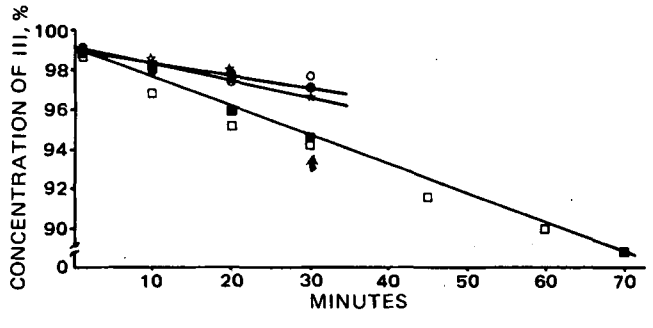

Figure 2—*Consecutive runs of the reflection boundary experiment with III using the same piece of full-thickness skin. The solid symbols are data from Mouse I; the open symbols are data from Mouse J. Lines are the linear regression of data of solid marks. Key:* ■, □, *the first run, which started immediately after preparation, where the arrow indicates the time when the bulk solution was separated from the skin;* ★, ☆, *the second run, which started 2 hr after the zero time of the first run; and* ●, ○, *the third run, which started 1 hr after the zero time of the second run. The system was soaked and rinsed thoroughly with saline between runs.*

RESULTS AND DISCUSSION

Since preliminary data (2) indicated that esterase leaches out from the dermis side of skin, it was desirable to determine if there is a steady level of remaining esterase activity. Therefore, consecutive runs of the reflection boundary experiment with vidarabine-5′-valerate (III) were carried out using a single piece of full-thickness skin (Fig. 2). After 2 hr of leaching, the remaining esterase activity reduced to about one-half of the activity of nonleached skin. An additional hour of leaching did not

[a] Raw data are shown in Fig. 5. [b] The dermis diffusivity is 1.34×10^{-6} cm^2/sec; the thicknesses of the epidermis and the dermis are 10 and 190 μm, respectively; the aqueous permeability coefficient is 1.08×10^{-3} cm/sec; and the partition coefficient is 1.0. [c] D is the donor chamber and R is the receiver chamber. [d] Average value of the second and third runs from Fig. 2.

further reduce the remaining esterase activity. Moreover, as indicated in Fig. 2, the bulk solution after separation from the skin continued to show esterase activity. All of these observations strongly indicate that the leaching of esterase is essentially completed within the first 2 hr. The viability of the skin esterase essentially remains the same for at least 3 hr. Additional data from in-and-out experiments using skin preparations from different mice of the same age gave similar results (Table I).

The leaching effect also was clearly seen in the go-through experiment with nonleached stripped skin. Figure 3 shows the results of two go-through experimental runs carried out consecutively using a single stripped skin preparation (Mouse F). In the first run, the epidermis was in contact with the donor chamber; in the second run, after the system was rinsed thoroughly with saline, the donor and the receiver compartments were reversed so that the dermis side was in contact with the donor chamber. The fluxes[1] for these experiments are given in Table II. Similar experiments with reversed running order (*i.e.*, first run, dermis → epidermis; second run, epidermis → dermis) used stripped skin from another mouse (Mouse G) (Fig. 4 and Table III).

Comparison of Tables II and III reveals that the back-diffusion flux of I was larger when it was obtained from the first run than when it was obtained from the second run, especially for the dermis → epidermis case. The phenomenon was quite reproducible, as was observed in repeat experiments (5). To demonstrate the effect of leaching on the flux determination in a go-through experiment in another manner, a fresh piece of skin (Mouse H) was used for the go-through experiment, as usual, and then, after the system was rinsed thoroughly with saline, the same piece of skin was used for a repeat run (Table IV). Again, there was a twofold difference in the backflow fluxes before and after leaching.

Because of the profound effect of the esterase leaching on the determination of the fluxes, only experimental runs using a preleached skin may give meaningful data for esterase activity determination. Figures 5 and 6 show the results of duplicate runs with preleached skin preparations from the same mouse (Mouse K) conducted by two persons at the

Σ dev.^{2}		—	2.04	2.06	0.78	0.78

[a] Raw data are shown in Fig. 6. [b] The dermis diffusivity is 1.34×10^{-6} cm^2/sec; the thicknesses of the epidermis and the dermis are 10 and 190 μm, respectively; the aqueous permeability coefficient is 1.08×10^{-3} cm/sec; and the partition coefficient is 1.0. [c] D is the donor chamber and R is the receiver chamber. [d] From Table VI instead of Table VIII because of the unreasonably small permeability in that particular experimental run. [e] Average value of the second and third runs from Fig. 2.

same time. One person conducted experiments in which the epidermis → dermis permeation was run first (Fig. 5), and the other person ran the experiments with dermis → epidermis permeation first (Fig. 6).

The results of the go-through experiments with I using preleached skin (Mouse L) in the deaminase activity determination are shown in Fig. 7. Of the two experiments, the epidermis → dermis permeation preceded the dermis → epidermis permeation.

The following conclusions may be reached from the results using preleached skin:

1. The total fluxes as well as the flux ratio of the two species entering the receiver compartment are independent of direction (*i.e.*, from epidermis side to dermis side or from dermis side to epidermis side).
2. The backflow of metabolite into the donor compartment in the epidermis → dermis run is smaller than that in the reversed direction run.
3. The percentage rates of change in the donor concentrations of III are small. Consequently, these data were not used in the analysis.

Table V lists the results of computer iterations using Eqs. 17–20 to fit the calculated fluxes to the experimental data shown in Table IV. Nonlinear least-squares regression was employed for the best-fit procedure. The analyses were conducted for the nonhomogeneous case in which an epidermis layer was distinguishable from the dermis layer (from the standpoint of diffusivity and esterase activity), in contrast to the homogeneous case in which the two layers were different only in diffusivity and not in esterase activity. In addition to the two-layer model, a three-layer model, taking into account the possible presence of the residual stratum corneum due to incomplete stripping, also was considered.

Three adjustable parameters were involved in the fitting: the epidermis diffusivity, D_{epi}, and the esterase rate constants in the epidermis and the dermis, k_{1e} and k_{1d}, respectively. In the three-layer model, the residual (*i.e.*, if the skin was incompletely stripped) stratum corneum permeability, P_{sc}, is an additional adjustable parameter. The rest of the parameters required for the calculation of fluxes were predetermined experimentally, except for the thickness of the epidermis that was approximated anatomically to be 10 μm.

As seen in Table V, the best-fit iteration parameters under the nonhomogeneous column give calculated fluxes much closer to the experi-

Reflection boundary experiment		114[d]	90.1	—	90.5	—
Σ dev.^{2}		—	1.16	—	1.17	—

[a] Raw data are shown in Fig. 7. [b] The dermis diffusivity is 1.34×10^{-6} cm^2/sec; the thicknesses of the epidermis and the dermis are 10 and 190 μm, respectively; the aqueous permeability coefficient is 1.08×10^{-3} cm/sec; and the partition coefficient is 1.0. [c] D is the donor chamber and R is the receiver chamber. [d] From Ref. 2.

mental values than do those under the homogeneous column. Thus, the nonhomogeneous model clearly is superior to the homogeneous model. The resultant esterase rate constants, k_{1e} and k_{1d}, reveal an esterase activity that is nine times higher in the epidermis than in the dermis. This result is in good agreement with the previous observation from tissue homogenates (4).

Table V also reveals that the best-fit parameters and calculated fluxes are only slightly different between the two-layer and the three-layer models for both the homogeneous and nonhomogeneous cases. The additional freedom for interaction contributes very little to the goodness of fit as seen from the statistics (Σ dev.^{2}). Moreover, the best-fit values of P_{sc} are on the order of 10^{-3} cm/sec, which is negligible compared to the overall permeability. In other words, the three-layer model essentially regresses to the two-layer model when applied to the present data. The effect of residual stratum corneum is negligible.

Similar analyses for the data shown in Figs. 5 and 6 are given in Tables VI and VII. These analyses lead to the same conclusion.

Results of the deaminase analyses are shown in Table VIII. The analysis based on nonhomogeneous deaminase distribution gave essentially the same results as those based on homogeneous deaminase distribution. The best-fit fluxes gave $k_{2e} = k_{2d} = 7.14 \times 10^{-3}$ sec^{-1}, which is in good agreement with previous observations (4).

The enzyme rate constants thus obtained, together with the transport parameters determined previously (3), give, according to the proposed physical model, the detailed description of concentration profiles of all three species in the viable cutaneous tissue. Figure 8 shows such plots generated from the computer simulation using $k_{1e} = 4.04 \times 10^{-3}$ sec^{-1}, $k_{1d} = 0.97 \times 10^{-3}$ sec^{-1}, $k_{2e} = k_{2d} = 7.14 \times 10^{-3}$ sec^{-1}, and the other required parameters as specified in the legend.

The bioavailability of the topically applied prodrug may be readily assessed quantitatively based on the concentration profiles. The area under the curve of the active parent drug species is ~25% of that of the prodrug species (Fig. 8) in the epidermis where the herpes virus is believed to proliferate. The somewhat low availability of the parent drug in this investigation is primarily due to the relatively slow conversion rate of the prodrug by the esterase. In a theoretical study reported previously (1), the parent drug was ~10 times more abundant than its prodrug when the esterase rate constant was nine times the value of the deaminase rate constant. A high esterase activity becomes a prerequisite in the search for promising prodrug candidates.

Recent studies (6) in this laboratory revealed that the esterase rate constant for the 5-monoesters of I with different chain lengths varies significantly in cultured KB cell suspension systems. The relative rate constants in that study were 22:3:1 for octanoate, valerate, and acetate, respectively. The chain length effect of these esters on the esterase activity of the hairless mouse skin is under investigation.

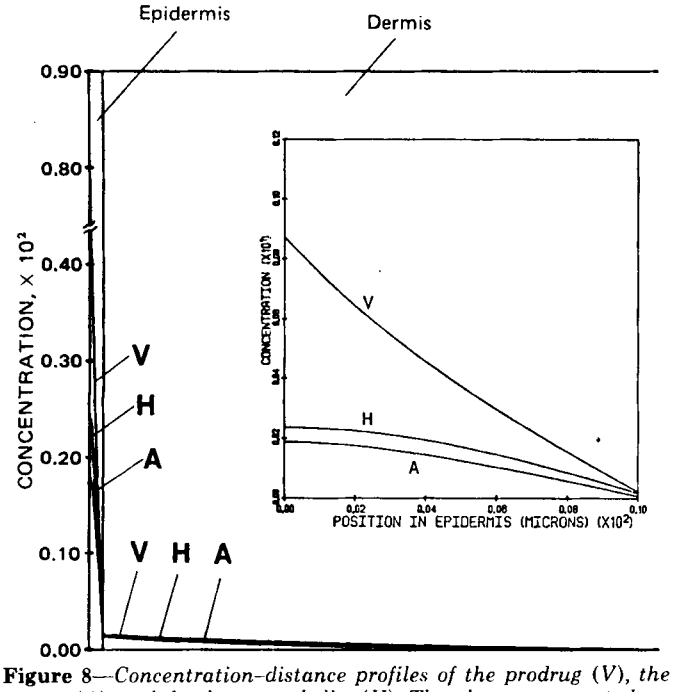

Figure 8—*Concentration-distance profiles of the prodrug (V), the parent (A), and the drug metabolite (H). The plot was generated according to the model using the following parameters: dose on the stratum corneum side of the skin was 1.0 M; diffusivities in the stratum corneum, the epidermis, and the dermis were 1.2×10^{-10}, 2.24×10^{-9}, and 1.34×10^{-6} cm^2/sec, respectively; and thicknesses of the stratum corneum, the epidermis, and the dermis were 40, 10, and 200 μm, respectively. The enzyme rate constants used were described in the text.*

Permeation of Hairless Mouse Skin I: Experimental Methods and Comparison with Human Epidermal Permeation by Alkanols

HUGO DURRHEIM, GORDON L. FLYNN ˣ, WILLIAM I. HIGUCHI, and CHARAN R. BEHL

Received July 31, 1979, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication February 1, 1980.

Abstract □ The permeation of intact hairless mouse skin by alkanols was studied. The method is described, and data for the quasi-steady-state and nonstationary-state aspects of mass transfer are given. Partitioning data also are presented. The permeability coefficients increased exponentially up to a carbon chain length of about eight (octanol). There was a marked temperature dependency ($E_a \simeq 19$ kcal for the series), and the partitioning was biphasic, increasing exponentially for alkanols larger than butanol. These data are compared with literature data on human skin tissues, and great similarity in all facets of behavior is noted.

Keyphrases □ Permeation—*n*-alkanols through intact hairless mouse skin and human skin, effect of temperature and carbon chain length, biphasic partitioning □ Partition coefficients—*n*-alkanols in intact hairless mouse skin and human skin, effect of temperature and carbon chain length, biphasic partitioning □ Alcohols, normal—permeability coefficients in hairless mouse skin and human skin, effect of temperature and carbon chain length, biphasic partitioning

The present studies were initiated to answer questions about the usefulness of the hairless mouse for developing clinically relevant insights into percutaneous absorption and for evaluating topical products intended for humans. Scattered reports allude to a barrier property similarity between hairless animal skins, particularly porcine and mouse, and the human integument. However, a high degree of sameness in permeability with respect to human skin has yet to be substantiated for any animal skin, although close parallelism in the permeation of select drugs between human and hairless mouse skin has been reported (1). More data are needed to generalize such unrelated observations into a broad conclusion.

A second, narrower basis for this work was the establishment of permeation baselines for the hairless mouse in preparation for the evaluation of the general consequences of burning and other traumatizing treatments on the permeation of skin tissue. Therefore, the present studies represent the development of analytical procedures suitable for studying mass transport through mechanically, chemically, and physically processed skins aimed at the quantitative definition of the effects of injury on percutaneous absorption. The permeation of select homologous *n*-alkanols (methanol through octanol) through intact hairless mouse skin is reported since these results can be compared with literature data on human epidermal permeation of the same compounds (2–6).

EXPERIMENTAL

Chemicals—The following homologous *n*-alkanols were used: [^{14}C]-methanol[1], [^{3}H]ethanol[1], [^{14}C]*n*-propanol[2], [^{3}H]*n*-butanol[1], [^{14}C]*n*-pentanol[2], [^{14}C]*n*-hexanol[1], [^{14}C]*n*-heptanol[2], [^{14}C]*n*-octanol[1], [^{14}C]*n*-nonanol[2], and [^{14}C]*n*-decanol[1].

The alkanols were diluted in 0.9% NaCl for irrigation[3], henceforth referred to as normal saline, and the actual permeation solutions were prepared from these stock solutions. The preparation of a stock solution was individualized to each alkanol since each compound was received with a different radioactivity. In every case, the stock solution was brought to ~50 μCi/ml. The alcohol concentrations were $\leq 10^{-4}$ *M*, precluding any direct effect of the alcohols on the membrane.

Diffusion—Small diffusion cells were machined from a polycarbonate plastic or were prepared from tempered glass in local shops. These cells were in the form of two cylindrical half-cells that had an inside diameter of ~1.0 cm and were ~2.5 cm deep, yielding a half-cell volume of ~1.5 ml. Each half-cell was equipped with two ports; one, ~2.5 cm long, was to accommodate the shaft of the stirring device; and the other, 1 cm long, was used for sampling and filling of the compartments. One half-cell contained a solid plastic or glass cylindrical extension of ~2.5 cm, which allowed it to be clamped rigidly in place in the constant-temperature bath. Each half-cell also was fitted with a flange at the open end to allow tight sealing of the membrane (Fig. 1*a*).

The cell halves were assembled, with the full-thickness, freshly excised, abdominal mouse skin between the half-cells, using a No. 18 ball-joint clamp (Fig. 1*b*). The assembled cell then was immersed in a constant-temperature bath, with the cell ports being the only components above the surface. The cell contents were stirred by motors mounted above the cell system[4]. The stirrers were small propellers placed in close proximity to the membrane surface. The stirring propeller was mounted on the end of the stirring shaft prior to clamping the half-cells since the propeller diameter was larger than the porthole. The stirrer shaft was attached to the motor by tightly fitting pieces of polymeric tubing. Care was taken to center the stirrer exactly in the cell to keep it from contact with the walls. The stirring speed of 150 rpm was checked after each assembly. By using a drop of dye solution, it was found that the mixing was gentle but adequate to distribute the color homogeneously in <2 min.

The diffusion cell was designed to have a large membrane surface area to half-cell volume ratio (~0.5) and also to have a small half-cell volume so that a minimal amount of radiolabeled compound was needed for each experiment. Construction materials were selected that had little tendency to adsorb the alkanol permeants but that also would allow viewing of the events inside the cell compartments. The cells were tested for tightness of the seal around the membranes, and no leakage was observed.

Membrane—The membranes were full-thickness skin taken from the abdominal surface of the hairless mouse, HRS/J strain[5]. Hairless mice (males), 4–6 weeks old, were sacrificed by snapping the spinal cord at the neck. A rectangular section of abdominal skin, several centimeters in each dimension (Fig. 2), was excised from the animal with surgical scissors. Since the skin was not firmly attached to the viscera, it was lifted easily from the animal after the incision was made. Adhering fat and other visceral debris were removed carefully from the undersurface with tweezers.

Prior to skin removal, a uniform circle was made on the abdomen marking the precise skin section to be positioned between the half-cells. After the excised skin was trimmed into an oversized, rough circle, it was mounted between the half-cells with the marked section centered. Stretching of the skin, as evidenced by distortion or expansion of the circular outline, was corrected, and the cell halves were held fast by a spring clamp. The dotted circular section in Fig. 2 indicates the area of skin used. The cell compartments then were filled with normal saline to keep the membrane moist. The areas available for diffusion between

compartments were 0.713 cm^2 for the plastic cell and 1.094 cm^2 for the glass cell.

Permeation—The assembled saline-filled cell was immersed in a constant-temperature bath, the stirrer shafts were attached to the motor, and stirring was commenced. The contents were mixed for 30 min, at which time the compartments were evacuated with a syringe and refilled with fresh saline. Then the compartments were evacuated a second time, refilled, evacuated a third time, and finally refilled with normal saline preequilibrated to the experimental temperature. After mixing for 2 min, a sample of saline was withdrawn from the receptor compartment and counted to ensure that there was no residual activity from previous runs.

At this point, the donor compartment was charged with radioactive alkanol or alkanols (dual-absorption procedure), and the runs were commenced. Fifty microliters of concentrated solutions of the labeled alkanols in normal saline constituted the charge. The cell contents were stirred and, at predetermined times, samples were withdrawn from the respective compartments and transferred immediately using disposable Eppendorff[6] pipets to vials containing 10 ml of scintillation cocktail[7] for radiochemical assay[8].

In one set of experiments, aimed at determining the influence of pH on the permeation rate, isotonic buffers were used instead of normal saline (Table I). In the pH dependency experiments, the half-cells were rinsed with buffer in the final two rinses and filled with buffer prior to charging the donor compartment and initiating a run.

The moment of charging the donor half-cell marked the beginning of the diffusion run, and the receptor samples were referenced to this time. However, to allow for mixing to a uniform concentration, a minimum of 2 min was allowed to elapse before the initial donor sample was withdrawn. This sample was used as a close estimate of the initial donor cell concentration.

The overall procedure was designed such that depletion of the donor phase concentration was never an appreciable fraction of the donor concentration. There was no problem meeting this condition for water or the alkanols up to a chain length of seven. However, because partitioning from the aqueous medium into the lipoid phase of the tissue grows exponentially, a point is reached for longer chain length alkanols where the amount of alkanol retained in the membrane is a significant fraction of the total amount that has entered the membrane during the entire experiment. This problem is more acute when small donor and receiver volumes are involved, as is the case here, and a necessary condition for "stripping" the permeability coefficient from pseudo-steady-state slopes is violated.

The problem began with octanol in these studies, but the error induced was estimated not to be large enough to warrant discarding octanol results from the overall trend[9]. However, under the specified appropriate circumstances, the permeation enters a pseudo-steady state from which the permeability coefficient of each alkanol can be ascertained readily. If the concentration in the donor compartment changed significantly during the 2-hr run, as occurred for alkanols above a chain length of six, the donor compartment contents were replaced totally with fresh permeant solution periodically, as necessary, to maintain the concentration as essentially invariant.

Table I—Buffer Compositions [a]

Buffer Component	pH 3	pH 6	pH 8
$NaH_2PO_4 \cdot H_2O$	13.8 g	13.8 g	0.7 g
1.0 *N* HCl	11.7 ml	—	—
1.0 *N* NaOH	—	16.0 ml	—
NaCl	2.9 g	3.2 g	2.0 g
Na_2HPO_4	—	—	13.5 g

[a] All buffers were brought to a volume of 1000 ml with water.

In the initial experiments, the permeability of a membrane remained essentially unchanged for up to 12 hr using the lower molecular weight alkanols (*i.e.*, methanol and ethanol). Therefore, as many as four or five runs could be accomplished on a given piece of skin as long as the residual radioactive species from previous runs were fully washed out. Between runs on a given piece of skin, the cell volume was exchanged 12 times on each side with fresh saline. The skin, still mounted in the diffusion cell, was kept in contact with fresh saline for 45 min and then rinsed twice more with saline solution. The entire cleanup operation involved 14 rinses with an intermittent 45-min period of equilibration. The compartments then were refilled, the donor compartment was recharged, and a new run was commenced.

In subsequent extensive work (to be reported later), it was observed that invariant permeability as a function of the duration of skin immersion in the saline medium was strictly true only for water and the most polar alkanols, methanol and ethanol. For the higher homologs, there was up to a twofold change in the permeability coefficients over the initial 10 hr of skin hydration. Invariance was seen for all compounds after 10 hr of immersion. Partly because of the order of sequencing runs (lower alkanols preceding higher) and because of the small magnitude of change within compounds as compared to between compounds, these hydration-induced permeability alterations had no significant effect on the actual values or on the conclusions presented in this paper.

In the present studies, the permeation rates were assessed for selected *n*-alkanols through octanol at 20, 25, and 37°. The 20 and 25° data represent individual runs on each even-numbered alkanol. The 37° data represent averages of multiple runs for each alkanol on the uninterrupted homologous series from C_1 to C_8. The permeability data were plotted as counts (amount of permeant) collected in the receptor compartment as

[9] Techniques were used to check the validity of this procedure and will be reported later. It was found that for octanol and above, the pseudo-steady-state procedure introduced an error, but this error was <15% with octanol, so these data are reported. The influence of membrane retention will be discussed quantitatively and theoretically in future reports.

Table II—Partitioning of the *n*-Alkanols into Full-Thickness Hairless Mouse Skin and Human Stratum Corneum

Alkanol	Partition Coefficient, cm^3/g: Hairless Mouse[a], 37°	Human Stratum Corneum[b], 25°
Methanol	5.5	0.6
Ethanol	5.4	0.9
n-Propanol	6.0	1.1
n-Butanol	6.6	2.5
n-Pentanol	7.7	5.0
n-Hexanol	10.7	10 0
n-Heptanol	24.0	30.0
n-Octanol	40.8	50.0
n-Nonanol	86.7	—

[a] Based on the weight of the full-thickness tissue and distribution from normal saline. [b] Obtained from Ref. 2. These data are for human stratum corneum and were obtained using dilute aqueous solutions rather than dilute saline solutions of the alkanols.

Table III—Permeability Coefficients of Full-Thickness Hairless Mouse Skin at 20, 25, and 37° and Human Epidermis at 25°

Alkanol	$P \times 10^3$, cm/hr: Hairless Mouse Skin 20°	37°	25°[a]	Human Epidermis[b], 25°[a]
Methanol	0.41	2.6 (0.46)[c]	0.93	0.5
Ethanol	0.72	4.8 (0.43)	1.23	0.8
n-Propanol	—	5.4	—	1.2
n-Butanol	2.9	14.6 (0.81)	4.4	2.5

Butanol, pH 6	—	10.66	—	—
Butanol, pH 8	—	11.75	—	—
n-Pentanol	—	22.0	—	6.0
n-Hexanol	5.25	48.0 (1.2)	8.6	13.0
n-Heptanol	—	92.9	—	32.0
n-Octanol	18.9	97.2 (2.4)	31.5	52.0
n-Nonanol	—	—	—	60.0
n-Decanol	—	—	—	80.0

[a] The 25° data were placed side by side for comparison. The hairless mouse permeation solutions were made in normal saline. [b] Obtained from Refs. 2 and 4. These data were obtained using dilute aqueous solutions. [c] Standard deviations of multiple runs.

a function of time. Correction was made for sampling, which was done by replacement using normal saline. The permeability coefficient for a given run was calculated from:

$$J_T = PA\,\Delta C \qquad \text{(Eq. 1)}$$

where J_T is the total flux and also the slope of plots of the amount penetrated *versus* time (counts per minute); P is the permeability coefficient (centimeters per hour); A is the diffusional area (square centimeters); and ΔC is the concentration differential across the membrane, which was taken to be equal to the donor phase concentration (counts per cubic centimeter).

The concentrations were expressed in terms of counts from a 50-μl sample. Thus, the permeability coefficient is calculated from:

$$P = \frac{J_T}{A\,\Delta C} \qquad \text{(Eq. 2)}$$

and since $J_T = dM/dt = V(dC/dt)$:

$$P = \frac{V\left(\frac{dC}{dt}\right)}{A\,\Delta C} \qquad \text{(Eq. 3)}$$

where V is the half-cell volume and the volume of the receptor compartment (cubic centimeters) and dC/dt is the steady-state slope in counts per minute per cubic centimeter. The computed permeability coefficients were converted to centimeters per hour by multiplying by 60.

Skin Partitioning—The skin–water partition coefficients of the alkanols also were assessed. These values were evaluated crudely by equilibrating the alkanol solutions with a known mass of skin, 20–50 mg, weighed immediately after removal from the animal. These skin pieces were immersed in 2 ml of normal saline containing the radiolabeled alkanol. The samples were equilibrated in a shaker bath at 37° overnight, which was sufficient to attain equilibrium.

Distribution of the alkanols between the aqueous phase of the tissue was estimated by the method of Scheuplein (2) as the difference between the initial aqueous phase concentration and the aqueous phase concentration at equilibrium. The relationship used was:

$$K = \frac{(C_0 - C_e)/W_T}{C_0/V_{aq}} \qquad \text{(Eq. 4)}$$

where C_0 is the initial alkanol solution concentration, C_e is the solution concentration at equilibrium, W_T is the tissue weight in grams, and V_{aq} is the solution phase volume (2 ml) in milliliters. Therefore, the partition coefficients are in cubic centimeters per gram. Given the obvious heterogeneity (multiphasic nature) of the tissue, no attempt was made to factor in density to obtain unitless values.

RESULTS

The data for the partitioning of the *n*-alkanols at 37° between full-thickness hairless mouse skin and saline are tabulated in Table II. The partition coefficients appeared to increase only slightly up to a chain length of five but then increased exponentially from pentanol to nonanol. The slope of the plot in the exponential growth region was ~0.285, corresponding to an increase in the partition coefficient by an average factor of 1.9 per chain unit (per methylene unit) past an alkyl chain length of five. Straightforward attempts to obtain a partition coefficient for decanol were unsuccessful since the small skin pieces absorbed essentially all of the C_{10} compound, making the estimate unreliable. The exponential trend was presumed to continue to C_{10}, and the experimental procedure was not adjusted to obtain a firm value for this compound.

Raw permeation profiles of the receptor phase concentration in moles per liter as a function of time for *n*-butanol are displayed in Fig. 3 for runs carried out at 20, 25, and 37°. Similar data were collected at 20 and 25° for select, mostly even homologs through *n*-octanol and at 37° for the uninterrupted homologous series from C_1 to C_8. Permeability coefficients were calculated from the terminal slopes of such plots, and lag times also were estimated graphically. The estimated permeability coefficients at each temperature are summarized in Table III, which also includes *n*-butanol data at 37° obtained using isotonic buffers at pH 3, 6, and 8.

An Arrhenius-like plot of the permeability coefficients is given in Fig. 4, where log P is plotted *versus* the reciprocal of temperature. In Fig. 5, the permeability data are plotted as log P *versus* alcohol chain length. Several significant trends are immediately evident from these data. There was a dramatic temperature dependency for the permeation process. Within the accuracy of the data, the apparent activation energy did not appear to vary among the homologs and was ~19 kcal/mole based on the slopes of statistically fitted lines through the data in Fig. 4. In both Figs.

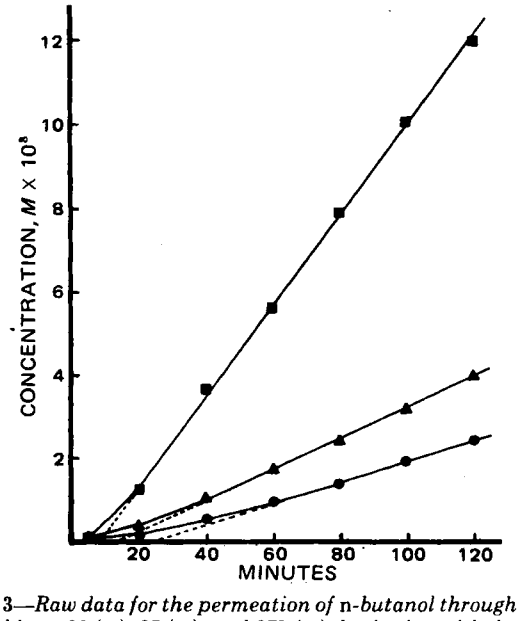

Figure 3—*Raw data for the permeation of* n-*butanol through hairless mouse skin at 20* (●), *25* (▲), *and 37°* (■), *beginning with donor solutions at* ~10^{-5} M. *Changes in diffusivity through the tissue as a function of temperature are indicated by shortened lag times (dotted extrapolations to the time axis) and increased slopes with increased temperature.*

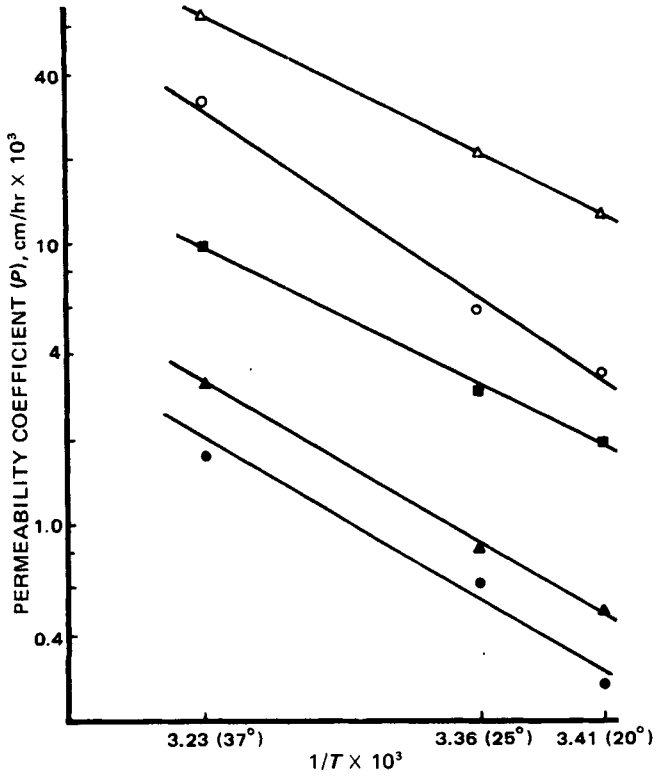

Figure 4—*Arrhenius plot of permeability coefficients for select (mostly even) alkanols. These data indicate an activation energy for the permeation process on the order of 19 kcal/mole. Key: ●, methanol; ▲, ethanol; ■, butanol; ○, hexanol; and △, octanol.*

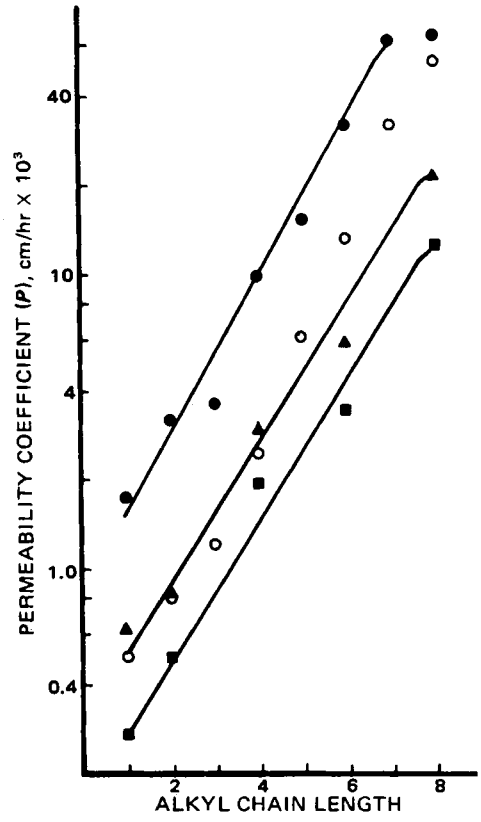

Figure 5—*Semilogarithmic plot of hairless mouse skin permeability coefficients against alkyl chain length for the alkanols at 20 (■), 25 (▲), and 37° (●) and human epidermis permeability coefficients (2, 4) at 25° (○). A general exponential increase in the permeation rate is evident from C_1 to C_8 in both hairless mice and humans, and the 25° data for the two species are in surprisingly close agreement.*

3 and 6, the lag times appear to shorten with increasing temperature, which is consistent with increasing diffusivity in the tissues. The lag times are considered as rough estimates since they are sensitive to placement of the steady-state line through the data. Nevertheless, the expectation that the lag times will be shorter at higher temperatures is supported by the data, even with this uncertainty. It also appears that the lag times tend to increase with increasing length of the alkyl chain (Fig. 6).

DISCUSSION

A nonhuman skin membrane that is sufficiently similar to the human integument is needed so that it can be substituted for human skin in *in vitro* percutaneous absorption and topical bioavailability studies. The human membrane is not procured as easily as an animal membrane, and its properties vary from sample to sample due to differences in the age, sex, race, and health of its donor (generally a cadaver) even if it is removed from the same anatomical site (7). It is not available on demand and must be stored frozen for variable periods (2), a condition that probably induces some physicochemical alteration. Furthermore, preparation of the excised human membrane for permeability studies is relatively complicated, requiring special equipment and demanding skill because the prepared membrane must be of uniform thickness and free of holes and other defects (2, 8, 9). These are surmountable but difficult experimental problems.

Alternatives to using excised human skin for percutaneous absorption assessment are *in vivo* studies in humans, such as the vasoconstriction assay for steroids, and the use of excised animal skins in *in vitro* diffusional systems. Studies on living human subjects are costly and time consuming due to the necessary safeguards, including approved clinical protocols that must be processed through local human use committees and the Food and Drug Administration. Thus, an animal membrane that behaves like human skin and is easily obtainable and relatively invariant from animal to animal could simplify the process of screening topical drugs. The development of critical structure–permeation relationships and of operationally superior drug delivery systems would be forwarded.

Montagna (10) pointed out that no animal skins sufficiently resemble human skin to serve as a general model. Instead, the skins of animals exhibit extraordinary variation and specialization. However, certain animal skins may be likened to human skin in one specific property or another, and an animal may prove suitable for a particular type of study. In terms of anatomical features that contribute to the unique chemical barrier properties of human skin, such as sparse hair distribution and a thickened epidermis with a highly cornified outer layer, the skins of essentially nude mammalian species have been suggested as suitable approximations. The pig, minipig, and hairless mouse are among the useful species; of these, only the latter is sufficiently small and inexpensive to make animal sacrifice for individual experiments practical.

The hairless mouse has another important and experimentally exploitable feature. The skin over both the dorsal and abdominal surfaces is loose and nonadhering to the viscera, making it possible to remove skin membranes of uniform thickness (several square centimeters in area) without recourse to microtomy. Thus, the hairless mouse has distinct advantages as an experimental animal for skin permeation studies *in vitro*. However, to be useful in research and development, it must behave at least qualitatively and, ideally, quantitatively like human skin as a chemical barrier.

The present studies deal with the question of similarity by comparing the permeabilities of hairless mouse skin and human skin to a homologous series of compounds, the *n*-alkanols, between 20 and 37°. These compounds were studied previously over a similar temperature span in human skin (2–6). The extent of barrier parallelism should be evident in permeability coefficients at a given temperature, in temperature dependency, and in partitioning.

Partitioning—In Table II, the partitioning of the alkanols into full-thickness hairless mouse skin is compared with the most recent literature values for humans (5). The comparison is made between the 37° distribution coefficients in mouse skin and the 25° distribution coefficients in human stratum corneum free of epidermal cells. Thus, the tissues are substantially different, with the mouse skin containing a significant living volume fraction (the living epidermis, the full dermis, and a subdermal basement membrane). Also, the literature values were obtained with water as the bathing medium, while the present data were obtained using normal saline. Nevertheless, the comparison is useful, particularly when considered along with permeation data.

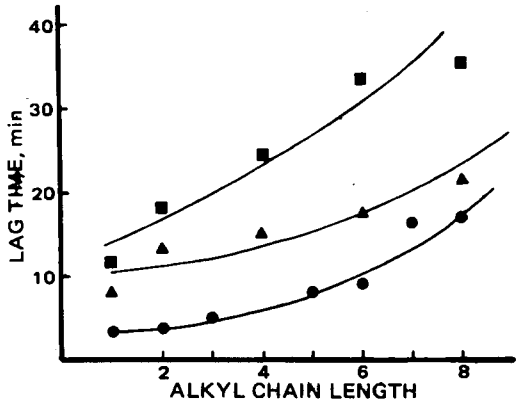

Figure 6—*Plot of lag times against alkyl chain length for data obtained at 20 (■), 25 (▲), and 37° (●). Both temperature and molecular size (alkyl chain length) effects are apparent. Lines through the data serve only to draw attention to the temperature groups and do not represent a best fit.*

In each case, the lower alkanols, methanol through propanol or butanol, did not exhibit a marked chain length sensitivity in phase distribution, with a value of slightly less than 1 for the human stratum corneum and a value of somewhat less than 6 for the hairless mouse tissue. The insensitivity suggests that the lower alkanols distribute into a polar phase in the tissue. One might speculate that this phase is imbibed water in human callus, which hydrates and swells up to 30% when immersed, and imbibed, cellular, intercellular, and interstitial water in the hairless mouse skin. Values greater than unity in the hairless mouse indicate that the tissue fluids or other tissue components have a greater affinity for the alkanols than the bathing saline phase. Whether the increased affinity is due to an actual solubility difference, adsorptive tissue binding, or another manner of tissue incorporation is unclear. What is clear is that the phenomenon responsible is not energetically dependent on hydrophobic factors since there is no chain-length effect (11, 12).

Partition coefficients above C_4 tended to increase rapidly; for the *n*-hexanol through *n*-nonanol homologs, the increase was exponential. Table II indicates that human data for the stratum corneum behave similarly; in each tissue, an approximately twofold increase in the partition coefficient per methylene group was experienced in the exponential region. The overall pattern of behavior (little or no chain-length effect for short homologs and an exponential growth with chain length for long homologs) is characteristic of a bi- or multiphasic tissue, with one phase (or collection of phases) polar and essentially aqueous and the other phase (or collection of phases) hydrophobic. In the intact hairless mouse skin, the hydrophobic phases would include the nonpolar elements of the stratum corneum and the Malpighian layer cell membranes, nonpolar elements of the dermis, fatty subdermal deposits, and, possibly, elements of the basement membrane.

Not only are the overall data trends for partitioning similar between human stratum corneum and full-thickness hairless mouse skin, but there also is an order of magnitude agreement in the values, despite the obvious differences in the tissues. In fact, at middle to long chain lengths, the agreement between the tissues is surprisingly close. Thus, the physicochemical natures of the tissue components apparently are similar.

Steady-State Permeability—The partitioning data suggest some gross physicochemical parallel between human stratum corneum and hairless mouse skin. However, this similarity need not correspond to a similarity in membrane barrier properties. Therefore, studies were begun to evaluate the permeability of hairless mouse skin to the alkanols. In Table III, permeability coefficient data are given as a function of temperature and pH for the various homologs studied. Also included are the 25° permeability coefficients obtained for heat-separated human epidermis (2). The hairless mouse data at 25° are tabulated immediately to the left of the human data for comparative purposes.

From the 37° data on butanol in isotonic buffers at pH 3, 6, and 8, it can be seen that pH had essentially no effect on membrane permeation over the wide pH range studied. Therefore, strict pH control (buffers) was not necessary in the remaining studies since the pH of saline solutions bathing the mouse skin for extended periods always was well within the specified pH range (the measured values were about pH 5 on both sides of the membrane).

In Fig. 4, the permeability coefficients for the C_1, C_2, C_4, C_6, and C_8 homologs are plotted semilogarithmically against the reciprocal of temperature. The average activation energy for these compounds based on the statistically evaluated slopes is ~19 kcal/mole with an uncertainty of several kilocalories per mole. This average activation energy is somewhat larger than the values obtained by Blank *et al.* (4) for the heat-separated human epidermis. Their average value for the alcohols ethanol through pentanol was 16.4 ± 2 kcal/mole and, above 25°, was comparably larger for hexanol through octanol. For the more nonpolar alkanols, biphasic temperature dependency was noted; below 25°, the activation energy was estimated to be about 10 kcal (4). In the present studies, this low temperature region was not investigated. Generally, the temperature dependencies for human epidermis and hairless mouse skin exhibited a marked similarity, with the animal membrane appearing slightly more temperature sensitive.

The data from Table III are treated graphically in Fig. 5 to illustrate the alkyl chain length dependency of the permeation process. At each temperature, the permeability coefficient initially increased exponentially as the alkyl chain was extended, except at 37° where octanol appeared to enter boundary layer control. The latter behavior is consistent with a series barrier consisting of a lipid or nonpolar phase of high diffusional resistance, presumably the stratum corneum, in series with an essentially aqueous phase or phases. At short chain length, the nonpolar barrier (stratum corneum) is rate determining, and the differences from compound to compound reflect differences in partitioning into this rate-limiting membrane phase. The permeability coefficient equation takes the following general form in this region (12, 13):

$$P = \frac{D_{sc}(K_{sc/aq})_0\, 10^{\pi n}}{h_{sc}} \qquad \text{(Eq. 5)}$$

which recognizes the exponentially increasing nature of the stratum corneum–water partition coefficient. Here D_{sc} is the effective stratum corneum diffusivity, $(K_{sc/aq})_0$ is a hypothetical zero chain length partition coefficient, h_{sc} is the tissue thickness, and n is the alkyl chain length. The π value in the exponent is the incremental increase in log P per unit increase in alkyl chain length. The slope of the plot at 37° indicates that the π_{CH_2} value (or incremental partitioning constant value) is ~0.263, and it appears to be of similar magnitude at 20 and 25°. The π_{CH_2} value for human stratum corneum may be obtained similarly from the data given previously (2–6) and is about 0.333, higher than but in reasonable agreement with that for the mouse skin. Values of π_{CH_2} can be expected to range to 0.62, the specified value for perfectly nonpolar, water-immiscible phases such as heptane or carbon tetrachloride (11).

The alkanol range where partition coefficients seemingly are invariant with chain length is a range where an exponential increase in permeability due to partitioning phenomena is observed. At first appearance, this finding may seem incongruent, but the respective observations in fact are internally consistent. Whereas the relative solubility in the stratum corneum and other lipid phases is small, the amounts partitioning into aqueous phases will determine the apparent partition coefficient. However, where the relative solubility in the stratum corneum is small, the molecular diffusional current across this stratum will be small and the stratum corneum will be the rate-determining tissue in the series. The limiting slope of the partitioning on the semilog plot, 0.285 (Fig. 5), is in very close agreement with the value of 0.263 obtained as the π_{CH_2} value for the permeability experiments. The difference is in the direction of an expected slight diffusion coefficient effect due to the increased molecular volume as the alkyl chain becomes longer.

Nonstationary State—The nonstationary-state data obtained in the present studies were crude. Slight differences in estimating the steady-state slopes led to large differences in estimating the lag time intercepts, particularly at short chain lengths where the slopes were relatively shallow. Nevertheless, several important patterns of behavior may be noted. The lag time for a given compound was dependent on temperature; lag times decreased as temperature was increased. This trend is consistent with a significant activation energy for the effective diffusivity in the membrane. The temperature dependency of the permeability coefficient seen in Fig. 4 is largely dependent on the temperature dependency of the diffusion coefficient, which directly affects the lag times. The increasing lag time with increasing molecular size may be a size effect on diffusivity or may be the result of increasing membrane binding (13).

CONCLUSIONS

The hairless mouse skin is an easily prepared membrane for permeation studies. Moreover, based on the permeability of homologous alcohols, the barrier properties are qualitatively and in some regards quantitatively similar to those of human epidermis. The membrane behaves as a complex barrier with a highly impermeable lipid phase (the stratum cor-

neum), in series with the viable tissues of the epidermis and connective tissue of the dermis. On the basis of this evidence, the hairless mouse might prove generally useful in sorting out membrane contributions to the relative activities of topical drugs and in evaluating the influence of formulation on the activity of a given topical therapeutic compound.

Pharmacokinetic Studies of Propoxyphene I: Effect of Portacaval Shunt on Systemic Availability in Dogs

KATHLEEN M. GIACOMINI *, SHAHEEN M. NAKEEB ‡, and GERHARD LEVY *x

Received August 20, 1979, from the **Department of Pharmaceutics and the* ‡*Department of Laboratory Animal Science, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication February 6, 1980.

Abstract □ The elimination kinetics and systemic availability of *d*-propoxyphene were determined in dogs before and after construction of a portacaval shunt. For this purpose, the drug was administered intravenously and orally, in aqueous solution, according to a balanced experimental design. The total plasma clearance of propoxyphene ranged from 14.4 to 31.8 ml/min/kg before the shunt and decreased appreciably in two of four dogs after shunting. There was no significant change in the serum protein binding of the drug. The systemic availability increased from an average of 25% before to an average of 54% after shunting ($p < 0.05$). The ratio of areas under the plasma concentration–time curve of norpropoxyphene to propoxyphene was not significantly affected by the shunt when propoxyphene was administered intravenously; it decreased substantially after shunting when the drug was administered orally. Pharmacokinetic analysis indicates that orally administered propoxyphene is subject to prehepatic as well as hepatic first-pass elimination in dogs. The magnitude of the first-pass effect is similar to that in humans. These results suggest that the dosage of orally administered propoxyphene should be reduced in patients with portacaval shunt or with cirrhosis of the liver.

Keyphrases □ Pharmacokinetics—propoxyphene, effect of portacaval shunt on systemic availability, dogs □ Propoxyphene—pharmacokinetics, effect of portacaval shunt on systemic availability, dogs □ Systemic availability—propoxyphene, effect of portacaval shunt, dogs

The analgesic propoxyphene (*d*-propoxyphene) is one of the most frequently prescribed drugs in the United States. About 31 million prescriptions for it were issued in 1978 (1). Large doses can be fatal and often have been used to commit suicide. Propoxyphene also has been implicated in accidental deaths. A number of these deaths apparently occurred as a result of the consumption of propoxyphene in quantities only slightly larger than the upper limit of the recommended dosage, usually together with alcohol and/or other central nervous system (CNS) depressants (1).

BACKGROUND

Propoxyphene is subject to a pronounced first-pass effect in that only a small fraction of the absorbed dose enters the general circulation in unmetabolized form (2–4). Moreover, there are very large and apparently relatively consistent interindividual differences in the systemic availability of propoxyphene in humans (2–6). This fact suggests that certain accidental (as opposed to suicidal) poisonings due to propoxyphene may result from an unfortunate coincidence of a large (probably larger than prescribed) dose, an unusually small first-pass effect relative to the population average, and ingestion of one or more CNS depressants. For this and other obvious reasons, it is important to determine the factors responsible for interindividual differences in the first-pass effect on propoxyphene.

An orally administered drug may be subject to hepatic as well as prehepatic (intestinal) first-pass effects. The relative contribution of these two sites of biotransformation is important in assessing the reasons for interindividual differences in the systemic availability and for predicting the possible effect of surgically induced or endogenous portacaval shunts (*i.e.*, shunts due to hepatic cirrhosis). There are indirect indications, based on pharmacokinetic analysis of systemic availability relative to total clearance, that propoxyphene may be subject to some prehepatic biotransformation in humans (3, 4).

It is not possible to determine the magnitude of the prehepatic biotransformation of a drug such as propoxyphene by comparing its systemic availability in normal subjects and in patients with surgically constructed portacaval shunts. Such shunts are used to relieve variceal bleeding secondary to portal hypertension caused by hepatic cirrhosis and other pathological conditions associated with obstruction of portal blood flow. Liver disease and the drugs taken by the recipients of a portacaval shunt may modify the metabolic clearance of propoxyphene and thereby introduce an additional variable that cannot be controlled or defined readily because propoxyphene is not available for intravenous injection. Moreover, patients with portacaval shunts can develop various degrees of collateral circulation. Therefore, it is necessary to conduct studies on a suitable animal model.

Some published evidence suggested that the dog, like humans, exhibits a pronounced first-pass effect on orally administered propoxyphene (7). Demethylation to norpropoxyphene is a major elimination pathway of propoxyphene in both species (8). The dog is large enough for the convenient surgical construction of a portacaval shunt. Other investigators successfully used dogs to study the first-pass effect on orally administered drugs before and after a portacaval shunt (9).

In the present investigation, propoxyphene was administered both orally and intravenously to dogs before and after a portacaval shunt, according to a balanced experimental design. Propoxyphene was administered intravenously before and after surgery because the shunt may affect the plasma clearance of a drug (9). There is conflicting evidence concerning the dose dependence of the first-pass effect on propoxyphene in humans (2–4, 10, 11). The intravenous dose in this study was lower than the oral dose so that the areas under the concentration–time curve produced by both routes of drug administration would be similar.

Table I—Experimental Design Indicating the Order of Intravenous and Oral Propoxyphene Administration [a]

Dog	Before Shunt		After Shunt	
	Intravenous	Oral	Intravenous	Oral
1	1	2	3	4
2	1	2	4	3
3	2	1	3	4
4	2	1	4	3

[a] Intravenous and oral doses of *d*-propoxyphene hydrochloride were 2.0 and 7.5 mg/kg, respectively.

Norpropoxyphene, a major metabolite of propoxyphene, is eliminated from the body much more slowly than its precursor and appears prominently in the circulation following propoxyphene administration (12, 13). The formation and elimination kinetics of norpropoxyphene are of clinical interest because this metabolite, like propoxyphene, can depress cardiac conduction and may contribute to the cardiac toxicity produced by ingestion of large amounts of propoxyphene (14–16). Therefore, norpropoxyphene concentrations also were determined in this investigation.

EXPERIMENTAL

Four male mongrel dogs, 14–27 kg, received *d*-propoxyphene hydrochloride intravenously (cephalic vein of the foreleg) in saline solution (0.5 ml/kg) at a dose of 2 mg/kg and orally in 100 ml of water *via* a stomach tube at a dose of 7.5 mg/kg. The dogs were fasted overnight and during the study. The doses were administered according to a crossover design (Table I) at 1-week intervals. Prior to each dose, a heparin trap was placed in a cephalic vein and 10 ml of blood was withdrawn. After drug administration, 10-ml blood samples were withdrawn serially for 8 hr.

One week after administration of the second dose, a modified side-to-side portacaval shunt was constructed under pentobarbital sodium anesthesia (30 mg/kg). The technique employed was that of a straight Eck fistula (17). Basically, this technique involved anastomosing the side of the portal vein to the side of the vena cava and then tying off the portal vein just proximal to the liver. Thus, a complete shunt of blood from the portal vein to the vena cava was produced.

One to 2 weeks after construction of the shunt, the dogs again received propoxyphene orally and intravenously (same dose per kilogram as before the shunt). As before, 1 week elapsed between administration of the two doses. Blood samples were collected as described.

Plasma was assayed simultaneously for propoxyphene and norpropoxyphene by the GLC method of Verebely and Inturrisi (18) with the following minor modifications. The gas chromatograph[1] had a 182.9-cm long × 2-mm i.d. glass spiral column. The column, detector, and injector port temperatures were 220, 240, and 230°, respectively. The carrier gas flow was 40 ml/min. The internal standard was trifluperazine. Under these conditions, the retention times for propoxyphene, norpropoxyphene, and trifluperazine were 2.5, 7.0, and 10 min, respectively. The assay is sensitive to 50 ng of propoxyphene and 100 ng of norpropoxyphene. The volume of plasma used for the assay was adjusted to yield amounts of the drug and the metabolite in the 500–3500-ng range. The coefficient of variation of the assay in this range was 6.3% for propoxyphene and 7.0% for norpropoxyphene.

The plasma protein binding of propoxyphene in each dog before and after portacaval anastamosis was determined by equilibrium dialysis. Two 1.5-ml predose plasma samples from each dog were dialyzed at 37° against an equal volume of pH 7.4 Sorensen phosphate buffer (0.13 *M*) containing *d*-propoxyphene hydrochloride (1.2 μg/ml), using Plexiglas cells separated by a cellophane membrane[2]. The dialysis time was 12 hr.

The total protein concentrations in the plasma of each dog before and after portacaval shunt were determined by the method of Gornall *et al.* (19) with crystalline dog albumin as the standard. The albumin fractions were determined by electrophoresis[3], and albumin concentrations were obtained by multiplying the total protein concentration by the fraction of albumin.

The area under the plasma concentration–time curve (*AUC*) after oral drug administration was calculated by the trapezoidal method for the first 8 hr and then extrapolated to infinity according to $AUC_{t-\infty} = C_t/\beta$, where $AUC_{t-\infty}$ is the area under the plasma concentration–time curve from the last observed plasma concentration (obtained at 8 hr) to infinity, C_t is the plasma concentration at 8 hr, and β is the terminal disposition rate constant (determined after intravenous injection). The $AUC_{t-\infty}$ was ~20% of $AUC_{0-\infty}$ before the shunt and ~28% after the bypass.

The plasma propoxyphene concentrations obtained after intravenous injection were fitted to the equation $C = Ae^{-\alpha t} + Be^{-\beta t}$ by a nonlinear least-squares regression procedure (20). The data were weighted by use of their reciprocal. The $AUC_{0-\infty}$ value was determined as the sum of A/α and B/β.

The total clearance, *Cl*, was calculated according to $Cl = D_{iv}/AUC_{iv}$, where D_{iv} is the intravenous dose of the free base and AUC_{iv} is the area under the intravenous plasma concentration–time curve from time zero to infinity.

The systemic availability, *F*, was calculated from $F = (100 \times D_{iv} \times AUC_{po})/(D_{po} \times AUC_{iv})$, where D_{iv} and D_{po} are the respective intravenous and oral doses and AUC_{po} and AUC_{iv} are the respective total areas under the plasma concentration–time curves following the oral and intravenous doses.

Table II—Pharmacokinetics of Propoxyphene in Dogs before and after Portacaval Shunt

Parameter[a]	Before	After
A, ng/ml	1360 ± 390[b]	1530 ± 435
B, ng/ml	237 ± 70	425 ± 30
α, hr^{-1}	4.13 ± 1.22	5.48 ± 1.30
β, hr^{-1}	0.202 ± 0.033	0.223 ± 0.032
Free fraction in plasma[c]	0.129 ± 0.037	0.159 ± 0.031

[a] Based on the relationship $C = Ae^{-\alpha t} + Be^{-\beta t}$, where *C* is the drug concentration in plasma at time *t* after intravenous injection of 1.81 mg (expressed as the base)/kg of body weight. [b] Mean ± *SEM*, $n = 4$. [c] At a total drug concentration at equilibrium of ~1000 ng/ml.

RESULTS

The propoxyphene concentrations in plasma declined biexponentially after intravenous injection. The drug was absorbed very rapidly after oral administration (Figs. 1 and 2). The pharmacokinetic constants for the elimination of injected propoxyphene are listed in Table II. The plasma total protein and albumin concentrations were 6.5 ± 0.2 and 3.0 ± 0.1 g/100 ml before the shunt and 6.0 ± 0.6 and 2.6 ± 0.2 g/100 ml after the shunt (mean ± *SEM*, differences not significant), respectively. The free fraction values of propoxyphene in plasma were similar before and after shunting (Table II).

The plasma clearance of injected propoxyphene was high (Table III) and comparable in magnitude to the hepatic plasma flow rate in dogs (21). It decreased appreciably after the portacaval shunt in the two dogs that exhibited the highest clearance values before the shunt (Dogs 2 and 3). The systemic availability of orally administered propoxyphene increased substantially after shunt construction in all of the animals; the average increase was from 25% before to 54% of the dose after the shunt (Table III). The areas under the concentration–time curve, time zero to infinity, following oral administration of propoxyphene increased even more, changing from 1470 ± 450 (ng hr)/ml before to 4390 ± 645 (ng hr)/ml after the bypass (mean ± *SEM*, $p < 0.025$).

Pertinent information concerning the norpropoxyphene concentrations in plasma is summarized in Table IV. The delayed occurrence of maxi-

mum concentrations and apparently increased areas under the 0–8-hr concentration–time curve after intravenous injection of propoxyphene suggest decreased clearance of the metabolite after the shunt, but the differences were not statistically significant. The ratio of areas under the concentration–time curve (*AUC* ratio) of norpropoxyphene to propoxyphene after intravenous injection of propoxyphene was not affected by the portacaval shunt. The *AUC* ratio after oral administration of the drug was much higher than after intravenous injection and decreased appreciably after construction of the portacaval shunt (Table IV).

DISCUSSION

The dogs in this study received oral propoxyphene as an aqueous solution. Consistent with the results of clinical studies (2, 4–6, 8, 11–13), the drug was absorbed rapidly after oral administration. A clinical study showed that there is no apparent difference in the systemic availability of propoxyphene administered in capsules and in solution (11). The urinary recovery of radioactivity following oral and intravenous administration of [^{14}C]propoxyphene is not significantly different (4). On the basis of this information, it is reasonable to conclude that the incomplete systemic availability of propoxyphene observed in this study is due to presystemic biotransformation rather than incomplete absorption.

Gram *et al.* (4) found that the systemic availability of orally administered propoxyphene hydrochloride in humans was independent of the dose in the 65–195-mg dose range. The use of oral to intravenous *AUC* ratios in the present study to determine the systemic availability of orally administered propoxyphene in dogs was based on the assumption that the kinetics were linear under the experimental conditions. Moreover, the oral and intravenous doses were chosen to produce similar *AUC* values to minimize the effect of possible nonlinearity on the systemic availability determinations.

As in humans, the plasma clearance of injected propoxyphene in dogs is high and comparable in magnitude to the hepatic plasma flow rate. Since the renal clearance of propoxyphene is very low (8, 12), the plasma clearance of the drug is due almost entirely to metabolism. Therefore, propoxyphene should be subject to a large first-pass effect, based on theoretical pharmacokinetic considerations (3). Its plasma clearance after intravenous injection should be affected by the activity of drug-metabolizing enzyme systems and by hepatic blood flow (3), both of which may be reduced following the portacaval shunt (9, 22). Indeed, the plasma clearance of propoxyphene was substantially decreased in two of four dogs after the shunt. The two affected animals had the highest propoxyphene clearance before surgery and, therefore, were most sensitive to a reduction of hepatic blood flow. Other investigators reported reduction of lidocaine and antipyrine clearance after portacaval shunting in dogs (9).

The systemic availability of propoxyphene increased, but was not complete, after the portacaval shunt. This result suggests that the drug is subject to a prehepatic first-pass effect, which is consistent with the tentative conclusions of investigators who noted that the observed first-pass effect on propoxyphene in humans is larger than the magnitude of the hepatic first-pass effect predicted on the basis of pharmacokinetic considerations (3, 4).

If a drug is subject to prehepatic as well as hepatic first-pass biotransformation, then the fraction of the dose available systemically, F,

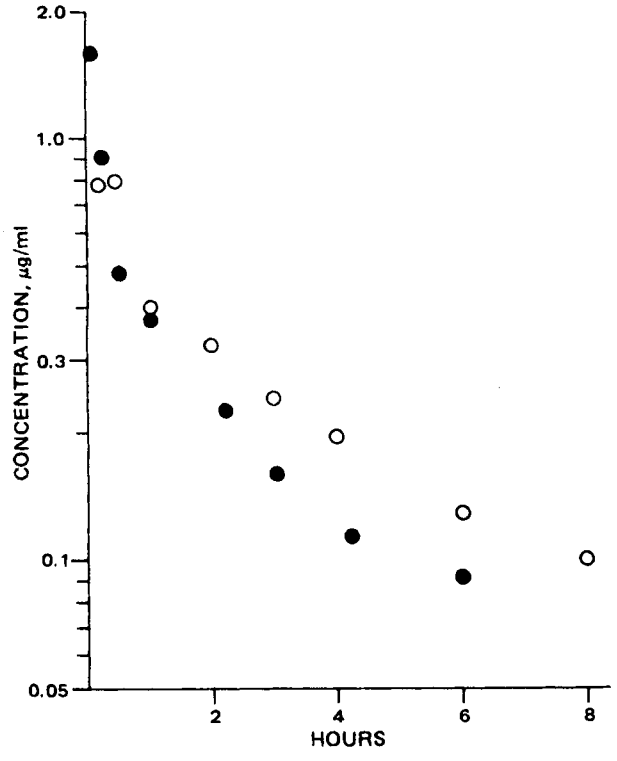

Figure 1—*Concentrations of* d-*propoxyphene in plasma of Dog 4 after oral administration of 7.5 mg/kg* (○) *and intravenous injection of 2.0 mg/kg* (●) *of propoxyphene hydrochloride in separate experiments before portacaval shunt.*

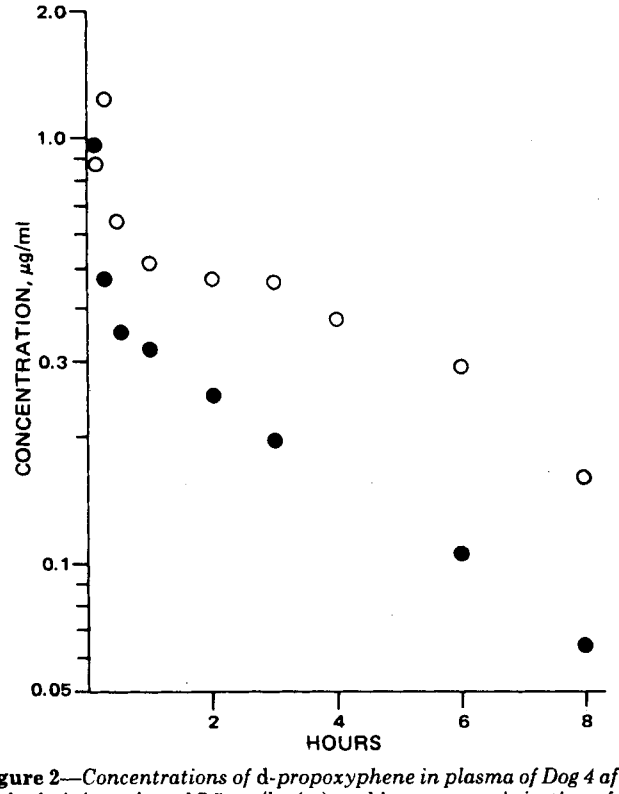

Figure 2—*Concentrations of* d-*propoxyphene in plasma of Dog 4 after oral administration of 7.5 mg/kg* (○) *and intravenous injection of 2.0 mg/kg* (●) *of propoxyphene hydrochloride in separate experiments after portacaval shunt.*

is $F_{PH}F_H$, where F_{PH} is the fraction of the dose reaching the liver as intact drug and F_H is the fraction of the drug reaching the liver intact that enters the systemic circulation in unmetabolized form. If $F_{PH} = F$ after portacaval shunt (assuming that F_{PH} was not affected by the surgery and that there was no significant development of collateral circulation after the surgery), then F_H before surgery was 0.253/0.542 or 0.47 (based on the average systemic availability values from Table III). Thus, the prehepatic and hepatic first-pass effects on propoxyphene appear to be of similar magnitude in the dog.

Hepatic cirrhosis often is associated with the formation of portacaval shunts and reduction of drug-metabolizing enzyme activity (23, 24). These changes should increase the systemic availability of a drug with the pharmacokinetic characteristics of propoxyphene. This increase should be less pronounced if a substantial part of the first-pass effect is due to prehepatic biotransformation, provided that liver disease does not affect the prehepatic metabolism of propoxyphene. Unfortunately, the effect of liver disease on the prehepatic biotransformation of drugs is not known. However, it appears prudent to reduce the dosage of propoxyphene in patients with portacaval shunt or with cirrhosis of the liver.

Anti-Inflammatory and Analgesic Profile of Amidines of 3-Amino-1,2,4-benzotriazine and 3-Amino-1,2,4-benzotriazine-1-oxide

B. A. REGAN, J. W. HANIFIN, M. J. LANDES, A. C. OSTERBERG, G. J. PATEL, D. N. RIDGE, A. E. SLOBODA, and S. A. LANG, Jr. ˣ

Received March 19, 1979, from the *Medical Research Division, American Cyanamid Company, Pearl River, NY 10965.* Accepted for publication February 6, 1980.

Abstract □ Several formamidine and acetamidine derivatives prepared from 3-amino-1,2,4-benzotriazine and 3-amino-1,2,4-benzotriazine-1-oxide displayed an aspirin-like anti-inflammatory and analgesic profile. The test systems included adjuvant-induced arthritis in rats, carrageenan-induced edema in rats, UV-induced erythema in guinea pigs, the analgesic gait test, the antipyretic test, and GI ulcer studies.

Keyphrases □ Anti-inflammatory activity—amidine derivatives of 3-amino-1,2,4-benzotriazines and their 1-oxides, synthesis and testing, rats □ Analgesic activity—amidine derivatives of 3-amino-1,2,4-benzotriazines and their 1-oxides, synthesis and testing, rats □ 3-Amino-1,2,4-benzotriazines—amidine derivatives, synthesis and testing for anti-inflammatory and analgesic activity, rats

Various new, nonsteroidal, anti-inflammatory agents such as ibuprofen, tolmetin, fenoprofen, naproxen, and sulindac have been introduced to the medical community in the past several years (1). Although these agents ameliorate the arthritic condition, they are not curative and have adverse effects, largely GI disturbances (1).

The continuing interest and need for more efficacious and safe anti-inflammatory agents prompted the synthesis of various formamidine and acetamidine derivatives of 3-amino-1,2,4-benzotriazine and 3-amino-1,2,4-benzotriazine-1-oxide. These agents were tested for analgesic, anti-inflammatory, and antipyretic properties in a battery of tests including adjuvant-induced arthritis, carrageenan-induced edema, and UV-induced guinea pig erythema (2, 3). Particular emphasis was placed on GI toxicity. The results are presented, and the potential of the active series is discussed.

RESULTS AND DISCUSSION

is $F_{PH}F_H$, where F_{PH} is the fraction of the dose reaching the liver as intact drug and F_H is the fraction of the drug reaching the liver intact that enters the systemic circulation in unmetabolized form. If $F_{PH} = F$ after portacaval shunt (assuming that F_{PH} was not affected by the surgery and that there was no significant development of collateral circulation after the surgery), then F_H before surgery was 0.253/0.542 or 0.47 (based on the average systemic availability values from Table III). Thus, the prehepatic and hepatic first-pass effects on propoxyphene appear to be of similar magnitude in the dog.

Hepatic cirrhosis often is associated with the formation of portacaval shunts and reduction of drug-metabolizing enzyme activity (23, 24). These changes should increase the systemic availability of a drug with the pharmacokinetic characteristics of propoxyphene. This increase should be less pronounced if a substantial part of the first-pass effect is due to prehepatic biotransformation, provided that liver disease does not affect the prehepatic metabolism of propoxyphene. Unfortunately, the effect of liver disease on the prehepatic biotransformation of drugs is not known. However, it appears prudent to reduce the dosage of propoxyphene in patients with portacaval shunt or with cirrhosis of the liver.

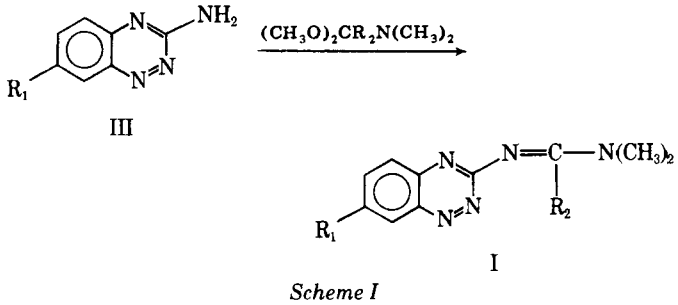

Scheme I

aminobenzotriazines (III) and their 1-oxides (IV) with excess dimethylformamide dimethylacetal or dimethylacetamide dimethylacetal (Schemes I and II).

Workup gave the derivatives of III (I) and the derivatives of IV (II) in 20–85% yields. Table I lists the 12 synthesized amidines.

Biological—Amidines Ia–If and IIa–IIf were first evaluated for activity against adjuvant-induced arthritis in rats (4). Groups of three Royal Hart Wistar rats, 200 ± 10 g, were injected intradermally in the right hindpaw with dried human tubercle bacilli in a mineral oil vehicle[1] at 2 mg/kg. The test compounds were administered orally in a 1.5% starch vehicle at the indicated dosage (Table II) once daily on Days 0–13 postchallenge. Control rats were treated similarly but were given the starch vehicle instead of the test compound.

On Days 14 and 21 postchallenge, the diameter of the injected paw (primary lesion) was measured with a micrometer caliper (6), the volumes of the inflamed paws were estimated from these measurements, and the results were expressed as percent inhibition of swelling as compared to 12 controls. If the percent inhibition was ≥24%, the compound was tested again. After the second test, the mean inhibition of swelling for both tests was calculated; if it was ≥26%, the compound was tested a third time. If the mean inhibition of all three tests was ≥25%, the compound was accepted as active. Such compounds were completely retested again in the same manner to confirm activity. Thus, no compound was considered to have confirmed activity until the test was repeated a minimum of six times (total of 18 rats).

In the dose–response experiments, the other inflamed sites such as the ears, paws, and tail (secondary lesions) were observed and graded. The mean grade was calculated and similarly expressed as the percent inhibition as compared to controls.

The active compounds (those showing at least 25% mean inhibition

[a] There were 12 control arthritic rats in each experiment with six treated rats per group in dose–response experiments and three treated rats per group in screening tests. Each experiment was repeated several times, as reflected by the total number of animals shown. Statistical comparisons were performed using paw diameters or arthritic grades, although results were expressed as percent inhibition. The statistical significance of each test result also was determined by a *t* test. Since the data from all available testing were pooled, the probabilities obtained in the individual Student *t* test analysis were combined as described by Snedecor and Cochran (5). For the control rats, eight of 186 had died by Day 21. [b] By gavage. [c] Historical data. [d] Statistically significant activity ($p < 0.05$) by the Student *t* test).

of swelling based on a total of 18 rats) then were tested against acute inflammatory conditions in carrageenan-induced edema in rats and UV-induced erythema in guinea pigs.

The method for the carrageenan-induced edema assay used was similar to that described by Winter *et al.* (7). Royal Hart Wistar rats, 80–90 g, were fasted overnight prior to dosing but had free access to water. Drugs in an aqueous suspension were administered by gavage in a volume of 1.7 ml/50 g of body weight (corresponding to the hydration volume used by Winter *et al.*).

The phlogistic agent, carrageenan[2], was prepared as a sterile 1% suspension in 0.9% NaCl for routine testing. A volume of 0.05 ml was injected through a 26-gauge needle into the plantar tissue of the right hindpaw. Measurements were made 5 hr after drug administration (4 hr after carrageenan challenge) unless otherwise indicated.

Volumes of both the normal and carrageenan-inflamed feet were determined, and the difference between the two measurements was considered to be the increased edema due to carrageenan administration. Results were expressed as a C/T efficacy ratio (mean edema of control animals/mean edema of treated animals). Each screening test had eight control rats and two treated rats. If the C/T ratio was ≥1.41, the test was repeated. If the mean ratio for Tests 1 and 2 was >1.43, the compound was considered active and the procedure was repeated for confirmation. Thus, no compound was considered to have confirmed activity until each test was repeated four times (32 controls, eight treated rats). The results for the amidines along with several reference agents are listed in Table III.

The method used to determine erythema in guinea pigs was similar to that of Winder *et al.* (8). Albino guinea pigs[3] were depilitated on their flanks the evening before testing with a standard mixture of barium sulfide and gum acacia. On the morning of testing, groups of four guinea pigs were dosed by gavage 1 hr prior to UV exposure (−1 hr). At 0 hr, they were restrained in a plastic container, which allowed exposure of three circular spots. They then were exposed to UV irradiation[4] for 60 sec. At +1 and +4 hr, the degree of erythema for each of the three sites was assessed according to the following scoring system: 0 = no erythema, 0.5 = incomplete circle or faint erythema, and 1.0 = complete circle of distinct erythema. Thus, the maximum score for each animal was 3.0. The results for a select group of amidines and reference drugs are shown in Table IV.

A modification of the method described by Atkinson and Cowan (9) was used to assess analgesic activity. A 40% suspension of Brewer's yeast in normal saline (0.25 ml/rat) was injected into the plantar surface of the left hindpaw of each rat. After 3 hr, predrug assessment of walking gait on a wire-mesh platform was made for each rat according to the following scoring system: 0 = normal gait, 0.5 = intermittent mild limp, 1 = constant limp with continuous use of foot pad, 1.5 = limping with occasional three-legged gait or intermittent use of digits in combination with foot pad, and 2 = continuous three-legged gait or continuous use of only the tips of the digits without any use of the inflamed foot pad.

Rats with a score of <2 were excluded from the experiment. The test compounds or vehicle then were administered orally to groups of six rats, and postdrug assessments were recorded after 90 min. A positive analgesic response was considered to be a ≥50% reversal of the pretreatment score (*i.e.*, posttreatment score of ≤1).

For selected compounds, subsequent experiments were performed with at least three graded dosage levels and five rats per group. Pre- and postdrug assessments were made as described.

The dose estimated to cause a positive analgesic response in 50% of the rats (ED_{50}) was calculated according to the arc-sine linear transformation method of Finney (10). The ED_{50} values for the remaining compounds were approximated.

The effect of the amidines on experimental elevated temperatures was examined during the analgesic gait test. The body temperature of rats increases after the plantar injection of Brewers' yeast, thus providing a good experimental model for studying antipyresis.

The rectal temperature of each rat was measured immediately after pretreatment scoring of abnormal gait by a rectal probe[5]. Ninety minutes after treatment with the compounds, the temperature was recorded again. The average change of each group of rats was calculated from the difference of the pretreatment and posttreatment temperatures.

The antipyretic and analgesic data are summarized in Table V.

GI ulcer studies were conducted in male Royal Hart Wistar rats weighing 190–210 g. The rats were distributed among control and treatment groups (five rats per group) and housed with one rat per cage. During the 52-hr test period, the rats were permitted free access to food and drinking water for the first 33 hr but were fasted overnight prior to

[a] There were eight control edematous rats in each experiment with four rats per treated group in dose–response experiments and three rats per treated group in screening tests. Each experiment was repeated several times, as reflected by the total number of rats shown. Statistical comparisons were performed using rat paw edema volumes, although the results were expressed as control/treated ratios. The statistical significance of each test result was determined by the Student *t* test. Since all available data were pooled, the probabilities obtained in each individual Student *t* test were combined as described by Snedecor and Cochran (5). [b] Edema of control animals/edema of treated animals. [c] Historical data. [d] Active ($p < 0.05$ by the Student *t* test).

sacrifice. Drugs were suspended in a 1.5% starch–phosphate buffer solution and injected by gavage or subcutaneously twice daily on Days 0 and 1. The rats received only one injection on Day 2, and 6 hr later they were killed with chloroform.

The stomachs were dissected, opened along the greater curvature, and rinsed briefly in tap water. They then were spread with the mucosal surface facing upward and were pinned onto corks (6.35-cm diameter) individually numbered on the back. The identification number for each stomach was not known to the investigator, and the stomachs were randomly graded according to the following scheme (11): 0 = normal; 1 = petechial hemorrhage or pinpoint ulcers; 2 = one or two small ulcers or hemorrhagic erosions; 3 = many areas of hemorrhagic erosion or ulcers, a few large; and 4 = massive areas of hemorrhagic erosion or many ulcers, mainly large.

The intestines also were removed and examined for ulcers. The intensity of intestinal ulceration was graded according to the following scheme: 0 = normal intestine; 1 = mucosa thin, petechial hemorrhage; 2 = "blow-outs" (intestine inflated with air); 3 = few ulcers—gut more fragile than normal and tears along line of mesentery attachments when removed; and 4 = many large perforating lesions, adhesions, gut hemorrhage (very fragile and tears readily and cannot be removed intact; *graded in situ*).

The results of two amidines and reference drugs are shown in Table VI.

Of the amidines reported in Table I, Ia, Id, IIa, and IId had the broadest scope of anti-inflammatory and analgesic activity, showing that the 3-amino-1,2,4-benzotriazines and 3-amino-1,2,4-benzotriazine-1-oxides with a fluorine or chlorine in the 7-position were the most active. The difference between the activity of the parent and the *N*-oxide in pairs Ia and IIa and Id and IId was marginal. Of the nonhalogenated compounds, Ib, featuring a methyl group at C-7, possessed significant activity in most tests.

The acetamidines Ie, If, and IIf were active, but If and IIf were significantly lower in overall activity than their formamidine counterparts. 7-Fluoroacetamidine (Ie) was slightly less active than Ia overall.

Many of the amidines tested in the anti-inflammatory and analgesic tests possessed an acceptable therapeutic index. However, one serious side effect involves ulceration or hemorrhaging in the GI tract. Two of the most interesting compounds, Ia and IId, were administered to rats, and the GI tracts were examined (Table VI). Both compounds exhibited severe GI problems in the form of gastric ulceration and hemorrhaging. At doses of 200 and 100 mg/kg, respectively, both exhibited a gastric ulcer grade of 3.6–4.0 out of a possible 4.0. The severe GI ulceration and hemorrhaging problem precludes further development of amidines of 3-amino-1,2,4-benzotriazines and their 1-oxides.

EXPERIMENTAL[6]

Preparation of Amidines (12, 13)—A suspension of the aminobenzotriazine or *N*-oxide in dimethylformamide dimethylacetal or dimethylacetamide dimethylacetal was stirred and heated under reflux for 5 hr. If solution was not attained, 10–20 ml of dimethylformamide or dimethylacetamide was added at the 2-hr point. The excess acetal was removed *in vacuo*, and the residue was recrystallized directly or chromatographed and recrystallized.

***N'*-(7-Fluoro-1,2,4-benzotriazin-3-yl)-*N,N*-dimethylformamidine (Ia)**—A suspension of 10 g (0.06 mole) of 3-amino-7-fluoro-1,2,4-benzotriazine in 20 ml of dimethylformamide dimethylacetal was refluxed for 5 hr. On cooling, the solution was evaporated to dryness *in vacuo*. The residue was recrystallized twice from chloroform–hexane, giving yellow-orange plates, mp 106–109° (6.3 g, 48% yield); NMR ($CDCl_3$): 3.15 (s, 3), 3.20 (s, 3), 7.5 (m, 1), 7.7 (m, 1), 7.95 (m, 1), and 8.95 (s, 1).

***N'*-(7-Chloro-1,2,4-benzotriazin-3-yl)-*N,N*-dimethylformamidine (IId)**—A suspension of 10 g of 3-amino-7-chloro-1,2,4-benzotriazine in 20 ml of dimethylformamide dimethylacetal was refluxed for 5 hr. On cooling, the solution was evaporated *in vacuo*. The residue was recrystallized from chloroform–hexane, giving 10.1 g (84% yield) of orange needles, mp 135–137°; NMR ($CDCl_3$): 3.3 and 3.5 (s, 6), 7.6 (aryl, 2), 8.21 (aryl, 1), and 8.88 (s, 1).

[6] All melting points were taken on a Mel-Temp apparatus. Samples for elemental analyses were dried at 55° for 5–24 hr. NMR spectra were determined with a Varian model HA-100 spectrometer; chemical shifts are reported in parts per million relative to the internal standard tetramethylsilane.

Table VI—GI Ulcer Studies

Compound	Oral Dose[a], mg/kg	Dead/Treated	Grade of Gastric Ulcer[b] (95% confidence limits)	Grade of Intestinal Ulcer (95% confidence limits)
Aspirin[c]	250	0/9	2.7 (1.8–3.6)	0.6 (0–1.5)
	83	0/10	1.7 (0.9–2.5)	0

Id	200	0/5	4.0[d] (3.2–4.5)	0
	100	0/5	3.6[d] (2.8–4.0)	0
Controls	—	0/25	0.2 (0–0.4)	0

[a] Twice daily for 2 days and once on the 3rd day for a total of five doses. [b] Both the stomach and the intestines were removed during the autopsy and inspected for lesions. The severity of lesions was expressed by a grading system ranging from 4 (many large ulcers or severe hemorrhagic erosion) to 0 (normal). [c] Historical data. [d] Severe GI hemorrhaging.

***N'*-(7-Bromo -1,2,4- benzotriazin-3-yl-1-oxide) -*N,N*- dimethylformamidine (IIe)**—A suspension of 10 g of 3-amino-7-bromo-1,2,4-benzotriazine-1-oxide was refluxed in 20 ml of dimethylformamide dimethylacetal. At 2 hr, a suspension still was evident; 10 ml of dimethylformamide was added, and reflux was resumed for 3 hr more. After cooling, the excess acetal was removed *in vacuo*. The residue was dissolved in chloroform, filtered through a silica gel plug, and heated to reflux. Hexane was added to induce cloudiness, and the solution was cooled, giving 5.1 g (35% yield) of yellow-brown cubes, mp 162–164°; NMR ($CDCl_3$): 3.26 and 3.29 (s, 6), 7.7 (d, 1, J = 8 Hz), 7.7 (d of d, 1, J = 1.0 and 8.1 Hz), 8.5 (d, 1, J = 1 Hz), and 8.8 (s, 1).

***N'*-(7-Fluoro - 1,2,4 - benzotriazin - 3-yl-1-oxide)-*N,N*-dimethylacetamidine (IIf)**—A solution of 10 g (0.056 mole) of 3-amino-7-fluoro-1,2,4-benzotriazine-1-oxide in 22 ml of dimethylacetamide dimethylacetal was refluxed for 5 hr and cooled, and the excess acetal was evaporated to dryness under vacuum. The residue was eluted through a short silica gel column with 20% ethyl acetate in hexane to provide 2.6 g (19% yield) of II*f*, mp 158–160°; NMR ($CDCl_3$): 2.24 (s, 3), 3.18 (s, 6), and 7.3–8 (m, 3).

***N'*-(7-Chloro-1,2,4-benzotriazin-3-yl) -*N,N*- dimethylacetamidine If)**—A solution of 5.0 g (0.03 mole) of 3-amino-7-chloro-1,2,4-benzotriazine in 11 ml of dimethylacetamide dimethylacetal was refluxed for 4 hr. The solution then was cooled, and the excess acetal was removed under vacuum. The residue was recrystallized from chloroform–hexane to yield 4.7 g of I*f* (58% yield), mp 141.5–143°; NMR ($CDCl_3$): 2.28 (s, 3), 3.26 (s, 6), 7.72 (m, 2), and 8.30 (m, 1).

***N'*-(7-Fluoro-1,2,4-benzotriazin-3-yl) -*N,N*- dimethylacetamidine (Ie)**—A solution of 10 g (0.06 mole) of 3-amino-7-fluoro-1,2,4-benzotriazine in 20 ml of dimethylacetamide dimethylacetal was refluxed for 5 hr. On cooling, the solution was evaporated to dryness under vacuum. The residue was dissolved in chloroform, eluted through a pad of silica gel, and concentrated. Trituration of the concentrate with petroleum ether (bp 30–60°) produced 9.4 g of a crystalline product (31% yield), mp 125–126.5°; NMR ($CDCl_3$): 2.24 (s, 3), 3.24 (s, 6), and 7.4–8.1 (m, 3).

Macro- and Micromethods for High-Performance Liquid Chromatographic Analysis of Oxaprozin in Plasma

SUZANNE L. McHUGH, SANDRA K. KIRKMAN, and JOHN A. KNOWLES ˣ

Received December 6, 1979, from *Wyeth Laboratories, Philadelphia, PA 19101.* Accepted for publication February 7, 1980.

Abstract □ A high-performance liquid chromatographic method for the analysis of oxaprozin in the presence of ketoprofen (the internal standard) was developed. Sample preparation involved macro- and microextraction procedures. An octadecylsilane reversed-phase system with an acetonitrile–phosphate buffer (pH 3.9) mobile phase was used to separate the compounds from the extracted plasma components and the oxaprozin metabolites. Linear UV detector response over a wide concentration range resulted in rapid and reproducible quantitation.

Keyphrases □ Oxaprozin—high-performance liquid chromatographic analysis with macro- and microextraction methods, comparison with GLC, human and rat plasma □ High-performance liquid chromatography—analysis, oxaprozin, macro- and microextraction methods, comparison with GLC, human and rat plasma □ Anti-inflammatory agents—oxaprozin, high-performance liquid chromatographic analysis, comparison with GLC

Oxaprozin (4,5-diphenyl-2-oxazolepropionic acid), a nonsteroidal, anti-inflammatory compound (1), was analyzed previously in plasma using GLC (2). This paper describes both macro- and micromethods for the high-performance liquid chromatographic (HPLC) determination of plasma oxaprozin concentrations. Time–concentration profiles obtained by each method also are presented.

EXPERIMENTAL

Materials—Anhydrous sodium acetate[1], monobasic and dibasic sodium phosphate[1], absolute ether[1], acetic acid[2], and hydrochloric acid[2] were analytical reagent grade. ACS grade 85% phosphoric acid[3] was used. Glass-distilled acetonitrile[4] was used in the mobile phase. The internal standard was ketoprofen[5].

Macromethod—Aliquots (0.5 ml) of unknown plasma or plasma spiked with standard oxaprozin were placed in 20 × 125-mm screw-capped test tubes to which were added 2.5 ml of distilled water and 1.0 ml of ketoprofen solution in 0.1 *M* acetate buffer (pH 4.8). The concentration of the internal standard ranged from 20 μg/ml for the low range samples and standards (1–10 μg of oxaprozin/ml) to 60 μg/ml for oxaprozin concentrations up to 200 μg/ml, but it was held constant in all cases for each set of samples analyzed. The control plasmas were treated with an identical volume of pH 4.8 buffer without the internal standard.

The samples were adjusted to pH 2 with 1.0 *N* HCl (~ 0.2 ml), and 8 ml of ether was added to each tube. The tubes then were capped, shaken mechanically for 10 min, and centrifuged to 2000 rpm for 5 min. Aliquots (7 ml) of the ether phase were transferred to clean test tubes and evaporated to dryness under reduced pressure at room temperature. The dried extracts were redissolved in 0.5 ml of the mobile phase, and 10-μl aliquots were injected onto the chromatographic column.

Analyses were performed using a high-performance liquid chromatograph[6] equipped with an octadecylsilane column[7]. Separation was achieved by reversed phase using a mobile phase of 62% acetonitrile in 0.05 *M* NaH_2PO_4 (adjusted to pH 3.9 with phosphoric acid) at a flow rate of 1.5 ml/min. The samples were introduced onto the column by means of a syringe-loaded sample injector[8]. At 290 nm, the detection range was 0.02 absorbance unit full scale (aufs) for the lower standards and 0.2–0.5 aufs for those of higher concentration.

A standard curve was generated by plotting the known concentrations of oxaprozin in the extracted standards against the ratios calculated by dividing the oxaprozin peak height (millivolts) by the internal standard peak height (millivolts). Quantitation of the unknowns was achieved by comparing the peak height ratios to this standard curve.

Micromethod—Aliquots (50 μl) of unknown or control plasma were placed in 6 × 50-mm disposable glass tubes. The control plasmas were spiked with 50-μl aliquots of oxaprozin standards (1.0–60 μg/ml) in 0.1 *M* phosphate buffer (pH 7.0). The unknowns were treated with an equal volume of buffer without the standard.

A 50-μl aliquot of a 5-μg/ml solution of ketoprofen in 0.1 *M* phosphate buffer (pH 7) was added to each sample and standard of the low range (0.1–2 μg/ml). Internal standardization of the high range (3–60 μg/ml) samples and standards was achieved with the addition of 50 μl of a 20-μg/ml ketoprofen solution in the same buffer. Two hundred microliters of fresh absolute ether was added to each sample, which then was mixed for 5 sec using a vortex mixer and centrifuged to break up the emulsion. The ether phases were transferred nonquantitatively to fresh tubes, and the extraction was repeated twice. The combined ether extracts were

[a] Concentrations represent the means for three normal human volunteers.

taken to dryness under a nitrogen stream. The dried extracts were redissolved in 50 μl of the mobile phase, and a 20-μl injection was made.

The HPLC instrument[9] was equipped with a precolumn in addition to the analytical column[7]. The precolumn (5 cm × 2.1 mm i.d.) was filled with dry octadecylsilane[10] by the tap and fill method. The mobile phase was similar to that used in the macromethod, except that the acetonitrile concentration was decreased to 60% to optimize separation. At 280 nm, the detection range was 0.002–0.016 aufs and the peak heights were measured manually. The method of quantitation was the same as for the macromethod.

RESULTS

Macromethod—The chromatograms in Fig. 1 illustrate the absence of interference from control plasma, the peak shape symmetry, and the sensitivity of the detector response. The method achieved good peak separation in <6 min with a lower limit of detectability of 0.5 μg of oxaprozin/ml of plasma. Peak height ratios of the standards over the oxaprozin concentration range of 1–200 μg/ml gave a linear regression line with a correlation coefficient of 0.9993.

The relative accuracy of the method was determined by comparing the HPLC results to the GLC results for a series of human plasma samples taken within 48 hr of an oral 600-mg dose of oxaprozin. The correlation between the two methods of analysis was 0.98. The accuracy of the GLC method was determined previously by comparison with radioactive monitoring of carbon 14 (2). The time–concentration profiles obtained by both HPLC and GLC are presented in Fig. 2. The recovery from plasma was 90.1 ± 3.7%. The coefficient of variation of the HPLC assay was 1.9%. Table I presents the mean drug concentrations in human plasma following a single oral 600-mg dose.

Micromethod—The chromatograms in Fig. 3 represent the analysis of rat plasma extracted by the micromethod. No interference from plasma components was observed, and oxaprozin was separated from its metabolites, including the hydroxylated compounds identified previously[11] (2). The lower limit of detectability was 0.1 μg of oxaprozin/ml of plasma, and the peak height of the standards between 0.1 and 60.0 μg/ml resulted

Key: 1, control plasma extract; and 2, extract of rat plasma obtained 4 hr after a 20-mg/kg oral dose of oxaprozin. The peaks represent 20 μg of ketoprofen/ml (I), 1.9 μg of oxaprozin/ml (II), and a nonquantified amount of oxaprozin metabolites (M).*

in a linear regression correlation coefficient of 0.9994. The coefficient of variation of the micromethod was 3.3%.

A plasma time–concentration profile resulting from an oral dose of 20 mg of oxaprozin/kg to a rat is presented in Fig. 4. The plasma recoveries were similar to those obtained using the macromethod.

DISCUSSION

The HPLC methods outlined here represent several advantages over the GLC method employed previously. Since derivatization is no longer necessary, sample preparation time is shortened and the use of hazardous

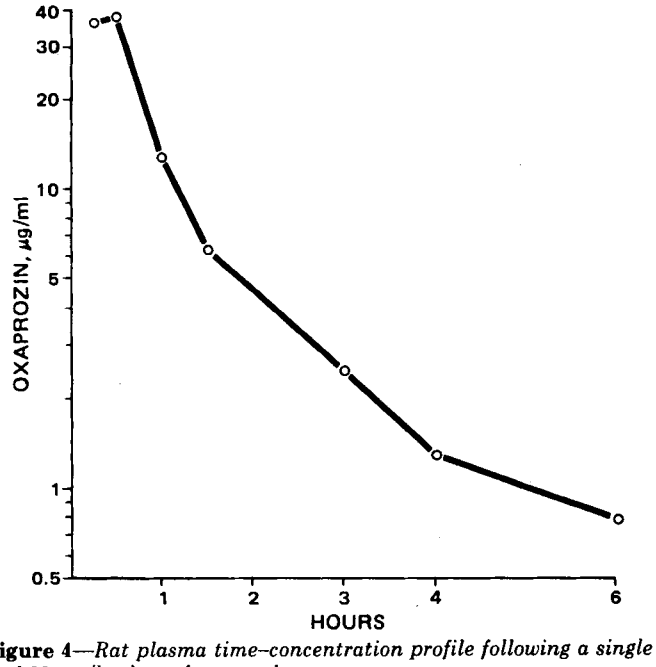

Figure 4—*Rat plasma time–concentration profile following a single oral 20-mg/kg dose of oxaprozin.*

diazomethane is eliminated. The precision of the macromethod is better than that reported for the GLC assay (2), while that of the micromethod is equal to that of the GLC method. The micromethod permits monitoring of drug concentrations in small volumes of plasma, making pharmacokinetic studies in rats and children feasible.

As reported for the GLC method (2), this procedure can be used to determine oxaprozin concentrations in urine by extracting the free drug at pH 7 rather than at pH 2. This modification is necessary in both urine and rat plasma[11] to avoid the partial extraction of oxaprozin glucuronide.

[11] F. W. Janssen and S. K. Kirkman, unpublished data.

Due to the chromatographic separation of oxaprozin from its major metabolites, no other modification in the extraction procedure is necessary.

Electronic Study of Receptor Binding of Analgesic Aryl Moiety II: Prodine Analogs

KHALID SABIH A. RAZZAK ˣ and KHAWLA A. HAMID

Received April 12, 1979, from the *College of Pharmacy, University of Baghdad, Baghdad, Iraq.* Accepted for publication February 5, 1980.

Abstract □ Analogs of the prodine analgesics were prepared and tested for analgesic activity. A good correlation seems to exist between the energy level of the highest occupied molecular orbital and biological activity. The energy level of the highest occupied molecular orbital of the aryl moiety of these analogs may permit a charge transfer interaction between the aryl groups of the analgesic molecules and their receptors with the aryl groups acting as charge donors.

Keyphrases □ Prodine analogs—synthesis, testing for analgesic activity, correlation between activity and energy level of highest occupied molecular orbital of aryl moiety □ Analgesic activity—prodine analogs, correlation between potency and energy level of highest occupied molecular orbital of aryl moiety □ Charge transfer interactions—prodine analogs, correlation between analgesic activity and energy level of highest occupied molecular orbital of aryl moiety, complex formation between aryl moiety and receptor

The synthesis of 1-methyl-4-(3-thienyl)-4-propionoxypiperidine (I) and its 2-pyridyl analog (II) was reported previously (1). A similar type of replacement of the benzene ring by heterocyclic rings, such as pyridine, also was reported for propoxyphene, tetralins, and chromanes (2). Compounds I and II were designed to study the receptor binding of the analgesic aryl moiety. The ED_{50} data obtained for I and II at 3.9 and 16.0 mg/kg, respectively, using the mouse–hot plate method and subcutaneous administration pointed to the possible interaction of the aryl group by forces (1) other than van der Waals forces (3, 4) or hydrophobic bonding (5). No further attempt was made to identify these possible forces.

BACKGROUND

Organic compounds containing aromatic rings form charge transfer complexes with other compounds, and they may act as donors or acceptors of the charge (6). Some biochemicals were found to interact in the biological system through the formation of charge transfer complexes (7). Their role as charge donors or acceptors depends on their respective highest occupied molecular orbital or lowest empty molecular orbital energy levels. Correlations between electron densities and the energy levels of the highest occupied molecular orbital or lowest empty molecular orbital and biological activity were described for cholinesterase inhibitors (8, 9), several antimalarials (10), hallucinogens (11), benzothiadiazine antihypertensives (12), and other compounds (13).

Charge transfer complex formation between the aryl moiety of the analgesic molecules and the analgesic receptor is one possibility for explaining variations in analgesic potency. This possibility can be studied by the synthesis of analogs of I and II with aryl groups having different energy levels for their highest occupied molecular orbital or lowest empty molecular orbital. Study of the analgesic activity of these analogs, expressed as their ED_{50} values, together with that of I and II may give more understanding as to how these groups interact with the receptors.

This paper describes the synthesis and analgesic activity of some prodine analogs and correlates the activity with the energy state of the highest occupied molecular orbital or lowest empty molecular orbital of the aryl groups in these analogs.

EXPERIMENTAL[1]

Formation of Aryl Lithium—The aryl halide (0.1 mole) was dissolved in 100 ml of dry ether, placed in a three-necked 500-ml flask, and cooled with a dry ice–acetone bath. An equivalent amount of *n*-butyl lithium[2] (2 moles in 100 ml of hexane) was added dropwise, with stirring, to the aryl halide solution under nitrogen.

Formation of 1-Methyl-4-arylpiperidine-4-ols (IV–VIII)—To the prepared aryl lithium salts was added, with stirring and cooling at the temperature of a dry ice–acetone bath, a solution of 1-methyl-4-piperidone[2] (0.1 mole, 11.3 g) in 100 ml of dry ether over 20 min. The temperature of the reaction mixture then was allowed to rise to 0° and was maintained for 45 min. The reaction mixture then was poured over 100 g of ice–hydrochloric acid (1:1).

The ether layer was separated and washed twice (~50 ml) with dilute hydrochloric acid, and the washings were added to the aqueous acid layer. The mixture was made basic with 10% NaOH and extracted three times (~100 ml) with ether and once with 100 ml of chloroform. The organic washings were mixed and dried over anhydrous sodium sulfate. Removal of the organic solvents under vacuum gave the required alcohols.

Microanalyses were performed on the pure products after recrystallization from the appropriate solvent or on the quaternary salts. The quaternary salts were prepared by treatment of the alcoholic product with methyl iodide or benzyl bromide in methanol and recrystallization from an alcohol–ether mixture.

The IR spectra (chloroform solution) of IV–VIII showed absorption bands in the region of the alcoholic hydroxyl group at 3400–3150 cm^{-1} and at 3100–3000 and 1600–1500 cm^{-1} due to the aryl rings introduced in the piperidine ring.

Esterification of IV–VIII—A solution of IV–VIII (0.02 mole) in 50

[1] All melting points were recorded in an oil bath and are uncorrected. IR spectra were recorded on a Perkin-Elmer model 257 spectrophotometer. All products had IR spectra in agreement with the assigned structures. The aryl halides (Fluka, AG, Bucks, Switzerland) and toluene were distilled before use. Ether was dried over anhydrous sodium sulfate. Microanalyses were performed at Midwest Microlab, Indianapolis, Ind., or by the Department of Medicinal Chemistry, University of Kansas, Lawrence, Kans.

diazomethane is eliminated. The precision of the macromethod is better than that reported for the GLC assay (2), while that of the micromethod is equal to that of the GLC method. The micromethod permits monitoring of drug concentrations in small volumes of plasma, making pharmacokinetic studies in rats and children feasible.

As reported for the GLC method (2), this procedure can be used to determine oxaprozin concentrations in urine by extracting the free drug at pH 7 rather than at pH 2. This modification is necessary in both urine and rat plasma[11] to avoid the partial extraction of oxaprozin glucuronide.

[11] F. W. Janssen and S. K. Kirkman, unpublished data.

Due to the chromatographic separation of oxaprozin from its major metabolites, no other modification in the extraction procedure is necessary.

Electronic Study of Receptor Binding of Analgesic Aryl Moiety II: Prodine Analogs

KHALID SABIH A. RAZZAK ˣ and KHAWLA A. HAMID

Received April 12, 1979, from the *College of Pharmacy, University of Baghdad, Baghdad, Iraq.* Accepted for publication February 5, 1980.

Abstract □ Analogs of the prodine analgesics were prepared and tested for analgesic activity. A good correlation seems to exist between the energy level of the highest occupied molecular orbital and biological activity. The energy level of the highest occupied molecular orbital of the aryl moiety of these analogs may permit a charge transfer interaction between the aryl groups of the analgesic molecules and their receptors with the aryl groups acting as charge donors.

Keyphrases □ Prodine analogs—synthesis, testing for analgesic activity, correlation between activity and energy level of highest occupied molecular orbital of aryl moiety □ Analgesic activity—prodine analogs, correlation between potency and energy level of highest occupied molecular orbital of aryl moiety □ Charge transfer interactions—prodine analogs, correlation between analgesic activity and energy level of highest occupied molecular orbital of aryl moiety, complex formation between aryl moiety and receptor

The synthesis of 1-methyl-4-(3-thienyl)-4-propionoxypiperidine (I) and its 2-pyridyl analog (II) was reported previously (1). A similar type of replacement of the benzene ring by heterocyclic rings, such as pyridine, also was reported for propoxyphene, tetralins, and chromanes (2). Compounds I and II were designed to study the receptor binding of the analgesic aryl moiety. The ED_{50} data obtained for I and II at 3.9 and 16.0 mg/kg, respectively, using the mouse–hot plate method and subcutaneous administration pointed to the possible interaction of the aryl group by forces (1) other than van der Waals forces (3, 4) or hydrophobic bonding (5). No further attempt was made to identify these possible forces.

BACKGROUND

Organic compounds containing aromatic rings form charge transfer complexes with other compounds, and they may act as donors or acceptors of the charge (6). Some biochemicals were found to interact in the biological system through the formation of charge transfer complexes (7). Their role as charge donors or acceptors depends on their respective highest occupied molecular orbital or lowest empty molecular orbital energy levels. Correlations between electron densities and the energy levels of the highest occupied molecular orbital or lowest empty molecular orbital and biological activity were described for cholinesterase inhibitors (8, 9), several antimalarials (10), hallucinogens (11), benzothiadiazine antihypertensives (12), and other compounds (13).

Charge transfer complex formation between the aryl moiety of the analgesic molecules and the analgesic receptor is one possibility for explaining variations in analgesic potency. This possibility can be studied by the synthesis of analogs of I and II with aryl groups having different energy levels for their highest occupied molecular orbital or lowest empty molecular orbital. Study of the analgesic activity of these analogs, expressed as their ED_{50} values, together with that of I and II may give more understanding as to how these groups interact with the receptors.

ml of dry toluene was added dropwise, with stirring at room temperature, to a solution of propionyl chloride (0.06 mole, 5.5 g) in 20 ml of dry toluene over 20 min. The reaction mixture then was refluxed for 4 hr and allowed to stand overnight at room temperature. Removal of the solvent under vacuum gave a white solid, which was treated with 5% sodium bicarbonate solution and extracted three times (~50 ml) with ether and once with 50 ml of chloroform.

The combined extracts were dried over anhydrous sodium sulfate. The organic solvents were removed under vacuum, and the residue was treated with excess methyl iodide or benzyl bromide in methanol. The quaternary salts were recrystallized from methanol–ether or chloroform–ether mixtures. The physical constants and microanalyses are shown in Table I.

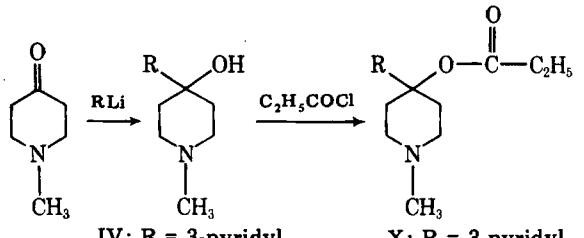
The IR spectrum of IX (chloroform solution) showed absorption bands at 3020, 2900–2800, 1620, and 1600 cm^{-1}. No absorption band was observed in the carbonyl region. The IR spectra of X–XIII (chloroform solutions) all showed strong absorption bands at 1740–1725 cm^{-1}, indicating an ester carbonyl group.

Biological Testing of X–XIII—Compounds X–XIII were tested for analgesic activity using the mouse–hot plate method and subcutaneous administration. The ED_{50} data are shown in Table II.

RESULTS AND DISCUSSION

Chemistry—Analogs of the prodine analgesics were synthesized according to Scheme I.

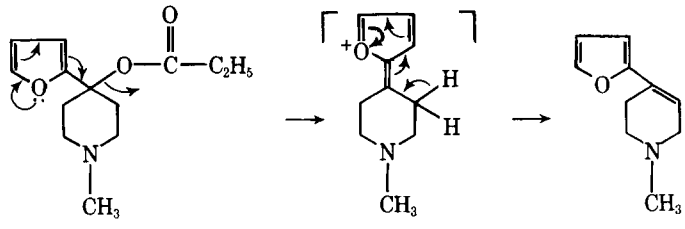
The lithium salts of the aromatic or heteroaromatic rings were prepared (14) by treatment of the corresponding bromo derivatives with an equivalent amount of *n*-butyl lithium. Addition of these lithium salts to



IV: R = 3-pyridyl
V: R = 1-naphthyl
VI: R = 2-naphthyl
VII: R = 3-quinolyl
VIII: R = 2-furyl

X: R = 3-pyridyl
XI: R = 1-naphthyl
XII: R = 2-naphthyl
XIII: R = 3-quinolyl

Scheme I



XIV IX

Scheme II

1-methyl-4-piperidone afforded the corresponding alcohols (IV–VIII) in high yields. Treatment of IV–VII with 3 equivalents of propionyl chloride afforded X–XIII. Similar treatment of VIII did not yield the expected ester; instead, olefin IX was the only product obtained from the reaction.

Evidence for the formation of IX was obtained from its IR spectrum, which did not show any absorption band in the carbonyl region and from microanalysis. Furthermore, treatment of 1-methyl-4-(2-thienyl)piperidino-4-ol with propionyl chloride under the same conditions afforded the same type of olefin (15), which was identified by IR and NMR spectroscopy and microanalysis. Changes in the reaction conditions (*i.e.*, ratio of VIII to propionyl chloride, temperature and time of the reaction, and workup of the crude product and solvent) did not change the situation. These results indicate that the heteroatom of the furan ring participates in the elimination of the propionate group after its formation.

If the mechanism of formation of IX was the facile *trans*-diaxial elimination of water from the alcohol during esterification, the same type of olefin would have been produced in all cases reported in this paper. However, the expected esters were obtained in high yields as the only products from the esterification of IV–VII as well as I and II (1). Since the olefin formation was limited to esterification of VIII and its 2-thienyl analog (15), a different mechanism may be involved in this type of elimination. The suggested mechanism involves the electron pair on the oxygen atom of the furan ring assisting in the elimination of the ester group after its formation to give XIV as an intermediate. Loss of a proton from the piperidine ring followed by a shift of the double bonds would produce IX (Scheme II).

Correlation of Pharmacological Data—Compounds IX–XII were tested for analgesic activity using the mouse–hot plate method and subcutaneous administration. The ED_{50} data are summarized in Table II together with those of I and II. The molecular orbital calculations (16) for the highest occupied molecular orbital and lowest empty molecular

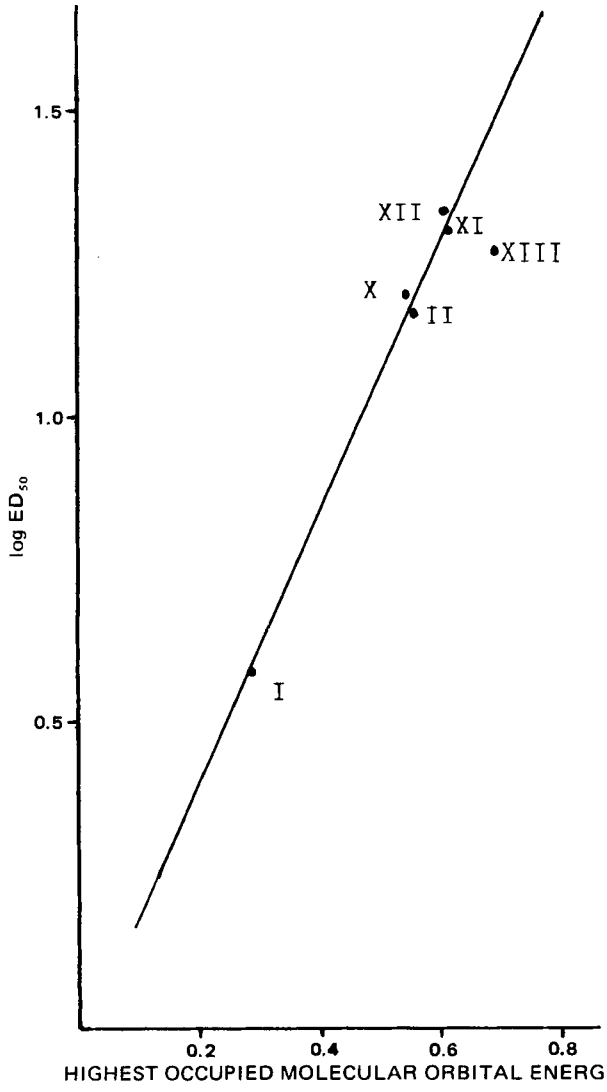


Figure 1—*Plot of log ED_{50} versus highest occupied molecular orbital energy.*

orbital energy levels of aromatic groups present in these molecules also are listed in Table II.

The choice of the aryl groups used in these derivatives was based on the energy level differences of the highest occupied molecular orbital and lowest empty molecular orbital and on the capability of these aryl groups to form charge transfer complexes *in vitro* (17) and *in vivo* (10). The molecular orbital treatment of these molecules was confined to the aromatic planar part, containing the π-electrons. These π-electrons are of primary concern in charge transfer complex formation (18). Other portions of the molecules that are not planar and are not conjugated with the major π-electron system were not included.

The electronic structure indexes considered here are the energy levels in units of the resonance integral (β) of the highest occupied molecular orbital and lowest empty molecular orbital. The energy of the highest occupied molecular orbital is a measure of electron donor ability, and that of the lowest empty molecular orbital is a measure of electron acceptor ability (7). These two energy levels are of primary importance in effecting charge transfer complex formation (7). They also are important in effecting charge transfer complex formation in the biological system (19). The smaller the energy level of the highest occupied molecular orbital, the lower is the energy required to remove a π-electron from the molecule and, thus, the greater are the electron donor properties (19–21). The closer to zero the energy level of the lowest empty molecular orbital, the greater is the electron affinity and, therefore, the greater are the electron acceptor properties (21, 22).

Compound I, the most active in the series, had an ED_{50} of 3.9 mg/kg. The energy levels of the highest occupied molecular orbital and lowest empty molecular orbital of the thienyl group were 0.2928932 and −1.00, respectively (16). These values indicate that the thiophene ring is most likely to form a charge transfer complex in the biological system and acts as a π-electron donor. However, it is the least likely π-electron acceptor because of the high energy level of the lowest empty molecular orbital relative to the other compounds.

Table II—ED_{50} Values and Highest Occupied Molecular Orbital and Lowest Empty Molecular Orbital Energy Data of I, II, and X–XIII

Compound	ED_{50}, mg/kg sc	Energy (π)	
		Highest Occupied Molecular Orbital	Lowest Empty Molecular Orbital
I	3.90	0.2928932	−1.00
II	16.00	0.5602315	−0.5602315
X	16.60	0.5602315	−0.5602315
XI	22.00	0.6180340	−0.6180340
XII	22.50	0.6180340	−0.6180340
XIII	20.00	0.7032833	−0.5270970

Compounds II and X contain a pyridine moiety at position 4 of the piperidine ring. The energy level of the highest occupied molecular orbital of pyridine is 0.5602315 (16), which is lower than that of thiophene. A charge transfer complex of II or X is expected to occur in the biological system in which the pyridine ring acts as a donor but requires a higher energy to transfer the π-electron than that required for the thiophene ring. Thus, a less firm charge transfer complex is expected in this case, which may have been reflected in the ED_{50} values of II and X at 16.0 and 16.6 mg/kg, respectively. The argument presented in comparing the biological activity of I with that of II and X also may hold for naphthalene- and quinoline-containing compounds. The energy levels of the highest occupied molecular orbital of XI–XIII were lower than those for I, II, and X. If a charge transfer complex is expected to occur between the biological system and XI–XIII, they would be weaker than those formed between the thiophene- and pyridine-containing compounds and the biological system. Also, they would require a higher energy for their formation. This difference in the energy requirement may have been the cause of the lower activity of XI–XIII as shown by their higher ED_{50} values.

To test the possibility of a charge transfer complex between the aryl groups of the analgesics and their receptors, the logarithm of the ED_{50} values given in Table II was plotted against the energy values of the corresponding highest occupied molecular orbital. Figure 1 shows a linear relationship between log ED_{50} and the energy of the highest occupied molecular orbital of these compounds. The line is the least-squares line (23) whose equation is $y = 2.2x - 0.04$. This linear relationship may indicate (13) the possibility of a charge transfer complex interaction between these compounds and their receptors, with the aryl groups acting as the charge donors. There was no simple linear relationship when the log ED_{50} values were plotted against the energy values of the lowest empty molecular orbital of these compounds. This finding may exclude the possibility that the aryl groups of these compounds function as electron acceptors.

Correlation of Hydrophobicity with Protein Binding for Clorobiocin Analogs

C. J. COULSON ˣ **and V. J. SMITH**

Received April 10, 1979, from the *Biochemistry Department, Pharmaceutical Division, May and Baker Ltd., Dagenham, Essex, RM10 7XS, England.* Accepted for publication February 1, 1980.

Abstract □ A new method of equilibrium dialysis was used to measure the binding of analogs of clorobiocin (18631 R.P.) to human serum albumin. Binding constants and numbers of binding sites on human serum albumin were calculated from the binding data and were used to calculate the percentage of compounds free in equilibrium with 4% albumin. Partition coefficients between *n*-octanol and phosphate buffer (0.05 *M*, pH 7.4) also were measured. A positive linear correlation ($r = 0.918$, $s = 0.240$, and $n = 10$) was obtained between log (bound/free compound) and log partition coefficient.

Keyphrases □ Hydrophobicity—clorobiocin analogs, correlation with protein binding □ Protein binding—clorobiocin analogs, correlation with hydrophobicity □ Clorobiocin analogs—correlation of hydrophobicity with protein binding

Clorobiocin (18631 R.P.) (1, 2) has been shown to be tightly bound to human serum albumin (3). In an effort to reduce this binding, various semisynthetic derivatives of the antibiotic were prepared, and the effect of these changes on the binding was monitored.

BACKGROUND

Binding of clorobiocin to human serum albumin was so high (99.97% with 10^{-5} *M* drug and 4% albumin) that the free drug concentration was in the range of 10^{-8}–10^{-9} *M*. To measure this drug level accurately by physicochemical means, radiolabeling of the drug would have been required. As an alternative, a method was developed whereby low concentrations of albumin were used so that the free drug concentration was sufficiently high for detection by UV spectrophotometry. From a plot of bound *versus* free drug, an iterative computer program gave binding constant values and the numbers of primary and secondary binding sites. These plots were used in a program that calculates the percentage of free drug in equilibrium with whole plasma.

The 4-hydroxycoumarin moiety probably contributes to the binding, since this group played a major part in the binding of the warfarin group of anticoagulants to human serum albumin (4). Various reports, listed by Jusko and Gretch (5), indicated that the hydrophobic nature was important for albumin binding. Accordingly, the partition coefficients of several clorobiocin derivatives were measured, and it was found that their hydrophobicity did play a major role in their binding to albumin.

EXPERIMENTAL

Equilibrium Dialysis—The technique was described initially by Coombs and Coulson (6). Two perspex blocks were screwed tightly together with a cellulose membrane[1] in between to form a complete unit with six compartments. Five units were used to hold 14 concentrations of compounds and two blanks (to allow for nonspecific UV absorbance).

For binding measurements, 2 ml of albumin[2] solution (0.25–2 mg/ml) was placed on one side of the membrane. The concentration of albumin appropriate for each compound was selected on the basis of the estimated partition using the Hansch aromatic substituent constants (7). The compounds[3] were dissolved in methanol at a concentration of 10 m*M* and diluted 1 in 50 in phosphate buffer (0.05 *M*, pH 7.4) to give the maximum concentration used. Further dilutions were made in the phosphate buffer. On the other side of the membrane was placed 2 ml of the compound solution (15–200 μM).

A plastic cap was fitted on each compartment to prevent evaporation. The units were shaken in a water bath for 8 hr at 37°, followed by 8 hr without shaking at room temperature. Aliquots from each side of the membrane were taken for the measurement of concentration by UV absorbance at a wavelength where there was no net change in absorbance on binding.

To examine the effect of methanol on the binding, methanolic and aqueous solutions of the sodium salts of clorobiocin and novobiocin were diluted in the buffer and tested; there was no significant difference in binding. The remaining compounds were dissolved initially in methanol since they were insoluble in water at higher concentrations.

Difference Spectra—The binding of each compound to human serum albumin was followed by UV spectroscopy as described previously (3) to find the wavelength for the measurement of the concentration of each compound, *i.e.*, to find the wavelength at which there was no net change in absorbance. Different albumin samples gave different results when binding clorobiocin derivatives according to the amount of dimer present. Therefore, albumin monomer was prepared using Sephadex G-100 as described previously (3).

Calculations—Binding constants and the number of binding sites were obtained from the binding data with an iterative computer program devised in these laboratories. The raw data were fitted to:

$$y = \frac{n_1 k_1 T}{1 + k_1 T} + \frac{n_2 k_2 T}{1 + k_2 T} \qquad \text{(Eq. 1)}$$

where y is the bound drug; T is the free drug; n_1 and n_2 are the numbers of primary and secondary binding sites, respectively; and k_1 and k_2 are the respective binding constants. The inclusion of a third set of binding sites did not improve the fit.

Arbitrary values for n_1, n_2, k_1, and k_2 were entered, and a standard deviation of the curve from the points was calculated. The value of n_1 is increased by 5%, k_1 and k_2 are kept constant, and the best value for n_2 is selected on the basis of a minimal standard deviation. If this standard deviation is lower than the previous one, then n_1 is increased further by

Correlation of Hydrophobicity with Protein Binding for Clorobiocin Analogs

C. J. COULSON ˣ **and V. J. SMITH**

Received April 10, 1979, from the *Biochemistry Department, Pharmaceutical Division, May and Baker Ltd., Dagenham, Essex, RM10 7XS, England.* Accepted for publication February 1, 1980.

Abstract □ A new method of equilibrium dialysis was used to measure the binding of analogs of clorobiocin (18631 R.P.) to human serum albumin. Binding constants and numbers of binding sites on human serum albumin were calculated from the binding data and were used to calculate the percentage of compounds free in equilibrium with 4% albumin. Partition coefficients between *n*-octanol and phosphate buffer (0.05 *M*, pH 7.4) also were measured. A positive linear correlation ($r = 0.918$, $s = 0.240$, and $n = 10$) was obtained between log (bound/free compound) and log partition coefficient.

Keyphrases □ Hydrophobicity—clorobiocin analogs, correlation with protein binding □ Protein binding—clorobiocin analogs, correlation with hydrophobicity □ Clorobiocin analogs—correlation of hydrophobicity with protein binding

Clorobiocin (18631 R.P.) (1, 2) has been shown to be tightly bound to human serum albumin (3). In an effort to reduce this binding, various semisynthetic derivatives of the antibiotic were prepared, and the effect of these changes on the binding was monitored.

BACKGROUND

Binding of clorobiocin to human serum albumin was so high (99.97% with 10^{-5} *M* drug and 4% albumin) that the free drug concentration was in the range of 10^{-8}–10^{-9} *M*. To measure this drug level accurately by physicochemical means, radiolabeling of the drug would have been required. As an alternative, a method was developed whereby low concentrations of albumin were used so that the free drug concentration was sufficiently high for detection by UV spectrophotometry. From a plot of bound *versus* free drug, an iterative computer program gave binding constant values and the numbers of primary and secondary binding sites. These plots were used in a program that calculates the percentage of free drug in equilibrium with whole plasma.

The 4-hydroxycoumarin moiety probably contributes to the binding, since this group played a major part in the binding of the warfarin group of anticoagulants to human serum albumin (4). Various reports, listed by Jusko and Gretch (5), indicated that the hydrophobic nature was important for albumin binding. Accordingly, the partition coefficients of several clorobiocin derivatives were measured, and it was found that their hydrophobicity did play a major role in their binding to albumin.

EXPERIMENTAL

Equilibrium Dialysis—The technique was described initially by Coombs and Coulson (6). Two perspex blocks were screwed tightly together with a cellulose membrane[1] in between to form a complete unit with six compartments. Five units were used to hold 14 concentrations of compounds and two blanks (to allow for nonspecific UV absorbance).

For binding measurements, 2 ml of albumin[2] solution (0.25–2 mg/ml) was placed on one side of the membrane. The concentration of albumin appropriate for each compound was selected on the basis of the estimated partition using the Hansch aromatic substituent constants (7). The compounds[3] were dissolved in methanol at a concentration of 10 m*M* and diluted 1 in 50 in phosphate buffer (0.05 *M*, pH 7.4) to give the maximum concentration used. Further dilutions were made in the phosphate buffer. On the other side of the membrane was placed 2 ml of the compound solution (15–200 μM).

A plastic cap was fitted on each compartment to prevent evaporation. The units were shaken in a water bath for 8 hr at 37°, followed by 8 hr without shaking at room temperature. Aliquots from each side of the membrane were taken for the measurement of concentration by UV absorbance at a wavelength where there was no net change in absorbance on binding.

To examine the effect of methanol on the binding, methanolic and aqueous solutions of the sodium salts of clorobiocin and novobiocin were diluted in the buffer and tested; there was no significant difference in binding. The remaining compounds were dissolved initially in methanol since they were insoluble in water at higher concentrations.

Difference Spectra—The binding of each compound to human serum albumin was followed by UV spectroscopy as described previously (3) to find the wavelength for the measurement of the concentration of each compound, *i.e.*, to find the wavelength at which there was no net change in absorbance. Different albumin samples gave different results when binding clorobiocin derivatives according to the amount of dimer present. Therefore, albumin monomer was prepared using Sephadex G-100 as described previously (3).

Calculations—Binding constants and the number of binding sites were obtained from the binding data with an iterative computer program devised in these laboratories. The raw data were fitted to:

$$y = \frac{n_1 k_1 T}{1 + k_1 T} + \frac{n_2 k_2 T}{1 + k_2 T} \qquad \text{(Eq. 1)}$$

where y is the bound drug; T is the free drug; n_1 and n_2 are the numbers of primary and secondary binding sites, respectively; and k_1 and k_2 are the respective binding constants. The inclusion of a third set of binding sites did not improve the fit.

Arbitrary values for n_1, n_2, k_1, and k_2 were entered, and a standard deviation of the curve from the points was calculated. The value of n_1 is increased by 5%, k_1 and k_2 are kept constant, and the best value for n_2 is selected on the basis of a minimal standard deviation. If this standard deviation is lower than the previous one, then n_1 is increased further by

[a] Percent of free compound calculated at 40 mg/ml of human serum albumin and 10^{-5} *M* compound.

5%, and the best value for n_2 is obtained. If the second standard deviation is higher, then a 5% reduction in n_1 is made, and the calculation is carried out as before.

The values selected for n_1 continue to fall by 5% until the standard deviation starts to rise, at which point 1% increments are made to n_1 until the lowest standard deviation and corresponding n_2 value are obtained. This value for n_1 is retained while first k_1 and then k_2 are treated in the same way to achieve one complete iteration. Then the process is repeated. At the next stage, n_2 takes the place of n_1, and the process is repeated. A second iteration follows. The process is considered complete when an entire cycle of four iterations (two on n_1 and two on n_2) does not improve the standard deviation by more than 0.1%.

The minimum standard deviation obtained is reported in Table I as the average of two or more runs on each compound. The percentage of free compound at 10 μg/ml in equilibrium with 4% albumin then was calculated (8). This value indicated how much free compound would be present in plasma. The log of bound to free compound was plotted against the log partition coefficient by least-squares regression analysis. All programs were computed on a minicomputer[4].

Partition Coefficients—Partition coefficients between *n*-octanol and phosphate buffer (0.05 *M*, pH 7.4) were measured at five concentrations of the compound between 0.1 and 2.0 m*M*. The UV spectrum of the compound indicated the concentration in both octanol and the buffer. A standard curve was performed in both solvents. This procedure was adopted to detect any glass binding of the compounds, but none was found. The results were averaged (Table I).

Materials—The *n*-octanol was obtained commercially[5], and its absorbance was checked before use to show that it was less than one-tenth of a unit in the range of 270–315 nm[6]. Cellulose membranes were used in the equilibrium dialysis units[7] (Fig. 1).

RESULTS AND DISCUSSION

The partition data and the percentage of free compound in equilibrium with 4% albumin are listed in Table I. The partitions ranged from 1 to 776, and the percentage of free compound ranged from 0.02 to 0.71.

Although at neutral pH the clorobiocin series carried one negative charge due to the 4-hydroxycoumarin residue, the partition coefficients still were noticeably hydrophobic. This result may partially explain the tight binding of the series since, in general, albumin binding is related to hydrophobicity in a positive linear fashion as was shown for numerous series that bind to bovine and human serum albumin (5). These data are in agreement with those of O'Reilly (9), who found that the decrease in lipophilicity produced by the insertion of a hydroxy group into the 6, 7, or 8 position of the 4-hydroxycoumarin nucleus in warfarin reduced binding to human serum albumin of an order of magnitude (albeit at pH 10) when compared with warfarin. Clorobiocin and warfarin probably bind at the same site. In addition, human serum albumin is adapted to carrying anions of fatty acids and tryptophan among others. The methylpyrrole residue present in some derivatives clearly plays a major part in the binding, as is expected from such a hydrophobic structure.

The correlation coefficient for the graph of log bound to free compound against log partition coefficient is 0.918 (s = 0.240, n = 10, F = 43.0, and p = 0.0002), and the relationship is described by log (bound/free compound) = 0.633 log P + 1.839.

Bird and Marshall (10) used the ratio of bound to free compound in analyzing the binding data for 79 penicillin derivatives and human serum on the basis that the ratio was more meaningful and formally analogous to a partition coefficient. In addition, this ratio gave a more complete estimate of the binding, since calculation based on either the binding constant or the number of binding sites failed to indicate the extent of binding. Both parameters were required along with the data from secondary binding sites. The latter contribution was considerable in some cases. Dividing a small figure into a large one clearly will increase the small error in the percentage of free compound. To offset this error, a large number of points was taken to increase the accuracy of each determination.

The binding specificity is supported further by the positive intercept obtained. When the compound is distributed evenly between octanol and buffer (log P = 0), then more compound is bound to the albumin than to the buffer phase. This result implies either that albumin binding is much more hydrophobic than octanol or that some specific binding of these compounds is taking place (the partition then may be seen as an additional factor that modulates this binding). Support for the latter view may be taken from the intercepts obtained by Bird and Marshall (10),

Krieglstein *et al.* (11), who investigated the binding of 10 phenothiazines to bovine serum albumin, and Deutsch and Hansch (12), who studied barbiturate binding to the same protein. In each case, log (bound/free) was plotted; negative intercepts of 0.628, 0.578, and 1.22 were obtained, respectively. Penicillins, phenothiazines, and barbiturates apparently do not have as marked a binding site on albumin as do clorobiocins.

The difference in log P of 1.06 between VI and clorobiocin, which differ only by a chlorine atom, is only partially explained by the π value for aromatic chlorine of 0.71 (7), whereas the hydrophobic fragment constant of 0.92 (13) approaches it much more closely. Nevertheless, it seemed important to develop a mathematical relationship based on experimental results rather than on theoretical data for those complex molecules having a great deal of conformational interaction.

Salicylate binding to whole plasma gave a value of −1.32 for log P and 94% drug bound at a concentration of 13.8 μg/ml (6), a result that clearly does not fit the correlation obtained in this work. Other compounds with structures unrelated to either salicylate or clorobiocin also did not fit the correlation, which suggests that they might be binding at a different protein site. Sudlow *et al.* (14) reported that more than one binding site exists on human serum albumin for foreign compounds. The correlation obtained in this study applies to the clorobiocin derivative series. It also may apply to any structure that binds at the same site.

Use of the equilibrium dialysis units has facilitated accurate and reproducible work, which is difficult to carry out by dialysis in a large number of tubing bags. The alternative is to purchase an expensive instrument. The units described here combine the accuracy of the instrument with little more than the cost of the dialysis tubing. Used with the two computer programs, they estimate the binding to plasma albumin of drugs that are tightly bound and are not available in radioactive form. In addition, these units can be used to measure the binding of radioactive drug to whole plasma (6) and, potentially, the binding of any ligand to a macromolecule.

Pharmacokinetics of Subcutaneous and Intramuscular Butorphanol in Dogs

M. PFEFFER ˣ, R. D. SMYTH, K. A. PITTMAN, and P. A. NARDELLA

Received September 21, 1979, from *Bristol Laboratories, Syracuse, NY 13201.* Accepted for publication February 8, 1980.

Abstract □ Butorphanol tartrate was administered intramuscularly and subcutaneously to adult male and female dogs at a dose of 0.25 mg/kg. No significant absorption lag time and no significant difference between peak intramuscular and subcutaneous serum concentrations were observed. The mean peak serum concentration was 29 ng/ml at mean times of 28 min after subcutaneous administration and 40 min after intramuscular administration. There were no significant differences in the pharmacokinetics of butorphanol in dogs with either route. The serum half-life was 1.62 hr, and the serum clearance was 3.45 liters/kg/hr. The apparent volume of distribution of butorphanol was 7.96 liters/kg. Although considerable inter- and intraanimal variation in C_{max} and AUC was observed, there was no significant difference in the area under the serum concentration *versus* time curves, and the two administration routes were considered bioequivalent.

Keyphrases □ Butorphanol—pharmacokinetics following subcutaneous and intramuscular administration, dogs □ Pharmacokinetics—butorphanol, subcutaneous and intramuscular administration, dogs □ Analgesics—butorphanol, pharmacokinetics following subcutaneous and intramuscular administration, dogs

Butorphanol tartrate [17-(cyclobutylmethyl)morphinan-3,14-diol tartrate], a new narcotic agonist–antagonist analgesic, is available[1] for use in humans and dogs (1). Previous studies indicated that loss processes account for a decrease in the extent of drug availability from extravascular parenteral injection sites (2). Deposition (3) and degradation (4) of the drug at the injection site can decrease both the rate and extent of absorption. The injection

site also was demonstrated to be a critical factor in absorption rates due to differences in blood flow (5).

The present study was undertaken to examine and compare the pharmacokinetics and disposition of parenteral butorphanol following intramuscular and subcutaneous administration to dogs and to determine whether any observable differences were attributable to differences in the administration route.

EXPERIMENTAL

Animals—Six healthy adult beagles [three males (10.3 ± 1.8 kg) and three females (11.9 ± 1.9 kg)] were selected. The study was a complete, two-way crossover comparison of intramuscular and subcutaneous butorphanol tartrate at a nominal dose of 0.25 mg/kg (as butorphanol free base equi alent). There was a 2-week recovery period between successive doses.

Treatment—The intramuscular formulation was a solution of 5 mg of butorphanol base (7.29 mg of butorphanol tartrate)/ml of sterile water. The solutions were prepared immediately before administration. The dosing solution was administered into the caudal thigh muscle at a dose of 0.25 mg (0.05 ml)/kg. The subcutaneous formulation contained 1.38 mg of butorphanol base (2.01 mg of butorphanol tartrate)/ml of vehicle. The vehicle formulation was 3.300 g of citric acid USP, 6.400 g of sodium citrate USP, 6.412 g of analytical reagent grade sodium chloride, and water for injection USP to bring the solution to 1 liter. Butorphanol tartrate was stable in this formulation for a minimum of 1 year. Subcutaneous administration was made into the loose skin between the shoulder blades at a dose of 0.25 mg (0.18 ml)/kg.

The dogs had access to food overnight. A 10-ml/kg oral waterload was administered just prior to dosing. A continuous infusion of sterile 0.9% saline solution (25 ml/hr) was maintained for the first 6 hr of the study. The purpose of this waterloading was to eliminate the degree of hydration of individual animals as a variable since the volumes of distribution of solutes can vary with the degree of hydration (6).

Blood samples were collected from a catheterized saphenous vein immediately before the dose (zero time) and at 0.25, 0.50, 0.75, 1, 1.5, 2, 3, 5, and 7 hr after injection. At least 4 ml of serum was prepared from each blood sample and frozen at −20° until it was assayed within 3 weeks of collection. Butorphanol was stable in frozen dog serum for a minimum of 5 weeks.

Serum Butorphanol Assay—All reagents were USP, NF, or ACS grade or better and were used without further purification.

Twenty-five microliters of a 10-ng/μl solution of codeine phosphate, the internal standard, in methanol was added to 3.0 ml of serum. The serum was alkalinized by the addition of 0.1 ml of 5.0 *N* NaOH and shaken[2] for 15 min with 10 ml of chloroform. The mixture was centrifuged[3] for 10 min at 3000 rpm to separate the aqueous and chloroform phases. The chloroform layer was transferred to a clean extraction tube, 4 ml of 0.1 *N* H_2SO_4 was added, and the mixture was shaken for 15 min. The phases then were separated by centrifugation at 3000 rpm for 10 min.

The aqueous acid layer then was transferred to a clean extraction tube and made basic with 0.2 ml of 5 *N* NaOH. Five milliliters of chloroform was added, and the mixture was shaken for 15 min. The chloroform extract was evaporated to dryness under a gentle stream of air[4], the dried residue was dissolved in 95 μl of acetonitrile, and 5 μl of heptafluorobutyric anhydride[5] was added to the acetonitrile solution. After incubation for 10 min at room temperature, the solvent and reagent were evaporated under a gentle stream of air, and the dried residue was reconstituted with 40 μl of acetonitrile.

A 1-μl portion of the final acetonitrile solution was injected[6] into a gas chromatograph[7] equipped with a scandium tritide electron-capture detector operated at 265° with a standing current of 3.2×10^{-8} amp and a nitrogen flow rate of 30 ml/min. The chromatographic column was 3% SE-30 on 100–200-mesh Gas Chrom Q in a 30.5-cm × 4-mm i.d. glass U tube[8]. The retention times of butorphanol and codeine were 6.6 and 3.7 min, respectively.

[a] Mean ± *SD*. [b] Mean difference between subcutaneous and intramuscular routes ±95% confidence limit.

A standard curve was prepared by plotting the peak area ratio, the area under the butorphanol peak divided by the area under the codeine peak, *versus* the concentration of butorphanol (as free base equivalent) in spiked serum standards.

Pharmacokinetic and Statistical Analysis—The serum butorphanol *versus* time data for the individual dogs conformed to the linear, open, one-compartment model with first-order drug absorption. The data are described by:

$$C = [K_a C_0/(K_a - K_{el})][\exp(-K_{el}t') - \exp(-K_a t')] \quad \text{(Eq. 1)}$$

where C is the serum concentration; K_a is the first-order absorption rate constant; K_{el} is the first-order elimination rate constant; $C_0 = D/V$, in which D is the dose and V is the volume of distribution; and $t' = t - t_0$, in which t is the time after drug injection and t_0 is the absorption lag time.

The area under the serum concentration *versus* time curve from $t' = 0$ to ∞ (AUC) was found by integrating Eq. 1 between these time limits and simplifying:

$$AUC = C_0/K_{el} \quad \text{(Eq. 2)}$$

The volume of distribution was $V = D/C_0$, and the serum clearance (Cl_s) was $Cl_s = VK_{el} = D/AUC$.

The serum half-life ($t_{1/2}$) was $t_{1/2} = 0.693/K_{el}$. The observed peak serum concentrations, C_{max}, and the time from the dosage to the peak concentration, t_{max}, also were tabulated and analyzed.

The individual serum concentration *versus* time data were optimized and fitted to Eq. 1 by nonlinear regression analysis. The digital computer program AUTOAN, which incorporates Hartley's modification of the Gauss–Newton method, was employed (7, 8).

The values for C_{max}, t_{max}, AUC, $t_{1/2}$, K_a, C_0, Cl_s, and t_0 for the intramuscular and subcutaneous dosing routes were statistically compared using an analysis of variance suitable for a complete, two-way crossover experimental design (9). The K_{el} value was not tested since $t_{1/2}$ was equivalent. The analysis of variance was used to determine whether there were significant differences, at the 5% level, between these parameters on the basis of study periods, interanimal variation, and differences in administration route. The 95% confidence limits for differences in administration routes were calculated using the error term from the analysis of variance and the standard formula (10).

RESULTS

Assay—The linear relationship between butorphanol concentrations and peak area ratios was highly significant ($p < 0.01$) by linear regression analysis. The lower limit of quantitative detectability was equivalent to a serum butorphanol concentration of 0.9 ng/ml. The linear range of the assay was 2–50 ng of butorphanol/ml of serum. The accuracy of the assay with serum standards at a concentration of 15 ng/ml was 97%; there was no significant difference ($p > 0.05$) between the observed and actual concentrations of serum butorphanol as determined by an independent t test.

The reproducibility of the assay was confirmed by replicate analyses of 15 serum samples in the range of 0–37 ng of butorphanol/ml. The mean absolute difference between replicates was 2 ng/ml with a standard deviation of 1.7 ng/ml. There was no significant difference ($p > 0.05$) between the replicate assays as determined by an independent t test.

Serum Butorphanol Concentration—The mean serum concentrations of butorphanol after intramuscular and subcutaneous adminis-

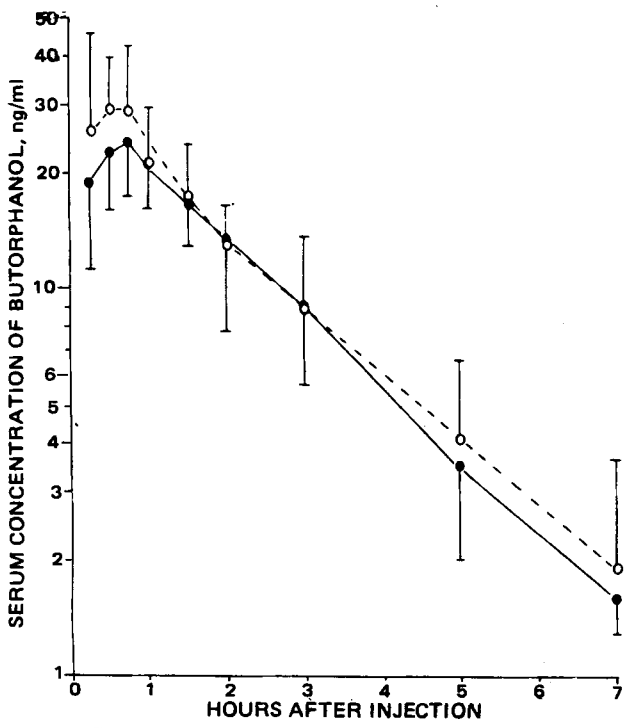

Figure 1—*Serum concentrations of butorphanol in dogs following intramuscular (●) and subcutaneous (○) administration. Mean values from six dogs with standard deviations (vertical bars) are given.*

tration are presented in Fig. 1. The mean pharmacokinetic parameters for intramuscular and subcutaneous administration for male and female dogs are listed in Table I. An analysis of variance indicated that there were no significant differences ($p > 0.05$) between the values of the pharmacokinetic parameters for different administration routes, dosing periods, and animals. There was significant interanimal variability ($p < 0.05$) in the absorption rate constant.

However, inspection of the 95% confidence limits of the mean difference between administration routes indicated considerable variability. This variability was due to both inter- and intraanimal variation. Determination of the bioequivalence of the two routes of administration by comparison of C_{max} and *AUC* within the individual animal demonstrated 85 and 97% relative bioavailability of the intramuscular dose as compared to the subcutaneous dose, respectively, with a coefficient of variation of 35% in both parameters. Although large differences could go undetected in the analysis of variance, the observed differences in the administration route in this study have no clinical, pharmacological, or toxicological significance (1).

DISCUSSION

The extent and time course of drug action can be affected significantly by the route of drug administration (2). There will be an initial lag between injection and the entrance of the drug into the circulation following extravascular parenteral administration. If drug partitioning from subcutaneous tissue and muscle to blood is similar, then the clearance of the drug from the injection site will depend primarily on blood flow. Since butorphanol is a basic (pKa 8.6), moderately lipophilic compound, differences in partitioning between the more lipophilic subcutaneous compartment and the intramuscular compartment could occur. The present studies indicated there were no significant differences in absorption, disposition, or clearance of butorphanol from these extravascular injection sites.

The absorption lag time for butorphanol tartrate in dogs on subcutaneous and intramuscular administration was -1.2 ± 6.9 min, indicating that absorption started immediately. The mean absorption half-times were 5.7 min for subcutaneous administration and 6.8 min for intramuscular administration. There should be a rapid onset of the effect of butorphanol in dogs following parenteral extravascular administration.

The disposition of butorphanol in dogs proceeded independently of the administration route. Although significant inter- and intraanimal variability was observed, the lack of a statistical or biologically significant difference between the *AUC* values indicated that the two routes were bioequivalent. The overall mean serum half-life of butorphanol was 1.62 hr, and the overall mean serum clearance was 3.45 liters/kg/hr. The mean volume of distribution of butorphanol was 7.96 liters/kg. When the apparent volume of distribution exceeds the true body weight in this manner, it usually is interpreted as indicating that the drug is distributed extensively to tissues.

Rectal Bioavailability of Lidocaine in Rats: Absence of Significant First-Pass Elimination

A. G. de BOER *x, D. D. BREIMER, J. PRONK, and J. M. GUBBENS-STIBBE

Received April 27, 1979, from the *Department of Pharmacology, Subfaculty of Pharmacy, University of Leiden, Wassenaarseweg 72, Leiden, The Netherlands.* Accepted for publication December 14, 1979. *Present address: Department of Pharmaceutical Technology and Biopharmacy, Subfaculty of Pharmacy, Gorlaeus Laboratories, Wassenaarseweg 76, 2300 RA Leiden, The Netherlands.

Abstract □ Drugs administered rectally generally are considered to enter the systemic circulation without passing first through the liver since the lower hemorrhoidal veins do not drain into the portal system. To test this hypothesis, the systemic availability of the high clearance drug lidocaine was investigated in rats following oral (20 mg) and rectal (20 mg) administration to six rats and intraarterial (5 mg) administration to another six rats. Whole blood concentrations of lidocaine were determined by capillary GLC with nitrogen detection. Systemic availability was evaluated by two methods. For the rectal route, the results were 105.6 ± 43.3 and 83.1 ± 22.3% compared to those for intraarterial administration; for the oral route, these values were 7.7 ± 2.3 and 7.1 ± 2.3%. These results clearly indicate a significant bypass of the liver following rectal administration of lidocaine. Mean elimination half-lives following oral (54 ± 9 min) and rectal (79 ± 36 min) administration were not significantly different; however, rectal elimination half-lives sometimes were slightly prolonged. The mean peak concentration times of 11.5 ± 7.5 (oral) and 15.6 ± 10.6 (rectal) min were not significantly different whereas the mean peak concentrations were significantly different ($p < 0.01$) [0.92 ± 0.49 (oral) and 8.71 ± 3.30 (rectal) μg/ml]. The mean elimination half-life following intraarterial administration (33 ± 3 min) was significantly shorter than both the mean oral and rectal half-lives, and the calculated total blood clearance of lidocaine had an average value of 36 ± 9 ml/min. The results show that it is possible to bypass the liver, at least partially, when giving a high clearance drug rectally to rats. For lidocaine, this bypass is almost complete.

Keyphrases □ Lidocaine—pharmacokinetics following rectal, oral, and intraarterial administration, rats □ Pharmacokinetics—lidocaine following rectal, oral, and intraarterial administration, rats □ First-pass effect—lidocaine following rectal and oral administration, rats □ Bioavailability—lidocaine following rectal, oral, and intraarterial administration, rats

The drug administration route can affect bioavailability markedly. High clearance drugs in particular show substantially decreased bioavailability following oral administration, caused by liver and/or gut wall metabolism. This phenomenon is called the first-pass effect, and it has been demonstrated in several animal species and in humans. Such drugs include lidocaine (1–3), propranolol (4, 5), meperidine (6), salicylamide (7), and nitroglycerin (8, 9).

It has often been speculated that drugs given rectally to humans enter into the general circulation without passing first through the liver (10), but sufficient data are lacking to support this hypothesis. However, the rectal bioavailability of lidocaine (aqueous solution) in humans recently was shown to be about twice as high as the oral bioavailability, indicating a difference in the first-pass effect between the oral and rectal routes (11).

To determine if a similar difference occurs in rats, the systemic availability of lidocaine was studied following oral, rectal, and intraarterial administration. Lidocaine was chosen as the model substrate because it undergoes a substantial first-pass effect on oral and portal administration in humans (1, 2), dogs (3), and monkeys (1) and in rat liver perfusions (12–14).

EXPERIMENTAL

Animals and Sampling Techniques—Male Wistar rats, 200–250 g, were used. Before each experiment, the animals were starved overnight with free access to water. During that period, the animals were kept in a metabolic cage to prevent them from eating their own feces or sawdust.

In the 7-day period between two experiments with one rat, the body weight of the animals generally increased 5–10%.

A cannula[1] (polyvinyl chloride; 50 cm long × 0.5 mm i.d. × 1.0 mm o.d.) filled with heparinized saline[2] (200 IU/ml) was inserted between 9 and 10 am into the right vena jugularis externa ~40 mm from the midpoint of the vena jugularis externa, the vena jugularis anterior, and the acromiodeltoid and cephalic vein under light ether anesthesia. In this way, the end of the cannula was close to the right atrium. To avoid destruction by the animal, the cannula was pulled subcutaneously, emerging on the nape of the neck. The animals then were placed in restraining cages constructed to allow free movement and withdrawal of blood samples without touching the animals.

Each rat received lidocaine orally and rectally with an interval of 1 week. The oral and rectal administrations were given to the same animal. Because no attempt was made to keep the cannula open, the left vena jugularis externa was cannulated after 1 week.

Blood samples were taken at 0, 3, 6, 10, 15, 20, 30, 45, 60, 75, 90, 120, 150, and 180 min following intraarterial and rectal administration and at 3, 6, 10, 15, 20, 30, 45, 60, 75, 90, and 120 min following oral administration. No blood samples were taken during the infusion.

Blood samples, 0.15 ml, were taken with a 1-ml disposable syringe[3] (polypropylene) after discarding the contents of the cannula (±0.10 ml) together with the mixed blood–heparinized saline (total 0.15 ml). After sampling, the cannula was filled with heparinized saline (0.10 ml). The samples were stored in closed heparinized polyethylene containers in a refrigerator at 4° and were assayed the next day.

A check confirmed that no measurable adsorption of lidocaine occurred in the concentration range of 0.1–10.0 μg of lidocaine/ml of blood at the polyvinyl chloride cannula or at the polyethylene containers.

Treatments—Lidocaine was administered intraarterially by introducing a cannula (polyvinyl chloride; 50 cm long × 0.5 mm i.d. × 1.0 mm o.d.) about 1 cm into the left common carotid artery in the caudal direction. To avoid destruction of the cannula by the animal, the cannula was pulled subcutaneously, emerging on the nape of the neck. Lidocaine[4], 5.0 mg in saline solution (0.1 ml), was infused over 2 min by an infusion pump[5] and was followed immediately by a saline infusion (0.2 ml) for 4 min.

Lidocaine was administered orally (20 mg) as a lidocaine[4] solution (0.4 ml) by introduction into the stomach using a stomach tube. It was administered rectally (20 mg) as a lidocaine[4] solution (0.4 ml) through a septum using a syringe with a sharp needle. To prevent expulsion of the solution, the end of the rectum was closed by introduction of the septum. This septum was the tip of the plunger of a 2.5-ml disposable syringe[6] (sterile polypropylene). The septum was kept in place by a ligature with a thread that was introduced subcutaneously around the anus.

Assay of Lidocaine in Plasma—To 0.1 ml of whole blood were added 1.0 ml of distilled water and 50 μl of ethanol containing 0.50 μg of *N*-methylhexobarbital as the internal standard. The mixture was extracted twice with 3 ml of pentane on a whirl mixer for 10 sec. After centrifugation for 3 min at 2500×*g*, the upper organic layers were transferred to a conical

evaporation tube. The solvent was evaporated on a water bath (40°) under a stream of dry nitrogen, and the residue was dissolved in 100 μl of ethanol.

Two microliters of this solution was brought onto the needle of a GLC solid injection system, similar to that used previously for the determination of underivatized nitrazepam in plasma (15). After evaporation of the ethanol, the needle was injected into the injection port of the gas–liquid chromatograph[7] equipped with a dual nitrogen–phosphorus detector[8]. The temperatures were 160° (column), 250° (injection port), and 300° (detector). A 10-m × 0.40-mm i.d. capillary SCOT column[9] was used. The support layer consisted of silanized, fumed silica[10] (particle size of <10 μm) coated with a stationary phase[11].

Linear calibration curves were obtained between 0.10 and 10.0 μg of lidocaine/ml of blood. The sensitivity limit of this method is ~50 ng of lidocaine/ml of blood.

Calculations and Pharmacokinetic Analysis—The postinfusion whole blood concentrations of lidocaine were fitted according to two-compartment kinetics (16). Clearance values were determined by dividing the given dose by the integrated total area under the concentration curves. In the oral and rectal experiments, the elimination rate constant, k_{el}, was obtained by regression analysis of log plasma concentration *versus* time, generally beginning 30 min after dosing. Elimination half-lives, $t_{1/2el}$, subsequently were calculated from:

$$t_{1/2el} = 0.69/k_{el} \qquad \text{(Eq. 1)}$$

The bioavailability, F, of the oral and rectal doses compared to the intraarterial dose was calculated as the ratio of the corresponding areas under the experimental curves (obtained by the trapezoidal rule) corrected for the undetermined area. The area beyond the last sampling point was obtained by two methods (17): (*a*) extrapolating the apparent exponential concentration decay phase of the individual experimental oral and rectal curves to infinite time (Method I); and (*b*) dividing the last experimentally determined concentration by the mean elimination rate constant after intraarterial infusion (Method II).

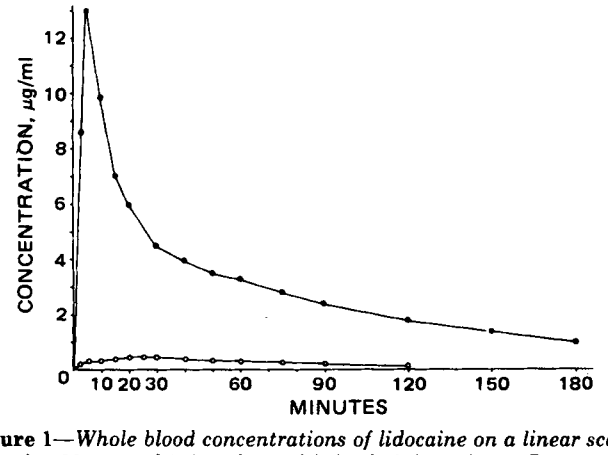

Figure 1—*Whole blood concentrations of lidocaine on a linear scale following 20-mg oral (○) and rectal (●) administration to Rat 1.*

[8] Hewlett-Packard model 18789A.
[9] Duran 50 glass.
[10] Tullanox, Cabot Corp., Boston, Mass.
[11] Carbowax 20M-KOH.

Corrections also were made for differences in the given dose by:

$$F = \frac{D_{ia}AUC_x}{D_xAUC_{ia}} \qquad \text{(Eq. 2)}$$

where D_{ia} and D_x are the intraarterial and the oral or rectal dose, respectively, and AUC_{ia} and AUC_x are the intraarterial and the oral or rectal areas under the curve, respectively. The oral and rectal parameters were determined for each animal and compared to the mean intraarterial value, and statistical differences were tested by a paired t test. When differences between the two groups of animals (intraarterial and rectal or oral) were tested, a nonpaired t test was used.

RESULTS

Figures 1 and 2 show the whole blood lidocaine concentration–time curves for a representative rat following oral and rectal administration. There was a remarkable difference in the concentration peaks. Table I gives the experimentally determined areas under the curve after oral and rectal administration. The AUC_{rect}/AUC_{or} ratios calculated by Methods I and II are given in Table II, indicating that the mean rectal systemic availability was 14.7- (Method I) and 13.0- (Method II) fold higher than the mean oral systemic availability.

A substantial amount of the dose absorbed rectally bypassed the liver and entered directly into the systemic circulation. Although substantial intraindividual differences were noted among the elimination half-lives of lidocaine on oral and rectal administration (Table I), the respective mean values of 54 and 79 min were statistically significantly different (paired t test, $p > 0.10$). Rats 4 and 5 in particular had rectal elimination half-lives that were prolonged compared to the oral administration ones. It is possible that the absorption phase extends partially into the elimination phase.

The peak concentration times, t_{max}, and peak concentrations, C_{max}, were determined with respect to the absorption rate (Table III). The mean t_{max} was 11.5 min orally and 15.6 min rectally ($p > 0.10$). However, the large difference in the mean C_{max} values of 0.92 and 8.71 μg/ml orally and rectally, respectively ($p < 0.01$), reflects the enormously increased *AUC* following rectal administration.

Following intraarterial administration of lidocaine to a second series of rats, the blood concentration–time curves exhibited two distinct phases (Fig. 3) and could be fitted to two-compartment kinetics (16). Table IV shows the data obtained following intraarterial infusion of lidocaine to

SD	2.3	43.3	2.3	22.3

[a] Corrections were made for differences in the administered dose.

these rats. The mean elimination half-life was significantly shorter (33 min) than the mean oral and rectal half-lives ($p < 0.001$ and $p < 0.010$, respectively). The total blood clearance of lidocaine calculated by dose/AUC_{ia} had an average value of 36 ml/min (Table IV).

The absolute oral and rectal bioavailability values of lidocaine were calculated for each rat by dividing the corrected individual AUC_{or} or AUC_{rect} by the mean AUC_{ia}. These values varied from 60.3 to 180.8% (Method I) and from 60.1 to 119.4% (Method II), with an average of 105.6 and 83.1%, respectively, for the rectal route, and from 4.5 to 10.6% (Method I) and from 3.9 to 9.6% (Method II), with an average of 7.7 and 7.1%, respectively, for the oral route (Table V).

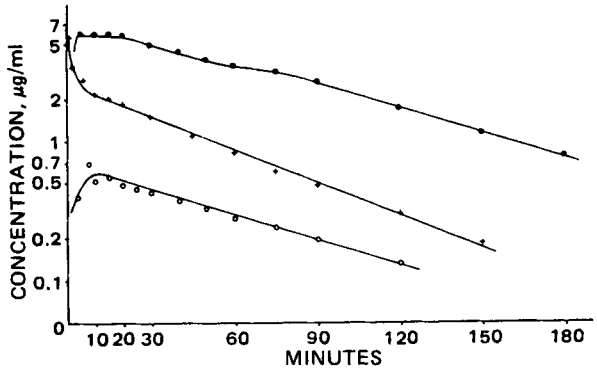

Figure 3—*Mean whole blood concentrations of lidocaine on a semilog scale following oral (○, 20 mg) and rectal (●, 20 mg) administration to Rats 1–6 and intraarterial (+, 5 mg/2 min) administration to Rats A–F.*

DISCUSSION

The experimental results demonstrate that the bioavailability of lidocaine following rectal administration to the rat is far greater than that following oral administration. This result strongly supports the hypothesis that rectal administration can result in a bypass of the liver. For a high clearance drug such as lidocaine, this bypass means increased systemic availability. As derived from the ratio of AUC_{rect} to AUC_{ia} (Table V), the mean bypass of the liver according to Methods I and II was roughly 100 and 80%, respectively, although substantial variations were observed. In addition, Table V shows that calculation of the systemic availability following rectal administration according to Methods I and II results in different mean values, which are due mainly to variations in the data of Rats 4 and 5. This difference also can be observed in Table I, where the oral and rectal *AUC* are calculated according to Methods I and II. The ratio of I to II in Table II shows that only the data of Rats 4 and 5 changed. Both data sets are given since there is no reason to prefer one method to the other (17).

If the liver is not bypassed before a high clearance drug reaches the systemic circulation, the result is extensive drug loss caused by hepatic first-pass metabolism, indicated by the present oral results with lidocaine. In general, differences in the extent of absorption might explain the observed differences in systemic availability. However, lidocaine was administered orally and rectally in an aqueous solution, which probably gives the least chance of pharmaceutical bioavailability problems. The results of this study do not permit definite conclusions about the extent of absorption. To assess the exact amount of lidocaine absorbed following a certain administration route, experiments with radiolabeled drug are indispensable. However, if rectal absorption is not complete whereas oral absorption is, the difference between oral and rectal availability will be even more in favor of the avoidance of first-pass metabolism by the rectal route.

Some pharmacokinetic factors also should be considered. Lennard *et al.* (12) indicated that with low doses of lidocaine, which resulted in initial blood concentrations of ~2 μg/ml, the drug was extracted almost completely by the perfused rat liver (>97%). Similarly, Nyberg *et al.* (13) showed that extraction was ~100% in the perfused rat liver at an initial concentration of 10 μg/ml. Shand *et al.* (14) determined, in the same system, an extraction ratio of 0.95 during constant infusion of lidocaine into the perfusion reservoir at concentrations entering the liver of 5–10 μg/ml. Linear kinetics were observed in all of these cases. One might infer from the shape of the single rectal concentration curve that nonlinear kinetics are involved, but no definite conclusions may be drawn concerning saturation phenomena due to limited data (only Rats 4 and 5 showed this curve shape) (12). Other factors also may be involved; one example is of hemodynamic origin, *i.e.*, a reduced blood flow through the liver results in a lower clearance. In addition, high lidocaine concentrations can cause bradycardia and cardiac depression (18). Finally, it is difficult to distinguish between the experimental situation where the absorption phase extends into the elimination phase and saturation kinetics. In both situations, the experimental curves may look much the same.

The lidocaine clearance value of 36 ml/min (115 ml/min/kg) following intraarterial administration is substantially higher than that reported for liver blood flow (19–23). Following intraarterial administration, ~20% of the cardiac output flows directly through the liver; therefore, with

reference to the venous blood sampling site, this flow will result in a first-pass effect and the actual systemic clearance will be overestimated (24). Even after correcting for this effect by assuming a hepatic extraction of 0.97 (12), the mean systemic clearance of 28.8 ml/min still is greater than the normal liver blood flow. This result could indicate extrahepatic elimination in the rat or an acute hemodynamic effect of lidocaine on its own disposition as a result of an increase in liver blood flow. Such an increase in flow was observed in humans following steady-state intravenous infusion (25).

Use of Molecular Negentropy to Encode Structure Governing Biological Activity

LEMONT B. KIER

Received October 5, 1979, from the *Department of Pharmaceutical Chemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication February 12, 1980.

Abstract □ A drug molecule is considered to be an information source with an information content available to receptive tissue. In nonspecific interactions, much of the information content has quality as judged by the receptor. Quantitation of the information content using Shannon's equation gives the molecular negentropy. This index is shown to rank molecules according to symmetry and to encode structural characteristics influencing physical properties and biological activity in certain cases.

Keyphrases □ Structure–activity relationships—quantitation of molecular information content by negentropy calculations, correlation between biological activity and molecular structure □ Negentropy—mathematical analysis of correlation between biological activity and molecular structure, molecular information content available to receptor molecule □ Drug–receptor interaction—structure–activity relationships, negentropy of molecules, mathematical analysis of molecular structure and biological potency

A drug molecule may be regarded as a message containing information in the form of electron probability fields distributed in space around a framework of atomic nuclei. Therefore, drug–receptor interaction may be viewed as a presentation of the message, with its information content, to a receiver. Some information in the message may be interpretable by the receiver or receptor, leading to the beginning of events culminating in a biological response.

It follows that the efficacy of a drug depends on the information content and its quality as judged by the receptor. The quality of the information content in the drug molecule depends on the ability of the receptor to interpret the fields and to translate the interactions into a significant change in the receptor and its adjacent structures.

BACKGROUND

Under some circumstances, most if not all of the information content of a drug molecule has quality; that is, a receptor may be capable of interpreting the entire message presented by the drug. These circumstances are commonly referred to as nonspecific actions. In this category are molecules which, by virtue of the mere presence of atoms and bonds, are capable of eliciting a biological response. There usually is a rough correlation between size, expressed as the number of atoms, and the potency. However, various isomers frequently have different potencies. For example, in *in vitro* studies, there often is a decline in activity for the isomer series butanol > isobutanol > *tert*-butanol. Several physicochemical correlates have been presented to explain this trend, but all point to bulk phase phenomena, not to events occurring at the molecular level between the drug and the receptor.

If the information content of a nonspecific-acting molecule is of considerable importance to the potency, then quantitation of this characteristic would be a productive approach in analyzing the structure–activity relationships and the molecular level mechanism.

The information content of a message, whether it is a molecule, a book, or communication network, can be quantitated through information theory (1), particularly by use of the equation developed by Shannon and Weaver (2). This equation has its roots in the probabilities of choice among items classified into sets of equivalent items. A specific example using the propane molecule illustrates the assignment of equivalent atoms

Use of Molecular Negentropy to Encode Structure Governing Biological Activity

LEMONT B. KIER

Received October 5, 1979, from the *Department of Pharmaceutical Chemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication February 12, 1980.

Abstract □ A drug molecule is considered to be an information source with an information content available to receptive tissue. In nonspecific interactions, much of the information content has quality as judged by the receptor. Quantitation of the information content using Shannon's equation gives the molecular negentropy. This index is shown to rank molecules according to symmetry and to encode structural characteristics influencing physical properties and biological activity in certain cases.

Keyphrases □ Structure–activity relationships—quantitation of molecular information content by negentropy calculations, correlation between biological activity and molecular structure □ Negentropy—mathematical analysis of correlation between biological activity and molecular structure, molecular information content available to receptor molecule □ Drug–receptor interaction—structure–activity relationships, negentropy of molecules, mathematical analysis of molecular structure and biological potency

A drug molecule may be regarded as a message containing information in the form of electron probability fields distributed in space around a framework of atomic nuclei. Therefore, drug–receptor interaction may be viewed as a presentation of the message, with its information content, to a receiver. Some information in the message may be interpretable by the receiver or receptor, leading to the beginning of events culminating in a biological response.

It follows that the efficacy of a drug depends on the information content and its quality as judged by the receptor. The quality of the information content in the drug molecule depends on the ability of the receptor to interpret the fields and to translate the interactions into a significant change in the receptor and its adjacent structures.

BACKGROUND

Under some circumstances, most if not all of the information content of a drug molecule has quality; that is, a receptor may be capable of interpreting the entire message presented by the drug. These circumstances are commonly referred to as nonspecific actions. In this category are molecules which, by virtue of the mere presence of atoms and bonds, are capable of eliciting a biological response. There usually is a rough correlation between size, expressed as the number of atoms, and the potency. However, various isomers frequently have different potencies. For example, in *in vitro* studies, there often is a decline in activity for the isomer series butanol > isobutanol > *tert*-butanol. Several physicochemical correlates have been presented to explain this trend, but all point to bulk phase phenomena, not to events occurring at the molecular level between the drug and the receptor.

If the information content of a nonspecific-acting molecule is of considerable importance to the potency, then quantitation of this characteristic would be a productive approach in analyzing the structure–activity relationships and the molecular level mechanism.

The information content of a message, whether it is a molecule, a book, or communication network, can be quantitated through information theory (1), particularly by use of the equation developed by Shannon and Weaver (2). This equation has its roots in the probabilities of choice among items classified into sets of equivalent items. A specific example using the propane molecule illustrates the assignment of equivalent atoms

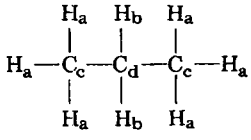
into sets and the calculation of the information content. Before proceeding with this illustration, the term molecular negentropy, the negative of information entropy, will be adopted as a measure of the information content of a molecule as suggested previously (1, 3).

THEORETICAL

Calculation of Molecular Negentropy—An approach to the calculation of the negentropy of a molecule can be derived from a consideration of molecular graphs as shown by Rashevsky (4), who pointed out the biological implications of such a parameter. Consider the propane molecule (Fig. 1) as an assemblage of atoms where the six methyl hydrogens are regarded as equivalent. This equivalence is apparent from the performance of symmetry operations on a model and from experimental evidence such as NMR. Each methyl hydrogen possesses the same physical and chemical properties as the other five by virtue of its equivalent topology relative to all of the other atoms.

These six hydrogens comprise a set. Similarly, the two methylene hydrogens are equivalent and comprise a different set with a multiplicity (number in the set) of two. The two methyl carbons comprise a third set with a multiplicity of two. The methylene carbon is in a fourth set with a multiplicity of one. Figure 1 shows the molecule labeled by sets with multiplicities.

The probability of a random selection of a methyl hydrogen is 6/11



sets	[aaaaaa]	[bb]	[cc]	[d]
multiplicity	6	2	2	1
probabilities of random selection	6/11	2/11	2/11	1/11

Figure 1—*Decomposition of the propane molecule into sets of topologically equivalent atoms, their multiplicities, and probabilities of random selection.*

Table II—Enzyme Inhibitory Potency of Alcohols and Molecular Negentropy

2-Methylbutanol	18.53	4.70	4.74
Nonanol	38.07	6.30	6.40
1,2-Dimethyl-propanol	15.89	4.08	4.52
1-Methyl-3-phenyl-propanol	29.91	5.55	5.71
1-Phenylethanol	20.46	4.98	4.91
1-Phenylpropanol	25.09	5.35	5.30

while that for a methylene hydrogen is only 2/11. The complete array of probabilities, P_j, for the four sets is shown in Fig. 1.

The negentropy per atom, i, is computed for propane from Shannon's formula:

$$i = -K \sum_j P_j \log P_j \qquad \text{(Eq. 1)}$$

where K is a constant depending on the logarithmic base and j is the set. For propane, the calculation is:

$$i = -\frac{6}{11}\log\frac{6}{11} - \frac{2}{11}\log\frac{2}{11} - \frac{2}{11}\log\frac{2}{11} - \frac{1}{11}\log\frac{1}{11} \qquad \text{(Eq. 2)}$$

where $i = 0.507$. The molecular negentropy, I for $N = 11$ atoms, is $iN = 5.582$. Note that $\log_{10}$ is used for convenience. Use of $\log_2$ leads to negentropy expressed in bits.

Several properties of negentropy are apparent:

1. The negentropy is maximal when all parts of a structure are unique, resulting in equal probabilities for all parts.

2. The negentropy is zero when all parts of a structure are equivalent.

3. The numerical value of the negentropy decreases with greater multiplicity within each set or for a smaller number of sets. This observation translates into awareness that molecular negentropy ranks molecules according to symmetry. Bonchev *et al.* drew a relationship between negentropy and symmetry only among homologs (5). An example is shown in Table I, in which the nine isomers of heptane are ranked by molecular negentropy. It is apparent that this ranking is the same as that by symmetry and presents the possibility of quantitating the degree of symmetry among molecules. An alternative quantitation would be the use of redundancy, R (1), where $R = 1 - i/\log N$.

Molecular Negentropy as a Structure–Activity Relationship Parameter—If it is hypothesized that in some cases of biological activity the entire information content of a molecule is of quality to the receptor, then the molecular negentropy is a potentially useful parameter of structure. This approach is possible because molecular structure obviously governs the information content (Table I).

[a] Alcohols calculated from Eq. 6, and esters calculated from Eq. 7.

Sheep Liver Esterase Inhibition—One example of such a relationship is the inhibition of sheep liver esterase by several alcohols (6). In this study, the concentration required to inhibit the enzyme *in vitro* by 25% was deduced from plots of concentration *versus* percent inhibition (Table II). The low activities for 2-butanol and 2-methyl-2-butanol are suspicious. An examination of the original study revealed that these two molecules never achieved 25% inhibition within the concentration range reported. The reported concentration values for these two molecules were extrapolations beyond the concentration range studied. The large uncertainty in those values indicates that they should be deleted in a structure–activity relationship analysis.

The molecular negentropies were computed for each alcohol in Table II. The assignment of atoms into sets and their multiplicities was based on the topological equivalence of the atoms. The equation and statistics are:

$$pC = 0.085(\pm 0.000)\, I + 3.174(\pm 0.16) \qquad \text{(Eq. 3)}$$

$$r = 0.970 \quad s = 0.200 \quad n = 17 \quad F = 239$$

By comparison, a correlation with molecular weight gives $r = 0.940$; a correlation with log P yields $r = 0.931$. The predicted values from Eq. 3 are found in Table II.

Lipoxygenase Inhibition—A second example of alcohol enzyme inhibitors in which molecular negentropy encodes structural features governing potency is found with the enzyme lipoxygenase (7). The data are shown in Table III with *in vitro* potencies predicted from:

$$pK_I = 0.108(\pm 0.000)\, I - 0.450(\pm 0.12) \qquad \text{(Eq. 4)}$$

$$r = 0.986 \quad s = 0.140 \quad n = 12 \quad F = 353$$

A correlation with molecular weight gives $r = 0.974$; a correlation with log P gives $r = 0.984$.

Nonspecific Narcotic Agents—Kier and Hall (8) analyzed several compounds of diverse structure that exhibited narcosis on frog tadpoles (9). The original list of compounds was factorable into two distinct lists based on the relationship between potency (log 1/c) and molecular structure, described by a molecular connectivity index. Two separate nonspecific mechanisms influencing the potency of each list were postulated.

Table V—Vapor Toxicity of Alcohols and Molecular Negentropy

tert-Pentanol	11.97	3.75	3.55
3-Pentanol	14.31	3.81	3.73
2-Pentanol	18.53	3.90	4.06
2-Methylbutanol	18.53	3.96	4.06
Isobutanol	11.77	3.72	3.54
tert-Butanol	7.62	3.28	3.22

In the present study, 32 molecules (10 alcohols, four ketones, two ethers, 12 esters, two carbamates, one nitrile, and one oxime) were analyzed (Table IV). Dichloropropanol was omitted from the list. The relationship between the negentropy (I) and potency (log 1/c) and the statistics are:

$$\log \frac{1}{c} = 0.102(\pm 0.000)\, I + 0.130(\pm 0.09) \qquad \text{(Eq. 5)}$$

$$r = 0.975 \quad s = 0.187 \quad n = 32 \quad F = 582$$

Analyses of the alcohol and ester subclasses show a definite improvement in the correlations:

$$\log \frac{1}{c}\,(\text{alcohols}) = 0.104(\pm 0.000)\, I - 0.019(\pm 0.077) \qquad \text{(Eq. 6)}$$

$$r = 0.994 \quad s = 0.101 \quad n = 10 \quad F = 654$$

and:

$$\log \frac{1}{c}\,(\text{esters}) = 0.091(\pm 0.000)\, I + 0.396(\pm 0.09) \qquad \text{(Eq. 7)}$$

$$r = 0.994 \quad s = 0.083 \quad n = 12 \quad F = 768$$

Predicted values based on the calculated I values are shown in Table IV for the entire list of compounds (Eq. 5) and for the alcohols (Eq. 6) and esters (Eq. 7).

Toxicity of Alcohols—A number of alcohols have a toxic effect on red spiders when they are exposed to the vapors (10). The potency, expressed as pC, is related to the molecular negentropy by:

$$pC = 0.077(\pm 0.000)\, I + 2.630(\pm 0.14) \qquad \text{(Eq. 8)}$$

$$r = 0.959 \quad s = 0.119 \quad n = 14 \quad F = 136$$

The values calculated from Eq. 8 are shown in Table V.

Heat of Vaporization of Alcohols—A test of the relationship between molecular negentropy and dispersion forces can be made using heats of vaporization available for alcohols found in the described studies. This property is related to molecular negentropy by:

$$\Delta H_{vap} = 0.265(\pm 0.000)\, I + 8.566(\pm 0.29) \qquad \text{(Eq. 9)}$$

$$r = 0.989 \quad s = 0.414 \quad n = 15 \quad F = 563$$

The values calculated from Eq. 9 are shown in Table VI.

DISCUSSION

The significant correlations of molecular negentropy with enzyme inhibitory potencies suggest that this structural index encodes an appreciable description of the structure influencing the activity. Variation in nonspecific activity in these *in vitro* studies may be proposed to result from variation in the receptor interaction rather than the effects on accumulation at, or disturbance of, the receptor environment. This conclusion evolved from a comparison with log P or molecular weight.

In these studies, the receptor may be viewed as responding to the hydroxyl group in a specific way. The response of the receptor to the remainder of the molecule probably is nonspecific; that is, there is no particular need for a specific atom or group to enhance the interaction. The receptor responds to all bonds and atoms in a roughly cumulative way, which is characteristic of dispersion forces among nonpolar moieties.

Table VI—Heat Vaporization of Alcohols and Molecular Negentropy

Alcohol	I	ΔH_{vap}, kcal/mole	
		Found	Calc.
Methanol	3.24	8.94	9.45
Ethanol	6.55	10.18	10.29
Propanol	10.32	11.34	11.25
2-Propanol	7.68	10.90	10.58
Butanol	14.40	12.50	12.29
2-Butanol	14.18	11.89	12.23
2-Methylpropanol	11.77	12.15	11.62
2-Methyl-2-propanol	7.62	11.14	10.56
Pentanol	18.76	13.61	13.40
2-Pentanol	18.53	12.56	13.34
3-Pentanol	14.31	12.36	12.27
2-Methylbutanol	18.53	13.04	13.34
3-Methylbutanol	17.93	13.15	13.19
3-Methyl-2-butanol	15.89	12.27	12.67
Hexanol	23.33	15.00	14.56
Heptanol	28.08	16.20	15.77
Octanol	33.00	17.00	17.03
2-Ethylhexanol	32.77	16.12	16.97
Nonanol	38.07	18.60	18.32
Decanol	43.26	19.82	19.64

Dispersion forces are notable only at close distances, are maximized between similar structural features, and are always attractive (11). Therefore, a molecule with a greater variety of structural features (a molecule with little topological equivalence or symmetry) should be capable of interaction with a greater variety of structural features on a receptor. Stated quantitatively, the greater the information content (negentropy) in a molecule, the greater is its potential for dispersion-type interaction with nonspecific receptive surfaces. Negentropy, which encodes the information content in the molecule, quantitates the variety of structural features and the associated probabilities of interaction with the receptor.

As a test of the relationship between negentropy and dispersion forces, a good correlation can be found between the molecular negentropy of alcohols and the heat of vaporization. This property reflects intermolecular forces in this series due to structural variation, in addition to the common hydroxyl group, for the 15 alcohols in Table VI.

Equations 5–8, which correlate molecular negentropy and the biological activity, show that this index has encoded molecular information of importance to the activity. The operating model of nonspecific interaction admittedly is simplistic. Nevertheless, the probabilities leading to the calculated molecular negentropy values are of great importance to the potencies. The quality of the correlations is good.

In the narcosis study, the greater the variety of information or negentropy, the greater is the potency. The receptive tissue responds to a greater degree to a molecule possessing a greater mix of atoms in differing structural environments. Isomers are ranked correctly by potency with the I value. As an example, the rankings for the observed and calculated potencies for the isomers may be compared (Table IV): propanol > isopropanol, butanol > isobutanol > *tert*-butanol, isopentanol > *tert*-pentanol, 2-pentanone > 3-pentanone, ethyl propionate = propyl acetate, ethyl valerate = isoamyl acetate, and ethyl isobutyrate = isobutyl acetate.

The subclassification into alcohols (Eq. 6) and esters (Eq. 7) (Table IV) considerably improves the correlations. The slopes in Eqs. 6 and 7 are nearly identical and are close to the slope in Eq. 5. It can be concluded that the mechanism is quite similar for alcohols and esters but that there is a uniform difference in potency running through both types of molecules. This difference undoubtedly is due to the roles played by the hydroxyl group and the carbonyl group at receptive tissue, apart from a completely nonspecific definition. Thus, a nonspecific model is useful as a first approximation, and molecular negentropy can encode most of the salient structural characteristics among both types of molecules.

The discussion of the mechanism of action in these studies takes on a probability description. It is evident why, in some studies of nonspecific effects (10, 12, 13), the range of potencies is butanol > isobutanol > *tert*-butanol since the negentropies of these molecules are 14.40, 11.77, and 7.62, respectively. Butanol is composed of 12 different sets of equivalent atoms, isobutanol has eight sets, and *tert*-butanol has five sets. Butanol, with its greater variety of topologically different atoms, can interact with a greater variety of features on a receptor. Its potency would be expected to be higher based on its structure, which governs the probabilities.

A similar situation can be found in observations of the relative affinity contributions of onium groups of muscarinic antagonists (14): $N(CH_3)_3 < N(CH_3)_2(C_2H_5) < N(CH_3)(C_2H_5)_2 > N(C_2H_5)_3$. The calculated negentropies for these moieties parallel the affinity contributions; they are 4.462, 11.962, 14.583, and 13.413, respectively. A similar trend and negentropy relationship can be found in the onium group contribution to affinities among nicotinic agents (15).

It is proposed here that a molecule of biological interest also may be regarded as a message made up of atoms and bonds containing information transmitted to a receptor or receptive tissue. The information content or negentropy is a meaningful parameter in some structure–activity relationship analyses such as in some nonspecific interactions.

It remains to be seen whether molecular negentropy as a structure–activity relationship parameter needs to be confined exclusively to drug molecules postulated to act in a nonspecific manner. Drug molecules that are active at highly structured, specific receptors certainly contain information. The probabilities of atom interaction are altered in a complex way from purely random choice due to marked differences in interaction forces between certain atoms in an agonist molecule and complementary portions of a receptor. Thus, acetylcholine engages its receptor through strong dipolar forces centered on the carbonyl oxygen and the onium group. The statistical picture describing the information content in the previous discussion must be altered to reflect the much greater probability of the onium group and the carbonyl oxygen atom of acetylcholine engaging the receptor. This issue remains for future study.

In conclusion, the calculation of the molecular negentropy of a molecule leads to the quantitation of its relative information content. Molecular negentropy encodes the salient structural characteristics of molecules in some cases where biological activity is nonspecific. It correctly ranks them according to nonspecific biological potency and provides a mechanistic interpretation of action at the molecular level based on probability considerations.

Acid–Base Equilibria of Tetracycline in Sodium Montmorillonite Suspensions

JEFFREY E. BROWNE *, JOSEPH R. FELDKAMP ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received June 14, 1979, from the **Industrial and Physical Pharmacy Department and the* ‡*Department of Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication February 29, 1980.

Abstract □ Changes in the partial molar free energy of the ionic species of tetracycline as a result of interaction with sodium-saturated montmorillonite were monitored by UV spectroscopic titrations. The stronger interaction between the clay and the protonated (H_3T^+) species relative to the zwitterionic (H_2T^0) species is responsible for the apparent displacement of pK_1 in clay suspensions. The displacement of the first equilibrium favors the H_3T^+ species due to its stabilization by the negative clay surface. Little effect of the clay was observed on pK_2 and pK_3, because the ionic species of tetracycline associated with these equilibria (H_2T^0, HT^-, and T^{2-}) did not interact strongly with the negative clay surface. Therefore, the ionic species distribution of tetracycline in a sodium montmorillonite suspension is significantly different than that expected based on solution equilibria. The degree of equilibrium displacement depended on the accessibility of the negative charge at the clay surface. Fraction bound curves support the hypothesis that the clay surface causes a change in tetracycline equilibria. The H_3T^+ form of tetracycline was highly bound to the sodium montmorillonite, but little adsorption was observed for the H_2T^0 species.

Keyphrases □ Tetracycline—acid-base equilibria in sodium montmorillonite suspensions □ Adsorption—bonding of tetracycline to sodium montmorillonite, acid-base equilibria of tetracycline □ Sodium montmorillonite—effect on acid-base equilibria of tetracycline

The mechanism of adsorption of tetracycline by montmorillonite was studied recently by X-ray diffraction and IR spectroscopy and was found to be highly dependent on the ionic form of tetracycline (1). Feldkamp and White (2) recently examined the effect of clay surfaces on the acid–base equilibria of weak bases in aqueous clay suspensions and showed that protonation was enhanced as a consequence of weak base–clay interactions. Since any changes in the distribution of ionic species present in a system have important consequences, the effect of sodium montmorillonite on the acid–base equilibria of tetracycline was studied.

THEORY

In the thermodynamic analysis given by Feldkamp and White (2), the behavior of the acid–base equilibrium for any weak base, B, was considered in clay suspensions (Scheme I).

$$BH^+ \rightleftarrows B + H^+$$

Scheme I

It was shown that the equilibrium can be displaced due to interactions between constituents participating in the equilibrium (B, BH^+, and H^+) and the clay surface. In particular, protonation in excess of that predicted based on the pK value of the compound and the bulk solution pH of the suspension (pH^b) results from a stronger BH^+–clay interaction than a B–clay interaction. In more concise terms, $\Delta\bar{G}_{BH^+}$ is less than $\Delta\bar{G}_B$, where $\Delta\bar{G}_i$ (i = BH^+, B) is the change in the partial molar Gibbs free energy for constituent i accompanying the addition of clay to the system at constant temperature, pressure, and composition. If $\Delta\bar{G}_{BH^+} = \Delta\bar{G}_B$, indicating that both BH^+ and B interact equally well with the clay, no enhanced protonation effect arises.

The $\Delta\bar{G}_{BH^+}$ and $\Delta\bar{G}_B$ values are related by:

$$\Delta\bar{G}_{BH^+} - \Delta\bar{G}_B = RT \ln \frac{K_{eff}}{K} \qquad \text{(Eq. 1)}$$

where:

$$K = a_{H^+} \frac{a_B}{a_{BH^+}} \qquad \text{(Eq. 2)}$$

and:

$$K_{eff} = a_{H^+} \frac{\bar{C}_B}{\bar{C}_{BH^+}} \qquad \text{(Eq. 3)}$$

The activities are defined by $\bar{G}_i = \bar{G}_i^* + RT \ln a_i$. Because the system is heterogeneous, external electric fields are present (due to the charged clay). As a consequence, $\Delta\bar{G}_i$ may be identified with the electrochemical potential (3), and the activity a_i is regarded as the total activity as described by Low (4). This activity is not to be confused with the activity commonly applied to homogeneous systems (*i.e.*, solutions, for which the activity is defined in terms of the chemical potential and relates to field-free systems). The K_{eff} value is simply an effective or apparent equilibrium constant, and $\bar{C}_i$ (i = B, BH^+, H^+) are average suspension concentrations.

If the ratio of K_{eff} to K is less than one (*i.e.*, $pK_{eff} - pK > 0$), then $\Delta\bar{G}_{BH^+} < \Delta\bar{G}_B$. In addition, when $K_{eff}/K = 1$, then $\Delta\bar{G}_{BH^+} = \Delta\bar{G}_B$. Consequently, K_{eff}/K and $pK_{eff} - pK$ serve as parameters indicating the degree of equilibrium displacement (or enhanced protonation) due to BH^+–clay and B–clay interactions.

The $\Delta\bar{G}_{BH^+}$ and $\Delta\bar{G}_B$ values can be measured individually under certain experimental conditions. If the system is sufficiently dilute with respect to clay and all other solutes, then $\Delta\bar{G}_{BH^+}$ and $\Delta\bar{G}_B$ are given by:

$$\Delta\bar{G}_{BH^+} = RT \ln (1 - f) \left(\frac{K_{eff} + a_{H^+}}{K + a_{H^+}}\right) \qquad \text{(Eq. 4)}$$

$$\Delta\bar{G}_B = RT \ln (1 - f) \left(\frac{K}{K_{eff}}\right) \left(\frac{K_{eff} + a_{H^+}}{K + a_{H^+}}\right) \qquad \text{(Eq. 5)}$$

where f is the fraction of base initially added to the system that is bound to the clay.

This approach may be applied to any acid–base equilibrium of tetracycline (Schemes II–IV) (5), and either K_j (j = 1, 2, 3) or $K_{j,eff}$ can be determined.

$$H_3T^+ \overset{K_1}{\rightleftarrows} H_2T^0 + H^+$$

Scheme II

$$H_2T^0 \overset{K_2}{\rightleftarrows} HT^- + H^+$$

Scheme III

$$HT^- \overset{K_3}{\rightleftarrows} T^{2-} + H^+$$

Scheme IV

Both $K_{j,eff}$ and $\Delta\bar{G}_i$ (i = H_3T^+, H_2T^0, HT^-, T^{2-}) depend on the composition of the system, *i.e.*, pH, ionic strength, temperature, pressure, other solutes, and $\bar{C}_i$. As $\bar{C}_i \to 0$, $K_{j,eff}$ and $\Delta\bar{G}_i$ approach a definite value that reflects an intrinsic interaction of species i with the clay surface, independent of $\bar{C}_i$.

EXPERIMENTAL

Materials—Tetracycline hydrochloride and all other chemicals were official or reagent grade. All water was double distilled. Wyoming bentonite[1] was the source of the montmorillonite used. Characterization by X-ray diffraction[2] and IR spectroscopy[3] showed the Wyoming bentonite

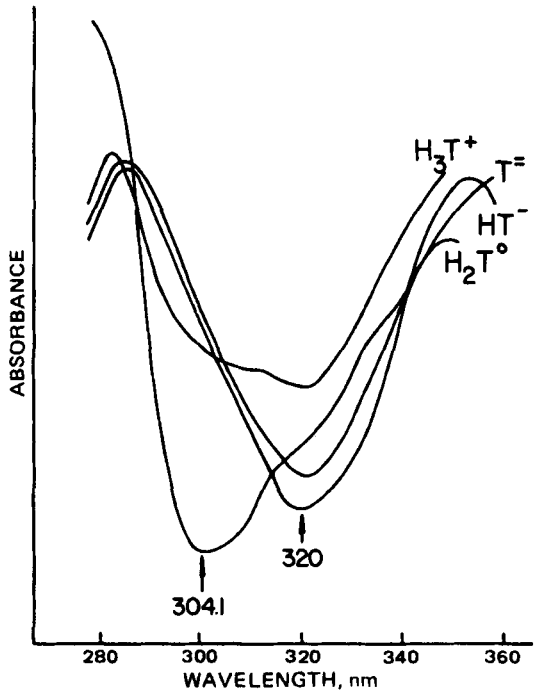

Figure 1—*UV spectra of the four ionic species of tetracycline in aqueous solution (20 mg/liter).*

to be montmorillonite containing a small amount of quartz. The Wyoming bentonite fraction (<2 μm) was washed five times with 1 *M* NaCl and then washed with water until it was salt free, as evidenced by the silver nitrate test to produce the sodium-saturated montmorillonite used. The suspension was passed through a 300-mesh screen to remove any extraneous matter and diluted to obtain a 1% sodium-saturated montmorillonite suspension.

Stock solutions of tetracycline, 200 mg/liter, were prepared fresh before each titration and passed through an ultrafine sintered-glass filter.

Determination of *K* and K_{eff}—UV spectroscopic titrations (6) were performed to determine $\overline{C}_B/\overline{C}_{BH^+}$ as required for Eq. 3. In very dilute solutions (clay free), $\overline{C}_B/\overline{C}_{BH^+} = a_B/a_{BH^+}$ in Eq. 2. The absorbance, A, of a tetracycline solution is related to $\overline{C}_B/\overline{C}_{BH^+}$ by:

$$\frac{\overline{C}_B}{\overline{C}_{BH^+}} = \frac{A - A^+}{A^- - A} \qquad \text{(Eq. 6)}$$

where A^+ is the absorbance when all of the tetracycline is present as BH^+ and A^- is the absorbance when all tetracycline is present as B.

Thus, experimental values for $\overline{C}_{H_2T^0}/\overline{C}_{H_3T^+}$, $\overline{C}_{HT^-}/\overline{C}_{H_2T^0}$, and $\overline{C}_{T^{2-}}/\overline{C}_{HT^-}$ were obtained.

The titrations were performed at a wavelength where A^+ and A^- were significantly different. As shown in Fig. 1, the greatest absorbance difference between H_3T^+ and H_2T^0 occurs at 304.1 nm, while the maximum difference among H_2T^0, HT^-, and T^{2-} occurs at 320 nm. The bandwidth was set at 0.8 nm for all titrations.

Titration curves were constructed by preparing a series of solutions or suspensions at different pH^b values and determining the absorbance at 304.1 nm for the first ionization or 320 nm for the second and third ionizations of tetracycline. Equal volumes of 0.01 *N* HCl and NaOH were pipetted into two 100-ml volumetric flasks, depending on the pH^b desired. Ten milliliters of a 200-mg/liter tetracycline stock solution was added to the sample flask. If sodium chloride was to be added, a level of either 25 mg/liter or 5.844 g/liter was added to both the sample and reference flasks. The sample and reference flasks were diluted to ~95 ml with water. Two milliliters of the 1% sodium-saturated montmorillonite suspension was added to both flasks prior to dilution to 100 ml with water. This procedure minimized the change in pH^b while mixing the tetracycline with the clay. All sample suspensions contained 20 mg of tetracycline and 200 mg of sodium-saturated montmorillonite/liter.

The pH^b of a stirred 50-ml aliquot of the sample suspension was measured[4] after the pH^b had stabilized.

The difference in the absorbance[5] of the sample and reference suspensions, $A_s - A_r$, at the appropriate wavelength was taken as A in Eq. 6. The absorbance at different pH^b values was plotted to construct the titration curves.

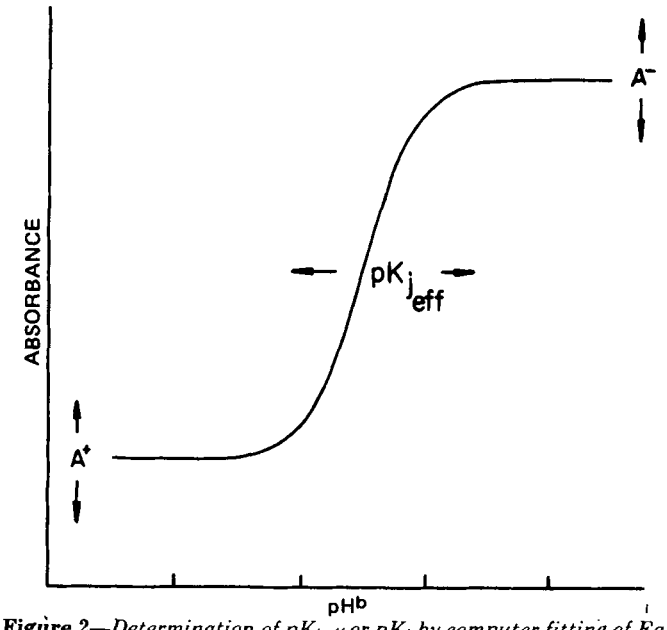

Figure 2—*Determination of $pK_{j,eff}$ or pK_j by computer fitting of Eq. 7 to pH^b versus A.*

The average concentration ratio was computed from the titration curve and used in Eq. 4 to obtain $pK_{j,eff}$. These calculations were restricted to values of $a^b_{H^+}$ such that $0.1K_{j,eff} \leq a^b_{H^+} \leq 10K_{j,eff}$.

In theory, the value of $pK_{j,eff}$ pertains only to the pH^b at which it is measured. However, $pK_{j,eff}$ usually is independent of pH^b over the range of interest, and the plot of pH^b *versus* A has a sigmoidal appearance. Based on this assumption, the Henderson–Hasselbalch equation (rewritten here in the terms of absorbance) describes the pH^b *versus* A graph:

$$A = \frac{A^+ + A^- 10^{(pH^b - pK_{j,eff})}}{1 + 10^{(pH^b - pK_{j,eff})}} \qquad \text{(Eq. 7)}$$

With a computer, the values for A^+, A^-, and $pK_{j,eff}$ were varied until Eq. 7 gave the best fit for the experimental values of pH^b and A (Fig. 2).

Determination of $\Delta\overline{G}_i$—Equations 4 and 5 may be used to calculate $\Delta\overline{G}_i$ following the determination of the fraction bound at a particular pH^b. This determination was accomplished following the pH^b and A measurements described in the preceding section by centrifuging ~30 ml of the remaining sample and reference suspensions and collecting the supernate. Sufficient acid was added to 15 ml of the supernate to ensure that all of the tetracycline was in the protonated form. The absorbance of the sample supernate, A_s, and the reference supernate, A_r, was measured at 304.1 nm.

The fraction bound, f, was calculated from:

$$f = \frac{A_0 - (A_s - A_r)}{A_0} \qquad \text{(Eq. 8)}$$

where A_0 represents the absorbance for a solution containing only the protonated species having a concentration equal to C_0, the initial concentration.

Since $\Delta\overline{G}_i$ is in general a function of pH^b, its value pertains only to the pH^b at which it is calculated. In addition, Eqs. 4 and 5 were developed based on a single equilibrium where only two species are present at any $a^b_{H^+}$ value. These equations cannot be applied to compounds exhibiting multiple acid–base equilibria if significant quantities of a third species are present at the $a^b_{H^+}$ value of interest. Furthermore, $\Delta\overline{G}_i$ values should not be determined at $a^b_{H^+}$ values where very little of species i exists. In general, $\Delta\overline{G}_i$ values are most accurate when measured at pH^b conditions where a substantial amount of species i exists (which can be monitored readily) and where any interference from a second ionization is minimal. These restrictions were followed in all of the $\Delta\overline{G}_i$ determinations.

RESULTS AND DISCUSSION

The first acid–base equilibrium of tetracycline was strongly affected by sodium-saturated montmorillonite as seen in Fig. 3, where titration

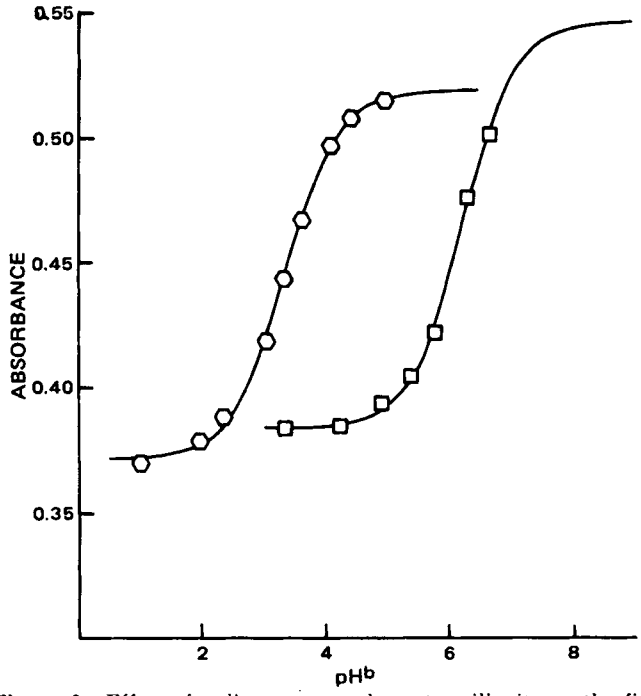

Figure 3—*Effect of sodium-saturated montmorillonite on the first acid–base equilibrium of tetracycline. Key:* ○, *aqueous solution; and* □, *sodium-saturated montmorillonite.*

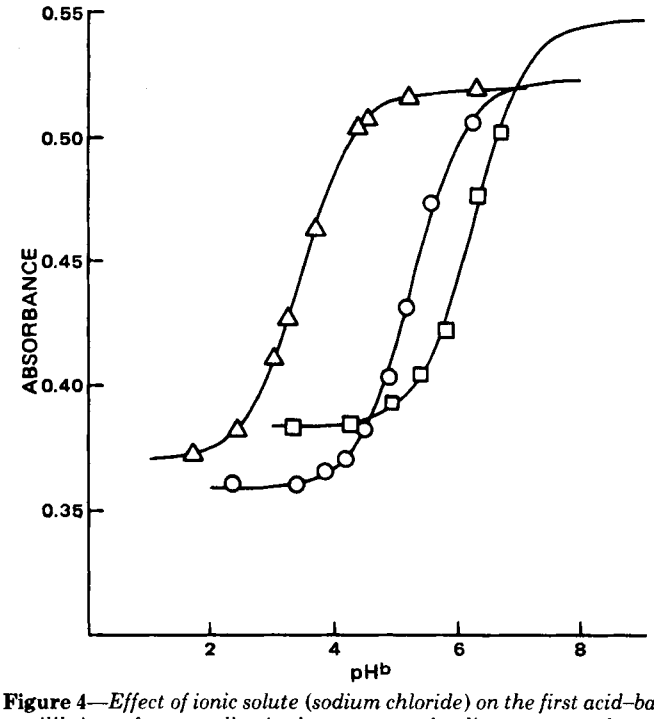

Figure 4—*Effect of ionic solute (sodium chloride) on the first acid–base equilibrium of tetracycline in the presence of sodium-saturated montmorillonite. Key:* □, *no sodium chloride;* ○, *25 mg of sodium chloride/liter; and* △, *5.844 g of sodium chloride/liter.*

curves that best fit the experimental pH^b *versus A* data are plotted. In aqueous solution, pK_1 was 3.34, which agrees well with previously reported values (5, 7). However, in the presence of sodium montmorillonite, $pK_{1,eff}$ was 6.23. The interaction of the protonated species of tetracycline, H_3T^+, with the negative clay surface was responsible for this shift of almost three pH^b units.

As seen in Table I, $\Delta\overline{G}_{H_3T^+}$ was −3.99 kcal/mole, indicating a much greater stabilization of the H_3T^+ species than the H_2T^0 species ($\Delta\overline{G}_{H_2T^0}$ = −0.03 kcal/mole). This stabilization of the H_3T^+ species caused a shift in the acid–base equilibrium in favor of the H_3T^+ species.

The interaction of H_3T^+ with sodium-saturated montmorillonite was affected by other ionic species in the system. As seen in Fig. 4, the shift in the titration curve was reduced in the presence of 25 mg of sodium chloride/liter and approached the solution titration curve when large amounts of sodium chloride (5.844 g/liter) were present.

The value for $pK_{1,eff}$ calculated from Fig. 4 approached pK_1, and $\Delta\overline{G}_{H_3T^+}$ approached zero as large sodium chloride concentrations were added to the tetracycline–sodium-saturated montmorillonite suspension (Table I). The interaction of the H_2T^0 species remained negligible ($\Delta\overline{G}_{H_2T^0}$ = −0.04 kcal/mole) in the presence of sodium chloride.

The titration curve for the second ionization was displaced slightly in the presence of sodium montmorillonite (Fig. 5). As was observed in the first ionization, sodium chloride reduced the displacement of the titration curve.

Calculation of $pK_{2,eff}$, $\Delta\overline{G}_{H_2T^0}$, and $\Delta\overline{G}_{HT^-}$ based on the titration curves in Fig. 5 is tenuous due to the weak interaction of the H_2T^0 and HT^- species with the clay. In addition, the close proximity of pK_2 and pK_3 (7.86 and 9.51, respectively) means that more than two ionic species of tetracycline probably are present in the system in the pH range of interest. However, Eq. 7 was applied to the titration data in Fig. 5, and the resulting increase in $pK_{2,eff}$ was only 0.15 in the presence of the sodium-saturated montmorillonite. This slight increase in $pK_{2,eff}$ may suggest that the zwitterionic form of tetracycline, H_2T^0, interacts slightly with the clay surface. However, this conclusion is made cautiously because of the cited limitations. Furthermore, the values obtained for $\Delta\overline{G}_{H_2T^0}$ and $\Delta\overline{G}_{HT^-}$ were too small to be considered significant.

Virtually no change in the titration curve for the third ionization of tetracycline was observed in the presence of sodium-saturated montmorillonite (Fig. 6), and it was concluded that the clay does not interact significantly with the HT^- and T^{2-} species.

The data in Figs. 3–6 and Table I indicate that the negatively charged sites on montmorillonite are responsible for the strong interaction with the protonated species of tetracycline, H_3T^+. However, this interaction

Table I—Effects of Sodium-Saturated Montmorillonite on Acid–Base Equilibria of Tetracycline

Key:* ○, *aqueous solution;* □, *sodium-saturated montmorillonite suspension;* ○, *sodium-saturated montmorillonite suspension containing 25 mg of sodium chloride/liter; and* △, *sodium-saturated montmorillonite suspension containing 5.844 g of sodium chloride/liter.*

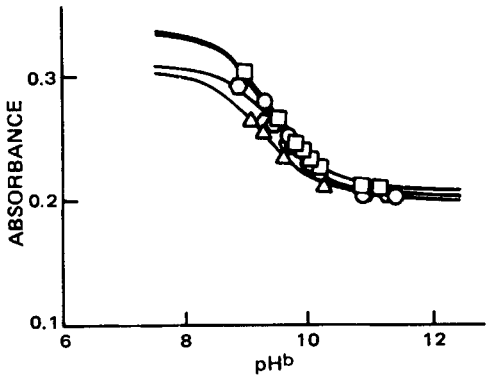

Figure 6—*Effect of sodium-saturated montmorillonite and added ionic solute (sodium chloride) on the third acid–base equilibrium of tetracycline. Key: ○, aqueous solution; □, sodium-saturated montmorillonite suspension; ○, sodium-saturated montmorillonite suspension containing 25 mg of sodium chloride/liter; and △, sodium-saturated montmorillonite suspension containing 5.844 g of sodium chloride/liter.*

is reduced in the presence of other ions such as sodium chloride. It is hypothesized that sodium ions compete with H_3T^+ for the negative sites on the clay surface or, equivalently, that sodium ions screen the negatively charged clay surface, thereby reducing the apparent negative charge of the clay surface. Sodium chloride also may affect the interaction by altering the state of dispersion of the clay so that negative sites are less accessible to the H_3T^+ ions.

Figure 7 shows that $\Delta\overline{G}_{H_3T^+}$ is affected by pH^b and the presence of an additional ionic solute such as sodium chloride. The $\Delta\overline{G}_{H_3T^+}$ value was calculated at each pH^b using Eq. 4 when $(A - A^+)$ and $(A^- - A)$ in Eq. 6 were large enough to determine $pK_{1,eff}$ accurately; if $a^b_{H^+} \gg K_{1,eff}$, $\Delta\overline{G}_{H_3T^+}$ was calculated from:

$$\Delta\overline{G}_{H_3T^+} = RT \ln (1 - f) \frac{a_{H^+}}{K + a_{H^+}} \qquad \text{(Eq. 9)}$$

The change in $\Delta\overline{G}_{H_3T^+}$ seen in the salt-free sodium-saturated montmorillonite suspension and the clay suspension containing a small amount of sodium chloride (25 mg/liter) indicate that increased interaction between H_3T^+ and the clay occurred as the pH^b was increased. At low pH^b values, protons apparently compete with H_3T^+ for the negative clay sites. At pH 4–6, $\Delta\overline{G}_{H_3T^+}$ reached a constant value, indicating an interaction free of competition with H^+. The plateau value of $\Delta\overline{G}_{H_3T^+}$ probably represents an intrinsic interaction of H_3T^+ with the clay since large changes in $\overline{C}_{H_3T^+}$ have little effect on $\Delta\overline{G}_{H_3T^+}$.

The $\Delta\overline{G}_{H_3T^+}$ values seen in Fig. 7 clearly show the reduced interaction of H_3T^+ and the sodium-saturated montmorillonite due to the competitive effect of the added ionic solutes. The effect of pH on $\Delta\overline{G}_{H_3T^+}$ was diminished in the presence of a low level of sodium chloride (25 mg/liter) and could not be observed in a suspension containing 5.844 g of sodium chloride/liter.

The fraction bound curves in Fig. 8 support the conclusions reached based on the titration curves. The fraction of tetracycline bound to the sodium-saturated montmorillonite increased with pH^b until a maximum

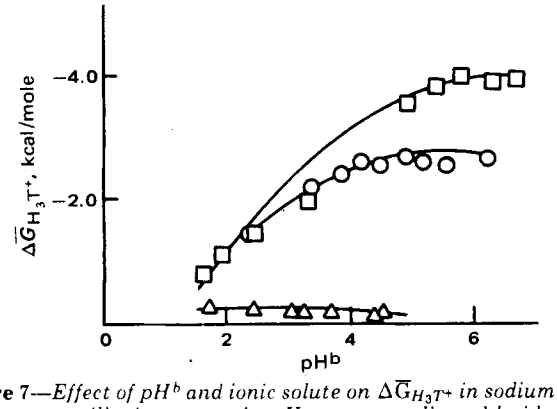

Figure 7—*Effect of pH^b and ionic solute on $\Delta\overline{G}_{H_3T^+}$ in sodium-saturated montmorillonite suspension. Key: □, no sodium chloride; ○, 25 mg of sodium chloride/liter; and △, 5.844 g of sodium chloride/liter.*

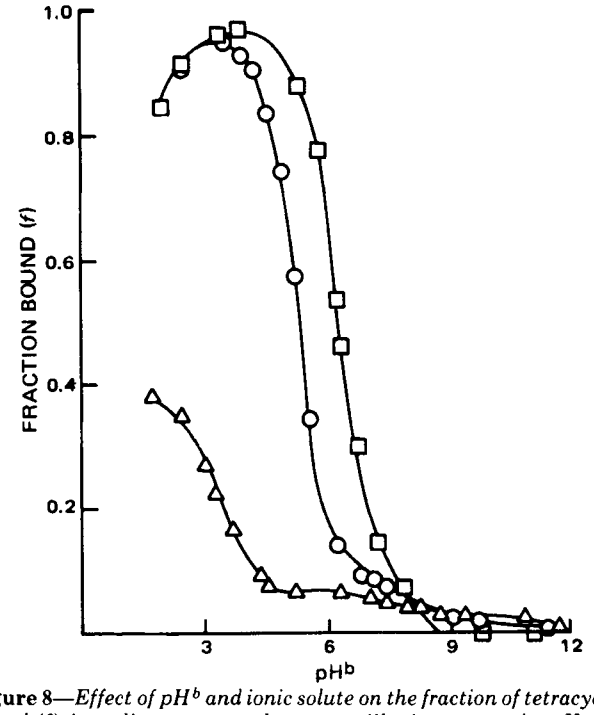

Figure 8—*Effect of pH^b and ionic solute on the fraction of tetracycline bound (f) in sodium-saturated montmorillonite suspension. Key: □, no sodium chloride; ○, 25 mg of sodium chloride/liter; and △, 5.844 g of sodium chloride/liter.*

was observed at pH^b 3.8. This behavior agrees with the reduced interaction of H_3T^+ and clay in the presence of high proton concentrations (Fig. 7). A maximum in the adsorption of tetracycline occurred under pH^b conditions at which the competitive effect of protons was low and the H_3T^+ concentration was still high. This situation occurred at pH 3.8 when no added salt was present. The concentration of H_3T^+ was very high at this pH^b because the $pK_{1,eff}$ under these conditions was 6.23 (Table I).

In the presence of low concentrations of sodium chloride (25 mg/liter), a high fraction of tetracycline was bound by the clay. However, the maximum adsorption occurred at pH^b 3.4, probably reflecting the smaller displacement of $pK_{1,eff}$ in the presence of sodium chloride (Table I).

At high added salt concentrations (5.844 g/liter), only 38% of the tetracycline was adsorbed by the clay (Fig. 8). Under these conditions, H_3T^+ and H^+ cannot compete effectively with sodium ions for negative clay adsorption sites. As a result, $\Delta\overline{G}_{H_3T^+}$ was −0.27 kcal/mole and $pK_{1,eff}$ approached pK_1 (Table I). Thus, a greatly diminished fraction bound curve is seen.

The fraction of tetracycline bound to the sodium-saturated montmorillonite decreased rapidly in all three conditions shown in Fig. 8 because the pH^b conditions allowed the zwitterionic form of tetracycline, H_2T^0, to appear in the system. The $\Delta\overline{G}_{H_2T^0}$ values ranging from −0.03 to −0.04 kcal/mole (Table I) indicate little interaction of this ionic species with the clay.

In the pH^b region above 8.5, the fraction of tetracycline bound to the clay approached zero (Fig. 8) since the pH^b was above $pK_{2,eff}$ (Table I) and only the anionic forms of tetracycline (HT^- and T^{2-}), which cannot interact with the negative clay surface, were present.

Figure 8 shows that a small fraction of tetracycline was bound to the sodium-saturated montmorillonite in the pH region where the anionic forms of tetracycline were present in suspensions containing excess sodium chloride. The added sodium ions are believed to screen the anion–clay repulsive forces by collapsing the electrical double layer associated with the clay and thus allow physical adsorption of the HT^- and T^{2-} species.

The behavior of the fraction bound curves at higher pH^b conditions provides further understanding of the small shift in the titration curve for the second acid–base equilibrium of tetracycline shown in Fig. 5. The interaction of the zwitterionic form of tetracycline with the clay probably is a physical adsorption indicated by the low $\Delta\overline{G}_{H_2T^0}$ value associated with the interaction. This weak interaction led to the displacement of pK_2 from 7.86 to a $pK_{2,eff}$ of 8.02 in the presence of clay. The addition of sodium chloride to the system allows the anionic conjugate base, HT^-, to interact with the clay by collapsing the electrical double layer, and $pK_{2,eff}$ decreased to 7.98 and 7.92 with 25 mg and 5.844 g of sodium chloride/liter,

respectively. This result suggests that H_2T^0 and HT^- interact to approximately the same degree with the clay surface so that $\Delta\bar{G}_{H_2T^0}$ is approximately equal to $\Delta\bar{G}_{HT^-}$, as would be expected if the mechanism of adsorption for each species is physical adsorption.

The distribution of the ionic species of tetracycline in an aqueous solution and in an aqueous sodium-saturated montmorillonite suspension, based on the respective values of pK_1, pK_2, and pK_3 and $pK_{1,eff}$, $pK_{2,eff}$, and $pK_{3,eff}$ found in this study, is shown in Fig. 9. The changes in the acid–base equilibria of tetracycline due to the stabilizing effect of the montmorillonite surface caused the H_3T^+ species to be present over a wider pH range than expected based on acid–base equilibria in solution. In addition, the H_2T^0 form was present over a much smaller pH region when in a clay suspension.

Previous investigators concluded that the zwitterion, H_2T^0, was adsorbed significantly by montmorillonite (1). This conclusion was based on the pK_j (j = 1, 2, 3) values for tetracycline in aqueous solution rather than the $pK_{j,eff}$ (j = 1, 2, 3) values appropriate for clay systems. Feldkamp and White (8) suggested that the ability of a clay to interact with weak bases may increase in concentrated mixtures. Thus, dramatic shifts in species distributions may occur in concentrated suspensions of tetracycline and montmorillonite.

The changes in the distribution of the ionic species of a drug due to interactions with a clay surface may have important consequences in drug therapy. For example, the antimicrobial activity of tetracycline and other antibiotics was reported to be diminished in the presence of clays (9). Tetracycline exhibits its maximum antimicrobial activity between pH 5.5 and 6.0 (10), the region where the zwitterionic form predominates in aqueous solution (Fig. 9). The H_2T^0 species appears to be absorbed preferentially across the GI membranes due to its lipophilic nature (7). In the presence of montmorillonite, the zwitterionic form of tetracycline exists over a dramatically reduced pH region. As a consequence, the most readily absorbable form of tetracycline may be present over a smaller region of the GI tract.

The distribution changes for the ionic forms of a drug also may provide insights into the catalytic effects of a clay on drug degradation. For example, the sequence of steps illustrated in Scheme V is associated with acid-catalyzed hydrolysis of drugs.

$$\text{drug} + H^+ \rightleftarrows \text{drug-}H^+ + H_2O \rightarrow \text{degradation products}$$

Scheme V

The first step of the hydrolysis involves protonation of the drug, followed by nucleophilic attack by water. The degradation rate depends on the concentration of protonated drug. Interaction of the drug with a clay surface may cause a shift in the acid–base equilibrium of the drug that favors the protonated form and thus leads to an accelerated hydrolysis rate in the presence of a clay.

Along with the effect of an increased concentration of reactant (protonated drug), there is the possibility that the activation energy for the hydrolysis reaction might be increased due to the drug–clay interaction. The net effect on the reaction rate will vary for each system, depending on the relative magnitudes of each factor.

Clays have been suggested as a vehicle for controlled-release dosage forms (11). An understanding of the effect of drug–clay interactions on the acid–base equilibria of the drug should provide the information needed to select the proper drug and clay to obtain the desired *in vivo* release pattern.

In summary, the acid–base equilibria of drugs can be affected greatly by interaction with clay surfaces. The thermodynamic quantities, $K_{j,eff}$ and $\Delta\bar{G}_i$, are useful for quantifying and monitoring drug–clay interactions and should be used in the formulation of clay-containing drug products as well as in the evaluation of the effects of the coadministration of drugs and clays.

Abstract □ The adsorption of tetracycline by clays commonly used in pharmacy can be predicted if the identity and character of the commercial clay sample are established. X-ray diffraction, IR spectroscopy, and chemical analysis were used to identify the clay component and any nonclay diluents present in a series of commercial pharmaceutical grade clays. The major clay components were montmorillonite, hectorite, attapulgite, saponite, and kaolinite. The clay structure, the nature of the exchangeable cation, and the presence of nonclay components are important factors affecting the tetracycline–clay interaction. In general, clay structures with a high surface charge lead to a greater interaction with the protonated form of tetracycline, while interaction with the zwitterionic form of tetracycline occurs in clay structures with minimal surface charge. The presence of multivalent, exchangeable cations on the clay surface diminishes interaction with the protonated form of tetracycline. Nonclay components such as calcite and dolomite increase the interactions of the zwitterionic and anionic forms of tetracycline with the clay.

Keyphrases □ Tetracycline hydrochloride—adsorption onto clay, interaction with pharmaceutical grade clay, adsorptive properties of clay □ Clay—pharmaceutical grade, adsorption of tetracycline, isomorphous substitution □ Adsorption—tetracycline onto pharmaceutical grade clays

The unique properties of clays have led to their use in pharmaceuticals for both therapeutic effects and excipient action. The crystal structure of clay minerals is well understood, and the behavior of clays in pharmaceutical systems is predictable based on structural considerations. Thus, the identity and characterization of a clay are of prime importance to the pharmaceutical scientist.

The purpose of this study was to illustrate the importance of a complete characterization of clays used in pharmaceuticals so that their behavior in formulations and in a patient's drug regimen can be predicted. The influence of clay structure, the nature of the exchangeable cation, and the presence of nonclay components on the interaction of tetracycline with reference or commercial samples of montmorillonite, hectorite, saponite, attapulgite, and kaolinite were studied.

BACKGROUND[1]

The basic structure of clays consists of octahedra of aluminum and magnesium in combination with silica tetrahedra to give layer-like or fibrous structures. Cationic-exchange properties can arise in these structures through isomorphous substitution, *i.e.*, aluminum for silicon, magnesium for aluminum, *etc.* A manifestation of isomorphous substitution is the swelling properties of certain clays with high cation-exchange capacity.

The kaolin group of minerals consists of sheets of silica tetrahedra and alumina octahedra shared in a 1:1 ratio. These minerals have little or no isomorphous substitution and normally are nonswelling in aqueous solutions.

Smectites belong to the 2:1 (ratio of silica tetrahedra to alumina and/or magnesia octahedra) structural group of clays and include montmorillonite, hectorite, and saponite. In these structures, an alumina or magnesia octahedral layer is sandwiched between two silica tetrahedral sheets. Structures are designated as dioctahedral when aluminum occupies the octahedral sites and as trioctahedral when magnesium (or other divalent ions) or lithium occupies the octahedral sites.

Isomorphous substitution occurs in both the tetrahedral and octahedral layers of the 2:1 minerals and gives rise to moderate to high cation-exchange capacities.

Isomorphous substitutions also influence the lattice parameters in clays and appear to be correlated to the swelling properties of smectites. As a consequence of the expanding properties, the smectites also possess very high surface areas.

Montmorillonite represents the aluminum-containing smectite group (dioctahedral). The magnesium end member of the smectite group is designated as saponite (trioctahedral). Substitution of lithium for a portion of the magnesium in trioctahedral compositions results in a clay mineral designated as hectorite (trioctahedral).

Fibrous minerals are represented by sepiolite and attapulgite. These minerals are classified as 2:1-type minerals, but the crystal growth is limited to the c dimension, resulting in ribbons of the 2:1 layer attached at their longitudinal edges. A cross section of the fiber gives a checkerboard arrangement of ribbons and voids with no possibility of expansion.

It appears that fibrous minerals have little or no true cation-exchange capacity. However, because of the very thin nature of the ribbons, the external surface area is moderately high. Fibrous minerals also are very porous due to the channels between the ribbons. However, the dimensions of the pores are such that only small molecules such as water, ammonia, and lower alcohols can be accommodated in them.

EXPERIMENTAL

Materials—Tetracycline hydrochloride and all other chemicals were official or reagent grade. Montmorillonite (Wyoming bentonite), hectorite (Hector, Calif.), attapulgite (Georgia palygorskite), and kaolinite (Hydrite-10) were the reference standards[2]. Samples of pharmaceutical grade clays claimed to represent these minerals were obtained commercially as follows: bentonite USP[3], hectorite[4], saponite[5], attapulgite[6], and kaolin NF[7].

Unless otherwise indicated, all clays were used as received.

The sodium form of the reference clays was prepared by washing a 2% suspension of the clay with 1 *M* NaCl. The washing procedure was repeated five times, and excess salt was removed by repeated washing with water until the addition of silver nitrate to the supernate gave a negative chloride test. Clays exhibiting a cation-exchange capacity that were treated in this manner are termed sodium saturated; clays such as kaolinite and attapulgite, which have little or no cation-exchange capacity, are termed sodium treated if washed with sodium chloride in this manner.

The calcium form of montmorillonite was prepared in an analogous manner using 1 *M* $CaCl_2$ as the exchanging solution.

Preliminary examination of the samples of hectorite and commercial saponite by X-ray diffraction showed significant quantities of calcite and dolomite as nonclay diluents. The removal of these carbonates was attempted by a modification of the pH-stat technique (1). A 2% clay sus-

pension, 250 ml, was reacted for 24 hr at pH 5.0 in an automatic titration apparatus[8]. The suspension then was washed repeatedly with water until it was salt free as evidenced by the silver nitrate test. The diffractograms of hectorite in Fig. 1 show that the procedure was effective in removing calcite but not dolomite. Clay samples treated in this manner will be referred to as purified.

X-Ray Diffraction—Randomly oriented powder specimens of each clay were prepared using the McCreery method (2), and diffractograms[9] were recorded from 5 to 63° 2θ.

The X-ray step scans were used to determine accurately the 060 peak of commercial saponite. A mixture containing 15% silicon[10] was prepared by trituration and filled into a McCreery mount; X-ray step scans were recorded from 58 to 63° 2θ at a step of 0.02° and a time interval of 90 sec. The 060 spacing of commercial saponite was determined in comparison to the silicon peak at 56.12° 2θ (3).

The Greene-Kelly test (4) is useful in distinguishing between dioctahedral and trioctahedral structures within the smectite group of clays and was utilized in the characterization of the commercial saponite sample. A 1% clay suspension, consisting of the <2-μm fraction, was washed five times with 1 *M* lithium chloride. Excess salt then was removed by washing with double-distilled water until it was salt free by the silver nitrate test. The lithium-saturated clay was air dried on a glass slide and then heated to 200–300° for 12 hr. The sample then was saturated with glycerol using the vaporization method (5); X-ray diffractograms were recorded from 3 to 11° 2θ.

Glycerol solvation was used to investigate the presence of montmorillonite-like impurities in attapulgite, commercial attapulgite, kaolinite, and kaolin NF. Glycerol enters montmorillonite-type minerals and causes a characteristic expansion of the basal spacing to ~17.5 Å (6). Glycerol solvation was achieved by dispersing the clay in a 3% glycerol solution through moderate agitation produced by an ultrasonic probe[11]. The dispersions were air dried on a glass slide, and X-ray diffractograms were recorded from 4 to 8° 2θ.

IR Spectroscopy—Air-dried films of clay were prepared on zinc sulfide windows[12] (7) and used to record the IR spectra[13].

Studies of pleochroism of the IR bands associated with hydroxyl stretching may be used to determine the orientation of hydroxyl bond axes in layer silicates (8) and were used in characterizing commercial saponite and commercial hectorite. An orientation effect is positive evidence for a structure containing trioctahedral character. Self-supporting clay films were prepared by air drying 1% clay suspensions on polyethylene terephthalate films[14]. The clay films were separated from the polyethylene terephthalate film by bending over a sharp corner. IR spectra of the clay films were recorded from 4000 to 3300 cm^{-1} at perpendicular and various incident angles to the IR beam.

Transmission Electron Photomicrographs—Electron microscopic examination[15] of attapulgite was undertaken to confirm the presence of a montmorillonite-type impurity.

Presence of Organic Matter—The peroxide test (9) was used to detect organic matter in the clay samples. Thirty milliliters of 30% H_2O_2 was added to 15 ml of a 1% clay suspension and heated on a steam plate for 15 min. The treated clay was centrifuged along with an untreated reference suspension. The color of the sample sediment was compared to that of the reference sediment. The presence of organic matter was indicated when the color of the sample sediment was significantly lighter than that of the reference sediment.

UV Spectroscopic Titrations—Displacement of the pK_1 of tetracycline in clay suspensions was determined by spectroscopic titration. The $pK_{1,eff}$ and partial molar Gibbs free energy, $\Delta\bar{G}_i$, for H_3T^+ and H_2T° were calculated from the spectroscopic titration curve using the procedure of Feldkamp and White (10).

Titration curves were constructed by preparing a series of tetracycline–clay suspensions at different pH^b (bulk pH) values and determining the absorbance at 304.1 nm. A typical point on the titration curve was obtained by adding equal volumes of 0.01 *N* HCl or NaOH to two 100-ml volumetric flasks, depending on the pH^b desired. Ten milliliters of a

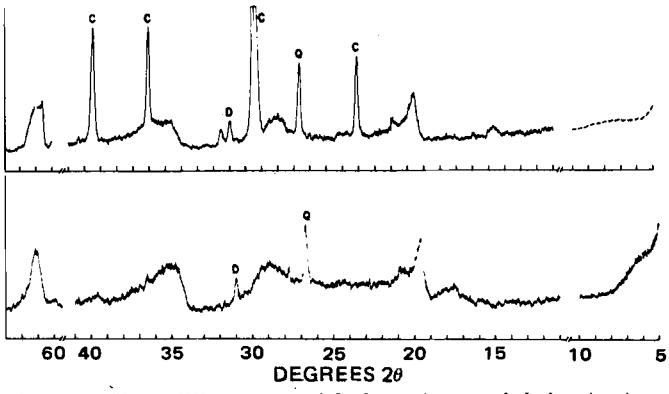

Figure 1—*X-ray diffractogram of the hectorite sample before (top) and after (bottom) carbonate removal using the pH-stat technique at pH 5.0. Key: Q, quartz; C, calcite; and D, dolomite. The solid line represents 100 counts/sec (cps) full scale. The dashed line represents 1000 cps full scale.*

200-mg/liter stock solution of tetracycline hydrochloride was added to the sample flask, and the sample and reference flasks were diluted to near volume with double-distilled water. Two milliliters of a 1% clay suspension was added to both flasks, and the flasks were diluted to 100 ml with distilled water. All sample suspensions contained 20 mg of tetracycline and 200 mg of clay/liter. The pH of the sample suspension was determined[16] after the pH reading stabilized. This value was checked by measuring the pH of the supernate (pH^b) after centrifugation. These pH readings differed by <1%.

This agreement in pH values was expected since the difference in the pH of the suspension and the pH of the supernate (*i.e.*, the suspension effect) increases as the concentration of the suspension increases (11). The clay suspensions studied were dilute enough so that the pH of the suspension accurately represented the system, *i.e.*, $pH_{susp} \simeq pH^b$.

The difference in the absorbance of the sample and the reference suspension ($A_s - A_r$) was measured and plotted *versus* pH^b to construct the titration curves.

Adsorption—The fraction of tetracycline bound by the clay at different pH^b conditions was determined using the samples from the spectroscopic titration experiment. A sample of each suspension was centrifuged, and 15 ml of supernate was collected. Sufficient hydrochloric acid was added to ensure that all of the tetracycline was in the protonated form. The absorbance was measured at 304.1 nm.

The fraction bound, f, was calculated from:

$$f = \frac{A_0 - (A_s - A_r)}{A_0} \qquad \text{(Eq. 1)}$$

where A_0 is the absorbance of a tetracycline solution (20 mg/liter) containing only the protonated form of tetracycline.

RESULTS AND DISCUSSION

Montmorillonite—The X-ray diffractogram of bentonite USP is compared to sodium-saturated montmorillonite in Fig. 2. A comparison of the reflections indicates that montmorillonite was the major clay component in bentonite USP. However, peaks other than those established for montmorillonite appeared in the region between 11 and 41° 2θ in the bentonite USP sample. The intense peak at 26.64° 2θ, corresponding to an interplanar spacing of 3.55 Å, indicates the presence of quartz (12). Other less intense peaks occurring at 11.7, 20.76, and 29.18° 2θ, corresponding to spacings of 7.56, 4.27, and 3.059 Å, are typical of gypsum (12). The peaks at 23.10, 29.42, and 39.40° 2θ, corresponding to spacings of 3.85, 3.035, and 2.285 Å, are associated with calcite (12).

The IR spectra shown in Fig. 3 also indicate that montmorillonite was the major clay constituent in the bentonite USP sample. Characteristic absorption bands for montmorillonite were observed in both samples at 3620, 1200–1000, 915, 878, and 850 cm^{-1} (13–15).

The presence of organic material was confirmed in bentonite USP but not in sodium-saturated montmorillonite using the peroxide test.

The dominant exchangeable cation in the bentonite USP sample was sodium, although 7.1 and 2.7% of the exchange capacity were satisfied by calcium and magnesium ions, respectively (7).

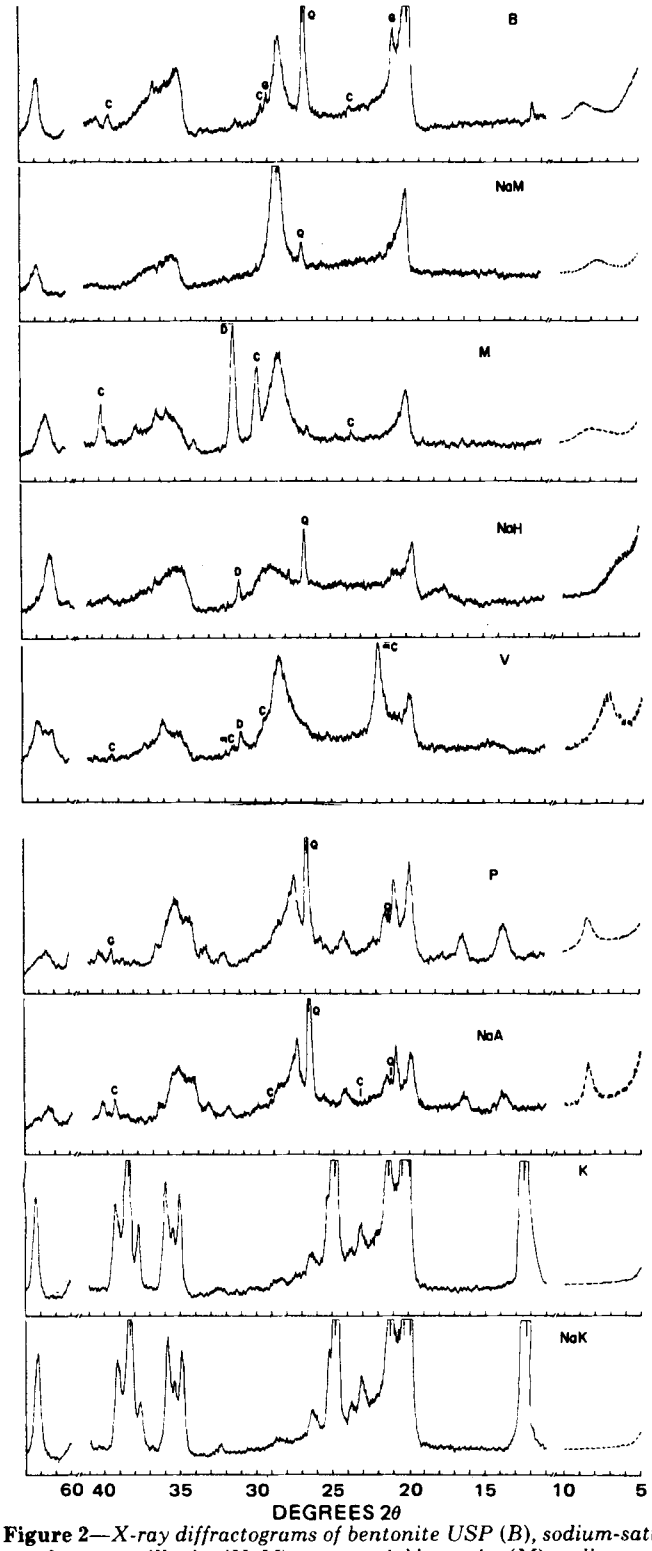

Figure 2—*X-ray diffractograms of bentonite USP (B), sodium-saturated montmorillonite (NaM), commercial hectorite (M), sodium-saturated hectorite (NaH), commercial saponite (V), commercial attapulgite (P), sodium-treated attapulgite (NaA), kaolin NF (K), and sodium-treated kaolinite (NaK). Peaks corresponding to quartz (Q), gypsum (G), dolomite (D), calcite (C), and α-cristobalite (αC) are identified. The solid line represents 100 cps full scale. The dashed line represent 1000 cps full scale.*

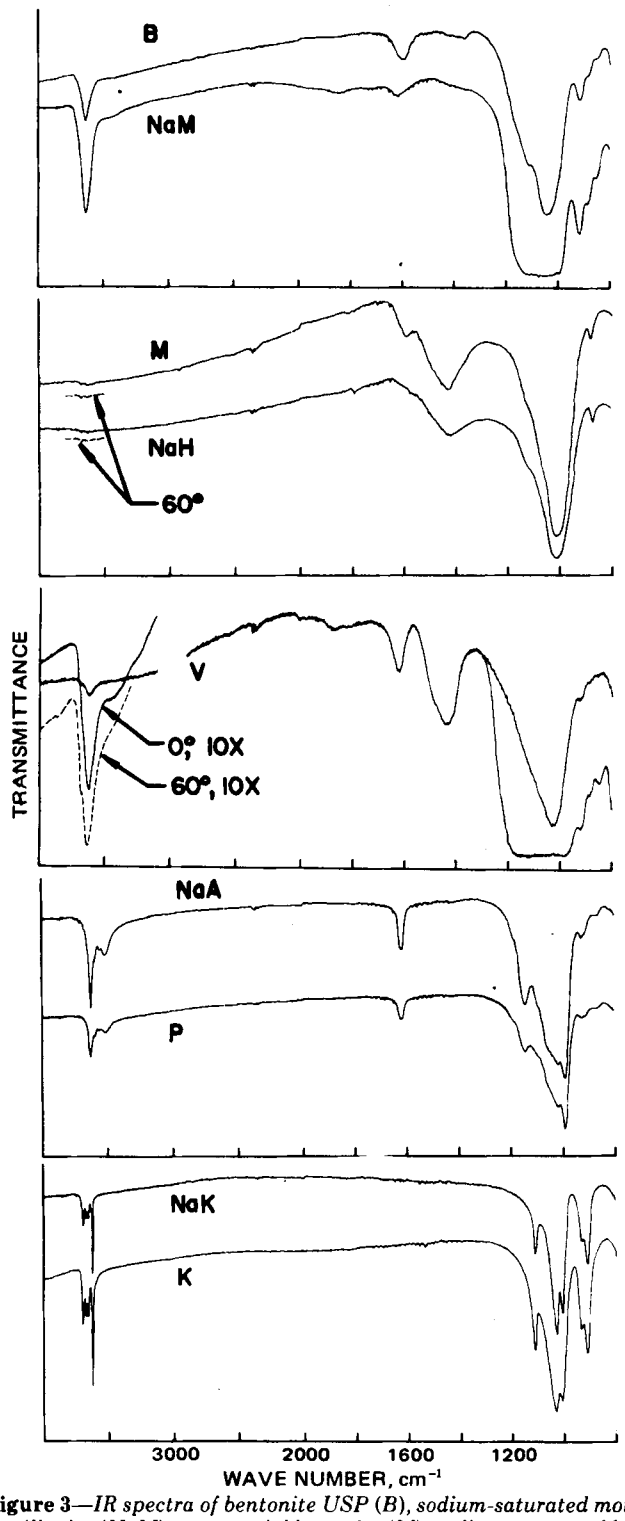

Figure 3—*IR spectra of bentonite USP (B), sodium-saturated montmorillonite (NaM), commercial hectorite (M), sodium-saturated hectorite (NaH), commercial saponite (V), commercial attapulgite (P), sodium-treated attapulgite (NaA), kaolin NF (K), and sodium-treated kaolinite (NaK).*

These findings for the composition of the bentonite USP sample are consistent with previous reports, which indicated that sodium montmorillonite is the major component of bentonite USP (16, 17). However, exchangeable calcium and magnesium ions may constitute 35–65% of the exchange capacity of bentonite USP, and bentonite USP has been found to contain 10–15% quartz as the primary nonclay diluent (18). Other nonclay minerals known to affect the behavior of bentonites include gypsum, calcite, biotite, feldspar, and cristobalite.

The effect of the exchangeable cation on the adsorptive properties of bentonite USP will be illustrated by examining the interaction of bentonite USP, sodium-saturated montmorillonite, and calcium-saturated montmorillonite with tetracycline. As indicated in Table I, interaction with all three forms of montmorillonite caused a shift in the first acid–base equilibrium of tetracycline so that the apparent equilibrium constant

Purified, sodium-saturated hectorite	5.99	−3.52	−0.04
Commercial saponite	4.27	−1.26	−0.17
Purified, sodium-saturated commercial saponite	5.23	−2.97	−0.05
Commercial attapulgite	3.51	−0.33	−0.14
Sodium-treated attapulgite	3.46	−0.20	−0.07
Sodium-treated kaolinite	3.02	0.00	−0.16

($pK_{1,eff}$) was significantly different than that observed in solution (pK_1). The magnitude of the shift reflects the degree of perturbation of the equilibrium (10). The greatest shift resulted from interaction with sodium-saturated montmorillonite.

The $pK_{1,eff}$ values of tetracycline in the presence of the sodium and calcium forms of montmorillonite, 6.23 and 4.39, respectively, remained relatively constant over the pH^b range of interest, indicating that $pK_{1,eff}$ was independent of pH^b. However, the $pK_{1,eff}$ values ranged from 4.15 to 4.74, depending on the pH^b of the bentonite USP suspension. This dependency of pK_{eff} on pH^b is attributed to the presence of organic material in the bentonite USP sample since pK_{eff} was found to be dependent on pH^b in suspensions of organic-containing soils (19).

The relative strength of the interaction of the clay with the protonated, H_3T^+, or zwitterionic, H_2T^0, form of tetracycline is expressed by the magnitude of $\Delta\bar{G}_i$ given in Table I, where $\Delta\bar{G}_i$ is the change in the partial molar Gibbs free energy accompanying the addition of clay to the system. Sodium-saturated montmorillonite interacted strongly with H_3T^+ but showed virtually no interaction with H_2T^0. In contrast, calcium-saturated montmorillonite and bentonite USP showed less interaction with H_3T^+, but the $\Delta\bar{G}_{H_2T^0}$ value indicates that a weak interaction occurred with the zwitterionic form.

The fraction of tetracycline bound to the clay (Fig. 4) also indicates that sodium-saturated montmorillonite only interacted with the cationic form because adsorption was observed only under pH^b conditions when H_3T^+ was present.

Tetracycline was bound strongly by calcium-saturated montmorillonite (Fig. 4) under pH conditions favoring the cationic form, as evidenced by the maximum at pH 2.7. However, adsorption also occurred at pH^b conditions favoring the zwitterionic and anionic forms, which caused the secondary maximum at pH 8.

Increased adsorption of tetracycline by calcium-saturated montmorillonite above pH 9.5 is due to complexation of the T^{2-} form of tetracycline with exchangeable calcium ions to form a positively charged calcium–tetracycline complex, which is adsorbed readily by the negative clay surface. The added sodium ions (arising from the sodium hydroxide needed to adjust the pH) cause the displacement of calcium ions from the clay. These calcium ions are available to form higher calcium–tetracycline complexes, which are positively charged and therefore are adsorbed by the clay.

The fraction bound curve for the bentonite USP sample (Fig. 4) showed a maximum adsorption of ~80% of the tetracycline in the system. This degree of adsorption was significantly less than the maximum adsorption of tetracycline by sodium- or calcium-saturated montmorillonite.

The adsorption of tetracycline by bentonite USP had a greater similarity to the fraction bound curve of calcium-saturated montmorillonite than to the fraction bound curve of sodium-saturated montmorillonite. The presence of calcium and magnesium as exchangeable cations in the bentonite USP sample and the calcite impurity was responsible for adsorption of tetracycline at pH conditions where no adsorption would be expected if the montmorillonite were completely sodium saturated.

The lower maximum adsorption of tetracycline by bentonite USP in comparison to sodium-saturated montmorillonite probably was due to the significant nonclay component, which includes quartz, gypsum, calcite, and organic material.

Thus, the nature of the exchangeable cations and the amount of nonclay material have a significant effect on tetracycline adsorption by bentonite USP.

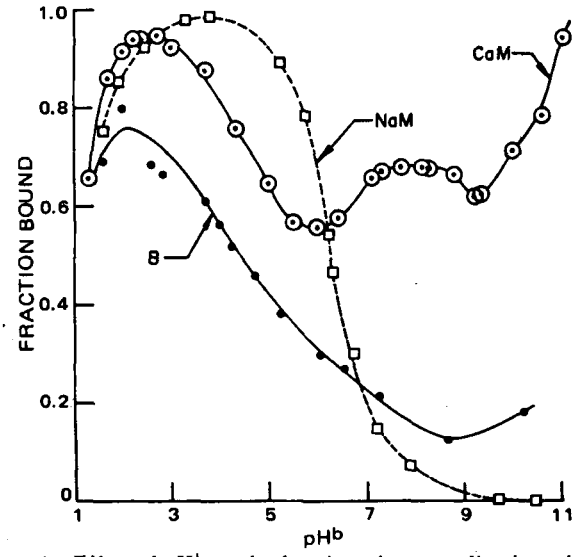

Figure 4—*Effect of pH^b on the fraction of tetracycline bound* (f) *in sodium-saturated montmorillonite (NaM), calcium-saturated montmorillonite (CaM), and bentonite USP (B) suspensions.*

Hectorite—In general, the X-ray reflections for commercial hectorite in Fig. 2 correspond fairly well to those for purified, sodium-saturated hectorite, indicating that hectorite was the major clay mineral contained in the commercial hectorite sample. However, in the region between 60 and 63° 2θ, the 060 reflection of the samples of commercial hectorite and purified, sodium-saturated hectorite had unequal spacings of 1.509 and 1.514 Å, respectively. These differences were expected and probably reflect composition differences due to the amount of lithium substituted for magnesium within the clay structure.

Several nonclay peaks were observed for the sample of commercial hectorite in the region from 11 to 41° 2θ. A very strong, sharp peak was located at 31.12° 2θ, corresponding to a spacing of 2.87 Å, a characteristic spacing for dolomite (11). Additional peaks were found at the established spacings for calcite (3.85, 3.035, and 2.285 Å) and quartz (3.35 Å).

The IR spectra of commercial hectorite and purified, sodium-saturated hectorite (Fig. 3) were essentially identical, thus confirming that hectorite was the major clay contained in the commercial hectorite sample. The absorption shoulder at 1012 cm^{-1} and a weak absorption shoulder at 1120 cm^{-1} typically are observed in hectorite samples. Large quantities of carbonate minerals (calcite and dolomite) were indicated by the 1430- and 877-cm^{-1} bands.

Pleochroism can be used to identify dioctahedral and trioctahedral structures in the smectite group. In trioctahedral minerals, such as hectorite, the transition moment of the hydroxyl group is perpendicular to the plane of the layer, while the hydroxyl groups are tilted out of the plane in dioctahedral minerals (8). Thus, the orientation of an oriented film of a trioctahedral mineral will affect the intensity of the hydroxyl absorbance bands but the IR spectra of dioctahedral minerals are not affected.

Oriented films of commercial hectorite and hectorite, both trioctahedral, are expected to show an orientation effect. When perpendicular to the IR beam, the absorption band at 3680 cm^{-1}, corresponding to the stretching frequency of structural hydroxyl groups in a magnesium-containing trioctahedral mineral, was absent in both spectra (Fig. 3). No increase in intensity was observed at 3680 cm^{-1} when the oriented films were placed at 60° incidence to the IR beam. This finding suggests that the structural hydroxyl groups were replaced by fluorine atoms. These findings agree well with a chemical analysis of hectorite, which indicated the presence of 4.5% fluorine (20).

It was not possible to examine the acid–base equilibria of tetracycline in the presence of commercial hectorite due to severe light scattering. To obtain some indication of the interaction of commercial hectorite with tetracycline, the behavior of tetracycline in the presence of purified, sodium-saturated hectorite was studied. Annoying light-scattering effects did not occur for titrations performed in purified, sodium-saturated hectorite suspensions. Thus, both the presence of carbonate impurities and multivalent ions as exchangeable cations appear to affect significantly the dispersion state of the clay.

As seen in Table I, the displacement of the first acid–base equilibrium of tetracycline in the presence of purified, sodium-saturated hectorite

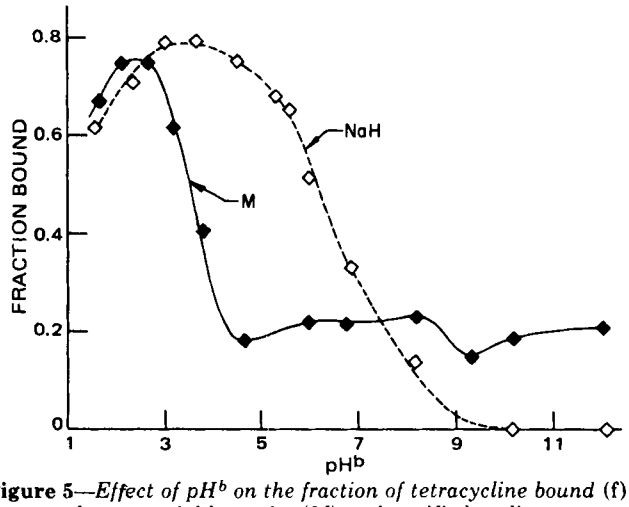

Figure 5—*Effect of pH^b on the fraction of tetracycline bound (f) in untreated commercial hectorite (M) and purified, sodium-saturated hectorite (NaH) suspensions.*

was almost as large as that produced by sodium-saturated montomorillonite. The $pK_{1,eff}$ value of 5.99 remained fairly constant over the pH^b range, indicating that $pK_{1,eff}$ was independent of pH^b. The H_3T^+ species was strongly stabilized by purified, sodium-saturated hectorite, as indicated by the large value of $\Delta\overline{G}_{H_3T^+}$, although virtually no interaction with H_2T^0 was observed.

The fraction bound curve for purified, sodium-saturated hectorite (Fig. 5) showed that adsorption of tetracycline occurred under pH^b conditions where H_3T^+ was present. This adsorption pattern was expected based on the structural similarities between hectorite and montmorillonite. However, a lower maximum was observed in the presence of purified, sodium-saturated hectorite in comparison to sodium-saturated montmorillonite (Fig. 4). It is believed that protons more effectively compete with H_3T^+ for the negative charge sites on the surface of hectorite than on montmorillonite due to differences in the distribution of negative charges arising from the clay structure.

In contrast, the fraction bound curve for commercial hectorite showed a constant adsorption above pH^b 4 in addition to a maximum at pH^b 2.7. The adsorption maximum is believed to represent adsorption of H_3T^+ by the hectorite present in the sample of commercial hectorite, while the constant adsorption above pH^b 4 may be due to complexation of the zwitterionic and anionic species of tetracycline with calcium in the nonclay components. Stern (21) reported that the anionic species of tetracycline is adsorbed onto calcium fluoride surfaces. In a similar manner, it is proposed that tetracycline is adsorbed onto the surfaces of calcite and dolomite present in commercial hectorite.

The adsorptive properties of commercial hectorite cannot be understood based on the structure of hectorite. However, the adsorptive properties of commercial hectorite are predictable when the nonclay components are recognized.

Saponite—The X-ray analysis of commercial saponite (Fig. 2) showed reflections typical of the smectite group of clay minerals. In addition to the smectite reflections, a very sharp, strong peak was noted at 21.40° 2θ, corresponding to an interplanar spacing of 4.15 Å. This peak and a much less intense peak at 31.38° 2θ (2.845 Å) indicated the presence of α-cristobalite (12) in the commercial saponite sample. Other peaks in the region from 11 to 41° 2θ corresponded to dolomite and calcite.

As seen in Fig. 6, the X-ray step scan of the 060 reflection of the commercial saponite sample resulted in spacings at 62.02 and 61.01° 2θ, corresponding to spacings of 1.496 and 1.518 Å. The dioctahedral smectite minerals, such as montmorillonite, have a characteristic 060 spacing of 1.48–1.50 Å, while the trioctahedral smectites, such as saponite and hectorite, are characterized by a spacing of 1.51–1.53 Å for the 060 reflection (22). The 060 reflections suggest that commercial saponite is a mixture of dioctahedral and trioctahedral smectites, with the sample being richer in the dioctahedral component based on the larger peak at 1.496 Å.

The IR spectrum (Fig. 3) of oriented films of the commercial saponite sample produced a number of absorbance bands whose assignments are characteristic of montmorillonite. The absorption band at 3620 cm^{-1} was similar to the hydroxyl-stretching frequency observed in montmorillonite. Characteristic bands for hydroxyl-bending frequencies in montmorillonite at 915, 878, and 850 cm^{-1} also were found in the spectra for commercial saponite. Carbonates are indicated due to the large absorption band at 1430 cm^{-1}.

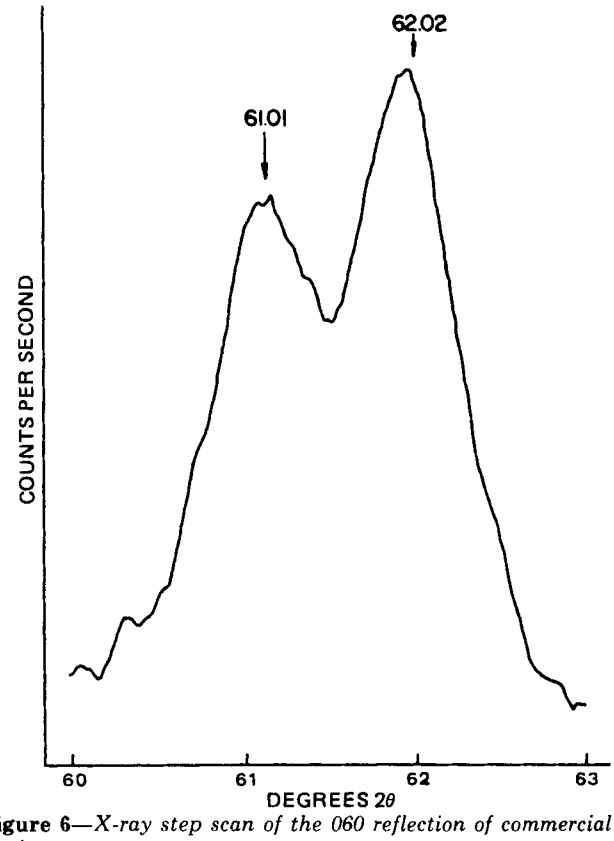

Figure 6—*X-ray step scan of the 060 reflection of commercial saponite.*

An orientation effect was observed in the 10× magnification of the IR spectrum of commercial saponite (Fig. 3) when the sample was placed at 60° incidence to the beam. This prompted further pleochroic studies of commercial saponite, which established the presence of dioctahedral and trioctahedral structures in the clay.

As seen in Fig. 7, the intensity of the band at 3680 cm^{-1} increased with the angle of rotation, confirming the presence of a trioctahedral smectite in commercial saponite. A dioctahedral mineral also was present since no orientation effect was observed for the IR band at 3620 cm^{-1}, which was assigned to the characteristic hydroxyl-stretching frequency of dioctahedral structures. Thus, IR analysis also indicated that the commercial saponite was a mixture of dioctahedral and trioctahedral mineral phases.

Figure 8 shows the results of the Greene-Kelly test on commercial saponite. This test depends on the observation that lithium-saturated smectites (dioctahedral) collapse irreversibly when heated to 200–300°, whereas the collapse of trioctahedral smectites treated similarly is reversible. Upon glycerol solvation of commercial saponite, a collapsed basal (001) spacing of 9.5 Å and an expanded 001 spacing of 18.4 Å were observed, which indicated the presence of dioctahedral and trioctahedral components.

Both X-ray and IR analyses indicated that the commercial saponite sample contained a mixture of dioctahedral and trioctahedral minerals and several nonclay components. The conclusion was supported by a chemical analysis, which reported 13.7% equivalent magnesium oxide in the commercial saponite sample (23). Ross and Hendricks (24) reported the equivalent magnesium oxide content of several montmorillonite samples and found a range of 0.16–8.67% equivalent magnesium oxide. Their analysis of a group of trioctahedral smectites, including saponites and hectorites, yielded an equivalent magnesium oxide content, which ranged from 19.4 to 26.5%.

Because no known smectite mineral contains 13.7% equivalent magnesium oxide and the X-ray and IR studies clearly showed both dioctahedral and trioctahedral character, it is concluded that the sample of commercial saponite was not a one-phase material but a mixture of at least two phases, one similar to montmorillonite and a lesser phase similar to saponite.

The commercial saponite sample caused a shift of the first acid–base

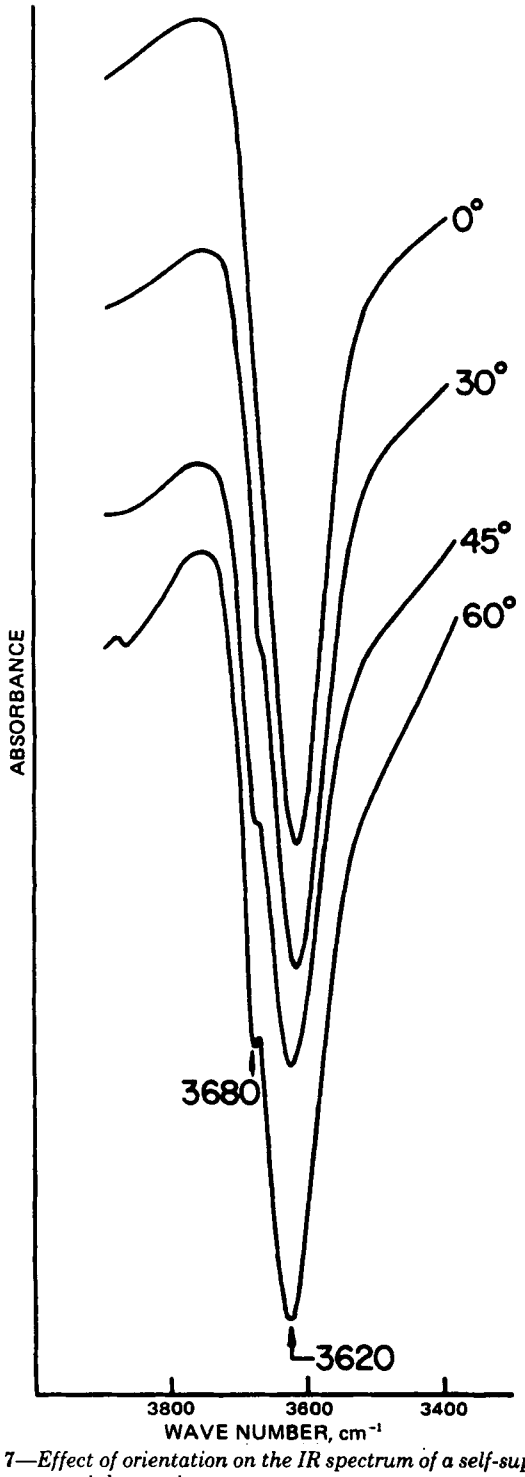

Figure 7—*Effect of orientation on the IR spectrum of a self-supporting film of commercial saponite.*

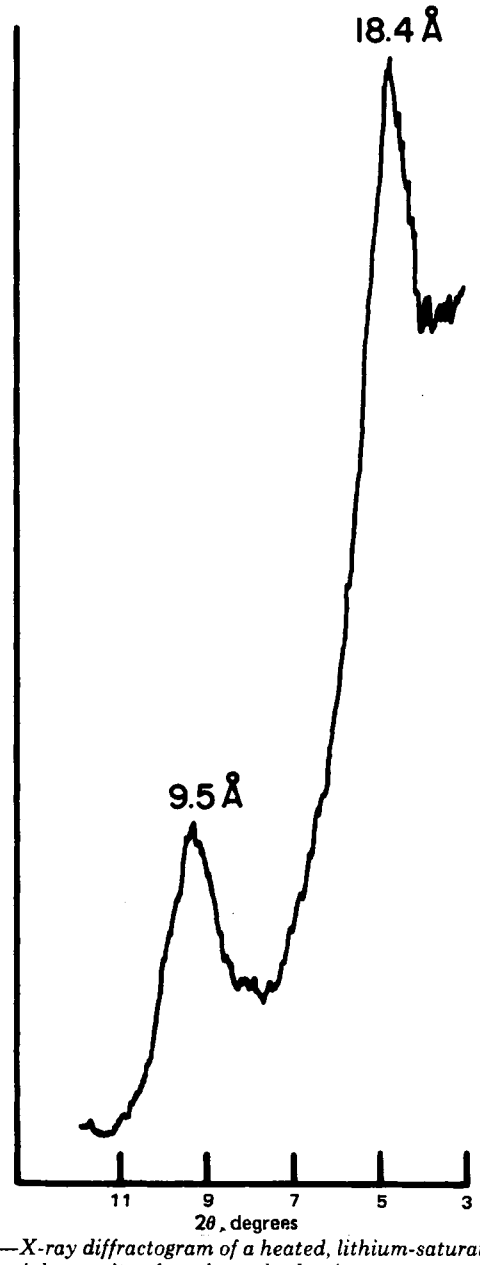

Figure 8—*X-ray diffractogram of a heated, lithium-saturated sample of commercial saponite after glycerol solvation.*

equilibrium of tetracycline to a $pK_{1,eff}$ of 4.27 (Table I). This shift reflects a much stronger interaction with H_3T^+ than H_2T^0, as indicated by the $\Delta\bar{G}_i$ values reported in Table I.

Because both montmorillonite and saponite contain exchangeable cations and the commercial saponite sample contains nonclay diluents, the effect of commercial saponite on the acid–base equilibrium of tetracycline also was studied following purification to remove carbonate impurities and sodium saturation. The displacement in the acid–base equilibrium of tetracycline was much greater in the presence of the purified, sodium-saturated commercial saponite than that observed for commercial saponite (Table I).

The findings are similar to the values observed with sodium-saturated montmorillonite and purified sodium-saturated hectorite, the other smectite minerals studied. Thus, it appears that exchangeable cations other than sodium are present in commercial saponite.

The fraction bound curve for tetracycline in the presence of purified, sodium-saturated commercial saponite (Fig. 9) was very similar to the adsorption profile seen for sodium-saturated montmorillonite (Fig. 4) and purified, sodium-saturated hectorite (Fig. 5). Adsorption only occurred when pH^b conditions permitted H_3T^+ to be present and was close to 100% at the pH^b of maximum adsorption.

The fraction bound curve for tetracycline in a commercial saponite suspension showed a lower maximum fraction bound and also indicated that adsorption occurred at higher pH^b conditions, where the zwitterionic and anionic forms of tetracycline were present. As with bentonite USP and commercial hectorite, the unexpected adsorption profile for commercial saponite is attributed to the effects of the exchangeable cations and the nonclay impurities present in the sample.

Attapulgite—Examination of the X-ray diffractograms in Fig. 2 for commercial attapulgite and sodium-treated attapulgite indicates that attapulgite is the major clay component of commercial attapulgite. Peaks corresponding to quartz and calcite also were seen in the diffractograms. In addition, the presence of a montmorillonite-like component in both commercial attapulgite and sodium-treated attapulgite is suggested since treatment of each sample with glycerol resulted in an expanded spacing

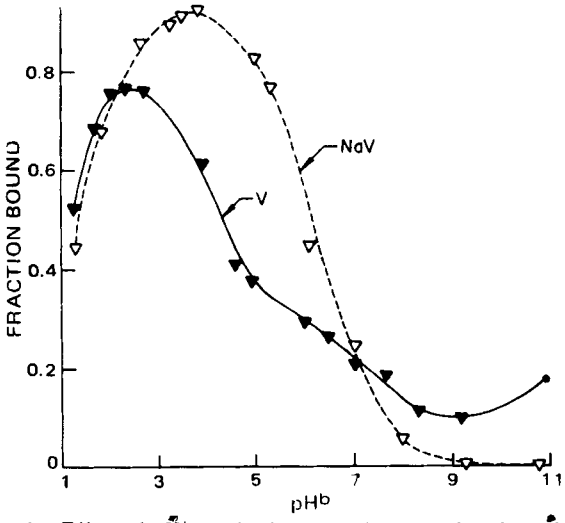

Figure 9—*Effect of pH^b on the fraction of tetracycline bound (f) in untreated commercial saponite (V) and purified, sodium-saturated commercial saponite (NaV) suspensions.*

of 14.5 and 15.2 Å for the 001 reflection of commercial attapulgite and sodium-treated attapulgite, respectively.

Cation-exchange capacity values have been reported for attapulgite. However, some of the higher values reported were attributed to montmorillonite impurities (25).

Transmission electron photomicrographs of sodium-treated attapulgite (Fig. 10) showed elongated, lath-shaped particles characteristic of attapulgite. The irregularly shaped aggregates interwoven among the attapulgite fibers are believed to be the montmorillonite-like impurity and illustrate the difficulty of obtaining pure attapulgite samples.

The IR spectra (Fig. 3) of commercial attapulgite and sodium-treated attapulgite were essentially identical. Both spectra showed the characteristic IR bands for attapulgite at 3625, 3595, 3560, 3505, 1192, 1145, 1090, 1036, 988, and 925 cm^{-1}. Very weak bands were noted at 1425 and 876 cm^{-1}, corresponding to calcite.

A shift of only 0.17 pK unit was observed in the first acid–base equilibrium of tetracycline in the presence of commercial attapulgite (Table I) and was accompanied by a small change in the partial molar Gibbs free energy of the H_3T^+ species. No substantial interaction was expected based on the cation-exchange capacity arising from the clay's structure. The observed interaction is believed to be due largely to interaction of H_3T^+ with the montmorillonite-type impurity in commercial attapulgite.

The effect of pH^b on the fraction of tetracycline bound to the sample of commercial attapulgite also indicates the presence of a montmorillonite-like component. A maximum in the fraction bound curve (Fig. 11) was observed at pH^b conditions favoring the protonated species, H_3T^+. This maximum arose from the cation-exchange capacity due to any isomorphous substitution in attapulgite and the contribution of the montmorillonite. The degree of adsorption decreased from the maximum of 35% as the pH^b increased. Adsorption remained relatively constant at ~15% at pH conditions that favor the zwitterionic and anionic forms of tetracycline.

Although calcium from the calcite impurity may reduce the amount of tetracycline in solution through the formation of calcium–tetracycline complexes, it is more likely that the constant, weak adsorption observed above pH^b 5 was due to physical adsorption. This type of adsorption pattern is expected based on the uncharged structure of attapulgite.

The selective adsorption of the H_3T^+ species indicated by the maximum at pH^b 3 is the adsorption pattern typical of the montmorillonite group of clays and indicates the important effect of the montmorillonite-like impurity on the adsorptive properties of commercial attapulgite.

Sodium-treated attapulgite caused a slightly smaller displacement of the first acid–base equilibrium of tetracycline than did commercial attapulgite and thus resulted in a smaller effect on $pK_{1,eff}$ (Table I). It was less effective in adsorbing tetracycline in comparison to commercial attapulgite (Fig. 11). It is believed that the heat and acid treatments employed to activate commercial attapulgite increase the availability of adsorption sites in attapulgite due to either an increase in the specific surface area of commercial attapulgite or the removal of adsorbed species. Thus, the fraction of tetracycline bound by commercial attapulgite was greater throughout the entire pH range than was observed for sodium-treated attapulgite.

Kaolinite—Identical X-ray diffractograms (Fig. 2) were obtained for sodium-treated kaolinite and kaolin NF and were characteristic of

Figure 10—*Electron photomicrograph of sodium-treated attapulgite showing the elongate lath-shaped particles (A) that are characteristic of attapulgite and the irregularly shaped aggregates (M) believed to be the montmorillonite-like impurity (magnification = 30,000×).*

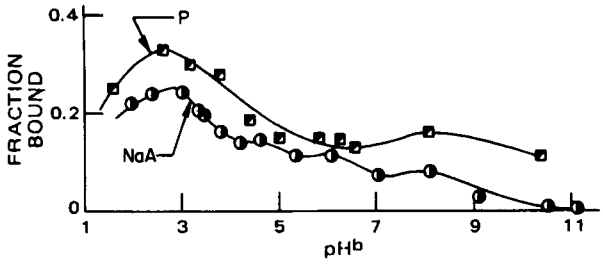

Figure 11—*Effect of pH^b on the fraction of tetracycline bound* (f) *in commercial attapulgite (P) and sodium-treated attapulgite (NaA) suspensions.*

kaolinite, indicating that kaolinite is the major clay present in kaolin NF. Both samples were pure as evidenced by the absence of reflections corresponding to nonclay diluents and the absence of expansion following glycerol treatment.

The IR absorption spectra of sodium-treated kaolinite and kaolin NF showed the characteristic IR bands for kaolinite at 3695, 3670, 3650, 3620, 1108, 1038, 1012, 940, and 915 cm^{-1} (Fig. 3).

Light scattering prevented the study of the acid–base equilibrium of tetracycline in the presence of kaolin NF. However, the first acid–base equilibrium of tetracycline in the presence of sodium-treated kaolinite was examined. As seen in Table I, $pK_{1,eff}$ was decreased slightly in the presence of sodium-treated kaolinite, indicating a displacement in favor of the zwitterionic form of tetracycline. No interaction was found with H_3T^+, but a weak interaction was observed with H_2T^0, as evidenced by the $\Delta\bar{G}_{H_2T^0}$ value of −0.2 kcal/mole.

This behavior is in contrast to the effect of montmorillonite, hectorite, and commercial saponite, where $pK_{1,eff}$ increased due to stabilization of H_3T^+ by the clay. However, kaolinite has little or no cation-exchange capacity and hence no stabilization of H_3T^+ occurs. The shift of $pK_{1,eff}$ in favor of H_2T^0 is consistent with the structure of kaolinite.

Since kaolinite is a nonexpanding mineral, the edge surface comprises a substantial portion (10–20%) of the total surface area. Broken bonds at the edges of the tetrahedral sheet give rise to a small permanent positive charge. A negative charge whose magnitude is related directly to pH results from broken edges of the octahedral sheet (26). Thus, at low pH^b conditions, kaolinite exhibits a small positive charge arising from the tetrahedral sheet; at higher pH^b conditions, the negative charge from the octahedral sheet predominates.

The fraction bound curve for tetracycline in the presence of sodium-treated kaolinite (Fig. 12) showed a very low degree of adsorption. The adsorption profile can be related to the pH-dependent charge arising from broken edges. No adsorption is seen at low pH^b values because the H_3T^+ species is repelled by the positive edge charge. Likewise, at basic pH^b conditions, the anionic forms of tetracycline are repelled by the negative edge charge. A small degree of physical adsorption occurs in the pH^b range where the H_2T^0 species is present.

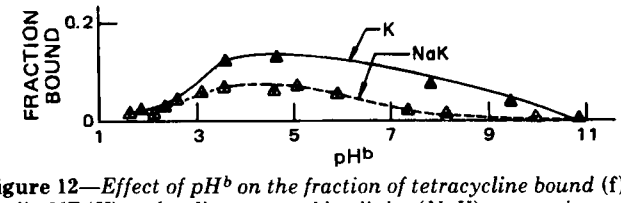

Figure 12—*Effect of pH^b on the fraction of tetracycline bound* (f) *in kaolin NF (K) and sodium-treated kaolinite (NaK) suspensions.*

The fraction bound curve (Fig. 12) for tetracycline in the presence of kaolin NF showed a similar adsorption profile to that of sodium-treated kaolinite. This finding was expected because both X-ray and IR analyses showed that kaolin NF was pure kaolinite.

Model of Interaction of Ajmaline with Polyvinylpyrrolidone

TOSHIHARU HOSONO *, SEISHI TSUCHIYA, and HIDEO MATSUMARU ˣ

Received August 8, 1979, from the *Tokyo College of Pharmacy, 1432-1 Horinouchi, Hachioji, Tokyo 192-03, Japan.* Accepted for publication February 13, 1980. *Present address: Institute of Research and Development, Yamanouchi Pharmaceutical Co., Ltd., 1-8 Azusawa-1, Itabashi, Tokyo 174, Japan.

Abstract □ The chemical shifts in the Fourier transform ^{13}C-NMR spectrum of ajmaline were assigned from consideration of the acetylation shifts and multiplet splitting in the off-resonance decoupled spectrum. On the basis of the assigned signals, the changes of chemical shifts in ajmaline induced by polyvinylpyrrolidone were investigated, and an interaction model of ajmaline with polyvinylpyrrolidone in chloroform was proposed.

Keyphrases □ Ajmaline—model of interaction with polyvinylpyrrolidone □ Polyvinylpyrrolidone—model of interaction with ajmaline □ ^{13}C-NMR spectroscopy—ajmaline, chemical shifts assigned

Tachibana and Nakamura (1) reported a new method for enhancing the dissolution rates of poorly soluble drugs by using water-soluble polymers such as polyvinylpyrrolidone. The coprecipitate of ajmaline with polyvinylpyrrolidone was prepared (2) in the same manner as the coprecipitate of reserpine (3) and griseofulvin (4), and the enhancement of the dissolution rate of ajmaline from this coprecipitate was ascertained. This effect seemed to be caused largely by some interaction between polyvinylpyrrolidone and ajmaline in chloroform, the solvent in which this coprecipitate was prepared. The interaction sites of polyvinylpyrrolidone and ajmaline in chloroform were investigated. The hydrogen bond formed between the C-21 hydroxyl group in ajmaline and the carbonyl groups in polyvinylpyrrolidone was confirmed (2), and complexation between the aromatic ring in ajmaline and the amide groups in polyvinylpyrrolidone was suggested (5).

This study was conducted to confirm these interactions using Fourier transform ^{13}C-NMR spectroscopy and to propose a model of interaction of polyvinylpyrrolidone with ajmaline in chloroform.

EXPERIMENTAL

The ajmaline, 17,21-diacetylajmaline[1], and polyvinylpyrrolidone[2] (K-15) employed were of the same origin and were purified as described previously (2). ^{13}C-NMR spectra[3] were obtained in deuterochloroform with tetramethylsilane as the internal reference.

RESULTS AND DISCUSSION

To clarify the behavior of the electron density of the carbon atoms in ajmaline caused by the interaction with polyvinylpyrrolidone, the influence of polyvinylpyrrolidone on the ^{13}C-NMR spectrum of ajmaline was investigated. Since there were no previous reports on the ^{13}C-NMR spectrum of ajmaline, the signal assignment was performed initially. The number of signals observed in the complete proton-decoupled ^{13}C-NMR spectrum was equal to the number of carbon atoms constituting ajmaline (Fig. 1). Therefore, no overlap of signals was detected.

From consideration of the chemical shift rules (6) and the multiplet splitting in ^1H-signal frequency off-resonance decoupling experiments, the carbons constituting ajmaline were classified as aromatic carbons (C-8–C-13), carbons adjacent to hydroxyl groups (C-17 and C-21), a quaternary carbon (C-7), methyl carbons (C-18 and C-22), methylene carbons (C-6, C-14, and C-19), and methine carbons (C-2, C-3, C-5, C-15, C-16, and C-20).

The signals of the aromatic carbons in ajmaline were assigned according to previous reports about various compounds containing an indole ring (7, 8) (Table I).

Three signals were observed in the magnetic field of the carbon atoms adjacent to hydroxyl groups, except for the signals derived from deuterochloroform. The signal of δ 88.10 ppm was derived from C-21 because it was adjacent to the nitrogen atom and a hydroxyl group. Generally, the carbon atoms at the α- and β-positions are shifted downfield and upfield, respectively, due to the substituent effects produced by replacement of the hydroxyl group by the acetoxy group (9). Therefore, it seems reasonable that the signal of δ 88.10 ppm was shifted downfield by diacetylation (Table I, $\delta_b - \delta_a$).

On the other hand, the signal of either δ 79.19 or 77.72 ppm corresponded to C-17. The C-17 signal was expected to be shifted significantly downfield by diacetylation because of its α-position to the hydroxyl group. Accordingly, the δ 77.72-ppm signal was determined to be C-17, in spite of the interchangeability of the C-17 assignment with C-2 in the diacetate (δ_b).

The quaternary carbon atom, C-7, was assigned easily from multiplicity.

In the two signals of the methyl carbon atoms (quartet), the δ 34.11-ppm signal was determined to be C-22 because of its adjacency to the nitrogen atom.

For the methylene carbons (C-6, C-14, and C-19), the side-chain carbon (C-19) was attributed to δ 25.39 ppm. Although the assignments of C-6 and C-14 were attempted, the discrimination remained uncertain because one of these signals exhibited the large downfield shift (+1.50 ppm) from diacetylation in spite of the distance from the hydroxyl groups, and this large shift could not be explained by the inductive effect of the acetoxy groups. Further investigation involving an additional steric effect is required to assign these signals.

The signals of the methine carbons (C-2, C-3, and C-5) adjacent to the nitrogen atom were downfield. The signal of C-2 adjacent to the aromatic nitrogen atom in the indole ring was expected to appear considerably downfield (10), and the signal of δ 79.19 ppm was assigned to C-2. The large shift of the δ 77.72-ppm signal by diacetylation also provided convincing evidence that this signal was not derived from C-2.

The signals due to C-15, C-16, and C-20 were expected to be farther upfield than those of C-2, C-3, and C-5. Since C-20 is located at the β-position to C-18 in the aliphatic side chain, this signal seemed to appear significantly upfield. The signal of δ 28.12 ppm was assigned to C-20 and exhibited a reasonable upfield shift by diacetylation (−0.85 ppm). The C-15 and C-16 carbons exist in the ring system, so these signals appear relatively downfield compared with that of C-20. It appears that C-16 is almost as susceptible to influence as C-7 because it is located at the same β-position as C-7 to C-17. The C-15 signal is not influenced by diacetylation due to the long distance between C-15 and either hydroxyl group.

On the basis of these chemical shift rules and acetylation shifts, the possibility that the signals of C-15 or C-16 in ajmaline occur at δ 52.78 or 47.95 ppm is excluded. Consequently, it was concluded that the C-16 signal corresponds to δ 45.22 ppm and that the δ 43.08-ppm signal corresponds to C-15 because the latter was not influenced appreciably by diacetylation. These assignments remained unaltered in spite of the interchangeability of δ 43.65 and 43.01 ppm in the diacetate.

Subsequently, on the basis of these assignments, the change of signals in 0.34 *M* ajmaline by the addition of various concentrations of poly-

vinylpyrrolidone was investigated (Fig. 2). Although the chemical shift of the C-17 signal was not distinctly observed by addition of 0.015 and 0.06 *M* polyvinylpyrrolidone due to overlapping with the signals derived from deuterochloroform, the signals of C-21 and C-17 tended to be shielded by an increase in the polyvinylpyrrolidone concentration. However, no significant changes of linewidth in the ajmaline signals induced by polyvinylpyrrolidone could be detected.

By using UV and ^1H-NMR spectra, the hydrogen bond formed between the C-21 hydroxyl group in ajmaline and the carbonyl groups of the pyrrolidone rings in polyvinylpyrrolidone was recognized previously (5). The upfield shifts of C-17 and C-21 were observed by the addition of polyvinylpyrrolidone in the present study. In ^{13}C-NMR spectra, the chemical shift variation is dominated by the electron density (11). The enhancements of electron density in C-21 and C-17 of ajmaline provide sufficient grounds to expect hydrogen bond formation with polyvinylpyrrolidone.

To ascertain this point, the effect of acetone on 2-butanol was examined. The C-2 in 2-butanol was shifted upfield by the addition of 1 drop of acetone (not shown). This upfield shift of C-2 in butanol obviously was attributable to the hydrogen bond formed between 2-butanol and acetone. Accordingly, it is almost certain that the C-17 and C-21 hydroxyl groups in ajmaline formed hydrogen bonds with the carbonyl groups of the pyrrolidone rings in polyvinylpyrrolidone. The fact that the upfield shift of C-21 was smaller than that of C-17 by hydrogen bond formation seemed to result from the smaller influence of C-21 than of C-17 by diacetylation. In addition, from consideration of the changed C-7 signal by diacetylation, the upfield shift of C-7 by the addition of polyvinylpyr-

I

rolidone seemed to be influenced by hydrogen bond formation (Table I).

In addition to the influence in the signals of C-7, C-17, and C-21, there was a relatively large influence in the signals of aromatic carbons in ajmaline by polyvinylpyrrolidone; that is, the signals of C-8 and C-13 tended to shift upfield and those of C-9 and C-10 shifted downfield. The electron densities of C-8 and C-13 became higher due to the presence of polyvinylpyrrolidone, and those of C-9 and C-13 became lower.

Considering the relatively small changes of the aromatic carbons by diacetylation, it does not seem that these electron density changes were brought about indirectly through hydrogen bond formation. Furthermore, the upfield shift of C-13 and the downfield shift of C-10 do not seem to support the interaction with the nitrogen atom at position 1 in ajmaline. Accordingly, it is reasonable to consider that a complex was formed between the amide groups of the pyrrolidone ring in polyvinylpyrrolidone and the aromatic ring in ajmaline, as suggested previously (5). It is expected that the electron densities of C-8 and C-13 of the aromatic ring in ajmaline are affected and become higher because of the approach of the positively charged nitrogen atom of the amide group of the pyrrolidone rings of polyvinylpyrrolidone. Considering such mechanisms of complex formation, Laszlo (12) described it as a dipole–induced dipole complex in view of the nomenclature of these complexes.

From these results, an interaction model between polyvinylpyrrolidone and ajmaline is proposed (I). In the coprecipitate, ajmaline apparently was molecularly dispersed in solid polyvinylpyrrolidone through these interactions. As a result, the dissolution rate of ajmaline from the coprecipitate was enhanced markedly.

Polarographic Determination of Edetate Disodium in Eyewash and Ophthalmic Decongestant Solutions

MARVIN CARLSON ˣ and LARRY E. HABEGER

Received August 20, 1979, from the *Minneapolis District, Food and Drug Administration, Public Health Service, Department of Health, Education, and Welfare, Minneapolis, MN 55401.* Accepted for publication February 25, 1980.

Abstract □ The quantitative analysis of edetate disodium in nonprescription eyewash and ophthalmic solutions is described. The method involves differential pulse polarography using a dropping mercury electrode. A known concentration of cadmium or zinc is added to a buffer in a polarographic cell. The sample solution is incremented into the cell with a micropipet. The peak current decreases because the resulting chelate is not reducible at the potentials used. The quantity of edetate disodium in the sample then is determined graphically. Some contact lens cleaning and wetting solutions containing polymeric compounds are amenable to assay for edetate disodium if extraction, precipitation, centrifugation, or dilution steps minimize the maximum suppressor effect of the additives. These steps are very effective with cellulose ether compounds but are ineffective with polyvinyl alcohol.

Keyphrases □ Edetate disodium—polarographic determination in eyewash and ophthalmic decongestant solutions □ Polarography, differential pulse—analysis, edetate disodium in eyewash and ophthalmic decongestant solutions □ Ophthalmic preparations—polarographic determination of edetate disodium in eyewash and ophthalmic decongestant solutions

Edetate disodium (I) is added to eyewash and ophthalmic solutions containing bactericides such as benzalkonium chloride, chlorobutanol, and thimerosal to increase their bactericidal properties (1). Compendial methods (2–4) employ classical titrimetric procedures for the quantitative determination of I, but these methods are not suitable for the levels encountered in the drug preparations (0.01–0.25%).

A literature search revealed two methods used to determine I in pharmaceutical preparations. One employed colorimetric detection for ophthalmic solutions (5); the other used atomic absorption for an antibiotic preparation (6).

This paper proposes a sensitive, rapid, and quantitative polarographic method for determining I concentrations by stepwise addition of sample to the cell. The resulting

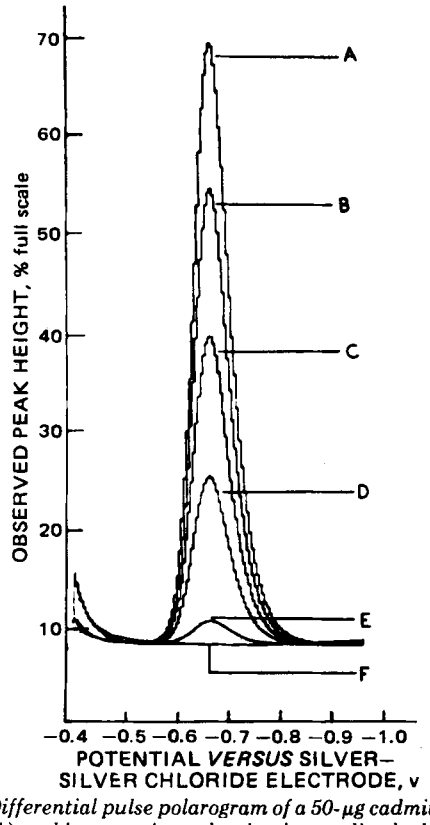

Figure 1—*Differential pulse polarogram of a 50-μg cadmium standard in the cell (A) and its stepwise reduction in amplitude due to the addition of 40-μl increments of a standard 0.1% edetate disodium solution (B–F) (5 μamp full scale).*

chelation causes a corresponding decrease in the peak amplitude of the free metal (cadmium or zinc) originally in the cell.

EXPERIMENTAL

Reagents and Chemicals—Analytical reagent grade chemicals were used.

Solution Preparation—An ammonium–ammonia buffer supporting electrolyte was prepared by diluting 2.0 g of ammonium nitrate and 1.75 ml of concentrated ammonia to 500 ml with water. A maximum suppressor was prepared by dissolving 100 mg of gelatin powder[1] in 100 ml of water. The mixture was warmed to promote dissolution. Gelatin solutions older than 72 hr were not used.

Metal standard solutions (1000 μg/ml) were made by dissolving cadmium wire[2] or zinc shot[2] (99.99%) in 100 ml of 20% HNO_3 and diluting to 1 liter with water. Edetate disodium[3] (99.0–101.0% pure) was assayed (3) and then employed in preparing standard solutions in water and in simulated commercial eye drop and eyewash preparations. Triple-distilled mercury[4] was washed with 10% HNO_3 in a mercury cleaning tower[5] and then pinholed to remove residual wash water.

Instrumentation—Experiments were performed with a commercial polarographic system[6] and an x–y recorder[7]. Adjustable micropipets[8] having volumes of 5–50, 50–250, and 200–1000 μl were used. Nitrogen was passed through a scrubbing tower[9] of vanadous chloride followed by a gas washing tower containing the supporting electrolyte.

Table I—Linearity Data [a] Relating Volume of Sample Added to Adjusted Net Current

0.1% (w/v) edetate disodium added, μl	0	40	80	120	160
Adjusted net current, μamp	3.07	2.35	1.59	0.87	0.12

[a] Linear regression value at x intercept (9) = 166.7 μl, and coefficient of determination (9) = 0.999.

Instrument Parameters—A potential scan from −0.4 to −1.0 v (cadmium) or from −0.8 to −1.5 v (zinc) at a rate of 5 mv/sec was used. The differential pulse mode was employed at a modulation amplitude of 50 mv and a current range of 5 μamp full scale. A dropping mercury electrode with a drop time of 1 sec also was used.

Assay—To the polarographic cell were added 10.0 ml of buffer, 250 μl of gelatin solution, and 50 μl of cadmium or zinc standard solution. Oxygen was removed from the solution by purging with nitrogen for 5 min, and the solution then was scanned to obtain the metal peak. A micropipet was used to add sample to the cell. If the sample solution contained 0.1% I and was complexed with cadmium, 40-μl aliquots were added to the cell. For the sample solutions containing 0.01% I, 400-μl increments were added to the cell. The cell contents were purged for 1 min after each sample addition. Chelation resulted in an ~20% decrease in the observed current for the polarographic peak (Fig. 1). The sample additions were continued until there was no observed metal peak (Fig. 1).

The cadmium–I complex was not readily observed in the potential scan range of 0 to −1.5 v using the differential pulse mode. A broad, low-amplitude wave was observed at ~−1.1 v, which increased in a nonlinear fashion with the addition of I to the cell. Cadmium metal was reduced at −0.67 v.

The zinc–I complex did not exhibit a reduction wave in the potential scan range of 0 to −1.5 v, while zinc metal was reduced at −1.25 v. These potentials were peak maxima *versus* a silver–silver chloride reference electrode. The data of Meites (7) on cadmium and zinc in ammonia–ammonium chloride and I supporting electrolytes agree with the experimental observations.

Calculations—The following formula was used to calculate the adjusted net current after each sample addition:

$$I_A = I_O\left(\frac{V_2}{V_1}\right) \qquad \text{(Eq. 1)}$$

where I_A is the adjusted net current in microamps, I_O is the observed current in microamps, V_1 is the original cell volume in milliliters, and V_2 is the total cell volume in milliliters after each sample addition.

The I_A value is the observed current adjusted to the original cell volume, assuming a linear decrease in response due to dilution.

The sample volume added (microliters) was plotted on the x axis *versus* the adjusted net current on the y axis (Table I).

The x intercept represents the volume of the sample in microliters equivalent to the metal originally present in the cell. The following formula was used to calculate I in the sample:

$$\text{percent sample (w/v)} = V_{std}C_{std}\left(\frac{D}{A}\right)\left(\frac{0.1}{V_{sam}}\right) \qquad \text{(Eq. 2)}$$

where percent sample (w/v) is the percent edetate disodium in the sample calculated on a weight to volume basis, V_{std} is the volume of the metal standard solution in microliters, C_{std} is the concentration of the metal standard solution in micrograms per microliter, D is the molecular weight of edetate disodium, A is the atomic weight of the standard metal (cadmium or zinc), V_{sam} is the end-point volume of the sample solution in microliters, and 0.1 is a factor converting microliters to milliliters, micrograms to grams, and grams per milliliter to percent. The molecular weight of edetate disodium is 372.24, and the atomic weights of cadmium and zinc are 112.40 and 65.37, respectively.

DISCUSSION

The graph of the polarographic peak heights, corrected for dilution, is linear with respect to the sample volume (titrant) added. The most convenient method for calculating sample concentration is to perform a linear regression for the best line fit of the data points (adjusted net current, microamperes *versus* microliters of sample added). A coefficient of determination calculation then is performed to see how well the data fit the linear regression (Table I). Edetate disodium forms 1:1 complexes with many metal ions, but the degree of complex formation is strongly influenced by pH. Since the cadmium and zinc chelates are stable in basic

or weakly acidic solutions (8), the pH 9.95 buffer used in this assay satisfies a major condition for quantitation in that the uncomplexed metal-ion concentration decreases linearly throughout the titration.

Sample eyewash and eye drop solutions have a pH of ~6–7, so their effect is minimal upon addition to the buffer in the polarographic cell. Some eye drop preparations contain methylcellulose, a viscosity-increasing agent. Since these solutions tend to wet the surface of the plastic micropipet tips, care must be taken to ensure complete removal of the entire sample aliquot from the micropipet tip.

Contact lens cleaning and wetting solutions comprise a large class of samples. These solutions commonly contain I but also may contain polymeric compounds such as methylcellulose and other closely related cellulose ethers, polyvinyl alcohol, and tyloxapol in relatively significant concentrations. From a polarographic analysis viewpoint, these polymers exhibit a strong maximum suppressor effect, resulting in an unusable polarogram.

[a] Average of two determinations. [b] Average of three determinations. [c] Clear Eyes, Abbott Laboratories. [d] Visine, Pfizer. [e] Murine Plus, Abbott Laboratories. [f] Simulated preparation, Minneapolis District, Food and Drug Administration. [g] Lavoptik, Lavoptik Co. [h] Softmate, Barnes-Hind Pharmaceuticals. [i] Ten-milliliter sample extracted with 10 ml of water-washed chloroform and then centrifuged for 20 min at 1500 rpm. [j] Contique, Alcon Laboratories. [k] Five-milliliter sample diluted with 15 ml of water, extracted, centrifuged for 20 min at 1500 rpm, and then allowed to stand until adequately cleared.

The cellulose ether compounds may be precipitated from solution by an extraction procedure using water-washed chloroform. Any remaining suspended material may be removed completely by centrifugation and standing. A preliminary 10-fold sample dilution with water also may reduce cellulose interference, providing the original concentration of I is ≥0.1%. In many instances, this treatment is sufficient for successful sample analysis if polyvinyl alcohol is absent. Polyvinyl alcohol presents several problems: the maximum suppressor effect cannot be diluted out due to the low levels of I present in the samples, extraction of the polymer is compromised due to the freely soluble nature of the alcohol in aqueous solutions, and the alcohol causes undesirable frothing when the polarographic cell contents are purged with nitrogen.

If lens cleaning solutions contain no polyvinyl alcohol, this method can determine the edetate disodium concentration in these samples.

The results in Tables II and III demonstrate the validity of analyzing commercial eyewash, eye drop, and some contact lens cleaning solutions for I. The assay values (Tables II and III) for edetate disodium were generally higher when standard zinc solution was used; however, cadmium exhibited a more reproducible baseline upon addition of certain sample matrixes such as lens cleaning solutions. Based on examination of the tabular data and the experience gained using both cadmium and zinc, cadmium is recommended as the preferred standard.

An important aspect of this assay is the need for accurate dispensing of edetate disodium sample and standard solutions using adjustable micropipets. Since these volumes are <1 ml, the micropipets should be calibrated.

This procedure can be readily used to analyze I in powder and injectable forms as presented in the USP and "Food Chemicals Codex."

Edetate disodium also is widely used in the food industry as a preservative, sequestrant, and stabilizer. It is feasible that I can be extracted from food into a water phase and subjected to further cleanup and that the concentration then can be determined as specified in this method.

Size Distribution Characteristics of Mineral Phase in Renal Stones

S. I. ISMAIL and R. TAWASHI ˣ

Received April 16, 1979, from the *Faculté de Pharmacie, Université de Montréal, Montréal, Québec, Canada.* Accepted for publication February 12, 1980.

Abstract □ The size distribution of the mineral phases in three renal stones (whewellite, struvite, and whitlockite) was determined using a particle-counting technique after removal of the organic matrix. The multisized crystallites of the investigated stones revealed close similarity in size distribution characteristics. Whewellite size parameters were in good agreement with the parameters of calcium oxalate monohydrate crystals formed in the kidneys of rats injected with L-4-hydroxyproline. However, these parameters differed significantly from the values calculated from the size distribution of calcium oxalate crystals voided in the urine of recurrent stone formers. The data obtained suggest that critical size distribution characteristics may be instrumental in causing the mineral phase to agglomerate and adopt a close packing in renal stones.

Keyphrases □ Renal stones—size distribution characteristics of mineral phase □ Size distribution—mineral phase of renal stones □ Urinary stones—size distribution characteristics of mineral phase □ Minerals—size distribution characteristics in renal stones

The study of crystal deposits in freshly voided urine and their relation to stone formation has received considerable attention (1–4). The ultrastructure of renal calculi was investigated by various methods to understand stone etiology and growth mechanisms (5–7). However, the size distribution and geometrical characteristics of individual crystals forming the renal calculus were overlooked. The basic question of whether there exists a critical dimension or a critical size range favoring stone construction in humans has not been answered. The quantitative evaluation of these parameters promises a better understanding of the clustering process and the packing stability of the mineral phase in urolithiasis.

The purposes of the present study were to determine the crystal size distribution of calcium oxalate, ammonium magnesium phosphate, and tribasic calcium phosphate in stones using different measuring techniques and to compare the data obtained with data on calcium oxalate crystals formed in the kidneys of rats injected with L-4-hydroxyproline.

EXPERIMENTAL

Three urinary stones[1] characterized as whewellite (calcium oxalate monohydrate), struvite (ammonium magnesium phosphate hexahydrate), and whitlockite (tribasic calcium phosphate) were obtained from recurrent stone formers.

A series of experiments was conducted using different solvents and conditions to remove the organic matrix and to deaggregate the individual crystals from the polycrystalline mass without acting on the mineral phase or changing the crystal morphology. Ten milliliters of an aqueous solvent was added to ~10 mg of the stone and left at room temperature for 7–14 days. The best results were obtained when whewellite, struvite, and whitlockite stones were digested in aqueous 80% ethylenediamine, 30% NaOH, and 12% sodium hypochlorite solutions, respectively. The digested stones were filtered, and the mineral phase residue was washed repeatedly with the respective solvent and subjected to size analysis.

The deaggregated mineral phase of the different stones was analyzed by a particle counter[2] with a 16-channel analyzer and a 100-μm tube. A "clean" electrolyte solution (0.9% NaCl) saturated with the stone material was used as the suspension medium to ensure that no part of the mineral phase dissolved in the electrolyte solution during the size analysis.

RESULTS AND DISCUSSION

Mineral Phase in Renal Stones—Renal stones generally consist of coherent compact mineral phases of very low voidage. The mucoproteinous matrix accounts for 2–2.5% (w/w) (8, 9). The particle-size distribution of the deaggregated mineral phase of the investigated stones is given in Figs. 1 and 2. Particle-size distributions based on the number and volume showed a close similarity among the investigated stones. For example, the number distribution curves (Fig. 1) showed that 50% of the particle population was <5 μm. On the other hand, the volume distribution curves (Fig. 2) indicated that the median sizes (r_{50}) of the investigated stones was 25–30 μm.

The size data in Figs. 1 and 2 were used to estimate the particle population parameters of the mineral phase. The Rosin–Rammler distribution (10), which is given by $G_r = 100[\exp - (r/r_{mean})^{\gamma}]$, was used to describe the multisized particle population, where G_r is the total cumulative volume of the mineral phase oversize in percent, r is the particle size in micrometers, r_{mean} is the statistical mean particle size in micrometers derived graphically (corresponding to the coordinate G_r = 36.8%), and γ is the degree of uniformity of the size distribution, which

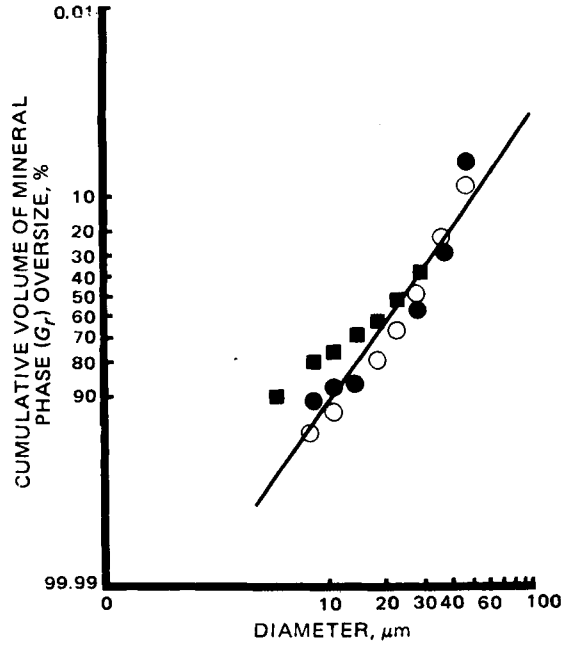

Figure 3—*Scattergraph of the mineral phase size distribution of the investigated renal stones based on the Rosin–Rammler extrapolation. Key: ○, calcium oxalate monohydrate; ●, calcium phosphate; and ■, ammonium magnesium phosphate.*

also is obtained graphically as the slope of the linear relation between log (log $100/G_r$) and log r. The most probable crystal size in the size (10) distribution (r_m) is obtained from $r_m = r_{mean}(\gamma - 1/\gamma)^{1/\gamma}$.

Figure 3 shows a scattergraph and a linear representation of the mineral phase size distribution of the investigated stones. From this plot, the median size (r_{50}) is 25.5 μm, the most probable size in the distribution (r_m) is 26.9 μm, the uniformity factor of the size distribution (γ) is 2.8, and the coefficient of variation (CV) is 63.7%. The coefficient of variation is calculated from $CV\ (\%) = 100[(r_{16} - r_{84})/2r_{50}]$, where r_{16} and r_{84} are the particle sizes when $G_r = 16$ and 84%, respectively.

The examination of the calcium oxalate crystals from the whewellite stone using a scanning electron microscope supported these findings. The mean projected diameter was 28 μm (Fig. 4). This mean projected diameter correlated well with the median size (r_{50}) and the most probable size in the mineral phase size distribution (r_m) obtained by the counter.

***In Vivo* Crystallization of Calcium Oxalate Monohydrate**—The detailed growth history of urinary stones is unknown, and no information is available on the size distribution of the individual crystallites that occur immediately after *in vivo* crystallization. In this study, the size distribution data of calcium oxalate crystallites in renal stones were compared with data for the calcium oxalate crystals produced in rat kidneys after

Table I—Size Characteristics of Calcium Oxalate Monohydrate Crystallized *In Vivo*

Source of Calcium Oxalate Crystals	Median Size (r_{50}), μm	Mean Size (r_{mean}), μm	CV, %	Uniformity Factor (γ)	Most Probable Crystal Size in Size Distribution (r_m), μm
Urinary stone	25.5	31.5	63.7	2.8	26.9
Rat kidneys (experimental urolithiasis)	26.0	31.0	57.7	2.7	26.1
Urine of recurrent stone formers	9.7	14.0	63.8	3.5	8.8

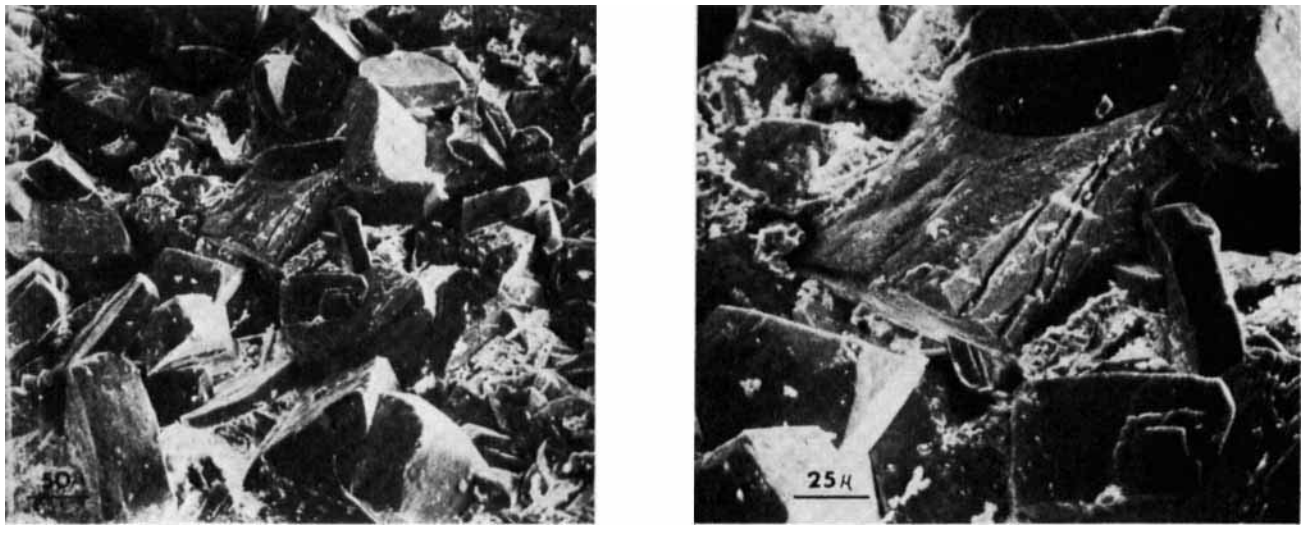

Figure 4—*Scanning electron micrograph of calcium oxalate monohydrate crystals in a calcium oxalate renal stone. The mean projected diameter is 28 μm.*

the injection of L-4-hydroxyproline. The experimental details on the formation of calcium oxalate crystals in rat kidneys by injection of L-4-hydroxyproline was described recently (11).

Figure 5 illustrates the size distribution curves of calcium oxalate crystals in the renal stone and calcium oxalate crystals formed in rat kidneys, clearly showing a close similarity in the size distribution of the mineral phase in the rat kidneys and in the human stone. This observation suggests that crystal growth in rat kidneys (experimental urolithiasis) and in the urinary stones may be controlled by similar biological and physicochemical variables.

On the other hand, Robertson and Peacock (12) studied the size distribution of calcium oxalate crystals voided in the urine by recurrent stone formers (those having a history of stones over a period of years). The recurrent stone formers excreted calcium oxalate crystals that gave a bimodal distribution. The examination of the data reported by Robertson and Peacock and data on urinary stones revealed wide variation. To compare the size distribution parameters of calcium oxalate crystals passed in the urine of stone formers with those of calcium oxalate crystals of both renal and rat kidney stones, the Robertson and Peacock data were recalculated and plotted (Fig. 6). The size parameters of calcium oxalate crystals were determined and are given in Table I. The values given in Table I indicate that while the size parameters of the calcium oxalate crystals in both the renal stone and rat kidneys were very close, significant differences existed with calcium oxalate crystals voided in the urine of stone formers. For example, the r_{50} value for crystals in the renal stone was 25.5 μm, and in rat kidneys it was 26.0 μm; for the crystals passed by the recurrent stone formers, it was 9.7 μm.

The uniformity factor (γ), a measure of the uniformity of the distribution, also showed a significant difference between the crystals of the stone and those voided in the urine of stone formers.

Some investigators (9, 13) stated that the coherence of the particles in stones is a function of the surface and shape of the mineral phase particles as well as the presence of the organic matrix. The contribution of the grain size and size distribution characteristics in particle retention and packing still is unclear. More studies are necessary for complete characterization of this problem and for the eventual understanding of stone genesis.

Solubility and Dissolution Rate Studies of Ergotamine Tartrate

JOHN R. ANDERSON and IAN H. PITMAN ×

Received January 25, 1980, from the *School of Pharmaceutics, Victorian College of Pharmacy, Parkville, Victoria, Australia 3052.* Accepted for publication February 27, 1980.

Abstract □ The solubility of ergotamine tartrate in aqueous solutions of tartaric acid, citric acid, hydrochloric acid, and caffeine and the dissolution rate of ergotamine tartrate in aqueous mixtures containing hydrochloric acid, caffeine, citric acid, or sodium acetate were studied. The Noyes–Whitney model of dissolution is useful for predicting the dissolution rate of ergotamine tartrate in most of the dissolution media. The relative slowness with which ergotamine chloride (a substance with low water solubility) precipitated when ergotamine tartrate was dissolved in 0.1 *M* HCl resulted in the solid dissolving faster in this medium than was predicted using the Noyes–Whitney equation.

Keyphrases □ Ergotamine tartrate—solubility and dissolution rate □ Analgesics—ergotamine tartrate, solubility and dissolution rate □ Solubility—ergotamine tartrate, various dissolution media □ Dissolution rates—ergotamine tartrate, various dissolution media

Relief of migraine headaches by the ergot alkaloid ergotamine depends on its rapid entrance into the systemic circulation during the initial phase of the migraine attack (1). Ergotamine has very low water solubility (2), and its more soluble salts, especially ergotamine tartrate (ergotamine:tartaric acid, 2:1), are used in injections and in solid dosage forms from which rapid drug release is desirable (3).

Although ergotamine tartrate, with a solubility of 1:500 in water (2), is more soluble in water than ergotamine, some confusion exists about the nature of its aqueous solutions. For example, it was stated that ergotamine tartrate is soluble in water but that the addition of tartaric acid often is necessary to maintain a clear solution (4). The present studies concern the solubility of ergotamine in aqueous solutions of tartaric acid, citric acid, hydrochloric acid, and caffeine and the dissolution rate of ergotamine tartrate in several aqueous mixtures. Caffeine was included in some solutions because it is a common ingredient in many dosage forms of ergotamine and it has been postulated that caffeine forms one or more molecular complexes with ergotamine (5).

EXPERIMENTAL

Solubility Studies—Solutions of caffeine, citric acid, and tartaric acid were prepared in the concentration ranges of 0–0.025, 0–0.25, and 0–0.25 *M*, respectively. The pH values of these solutions were adjusted with sulfuric acid, hydrochloric acid, or sodium hydroxide (Table I).

Constant amounts of ergotamine tartrate, in excess of its solubility, were added to screw-capped vials containing a fixed volume of dissolution medium. The vials were sealed and shaken in a water bath at 25.0 ± 0.1°. Preliminary studies were conducted to determine the time required for the solutions to reach equilibrium.

The ergotamine concentration in each equilibrated solution was determined by filtering the contents of the screw-capped vials through a 0.22-μm membrane filter, diluting the filtrate with 1.0% (w/v) tartaric acid solution, and measuring the absorbance of these solutions at 317 nm against an appropriately diluted dissolution medium. Absorbance values were converted to ergotamine concentrations using a Beer's law plot. The Beer's law plot was constructed over the ergotamine concentration range of 0–1.52×10^{-4} *M* and was found to fit $y = 7318x$ ($r = 0.999$), where y is the absorbance and x is the molar concentration of ergotamine.

The amounts of ergotamine tartrate, the volumes of the dissolution media, and the shaking times for each solubility experiment are shown in Table I.

Analysis of Solids—The solid phases remaining in several solubility experiments were collected and dried at 100°. The percentage by weight of ergotamine in the solid phase was determined by dissolving a known amount of the solid and measuring its absorbance at 317 nm. The concentration of ergotamine in the solution was determined from a standard curve, thus allowing the percentage composition of ergotamine in the solid phase to be calculated.

Dissolution Studies—The apparatus used in the dissolution studies was a slight modification of the assembly described in USP XIX. A flow inducer[1] was used to pump the dissolution medium into a flow-through cell mounted in a spectrophotometer[2] and back into the dissolution vessel. The absorbance of ergotamine in the circulating dissolution medium was measured at 317 nm, and a dissolution curve was constructed by plotting ergotamine concentration *versus* time.

The dissolution tests were conducted on 100-mg disks of ergotamine tartrate, manufactured by compression at a force of 5 tons in a hydraulic press. The dissolution medium (1000 ml) was maintained at 25.0 ± 0.1°, and the basket of the dissolution apparatus was rotated at 100 rpm.

The compositions of the dissolution media (Table II) were designed to determine the influence of caffeine and citric acid on the dissolution rate of ergotamine in simulated gastric fluid (0.1 *M* HCl) and at the approximate pH value of the region where the stomach empties its contents into the duodenum (pH 5.0, 0.1 *M* sodium acetate–acetic acid buffer).

RESULTS AND DISCUSSION

Ergotamine Solubility in Aqueous Tartaric Acid Solutions—The phase solubility diagram for ergotamine in aqueous tartaric acid solutions is shown in Fig. 1. The points were calculated from the results of experiments in which water or the tartaric acid solutions were saturated with ergotamine tartrate. The pH values of the various solutions are indicated in Fig. 1. The solution that was prepared by saturating water with ergotamine tartrate [$(EH)_2T$] had a pH value of <5.2, which is the calculated pH value of such a solution [the solution contained 3.2×10^{-3} *M* ergotamine plus ergotamine cation; the pKa value of ergotamine cation is 6.4 (6), and the pKa values for tartaric acid are 2.93 and 4.23 (2)]. This point will be discussed more fully later, but it is believed to arise because the ergotamine tartrate sample was contaminated with tartaric acid or ergotamine acid tartrate (EHTH).

The fact that ergotamine cation has pKa value of 6.4 leads to the conclusion that ergotamine is essentially fully protonated between pH 3 and 1.86, so changes in solubility that accompany changes in tartaric acid concentration cannot be accounted for by changes in the degree of ionization of ergotamine.

The solid phase in the presence of 0.25 *M* added tartaric acid contained 80.3% ergotamine and 19.7% tartaric acid. Since this is a 1:1 molar ratio of ergotamine and tartaric acid, the compound is postulated to be ergotamine acid tartrate. The solid phase in the presence of 0.025 *M* added tartaric acid had an ergotamine to tartaric acid ratio of 1.4:1 and most likely was a mixture of EHTH and ergotamine tartrate [$(EH)_2T$].

These observations and the phase solubility diagram can be accounted for on the basis that the reactions shown in Schemes I–IV occur in saturated aqueous solutions of ergotamine tartrate. In Schemes I–IV, EH^+ is the ergotamine cation; TH_2, TH^-, and T^{2-} are tartaric acid, acid tartrate ion, and tartrate ion, respectively; K_s^1 and K_s^2 are the solubility products of $(EH)_2T$ and EHTH, respectively; and K_a^1 (1.04×10^{-3}) and K_a^2 (4.55×10^{-5}) are the acid dissociation constants of tartaric acid (2).

$$(EH)_2{\cdot}T_{solid} \overset{K_s^1}{\rightleftharpoons} 2\,EH^+ + T^{2-}$$

Scheme I

$$TH_2 \overset{K_a^1}{\rightleftharpoons} TH^- + H^+$$

Scheme II

$$TH^- \overset{K_a^2}{\rightleftharpoons} T^{2-} + H^+$$

Scheme III

$$EH{\cdot}TH_{solid} \overset{K_s^2}{\rightleftharpoons} EH^+ + TH^-$$

Scheme IV

The observation that the solid phase in the presence of 0.025 *M* tartaric acid was a mixture of ergotamine tartrate and ergotamine acid tartrate suggests that the solid phase throughout the ascending portion of the phase solubility diagram, *i.e.*, from 0 to 0.05 *M* added tartaric acid, was a mixture of $(EH)_2T$ and EHTH and that the equilibrium reactions in Schemes I and IV were established. Hence, throughout this region, the relationship:

$$\frac{K_s^1}{K_s^2} = \frac{[EH^+]K_a^2}{[H^+]} \qquad \text{(Eq. 1)}$$

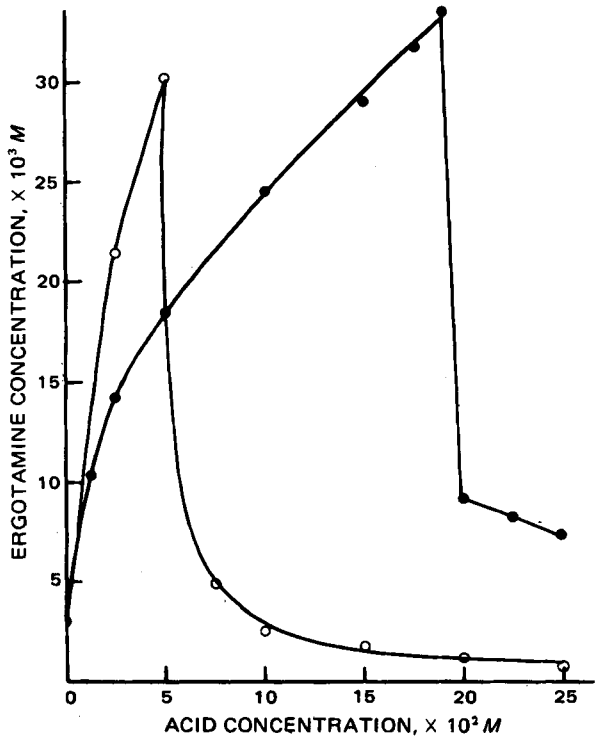

Figure 1—*Effect of the tartaric acid concentration* (○) *and citric acid concentration* (●) *on the solubility of ergotamine tartrate in water. The concentrations of tartaric acid added resulted in various pH values of equilibrated solution: 0* M, *3.0; 0.025* M, *2.33; 0.05* M, *2.15; 0.075* M, *2.10; 0.10* M, *2.04; 0.15* M, *1.98; 0.20* M, *1.92; and 0.25* M, *1.86.*

should apply. Substitution of measured values of $[EH^+]$ and $[H^+]$ in Eq. 1 led to a value of $2.0 \pm 0.1 \times 10^{-4}$ *M* for K_s^1/K_s^2. The solid phase in the presence of 0.25 *M* added tartaric acid was ergotamine acid tartrate. Hence, under these conditions, it is evident that the equilibrium reactions in Schemes II–IV are the only ones operating. Treatment of the data in this region resulted in a value of 2.1×10^{-5} M^2 for K_s^2. Subsequent solution of Eq. 1 gave a value of 4.2×10^{-9} M^3 for K_s^1. Hence, the phase solubility diagram in Fig. 1 may be accounted for by the described postulates and can be quantitated by using values of 4.2×10^{-9} M^3 and 2.1×10^{-5} M^2 for the equilibrium constants K_s^1 and K_s^2 at 25°, respectively.

The presence of EHTH in the EH_2T sample that was obtained commercially could account for the fact that its saturated solution in water had a pH value of 3.0 rather than 5.2 as expected. The analytical results found for this material were: C, 62.11; H, 5.83; N, 10.44; O, 21.52. The formula for $(EH)_2T$ ($C_{70}H_{76}N_{10}O_{16}$) requires: C, 64.01; H, 5.83; N, 10.66; O, 19.49. Therefore, the analytical results are consistent with it containing 50% $(EH)_2T$ and 50% EH·TH (C, 62.36; H, 5.74; N, 10.12; O, 21.77).

If this postulate is correct, then the determinations of ergotamine concentrations made in this study are probably in error by 5% because the Beer's law plots from which concentrations were calculated were constructed on the basis that 1 mole of ergotamine tartrate yielded 2 moles of ergotamine cation. In fact, whereas 1 g of ergotamine tartrate yields 1.52×10^{-3} mole of ergotamine cation, 1 g of a 50:50 mixture of ergotamine tartrate and ergotamine acid tartrate yields 1.45×10^{-3} mole of ergotamine.

Ergotamine Tartrate Solubility in Aqueous Citric Acid Solutions—The phase solubility diagram obtained by saturation of citric acid solutions with ergotamine tartrate is included in Fig. 1. The solid phase in the presence of 0.25 *M* citric acid was a 1:1 mixture of citric acid and ergotamine, presumably the monoergotamine salt of citric acid.

The pH values of solutions in this experiment were not controlled and ranged downward from 3.0. This system was not analyzed further because of its complexity, but it is reasonable to conclude that equilibria similar to those established in the tartaric acid system were in existence as well as others involving the various possible salts of citric acid.

The phase solubility diagram obtained when ergotamine tartrate was added to pH 5.0 citric acid–sodium hydroxide buffers is shown in Fig. 2.

Table II—Dissolution Rates of 100-mg Ergotamine Tartrate Disks in Various Dissolution Media

Composition of Dissolution Medium	pH Value	Gradient of Initial Portion of Dissolution Curve, absorbance units/min × 10^4
0.1 *M* HCl	1.0	35.3 ± 10.5
0.025 *M* caffeine and 0.1 *M* HCl	1.0	288.0 ± 93.1
0.15 *M* citric acid and 0.1 *M* HCl	1.0	83.0 ± 34.1
0.025 *M* caffeine, 0.15 *M* citric acid, and 0.1 *M* HCl	1.0	246.3 ± 99.2
0.1 *M* sodium acetate–acetic acid buffer (acetate buffer)	5.0	37.0 ± 19.1
0.025 *M* caffeine and acetate buffer	5.0	150.3 ± 49.8
0.15 *M* citric acid–sodium hydroxide in acetate buffer	5.0	6.7 ± 1.9
0.025 *M* caffeine and 0.15 *M* citric acid–sodium hydroxide in acetate buffer	5.0	18.3 ± 2.1

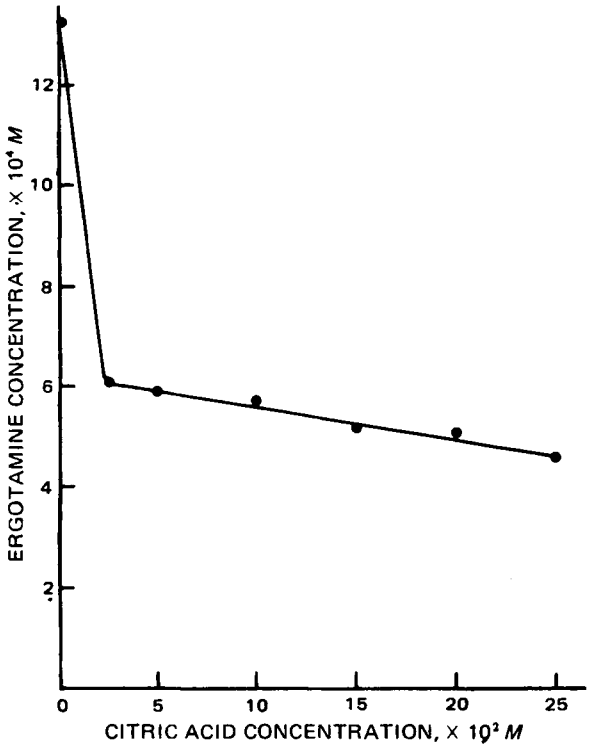

Figure 2—*Solubility of ergotamine tartrate in solutions of citric acid buffered to pH 5.0 with sodium hydroxide.*

In this case, increases in the total citrate concentration caused the ergotamine concentration in solution to decrease. The solid phase in the presence of 0.25 *M* added citric acid contained 72.3% ergotamine. This value is consistent with the solid phase being essentially the monosodium, monoergotamine salt of diionized citric acid, which contains 73.09% ergotamine (EH·HCit·Na). The equilibrium reaction under these conditions is:

$$(EH\cdot HCit\cdot Na)_{solid} \overset{K_2^3}{\rightleftharpoons} EH^+ + Na^+ + HCit^{2-}$$

Scheme V

The decrease in ergotamine concentration in solution that occurred as the sodium citrate concentration was increased resulted from precipitation of EH·HCit·Na by a common-ion effect.

Ergotamine Tartrate Solubility in Aqueous Hydrochloric Acid—The solubilities of ergotamine tartrate in aqueous hydrochloric acid solutions are summarized in Table III. The solid phases were not analyzed[3], but it is postulated that they contained ergotamine chloride. It is known from the pKa value of ergotamine cation (6.4) that the ionic nature of ergotamine does not change appreciably as the pH is lowered from 3.0 (10^{-3} *M* HCl) to ~1.0 (0.1 *M* HCl). Hence, increasing chloride-ion concentrations probably caused precipitation of ergotamine chloride by a common-ion effect. This conclusion is supported by the fact that the product of the concentrations of ergotamine cation [EH^+] and chloride ion in solution was essentially constant (Table III), *i.e.*, it was the solubility product of ergotamine chloride. The slight drift in values could be caused by the change in ionic strength that occurs when the chloride-ion concentration varies by a factor of >100.

The chloride-ion concentrations in the stomach and duodenum are

Table III—Solubility of Ergotamine in Aqueous Hydrochloric Acid

[HCl], *M*	10^4[EH^+], *M*	[Cl^-][a], *M*	K_{SP} = [EH^+][Cl^-], M^2
0.370	0.58	0.362	2.1×10^{-5}
0.100	0.64	0.093	5.9×10^{-6}
0.037	1.77	0.030	5.2×10^{-6}
0.010	7.76	0.003_2	2.5×10^{-6}

[a] Calculated on basis that the solid phase is ergotamine chloride.

[3] A UV spectrum and flame test were consistent with this conclusion.

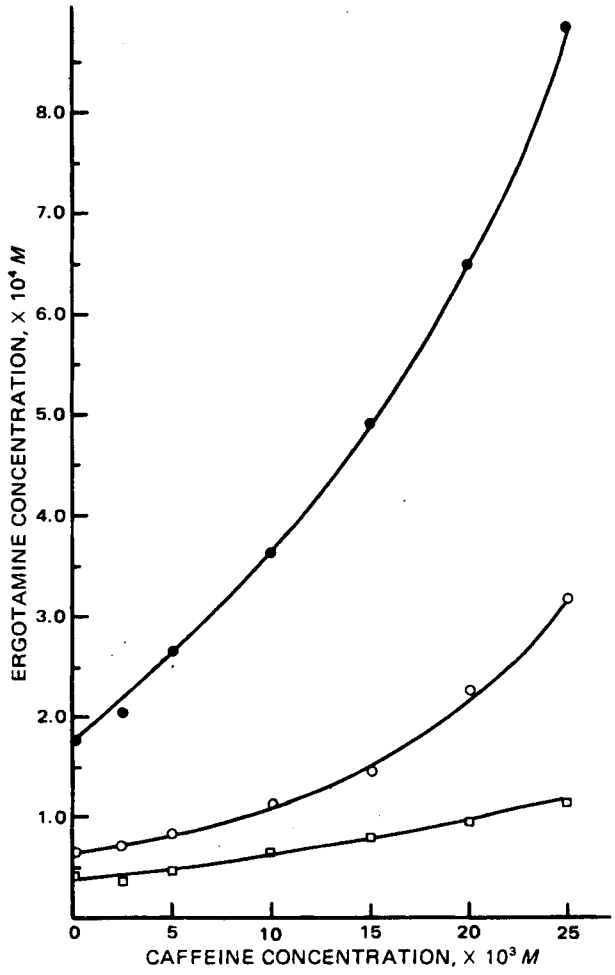

Figure 3—*Effect of caffeine concentration on the solubility of ergotamine in 0.370* M *HCl* (□), *0.100* M *HCl* (○), *and 0.037* M *HCl* (●).

~0.14 *M* (5 mg/ml) and 0.08 *M* (2.6–3.6 mg/ml), respectively (7). Hence, the precipitation of ergotamine chloride in the GI tract may lower the bioavailability of orally administered ergotamine salts.

Zoglio *et al.* (5) determined the solubility of ergotamine tartrate in 0.1 *M* HCl at 30.0° to be ~5.3×10^{-3} *M* ergotamine. This figure is substantially larger than the value of 8.1×10^{-5} *M* calculated in this study under identical conditions. No explanation for this difference can be offered.

Ergotamine Tartrate Solubility in Caffeine Solutions—The phase solubility diagrams that were obtained by saturation of caffeine solutions in aqueous hydrochloric acid with ergotamine tartrate are shown in Figs. 3 and 4. The influence of caffeine on ergotamine tartrate solubility was qualitatively similar to that obtained by Zoglio *et al.* (5) and may be attributed to complex formation between caffeine and ergotamine. The fact that the ergotamine–caffeine phase solubility diagrams are not straight lines suggests that complexes containing more than one caffeine molecule were formed (8).

Dissolution Studies—The dissolution rates of ergotamine from 100-mg ergotamine tartrate disks in various solvents are shown in Table II. The dissolution rates in 0.1 *M* HCl were increased 6.5 times when 0.025 *M* caffeine was included and 2.4 times when 0.15 *M* citric acid was included. The rate was increased seven times in the presence of 0.025 *M* caffeine and 0.15 *M* citric acid. The phase solubility studies indicated that ergotamine tartrate solubility (expressed as ergotamine solubility) in 0.1 *M* HCl was increased six times by 0.025 *M* caffeine and six times by citric acid. Hence, these results were approximately consistent with the Noyes–Whitney model for dissolution (9), which states that the dissolution rate of a solid is proportional to its solubility in dilute solutions.

It is surprising that the dissolution rate of ergotamine in a pH 5.0 acetate buffer was essentially the same as that in 0.1 *M* HCl, whereas its solubility was 20 times greater in the former solvent. A likely explanation is that precipitation of ergotamine chloride, the event that depresses ergotamine solubility in hydrochloric acid solutions, does not occur to an appreciable extent within the diffusion layer. The kinetics of this event apparently are slow with respect to the time taken for a molecule to dif-

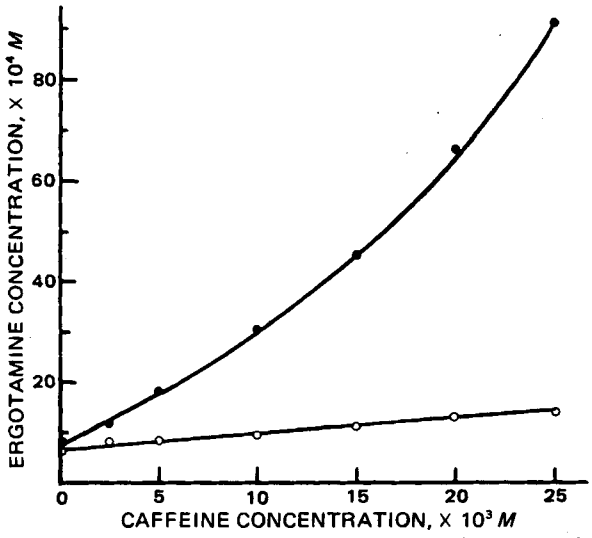

Figure 4—*Solubilizing effect of caffeine on ergotamine tartrate in 0.01 M HCl (●) and 0.50 M sulfuric acid (○).*

fuse from the solid–liquid interface into the bulk of the solution.

The inclusion of 0.025 *M* caffeine in a pH 5 acetate buffer increased the dissolution rate of ergotamine tartrate four times, whereas the inclusion of 0.15 *M* citric acid depressed the rate by a factor of five. The inclusion of 0.15 *M* citric acid in the acetate buffer that contained 0.025 *M* caffeine reduced the rate by a factor of eight.

The rate-enhancing effect of caffeine on ergotamine dissolution at pH 5.0 is consistent with the formation of a soluble molecular complex at this pH as well as at pH 1.0. These studies provided evidence of complex formation at pH 1.0, and Zoglio *et al.* (5) demonstrated complex formation at pH 6.65.

The results in Fig. 2 show that citric acid depressed ergotamine solubility in a pH 5 sodium acetate buffer by a factor of 2.4. Hence, the depressing effect of citric acid on the dissolution rate of ergotamine in a pH 5 buffer is consistent with predictions based on the Noyes–Whitney model.

CONCLUSIONS

1. Chloride ions, a common constituent of the contents of the stomach and duodenum, significantly reduce the concentration of ergotamine in solution by forming ergotamine chloride, a substance with a solubility product of $\sim 5 \times 10^{-6}\ M^2$.

2. The dissolution rate of ergotamine tartrate in water is not depressed appreciably by chloride ions because the precipitation rate of ergotamine chloride apparently is slow compared to the dissolution rate.

3. Protonation of the diionized tartrate anion of ergotamine tartrate by the addition of small amounts of citric acid or tartaric acid increases the solubility of ergotamine. Large amounts of these acids result in the precipitation of 1:1 salts of ergotamine and the acid monoanions. Sodium citrate depresses the solubility of ergotamine.

4. The Noyes–Whitney model for dissolution accounts for the rate-enhancing effect of caffeine and citric acid on ergotamine dissolution at pH 1.0 and the rate-depressing effect of citric acid at pH 5.0.

Wall-Coated Open Tubular Column Coupled with Nitrogen-Selective Detector for Routine GLC Determination of Diazepam, Meprobamate, Phenylbutazone, and Thioridazine in Serum

D. DEBRUYNE ˣ, M. A. MOULIN, R. CAMSONNE, and M.-C. BIGOT

Received March 28, 1979, from the *Laboratory of Pharmacology, Medical School, Laboratory of Functional Explorations B, University Hospital Center of Caen, 14000 Caen, France.* Accepted for publication February 26, 1980.

Abstract □ The selectivity and sensitivity provided by a wall-coated open tubular column coupled with a nitrogen-selective detector allowed rapid, accurate determination of diazepam, meprobamate, phenylbutazone, and thioridazine in serum in the same chromatographic system using 100–200 μl of sample.

Keyphrases □ Diazepam—GLC determination in serum, wall-coated open tubular column coupled with nitrogen-selective detector □ Meprobamate—GLC determination in serum, wall-coated open tubular column coupled with nitrogen-selective detector □ Phenylbutazone—GLC determination in serum, wall-coated open tubular column coupled with nitrogen-selective detector □ Thioridazine—GLC determination in serum, wall-coated open tubular column coupled with nitrogen-selective detector □ GLC—analysis, diazepam, meprobamate, phenylbutazone, and thioridazine in serum, wall-coated open tubular column coupled with nitrogen-selective detector

Various columns and detectors have been used in the GLC determination of diazepam (I) (1–7), meprobamate (II) (8, 9), phenylbutazone (III) (10–14), and thioridazine (IV) (15–17) in serum. Packed columns were used in all of the methods and were coupled to a ^{63}Ni-electron-capture detector (1–5, 7, 14), a flame-ionization detector (6, 8–13,

[a] Nitrogen U.

15, 17), or a ^{90}Sr-ionization detector (16). The columns were packed with Carbowax 20M (1), 3% OV-17 (2–4), 3% OV-225 (5), and 3% SE-30 (6) for I; 3% SE-30 (8) and 3.8% OV-17 (9) for II; 3% OV-210 (10), 3% Apiezon L (11), 3% OV-7 (12), 10% DC 200 (13), and 5% OV-17 (14) for III; and 3% XE-60 (15) and 3% OV-17 (16, 17) for IV.

To overcome the disadvantages of using many materials, one polyvalent chromatographic system, a high-performance wall-coated open tubular column coupled with a nitrogen-specific detector, was used for the determination in serum of these four drugs of various molecular weights and polarities.

The great efficiency (18, 19) and short elution time of the wall-coated open tubular column and the sensitivity and selectivity (20) of the nitrogen detector allow rapid, accurate determination of drugs at therapeutic levels with small samples (100–200 μl) using a simple extraction and no derivatization steps.

EXPERIMENTAL

Standard Solutions—Meprobamate[1] (50 μg/ml), thiopental[2] (5 μg/ml), phenylbutazone[3] (100 μg/ml), diazepam[4] (1, 5, and 100 μg/ml), thioridazine[5] (10 μg/ml), haloperidol[6] (10 μg/ml), and flunitrazepam[4] (5 μg/ml) solutions were prepared by dissolving the pure products in appropriate solvents as indicated in Table I. The solutions were stored at 4°.

Solvents—Chloroform, *n*-hexane, ether[7], and methanol[8] were of high grade purity.

Instrumentation—The gas–liquid chromatograph[9] was equipped with a nitrogen-selective detector[10] and a solid injector[10] and was connected to a recorder[11] with a scale range of 1 mv.

	2.5	2.37	5.2
	3	2.98	0.7
	3.5	3.54	1.7

The glass capillary column (11.5 m × 0.39 mm) with a phase of SE-30 0.4 μm thick was pretreated and tested by the manufacturer[12]. According to the spot test, it presents an effective number of theoretical plates (n = 16,600) for heptabarbital at 200° for a velocity of 18 cm/sec of the carrier gas (nitrogen U) and a capacity factor of three.

The chromatographic conditions were: injector temperature, 290°; detector temperature, 290°; make-up gas (nitrogen U) flow rate, 40 ml/min; hydrogen flow rate, 24 ml/min; air flow rate, 460 ml/min; and chart speed, 2.5 or 5 mm/min.

The other specific conditions for each compound are summarized in Table II.

Procedure—To 100 or 200 μl of human serum[13] in polytef-lined screw-capped glass test tubes (enveloped in a sheet of aluminum foil to ensure darkness for the thioridazine) were added the drug, the internal standard, acid or base, and the extracting solvent (Table I). The mixture was shaken and centrifuged for 5 min at 15° and 3500 rpm.

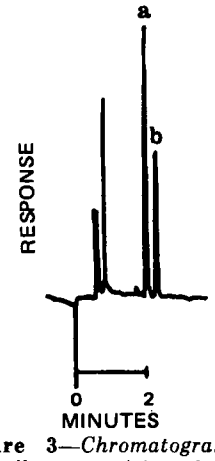

Figure 3—*Chromatogram of phenylbutazone (a) and diazepam as the internal standard (b).*

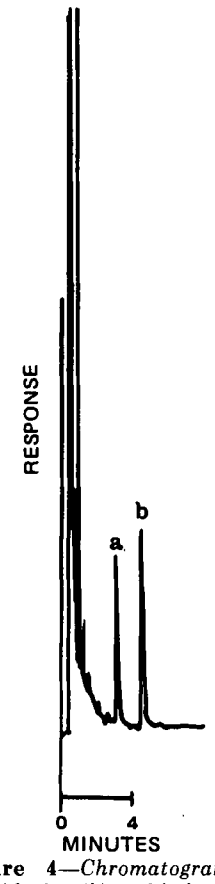

Figure 4—*Chromatogram of thioridazine (b) and haloperidol as the internal standard (a).*

An aliquot (2–10 μl) of the organic phase was injected directly into the chromatograph for II and III. The entire organic phase was evaporated to dryness for I (50° under an air stream) and IV (20° under a nitrogen stream), and the residue was dissolved in 50 μl of chloroform before injection.

RESULTS AND DISCUSSION

Figures 1–4 illustrate the chromatographic responses of the drugs and standards. The chromatographic conditions, retention time, and minimum detectable concentration of each compound are summarized in Table II.

The range of each drug was chosen according to the therapeutic concentrations: 0.7–1.5 (21) or 0.5–2.5 μg/ml (22) for I, 3.4–26.6 (21) or 10 μg/ml (22) for II, 60–150 (21) or 100 μg/ml (22) for III, and 1.1–6.2 (21) or 1–1.5 μg/ml (22) for IV.

The slopes of the regression lines were 1.312, 0.058, 0.015, and 0.527 for I, II, III, and IV, respectively. The correlation coefficient was 0.999 in all cases. The standard deviations ranged from 5 to 3% for 0.5–2 μg of I/ml, from 4 to 3% for 5–30 μg of II/ml, from 4 to 2.5% for 25–150 μg of III/ml, and from 6 to 3% for 1–35 μg of IV/ml over 3 months. Accuracy (Table III) was tested by analyzing spiked samples. Accuracy was improved by avoiding the evaporation step for drugs having sufficiently high therapeutic levels (II and III) and by evaporating the extraction mixture (IV) under nitrogen and in darkness.

For 100-μl serum samples, the minimum detectable concentrations were 0.05, 2, and 5 μg/ml for I, II, and III, respectively. For a 200-μl serum sample of IV, it was 0.3 μg/ml. The twofold determination of the patient serum levels gave the accuracy of the method (Tables III–V). No endogenous interfering substances were found. Exogenous substances such as phenobarbital and lidocaine did not interfere with II; nor did vincamine, quinidine, or clonazepam interfere with I, III, and IV.

The great sensitivity of the wall-coated open tubular column coupled with a nitrogen-specific detector allowed small samples to be used

Table IV—Serum Concentrations of Diazepam in Five Epileptic Patients

Age of Patient, years	Daily Diazepam Dose, mg	Comedication (Daily Dose)	Serum Concentration, μg/ml
8	10	Valproate sodium, 400 mg	0.30 ± 0.02
8	10	Valproate sodium, 800 mg	0.17 ± 0.02
13	8	Phenobarbital, 50 mg; valproate sodium, 600 mg	0.70 ± 0.01
50	15	Phenobarbital, 300 mg	0.42 ± 0.02

6	79.0 ± 2.5
11	66.0 ± 2.0

(100–200 μl), instead of the previous requirements of 1–3 ml for II and III (8, 10–13) and 4–5 ml for IV (15, 17), without increasing the lowest detectable serum concentration. The high resolution of the capillary column (23) reduced the extraction stage to a single step instead of the three steps often suggested to eliminate the interfering substances (12, 13, 15, 17). Furthermore, derivatization steps such as silylation (10) and methylation (12) were unnecessary. The rapid elution time (24) shortened the retention times. These conditions led to shorter extraction and chromatographic stages. Nevertheless, the accuracy and sensitivity were usually improvements over previous assays (3–5, 9, 11, 12, 15, 17).

The determination in serum of four drugs useful in toxicology (25–29) or therapeutic monitoring (30–32) demonstrated the versatility and potential of this chromatographic system and its possible routine use in view of the growing importance of serum level determinations of an increasing number of diverse drugs in clinical practice.

The method was demonstrated by the determination of serum concentrations of diazepam in five epileptic patients (Table IV), of meprobamate in four cases of voluntary overdose (Table V), and of phenylbutazone in a nursing mother given a 250-mg suppository twice daily for 10 days (Table VI).

Immobilization of Proteins in Microspheres of Biodegradable Polyacryldextran

PETER EDMAN, BO EKMAN, and INGVAR SJÖHOLM ˣ

Received November 13, 1979, from the *Department of Pharmaceutical Biochemistry, Biomedical Center, University of Uppsala, S-751 23 Uppsala, Sweden.* Accepted for publication February 28, 1980.

Abstract □ Macromolecules were immobilized by an emulsion polymerization technique in biodegradable microspheres of polyacryldextran, prepared by copolymerizing bisacrylamide with acryldextran. Such particles can be characterized by D–T–C expressions, where D denotes the concentration of derivatized dextran, T is the total concentration of acrylic compounds in the monomeric solution, and C denotes the fraction of cross-linker. In microparticles based on dextran T40 with a D–T–C of 11–1–75, the yield of immobilized protein was greater than in polyacrylamide particles. The properties of the immobilized proteins, *e.g.*, K_m and V_{max}, were retained. The heat stability of the proteins was improved so that 5–10% of carbonic anhydrase still was active after 30 min at 100°. However, the leakage of proteins from the polyacryldextran particles was greater than from polyacrylamide particles.

Keyphrases □ Microspheres—biodegradable polyacryldextran particles, immobilization of proteins □ Polyacryldextran—microspheres, immobilization of proteins □ Proteins—immobilization in polyacryldextran microspheres

The therapeutic use of proteins *in vivo* usually is hampered by rapid protein inactivation or by immunological reactions when the proteins are immunogenic. For instance, asparaginase is not active for long periods in the treatment of acute leukemias (1). However, the noncovalent immobilization of the proteins in microspheres of

(100–200 μl), instead of the previous requirements of 1–3 ml for II and III (8, 10–13) and 4–5 ml for IV (15, 17), without increasing the lowest detectable serum concentration. The high resolution of the capillary column (23) reduced the extraction stage to a single step instead of the three steps often suggested to eliminate the interfering substances (12, 13, 15, 17). Furthermore, derivatization steps such as silylation (10) and methylation (12) were unnecessary. The rapid elution time (24) shortened the retention times. These conditions led to shorter extraction and chromatographic stages. Nevertheless, the accuracy and sensitivity were usually improvements over previous assays (3–5, 9, 11, 12, 15, 17).

The determination in serum of four drugs useful in toxicology (25–29) or therapeutic monitoring (30–32) demonstrated the versatility and potential of this chromatographic system and its possible routine use in view of the growing importance of serum level determinations of an increasing number of diverse drugs in clinical practice.

The method was demonstrated by the determination of serum concentrations of diazepam in five epileptic patients (Table IV), of meprobamate in four cases of voluntary overdose (Table V), and of phenylbutazone in a nursing mother given a 250-mg suppository twice daily for 10 days (Table VI).

© 1980, American Pharmaceutical Association

highly cross-linked polyacrylamide significantly increases stability against denaturation by heat or proteolytic enzymes (2, 3).

BACKGROUND

The proteins are immobilized by two mechanisms: they are partially bound in the polymeric threads and partially entrapped in the polymeric network if they are sufficiently large (2). The leakage is negligible and the biological properties essentially are retained when the particles are small and macroporous (3–5). However, the yield of protein immobilized in the microparticles generally is low (5–10%). After being cleared from the circulation by the reticuloendothelial system, the particles are metabolized slowly, mainly in the liver and spleen (6). The half-life of microspheres injected intravenously or intraperitoneally in the mouse is 10–14 weeks in the liver (6), which in most cases is an inconveniently long half-life.

Preliminary experiments indicated that the yield of proteins in the microspheres can be increased by adding hydrophilic polymers (*e.g.*, dextrans, starch, and polyvinylpyrrolidones) to the monomeric solution during polymerization. In addition if dextran comprises a part of the hydrocarbon chain in the polyacrylamide and forms an intimate part of the microsphere, the polymer should be metabolized more easily. This result can be achieved if the polymeric microspheres are formed from a dextran substituted with acrylic groups and suitable cross-linking agents, *e.g.*, bisacrylamide.

The present paper describes the synthesis of an acryl ether of dextran, the preparation and characteristics of polyacryldextran microparticles, and the properties of the immobilized proteins.

EXPERIMENTAL

Materials—Human serum albumin[1], immunoglobulin G[1], bovine carbonic anhydrase[2] (EC 4.2.1.1), and catalase[3] (EC 1.11.1.6) were used without further purification. Acrylamide[4], *N,N'*-methylenebisacrylamide[4] (I), *p*-nitrophenyl acetate[2], *N,N,N',N'*-tetramethylethylenediamine[2], tris(hydroxymethyl)aminomethane[2], acrylic acid glycidyl ester[3], and other chemicals were analytical grade.

Synthesis of Acrylic Dextrans—Acrylic derivatives of dextran[5] were prepared by reacting acrylic acid glycidyl ester with aqueous alkaline solutions of dextrans of different molecular weights (10,000–2,000,000).

In a typical experiment, dextran (30 g) was dissolved in 250 ml of pH 11, 0.01 *M* carbonate buffer. Acrylic acid glycidyl ester (15 ml) was added, and the two-phase system was stirred magnetically for 5 days at room temperature. The dextran was precipitated with 1000 ml of ethanol and washed with ~300 ml of ethanol. The precipitated dextran was dissolved in 100 ml of distilled water, precipitated again, and washed with ethanol. The procedure was repeated at least four times to free the product from excess glycidyl ester.

Determination of Acrylic Groups—The content of acrylic groups in the dextran derivatives was measured by a method based on the halogenation of the double bonds (7). Aqueous bromine solution was added to the unsaturated acrylic groups, and the subsequent color reduction at 480 nm was measured. The number of acrylic groups was determined from a standard curve obtained with acrylamide as a standard.

Preparation of Microparticles—Microparticles with immobilized proteins were prepared according to a reported method (2, 3). The protein was dissolved in the acrylic monomer solution. In a typical example, the aqueous phase was composed of 3.75 ml of a 2% aqueous solution of I and 6.25 ml of an acryldextran solution (containing 177 mg of derivatized dextran T40/ml with 4.28 mg of acrylic groups/ml).

The water solution was homogenized together with 500 ml of chloroform–toluene (1:4) to produce a water-in-oil emulsion. By addition of catalysts, the water-phase droplets were polymerized to microparticles, which were freed from the organic phase by repeated washings with water and buffer. The microparticles were isolated easily by centrifugation.

^{14}C-Labeled particles were prepared as described by Sjöholm and Edman (6) with [^{14}C]I.

The polyacryldextran gels can be characterized by D–T–C expressions by analogy with the T–C nomenclature suggested by Hjertén (8) for homogeneous polyacrylamide. The first value (D) denotes the concentration of derivatized macromolecules (in this case, dextran) participating in particle formation (grams per 100 ml of solvent). The second value (T) denotes the total concentration of acrylic monomers (grams per 100 ml of solvent). The third value (C) denotes the relative amount of the cross-linker, I, expressed as the percentage (w/w) of the total amount of acrylic monomers. The example given for microparticle preparation yielded particles having a D–T–C of 11–1–75.

Protein Determination—The protein content of the microparticles was determined by amino acid analysis with an automatic amino acid analyzer after hydrolysis in 6 *M* HCl at 105° for 20 hr. The amount of proteins leaking out from the microparticles was determined according to the method of Lowry *et al.* (9). In each case, the protein studied was used as the standard.

Determination of Microparticle Density—The density of the microparticles was determined by density gradient centrifugation using a self-generating gradient medium[6] as reported earlier (2).

Determination of Carbonic Anhydrase Activity—The activity of the carbonic anhydrase was determined using *p*-nitrophenyl acetate as the substrate (10). The enzyme in free form or in microparticles was added to 4.7 ml of 0.05 *M* tris(hydroxymethyl)aminomethane hydrochloride buffer at pH 7.4. The hydrolysis of *p*-nitrophenyl acetate was followed spectrophotometrically at 400 nm at room temperature (22°). From the change of the absorbance, the velocity of the reaction was calculated [$\epsilon = 2.1 \times 10^4$ (10)] and expressed as micromoles hydrolyzed per minute. Correction was made for the spontaneous hydrolysis of the substrate. The microparticles of polyacryldextran did not cause any light scattering at the wavelength used.

Radioactivity—Radioactivity was measured by liquid scintillation counting.

Functional Capacity of Albumin—The functional capacity of albumin was determined as described previously (11). Microparticles with albumin were incubated with [^{14}C]salicylic acid. The amount of albumin binding salicylic acid was calculated from the binding degree and from a standard curve derived by equilibrium dialysis with different albumin concentrations.

Iodination of Human Serum Albumin—Human serum albumin (5 mg) in 0.3 ml of 0.01 *M* phosphate buffer at pH 7.5 was labeled with sodium [^{125}I]iodide[7] (1 mCi) in the presence of lactoperoxidase[2] (EC 1.11.1.7) (40 μg) and hydrogen peroxide (20 μl, 0.005 *M*) according to a literature method (12). The reaction was stopped after 10 min by dilution of the sample with buffer. Separation of ^{125}I-labeled human serum albumin from the reaction mixture was carried out by gel filtration on a column (43 cm^3) of Sephadex G-25[8].

RESULTS

Preparation of Acryldextrans—Acrylic acid glycidyl ester reacts with a hydroxyl group of a glucose residue in the dextran to form a 3-acryloyl 2-hydroxypropyl ether. The molecular weight of the dextrans used (T10, T40, T70, T500, and T2000) ranged from 10,000 to 2,000,000. All dextrans followed a zero-order reaction with the same rate. After 5 days at room temperature (22–24°), one acrylic group was introduced per 20 glucose residues, regardless of the molecular weight of the dextrans.

The best dextran derivative for preparation of the microparticles was T40 (mol. wt. 40,000). Dextrans of higher molecular weight (T70, T500, and T2000) had a solubility too limited for the particle preparation and gave too high a viscosity of the water phase. The lower molecular weight dextran derivative (T10) did not significantly increase the yield of proteins in the particles.

Immobilization of Proteins in Polyacryldextran—The amount of proteins immobilized in polyacrylamide microparticles depends on the size of the protein and the composition of the polymer, which is characterized by the concentration of monomers (T) and the fraction of cross-linking agent (C) in the water phase. The pore radius of the polymer formed is dependent on both T and C. In addition, the radius of the polymeric threads forming the polymeric network is directly proportional to C (2). This relationship generally means that the incorporation of proteins increases with C, but, at the same time, the functional availability of the immobilized proteins is impaired when the pore radius decreases. An increased yield of immobilized proteins also is achieved by increasing

Table I—Amount of Albumin Immobilized in Microparticles of Different Gel Compositions [a]

Particle Composition (D-T-C)	Total Amount of Protein Immobilized, mg	Total Amount of Active Protein in Particles, mg
0-8-35	46.5	17.8
(10)[b]-8-35	59.8	33.2
10-8-35	92.8	56.8
0-4-100	8.0	2.7
4-2-96	22.6	15.0
0-5-80	16.4	3.8
11-1-75	83.5	66.8

[a] The study was carried out with 5 ml of the water phase with 500 mg of ^{125}I-labeled human serum albumin. After the preparation of the particles, their content of protein was measured in a γ-counter. The amount of functionally active protein in the microparticles was determined by estimating the capacity of the albumin to bind [^{14}C]salicylic acid (11). [b] Underivatized dextran.

the concentration of hydrophilic polymers in the water phase, *e.g.*, by adding starch or dextran. Table I summarizes some results from studies on the incorporation of ^{125}I-labeled human serum albumin in different microspheres of highly cross-linked polyacrylamide and polyacryldextran based on dextran T40.

It is evident from Table I that addition of 10% dextran to microparticles with T–C values of 8–35 increased the total yield of protein from 46.5 to 60 mg under the conditions used. The yield was improved further when the dextran was bound covalently in the polymer, as in acryldextran. However, the functional availability measured by the amount of salicylic acid bound was still low. The effect of the acryldextran is illustrated further by the results from other particles. In particles with D–T–C values of 0–4–100 (*i.e.*, those using only I at a concentration of 4%), 8 mg of albumin was incorporated. By adding acryldextran (0.4 g/10 ml) containing 2% acrylic groups, which constitutes only 4% of the total number of monomeric acrylic groups in the water phase, the immobilization of protein was increased significantly. Not even by adding acrylamide (to 20% of the total amount) to D–T–C values of 0–5–80 could the same increase be achieved.

In the subsequent work, polyacryldextran microparticles with D–T–C values of 11–1–75 were used. Dextran T40 containing 2.3% acrylic side chains (w/w) was employed. The amount of I added thus corresponded to 0.075 g/10 ml. The total yield of albumin in such particles was ~83.5 mg, *i.e.*, 16.7% of the total amount present in the water phase, and 80% of this amount was functionally active, *i.e.*, it bound salicylic acid.

Density of Polyacryldextran Microspheres—The density of polyacrylamide microparticles is largely determined by the porosity of the gel (2, 3). Linear polyacrylamide has a density of 1.15 g/ml, which decreases initially when the fraction of the cross-linker increases up to 5–10%. Above this limit, the characteristics of the polymer change to a more macroporous structure, so that the density increases again with C.

Proteins immobilized in the gel decrease the density of the particles (2). As expected, the same phenomenon was seen when dextran was included in the gel. This result most probably was due to two effects: a decreased porosity of the gel and the lower density of dextran compared to that of polyacrylamide. Thus, microparticles with D–T–C values of 11–1–75 have a density of 1.030 g/ml as determined in the colloidal silica density gradient by centrifugation.

Properties of Immobilized Carbonic Anhydrase—The enzymatic properties of carbonic anhydrase in the free state and in polyacryldextran microparticles are compared in Fig. 1*a*. In the two series of experiments, the amounts of enzyme were the same, based on amino acid analysis. From this figure, the Michaelis constant (K_m) for free and immobilized carbonic anhydrase was calculated to be 18 and 22 mM, respectively. The maximal velocity (V_{max}) as calculated from the y axis intercepts was 15% lower with the immobilized enzyme, which means that the enzyme was not utilized efficiently in the microparticles.

Figure 1*b* shows the differences in the enzymatic properties of carbonic anhydrase immobilized in microspheres and after solubilization of the same spheres with dextranase[2] (EC 3.2.1.11) (4 IU/ml of particle suspension incubated for 3 hr at 22°). The Michaelis constant (K_m) was 21 mM for the immobilized enzyme compared to 18 mM for the enzyme released after solubilization of the spheres. This value is the same as that found with the free enzyme. In addition, the dextranase treatment of the microspheres resulted in a 10% increase in V_{max}.

Leakage of Proteins from Polyacryldextran Microspheres—Microparticles (based on dextran T40 with D–T–C values of 11–1–75) were prepared with proteins of various sizes, carbonic anhydrase [mol. wt. 31,000 (13)], human serum albumin [mol. wt. 66,500 (14)], human immunoglobulin G [mol. wt. 150,000 (15)], and catalase [mol. wt. 240,000 (16)]. The microspheres were suspended in pH 7.4 physiological saline so that the protein concentration was 0.2, 4.91, 0.9, and 0.21 mg/ml, respectively. Sodium azide (0.1%) was added as a preservative, and the samples were left at room temperature for 80 days. After centrifugation, the leakage of protein from the spheres was determined in the supernate. Figure 2 summarizes the results. Thus, 65% of carbonic anhydrase was lost from the particles after 80 days, while 33% of human serum albumin, 44% of immunoglobulin G, and 30% of catalase were lost.

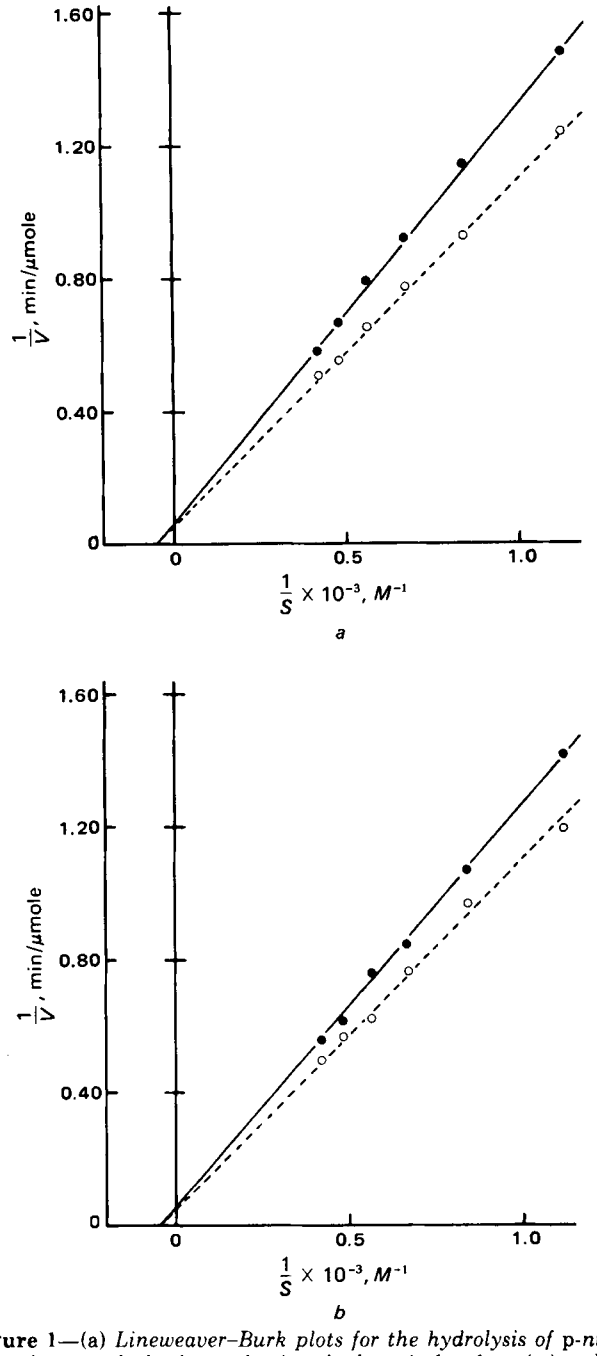

Figure 1—(a) *Lineweaver–Burk plots for the hydrolysis of* p*-nitrophenyl acetate by bovine carbonic anhydrase in free form* (○) *and immobilized* (●) *in microparticles of polyacryldextran.* (b) *Lineweaver–Burk plots obtained with carbonic anhydrase in microparticles before* (●) *and after* (○) *treatment with dextranase.*

Thermostability of Immobilized Carbonic Anhydrase—To investigate the heat stability of immobilized proteins, carbonic anhydrase was incorporated into microspheres of polyacryldextran (based on dextran T40). The spheres were exposed to elevated temperatures for 5 and 30 min. After treatment, the microspheres were cooled in an ice bath for

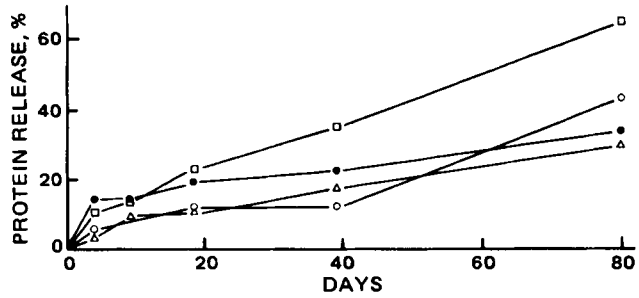

Figure 2—*Leakage of proteins from microspheres during storage at room temperature at pH 7.4. The immobilized proteins were carbonic anhydrase (□), human serum albumin (●), immunoglobulin (○), and catalase (△).*

5 min. After preincubation of the samples at room temperature for 30 min, the remaining activity was measured. Figure 3 shows that the immobilized enzyme was more resistant to heat treatment. All of the free enzyme and 50% of the immobilized enzyme were denatured at 65°. Approximately 5–10% of the enzyme activity was retained even after 30 min at 100°.

Hydrolytic Stability of Polyacryldextran Microspheres—The hydrolytic stability of the polymer, polyacryldextran, was investigated with particles with ^{14}C-labeled I as a cross-linking agent. The labeled microparticles then were incubated at different pH values (2–12) for 2, 4, 8, 12, and 24 hr at 37°. After centrifugation for 15 min at 4°, the supernate was withdrawn and the radioactivity content was measured in the scintillation counter. Figure 4 summarizes the results. The microspheres were not affected significantly at pH 2–9. At pH 11, ~20% of the particles were hydrolyzed in 24 hr. Essentially all of the particles were lost at pH 12 when stored at 37° for 24 hr.

DISCUSSION

The immobilization of proteins in acrylic polymers is influenced strongly by the composition of the polymer, *i.e.*, the total concentration of monomers and the relative fraction of the cross-linker (T and C) in the polymerization mixture. In the present study, the presence of polymers in the mixture, *e.g.*, dextrans or acrylic dextran derivatives, significantly affected the incorporation of protein in the microparticles formed by emulsion polymerization. The yield of protein in the microparticles was increased substantially, even when the total concentration of acrylic monomeric groups in the water phase was decreased substantially. To specify the composition of the polyacryldextran formed, it is suggested that the content of derivatized polymer present is given in grams per 100 ml by adding a D value to the existing nomenclature for characterizing polyacrylamide gels.

The yield of entrapped protein in polyacryldextran may be increased by two mechanisms. First, addition of dextran decreases the gel pore radius. Second, the dextran sterically retains the protein inside the gel during polymerization. The result is increased protein entrapment, implying that the fraction of protein immobilized in the polymeric threads is decreased. This result is evident from the heat stability of incorporated carbonic anhydrase and the leakage of proteins from the microparticles. The fraction of the enzyme that resists treatment at 100° for 30 min is smaller in polyacryldextran (10%) than in polyacrylamide [30% (3)], and the fraction leaking out from polyacryldextran when stored for prolonged periods is substantially larger.

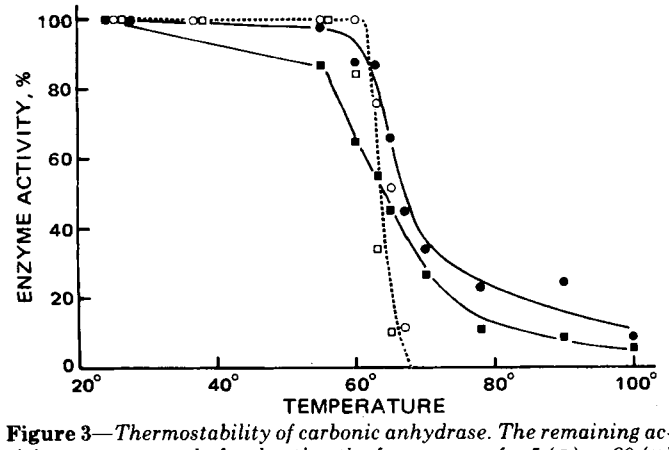

Figure 3—*Thermostability of carbonic anhydrase. The remaining activity was measured after heating the free enzyme for 5 (○) or 30 (□) min and the immobilized enzyme in polyacryldextran for 5 (●) or 30 (■) min.*

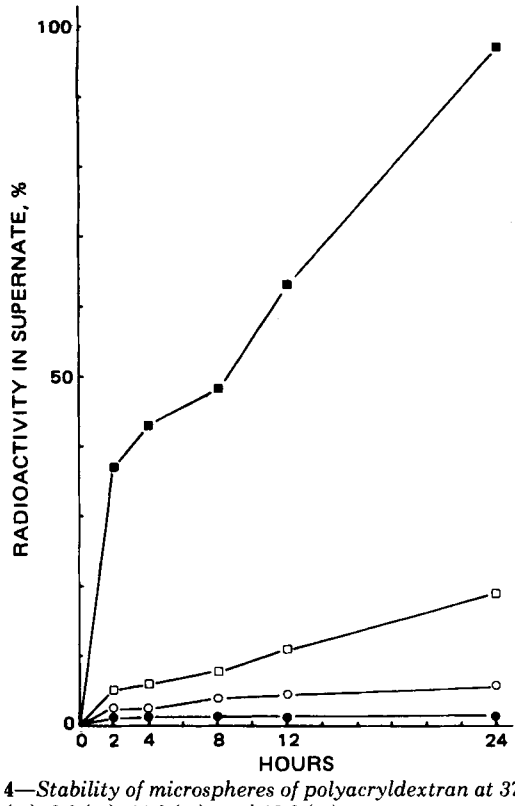

Figure 4—*Stability of microspheres of polyacryldextran at 37° and at pH 2–7 (●), 9.0 (○), 11.0 (□), and 12.0 (■).*

However, in other respects, immobilization in polyacryldextran offers the same advantages as in normal polyacrylamide. For example, the proteins retain their biological properties; K_m and V_{max} of carbonic anhydrase are affected only insignificantly, indicating that the equilibrium between enzyme and substrate is not diffusion dependent, which means that the substrate is not hindered sterically providing the particles are small. Moreover, the incorporation is a mild process as shown by the finding that the small loss in V_{max} and the increase in K_m are recovered almost completely after digestion of the polymer with dextranase.

In addition, other experiments[9] with 11–1–75 particles showed that polyacryldextran was metabolized more rapidly *in vitro* with rat liver homogenates and also was eliminated faster *in vivo* after intraperitoneal injection in mice than in the cases involving polyacrylamide (T–C value of 8–25). These findings were expected since dextran should be degraded easier *in vivo* than hydrocarbon chains, the content of which is comparatively small in polyacryldextran particles with D–T–C values of 11–1–75. The use of dextran thus offers a rich variation in the design of polymeric particles having different biological half-lives. The duration of the enzymatic effects *in vivo* can be controlled adequately without unwanted intracellular accumulation of polymers.

The results presented here were obtained with microparticles of polyacryldextran with D–T–C values of 11–1–75, *i.e.*, those with low T. The total yield of albumin immobilized in the particles was ~15% but could be increased up to ~20% by increasing T, *i.e.*, the concentration of the acrylic monomers in the polymerization mixture. However, the functional availability of the immobilized protein was impaired simultaneously, probably due to the decreased pore radius of the polymer. Furthermore, the leakage of protein from the microspheres was decreased.

In some applications, microparticles with larger amounts of proteins have advantages, even if such particles will be metabolized more slowly. Therefore, for each situation, a compromise must be made between total yield and functional availability and will depend on the desired rate of degradation of the gel, the cost of protein, the acceptable or desired rate of leakage of proteins, and the type of effect aimed at *in vivo*.

Isolation, Identification, and Synthesis of 4-Amino-6,7-dimethoxy-3-quinolinol, the Major Metabolite of Amiquinsin Hydrochloride in Rats and Humans

GEORGE C. WRIGHT *x, RONALD J. HERRETT ‡, JAMES P. HEOTIS ‡, and JAMES L. BUTTERFIELD ‡

Received March 20, 1978, from the **Chemical Research Division and the* ‡*Biological Research Division, Norwich-Eaton Pharmaceuticals, Division of Morton-Norwich Products, Inc., Norwich, NY 13815.* Accepted for publication February 26, 1980.

Abstract □ The metabolism of amiquinsin hydrochloride (4-amino-6,7-dimethoxyquinoline hydrochloride monohydrate, I) was studied in rats and humans. The major metabolite isolated from human urine was identified through synthesis as 4-amino-6,7-dimethoxy-3-quinolinol hydrochloride hydrate (II). Acid hydrolysis of the major metabolite from rat urine also gave II. The structure of the rat metabolite subsequently was tentatively identified as the potassium salt of the 3-*O*-sulfate of II. The pharmacological and toxicological properties of I and II are discussed.

Keyphrases □ Amiquinsin hydrochloride—rat and human metabolites, isolation and identification □ Antihypertensive agents—amiquinsin hydrochloride, rat and human metabolites, isolation and identification □ 4-Amino-6,7-dimethoxy-3-quinolinol—isolation and identification as metabolite of amiquinsin hydrochloride, rats and humans

Wright *et al.* (1) reported that amiquinsin hydrochloride (4-amino-6,7-dimethoxyquinoline hydrochloride monohydrate, I) (Scheme I) demonstrated hypotensive activity. Early biological studies with I included the pharmacological mechanism of action (2) and the absorption, distribution, and elimination of I in dogs (3, 4).

In the present investigation, the metabolism of I was studied in rats and humans. Williams (5) reported that 4-aminoquinoline administered to rabbits was metabolized to 4-amino-3-hydroxyquinoline, which was excreted mainly as an ether sulfate, and that glucuronic acid conjugation was low. Although 4-amino-7-chloroquinoline also was believed to be hydroxylated in rabbits to the 3-hydroxy derivative (5), hydroxylation of this compound in humans was not observed (6).

RESULTS AND DISCUSSION

Isolation and Identification of Metabolites—Metabolite studies with I were done initially in rats. When the rats were dosed orally with [3-^{14}C]I, the major excreted material was parent I; TLC followed by estimation of the activity of the radioactive materials showed the presence of I (61%) and substances at R_f 0.6 (25%), 0.0 (12%), and 0.9 (2%). The materials at R_f 0.0 and 0.9 were not identified.

A preparative method was developed for the isolation of the major rat metabolite at R_f 0.6 that involved separation and purification by gel filtration.

Treatment of the purified R_f 0.6 metabolite with hot methanolic hydrogen chloride gave a hydrolyzed product (hydrochloride of R_f 0.6 metabolite) with physical properties similar to those of the starting R_f 0.6 compound but with significant differences in the NMR spectra and TLC values (Table I). However, a comparison of the physical properties of the hydrolyzed product with those of the synthetic 3-hydroxy derivative II (Table I) clearly demonstrates that the two compounds are identical with respect to their NMR and UV spectra and TLC values. Thus, the hydrochloride of the hydrolyzed R_f 0.6 metabolite was identified as 4-amino-6,7-dimethoxy-3-quinolinol hydrochloride.

The R_f 0.6 metabolite was characterized further through enzymatic hydrolysis with a combination of β-glucuronidase and aryl sulfatase. Isolation of the end-products of enzymatic treatment was attained by extraction and TLC, and each spot then was counted for carbon 14. In the absence of enzymes, or by treatment with β-glucuronidase alone, the structure of the R_f 0.6 metabolite was not altered (Table II). However, treatment with aryl sulfatase and β-glucuronidase together converted the ^{14}C-labeled R_f 0.6 metabolite to [^{14}C]II. Thus, the enzymatic data indicate that the R_f 0.6 metabolite may be the sulfate conjugate of II. The IR spectrum showed a strong S=O stretching band at 8.1 μm, also indicative of a sulfate group in the molecule. The NMR spectra showed that both the R_f 0.6 metabolite and II are substituted in the 3-position. Considering the specificity of the enzymes used, the IR data, and the substitution pattern from the NMR spectra, the R_f 0.6 metabolite probably

TLC[d]	0.60	0.25–0.30	0.30–0.35

[a] 
[b] Exchanged with deuterium oxide. [c] These peaks did not appear, probably because of relatively low concentration. [d] Eastman chromatographic sheet type K-301R (silica gel) developed with water-saturated 1-butanol.

is the 3-*O*-sulfate of II. Elemental analysis of the R_f 0.6 metabolite suggested that the isolated form was a hydrated potassium salt, with potassium acetate cocrystallized with the metabolite. No further work on the structural elucidation of the R_f 0.6 metabolite is planned.

Human volunteers were given a single oral dose of I, and the urine was analyzed for metabolites as described under *Experimental*. Although free I was isolated from human urine (the ether–chloroform extract), none of the R_f 0.6 metabolite was present (Table III). However, the R_f values and fluorescence color observed in isopentanol (or 1-butanol) extracts of urine corresponded to values observed for the synthetic 3-hydroxy derivative (II). The structure of the human metabolite was supported further by a comparison of the NMR, fluorescence, and UV absorption spectra of the human metabolite with those of the synthetic compound (Table III). Controls were run on the human urine to rule out the possibility that the R_f 0.6 metabolite initially was present and subsequently was hydrolyzed to II during isolation. Therefore, the human metabolite was identified as 4-amino-6,7-dimethoxy-3-quinolinol hydrochloride hydrate (II).

Pharmacology—Studies were conducted to evaluate the cardiovascular activity of II in anesthetized dogs, the vasodepressor activities of I and II in anesthetized rats, and the LD_{50} values of I and II in mice (see *Experimental*). Significant hypotensive activity in dogs was observed for II. The intensities of the hypotensive responses elicited by comparable intravenous injections of I and II were similar in rats; however, the duration of the hypotensive response in rats was considerably longer for I than for II. The LD_{50} values for I and II administered intravenously to mice were comparable.

Table II—TLC Data on Enzymatic Treatment of R_f 0.6 Metabolite[a]

Compound	Enzyme	R_f
R_f 0.6 metabolite	β-Glucuronidase + aryl sulfatase	0.46
R_f 0.6 metabolite	None	0.96
R_f 0.6 metabolite	β-Glucuronidase	0.93
II	None	0.50

[a] Eastman chromatographic sheet type K-301R2 developed with benzene–95% ethanol (water) (9:1).

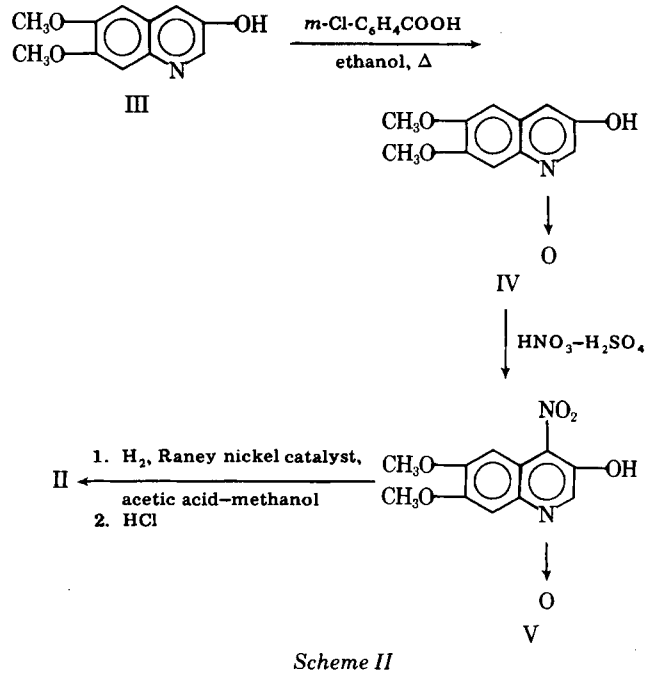
Synthesis—The synthesis of II from 6,7-dimethoxy-3-quinolinol (7) (III) was accomplished in a three-step sequence (Scheme II).

In the nitration of IV, it was assumed that the substitution was directed at position 4 to give V; this assumption was based primarily on the published results (8) of the nitration of quinoline 1-oxide, in which 4-nitroquinoline 1-oxide was obtained in 70% yield with only minor amounts of the 5- and 8-nitro isomers. Furthermore, the fact that the properties of synthetic II correspond to those of the metabolite (where the amino substituent must be in position 4) proves that the nitro substituent of V is in position 4.

EXPERIMENTAL[1]

Isolation of Rat Metabolites—A solution of [3-^{14}C]I was administered orally to fasted rats at 10 mg/kg. The excretion of carbon 14 in urine was determined periodically for 24 hr after dosing; of the total [3-^{14}C]I dosage, 81 and 17% were excreted in the urine and feces, respectively. A 50–250-μl aliquot of the urine collected during each period was suspended in thixotropic gel (9) and counted in the liquid scintillation spectrometer.

TLC[2] was used for identification of the ^{14}C-labeled urinary metabolites of [3-^{14}C]I. Several solvent systems were tested initially, but only butanol saturated with water was satisfactory in separating the metabolites of I. The chromatograms were scanned[3] for radioactivity.



Scheme II

[1] Melting points were determined on a Fisher-Johns hot-stage apparatus and are uncorrected. NMR spectra were determined in dimethylsulfoxide-d_6 with tetramethylsilane as an internal standard on a Varian A60A spectrometer. Fluorescence spectra were obtained on an Aminco-Bowman spectrophotofluorometer.

[a] Commercially prepared silica gel F-254 plates. [b] Found in ether–chloroform or hexanol–heptane (4:1 v/v) extracts. [c] Found in isopentanol or the 1-butanol extracts.

A preparative method was developed for isolation of the major metabolite (R_f 0.6). Forty milliliters of the composite urine sample was placed on a gel filtration column[4] (30 × 4 cm, previously equilibrated with water) and eluted with water (1200–1400 ml). Fractions of ~14 ml were collected with a fraction collector. The absorbance of each fraction was determined at 250 and 320 nm. The R_f 0.6 metabolite fraction was concentrated, placed on a second column[4] (12 × 6 cm), and eluted with water; this procedure resulted in purification of the R_f 0.6 metabolite, as shown by little change in the ratio of the absorbances at 250 and 320 nm, which was 2.9 for the first filtration and 2.8 for the second filtration. The purified R_f 0.6 metabolite was obtained through concentration with an evaporator[5].

The R_f 0.6 metabolite was converted to the hydrochloride of the hydrolyzed R_f 0.6 metabolite by the following procedure. Fifty milligrams of the isolated metabolite was dissolved in 3 ml of absolute methanol, and the resulting solution was purged with hydrogen chloride gas followed by refluxing for 1 hr. Atmospheric moisture was kept from the reaction vessel by a silica gel drying tube. The cooled (tap water) solution was filtered to remove a small amount of insoluble material, and the filtrate was concentrated and filtered with the original precipitate. This procedure yielded 25 mg of dry material. The same procedure was followed with the synthetic 3-hydroxy derivative (II), except that 60 mg of the starting material was used; the yield of the synthetic hydrochloride was 37 mg. Physical data were obtained on these hydrochloride products (Table I).

The enzymatic hydrolysis of the R_f 0.6 metabolite was carried out with β-glucuronidase–aryl sulfatase[6] and β-glucuronidase[7] of bovine origin. The glucuronidase–sulfatase enzyme mix (0.1 ml) was diluted to 5.5 ml with pH 4.5 acetate buffer. This dilution was followed by the addition of a neutral aqueous solution (0.5 ml) containing the ^{14}C-labeled R_f 0.6 metabolite or standard. The 0.5-ml standards were 200 μg of phenolphthalein glucuronide/ml for the β-glucuronidase activity and 200 μg of esterone sulfate/ml for the sulfatase activity. Test tubes containing no enzyme but with all other constituents were included as controls.

All samples were incubated at 37° for 18 hr. At that time, all of the samples of the ^{14}C-labeled R_f 0.6 metabolite and the controls were adjusted to pH 7.5 with 0.1 *N* NaOH and extracted twice with equal volumes of 1-butanol. The butanol extracts were set aside while enzyme activity was checked. This test was done by adding 0.5 ml of 30% trichloroacetic acid to precipitate the enzyme protein, followed by centrifugation and adjustment of the supernate to pH 10.4. Formation of a pink color indicated hydrolysis of the phenolphthalein–glucuronide conjugate to free phenolphthalein. The sulfatase activity was checked by adjusting the solution pH to 7.0 with 0.1 *N* NaOH, followed by extraction of the free estrogen with chloroform. The chloroform extract was reduced in volume *in vacuo*, spotted on thin-layer plates[2], and developed in benzene–95% ethanol (water) (9:1). The free estrone gave a blue spot against a yellow background when the chromatogram was sprayed with 10% phosphomolybdic acid in methanol and heated at 100° for several minutes. TLC[2] of the butanol extracts of samples containing the ^{14}C-labeled R_f 0.6 metabolite were performed with a chloroform–95% ethanol (water) (1:1) solvent system.

Isolation of Human Metabolite—Compound I in gelatin capsules was given to three male adult volunteers as a single oral 50-mg dose, equal to ~0.75 mg/kg. Urine was collected during 0–4 and 8–24 hr. These samples were refrigerated soon after collection and processed for metabolite separation within 1 or 2 weeks.

Solvent extraction of human urine was conducted as follows. The urine was adjusted to pH 10–11.5 with the addition of borate to glycine buffer at pH 10.5, and final adjustment was made with I or 5 *N* NaOH using a pH meter. Extraction with equal volumes of ether–chloroform or hexanol–heptane (4:1) was performed three times, and the extracts were pooled; free amiquinsin was removed in this process. The urines then were adjusted to pH 7–7.5 with 5 *N* HCl and extracted three times with either isopentanol or 1-butanol; free II was removed by this procedure.

Controls were run on the human urine to rule out the possibility that the R_f 0.6 metabolite initially was present and subsequently was hydrolyzed to II during isolation. The R_f 0.6 metabolite was not detected (by TLC) in isopentanol extracts of the human urine but definitely was observed in comparable isopentanol extracts of rat urine.

Additional evidence for the absence of the R_f 0.6 metabolite in human urine was obtained through gel filtration. The urine sample was filtered through a gel filtration column[4] followed by elution with water. The R_f 0.6 metabolite was not in the water eluates, which were examined for UV-absorbing material. However, when previously prepared R_f 0.6 metabolite was added to control human urine and passed through the column[4], it was readily detected by UV absorption at a concentration as low as 1 μg/ml. Thus, the R_f 0.6 metabolite apparently was stable under the conditions of the isolation procedure.

Pharmacology—*Cardiovascular Activity*—Compound II was evaluated for hypotensive activity in three anesthetized (pentobarbital sodium, 35 mg/kg iv) dogs. The compounds were administered intravenously as an aqueous solution, and the blood pressure was recorded from a cannulated femoral artery.

A dose of 1 mg of II/kg iv decreased the arterial blood pressure 48% below the control level within 1 min. After 45 min, the blood pressure returned to within 6% of the control value.

Five milligrams of II/kg given intravenously lowered the arterial blood pressure 68% in <1 min. The pressure gradually rose to a level only 7% below the control by ~120 min postinjection.

Two dogs died after receiving an intravenous 10-mg/kg dose of II.

Vasodepressor Activity—The vasodepressor activities of I and II were evaluated in anesthetized[8], adult male, albino rats[9]. Drug injections were made *via* the femoral vein, and the blood pressure was recorded from a cannulated carotid artery.

A relationship between the dose and the degree of hypotension elicited was not observed; both I and II exhibited a decrease in blood pressure, averaging 30–40% at the doses tested. For II, the time required for the blood pressure to return to 50% of the pretreatment value averaged 2, 3, and 6 min at dose levels of 0.5, 1.0, and 2.0 mg/kg, respectively. However, for I, the 50% return times averaged 8 min at 0.5 mg/kg, 4–55 min at 1.0 mg/kg, and >2 hr at 2.0 mg/kg.

Acute Toxicity—To compare the acute toxicities of I and II, groups of 10 male TFSW mice (19–24 g) were used. For each compound, two doses below and two above the LD_{50} value were administered intravenously. Death within 30 min postinjection was considered as a positive response. The LD_{50} values were calculated by a computerized probit–log dose regression analysis. The observed LD_{50} values for I and II were 67.1 and 66.8 mg/kg, respectively.

Chemistry—*6,7-Dimethoxy-3-quinolinol 1-Oxide (IV)*—A solution of 6,7-dimethoxy-3-quinolinol (6) (III) (52 g, 0.26 mole) in 95% ethanol (methanol) (786 ml) was treated portionwise with *m*-chlorobenzoic acid (73 g, 0.42 mole) with mechanical stirring. The reaction solution was refluxed for 45 min, stirred for an additional 2 hr, stored in the refrigerator overnight, and filtered to remove a small amount of solid. The filtrate was concentrated to near dryness, and the residue was slurried in ether (500 ml) and stored overnight. The solid product was collected by filtration (50 g), mp 235°. Recrystallization from 95% ethanol (methanol) gave 29.6 g (52% yield) of IV, mp 243–245°.

An analytical sample was prepared by further recrystallization from 95% ethanol (methanol), mp 250–251°; NMR: δ 3.93 (s, 6H, 2 OCH_3), 7.17 (d, 1, aromatic, J = 1.9 Hz), 7.30 (s, 1, aromatic), 7.78 (s, 1, heteroaromatic), 8.18 (d, 1, heteroaromatic, J = 1.6 Hz), and 10.3 (s, 1, OH, exchanged with D_2O).

Anal.—Calc. for $C_{11}H_{11}NO_4$: C, 59.72; H, 5.01; N, 8.33. Found: C, 59.32; H, 4.85; N, 8.29.

6,7-Dimethoxy-4-nitro-3-quinolinol 1-Oxide (V)—To IV (5.0 g, 0.023 mole) was added a cold solution of concentrated nitric acid (7.5 ml) in water (4.0 ml). Concentrated sulfuric acid (15 ml) then was added to the mixture at 10–20° over 15 min with hand stirring. The reaction mixture was allowed to warm (exothermic) to 35° over 6–10 min, warmed to 45° over 3 min, maintained at 45–50° for 30 min, and left at 25° for 1 hr. (Since the heat of reaction was erratic and difficult to control, the sample size was limited to 5 g.) The reaction mixture was added to ice (70 ml), and the resultant yellow, crystalline solid was collected by filtration and washed with cold water (20 ml).

This process was repeated a total of four times, the combined product was treated with hot nitromethane (140 ml), and the insoluble product, assumed to be the sulfate salt of V, was collected by filtration. The cooled filtrate yielded 2.0 g of yellow, crystalline V, mp 232–234°. The nitromethane-insoluble product (5.8 g) was dissolved in 10% Na_2CO_3 (29 ml) with cooling in an ice bath and subsequently acidified with acetic acid (4.0 ml) with cooling. The product (V) was collected by filtration and washed with cold water (4 × 3 ml), cold 2-propanol (2 × 4 ml), and ether to yield 4.4 g, mp 228–232° dec. The total yield was 6.4 g (27%).

An analytical sample was prepared by recrystallization from nitromethane, mp 228–232° dec.; NMR: δ 3.95 and 3.98 [2s, 6, $(OCH_3)_2$], 7.10 and 7.74 (2s, 2, aromatic), and 8.32 (s, 1, heteroaromatic).

Anal.—Calc. for $C_{11}H_{10}N_2O_6$: C, 49.63; H, 3.79; N, 10.52. Found: C, 49.22; H, 3.87; N, 10.93.

4-Amino-6,7-dimethoxy-3-quinolinol Hydrochloride Hydrate (II)—A mixture of V (7.0 g, 0.026 mole), methanol (470 ml), acetic acid (5.8 ml), and Raney nickel catalyst (18 g, wet basis) was subjected to hydrogenation at 48 psig. A pressure drop of 90% (of theory) was observed over 4.0 hr. The reaction mixture was cooled in an ice bath, treated with charcoal, and filtered. The filtrate was treated with a hydrogen chloride–2-propanol solution to pH 3–4, concentrated to 80 ml under reduced pressure, and cooled in an ice bath. The product was collected by filtration and washed with cold methanol, 2-propanol, and ether to give 4.9 g (70% yield), mp 264–267° dec.

An analytical sample was prepared *via* three recrystallizations from methanol, mp 265–267° dec.

Anal.—Calc. for $C_{11}H_{12}N_2O_3 \cdot HCl \cdot 2/3\ H_2O$: C, 49.16; H, 5.37; N, 10.43. Found: C, 49.38; H, 5.74; N, 10.34.

4-Amino-6,7-dimethoxy[3-^{14}C]quinoline Hydrochloride Hydrate ([3-^{14}C]I)—The [3-^{14}C]I was prepared by the same basic procedure as that reported previously (1) for the preparation of I.

Potassium Salt of 3-O-Sulfate of II (VI)—*Anal.*—Calc. for $C_{11}H_{11}KN_2O_6S \cdot 2CH_3COO^-K^+ \cdot H_2O$: C, 32.60; H, 3.47; N, 5.07; S, 5.80. Found: C, 32.87; H, 3.74; N, 4.77; S, 5.52.

Determination of Potential Content of Vitamin D_2 (Ergocalciferol) and Vitamin D_3 (Cholecalciferol) in Gelatin-Coated Beadlets, Oil-Based Mixtures, and Multivitamin Tablet and Capsule Formulations

GUSTAV A. WALKER ˣ, BRUCE E. CARPENTER, and DAVID L. TUESCHER

Received December 17, 1979, from *Control Analytical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication February 28, 1980.

Abstract □ A high-performance liquid chromatographic procedure was used to determine routinely the potential vitamin D content in raw materials and multivitamin formulations. The method employs a microparticulate silica column to separate vitamin D from its degradation products as well as other fat-soluble vitamins. Sample preparation is simple, and the chromatographic time is <20 min when progesterone is added to the injection mixture as an internal standard. Replicate analyses of complex multivitamin formulations demonstrate precision with a relative standard deviation of <4%. Spiked placebos typically show 98–100% recovery and a linear chromatographic response. The use of bulk drug as a working reference standard is recommended for the determination of the potential vitamin D concentration in pharmaceutical multivitamin preparations.

Keyphrases □ Vitamin D—high-performance liquid chromatographic determination of potential content of vitamins D_2 and D_3 in gelatin-coated beadlets, oil-based mixtures, and multivitamin tablet and capsule formulations □ Ergocalciferol (vitamin D_2)—high-performance liquid chromatographic determination of potential content in gelatin-coated beadlets, oil-based mixtures, and multivitamin tablet and capsule formulations □ Cholecalciferol (vitamin D_3)—high-performance liquid chromatographic determination of potential content in gelatin-coated beadlets, oil-based mixtures, and multivitamin tablet and capsule formulations □ High-performance liquid chromatography—analysis, potential content of vitamins D_2 and D_3 in gelatin-coated beadlets, oil-based mixtures, and multivitamin tablet and capsule formulations

High-performance liquid chromatography (HPLC) has been established as a rapid, reproducible, and selective method for the separation and analysis of vitamin D in pharmaceutical raw materials. In contrast, current compendial procedures (1) are imprecise and dependent on extensive, time-consuming sample preparation to confer tolerable specificity. For example, the compendial procedure is not suitable for formulations containing vitamin E without the removal of vitamin E from the sample preparation by TLC.

The HPLC methodology allows the separation of the D vitamins from the provitamins, previtamins, and photochemical isomers such as lumisterol, tachysterol, and *trans*-vitamin D. Isocratic separations with adsorption or reversed-phase chromatography have been reported as have gradient elution methods for the determination of vitamin D only or simultaneously with vitamins A and E (2–7).

BACKGROUND

The analysis of vitamin D in bulk drugs as in gelatin-coated beadlets or in oil by HPLC usually is easy and straightforward with minimum sample preparation. However, quantitation of vitamin D in multivitamin products with frequently complex matrixes is difficult without optimum chromatography. The variation in chromatographic cleanliness of excipient components from different suppliers constitutes a special challenge to HPLC methodology. Therefore, few reported HPLC procedures have been equally amenable to all vitamin formulations.

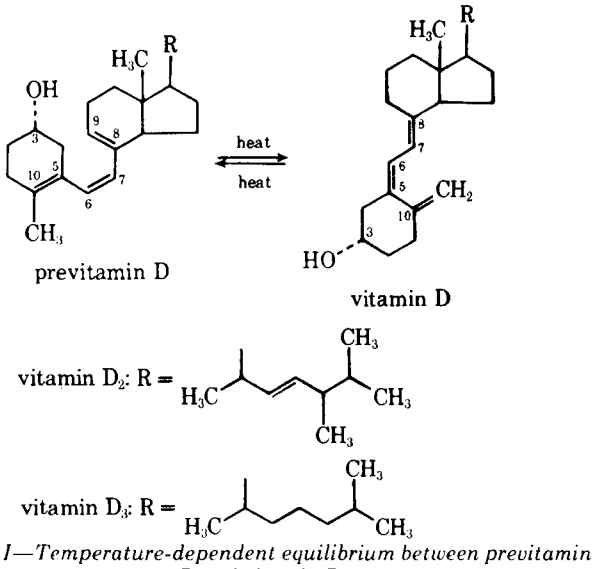
The analysis of vitamin D in pharmaceutical preparations is complicated further by whether this determination should account for the previtamin D content, which is in equilibrium with vitamin D (Scheme I). To allow for conversion of the previtamin into vitamin D, it is necessary to estimate the potential vitamin D content that can be determined through measurement of both the previtamin D (with the appropriate absorptivity correction) and the vitamin D areas. Unfortunately, previtamin D is not always adequately resolved from excipient peaks in the chromatography of products with complex matrixes. Under such chromatographic conditions, it is not quantitated easily.

To account for the previtamin D–vitamin D equilibrium in various products without measuring the previtamin directly, some pharmaceutical manufacturers have recommended a heat equilibration step wherein standards and samples are treated for the same time and at the same temperature (8). Only the vitamin D would have to be measured since the previtamin D should be the same in both the standard and the sample. However, when applied to some multivitamin preparations, this technique is imprecise, and its use frequently results in erroneous estimations of vitamin D content.

The applicability of HPLC methodology is demonstrated in this paper in the determination of vitamin D in bulk drug and in various multivitamin preparations. Sample preparation and chromatographic conditions, modified from previously reported procedures (3, 5, 8), are simple and require minimal changes to accommodate samples with different matrixes. In addition, a practical and reliable approach is recommended for the determination of potential vitamin D content by the use of a bulk drug working standard for samples treated similarly.

EXPERIMENTAL

Reagents and Solvents—Stabilizer-free chloroform[1], *n*-hexane[1], tetrahydrofuran[1], acetic acid[2], and diatomaceous earth[3] were obtained



Scheme I—Temperature-dependent equilibrium between previtamin D and vitamin D

commercially. Water was deionized. Ergocalciferol USP (vitamin D_2) and cholecalciferol USP (vitamin D_3) were used as reference standards. Progesterone USP served as the internal standard.

Apparatus and Column—The liquid chromatograph[4] was equipped with a fixed-wavelength UV detector[5] (254 nm). A microparticulate silica column[6] (250 × 4.6 mm i.d.) was used. The mobile phase was pumped at a flow rate of 1.5 ml/min and 1200 psi. The column was maintained at room temperature. Chromatograms were traced on a strip-chart recorder[7].

Mobile Phase—A mixture of chloroform–water-saturated *n*-hexane–dry *n*-hexane–tetrahydrofuran–acetic acid (60:15:25:1.5:0.4 v/v) was used. This ratio may be adjusted to achieve satisfactory system suitability.

Internal Standard Solution—The internal standard was prepared by adding ~6 mg of progesterone to 200 ml of mobile phase.

Reference Standard Solution—Approximately 18 mg of vitamin D USP reference standard was weighed accurately, transferred to a 100-ml low actinic volumetric flask, diluted to volume with isooctane, and mixed well. This was reference standard Solution A and could be kept for 1 week if maintained at 0° or below. Exactly 5.0 ml of Solution A was transferred into a 100-ml low actinic volumetric flask and diluted to volume with isooctane. This was reference standard Solution B and was prepared daily.

Prior to chromatography, a 1:1 mixture of Solution B and the mobile phase or the internal standard solution was prepared in a low actinic container and mixed well.

Reference standard Solution B was used to characterize the working standard.

Working Standards—The working standards were vitamin D beadlets USP or cholecalciferol USP in oil.

Approximately 8.0 mg of vitamin D gelatin beadlets was weighed accurately and transferred into a 250-ml centrifuge tube fitted with a 24/40 ground-glass joint. Duplicate weighings of a characterized lot were used. The analysis was continued as described under *Procedure A*.

With a syringe, cholecalciferol in oil equivalent to ~2.6 mg of vitamin D_3 was weighed accurately into a 250-ml low actinic volumetric flask. The flask was filled to volume with hexane, and the contents were mixed well. Duplicate weighings of cholecalciferol were used. The analysis was continued as described under *Procedure B*.

Sample Preparation—*Coated Compressed Tablets*—The weight of 25 tablets was measured accurately, and an average tablet weight was determined. Approximately 12 tablets at a time were ground to a fine powder with a mill[8] and were mixed. A sample equivalent to 20 tablets was weighed accurately and transferred into a 250-ml centrifuge tube fitted with a 24/40 ground-glass joint. The analysis was continued as described under *Procedure A*.

Soft Elastic Capsules—Eighteen capsules were transferred into a suitable container such as a 250-ml centrifuge cup fitted with a 24/40 ground-glass joint. The analysis was continued as described under *Procedure B*.

Oil-Based Mixtures—With a syringe, an accurately weighed sample equivalent to ~260 μg of vitamin D_3 was placed in a 25-ml low actinic volumetric flask. The flask was filled to volume with hexane, and the contents were mixed well. The analysis was continued as described under *Procedure B*.

Procedure A—To each centrifuge cup was added 80 ml of a 3:1 solution of dimethyl sulfoxide and water, which had been cooled to room temperature. The headspace was flushed with nitrogen. The centrifuge cups were stoppered tightly, sonicated for 10 min, and shaken vigorously for 1 hr on a mechanical horizontal shaker. The samples must be protected from heat and prolonged exposure to UV irradiation; contact with oxygen should be minimized.

To each centrifuge cup was added an exact volume of hexane (*e.g.*, 25 ml), and the cups were shaken for 45 min as described previously. The samples were centrifuged at ~1500 rpm for 5 min. For the final preparation of tablet formulations or gelatin-coated beadlets, an aliquot of the hexane layer was transferred into a suitable low actinic container and diluted 1:1 with the internal standard solution. The containers were capped tightly, and the contents were mixed well.

Samples with soft elastic capsules were analyzed for vitamin D as described under *Procedure B*.

Procedure B—Without exposing the samples to UV irradiation, an exact volume of the sample (hexane solution) was pipetted onto the column of diatomaceous earth. Then the column was washed with 100 ml of hexane, and the effluent was discarded. Vitamin D was eluted with the addition of 150 ml of toluene and collected in a suitable low actinic boiling flask containing 3.0 ml of the internal standard solution. The toluene was evaporated using a suitable evaporator and a water bath at 37° under vacuum. The residue was dissolved in 6.0 ml of the mobile phase.

Chromatography—The HPLC column was conditioned with the mobile phase until a relatively stable baseline was obtained. A vitamin D beadlet reference standard and not more than four sample preparations were injected alternately.

A chromatographic run should include at least two beadlet reference standard preparations injected in duplicate. The injection volume usually was 40–50 μl for both reference and sample analysis. Retention times of 8–9 and 14–16 min should be obtained for vitamin D and progesterone, respectively.

Calculations—The amounts of potential vitamin D_2 in micrograms per tablet (or capsule) and vitamin D_3 in micrograms per gram were determined from:

$$\text{amount} = \frac{PR_s}{PR_{std}} \frac{C_{std}}{WT_s} SV \times TW_t \times P_{std} \qquad \text{(Eq. 1}a\text{)}$$

or:

$$\text{amount} = \frac{PR_s}{PR_{std}} \frac{C_{std}}{SN} SV \times P_{std} \qquad \text{(Eq. 1}b\text{)}$$

where PR_s is the peak response ratio of the vitamin D peak to the internal standard peak in the sample preparation, PR_{std} is the peak response ratio of the vitamin D peak to the internal standard peak in the standard preparation, C_{std} is the concentration of the vitamin D reference standard [vitamin D_2 in gelatin beadlets (milligrams of beadlets per milliliter) or cholecalciferol USP in oil solution (milligrams per milliliter)], WT_s is the weight of the sample (grams), SN is the sample number (number of capsules, if applicable), SV is the sample dilution volume [equal to the volume of added hexane in the sample preparation (*e.g.*, 25 ml)], TW_t is the weight of one tablet in grams (factor not applicable when sample number is used), and P_{std} is the assigned potency of the vitamin D beadlet reference standard or cholecalciferol USP in oil in micrograms per milligram.

Calculation of Previtamin D—Previous studies showed that previtamin D and vitamin D form an equilibrium dependent on temperature (9). A solution of reference standard vitamin D_3 dissolved in isooctane and contained under nitrogen in a low actinic flask was heated overnight at 80°. Upon cooling, the solution was injected into the HPLC system, and the amounts of previtamin and vitamin D were determined by peak area. Comparisons were made between the vitamin D concentrations in the freshly prepared solution, which had no detectable traces of previtamin, and the vitamin D concentrations in the heat-treated solution. Since no other degradation products were observed, the amounts of previtamin D formed could be calculated from the decrease in the vitamin D peak. The expected areas of the previtamin (assuming an absorptivity identical to vitamin D) were compared with the areas observed, and the differences were equated with the differences in the respective absorptivities of previtamin D and vitamin D. Results from samples treated as described produced an average value for the absorptivity (254 nm) of the previtamin of 40% of that of vitamin D. This value agrees with the value found by Havingo *et al.* (10).

The concentration of previtamin D_2 was calculated from:

$$\frac{\text{area of previtamin } D_2}{\text{area of vitamin } D_2} \times \frac{\text{vitamin } D_2 \text{ (micrograms per tablet)}}{CF} = \text{micrograms of previtamin } D_2 \text{ per tablet} \qquad \text{(Eq. 2)}$$

and:

$$\frac{\text{previtamin } D_2 \text{ (micrograms per tablet)}}{\text{previtamin } D_2 \text{ (micrograms per tablet)} + \text{vitamin } D_2 \text{ (micrograms per tablet)}} \times 100 = \text{percent of previtamin } D_2 \qquad \text{(Eq. 3)}$$

where CF is the correction factor (0.4).

RESULTS AND DISCUSSION

The chromatographic system used separates vitamin D from its major degradation products. Figure 1 shows the resolved elution profile of the products of partially degraded vitamin D_2. The vitamin D_2 solution was

[4] Model ALC/GPC 244 equipped with a U6K injector, Waters Associates, Milford, Mass.

[8] Spex mixer/mill, Metuchen, N.J.

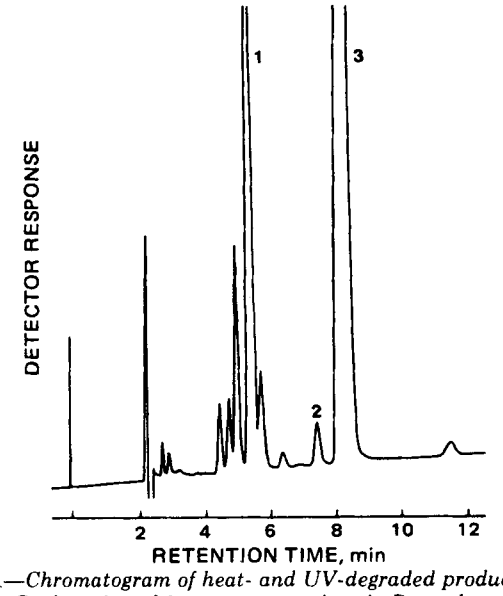

Figure 1—*Chromatogram of heat- and UV-degraded products of vitamin D_2. Peaks 1, 2, and 3 represent previtamin D_2, tachysterol, and vitamin D_2, respectively. The identity of the other peaks was not determined.*

degraded by 2 hr of heat treatment at 90° followed by irradiation for 2 hr at both long and short UV wavelengths. Approximately 6.2 μg of degraded vitamin D_2 was injected. The peaks of interest were associated with previtamin D_2, tachysterol, and vitamin D_2; the respective retention times were 5.4, 7.5, and 8.2 min. Degradation products of vitamin D_3 (not shown) showed a similar elution profile.

Figures 2 and 3 show representative chromatograms of multivitamin preparations. Included are chromatograms of vitamin D_2 in a multivitamin–mineral tablet formulation (Fig. 2) and in a multivitamin capsule formulation (Fig. 3). Chromatograms of placebos showed no interference with the vitamin D peak. Separation of vitamin D from interfering excipient peaks (due largely to degradation of vitamins A and E) and the previtamin D isomer was achieved in each example. Tachysterol was not detected in any preparation, although it was resolved from the vitamin D peak when the degraded D mixture was injected to determine system suitability. Progesterone, which served as an internal standard, was separated completely from vitamin D, its degradation products, and any excipient peaks.

Table I shows an example of a spike recovery study of vitamin D_2 from a multivitamin–mineral placebo formulation. The placebo was spiked with gelatin beadlets from 60 to 120% of theory and carried through the assay. The mean recovery for 10 samples was 99.4% with a relative standard deviation (*RSD*) of 2.2%.

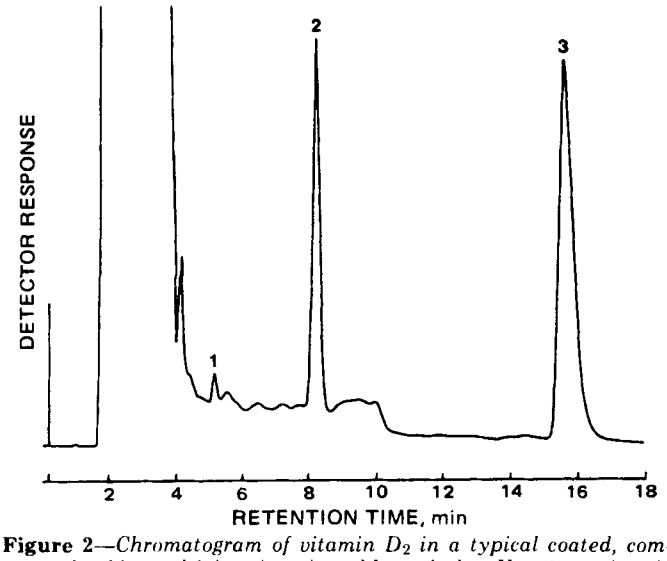

Figure 2—*Chromatogram of vitamin D_2 in a typical coated, compressed, tablet multivitamin–mineral formulation. Key: 1, previtamin D_2; 2, vitamin D_2; and 3, progesterone (internal standard).*

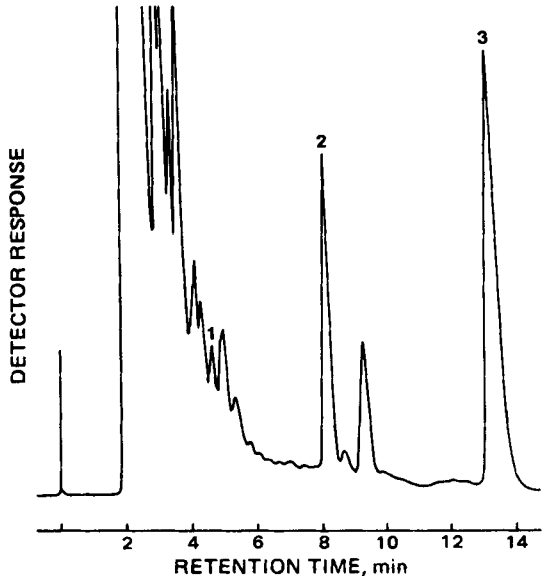

Figure 3—*Chromatogram of vitamin D_2 in a typical capsule multivitamin formulation. Key: 1, previtamin D_2; 2, vitamin D_2; and 3, progesterone (internal standard).*

The data from the recovery studies also provided a comparison of the previtamin D_2 concentration in the bulk drug and in the product formulation. A sample chromatogram (Fig. 2) shows that previtamin D_2 clearly was resolved from excipient peaks. The previtamin D_2 concentration in gelatin beadlets was constant. The mean value for the percentage of previtamin D_2 in seven lots of gelatin beadlets was 11.1% with a relative standard deviation of 3.2%. In comparison, the mean percentage of previtamin D_2 in 14 lots of product formulation was calculated to be 11.0% with a relative standard deviation of 4.2%. Although all product lots were assayed within the expiration date, the age of the samples varied across a range to the limit of expiration.

An alternative to the direct measurement of the previtamin is the use of a well-characterized lot of vitamin D in bulk drug (*i.e.*, gelatin beadlets) as the reference standard. As long as the bulk drug has been maintained at the same temperature as the product formulations and has not been exposed to prolonged UV irradiation, the percentage of previtamin D in the bulk drug is equal to that in the product formulation in accordance with the temperature-dependent equilibrium between these isomers. As indicated previously, the amount of previtamin D_2 in gelatin beadlets and in the formulations in which they had been added was found to be ~11% of the potential vitamin D content when both were stored at room temperature (25°). However, to maintain control of the assay, the potency of the bulk drug was determined periodically *versus* a ergocalciferol USP reference standard.

The use of a well-characterized lot of gelatin beadlets containing vitamin D_2 as a reference standard permits reproducible determinations of the potential vitamin D content in multivitamin formulations. For example, when 12 replicate samples of a multivitamin tablet formulation were assayed over 3 days, the relative standard deviation was 3.5%.

A comparison of assay results obtained by HPLC and the current compendial chemical procedure for the determination of vitamin D_2 in

Table I—Recovery of Vitamin D_2 in Gelatin Beadlets from a Multivitamin–Mineral Placebo Formulation

Day	Percent of Theory	Vitamin D_2 Added, μg	Vitamin D_2 Found, μg	Recovery, %

Table II—Potential Vitamin D Content for Several Lots of a Multivitamin–Mineral Formulation [a]

Lot	HPLC Assay Result, μg/tablet	Chemical Assay Result, μg/tablet
A	11.3	11.6
B	11.8	12.5
C	11.1	13.0
D	11.1	11.4
E	12.7	12.8
F	11.4	12.6
G	11.2	11.7
H	11.2	12.4
I	11.2	12.1
J	11.1	11.4
K	11.2	12.1
L	12.0	11.7
M	11.7	12.9
N	12.2	12.2
O	11.6	11.5
Mean	11.5	12.1

[a] Theoretical content was 11.7 μg/tablet.

15 lots of a multivitamin–mineral tablet formulation is shown in Table II. Vitamin D_2 in gelatin-coated beadlets was used as a reference standard for the HPLC analysis. Each assay result was the average of at least two determinations. The relative standard deviations associated with the HPLC and chemical assays were ~4 and 8%, respectively. For the 15 lots of multivitamin formulation, the mean value for the vitamin D content by the HPLC assay was 11.5 μg/tablet (98% of theory); by the chemical assay, it was 12.1 μg/tablet (103% of theory). The chemical assay results were statistically different at the 95% level of confidence from the results obtained by the HPLC assay.

If the photochemical isomers of vitamin D are held to a minimum, the assay values by the chemical procedure should be approximately equal to the sum of the values for previtamin D_2 and vitamin D_2 as determined by HPLC. However, if such isomers are present at a significant concentration, the results of the chemical assay should be significantly higher than those obtained by the HPLC assay because the chemical method is a colorimetric assay that does not distinguish between previtamin D_2, vitamin D_2, or any of the vitamin D_2 photochemical isomers, which, although separated by HPLC, would positively bias vitamin D_2 chemical analysis.

The use of bulk drug as a working reference standard for the determination of the vitamin D content in commercial multivitamin preparations is recommended when it is known that the bulk drug and product formulation have been handled and stored under similar conditions. These conditions preferably are met by storage and sample preparation at room temperature in the absence of UV irradiation. This approach in the quantitation of the potential vitamin D content in product formulations by HPLC is practical and reliable and does not require direct measurement of the previtamin concentration or time-consuming, frequently imprecise, heat equilibration experiments. Sample preparation is quick, with a single extraction step for most formulations. Assay time is <20 min/sample, and the assay can be automated easily. Chromatography is specific and selective. The assay results are reproducible and within 4% of manufacturing theory for the potential vitamin D content.

Ligand Interaction of Substituted Pyridines with Cytochrome P-450

JERRY L. BORN ˣ and SHERREL EARLY

Received March 12, 1979, from the *College of Pharmacy, University of New Mexico, Albuquerque, NM 87131.* Accepted for publication November 20, 1979.

Abstract □ A series of pyridyl ketones and alkyl pyridines was evaluated as type II ligands for cytochrome P-450. Activity as type II ligands was evaluated in terms of the lipid solubility and the pKa values of the compounds.

Keyphrases □ Ligands—interaction of substituted pyridines and pyridyl ketones with cytochrome P-450, effects of lipid solubility and pKa values on ligand activity □ Pyridines, substituted—ligand interaction with cytochrome P-450, effects of lipid solubility and pKa values on ligand activity □ Ketones, pyridyl—ligand interaction with cytochrome P-450, effects of lipid solubility and pKa values on ligand activity

Cytochrome P-450, the terminal oxidase responsible for many hydroxylation reactions (1, 2), binds to various substrates to produce type II difference spectra (1–6). Compounds that produce type II spectra include alcohols, primary amines, ketones, and pyridines (2).

BACKGROUND

Cytochrome P-450 is an iron-containing porphyrin in which the fifth ligand is a sulfhydryl group and the sixth ligand is a water molecule (7) or an imidazole ring (8). The displacement of the sixth ligand of cytochrome P-450 by pyridine or a pyridine ring of metyrapone[1] (2-methyl-1,2-di-3-pyridyl-1-propanone, I) is thought to result in a pyridine-coordinated cytochrome P-450. The ability of primary amines to produce type II spectra is a function of their ability to bind at a hydrophobic site (5). The base strength of pyridines, as well as an unhindered approach of the pyridine nitrogen to the enzyme, are essential for ligand interaction (9).

Figure 1 shows a proposed (7) binding model for I with cytochrome P-450. The pyridine ring, which is coordinated with the heme site, has a carbonyl attached at position 3; the alkyl-substituted pyridine ring binds at a site removed from the heme portion.

Although this model provides a convenient visualization of the cytochrome P-450 active site, no experimental evidence is available to indicate which pyridine ring of I interacts with the heme site. In addition, the role of secondary binding forces in the interaction of pyridine compounds and cytochrome P-450 has not been investigated.

The difference in the pKa values between the two pyridine rings of I is not likely to be as large as suggested by the pKa values of 5.85 and 3.18 for 3-picoline (II) (10) and 3-pyridyl methyl ketone (III) (11), respectively. Intramolecular steric interactions between the methyl groups of I and the carbonyl-substituted pyridine ring preclude coplanarity of the pyridine ring and the carbonyl group. This situation increases the pKa value of the carbonyl-substituted pyridine ring compared to that of III. Thus, it is not possible to predict which pyridine ring of I coordinates with cytochrome P-450 without considering the role of the carbonyl group in the interaction.

To evaluate further the mode of binding of pyridine compounds to cytochrome P-450, a series of 2-, 3-, and 4-substituted pyridines (Table I) was prepared and evaluated as type II ligands.

EXPERIMENTAL[2]

Pyridyl Ketones—Except for the commercially available pyridyl aldehydes and methyl pyridyl ketones, all pyridyl ketones were prepared by the addition of the appropriate cyanopyridine at 0.05 *M* in 75 ml of benzene to the appropriate alkyl magnesium bromide (ethyl, *n*-propyl, or *n*-butyl) at 0.1 *M* in 150 ml of ether. The reaction mixture was stirred and refluxed for 2 hr, 50 ml of 5% HCl was added slowly, and the mixture was refluxed overnight. The reaction mixture then was made basic with 10% NaOH, cooled, and extracted with ether; the extract then was dried under vacuum. The residue was distilled to give the expected pyridyl ketone. In each case, the physical characteristics of the compounds were as reported previously (12, 13).

4-Alkyl Pyridines—The 4-alkyl pyridines were prepared as described by Wibaut and Hey (14), except for the commercially available methyl- and ethylpyridines. The compounds were purified by repeated recrystallization of their picrates. The free base was obtained by treating the picrates with 10% NaOH and extracting the free base with ether. The ether was dried and removed, and the residue was distilled.

3-Alkyl Pyridines—The 3-alkyl pyridines were prepared by Wolff–Kishner reduction of the 1-(3-pyridyl) ketones. The 1-(3-pyridyl) ketone (0.019 *M*) was dissolved in 25 ml of diethylene glycol, which contained 3.5 g of potassium hydroxide (0.062 *M*) and 4 ml of 85% hydrazine hydrate, and then was refluxed for 4 hr. Distillation directly from the reaction vessel gave a mixture of water and the 3-alkyl pyridine. The 3-alkyl pyridine was separated from the water by extraction with ether, which then was dried and removed. The residue was distilled to give the expected 3-alkyl pyridine. The observed boiling points, literature (15) boiling points, and yields were: *n*-propyl, 76°/40 mm, 182–184°/743 mm, 32%; *n*-butyl, 88°/22 mm, 75–76°/7.5 mm, 41%; and *n*-pentyl, 115–116°/25 mm, 110–112°/20 mm, 37% (15).

Determination of Spectral Binding Constant (K_s)—Phenobarbital sodium (80 mg/kg) was injected intraperitoneally into male Sprague–Dawley rats for 3 consecutive days. The animals then were fasted for 24 hr and sacrificed by decapitation. During the isolation of microsomes, all tissue was maintained at 0–4°. The liver was removed, washed with 0.25 *M* sucrose, and then homogenized in 10 volumes of 0.25 *M* sucrose using a Potter–Elvehjem glass tube and a polytef pestle.

The homogenized material was centrifuged for 15 min at 10,000×*g*,

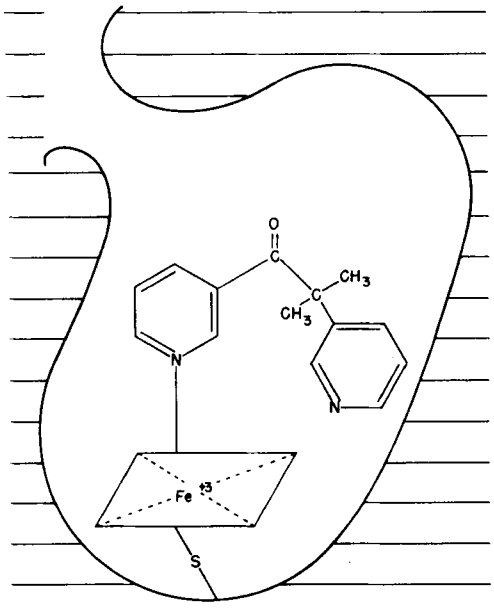

Figure 1—*Proposed interaction (7) of I with the heme portion of cytochrome P-450 via coordination of the carbonyl-substituted pyridine ring of I.*

and the supernate was removed and centrifuged at 100,000×*g* for 1 hr to produce a microsomal pellet. The microsomal pellet was resuspended in 0.15 *M* KCl and recentrifuged at 100,000×*g* for 1 hr. The microsomal pellet obtained by recentrifugation was resuspended in 0.05 *M*, pH 7.4 tromethamine buffer. Then the protein concentration was determined (16) and adjusted to 1 mg/ml with the buffer.

Difference spectra were recorded by placing 3 ml of the protein solution in both the sample and reference cells and then recording the baseline. After the baseline was established, 3-μl portions of the substrate dissolved in tromethamine buffer were added to the sample cell, and successive spectra were recorded. When the solubility of the substrate in the buffer was low, spectroanalyzed methanol was utilized to dissolve the compounds. Addition of as much as 21 μl of methanol to the sample cell did not change the spectra.

Each compound was examined in triplicate at six concentrations. The spectral binding constant, K_s, was determined by substituting the difference between the maximum (427 nm) and minimum (393 nm) absorbances in the spectrum for V in the classical enzyme substrate model (17). The correlation coefficient for the determination of K_s was >0.96 in each case.

Log P values were calculated utilizing the Hansch method (18, 19). Yeh and Higuchi (20) reported π values for methylene substitution on pyridine of 0.61 ± 0.01 and log P values of 3.750 and 3.128 for VII and XV, respectively.

RESULTS AND DISCUSSION

The 2-pyridyl carbonyl compounds investigated failed to produce typical type II spectra. Picolinaldehyde did not produce a recognizable spectrum while 2-pyridyl methyl ketone, 1-(2-pyridyl)propanone, and 1-(2-pyridyl)butanone gave weak type I spectra. 1-(2-Pyridyl)pentanone gave a weak type I spectrum at concentrations up to 2.7×10^{-3} *M*, but a modified type II spectrum was generated when concentrations exceeded 5.6×10^{-3} *M*. The lack of typical type II spectra for the 2-pyridyl carbonyls was not unexpected since their low pKa values, coupled with the steric inhibition of binding by the 2-substituent, would be expected to be unfavorable to type II binding.

On the basis of the pKa values of 3.18 (11) and 3.51 (21) for III and 4-pyridyl methyl ketone (IV), respectively, the 4-pyridyl ketones were expected to be more effective as type II ligands for cytochrome P-450 than the 3-pyridyl ketones. The spectral binding constants, K_s, of these compounds were quite similar, with only 1-(4-pyridyl)pentanone (V) exhibiting an increase in binding as compared to its 3-pyridyl analog (VI) (Table I).

The most basic compounds of this series, the 4-alkyl pyridines (10), also were the most potent type II ligands for cytochrome P-450. The K_s value of 1-(4-pyridyl)pentane (VII) was 1.4 times that of 1-(3-pyridyl)-pentane (VIII) and 2.9 times that of its parent ketone (V).

A plot of log P *versus* log K_s for the 3-alkyl pyridines (II and VIII–XI), the 4-alkyl pyridines (VII and XII–XV), the 3-pyridyl ketones (III, VI, and XVI–XVIII), and the 4-pyridyl ketones (IV, V, and XIX–XXI) produced in each case a straight line with a correlation coefficient of >0.93. This result suggests that lipid solubility of pyridine compounds is important in the ligand interaction.

The role of the carbonyl group in the ligand interaction is observed when alkyl pyridines and pyridyl ketones of similar log P values are compared. The strength of the ligand interaction of pyridyl ketones was surprising in view of their low pKa values. When K_s values for compounds with similar log P values are compared, the pyridyl ketones have equal or greater activity compared to that of the alkyl pyridines. Thus, the K_s values of 1-(3-pyridyl)butanone (XVIII) (log P 1.32) and 1-(4-pyridyl)-butanone (XXI) (log P 1.32) are essentially equal to the K_s value for 4-picoline (XII) (log P 1.26) and greater than that of 3-picoline (II) (log P 1.26). Comparison of the K_s values for V (log P 1.93), 1-(3-pyridyl)pentanone (VI) (log P 1.93), 4-ethylpyridine (XIII) (log P 1.87), and 3-ethylpyridine (IX) (log P 1.87) reveals a similar pattern. The 1-(3-pyridyl)-ketones are more potent ligands for cytochrome P-450 than the 3-alkyl pyridines of similar log P values, suggesting that the introduction of a carbonyl group in the 3-pyridyl series increases the strength of the ligand interaction. This increase in activity occurs in spite of the fact that the pyridyl ketones are less basic than the alkyl pyridines.

In summary, the data indicate that the carbonyl group in simple pyridine compounds is an important determinant in the strength of ligand interactions. The interaction of I with cytochrome P-450 is supported by the data (Fig. 1).

Saturation Adsorption at Interfaces of Surfactant Solutions

HANS SCHOTT

Received November 19, 1979, from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication February 7, 1980.

Abstract □ Plots of the surface or interfacial tension of aqueous surfactant solutions *versus* the logarithm of the bulk concentration of the surfactant frequently become linear at concentrations from 10 to 30% of the critical micelle concentration. According to the Gibbs equation, the surface excess concentration of the surfactant in the linear region is constant; saturation adsorption is said to exist. However, the surface or interfacial tension continues to decrease considerably with increasing bulk concentration of the surfactant throughout the saturation adsorption region until the critical micelle concentration is reached. This decrease is explained as follows. While the surface excess concentration of the surfactant reaches a constant upper limit at the onset of saturation adsorption, the total surfactant concentration in the surface layer, which consists of the surface excess concentration plus the surfactant concentration present in an equivalent volume of bulk solution, continues to increase slightly with increasing bulk concentration throughout the saturation adsorption region. As the bulk concentration approaches the critical micelle concentration, the total surface concentration of the surfactant exceeds its surface excess concentration by small but increasing amounts. Because the surfactant monolayer in the saturation adsorption region is densely packed, slight increases in the total surface concentration produce disproportionately large decreases in the surface or interfacial tension. This explanation is illustrated with experimental data.

Keyphrases □ Surface tension—decrease with increasing bulk concentration of surfactant in saturation adsorption region □ Surfactants—surface tension decrease with increasing bulk concentration of surfactant in saturation adsorption region □ Saturation adsorption region—surface tension decrease with increasing bulk concentration of surfactant

The surface or interfacial tension of aqueous surfactant solutions frequently becomes a linear function of the logarithm of the surfactant concentration when that concentration comes within ~20% of the critical micelle concentration (CMC). According to the Gibbs adsorption equation, the proportionality between the surface or interfacial tension and the logarithm of the bulk concentration of the surfactant indicates that its surface excess concentration has reached a constant value. This fact must be reconciled with the continued decrease of the surface or interfacial tension with increasing surfactant concentration until the critical micelle concentration is reached.

BACKGROUND

Plots of the surface or interfacial tension, γ, of surfactant solutions *versus* the logarithm of the surfactant concentration, c_2, commonly consist of three distinct regions as shown in Fig. 1 for surface tension. Interfacial tensions have lower values, but their curves have similar shapes (1, 2). The curve initially is nearly horizontal but turns gradually steeper as c_2 increases. Eventually, between points B and D, it becomes linear. This segment is followed by another linear segment, DE, that is practically horizontal. The concentration corresponding to point D, where the plot levels off, represents the critical micelle concentration. The surfactant concentration corresponding to point B frequently is reached at concentrations as low as 10–30% of the critical micelle concentration for surfactant adsorption at both air–water and oil–water interfaces (1–3).

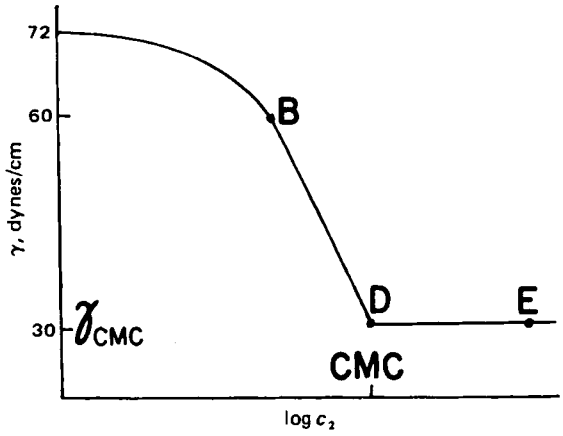

Figure 1—*Schematic plot of surface or interfacial tension* (γ) *versus logarithm of the surfactant concentration* (c_2). *The ordinate scale represents surface tension values.*

The Gibbs equation correlates the surface or interfacial tension of surfactant solutions with their bulk concentration. For nonionic surfactants, or for ionic surfactants in the presence of swamping concentrations of nonsurface-active salts with the same counterion, the equation is (1, 2):

$$\Gamma_2 = -\frac{1}{2.303RT}\frac{d\gamma}{d\log c_2} \qquad \text{(Eq. 1)}$$

where Γ_2 is the surface excess concentration, R is the gas constant (8.314×10^7 ergs/mole/°K), and T is the absolute temperature. The subscript 2 refers to the dissolved surfactant. The solution is assumed to be sufficiently dilute to use surfactant concentration instead of activity.

If a surface layer of area A in square centimeters and thickness τ in centimeters contains $m_2 + n_2$ moles of surfactant while an equal volume of solution $A\tau$ in the bulk contains m_2 moles of surfactant, the surface excess or surface excess concentration of the surfactant is:

$$\Gamma_2 = n_2/A \qquad \text{(Eq. 2)}$$

The surface excess concentration and the total surface concentration of the surfactant, $(m_2 + n_2)/A$, generally are nearly identical because, by definition, surfactants are adsorbed very strongly at interfaces, making $n_2 \gg m_2$.

Along the linear portion BD, the surface excess Γ_2 is constant because the slope $d\gamma/d\log c_2$ is constant. Saturation adsorption has been reached at point B, *i.e.*, the surface excess of the surfactant does not increase further as a result of increases in its bulk concentration beyond point B. However, the surface tension of the solution continues to decrease conspicuously with increasing bulk concentration of the surfactant until point D is reached (1–3). At first glance, these two facts, namely, a constant Γ_2 accompanied by a decreasing γ resulting from an increasing c_2, seem contradictory. In an attempt to reconcile them, it was postulated that as c_2 increases, it becomes easier to bring surfactant molecules to the surface from the progressively more concentrated bulk solution despite attainment of saturation adsorption (1). Surface tension commonly is determined by measuring the resistance to increases in surface area. The continued drop in γ with increasing c_2 along BD was ascribed mainly to the increased activity of the surfactant in the bulk phase rather than at the interface (2).

The purpose of this report is to show that the specific reason for the decrease in surface or interfacial tension of the solution with increasing

bulk concentration of the surfactant in a concentration range where saturation adsorption prevails is that beyond point B, and especially close to point D, $m_2 + n_2$ can no longer be considered equal to n_2. While the surface excess concentration Γ_2 is constant along BD, the total surface concentration $(m_2 + n_2)/A$ continues to increase moderately with increasing c_2 or m_2.

THEORETICAL

Rearrangement of Eq. 1 and integration between the limits γ, c_2 and γ_{CMC},CMC, where γ_{CMC} is the plateau surface tension along DE, yields:

$$\gamma - \gamma_{CMC} = 2.303RT\Gamma_2 \log \text{CMC} - 2.303RT\Gamma_2 \log c_2 \quad \text{(Eq. 3)}$$

The number of moles of surfactant, m_2, contained in $A\tau$ cm^3 of bulk solution is directly proportional to the bulk concentration c_2. If c_2 is expressed in moles per liter:

$$c_2 = 1000m_2/A\tau \quad \text{(Eq. 4)}$$

After substituting and transposing γ_{CMC}, Eq. 3 becomes:

$$\gamma = a - b \log m_2 \quad \text{(Eq. 5)}$$

for the region (BD) of saturation adsorption, where Γ_2 is constant. The constants a and b are equal to $\gamma_{CMC} + 2.303RT\Gamma_2 \log \text{CMC} - 2.303RT\Gamma_2 \log (1000/A\tau)$ and $2.303RT\Gamma_2$, respectively. According to Eq. 5, γ continues to decrease with increasing bulk concentration even after saturation adsorption is reached because c_2 and m_2 increase while Γ_2 and n_2 remain constant.

RESULTS

The values of m_2 at the lower and upper limits of the saturation adsorption range are compared here with the corresponding n_2 values for seven surfactants. Calculations are shown for the nonionic surfactant $C_{12}H_{25}O(CH_2CH_2O)_{12}H$. At 23° (296 °K), $d\gamma/d \log c_2$ in the region of saturation adsorption below the critical micelle concentration was reported as −12.2 dynes/cm (4, 5). Application of the Gibbs equation results in $\Gamma_2 = 2.15 \times 10^{-10}$ mole/cm^2. Hence, $n_2 = A\Gamma_2 = 2.15 \times 10^{-10}$ mole of surfactant for a surface area, A, of 1 cm^2. Saturation adsorption, shown by the linearity of the γ *versus* log c_2 plot, prevailed from the critical micelle concentration of 1.45×10^{-4} mole/liter down to at least $c_2 = 1 \times 10^{-5}$. A surface layer with a thickness, τ, of 20 Å (2×10^{-7} cm) and an area, A, of 1 cm^2 contains $m_2 = c_2A\tau/1000 = 2.0 \times 10^{-15}$ mole of surfactant if the bulk concentration, c_2, is 1×10^{-5} mole/liter but contains 2.8×10^{-14} mole if c_2 is 1.4×10^{-4}. Since $n_2 = 2.15 \times 10^{-10}$ mole, these two m_2 values represent 0.0009 and 0.013% of n_2, respectively. The increase in m_2 from point B to point D amounts to 0.013 − 0.0009 = 0.012% of n_2.

These numerical values and the corresponding data for six additional surfactant systems are listed in Table I. The lower concentration limits of the saturation adsorption range for the three oil–water interfaces probably are smaller than the values shown in the $c_{2,L}$ column since Ref. 3 listed interfacial tension values only at three or four concentrations. The values of m_2 increase by almost an order of magnitude from the lower to the upper concentration limit of the saturation adsorption region, *i.e.*, from point B to point D in Fig. 1. However, most of the m_2 values amount to <1% of n_2. Likewise, the increases in m_2 from the lower to the upper concentration limit of the saturation adsorption region represent <1% of n_2 in most cases. Systems with higher critical micelle concentration values have higher absolute values of m_2 and also higher percentage values of m_2 with respect to n_2 since all seven n_2 values are of the same order of magnitude.

The value of 20 Å for the thickness of the surface region used in the calculations was selected arbitrarily as corresponding approximately to the length of a fully extended surfactant molecule. According to Eq. 4, larger τ values would produce proportionally larger m_2 values for a given bulk concentration, thereby also increasing the percentage of m_2 with respect to the constant n_2 value proportionally.

Despite the fact that the increases in the m_2 values from the lower to the upper concentration limit of the saturation adsorption region constitute only a small fraction of the n_2 values, they are responsible for sizable decreases in surface tension, ranging from 13 dynes/cm for polyoxyethylated dodecanol (4, 5) to 21 and 22 dynes/cm for dodecylamine hydrochloride and potassium laurate (6), respectively, and to 26 dynes/cm for dodecyl alanine (7). The decreases in interfacial tension amount to only 8–13 dynes/cm, but interfacial tensions are lower than surface tensions. Furthermore, the interfacial tension values from Ref. 3 are not available for the entire range of saturation adsorption, so the actual decreases in that range probably are larger.

Evidently, once saturation adsorption is reached, small increases in the total surface concentration of the surfactant produce large decreases in surface or interfacial tension. At that point, the monolayer of surfactant molecules adsorbed at the surface or interface of the aqueous solution is packed so densely that crowding only a few additional surfactant molecules into it substantially reduces the resistance of the surface or interface against expansion in area, *i.e.*, its surface or interfacial tension.

DISCUSSION

The large decrease in surface or interfacial tension that occurs when a small percentage of additional surfactant molecules is crowded into a monolayer in the saturation adsorption region as a result of increases in c_2 and m_2 has an analogy in monomolecular films of insoluble substances spread on water. These insoluble monolayers are characterized by plots of film pressure *versus* area per molecule. Film pressure is the lowering of surface tension caused by the monolayer, *i.e.*, the difference between the surface tension of clean water and of water plus the monolayer. It represents the expanding pressure exerted by the monolayer, which opposes the surface or contracting tension of the clean surface. When a condensed monolayer is compressed beyond the point of close packing, the film pressure–area curve rises steeply. Further small reductions in the area per adsorbed molecule, the equivalent of crowding a few additional molecules into the monolayer, cause large reductions in the surface tension of the system and, hence, large increases in its film pressure (8).

Simultaneous GLC Analysis of Salicylamide, Phenylpropanolamine Hydrochloride, Caffeine, Chlorpheniramine Maleate, Phenylephrine Hydrochloride, and Pyrilamine Maleate in Capsule Preparations

FABRIZIO DE FABRIZIO

Received November 19, 1979, from *Adcock-Ingram Laboratories, P.O. Box 2368, Johannesburg 2000, South Africa.* Accepted for publication February 2, 1980.

Abstract □ A GLC method is described for the quantitative determination of salicylamide, phenylpropanolamine hydrochloride, caffeine, chlorpheniramine maleate, phenylephrine hydrochloride, and pyrilamine maleate. The sample was dissolved in ethanol, and an aliquot of the solution was brought to dryness and treated with 0.1 ml of 4-(dimethylamino)pyridine in pyridine–acetic anhydride (1:1). The components were isolated and measured by applying 1 μl of the reaction mixture to a chromatograph equipped with a flame-ionization detector and fitted with 8% OV-101 glass columns. The accuracy was good. Dicyclohexylphthalate was used as the internal standard.

Keyphrases □ GLC, flame ionization—simultaneous analysis of salicylamide, phenylpropanolamine, caffeine, chlorpheniramine, phenylephrine, and pyrilamine, capsule preparations □ Salicylamide—GLC analysis, capsule preparations □ Phenylpropanolamine hydrochloride—GLC analysis, capsule preparations □ Caffeine—GLC analysis, capsule preparations □ Chlorpheniramine maleate—GLC analysis, capsule preparations □ Phenylephrine hydrochloride—GLC analysis, capsule preparations □ Pyrilamine maleate—GLC analysis, capsule preparations

GLC procedures have been used extensively for the determination of salicylamide (I), phenylpropanolamine hydrochloride (II), caffeine (III), chlorpheniramine maleate (IV), phenylephrine hydrochloride (V), and pyrilamine maleate (VI) as drug substances and in certain combinations, but no single method has been developed for their simultaneous quantitation. In the preparation used in this study, phenylephrine was the only active ingredient that had to be derivatized before GLC. The other components could have been chromatographed directly using a suitable liquid phase (1, 2).

The determination of phenylephrine as the trifluoroacetate derivative (3) was not applicable to this preparation. The narrow margin allowed for temperature and reaction time was not compatible with those components that gave derivatives with the same reagent. Hista and Laubach (4) showed that a combination of phenylephrine, phenyltoloxamine, chlorpheniramine, and phenylpropanolamine could be chromatographed as trimethylsilyl derivatives using bis(trimethylsilyl)acetamide. However, following the same procedure during a preliminary analysis, the chromatogram exhibited interfering additional peaks, which made the determination of some components difficult.

In this work, the problems encountered were resolved by preparing acetyl derivatives of I, II, and V and using a mixture of 4-(dimethylamino)pyridine, pyridine, and acetic anhydride as the acetylating reagent. Connors and Albert (5) reported that 4-(dimethylamino)pyridine is an excellent catalyst for the formation of acetyl derivatives. It promoted the acetylation of various hydroxyl groups under milder conditions when compared with pyridine alone (6).

EXPERIMENTAL

Apparatus—The gas chromatograph[1] was equipped with a flame-ionization detector and an electronic integrator. The glass-coil columns, 1.8 m × 2 mm, were packed with 8% OV-101 on 80–100-mesh Chromosorb W-HP.

Reagents[2]—4-(Dimethylamino)pyridine (1.2%) in pyridine was prepared weekly. Acetic anhydride also was used.

Solution Preparation—Standard solutions[3] were prepared by weighing accurately ~58, 38, 72, and 49 mg of II, IV, V, and VI, respec-

tively, separately into 25-ml volumetric flasks and dissolving the solid and diluting the solution to 25 ml with ethanol. The internal standard solution was prepared by dissolving ~80 mg of dicyclohexylphthalate in 50 ml of chloroform.

Chromatography—The oven was programmed at 9°/min from 170 to 270° after an initial 3 min; the injection port and detector temperatures were 250 and 290°, respectively. The nitrogen carrier flow rate was 15 ml/min. Hydrogen and air flow rates were adjusted to give maximum response. The attenuation of 13 was reduced to 9 after 10 min.

Standard Preparation—About 240 mg of I and 40 mg of III were weighed accurately into a 50-ml volumetric flask. Standard solutions of II (4 ml), IV (1 ml), V (2 ml), and VI (4 ml) and 5 ml of the internal standard solution were added. The solution was brought to volume with ethanol. A 0.5-ml aliquot was evaporated in a 1-ml glass vial[4] with a gentle nitrogen stream at room temperature.

The residue was allowed to react with 0.1 ml of a 1:1 (v/v) mixture of

[a] n = 10 determinations.

1.2% 4-(dimethylamino)pyridine solution and acetic anhydride (mixed just before use) for 18 ± 1 min at 40° in a screw-capped vial. One microliter of the reaction mixture was injected.

Sample Preparation—The contents of a representative number of capsules[5] were mixed, and an aliquot of powder corresponding to ~240 mg of I was weighed accurately into a 50-ml volumetric flask. About 30 ml of ethanol was added, and the flask was heated in a water bath at 80° for 15 min. The flask then was shaken mechanically until it was cool. Five milliliters of the internal standard solution was pipetted into the flask, and ethanol was added to the mark. An aliquot of the solution was centrifuged, and 0.5 ml of the clear supernate was treated as described for the standards.

RESULTS AND DISCUSSION

The performance of each component was evaluated by measurement of the response factor, the ratio of the peak area/weight of the substance to the peak area/weight of the internal standard (Table I). The results were obtained by preparing five solutions for each component having the same concentration range as in the commercial preparation. Each solution was analyzed five times.

When the concentration of each component was varied between 80 and 120% of the label claim, the response factor of salicylamide increased by ~3% with the same reproducibility. The pyrilamine maleate response factor decreased by ~5%, and the percent relative standard deviation of solutions of different concentrations was 3.48% compared to 2.18% for one concentration. The remaining components showed similar response factors and reproducibility as for solutions of one concentration.

The acetylation reaction was completed in 5 min for phenylephrine and phenylpropanolamine at room temperature, while salicylamide gave two peaks. Heating the reaction mixture at 40° for 18 min resulted in complete acetylation and a single peak for salicylamide (Fig. 1). The other components, III, IV, and VI, did not undergo nucleophilic catalysis since they did not have active hydrogen atoms. Preliminary injections of the reagent mixture alone after heating at 40° for 18 min showed two peaks at 1.67 and 4.65 min, which did not interfere. Prolonging the heating time beyond 30 min or maintaining the temperature at 90° for 5 min caused a third peak to appear at 13.96 min, which also did not interfere. The reaction mixture of all components was analyzed over a 3-hr period without a significant drifting of the response factor.

The accuracy and precision of the procedure were estimated by analyzing a standard solution containing all six active ingredients plus the internal standard. This solution was determined eight times (Table II). The precision study also was carried out by analyzing capsules of a production batch. The sample was injected 10 times (Table III). The data presented, including the reproducibility, accuracy, and response factor, establish the validity of the method. The procedure is relatively simple and rapid. The six active ingredients were chromatographed and determined in 17 min.

Structure–Activity Relationships of Benzohydroxamic Acid Inhibitors of Ribonucleotide Reductase

BART van't RIET *x, LEMONT B. KIER *, and HOWARD L. ELFORD ‡

Received July 5, 1979, from the **Department of Pharmaceutical Chemistry and the* ‡*Department of Biochemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication January 31, 1980.

Abstract □ A structure–activity relationship study of 28 substituted benzohydroxamic acids that inhibit ribonucleotide reductase was undertaken to discern the structural features of the molecule contributing to the inhibitory potency of these compounds. An equation containing three molecular connectivity indexes, but not including Hammett σ values, was developed which gives close correlation with observed values for ribonucleotide reductase inhibition. It is postulated that the inhibitory potency involves two parts of the benzohydroxamic acid molecule. One is the hydroxamic portion, which complexes with the metal component of the enzyme, providing a qualitative effect. The other is an interaction involving the benzene ring and its substituents and may provide the quantitative aspect of the observed inhibition values.

Keyphrases □ Hydroxyurea, analogs—substituted aryl hydroxamic acids, inhibition of ribonucleotide reductase, structure–activity relationships, molecular connectivity indexes □ Structure–activity relationships—substituted aryl hydroxamic acids, inhibition of ribonucleotide reductase, molecular connectivity indexes □ Molecular connectivity indexes—substituted aryl hydroxamic acids, inhibition of ribonucleotide reductase, structure–activity relationships □ Antitumor agents—substituted aryl hydroxamic acids, inhibition of ribonucleotide reductase, structure–activity relationships

The reduction of ribonucleotides to deoxyribonucleotides is a rate-limiting step in DNA biosynthesis and, hence, cellular replication. The required enzyme, ribonucleotide reductase, is inhibited by hydroxyurea, which presently is the only clinical antitumor agent with this primary mode of action. Replacement of the amino group of hydroxyurea by various aryl groups gives hydroxamic acids that inhibit ribonucleotide reductase at concentrations lower than those of hydroxyurea (1). The aryl hydroxamic acids also prolong the life of mice with L1210 leukemia (2, 3). Several aryl hydroxamic acids were reported to inhibit DNA synthesis (4, 5).

The possibility of improving on existing chemotherapeutic agents led to an examination of the relationship between the enzyme inhibitory potency and the structures of 28 pyridyl and benzohydroxamic acids, which were tested in this laboratory.

METHODS

Molecular structures can be analyzed in terms of the number of atoms, the kind of atoms, bonding types, and the adjacent environment by the molecular connectivity method (6–10). Molecular connectivity indexes have been computed for each compound in this study (7). In addition, the Hammett σ values for the substituents were summed for each compound and included as an electronic contribution variable. A multivariable search for the best correlation was conducted in a regression analysis.

The synthesis and testing of the *in vitro* inhibitory potency of the aryl hydroxamic acids were reported elsewhere (1, 3). The concentration for the ID_{50} used in this study is expressed as the pC value (Table I). The pC values were determined graphically from at least three concentrations within 1 log unit after determining the inhibition range. In repetitive experiments, the observed pC values agreed within 0.15 pC unit.

RESULTS AND DISCUSSION

A search for the best three-variable equation relating potency (expressed as pC) and structure (encoded with connectivity indexes) was conducted. Hammett σ values were included in the search but did not appear in any equation with a high correlation. The best equation is:

$$pC = 2.36(\pm0.04)^3\chi_p - 3.98(\pm0.53)^0\chi^v + 0.97(\pm0.05)(^1\chi^v)^2 + 9.20(\pm5.50) \quad \text{(Eq. 1)}$$

$$r = 0.943 \quad s = 0.21 \quad n = 28 \quad F = 64$$

Equation 1 explains about 90% of the variation in the data. Because of the experimental variation in pC determinations, the equation is nearly as good as can be expected from the data. Predicted values are found in Table I.

The $^3\chi_p$ index is a weighted count of contiguous three-path fragments, the $^0\chi^v$ index is based on atom deltas, and the $^1\chi^v$ index is a weighted count of bonds. The last two indexes are based on valence deltas. The connectivity index is computed by the general formula $^m\chi_t = \Sigma(\delta_i\delta_j \ldots \delta_n)^{-1/2}$, where m is the order (number of bonds), t is the type (the path in these cases), and the number of deltas in parentheses is equal to the number of bonded atoms in the fragment of order m.

It is apparent that the $^3\chi_p$ index quantifies a structure fragment that plays a favorable role in the pC value. The $^3\chi_p$ index can discriminate among compounds having the same number of substituents in different substitution patterns. Thus, the $^3\chi_p$ index is derived from an additional subgraph wherever two ring substituents are *ortho* to each other. Equation 1 thus describes this structural condition as more favorable for inhibitory potency than the alternative cases.

This situation is illustrated in several examples. Compounds IV, VI, and VIII have *ortho*-, *meta*-, and *para*-hydroxy substitution, respectively, and have the corresponding pC values of 3.82, 3.46, and 3.60. An identical case is found in the comparison of the monoamino derivatives, V, VII, and IX. Again, the *ortho*-substituent is described correctly by the equation as having a larger $^3\chi_p$ term and, hence, a larger pC value. Disubstituted derivatives reinforce this structural analysis (compare XIII–XVIII). Finally, XXVI is correctly described as having the largest pC value by virtue of having four adjacent ring substituents.

The influence of the $^0\chi^v$ and $^1\chi^v$ indexes essentially offsets the information encoded in $^3\chi_p$ (i.e., increasing size increases potency). This result leaves the $^3\chi_p$ index with the exclusive role of encoding the favorable influence of *ortho*-substituents.

The failure to find the Hammett σ term in any high correlation equation indicates that the electronic contribution of the ring substituents is not a prominent factor in the inhibitory potency.

Further evidence for this conclusion can be found in the direct comparison of several compounds. Compounds IV, V, and IX have significantly different Hammett σ values, but their pC values are close. Compounds VI and VII have appreciably different σ values whereas their observed pC values are the same. Thus, regression analysis reveals that electronic effects of the substituents are not prominent but that structural features encoded in the molecular connectivity indexes can account for most of the systematic variation in the pC values in this set of compounds.

These observations indicate that the ring substituents play a role in the inhibitory potency of the hydroxamic acid molecule. This role could take the form of an interaction involving the ring and its substituents or an interaction of the substituents themselves with the active site. Thus, the lack of an electronic contribution to the ring indicates that the general region of the ring must interact with an enzyme binding site. Therefore, it is postulated that two types of interaction occur: (*a*) an underlying constant activity of the hydroxamic acid function with the metal component of the enzyme and (*b*) an additional interaction due to the ring

Sensitive Method for Determination of Ethinyl Estradiol in Presence of Norethindrone

SHINICHIRO HIRAI, ANWAR HUSSAIN ˣ, and SALIM BABHAIR

Received November 14, 1979, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication February 8, 1980.

Abstract □ A sensitive spectrophotofluorometric procedure for the determination of microamounts of ethinyl estradiol is described. The method is useful for the determination of ethinyl estradiol in the presence of norethindrone and common tablet excipients, especially in dissolution media.

Keyphrases □ Ethinyl estradiol—spectrophotofluorometric analysis in the presence of norethindrone and common tablet excipients □ Spectrophotofluorometry—analysis, ethinyl estradiol in the presence of norethindrone and common tablet excipients □ Dissolution rates—ethinyl estradiol in tablets, spectrophotofluorometric analysis in the presence of norethindrone and common tablet excipients

To study the dissolution rate of ethinyl estradiol and norethindrone from tablets, a sensitive procedure is needed to determine microamounts of these drugs in the presence of each other. The spectrophotometric methods described in the USP (1) for the determination of the two drugs require at least 20 tablets of each and, consequently, cannot be used to determine very small amounts of ethinyl estradiol in the dissolution medium, especially in the pres-

ence of norethindrone and tablet excipients. It was shown that ethinyl estradiol exhibits fluorescence in the presence of sulfuric acid (2–5).

This report describes a sensitive spectrophotofluorometric procedure for the determination of very small amounts of ethinyl estradiol in dissolution media.

EXPERIMENTAL

Reagents and Equipment—Ethinyl estradiol[1] and norethindrone[1] were used as supplied. All other solvents and reagents were analytical reagent grade. A spectrophotofluorometer[2] was used.

Standard Solution and Sample Preparation—The standard stock solution of ethinyl estradiol was prepared to contain 3.5 μg of ethinyl estradiol/ml in chloroform. To determine if the common excipients used in tablet formulations interfere with the fluorometric analysis of ethinyl estradiol, four powder mixtures (Vials 1–4) were prepared (Table I). To determine the amount of ethinyl estradiol in the dissolution medium, two tablet formulations (Vials 2 and 4) were prepared[3] using 11.9-cm concave punches and die.

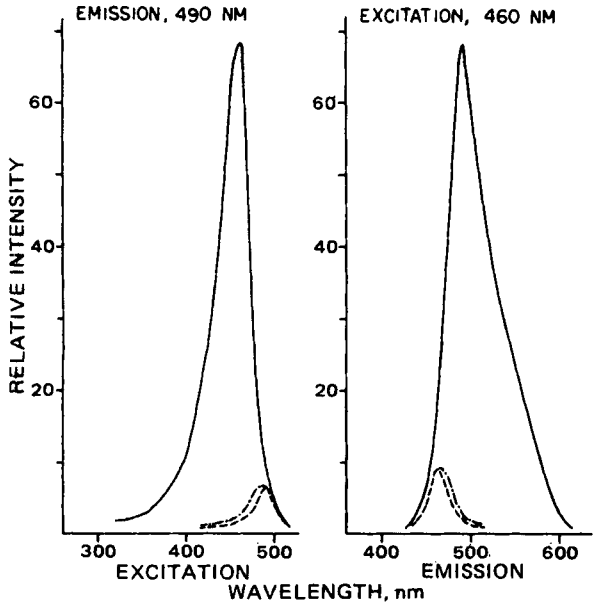

Figure 1—*Excitation and emission spectra of ethinyl estradiol. Key:* —, *ethinyl estradiol (140 ng/ml);* - · -, *norethindrone (2000 ng/ml); and* - - -, *blank.*

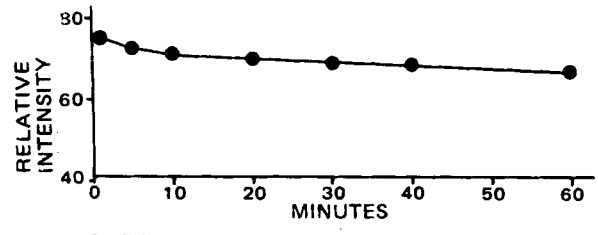

Figure 2—*Stability of fluorescence after the addition of sulfuric acid.*

Calibration Curve—Into screw-capped tubes were placed 0, 0.125, 0.25, 0.5, 1.0, and 2.0 ml of ethinyl estradiol in chloroform stock solution (3.5 μg/ml). The chloroform was removed under a nitrogen stream. The dry residue was redissolved in 0.5 ml of 4% sodium hydroxide–ethanol solution (4 g of sodium hydroxide in 100 ml of 10% ethanol–water). To this solution was added 2 ml of 80% sulfuric acid. The solution was mixed and left standing at room temperature for 30 min. The relative intensities of the fluorescence were measured at excitation and emission wavelengths of 460 and 490 nm, respectively.

Determination of Ethinyl Estradiol in Powder—Exactly 50 mg of each of the four powders (Table I) was suspended in 90 ml of water and extracted with 150 ml of chloroform. The chloroform layer was washed with 60 ml of water and dried over anhydrous sodium sulfate. Then 120 ml of the chloroform layer was evaporated to dryness under vacuum.

The residue was redissolved in 4 ml of ethanol, of which 0.5 ml was placed in a test tube and evaporated to dryness under a nitrogen stream. Ethinyl estradiol then was analyzed as described. The concentration was calculated by comparing the fluorescence of the sample to that of a known concentration treated similarly.

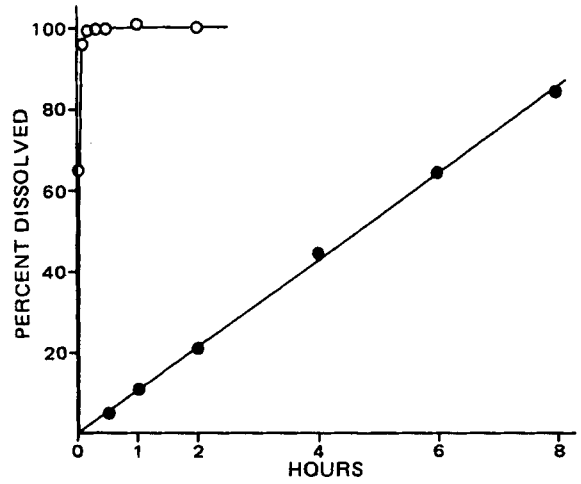

Figure 3—*Dissolution profile of ethinyl estradiol from tablets. Key:* ●, *sustained-release tablet (Vial 2); and* ○, *fast-release tablet (Vial 4).*

[2] Aminco 768G, American Instrument Co., Silver Spring, Md.
[3] Stokes model 511-1 tablet machine, F. J. Stokes Corp., Philadelphia, Pa.

Determination of Ethinyl Estradiol in Dissolution Study—The release rate of ethinyl estradiol was determined at 37° using the USP rotating-basket apparatus in a dissolution medium containing 900 ml of distilled water. The basket was rotated at 100 rpm. At each sampling interval, 6 ml of the medium was withdrawn and extracted with 5 ml of chloroform. Then 4 ml of the chloroform layer was evaporated to dryness under a nitrogen stream. Ethinyl estradiol was analyzed as described.

RESULTS AND DISCUSSION

Figure 1 shows the excitation and emission spectra of ethinyl estradiol. Ethinyl estradiol exhibited strong fluorescence spectra at excitation and emission wavelengths of 460 and 490 nm, respectively. However, norethindrone did not exhibit fluorescence, even at the very high concentration of 2000 ng/ml (Fig. 1).

Figure 2 shows fluorescence stability for 1 hr after sulfuric acid addition. As can be seen in Fig. 2, the fluorescence of ethinyl estradiol was relatively stable; moreover, an excellent linearity between the fluorescence intensity and the ethinyl estradiol concentration over 17.5–280 ng/ml was observed; the minimum detection limit for the drug was ~10 ng/ml using this procedure.

The results of this study also indicate that the reproducibility of the method is excellent and that common tablet excipients do not interfere with the determination of ethinyl estradiol (Table II).

Finally, the method was valuable for the determination of small amounts of the drug in the dissolution study. Figure 3 shows the release rate of ethinyl estradiol from the sustained-release tablet (Vial 2) and the rapid-release tablet (Vial 4).

Potential Errors in Kinetic Studies of Hydrolysis of Nitrogen Mustards Based on Chloride-Ion Determination

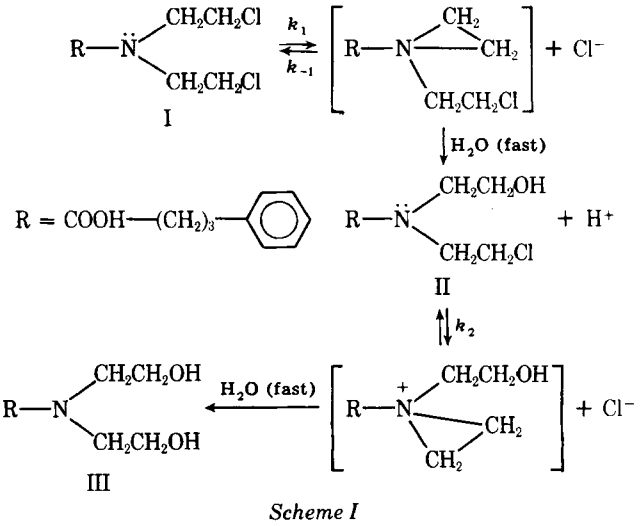
Keyphrases □ Chlorambucil—hydrolysis kinetics, potential errors based on chloride-ion determination □ Hydrolysis—chlorambucil, potential errors in kinetic studies based on chloride-ion determination □ Nitrogen mustards—chlorambucil, hydrolysis, potential errors in kinetic studies based on chloride-ion determination

To the Editor:

Chlorambucil (I), an aromatic nitrogen mustard, has been used clinically in the treatment of chronic lymphocytic leukemia and primary microglobulinemia and in the management of ovarian and testicular carcinomas (1). In aqueous solutions, I and other nitrogen mustards undergo hydrolysis, with the release of chloride ion and the formation of the cyclic ethyleneimmonium ion (1–3). This unstable cyclic intermediate then is attacked by water and other nucleophiles to yield II and other products. The same sequence then is repeated for the hydrolysis of the chloroethyl group in II (Scheme I).

Owen and Stewart recently reported (3) the kinetics of I hydrolysis using the chloride-ion measurement as a parameter for the concentration of intact I remaining. They plotted log $(Cl_\infty - Cl_t)/Cl_\infty$ *versus* time and calculated k_1, the degradation rate of I, from the apparent linear plots. In using chloride-ion measurements to obtain k_1, Owen and Stewart (3) made two important assumptions: (*a*) that the loss of I is always accompanied by the loss of two chloride ions, which is a valid assumption in the case of nitrogen mustards; and (*b*) that both chloride ions must be released simultaneously, *i.e.*, $k_2 \gg k_1$. However, there is no theoretical basis for assuming that $k_2 \gg k_1$.

The mechanism of cyclic ethyleneimmonium-ion formation should be the same for both the k_1 and k_2 steps, and there is no reason to expect that the presence of a hydroxyl function in II would make II much more unstable



Scheme I

relative to I. From a statistical consideration alone, the k_1 step probably should be faster, because there are two hydrolyzable chloro groups. Furthermore, if k_1 is not the rate-determining step, the plot of log $(Cl_\infty - Cl_t)/Cl_\infty$ *versus* time would be dependent on the relative magnitude of k_2/k_1. This relation can be shown theoretically from the classical kinetic treatment of consecutive reactions (4). Thus, for the reaction shown in Scheme II:

$$I \xrightarrow{k_1} II + Cl^- \xrightarrow{k_2} III + Cl^-$$

Scheme II

it follows that:

$$[I]_t = I_0 e^{-k_1 t} \quad \text{(Eq. 1)}$$

$$[II]_t = \frac{I_0 k_1}{(k_2 - k_1)}(e^{-k_1 t} - e^{-k_2 t}) \quad \text{(Eq. 2)}$$

$$[III]_t = \frac{I_0}{(k_2 - k_1)}[k_2(1 - e^{-k_1 t}) - k_1(1 - e^{-k_2 t})] \quad \text{(Eq. 3)}$$

$$[Cl]_t = [II]_t + 2[III]_t \quad \text{(Eq. 4)}$$

where $[I]_t$, $[II]_t$, $[III]_t$, and $[Cl]_t$ are the concentrations of

Potential Errors in Kinetic Studies of Hydrolysis of Nitrogen Mustards Based on Chloride-Ion Determination

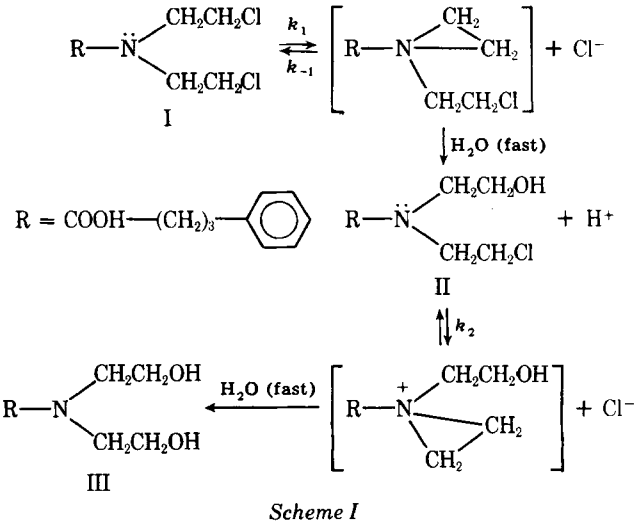
Keyphrases □ Chlorambucil—hydrolysis kinetics, potential errors based on chloride-ion determination □ Hydrolysis—chlorambucil, potential errors in kinetic studies based on chloride-ion determination □ Nitrogen mustards—chlorambucil, hydrolysis, potential errors in kinetic studies based on chloride-ion determination

To the Editor:

Chlorambucil (I), an aromatic nitrogen mustard, has been used clinically in the treatment of chronic lymphocytic leukemia and primary microglobulinemia and in the management of ovarian and testicular carcinomas (1). In aqueous solutions, I and other nitrogen mustards undergo hydrolysis, with the release of chloride ion and the formation of the cyclic ethyleneimmonium ion (1–3). This unstable cyclic intermediate then is attacked by water and other nucleophiles to yield II and other products. The same sequence then is repeated for the hydrolysis of the chloroethyl group in II (Scheme I).

Owen and Stewart recently reported (3) the kinetics of I hydrolysis using the chloride-ion measurement as a parameter for the concentration of intact I remaining. They plotted log $(Cl_\infty - Cl_t)/Cl_\infty$ *versus* time and calculated k_1, the degradation rate of I, from the apparent linear plots. In using chloride-ion measurements to obtain k_1, Owen and Stewart (3) made two important assumptions: (*a*) that the loss of I is always accompanied by the loss of two chloride ions, which is a valid assumption in the case of nitrogen mustards; and (*b*) that both chloride ions must be released simultaneously, *i.e.*, $k_2 \gg k_1$. However, there is no theoretical basis for assuming that $k_2 \gg k_1$.

The mechanism of cyclic ethyleneimmonium-ion formation should be the same for both the k_1 and k_2 steps, and there is no reason to expect that the presence of a hydroxyl function in II would make II much more unstable



Scheme I

relative to I. From a statistical consideration alone, the k_1 step probably should be faster, because there are two hydrolyzable chloro groups. Furthermore, if k_1 is not the rate-determining step, the plot of log $(Cl_\infty - Cl_t)/Cl_\infty$ *versus* time would be dependent on the relative magnitude of k_2/k_1. This relation can be shown theoretically from the classical kinetic treatment of consecutive reactions (4). Thus, for the reaction shown in Scheme II:

$$I \xrightarrow{k_1} II + Cl^- \xrightarrow{k_2} III + Cl^-$$

Scheme II

it follows that:

$$[I]_t = I_0 e^{-k_1 t} \quad \text{(Eq. 1)}$$

$$[II]_t = \frac{I_0 k_1}{(k_2 - k_1)}(e^{-k_1 t} - e^{-k_2 t}) \quad \text{(Eq. 2)}$$

$$[III]_t = \frac{I_0}{(k_2 - k_1)}[k_2(1 - e^{-k_1 t}) - k_1(1 - e^{-k_2 t})] \quad \text{(Eq. 3)}$$

$$[Cl]_t = [II]_t + 2[III]_t \quad \text{(Eq. 4)}$$

where $[I]_t$, $[II]_t$, $[III]_t$, and $[Cl]_t$ are the concentrations of

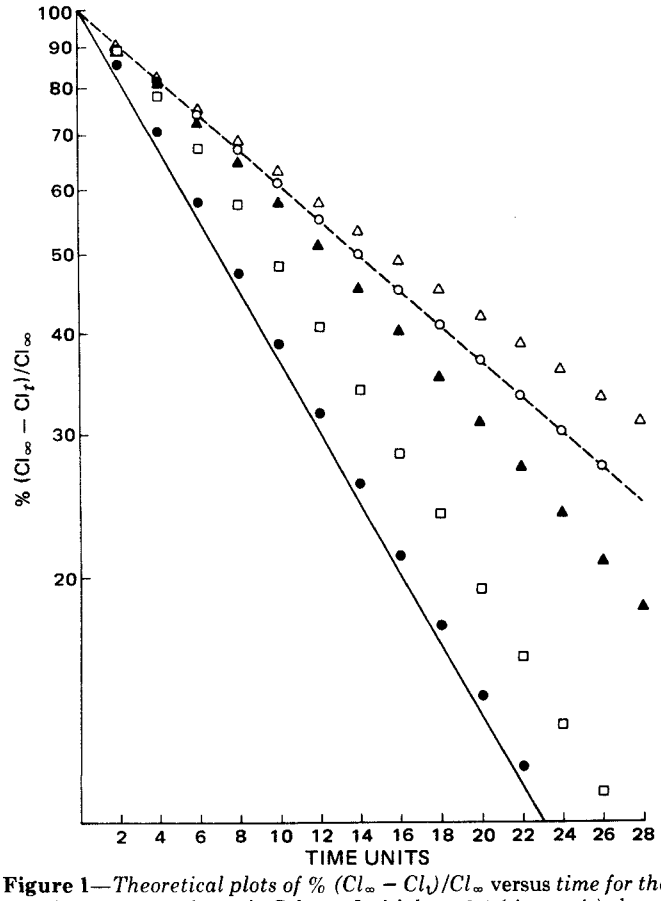

Figure 1—*Theoretical plots of % $(Cl_\infty - Cl_t)/Cl_\infty$* versus *time for the reaction sequence shown in Scheme I with* $k_1 = 0.1$ *(time unit)*$^{-1}$ *and* $I_0 = 1.0$ *and with various values of* k_2/k_1. *Key:* ●, *10.00;* □, *2.00;* ▲, *0.75;* ○, *0.50; and* △, *0.33. The solid line represents the theoretical plot of the percent of I remaining, thus representing the true* k_1 *value; the broken line has a slope equal to* $0.50k_1$.

I, II, III, and chloride ion, respectively, at time t, and I_0 is the initial concentration of I. Since each molecule of I eventually yields two molecules of chloride ion, it follows that the chloride-ion concentration at infinite time is given by:

$$Cl_\infty = 2I_0 \qquad \text{(Eq. 5)}$$

Figure 1 shows theoretical plots obtained by plotting log I or log $(Cl_\infty - Cl_t)/Cl_\infty$ *versus* time for various values of k_2/k_1 (the solid line represents the actual rate of loss of I). As seen in Fig. 1, in addition to the expected linearity of the chloride plot when $k_2 \geq 10k_1$, a perfect linear chloride plot also is obtained when $k_2 = 0.5k_1$[1]. However, the slopes of the two lines are different; only in the case where $k_2 \geq 10k_1$ does the slope yield a value close to k_1. The slope of the straight line plot when $k_2 = 0.5k_1$ is equal to $0.5k_1$.

Therefore, it is apparent that a linear first-order plot of the chloride ion produced does not necessarily establish k_1 as the rate-determining step. In fact, as seen in Table I, an apparent linear relationship of the chloride ion produced can be observed over a wide range of k_2/k_1 values, within experimental errors, particularly if the data are subjected to a computer-assisted linear regression without actually plotting the points. However, the apparent rate constants depend on the value of k_2/k_1 and are smaller than k_1 (Table I). As explained earlier, k_1 probably is not the rate-determining step for the hydrolysis of I, and k_2 probably is of the same magnitude as k_1. Therefore, it is possible that the apparent linear plots of chloride-ion concentrations obtained during I hydrolysis (3) do not yield the true degradation rate of I. To clarify this ambiguity, it is necessary to follow the hydrolysis of I by a method that actually determines the concentration of intact I and to compare the kinetic data obtained with those obtained from chloride titration.

Table I—Correlation of Theoretical Chloride-Ion Plots Shown in Fig. 1 with Similar Calculations for Additional Values of k_2/k_1 Not Shown in Fig. 1

k_2/k_1	Correlation Coefficient[a]	Apparent Rate Constant
20.00	1.0000	0.1000
10.00	0.9999	0.0995
5.00	0.9996	0.0977
2.00	0.9983	0.0880
1.00	0.9986	0.0694
0.75	0.9994	0.0608
0.50	1.0000	0.0500
0.33	0.9991	0.0419
0.25	0.9976	0.0372

[a] Obtained for 15 points, which are two time units apart, up to 28 time units (equal to ~4 half-lives for the k_1 step). The k_1 value was 0.1 (time unit)$^{-1}$ and $I_0 = 1.0$.

A high-pressure liquid chromatographic (HPLC) method was developed to assay intact I in the presence of its major degradation products, II and III. The method involves reversed-phase chromatography[2], in which the hydroxy compounds, II and III, elute earlier than intact I since they are more polar. The details of the HPLC method and the identification of degradation peaks will be reported later.

Solutions of I (0.15 mg/ml) in 0.05 *M* acetate buffer[3] (pH 3.0) and nitric acid solution[3] (pH 2.0) were kept in a 37° water bath. At suitable time intervals, they were assayed for their intact I content by HPLC and for their chloride-ion concentration by an automatic chloride titrator[4]. Figure 2 shows the plot of the I concentration or $(Cl_\infty - Cl_t)/Cl_\infty$[5] *versus* time. The plot of I gave straight lines with half-lives of 25 and 70 min at pH values of 3.0 and 2.0, respectively. However, the points for the chloride-ion plot did not coincide with the HPLC plots (Fig. 2). At pH 3.0, the points appeared to give a straight line with a half-life of 52 min; at pH 2.0, the chloride-ion points showed distinct curvature with an apparent half-life of 165 min (r = 0.993).

Therefore, it is obvious that k_1 is not the rate-determining step in the overall hydrolysis of I. This finding was substantiated further by HPLC analysis of I hydrolysis where the peak due to II was shown to be increasing, through at least one half-life of I, followed by a decrease, as would be expected of a consecutive reaction where the intermediate is not particularly unstable compared to the initial reactants. It also is apparent that the rates calcu-

[1] The straight line nature of the chloride plot, when $k_2 = 0.5k_1$, is mathematically correct, as can be seen by substituting values of $[II]_t$ and $[III]_t$ into Eq. 4 followed by simplification to yield a monoexponential expression, $(Cl_\infty - Cl_t)/Cl_\infty = e^{-0.5k_1t}$.

[2] A Zorbax-C_8 column (DuPont) was used with a running solvent containing 60% methanol, 5% acetonitrile, and 35% acetate buffer (0.15 *M*) (pH 5.0) at a flow rate of 1.6 ml/min. The retention times of I and II were 7.5 and 3.5 min, respectively.

[3] Buffers contained 5% acetone to keep I in solution.

[4] Model 4-4433, American Instrument Co., Silver Spring, Md.

[5] The Cl_∞ and Cl_t values plotted were corrected for the blank, *i.e.*, Cl_0, which is the amount of chloride ion present at time zero.

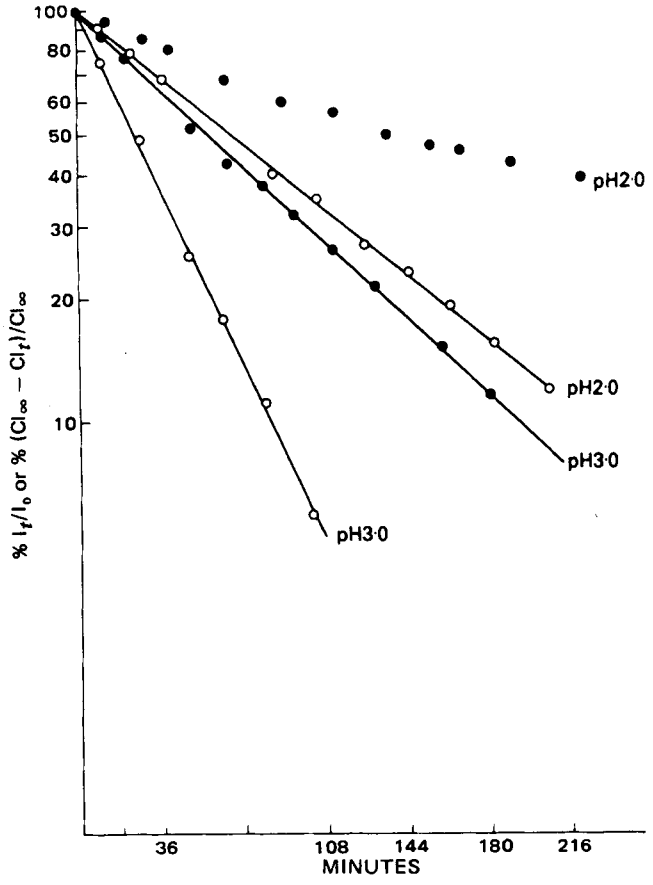

Figure 2—*Plots for the hydrolysis of I. Key:* ○, *data from HPLC runs (% I_t/I_0); and* ●, *data from the chloride-ion determination [% $(Cl_\infty - Cl_t)/Cl_\infty$]; in 0.05* M *acetate buffer (pH 3.0) and in dilute nitric acid (pH 2.0).*

lated from the chloride analyses would considerably overestimate the stability of I, at least in the two buffers tested.

These findings show the inherent potential error in obtaining kinetic parameters of a reactant by following the appearance of a degradation product, particularly when a consecutive reaction is involved as in the hydrolysis of I. The possible error in the rate constants reported for chlorambucil hydrolysis has potential practical implications. Compound I is administered routinely as oral tablets, in which case it is exposed to the pH range of the stomach (1.5–5.0). The relatively short half-lives observed for I hydrolysis at pH 2.0 and 3.0 suggest that a significant amount of I potentially may be degraded before absorption. This observation warrants a more careful study of I hydrolysis using a stability-specific assay. A more detailed kinetic study is in progress using the HPLC method for the analysis of I both to obtain practical stability data under physiological conditions and to elucidate the mechanism of I hydrolysis.

Potential Errors in Kinetic Studies of Hydrolysis of Nitrogen Mustards Based on Chloride-Ion Determination: A Reply

Keyphrases □ Chlorambucil—hydrolysis kinetics □ Nitrogen mustards—chlorambucil, hydrolysis kinetics □ Hydrolysis—chlorambucil, kinetics

To the Editor:

The hydrolysis of chlorambucil (I) is a complex reaction, involving several reversible and consecutive steps. Chatterji (1) treated the reaction as a consecutive one involving two steps and indicated that k_1 and k_2 may be of the same magnitude. Several comments are appropriate.

The production of chloride from the consecutive model for the hydrolysis of chlorambucil is biexponential, *i.e.*:

$$Cl_t = I_0(1 - e^{-k_1 t}) + \frac{I_0}{k_2 - k_1}[k_2(1 - e^{-k_1 t}) - k_1(1 - e^{-k_2 t})] \quad \text{(Eq. 1)}$$

where Cl_t is the chloride concentration at time t, I_0 is the initial concentration of chlorambucil, and k_1 and k_2 are the rate constants for the two consecutive steps.

Therefore, the theoretical plots of log $(Cl_\infty - Cl_t)/Cl_\infty$ *versus* time will be nonlinear except when $k_2 \gg k_1$ and $k_2 \rightarrow 0.5k_1$. Chatterji (1) suggested that "apparent linear relationships" could be observed over a wide k_2/k_1 range by subjecting data to "computer-assisted linear regression." Apparent linearity was proposed on the basis of the correlation coefficient values. However, this approach is a gross simplification of the model and a misrepresentation of the numerical techniques used in the original work (2).

Table II—Analysis of Variance for the Orthogonal Polynomial Analysis of the Data for Hydrolysis of Chlorambucil at 25.0°

Order of Fit	Regression Sum of Squares	Remainder Sum of Squares	Degrees of Freedom	Remainder Mean Square	Variance Ratio	p
0	0.306E + 01	0.110E + 01	27	0.406E − 01	0.754E + 02	<0.001
1	0.110E + 01	0.538E − 04	26	0.207E − 05	0.529E + 06	<0.001
2	0.101E − 07	0.528E − 04	25	0.215E − 05	0.468E − 02	0.94
3	0.203E − 04	0.335E − 04	24	0.140E − 05	0.145E + 02	0.001
4	0.425E − 06	0.331E − 04	23	0.144E − 05	0.295E + 00	0.60

The use of correlation coefficients to test the goodness of fit of the data to this model is inadequate. A statistical technique capable of testing for curvature of the regression is required. Linear regression with appropriate analysis of variance can be used but requires replicate data that are either extremely difficult or not possible to obtain. Orthogonal polynomial analysis, with the successive fitting of higher order polynomials and subsequent statistical testing to determine whether these higher order polynomials have significantly improved the fit, is the method of choice in these circumstances. The principal orthogonal polynomial algorithms were reviewed (3), and the Gram–Schmidt algorithm (4) was chosen for the original study.

Chatterji's theoretical data were regenerated with a random error variance typical of that obtained in the original study. The log $(Cl_\infty - Cl_t)/Cl_\infty$ *versus* time regressions were subjected to orthogonal polynomial analysis, and a summary of the analyses of variance is provided (Table I). Curvature was detected in all regressions, except in the limiting situations when $k_2 \gg k_1$ and $k_2 = 0.5k_1$. While there may be some doubt as to the linearity of the regression when $k_2/k_1 = 20$, the regression clearly is linear when $k_2/k_1 = 30$ and 50 and when $k_2/k_1 = 0.5$. These results demonstrate clearly the sensitivity of this numerical technique to detect curvature in regressions.

In the original study of chlorambucil hydrolysis (2), typical first-order plots (Fig. 2 in Ref. 2) showed no significant curvature when subjected to orthogonal polynomial analysis (Table II). The literature (5, 6) suggested that the chlorohydrin hydrolyzed much faster than the original dichloroethyl compound, and a rate-determining step involving the hydrolysis of the first chlorine thus was proposed.

Furthermore, Chatterji (1) plotted log $(Cl_\infty - Cl_t)/Cl_\infty$ *versus* time. While this method is satisfactory in the theoretical plots, the Cl_0 term should be added in the chlorambucil hydrolysis, *i.e.*, log $(Cl_\infty - Cl_t)/(Cl_\infty - Cl_0)$ *versus* time. For the true first-order model:

$$Cl_\infty - Cl_t = (Cl_\infty - Cl_0)e^{-kt} \qquad \text{(Eq. 2)}$$

and therefore:

$$\ln (Cl_\infty - Cl_t)/Cl_\infty = -kt + \ln (1 - Cl_0/Cl_\infty) \qquad \text{(Eq. 3)}$$

The absence of a Cl_0 term will force the regression through the zero intercept and cause an error in estimation of the rate constant.

Chatterji (1) also stated that Owen and Stewart assumed that the loss of chlorambucil always is accompanied by the loss of two chloride ions. This hypothesis was clearly tested in the original study by the chloride concentrations at time infinity (2), which demonstrated the loss of two chloride ions.

The present investigator agrees that analytical methods that determine original reactants are preferred over those measuring reaction products, particularly in complex reactions. The original research was initiated over 10 years ago, and methods to measure reactant concentrations, including high-pressure liquid chromatographic (HPLC) methods, were not available. The measurement of chloride ion by specially prepared selective-ion electrodes (3) was the most suitable method to follow the reaction at low concentrations and was amenable to continuous monitoring and automatic data collection. While HPLC methods possess a considerable advantage in the measurement and separation of products and reactants, such methods do have some limitations in fast reactions, *e.g.*, consideration of the extent of decomposition on the column during analysis, difficulties in the calibration of unstable compounds, long-term instability with subsequent changes in retention times, and reduction in the amount of data collected, causing a limitation in the use of numerical techniques.

In addition, the measurement of chloride ion in Chatterji's work may be subject to some error. In a previous study, Chatterji *et al.* (7) pointed out the inaccuracies of the use of the automatic chloride titration in faster reactions due to the production of chloride ion during the titration, the finite time to prepare samples and perform the analysis, and the inaccuracies in pipetting. The use of solid-state chloride-selective electrodes would overcome these difficulties.

Nevertheless, it is difficult to disagree with the results of the current kinetic study, where the k_2 value seems to be about half of the k_1 value. The conclusions in the original study were based on sound numerical techniques that tested for a limiting form of a more complex model ($k_2 \gg k_1$). Consideration was not given to a second limiting form ($k_2 \rightarrow 0.5k_1$) because of the literature indications to the contrary at that time. However, the current work does show that the second limiting form may be a realistic alternative, and further research is warranted.

Precorneal Retention of Topically Instilled Micronized Particles

Keyphrases □ Micronized particles—precorneal retention, effect of particle size □ Ophthalmic preparations—micronized particles, precorneal retention, effect of particle size

To the Editor:

Aqueous suspensions of micronized drugs are commonly used for topical delivery of low-solubility therapeutic agents to the eye. Previous work was performed to assess the *in vivo* performance of ocular suspensions (1–4), but these studies were primarily drug oriented; they did not quantitate the effects of the physical aspects of the dosage form itself. Parameters specifically important for an ophthalmic suspension include intrinsic solubility, dissolution rate, and particle size.

The particle size of a suspended drug determines the surface area available for dissolution of the drug into the tears and also largely determines the irritation potential of the dosing system. Irritation can cause excessive tearing and accelerated drainage of the instilled dose. To minimize this irritation potential, ophthalmic suspensions generally are prepared using various cost-increasing micronization techniques. This report presents recent preliminary data on the behavior of micronized particles in the precorneal area of the eye and demonstrates the influence of particle size on ocular retention.

Male albino rabbits were used for the particle dynamics studies since most previous ocular work was performed with this species. The animals were preconditioned to sit motionless in specially designed wooden boxes. A normal upright posture was maintained, and local or general anesthetics were not used due to their known effects on tear dynamics (5).

A topical dose of an aqueous suspension containing radiolabeled microspheres[1] was placed carefully into the ocular sac along the lower lid margin using a micropipet. The normal response of the animal is to blink upon instillation, so no further manual mixing or blinking was attempted since it might abnormally force a portion of the dose down the nasolacrimal duct. Immediately after dosing, a γ-probe[2] was positioned to cover the precorneal area without touching the animal; drainage loss and retention of the labeled particles were monitored as a function of time by external scintigraphy[3]. Animals were watched closely by a technician, and all head movements and blinking were recorded carefully. Head movement terminated an individual run due to alteration of the spacial relationship of the precorneal microsphere pool and the monitoring probe.

The results of the studies using 3- and 25-μm particles are shown in Fig. 1. The marked dependence of particle retention on both dosing volume and particle size is readily apparent from these data. Immediately upon instillation of a 3% (w/v) suspension of 3-μm spheres, a washout process swept away a fraction of the dose. Since the duration of this washout phase was dependent on the volume instilled, the percent retention for each dosing volume was different and decreased as the volume was increased. However, since the total number of spheres instilled also varied with the dosing volume, it was not sufficient simply to consider percent retention as a measure of the volume effect as illustrated by the data presented in Table I.

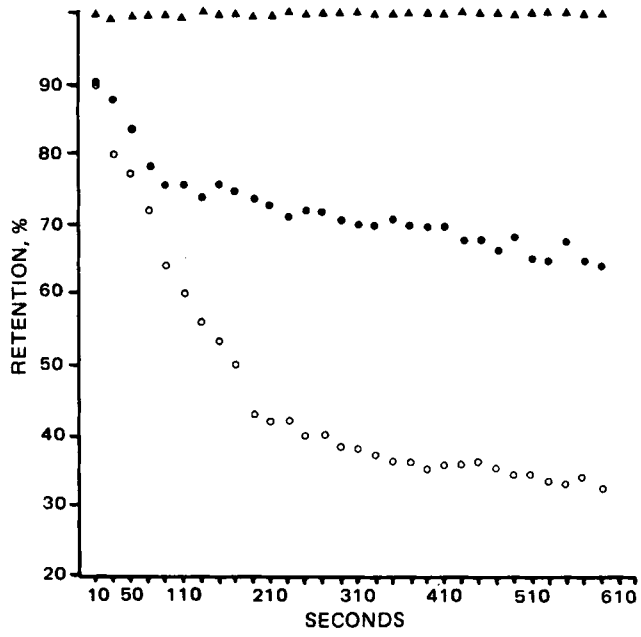

Figure 1—*Precorneal retention of topically instilled micronized particles. Key:* ●, *25-μl dose of 3% (w/v) 3-μm suspension;* ○, *50-μl dose of 3% (w/v) 3-μm suspension; and* ▲, *25- and 50-μl doses of 3% (w/v) 25-μm suspension (both dosing volumes gave virtually identical curves).*

It is clear from this analysis that the twofold increase in percent retention for the 25-μl dose compared with the 50-μl dose exactly offset the twofold sphere number difference between the two dosing volumes. As a result, the total number of spheres retained, as represented by the plateau region in Fig. 1, was the same. It would be tempting to attribute this effect to a maximum surface coverage limit for the conjunctival sac, but this cannot be stated with certainty. Theoretically, if such were the case, a 10-μl dose of the 3-μm suspension should give 100% retention since the total number of spheres instilled would be less than the plateau value for the larger doses. However, the data (Table I) show that the 3-μm spheres still suffered significant washout loss before being deposited within the protective folds of the conjunctiva.

The data for the 25-μm particles (Fig. 1) strikingly contrast with those for the smaller particles. Particle re-

Table I—Ocular Retention of a 3% (w/v) Suspension of 3-μm Particles as a Function of the Dosing Volume

Dose Volume, μl	Milligrams of Spheres	Total Number of Spheres	Percent Retention	Number Retained

[1] Tracer microsphere, Medical Products Division, 3M Co., St. Paul, MN 55101. Radiolabeled microspheres are polystyrene spheres that have been sized under rigid control standards, made radioactive, and annealed to seal radioactivity so that no leaching occurs. The microspheres may be obtained in a range of specific diameters labeled with various isotopes. The microspheres used in the current studies were 3.2 ± 0.6 and 25.7 ± 1.2 μm with a ^{141}Ce label, an isotope with a half-life of 32 days and 145 kev γ-energy. For these initial studies, the spheres were simply suspended in isotonic saline.

tention was rapid, complete, and independent of the dosing volume up to 50 μl, which is about the limit for a rabbit eye without spillage over the lids. Presumably, the larger diameter and greater particle mass resulted in faster deposition so that the suspending vehicle was drained away independently of the particles. The possibility that the observed retention for the larger particles was due to physical obstruction of the drainage apparatus was checked by subsequent instillation of a radioactive solution of [^{67}Ga]gallium citrate. The mean drainage rate constant obtained for a 25-μl dose of this solution in the presence of the 25-μm spheres was 0.52 min^{-1}, and this value corresponds well with the normal value of 0.545 min^{-1} reported previously for the rabbit (5). Particle size clearly plays a significant role in the rate and extent of particle retention for ophthalmic suspensions.

Studies also were carried out beyond the times indicated by Fig. 1. Only the early postinstillation time intervals are shown to define the washout process clearly. Individual runs lasting several hours were performed, and the presence of particles in the conjunctival sac was demonstrated for at least 12 hr. However, studies are continuing to determine the precise kinetics of the gradual loss of particles that follows the initial washout process, particularly for the 3-μm particles. Preliminary evidence shows that blinking and the associated movement of the tear film play a major role in redistributing small particles within the ocular sac. A blink normally pulls a fresh layer of the precorneal film up from the conjunctival sac and over the corneal surface. Lighter particles are pulled up with the film, and this process leads to gradual loss *via* the drainage apparatus during normal tear turnover.

The data from these studies indicate that a lower limit probably exists for particle-size retention in the eye, in addition to the previously recognized upper limit for irritation. This evidence suggests that caution should be used regarding the extent to which the particle size is reduced for such systems and also may explain the recently documented successes of so-called "economy suspensions," systems characterized by somewhat larger particle sizes than more traditional ophthalmic microsuspensions. Presumably, the smallest particles of the distribution range of a micronized suspension are lost rapidly with the washout of the suspending vehicle and contribute minimally to the ocular drug levels. Thus, the observed *in vivo* performance of an ophthalmic suspension probably is due mainly to the larger particles in the size distribution. Further studies are being conducted to establish more definitively the role of particle size for ocular retention and the influences of suspension concentration and vehicle pH.

Half-Life of *N*-Acetylprocainamide in Rats

Keyphrases □ Procainamide—metabolism to *N*-acetylprocainamide, half-life of *N*-acetylprocainamide in rats □ *N*-Acetylprocainamide—half-life in rats □ Antiarrhythmic agents—*N*-acetylprocainamide, half-life in rats

To the Editor:

Procainamide is eliminated from the body by renal excretion as unchanged drug and through metabolism to *N*-acetylprocainamide. This metabolite has been shown to have antiarrhythmic activity in animals (1, 2) and humans (3, 4) and is eliminated from the body by urinary excretion. Many patients receiving procainamide chronically have shown plasma levels of *N*-acetylprocainamide in excess of the unmetabolized drug (5).

A most significant therapeutic advantage of *N*-acetylprocainamide is that it does not cause development of lupus erythematosus in patients (6). Additionally, the biological half-life of *N*-acetylprocainamide in humans is more than twice that of procainamide (7, 8), which allows less frequent dosing. We showed previously that *N*-acetylprocainamide decreased the heart rate in rats when the plasma concentration was 16.8 μg/ml, which is quite similar to the therapeutic concentrations in humans (9).

Schneck *et al.* (10) investigated the disposition of procainamide and *N*-acetylprocainamide in rats and found biological half-lives of 55 and 51 min, respectively. These results are in contrast to the data obtained in our laboratory. Therefore, the purpose of this communication is to report our preliminary results showing that the half-life of *N*-acetylprocainamide is two to three times longer than that of procainamide in the same rat and that the disposition of both drugs is qualitatively similar to that in humans.

Eight male Charles River[1] rats, 250–450 g, were selected. A cannula was inserted surgically into the jugular vein of each rat 1 day before the experiment (11). Procainamide hydrochloride (75 mg/kg) and *N*-acetylprocainamide hydrochloride (86 mg/kg) were administered intravenously through the cannula in a randomized crossover design. A 3-day washout period was allowed between administration of the two drugs.

Serial blood samples (0.4 ml) were withdrawn at 0 (just before drug administration), 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 6, and 8 hr following dosing, and the plasma was separated immediately. Urine and feces were collected for 48 hr. The concentrations of procainamide and *N*-acetylprocainamide in plasma and urine were determined by a specific high-pressure liquid chromatographic method (12). Plasma concentrations of the unchanged procainamide and *N*-acetylprocainamide were fitted to one-and two-compartment open models, respectively, using a nonlinear re-

Table I—Pharmacokinetic Parameters of Procainamide and *N*-Acetylprocainamide

Parameter	Rats				Humans	
	Our Study		Ref. 10			
	Procainamide	*N*-Acetylprocainamide	Procainamide	*N*-Acetylprocainamide	Procainamide[a]	*N*-Acetylprocainamide[b]
Elimination half-life ($t_{1/2}$), hr	0.66	2.13	0.92	0.85	3.5	6.0
Plasma clearance, ml/min/kg	80.7	20.7	64.0	22.0	7.99	3.09
Apparent volume of distribution, liters/kg	4.60	3.82	4.92	1.64	1.91	1.61

[a] From Ref. 7. [b] From Ref. 8.

gression analysis program available in a statistical analysis system package[2].

The biological half-life ranged from 0.54 to 0.83 hr for procainamide and from 1.72 to 2.92 hr for *N*-acetylprocainamide. The ratio of the biological half-life of *N*-acetylprocainamide to that of procainamide in the same rat averaged 3.3. Table I summarizes the values of the pharmacokinetic parameters obtained by Schneck *et al.* (10), those obtained in our study, and values reported for normal subjects.

Determination of the biological half-lives of procainamide and *N*-acetylprocainamide in the same animal, with sufficient time for elimination of the drugs from the body, allowed a more meaningful comparison of the pharmacokinetic parameters of the two drugs. The discrepancy between these results and those reported by Schneck *et al.* (10) may be due to the study design and to the method of determination of pharmacokinetic parameters. Schneck *et al.* sacrificed groups of rats and followed the blood sampling for 4 hr, which appears to be inadequate for *N*-acetylprocainamide. In our study, a distribution phase of ~1 hr was noticed when *N*-acetylprocainamide was administered intravenously. Furthermore, Schneck *et al.* (10) calculated the volume of distribution by dividing the total body clearance by the elimination rate constant, which obviously results in an underestimated value (Table I).

The results of our study were qualitatively similar to those observed in normal human subjects. The ratio of the half-lives, volumes of distribution, and body clearances of procainamide and its metabolite in these two species are similar. These results have important implications in interpretations of metabolism data from acute and chronic toxicity studies.

shift rules, off-resonance spectral data, and spin-lattice relaxation time data of the low-field quaternary carbons. Verpoorte and Baerheim Svendsen (4) also reported on the ^{13}C-NMR spectroscopy of strychnine, brucine, and alcuronium, and Srinivasan and Lichter (5) reported on the ^{13}C-NMR spectroscopy of strychnine and brucine.

My extended studies of ^{13}C-NMR spectroscopy of a series of Strychnos alkaloids (6) showed that several assignments made by Srinivasan and Lichter were erroneous. Furthermore, this study (6) made it necessary to reverse my earlier assignment of the signals for C-1 and C-2 in strychnine. Leung and Jones (7) reported their investigation of the ^{13}C-NMR spectroscopy of some Strychnos alkaloids, and their assignment for the spectrum of strychnine was the same (except for C-1 and C-2) as in my second paper (6). Wenkert *et al.* (8) also reported on the ^{13}C-NMR spectroscopy of a series of Strychnos alkaloids. Their assignment of the strychnine spectrum was similar. All spectral data of Refs. 1–8 are summarized in Tables I and II.

If the results reported by Singh *et al.* (1) are compared with those reported by the other investigators, a great deal of discrepancy is observed. The multiplicity for some signals was not reported by Singh *et al.* [C-7 (52.0), C-11 (48.2), C-18 (52.8), and C-20 (50.4) in strychnine]; for other signals [*i.e.*, 42.5 (d), 42.9 (d), and 31.7 (t) in strychnine], the multiplicities were different from those reported in the other studies [42.3 (t), 42.8 (t), and 31.5 (d)] (2–8). In the off-resonance decoupled spectra of strychnine and brucine, not all of the signals show neat first-order splitting patterns. Also, second-order patterns are observed for some signals (9). This finding is readily understood if the PMR spectrum of strychnine is considered, where several methylene groups have the attached *geminal* protons at rather different shifts (10). However, by using different decoupling frequencies in the off-resonance decoupled spectra, the multiplicity of the signals can be established (11). The erroneous interpretation of the multiplicity of some signals necessarily leads to an erroneous assignment of these signals.

Furthermore, the assignment of C-17 by Singh *et al.* (1) is different from the assignments reported by other investigators. However, the assignment of the 42.8-ppm signal to this carbon is confirmed by comparison of the spectra of strychnine and pseudostrychnine (6). In the spectrum of the latter compound, the 26.8-ppm signal is shifted downfield considerably, which makes assignment of this signal to C-15 plausible. These arguments and the data given in Tables I and II indicate that the assignment of the strychnine and brucine spectra according to Singh *et al.* (1) is inaccurate. The assignment of the ^{13}C-NMR spectra of strychnine and brucine as reported by Wehrli (3), Verpoorte *et al.* (6), and Wenkert *et al.* (8) is correct.

Potential Effect of Early Blood Sampling Schedule on Calculated Pharmacokinetic Parameters of Drugs after Intravenous Administration

Keyphrases □ Pharmacokinetics—effect of blood sampling time on calculated parameters after intravenous administration □ Volume of distribution—effect of blood sampling time on values calculated after intravenous administration □ Blood sampling time—effect on calculated pharmacokinetic parameters after intravenous administration

To the Editor:

The disposition of a drug in the body often can be studied best by intravenous administration (1–5). Differences in experimental methodology are known to affect the results of a pharmacokinetic study. For example, an insufficient sampling period or the lack of a sensitive assay may result in the underestimation of terminal biological half-lives of drugs (4–9). A nonspecific assay can cause overestimation of the plasma area under the curve and underestimation of the total plasma clearance (10). Sampling devices (11) and blood containers (12) might also affect assay results and, hence, the calculated pharmacokinetic parameters. Marked differences in protein binding (possibly also the concentration) of several drugs and bilirubin in serum and heparinized plasma were demonstrated (13). Differences in the curve-fitting technique also might affect the characterization of pharmacokinetic properties (4, 5, 14, 15).

In conventional pharmacokinetic studies, plasma concentration profiles between the beginning of intravenous injection or infusion (*i.e.*, time zero) and the time of the first blood sample collected usually are extrapolated or predicted based on plasma level data obtained at later times. The accuracy of such an extrapolation method has been questioned (16, 17). Marked underestimations of extrapolated plasma concentrations at time zero and probably of extrapolated plasma areas under the curve between time zero and the first sampling time (15 min) after rapid intravenous injection of sulfamethizole to five dogs were found when a constant blood withdrawal device and the conventional multiple blood sampling techniques were employed simultaneously (16). Disposition kinetics of a drug within the first few minutes after intravenous injection are often more complicated than is commonly recognized (17). For example, the true peak plasma concentration might be several times higher than the extrapolated concentration (17). Furthermore, the peak concentration in humans might occur 0.5–2 min after the end of dosing; at time zero, the true plasma concentration at the normal sampling site should always be zero and not the extrapolated zero-time value.

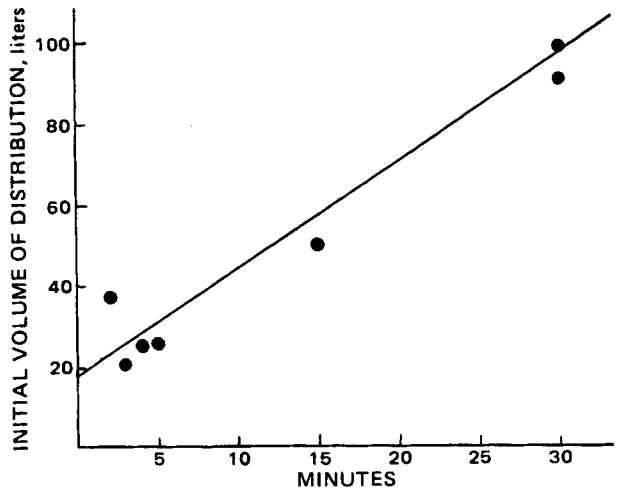

Figure 1—*Correlation between the average initial volume of distribution, V_c, and the time of the first blood sampling after an intravenous dose of digoxin in seven studies on humans with normal renal function; $V_c = 17.4 + 2.53t$ ($r^2 = 0.9452$).*

This review indicates that the early blood sampling schedule used in an intravenous study sometimes might significantly affect the obtained disposition function and, hence, the resultant multicompartmental modeling. In a recent study on quinidine, it was stated that the sampling pattern selected in a study also influences the choice of a model (15). Although it was not elaborated further, this statement is consistent with the contention of the possible early sampling schedule effect.

The literature often shows marked variability in the mean initial volume of distribution or mean volume of the central compartment reported in different intravenous studies on the same drug in similar subjects or patients. Although many factors might account for some of the differences, there often is a general pattern that the mean initial volume of distribution is smaller if the first blood sample is collected earlier in a study. The purpose of this communication is to point out this apparent trend using digoxin, gentamicin, and thiopental as examples.

Mean apparent initial volumes of distribution of digoxin reported or analyzed from six studies (18–23) on healthy adults with normal renal function are used for comparison. Subject characteristics, the duration of intravenous administration, the time of the first blood sampling, and the calculated mean volume value for each study are summarized in Table I. An apparent linear relationship between the mean initial volume of distribution and the time of the first blood sample was found (Fig. 1). The lowest volume, 20 liters, and the highest volume, 99 liters, were obtained from studies with the first blood sample collected at 3 and 30 min, respectively.

Although it is more meaningful to compare the volume of distribution in terms of volume per unit of body weight, this comparison usually is not possible since information on body weight was reported only in one study (21). For that study, the value (24.5 liters) reported in Table I was corrected for a 70-kg body weight. Since these studies involved normal adult subjects with a relatively narrow age range (no age information in Ref. 19), it is unlikely that body weight is a major factor for the marked variation in

Table I—Subject Characteristics, Duration of Intravenous Digoxin Dosing, Time of First Blood Sampling, and Calculated Initial Volume of Distribution of Digoxin from Six Studies in Normal Adult Subjects and One Study in Neonates and Infants

Study (Ref.)	Number of Subjects	Sex	Age Range, years	Duration of Intravenous Dosing	Time of First Blood Sampling after Dosing, min	Estimated Average V_c[a], liters
1 (18)	4	M	27–35	Bolus	2	37.4[b]
2 (19)	4	—	—	1 min	3	20.0[b]
3 (20)	4	2 M; 2 F	19–40	Bolus	4	25.0[b]
4 (21)	12	M	23–34	60-min infusion	5[c]	24.5[d]
5 (22)	4	3 M; 1 F	22–29	Bolus	15	50.0[b]
6 (23)	6	—	24–26	Bolus	30	99.0[e]
7 (25)	7	—	Neonates and infants	2–3 min	30	91.0[d]

[a] Initial volume of distribution. [b] Estimated by this investigator based on the graphical data from the previous study. [c] Four blood samples also were collected at 0.25, 0.5, 0.75, and 1 hr during infusion. [d] Corrected for 70-kg body weight for comparison. [e] Calculated by Reuning *et al.* (24).

the mean initial volume of distribution. The results (Table I) from a study in neonates and infants (25) also are consistent with the data from the adult studies. The mean initial volume of distribution in these neonates and infants after correction to 70 kg is 91 liters, and the first blood sample in that study (25) was collected at 30 min.

For gentamicin, the mean initial volume of distribution in normal subjects could be estimated as 0.045 liter/kg in one study (26) with the first sample collected 1.0 min after a bolus dose (1.5 mg and 2.0 mg/kg), and as 0.099 liter/kg from another bolus study (27), with the first sample collected at 15 min. In a multiple 1-hr infusion study in patients with normal and moderately impaired renal function, the mean initial volumes of distribution of gentamicin were 0.21 and 0.20 liter/kg, respectively.

The initial volume of distribution of thiopental in one normal subject could be estimated as 6.4 liters from a bolus intravenous study (28) with the first blood sample taken probably at 2.4 min. However, the initial volume of distribution of thiopental in another normal subject in a study conducted in the same laboratory could be estimated as 60.5 liters (29). In the latter study, the first blood sample was collected at ~45 min. In both studies, the data were analyzed based on the two-compartment open model. The plasma thiopental levels at 45 and 120 min in both studies, after correction for the different doses used, were approximately the same.

The results of this study on three drugs indicate that the determination of the apparent initial volume of distribution might be affected by the time at which the first (and probably also the second) blood sample is collected. Although the marked variation in the volume of distribution in these examples might be attributed to the real difference, this factor probably is not major. In general, the most important factor affecting the volume of distribution of the same drug in normal subjects is the body weight. The wide range of the mean initial volume of digoxin from several studies and of thiopental from two (typical) subjects is not accounted for by the presumably relatively much smaller differences in body weight used in each study. Differences in assay accuracy also can be ruled out as a major factor since most assays should be more accurate for plasma samples with higher drug concentrations, which usually were more important in the determination of the initial volume of distribution.

The intersubject variation in the initial volume of distribution from the same study often was much less than the interstudy variation (18, 21, 22, 25), indicating the possible influence of study design on the calculated pharmacokinetic parameter.

The method used in these comparisons of the three drugs is not perfect. A more scientifically designed experiment is being planned to eliminate or minimize most of the other potential contributing factors and to identify the exact mechanisms for the observed phenomena. The results of this preliminary report indicate that one should be prudent in interpreting the markedly different pharmacokinetic parameters, especially the initial volume of distribution, reported in the literature. Some guidelines or standardization of studying and reporting the initial volume of distribution might be useful.

Mesophase Formation during Cholesterol Dissolution in Ursodeoxycholate–Lecithin Solutions: New Mechanism for Gallstone Dissolution in Humans

Keyphrases □ Cholesterol—mesophase formation during dissolution in ursodeoxycholate–lecithin solutions, mechanism for gallstone dissolution in humans □ Gallstones—mechanism for dissolution in humans, mesophase formation during cholesterol dissolution in ursodeoxycholate–lecithin solutions

To the Editor:

It is well established that oral administration of chenodeoxycholic acid (I) induces bile desaturation in cholesterol and gradual dissolution of cholesterol gallstones in humans (1). Makino *et al.* (2) reported that ursodeoxycholic acid (II), the 7β-hydroxy epimer of I, also can induce bile desaturation in humans, an observation confirmed by other investigators (3).

The cholesterol saturation of bile (percent saturation) is defined as $(C_{sample}/C_s) \times 100$, where C_s is the concentration in the sample if it is saturated fully with cholesterol, *i.e.*, the solubility at equilibrium. In model systems, C_s is determined almost entirely by the molar proportions of bile acids and lecithin (4–6). The C_s value usually is assumed to be that value determined experimentally for the model system having an identical proportion of bile acids and lecithin, and the actual value for percentage saturation is determined graphically (7) or analytically (8). This approach has been assumed to be correct since C_s determined in bile samples from gallstone patients did not differ significantly from that of the model system (6). Accordingly, there has been rather satisfactory agreement between predicted and measured percent saturation in bile samples obtained from gallstone patients (9). The C_s value was considered to be uninfluenced by biliary bile acid composition since changing the relative proportion of the common bile acids (cholic, deoxycholic, and I) in model systems had little influence on C_s (4, 5).

Igimi *et al.* (10) reported that the ability of II to solubilize cholesterol both in the presence and absence of lecithin was strikingly inferior to that of I and concluded that II might well be less efficacious than I for gallstone dissolution. Carey and coworkers (11) confirmed these observations and also reported (12) that the maximum capacity of model bile systems to solubilize cholesterol was depressed in proportion to the percent of II conjugates in bile salt mixtures. Thus, the micellar zone in the phase diagram simulating bile appears to be reduced by the presence of II. Carey and Ko (12) also proposed that a new C_s value must be used to calculate the percent saturation in gallstone patients receiving II and presented an "urso-correction factor" to facilitate such calculations. Nevertheless, initial clinical studies (3) suggested that gallstone dissolution in patients receiving II did not occur more slowly than in those receiving I. Indeed, several instances of rather rapid dissolution were observed. To rationalize these discrepancies, we undertook a systematic study of cholesterol dissolution with II–lecithin solutions.

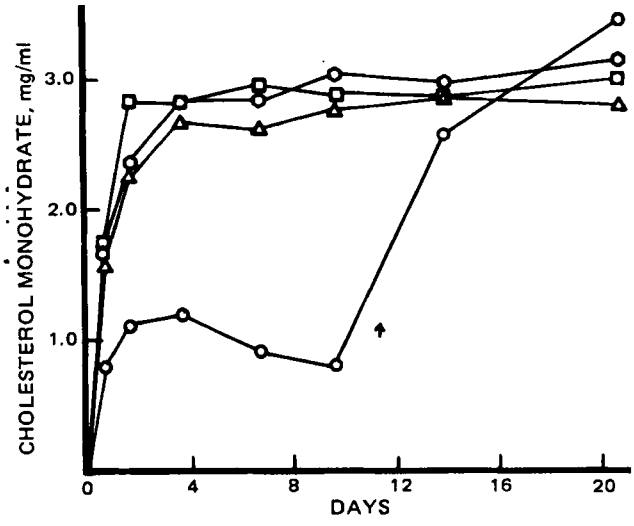

Figure 1—*Apparent solubility profiles of cholesterol monohydrate in 116 mM bile salt, 32 mM lecithin, 0.1 M NaCl, and 0.01 M phosphate buffer media at 37°. Key: ○, glycochenodeoxycholate; □, taurochenodeoxycholate; △, taurocholate; and ○, glycoursodeoxycholate; the arrow indicates the time of occurrence of a nonfilterable cloudiness due to mesophase formation in the glycoursodeoxycholate system.*

In recent dissolution studies[1] under sink conditions using methodology outlined previously (13), we found that over a wide range of bile acid, lecithin, and electrolyte concentrations, the initial dissolution rate of cholesterol monohydrate in II conjugate–lecithin media was two to 70 times lower than in corresponding I media. The dissolution of cholesterol and of gallstones *in vitro* was shown previously (9, 14) to be controlled interfacially, with the interfacial resistance $R = (h/D + 1/P)$ being a function of the dissolution medium composition. The evaluation of R and hence P (the effective permeability coefficient of the interfacial barrier) under sink conditions requires an estimate of C_s, the solute saturation concentration, since $R = AC_s/J$, where A is the area of the dissolving surface and J is the initial dissolution rate (15).

However, in contrast to media containing I and lecithin or I conjugates and lecithin, attempts to measure C_s with

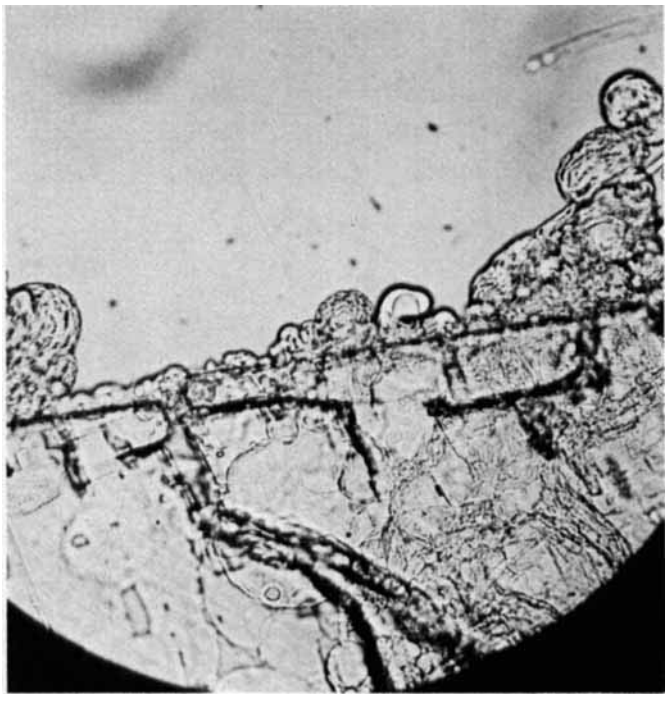

Figure 2—*Mesophase growth on cholesterol monohydrate crystal (original magnification 40×) immersed in a 174 mM ursodeoxycholate–lecithin (48 mM) medium at 37° for 20 hr.*

powder samples of cholesterol monohydrate in media containing II conjugates (glycine or taurine) and lecithin, using conventional methodology, were complicated by the development of turbidity in the supernate, which was not removed by filtration. In addition, the release of cholesterol into the II conjugate–lecithin media continued and even increased beyond the apparent equilibrium solubility (Fig. 1).

Microscopic examination of the cloudy supernate revealed a globular phase of a liquid-crystalline nature, which on analysis, following centrifugation, contained substantial amounts of lecithin (16) and cholesterol. The rate of formation of this mesophase in powder slurries, as judged by the appearance of turbidity and an increase in the apparent solubility, was dependent in the case of glycoursodeoxycholate (III) on the III–lecithin ratio and the total lipid concentration. For example, using a III–lecithin ratio of 3.61 and a III concentration of 116 m*M*, cloudiness did not occur until about the 10th day. However, at a ratio of 3.61 with a III concentration of 174 m*M* or at a ratio of 2.72 with a III concentration of 87 m*M*, the time for mesophase initiation was much shorter (~24 hr). Mesophase formation also was retarded greatly when compressed disks of cholesterol monohydrate were used rather than powder slurries.

These data and other studies[1] suggest that III has a much greater propensity than glycochenodeoxycholate (IV) to promote mesophase formation. To test this possibility, single crystals of cholesterol monohydrate were mounted as described previously (17) in a 1-cm spectroscopic cell and examined during dissolution under static conditions using a horizontally mounted microscope incubated at 37°. During dissolution in a 174 m*M* III–lecithin (48 m*M*) medium, mesophase growth on the cholesterol crystal surface became evident in a few hours. By 24 hr, the crystal surface was coated with mesophase spherulites (~40–150 μm in diameter) (Fig. 2). By contrast, crystals subjected to a IV–lecithin medium of similar composition did not show evidence of mesophase growth; dissolution was more rapid than in III.

In gallstone formation, the problem usually was considered in terms of a solid, crystalline cholesterol monohydrate phase separating from a supersaturated, isotropic micellar phase; for dissolution, the problem was thought to be the slow dissolution of crystalline cholesterol into an unsaturated micellar solution. Although a mesomorphic liquid crystalline phase occasionally has been observed in human bile samples (18, 19) or in animals in which supersaturated bile was induced (20), a mesomorphic phase generally was not considered to be involved in gallstone formation or dissolution since the mesomorphic phase occurred in model systems only at lower ratios of bile acids to lecithin than had been reported for bile samples from gallstone patients (21).

These observations indicate that mesophase formation and dispersion may occur during gallstone dissolution in patients receiving II. Since the mesophase density differs from bile, gallstone dissolution may involve flotation of a mesophase in addition to simple molecular and micellar diffusion and convection.

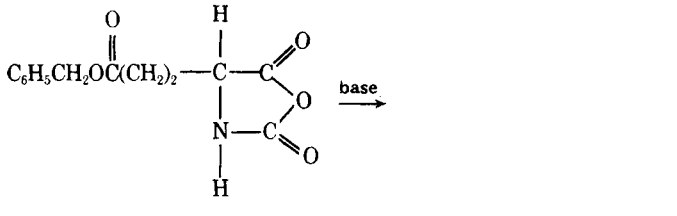
Coupling of Steroid Hormones to Biodegradable Poly(α-amino acids) I: Norethindrone Coupled to Poly-N^5-(3-hydroxypropyl)-L-glutamine

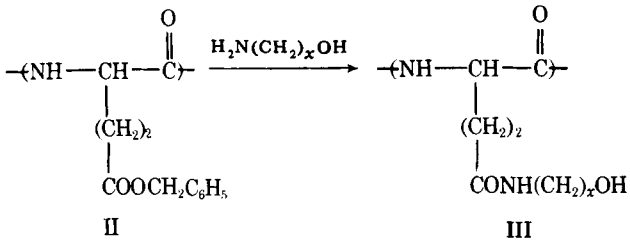
Keyphrases □ Norethindrone—coupling to poly(α-amino acids), controlled release from coupled compounds □ Contraceptives—norethindrone, coupling to poly(α-amino acids), controlled release from coupled compounds □ Polymers, biodegradable—poly(α-amino acids), coupling to norethindrone, controlled release of norethindrone from coupled compounds

To the Editor:

Sustained release of drugs from polymeric matrixes has received increased interest (1–5). Hormone release from such systems was investigated to obtain devices for long-term contraceptive purposes. A new approach in the release of hormones from polymeric systems is the use of covalently bound polymer–hormone compounds that are biodegradable and do not need removal after implantation. Although a few examples of steroids being bonded covalently to polymers have been reported (6–8), the coupling of steroids to biodegradable polymers was presented only recently (9). We wish to report a new derivatization of 17α-ethynyl-17β-hydroxy steroids, which are appropriate for attachment to biodegradable poly(α-amino acids).



I



II III

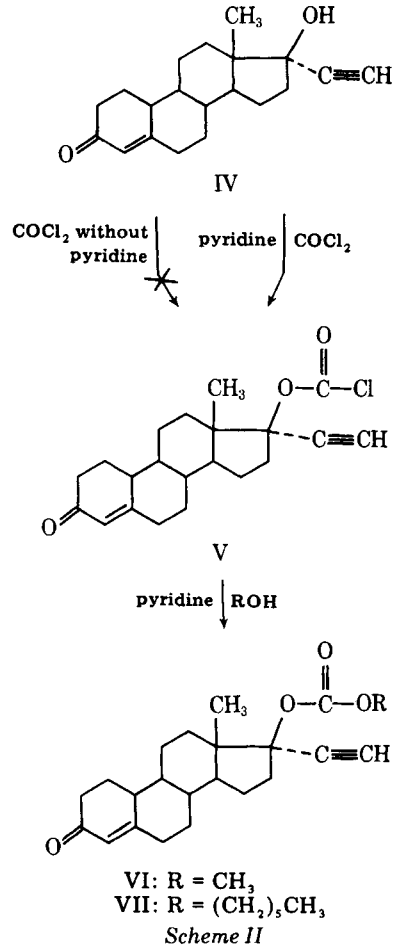
IIIa: $x = 3$

Scheme I

Poly(hydroxyalkyl)-L-glutamines (III) were studied by several investigators (10, 11). These polymers are prepared through the base-catalyzed polymerization of γ-benzyl-L-glutamate N-carboxyanhydride (I), giving the polymeric benzyl-L-glutamate (II), followed by displacement of the benzyl group with the desired hydroxyalkyl amines (12) (Scheme I). The polymers are water soluble but become water insoluble upon substitution with hydrophobic steroids.

The steroid selected for derivatization was norethindrone (IV), an active progestin (Scheme II). Reaction of IV in methylene chloride with a stoichiometric amount of pyridine and an excess of phosgene at room temperature resulted in a 77% yield of norethindrone-17β-chloroformate (V, mp 103–105° dec.). The reaction was monitored by TLC until IV had disappeared completely. The structure of V then was verified; IR (ν, KBr pellet): 1780 (chloroformate) cm^{-1}; ^{1}H-NMR (δ, $CDCl_3$): 5.80 (s, 1H, 4[1]), 2.77 (s, 1H, 21), and 1.00 (s, 3H, 18).

Compound V is unstable and was derivatized to further confirm its structure and to investigate its potential for the coupling with polymer IIIa. Compound V was reacted with



IV V

a stoichiometric amount of pyridine and excess methanol or hexanol in dichloromethane to give norethindrone-17β-methylcarbonate (VI, 84% yield, mp 153–154°) or norethindrone-17β-hexylcarbonate (VII, 94% yield, oil).

The spectroscopic data for VI were: IR (ν, KBr pellet): 1750 (carbonate) cm^{-1}; ^{1}H-NMR (δ, $CDCl_3$): 5.80 (s, 1H, 4), 3.77 (s, 3H, 23), 2.63 (s, 1H, 21), and 0.97 (s, 3H, 18); mass spectrum: *m/e* 356 (100%, M^+) and 342 (4.17, $M^+ - CH_3$); satisfactory combustion analysis was obtained. The spectroscopic data for VII were: IR (ν, oil film): 1750 (carbonate) cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 5.80 (s, 1H, 4), 4.10 (t, 2H, 23), 2.63 (s, 1H, 21), 0.95 (s, 3H, 18), and 0.86 (t, 3H, 28); mass spectrum: *m/e* 426 (3.5%, M^+) and 342 [45, $M^+ - (CH_2)_5CH_3$].

It has been claimed that a base is not necessary for the conversion of primary alcohols into their chloroformates. When tertiary alcohols are converted to their chloroformates, a base is required (13). To check whether a selective reaction with a primary alcohol group in derivatized IV (*e.g.*, the 3-oxime derivative) would be possible, norethindrone (IV) was reacted with phosgene in the absence of pyridine. As anticipated, no chloroformate was formed.

Coupling reactions to poly-N^5-(3-hydroxypropyl)-L-glutamine were monitored using tritiated norethindrone[2]. Compound III*a*[3] was dried for 5 days under high vacuum at room temperature, dissolved in a mixture of anhydrous dimethylformamide and pyridine, and then reacted with the tritiated V, which was synthesized as described. The polymer was isolated from unreacted products by repeated precipitation in ethyl acetate.

The degree of substitution of norethindrone onto the available hydroxyl groups of III*a* was up to 60% as determined by liquid scintillation counting techniques. The following spectroscopic data were obtained: IR (ν, mineral oil): 1760 and 1265 (carbonate) cm^{-1}, 1660 and 1550 (amide) cm^{-1}, and 3300 (hydroxyl) cm^{-1}.

In vivo release studies using norethindrone coupled to poly-N^5-(3-hydroxypropyl)-L-glutamine microparticles, which were implanted subcutaneously in rats, showed a near zero-order release rate for >200 days (14).

1980 United States Pharmacopeia–National Formulary. The United States Pharmacopeial Convention. 1980. 1505 pp. 21 × 28.5 cm. Price $90.00 postpaid (domestic and foreign), including all annual supplements to USP XX and NF XV; separately, $65.00 for the book and $7.00 for the first supplement. (Available from Mack Publishing Co., 20th and Northampton Streets, Easton, PA 18042; orders also may be placed with state pharmaceutical associations.)

For the first time, the United States Pharmacopeia and the National Formulary are published together in one volume. These compendia set forth legally enforceable standards for drug strength, quality, purity, packaging, and labeling.

USP XX comprises the first portion of this volume. Following a section of introductory material, additions, deletions, and title changes made since USP XIX are listed. Featured next are more than 2300 monographs covering drug substances and dosage forms. The monographs include definitions of identity, packaging and storage information, identification tests, and assays. Category, dose, sizes available, and dispensing information previously included in USP–NF monographs now appears in a separate book, USP Dispensing Information.

The 331-page section of general chapters that follows the monographs includes descriptions of microbiological tests, biological tests and assays, chemical tests and assays, and physical tests and determinations. The general chapters also include discussions of topics such as dosage form stability, controlled drug regulations, and child-resistant containers.

The next section includes descriptions of the reagents, indicators, and solutions that are required in conducting USP and NF tests and assays. The final section of USP XX contains reference tables, among which is a listing of pharmaceutical ingredients by category. A table that gives descriptive and solubility statements for USP and NF substances also is included.

The section of the book corresponding to NF XV also begins with an introductory discussion. Almost 200 monographs for inactive pharmaceutical ingredients are given in NF XV. These monographs also include identity statements along with packaging and storage information, identification tests, and assays.

A 128-page appendix to USP XX follows, which includes excerpts of Federal antibiotic regulations. The book concludes with a combined index to USP XX and NF XV.

The standards set forth by USP and NF are enforced by the U.S. government and by state governments. The USP XX–NF XV standards became official July 1, 1980.

United States Pharmacopeia Dispensing Information. The United States Pharmacopeial Convention. 1980. 20.5 × 28.5 cm. 816 pp. Price $18.75, including updates (quantity discounts available). (Available from Mack Publishing Co., 20th and Northampton Streets, Easton, PA 18042.)

This new companion to the United States Pharmacopeia–National Formulary presents dispensing information for both the practitioner and the patient. Over 300 experts in pharmacy, medicine, dentistry, and nursing participated in the review process, and additional review and input were provided by hundreds of other practitioners and patients.

The first of the three sections of this book contains information oriented toward the health care provider. There are nearly 600 pages of drug monographs arranged in alphabetical order by generic name. Each monograph includes a category statement, precautions to consider, side effects, patient consultation, general dosing information, and dosage forms. There are 364 general monographs providing information on almost 1200 drug substances and products which represent thousands of different brands.

The second section contains patient-oriented information presented in nontechnical language. This material should aid in reinforcing the therapy selected by the prescriber. There are 213 monographs, including 42 class monographs representing 155 drug substances. The information corresponds to that presented in the prescriber-oriented section.

The third section is an index listing drug entities by official names, categories of use, and selected medical information such as pregnancy warnings and breastfeeding warnings. There are cross-references by selected brand names (both U.S. and Canadian) and older nonproprietary names.

Bimonthly updates of this book will provide information on important new drugs as well as changes in information for previously included drugs. Updates are included in the stated price. The first update is provided with the main volume and concentrates on topical and vaginal products.

Fundamentals of Nuclear Pharmacy. By GOPAL B. SAHA. Springer-Verlag New York Inc., 175 Fifth Ave., New York, NY 10010. 1979. 272 pp. 15 × 23 cm. Price $19.90.

This book is meant to be used as a textbook for courses on nuclear pharmacy aimed toward nuclear pharmacists, nuclear medicine technologists, and nuclear medicine residents. It is based on courses taught to such students at the University of Arkansas for Medical Sciences. In the author's own words, "the topics included are comprehensive, ranging from the basic concept of atomic structure to practical clinical uses of radiopharmaceuticals."

Included are 12 chapters on the following topics: The Atom; Radioactive Decay; Production of Radionuclides; Radionuclide Generators; Radiopharmaceuticals; Radiolabeling of Compounds; Characteristics of Specific Radiopharmaceuticals; Quality Control of Radiopharmaceuticals; Radiopharmacy; Radiation Dosimetry, Safety, and Regulations; *In Vitro* Tests; and Radiopharmacology in Nuclear Medicine (which gives a brief description of a variety of nuclear medicine procedures). Each chapter is followed by a series of questions (answers are given in an appendix) designed to test the students' understanding of the material presented.

In general, the chapters are well written, with complex theoretical concepts explained in an easily understandable manner. The depth of the material is appropriate for the indicated audience. Especially well written are those chapters dealing with the more practical aspects of nuclear pharmacy such as the quality control of radiopharmaceuticals, radiopharmacy, safety, *in vitro* tests, and radiopharmacology. In all cases, ample illustrations and examples aid the reader in gaining a practical understanding of the material.

In summary, this is an excellent, reasonably priced textbook for the intended audience and should find widespread acceptance by both students and instructors.

Polarography of Molecules of Biological Significance. Edited by W. FRANKLIN SMYTH. Academic, 111 Fifth Ave., New York, NY 10003. 1979. 326 pp. 15 × 23 cm. Price $47.50.

This book covers the polarography of organic molecules that have applications in pharmacy, pharmacology, basic medical sciences, environmental sciences, and agriculture. The authors review the literature published since 1965.

The first part of the book is an introduction to voltammetric analysis and consists of two chapters. The first chapter has a brief outline of the voltammetric methods and their scope and advantages, sampling, initial treatment, separation techniques of the active component, and methods to make an electroactive molecule. Chapter 2 discusses the practical aspects of the voltammetric method, including the choice of solvents, supporting electrolytes, pH, electrodes, cells, and potentiostats. The theoretical aspects of the different voltammetric techniques are discussed to allow optimum selection.

The second part of the book (eight chapters) is the application of polarography to different fields. Three chapters deal with the analysis of pharmaceuticals. The substances discussed include psychotropic, hyp-

Polarography of Molecules of Biological Significance. Edited by W. FRANKLIN SMYTH. Academic, 111 Fifth Ave., New York, NY 10003. 1979. 326 pp. 15 × 23 cm. Price $47.50.

This book covers the polarography of organic molecules that have applications in pharmacy, pharmacology, basic medical sciences, environmental sciences, and agriculture. The authors review the literature published since 1965.

The first part of the book is an introduction to voltammetric analysis and consists of two chapters. The first chapter has a brief outline of the voltammetric methods and their scope and advantages, sampling, initial treatment, separation techniques of the active component, and methods to make an electroactive molecule. Chapter 2 discusses the practical aspects of the voltammetric method, including the choice of solvents, supporting electrolytes, pH, electrodes, cells, and potentiostats. The theoretical aspects of the different voltammetric techniques are discussed to allow optimum selection.

The second part of the book (eight chapters) is the application of polarography to different fields. Three chapters deal with the analysis of pharmaceuticals. The substances discussed include psychotropic, hyp-

notic, and sedative drugs, vitamins, CNS agents, antituberculins, purines, catechols, catecholamines, and antibiotics containing a nitro group. One chapter is concerned with the basic medical sciences, including clinical medicine, chemical carcinogenesis, neurophysiology, virology, immunology, and cells. The polarographic analysis of organic compounds in the aqueous environment is discussed in one chapter. Another chapter discusses the analysis of organic compounds used in agriculture. The last two chapters are concerned with the analysis of organometallic compounds containing mercury, tin, lead, germanium, and arsenic.

This much-needed update discusses developments in the polarographic analysis of organic molecules that have occurred since Peter Zuman wrote "Organic Polarographic Analysis" in 1965. The book is well edited and is easy to read and understand. Each chapter has its own table of contents, and there is a subject index that covers the entire book. Furthermore, each chapter has adequate references that enable the reader to extend beyond the scope of the present book.

There are minor flaws. Chapter 4 should have stated that the $E_{1/2}$ range of $-0.1 \rightarrow -0.4$ v (saturated calomel electrode) is for a nitro group conjugated to an aromatic system. There are other antibiotics containing a nitro group attached to an aliphatic system, such as everninomicins, that can be determined polarographically [Kabasakalian *et al., J. Pharm. Sci.*, **63,** 641 (1974)]. It also is unfortunate that the polarographic analysis of an important compound such as adriamycin (doxorubicin) was omitted [Rao *et al., J. Electrochem. Soc.*, **125,** 534 (1978)]. There is a printing error in the last paragraph on p. 19; ($-1.5 \rightarrow 17$ v) should be 1.7 v.

With the exception of these minor criticisms, the book succeeds admirably in its goal. It is recommended for addition to the library of research workers in the area of pharmaceuticals and allied medicine, analytical chemists, environmental scientists, and agriculture.

NEW JOURNALS

Biomaterials. Edited by S. D. BRUCK and G. W. HASTINGS. IPC Science and Technology Press, 205 E. 42nd St., New York, NY 10017. 1980. 20 × 30 cm. Price $117.00 (four issues per year).

notic, and sedative drugs, vitamins, CNS agents, antituberculins, purines, catechols, catecholamines, and antibiotics containing a nitro group. One chapter is concerned with the basic medical sciences, including clinical medicine, chemical carcinogenesis, neurophysiology, virology, immunology, and cells. The polarographic analysis of organic compounds in the aqueous environment is discussed in one chapter. Another chapter discusses the analysis of organic compounds used in agriculture. The last two chapters are concerned with the analysis of organometallic compounds containing mercury, tin, lead, germanium, and arsenic.

This much-needed update discusses developments in the polarographic analysis of organic molecules that have occurred since Peter Zuman wrote "Organic Polarographic Analysis" in 1965. The book is well edited and is easy to read and understand. Each chapter has its own table of contents, and there is a subject index that covers the entire book. Furthermore, each chapter has adequate references that enable the reader to extend beyond the scope of the present book.

There are minor flaws. Chapter 4 should have stated that the $E_{1/2}$ range of $-0.1 \rightarrow -0.4$ v (saturated calomel electrode) is for a nitro group conjugated to an aromatic system. There are other antibiotics containing a nitro group attached to an aliphatic system, such as everninomicins, that can be determined polarographically [Kabasakalian *et al., J. Pharm. Sci.*, **63,** 641 (1974)]. It also is unfortunate that the polarographic analysis of an important compound such as adriamycin (doxorubicin) was omitted [Rao *et al., J. Electrochem. Soc.*, **125,** 534 (1978)]. There is a printing error in the last paragraph on p. 19; ($-1.5 \rightarrow 17$ v) should be 1.7 v.

With the exception of these minor criticisms, the book succeeds admirably in its goal. It is recommended for addition to the library of research workers in the area of pharmaceuticals and allied medicine, analytical chemists, environmental scientists, and agriculture.

MAINTAINING NAS–NRC CREDIBILITY

This week I had eggs for breakfast—and not just once, but three times, in fact!

As in the case of many Americans who have been diet conscious regarding cholesterol, salt, saturated fats, roughage–fiber, and so on, in recent years I had significantly restricted my intake of cholesterol-rich foods. This regimen was followed in the belief that the risk of coronary disease would be substantially reduced.

But the National Academy of Sciences–National Research Council released a report in late May in which its Food and Nutrition Board said that, in general, there is no reason for a healthy person to reduce his or her intake of cholesterol and fat. Indeed, other than a rather mild caution about daily salt use, the report concluded that there was really no basis for any of the dietary changes of the type noted above.

This conclusion flew in the face of many other reports and recommendations from various other groups that had arrived at an opposite conclusion. For example, just last February the departments of HEW and Agriculture issued dietary guidelines which recommended that healthy Americans should watch how much cholesterol and fat they ate. Most physicians have been influenced by guidelines such as these, and, as such, they have been counseling their patients along these lines for at least the past few years. Consequently, widespread changes have occurred in the dietary practices of a significant portion of the population.

What, then, took place to cause this apparent 180° different conclusion by the NAS–NRC Food and Nutrition Board? They did no new studies; they conducted no new experiments or research; they drew upon no new journal reports or findings. Basically, they just looked at all the same information and data that the other groups had reviewed, but they arrived at quite an opposite conclusion.

Normally, if a single scientist, or even a single group of scientists, disagrees with the mainstream of scientific thought, opinion, or conclusion, little note is taken and little importance is attached. But the NAS–NRC Food and Nutrition Board is not your everyday sort of run-of-the-mill committee.

For example, this same body is responsible for establishing the recommended daily allowances of all vitamins, minerals, and so on that we are constantly reminded of when we see the package labeling for bread, cereals, milk products, and a host of other foods. Beyond their own individual professional credentials, as a group they (FNB members) carry the recognition and reputation of the prestigious NAS–NRC.

But in itself that is no guarantee that biases may not enter the picture. Stories in the public press brought out that the report author, the committee chairman, and a third member who reviewed the report all held paid consultantships with various food producers or food trade organizations. Moreover, several other panel members had connections with the food industry that would appear to render their objectivity suspect in regard to matters with an economic impact on the food industry. Some press reports have highlighted these relationships in an apparent effort to create doubts regarding the scientific objectivity of the FNB's report.

The federal government has made a major effort to eliminate conflict-of-interest considerations from arising within its bodies of advisors as well as staff. But when carried out to its maximum, it becomes difficult to identify highly qualified people because seemingly all the experts have accepted paid industry consultantships or other appointments involving some type of monetary consideration.

We don't know where the truth lies regarding the health hazard of the dietary factors including cholesterol and fat. We suspect that it lies somewhere in between the recent NAS–NRC position and the traditional stand. Perhaps there just aren't sufficient data to make any real decision at this time. But, whatever the case, the NAS–NRC image of prestige and objectivity has now been tarnished in the public eye.

Several years ago, certain elements in the drug industry exerted a major arm-twisting effort to attempt to reverse a position taken by the NAS–NRC Drug Research Board regarding modifying state antisubstitution laws. The drug industry effort came so close to being successful that the NAS–NRC hierarchy undertook a full-scale review of the matter and decided to abolish the Drug Research Board.

NAS–NRC credibility again appears to be at stake as a result of the FNB report. The voice of science in America is too important and too fragile to allow it to suffer the loss of the NAS–NRC as a respected and trusted beacon of scientific truth. Consequently, we hope that officialdom at NAS–NRC will conduct whatever review or investigation is needed to ascertain the objectivity of its FNB's conclusions and recommendations. And, further, we hope that it will institute stringent measures in its committee appointment process to avoid the future potential for any bias to creep into the reports of any of its panels or boards.

In commenting on the problem with the ill-fated Drug Research Board, one of the former DRB members candidly observed that we can hardly find true experts in any field who have no biases; but he suggested that what we must do is identify the experts' biases and then appoint the right mix of people to balance off the respective influences against each other. It would seem that the NAS–NRC would go far in restoring its bruised image if it could successfully follow that sage advice.

Mass Spectra of Dexamethasone and Betamethasone

The work of Attinà[1] in this issue of the Journal questions an earlier report[2] on the distinction between betamethasone and dexamethasone by mass spectrometry. The spectra referred to were obtained, using reference standard materials, on an instrument that was unsophisticated by modern standards. Indeed, the instrument belonged to a local university and was used in a service capacity by the university staff and students. At the time, our laboratories did not possess a mass spectrometer.

On learning of the work of Attinà[1], an attempt was made to repeat the spectra with modern equipment[3]. The spectra obtained were similar but not identical to those reported by Attinà[1].

We can only speculate as to why the spectra obtained in 1969 were so different from each other and from spectra obtained on more modern instruments. There may have been preliminary decomposition because of the minimal control over conditions existing within the instrument, or there may have been a "memory" effect owing to the service nature of the instrument. Nevertheless, based on the spectra received in 1969, the interpretation was reasonable and consistent with analogous work as cited.

We are grateful that this matter has been brought to our attention and thank those involved.

Commentary on Science

I would like to call attention to some lucid, perspicacious, and appropriate comments on science and then suggest that we all apply the stated criteria to our efforts in the pharmaceutical sciences.

". . .there is a natural history of science— (i.e.) *science, in any given field, goes through a patterned course of growth and development. For example, it seems to me right and natural that in any new field of scientific endeavor the observations are gross, the hypotheses speculative and full of errors, the measurements crude. More important, I hold the opinion that this is just as truly science as the use of the most refined hypotheses and measurements in a more fully developed field of study. The crucial question in either case is not the degree of refinement but the direction of movement. If in either instance the movement is toward more exact measurement, toward more clear-cut and rigorous theory and hypothesis, toward findings which have greater validity and generality, then this is a healthy and growing science. If not, then it is a sterile pseudo science, no matter how exact its methods. Science is a* developing *mode of inquiry, or it is of no particular importance. . . A science (should endeavor) to wrest from the phenomena of experience the inherent order they contain."*[1]

Sulfonamide Microcapsules from Gelatin–Acacia Coacervates

The authors of a recent research paper[1] pertaining to sulfamethoxazole microcapsules prepared from gelatin–acacia coacervates cited no studies relating the coacervation pH, the type or concentration of the flocculating (dehydrating) agent, or the exposure duration and concentration of formaldehyde to the properties of powdered products recovered therefrom. The effects of some of these factors as well as the extraction of sulfamerazine from intact microglobules retrieved from gelatin–acacia coacervates were, however, reported previously[2]. It should be apparent from a perusal of these papers[1,2] that there is considerable similarity between the methods used to produce and recover the sulfonamide microcapsules. Therefore, some substantive conclusions from the earlier study[2] would appear to be germane to the results and discussion of the more recent one[1].

More important, I hold the opinion that this is just as truly science as the use of the most refined hypotheses and measurements in a more fully developed field of study. The crucial question in either case is not the degree of refinement but the direction of movement. If in either instance the movement is toward more exact measurement, toward more clear-cut and rigorous theory and hypothesis, toward findings which have greater validity and generality, then this is a healthy and growing science. If not, then it is a sterile pseudo science, no matter how exact its methods. Science is a* developing *mode of inquiry, or it is of no particular importance. . . A science (should endeavor) to wrest from the phenomena of experience the inherent order they contain."*[1]

Sulfonamide Microcapsules from Gelatin–Acacia Coacervates

The authors of a recent research paper[1] pertaining to sulfamethoxazole microcapsules prepared from gelatin–acacia coacervates cited no studies relating the coacervation pH, the type or concentration of the flocculating (dehydrating) agent, or the exposure duration and concentration of formaldehyde to the properties of powdered products recovered therefrom. The effects of some of these factors as well as the extraction of sulfamerazine from intact microglobules retrieved from gelatin–acacia coacervates were, however, reported previously[2]. It should be apparent from a perusal of these papers[1,2] that there is considerable similarity between the methods used to produce and recover the sulfonamide microcapsules. Therefore, some substantive conclusions from the earlier study[2] would appear to be germane to the results and discussion of the more recent one[1].

Mass Spectra of Dexamethasone and Betamethasone

The work of Attinà[1] in this issue of the Journal questions an earlier report[2] on the distinction between betamethasone and dexamethasone by mass spectrometry. The spectra referred to were obtained, using reference standard materials, on an instrument that was unsophisticated by modern standards. Indeed, the instrument belonged to a local university and was used in a service capacity by the university staff and students. At the time, our laboratories did not possess a mass spectrometer.

On learning of the work of Attinà[1], an attempt was made to repeat the spectra with modern equipment[3]. The spectra obtained were similar but not identical to those reported by Attinà[1].

We can only speculate as to why the spectra obtained in 1969 were so different from each other and from spectra obtained on more modern instruments. There may have been preliminary decomposition because of the minimal control over conditions existing within the instrument, or there may have been a "memory" effect owing to the service nature of the instrument. Nevertheless, based on the spectra received in 1969, the interpretation was reasonable and consistent with analogous work as cited.

We are grateful that this matter has been brought to our attention and thank those involved.

Commentary on Science

I would like to call attention to some lucid, perspicacious, and appropriate comments on science and then suggest that we all apply the stated criteria to our efforts in the pharmaceutical sciences.

". . .there is a natural history of science— (i.e.) *science, in any given field, goes through a patterned course of growth and development. For example, it seems to me right and natural that in any new field of scientific endeavor the observations are gross, the hypotheses speculative and full of errors, the measurements crude. More important, I hold the opinion that this is just as truly science as the use of the most refined hypotheses and measurements in a more fully developed field of study. The crucial question in either case is not the degree of refinement but the direction of movement. If in either instance the movement is toward more exact measurement, toward more clear-cut and rigorous theory and hypothesis, toward findings which have greater validity and generality, then this is a healthy and growing science. If not, then it is a sterile pseudo science, no matter how exact its methods. Science is a* developing *mode of inquiry, or it is of no particular importance. . . A science (should endeavor) to wrest from the phenomena of experience the inherent order they contain."*[1]

Mechanisms of Anterior Segment Absorption of Pilocarpine following Subconjunctival Injection in Albino Rabbits

JOSEPH M. CONRAD and JOSEPH R. ROBINSON ˣ

Received December 14, 1979, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication March 13, 1980.

Abstract □ The present study was initiated to provide insight into the mechanisms of drug availability from subconjunctival injection. Pilocarpine nitrate was the probe drug, and the albino rabbit was the experimental animal. Several volumes, from 50 to 500 μl, of drug solution were injected subconjunctivally; drug levels were monitored in the tear, cornea, aqueous humor, and blood as a function of time. The injection site also was examined for residual drug postdosing. Finally, drug was placed in the subconjunctival space either by injection through the conjunctival membrane or through the eyelid. From these experiments, it was concluded that at high injection volumes, *i.e.*, >200 μl, reflux of the drug solution out of the injection site, followed by corneal absorption, is the primary mechanism to explain aqueous humor availability of the drug. At lower injection volumes, multiple mechanisms, including reflux of drug from the injection site and transconjunctival permeation, penetration of the globe of the eye, and systemic absorption followed by return *via* the vascular bed, are necessary to explain drug absorption. High aqueous humor levels of pilocarpine can be achieved from subconjunctival injection as compared to the topical route, provided that large injection volumes, *i.e.*, >200 μl, are employed and correspondingly greater amounts of drug are administered. No true sustaining of drug availability to the aqueous chamber was noted, but local sustaining at the injection site was evident.

Keyphrases □ Pilocarpine—mechanisms of distribution to cornea, tear, aqueous humor, and blood following subconjunctival injection, rabbits □ Absorption, ocular—pilocarpine, mechanisms of distribution following subconjunctival injection, rabbits □ Distribution, ocular—pilocarpine, mechanisms of absorption following subconjunctival injection, rabbits

Subconjunctival administration of ophthalmic drugs represents an important, albeit poorly understood, administration route. Some clinicians select this route because of the expected sustained drug delivery to the eye, whereas others choose it for the expected high drug levels that can be achieved in the anterior segment of the eye as compared to topical dosing. Whether a high level or a sustained effect is achieved appears to depend on the drug, the formulation, and the method of injection.

That drugs do penetrate the eye from subconjunctival injection is certain, although the penetration rate may vary considerably depending on the drug and formulation. However, it is not well understood how the drug moves from the injection site to the aqueous chamber. Until a clear mechanistic picture is established, drug release predictions for different drug entities or formulation changes will be based primarily on experience.

The purpose of the present study was to examine the mechanisms of aqueous chamber absorption from subconjunctival injection for the water-soluble drug pilocarpine.

BACKGROUND

The conjunctiva is the thin membrane covering the front of the eyeball from the lid margin to the corneoscleral junction. The subconjunctival space is the region between the conjunctiva and the eyeball, and subconjunctival injections place the drug in this area either for a local effect or as a repository to provide drug to the aqueous chamber.

Several mechanisms have been proposed to explain the movement of drugs from the subconjunctival site of injection to the anterior segment of the eye, *i.e.*, the aqueous chamber:

1. The drug is absorbed into the conjunctival blood vessels, enters the general circulation, and then enters the anterior segment of the eye.
2. The drug directly penetrates the sclera and underlying layers.
3. The drug refluxes out of the puncture hole produced in the conjunctiva by injection. It then mixes with tears and is absorbed across the cornea.
4. The drug diffuses across the conjunctiva, followed by mixing with tears and eventual corneal absorption.

One early explanation of ocular drug absorption from subconjunctival injection was systemic absorption followed by return to the eye. Without doubt, most of this injected dose is absorbed into the systemic circulation, which represents a considerable loss from the injection site. However, given the large volume of distribution of the vascular bed and the small amount of drug involved, as well as potential metabolism in the blood, it seems unlikely that this route of penetration would be major for most drugs.

The second potential route is direct scleral absorption of drug into the aqueous chamber. While this route is possible, the drug would have to permeate a relatively impermeable scleral coat (1–4) and traverse a rich vascular bed to gain entrance to the aqueous chamber. For most drugs,

0022-3549/80/0800-0875$01.00/0
© 1980, American Pharmaceutical Association

the difficulty of scleral penetration as well as loss to systemic circulation probably would cause little, if any, drug to reach the anterior segment of the eye. In addition, this mechanism would have to be compatible with the very early time of the peak drug level in the aqueous chamber that is commonly observed. Nevertheless, McCartney *et al.* (5), on the basis of autoradiographic techniques, felt that this route was a distinct mechanistic possibility for absorption of hydrocortisone.

Undoubtedly, the most widely accepted route for absorption is the needle puncture and reflux theory. Recent work (6) with small volumes (1 μl) of injected solutions raised doubts about its importance in humans. On the other hand, Wine *et al.* (7) systematically examined the mechanism of absorption of [^{14}C]hydrocortisone and found that the leakage mechanism was the most plausible. Aqueous humor drug levels from normal subconjunctival injections were compared with those achieved from injection through the upper eyelid, which kept the conjunctival membrane intact. The relatively high drug levels from subconjunctival injection compared to those from upper eyelid injection supported the puncture mechanism.

The last possible mechanism is direct permeation of the conjunctiva followed by corneal absorption. The conjunctival permeability coefficient for pilocarpine has been estimated (8) to be in the range of 10^{-3} cm/hr, which is in good agreement with the coefficient of 5×10^{-3} cm/hr found for sodium 22 (2, 9). This sufficiently large permeability coefficient explains the early peak times in the cornea and aqueous humor, provided the concentration of injected drug is very large and little or no drug is lost to the conjunctival blood vessels. Simple diffusion of drugs from subconjunctival injection has been compared with topical dosing (10). Early peaks in the cornea, sclera, and choroid can be attributed to extensive diffusion of drug across the conjunctiva, or leakage, to the tear film or to direct transfer of drug at the corneoscleral junction, presumably through limbal blood vessels.

For any individual drug entity, its physicochemical properties, such as solubility, diffusivity, and partitioning behavior, may give one mechanism precedence over another. In addition, vehicle composition, volume injected, and method of injection also may influence the mechanism. The present study examines some of these variables using pilocarpine as the drug probe.

EXPERIMENTAL

Materials—Tritiated pilocarpine alkaloid with a specific activity of 4.1 Ci/mmole was obtained commercially[1] and purified by vacuum distillation (11) immediately prior to use. All other chemicals were reagent or analytical grade and were used as received.

Male albino rabbits[2], 1.7–2.4 kg, were maintained on a regular diet with no restrictions on the amounts of food and water consumed. Lighting and auditory stimuli were kept constant on a 24-hr basis.

Preparation of Pilocarpine Solutions—Drug solutions were prepared by the addition of the purified labeled material to a 1×10^{-2} *M* (0.2%) pilocarpine solution. The buffer was pH 6.24 isotonic Sorensen buffer. Addition of [^{3}H]pilocarpine had no appreciable effect on the molarity of the final dosing solution. It was determined that 0.25 mCi of the labeled drug/ml of the final dosing solution was sufficient to give good counting efficiency. The dosing solution for injection corresponded to a final concentration of 2.08 μg of pilocarpine alkaloid/μl of solution.

Subconjunctival Injection Administration through Conjunctival Membrane—Rabbits were positioned in restraining boxes to minimize movement and to maintain the normal upright posture. Approximately 10 min prior to dosing, each eye received one drop of 0.5% tetracaine hydrochloride solution[3]. Although topical anesthetics have been shown to cause breakup of the tear film (1–3, 8, 12, 13), this step was necessary to obtain consistent injections.

Following local anesthesia, measured volumes of pilocarpine solution (50, 100, 200, and 500 μl) were injected accurately through the conjunctival membrane in the center of the upper quadrant bulbar conjunctiva, ~3–4 mm back from the corneoscleral junction. A 1-ml tuberculin syringe fitted with a 27-gauge, 1.27-cm needle was employed. Only one eye of each test animal received the dose, with the other eye serving as a control. Alternate eye dosing was used in each animal to eliminate any right to left or left to right eye bias.

Aqueous humor, blood, and corneal samples were obtained at 5, 10, 20, 30, 45, 60, and 120 min postdosing. For the 200-μl injection, samples also were obtained at 180 and 240 min postinjection. At the end of each period, the animal was sacrificed *via* rapid injection of a phenobarbital sodium overdose into the marginal ear vein.

Prior to sampling, the corneal surface was rinsed with isotonic saline and blotted dry with a tissue. Aqueous humor samples were obtained by aspirating the aqueous humor and analyzing the fluid *via* scintillation counting according to reported procedures (14–17). Corneal samples were obtained by excising the cornea immediately after aqueous humor aspiration. The method for obtaining and treating the corneal samples was described previously (14, 17).

Blood samples of 1 ml were obtained by direct cardiac puncture, and then two 100-μl samples were transferred[4] quantitatively to absorbent pads[5] contained in combustion cones[6]. These samples were allowed to dry for 24 hr prior to burning in a tissue oxidizer[7]. The oxidizer automatically deposited the tritiated sample, along with 10 ml of liquid scintillation counting solution[8], into a plastic vial[9]. The vial contents were allowed to cool to room temperature for 6 hr and then were counted and analyzed as described previously (14, 17). At least seven eyes were used for each data point. Mean values and standard errors of the mean were determined from the pooled data at each time point, and the concentration–time profile was fitted to a one-compartment pharmacokinetic model (18, 19).

Subconjunctival Injection Administration through Upper Eyelid—Rabbits were positioned in restraining boxes, and a drop of local anesthetic was instilled into each eye. Accurately measured volumes (50–100 μl) of pilocarpine solution were injected directly through the upper eyelid into the center of the upper quadrant under the bulbar conjunctiva. The injection was made so as to produce a bleb in the same location as the direct subconjunctival injection. Thus, the major difference between this study and the direct subconjunctival injection was that no puncture of the conjunctival membrane occurred.

Tissue sampling and analysis were identical to those described previously. The data treatment and analysis of data also were as described previously.

Tear Film Pilocarpine—*Single-Needle Puncture Hole*—Rabbits were placed in restraining boxes, but no local anesthetic was administered. Pilocarpine solution, 200 μl, was injected subconjunctivally; the tear film was sampled at 0, 0.5, 1, 2, 4, 5, 7, 10, 15, 20, and 30 min postdosing. The tear film samples were obtained by carefully touching a 1-μl capillary pipet[10] to the lacrimal lake at the edge of the lid and aspirating a 1-μl sample. The glass capillary tubes then were treated in a manner similar to that described for the aqueous humor samples. At least 13 eyes were used for each data point, and the data were treated as described previously.

Multiple-Needle Puncture Hole—The study was identical to that described for the single-needle puncture except that multiple punctures were made in the conjunctival membrane. Three protocols were employed: (*a*) nine punctures, followed by dosing of 200 μl of the pilocarpine solution injected during the 10th puncture; (*b*) five punctures, followed by dosing on the sixth puncture, followed by four more punctures into the resulting bleb; and (*c*) injection of 200 μl, followed by nine more punctures into the bleb.

Immediately following the 10th puncture of the conjunctival membrane, 1-μl tear samples were collected over the same period and analyzed in the same way as described for the tear film study.

At the end of the tear sampling period, *i.e.*, 30 min, the animals were sacrificed; the aqueous humor, cornea, and blood samples were obtained. These samples were analyzed as already described.

At least 14 eyes were used for each data point, and the results were treated as described previously.

No Puncture Hole—The dose was injected into the subconjunctival space without puncturing the conjunctival membrane by piercing the upper eyelid and threading the needle to approximately the same spot in the subconjunctival space as from a subconjunctival injection.

Tear samples were collected and analyzed as described previously. At least 11 eyes were used for each data point.

Conjunctival Bleb Analysis—Rabbits were prepared and placed in restraining boxes. Following administration of the topical anesthetic, 200 μl of pilocarpine solution was administered to each eye either by subconjunctival or through-the-eyelid injection. At the end of 60 min, the animals were sacrificed. The upper quadrant conjunctival membrane was

dissected and removed, including the bulbar and palpebral portions.

The obtained tissue was placed in a tared combustion cone[6] containing a combustion pad[5] to soak up any fluid and to aid in more even burning of the tissue in the combustion process. The wet weight of each conjunctiva then was determined. Subsequent analytical procedures were identical to those used in the corneal sample analysis.

At least 21 eyes were used for each point in the membrane puncture bleb analysis, and 18 eyes were used per point in the eyelid route bleb analysis. All data were subjected to the same analysis as described previously.

RESULTS

Subconjunctival Injection Delivered through Conjunctival Membrane—Drug concentration *versus* time profiles for each of the four dose volumes were obtained for the aqueous humor, cornea, and blood. Cornea and aqueous humor data were obtained for both the dosed and contralateral eyes.

The data are presented in Tables I–III for the four dose volumes studied. For visual comparison, the aqueous humor data are shown graphically in Fig. 1. An examination of Fig. 1 shows some expected trends. As the dosing volume increased, the amount of drug absorbed into the cornea or aqueous humor increased. The amount of drug absorbed was increased greatly by the increase in dosing volume from 100 to 200 μl. This result also occurred in the contralateral eye, although the drug levels were much smaller and the trend was not as clear.

Subconjunctival Injection Delivered through Upper Eyelid—Drug concentration *versus* time profiles for each of the two dose volumes were obtained for the aqueous humor, cornea, and blood. Cornea and aqueous humor data were obtained for both the dosed and contralateral eyes.

Tables IV–VI contain the pertinent data from this study, and Fig. 2 shows the representative aqueous humor data in graphical form. The drug levels in the cornea and aqueous humor were several orders of magnitude lower than those from the through-the-membrane injection. The levels in the contralateral eyes were about the same as those in the through-the-membrane injection. Finally, the circulating blood level data were comparable from both studies.

Lacrimal Fluid following Subconjunctival Injection—The tear film was monitored for drug as a function of time for three different experimental conditions: one puncture hole in the conjunctiva, multiple-puncture holes in the conjunctiva, and no puncture holes in the conjunctiva (through-the-eyelid injection). The data are shown in Table VII. Drug levels in the through-the-eyelid study were approximately three orders of magnitude less than those in the punctured conjunctival studies. These levels were so low that background radiation levels became important and should be considered when assessing the accuracy of the stated levels.

Data from the punctured conjunctiva are shown graphically in Fig. 3. The profiles were similar at all times except for the first 5 min. Previous reports from this laboratory described the procedures and problems of tear sampling (11, 20–22). Samples were collected for 30 min with emphasis on data obtained during the first 5 min. Therefore, considerable weight is given to the difference shown in Fig. 3 for the first 5 min post-injection.

After 30 min, the experimental animal was sacrificed; samples of the cornea, aqueous humor, and blood were taken (Table VIII). The aqueous humor drug levels for the dosed and contralateral eye in the through-the-eyelid study were not appreciably different. Cornea data from the same study showed the dosed eye levels to be about twice as large as those from the contralateral eye, although both were low relative to the injection study. The small, but measurable, difference in cornea levels is attributed to drug diffusing through the conjunctival membrane to the tear fluid and then absorbed into the cornea.

The aqueous humor and cornea data from the dosed eye in the punctured membrane case were two orders of magnitude greater than those from the through-the-eyelid study. Although the multiple-puncture

aqueous humor and cornea drug levels were slightly higher than the corresponding drug levels from single puncture, they were not statistically different. A partial explanation for this lack of difference is that, upon dissection of the bleb, the area appears as a sponge with numerous aqueous compartments. Multiple punctures do not appear to have a significant effect because it is not like puncturing a balloon but rather like puncturing a sponge.

The drug level in lacrimal fluid at 30 min was as anticipated, with large values in the puncture studies and a low level in the nonpuncture case. The lower lacrimal level in the multiple-puncture case was not statistically different from the single-puncture case. One would expect, *a priori*, lower levels in tears at the 30-min point in the multiple-puncture case if more drug is absorbed into the cornea.

Conjunctival Bleb Injection through Membrane or through Eyelid—The bleb created by subconjunctival injection remains for hours postinjection. It was of interest to determine if the drug also remained for hours or if the bleb merely contained the aqueous injection solution or inflammatory fluid. Thus, at 1 hr postinjection, the bleb was removed surgically and analyzed for drug content. Simple aspiration of the bleb was not possible because of its sponge-like characteristics. The results are shown in Table IX.

After 60 min, there was a considerable amount of pilocarpine in the punctured membrane compared to the through-the-eyelid study. From the wet weights obtained, it is clear that localization of the drug solution in the through-the-eyelid case was much more difficult than in the punctured case. The bleb created by through-the-eyelid injection was distinctly smaller; it was difficult to place it near the bulbar conjunctiva. Undoubtedly, the difference in physical placement and localization of drug solution in the two studies contributed to the difference shown in Table IX. The fact that considerable pilocarpine was left at the site long after appreciable drug levels appeared in the cornea and aqueous humor is significant. This result supports the sustained-release concept of subconjunctival dosing. However, whether the drug is released locally or to the aqueous chamber for long periods depends on the specific drug properties and injection formulation.

DISCUSSION

Each of the four proposed mechanisms for drug movement into the eye interior following subconjunctival injections will be examined, and the

results from the present study will be interpreted in light of these proposals. Each mechanism contributes to the overall movement of drug, and it is the magnitude of the contributions that is of concern.

The magnitude and shape of the cornea or aqueous humor pilocarpine–time profile from subconjunctival injection did not differ greatly from those achieved after topical dosing (14, 20, 23), despite the greater amount of drug administered by injection. For example, a 25-μl topical dose of 1×10^{-2} *M* pilocarpine (0.2% solution) produced a maximum level of ~1 μg/ml in ~30 min. A 200-μl injection of the same concentration produced a maximum level of ~1.8 μg/ml in ~30 min, less than a twofold difference despite an eightfold difference in the amount of drug instilled or injected. Moreover, the duration of drug levels was almost identical. Thus, with pilocarpine, no apparent sustaining effect was evident, unless it was at a low level, and only a modest increase in the peak level occurred. It was possible to produce higher aqueous humor levels of drug with the same drug concentration merely by injecting larger volumes.

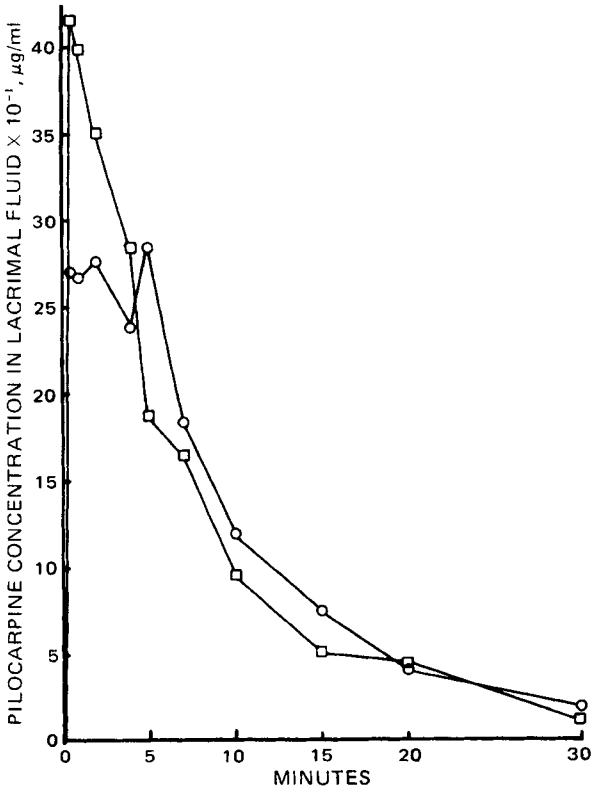

Figure 3—*Lacrimal fluid drug concentration* versus *time profiles for* 1×10^{-2} M *pilocarpine in 200 μl of pH 6.24 isotonic Sorensen buffer following subconjunctival injection* via *various routes in the dosed eye. Key:* ○, *single-puncture injection through the membrane; and* □, *multiple-puncture injection through the membrane. Each point represents a minimum of 13 determinations. Error bars were eliminated for clarity.*

To aid in assessing the experimental changes, the areas under the curve (*AUC*) were measured using a polar planimeter[11] (Table X). In addition, the peak levels and the time to achieve peak levels are important for mechanistic discussion purposes. An assessment of drug bioavailability from this administration route forms the basis for a separate report[12].

The data in Table X are depicted graphically in Figs. 4 and 5 to show the relationship between the dose volume and *AUC* for the cornea and aqueous humor. The insufficient number of points does not fully characterize the lines, but the sigmoidal shape is evident, particularly in the corneal data in Fig. 4. These two graphs may be contrasted with the data for the contralateral eye shown in Fig. 6. A linear relationship was evident over the dose volume range of 50–500 μl. With the contralateral eye, only one mechanism apparently was operative over the dose volume range studied; in the dosed eye, more than one mechanism probably was involved.

Mechanism 1: Drug Passes from Injection Site to Systemic Circulation and Back to Ocular Tissues and Fluids—For this mechanism

to be important, equivalent, or at least close to equivalent, drug concentration–time profiles should occur in both the dosed and the contralateral eyes. This clearly is not the case, and earlier studies that measured drug in both the dosed and contralateral eye (24, 25) agree with this finding. The time to achieve peak levels in the aqueous humor of the dosed eye was ~30 min, whereas it was ~60 min or longer in the contralateral eye. Moreover, the maximum concentrations achieved in the dosed and contralateral eyes differed by orders of magnitude, as did the *AUC*.

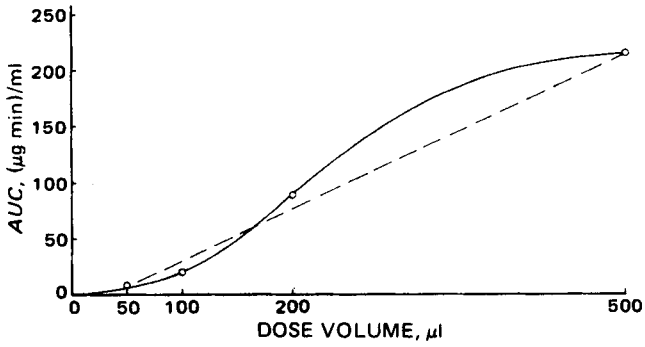

Figure 5—*Area under the curve* (AUC) *from aqueous humor drug concentration* versus *time profiles presented in Fig. 2 as a function of volume injected subconjunctivally through the conjunctival membrane. The dashed line represents the best-fit line through the points, whereas the solid line represents the interpretation of the correct shape of the curve.*

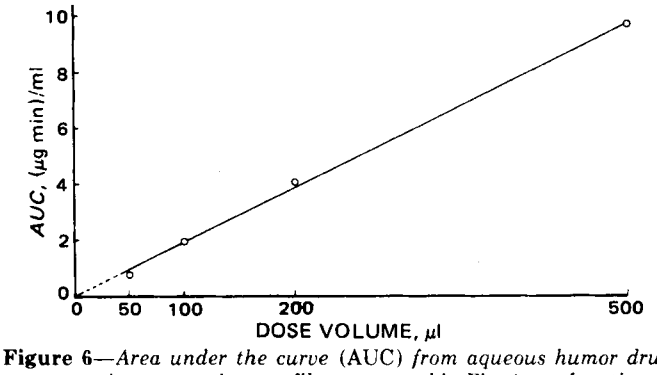

Figure 6—*Area under the curve* (AUC) *from aqueous humor drug concentration* versus *time profiles presented in Fig. 4 as a function of volume injected subconjunctivally through the conjunctival membrane.*

AUC is related directly to the dose volume injected (Fig. 7). Most of the injected drug will be absorbed into the systemic circulation, so a linear relationship is expected.

When the *AUC* for the circulating blood levels at each volume is plotted *versus* the aqueous humor *AUC* for the dosed and contralateral eyes, the relationships shown in Figs. 8 and 9 result. The intercept in the case of the contralateral eye is zero, suggesting that all of the drug in that eye came from drug in the blood. However, for the dosed eye, the intercept is not zero but intercepts on the blood *AUC* axis, suggesting a drug source other than the blood.

Another aspect of the blood level studies related to mechanistic in-

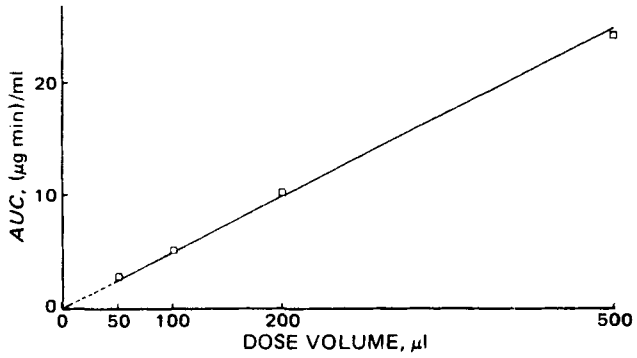

Figure 7—*Area under the curve* (AUC) *from circulating blood drug concentration* versus *time profiles presented in Table III as a function of volume injected subconjunctivally through the conjunctival membrane.*

terpretation is the time–concentration profile resulting from through-the-eyelid injection in contrast to through-the-membrane injection (Table XI). Aside from some minor differences in the peak time, the data are very similar. Moreover, the *AUC*s in these studies are very similar as seen in Table XI.

The present work was conducted in rabbits with an estimated blood volume of about 1 liter. The human eye is similar in size to that of the rabbit, but the circulating blood is 7–8 liters, so the dilution effect is expected to be even more dramatic. It seems reasonable to conclude that a minor amount of drug in the aqueous chamber of the dosed eye comes from the circulating blood.

Mechanism 2: Drug Penetrates Eye from Subconjunctival Injection Site by Simple Diffusion through Tissues Underlying Site—Earlier autoradiographic studies (5) showed that hydrocortisone penetrates the sclera, choroid, and other layers of the globe of the eye. In addition, it is expected that drug moves across limbal vessels to enter the iris and cornea. However, with pilocarpine, this mechanism does not appear to be major for drug gaining access to the anterior segment of the eye.

If movement of drug through the layers of the globe is the principal mechanism, then the method of placement, *i.e.*, puncture or no puncture, should have no effect on the drug levels. Clearly, the through-the-eyelid injection produced drug levels in the cornea and aqueous humor that were orders of magnitude lower (Table XII).

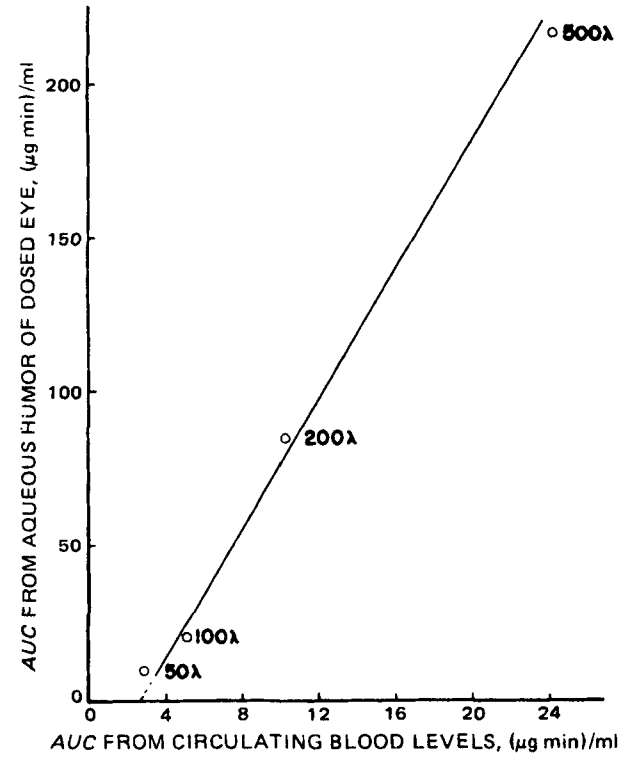

Figure 8—*Comparison of the area under the curve* (AUC) *from aqueous humor drug concentration* versus *time profiles presented in Fig. 2 to the area under the curve* (AUC) *from circulating blood drug concentration* versus *time profiles presented in Fig. 5 at each volume injected subconjunctivally through the conjunctival membrane.*

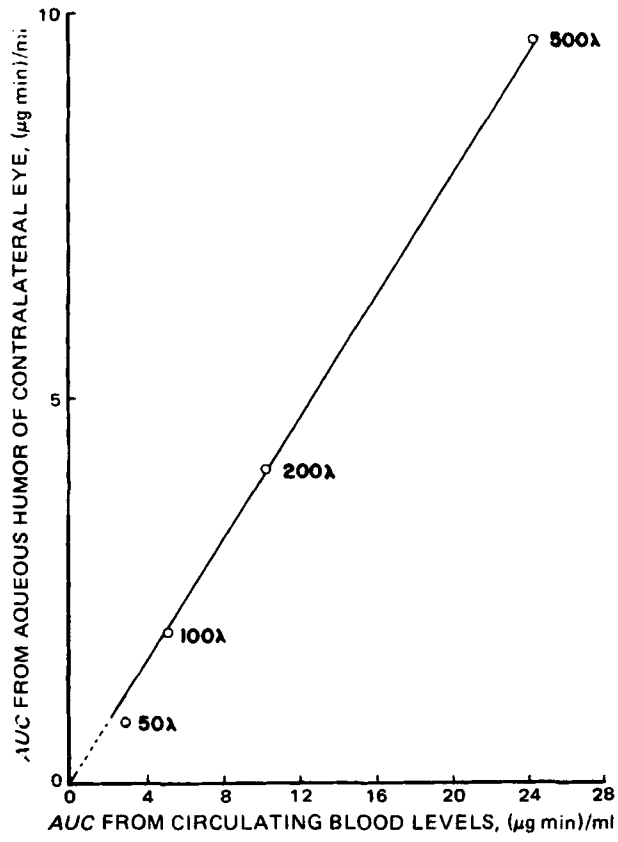

Figure 9—*Comparison of the area under the curve* (AUC) *from aqueous humor drug concentration* versus *time profiles presented in Fig. 4 to the area under the curve* (AUC) *from circulating blood drug concentration* versus *time profiles presented in Fig. 5 at each volume injected subconjunctivally through the conjunctival membrane.*

Additional support for the argument that the majority of drug does not come from penetration of the globe can be seen by comparing the drug level in the cornea with that in the aqueous humor (Fig. 10). The linearity of this plot, particularly at high dose volumes, suggests that almost all of the drug in the aqueous humor is being provided by the cornea. Earlier studies in this laboratory (11, 14, 20, 21, 23, 26) showed that back-diffusion from the aqueous humor to the cornea is not significant, so the high levels in the cornea and the linear relationship with aqueous humor levels suggest that the drug is provided by the cornea and not the globe of the eye.

Thus, for pilocarpine, direct penetration of the globe is not a major factor in getting the drug to the aqueous chamber. For more oil-soluble

drugs, such as some corticosteroids, this route may be important. Additional studies are needed to confirm or reject this possibility.

Mechanism 3: Drug Gains Entrance to Eye by Refluxing out of Injection Site followed by Corneal Absorption—The linearity of the data in Fig. 10 suggests that transcorneal absorption of drug is the primary mechanism for providing pilocarpine to the aqueous humor from a subconjunctival injection. In Fig. 10, the 50- and 100-μl dose volumes fall slightly off the line, suggesting that multiple mechanisms may account for the lower volumes, *i.e.*, Mechanisms 1–3; with larger volumes, a transcorneal mechanism appears predominant. Figures 4 and 5 indicated that multiple mechanisms may have occurred based on the relationship between the *AUC* and dose volume; as the injection volume increases, a back-pressure at the injection site may force leakage out of the puncture hole.

The case for leakage seems evident after comparing aqueous humor drug levels in the dosed eye from through-the-membrane and through-the-eyelid studies. Supportive data come from the lacrimal fluid studies. At the 200-μl injection volume, it is clear from the profiles given in Table VII and in Figs. 3 and 4, as well as from the *AUC* values found in Table XI, that leakage must have occurred in the membrane puncture studies. Injection of drug through the eyelid shows a small quantity of drug in the tear film, presumably from diffusion across the conjunctiva and into the tear film, but the three orders of magnitude difference in tear film concentration shown in Table VII apparently is due to leakage.

It is anticipated that at larger injected volumes, such as 500–1000 μl, the leakage mechanism would remain predominant. On the other hand, smaller volumes are not expected to be as dramatic and, for the 25–100-μl doses, far less drug is expected in the tear film since other mechanisms appear important.

A recent study on the mechanism of the release of fluorescein from subconjunctival injection in the rabbit was reported by Maurice and Ota (6). In this study, small injection volumes (*i.e.*, 1 μl) were employed to avoid a bleb and the drug was administered by membrane puncture and by eyelid puncture. These investigators visually observed the leakage of fluorescein out of the injection site, which is in agreement with the present findings.

Relationship of This Study to Other Drugs and to Humans—The present study was conducted with the water-soluble alkaloid pilocarpine. It is not possible to extrapolate from this single drug entity to other drugs as to their mechanisms of absorption from subconjunctival injection. However, since the principal mechanism for pilocarpine absorption involves leakage, a process independent of drug structure, it is reasonable to assume that a pulse of drug will exit from the injection site and enter the tear film in the early minutes after dosing. Whether this initial dose can establish a high level of drug in the cornea and aqueous humor is dependent primarily on the initial concentration of the drug injected and the injected volume. Presumably, increasing the viscosity of the injected solution or injection of a drug suspension would minimize the reflux process and thus diminish the peak drug level.

It seems unlikely that drugs with a more favorable partition characteristic for absorption will be absorbed so rapidly into the eye, either by direct scleral absorption or absorption across the conjunctiva followed by corneal absorption, so as to overwhelm the contribution from leakage during the early stages following injection. At later times, all drugs probably will show a local sustaining effect since pilocarpine was shown to be present in the bleb a long time after injection. Whether this localized drug can penetrate the globe of the eye over a long time to give a sustaining effect should be a function of its partitioning characteristics. The

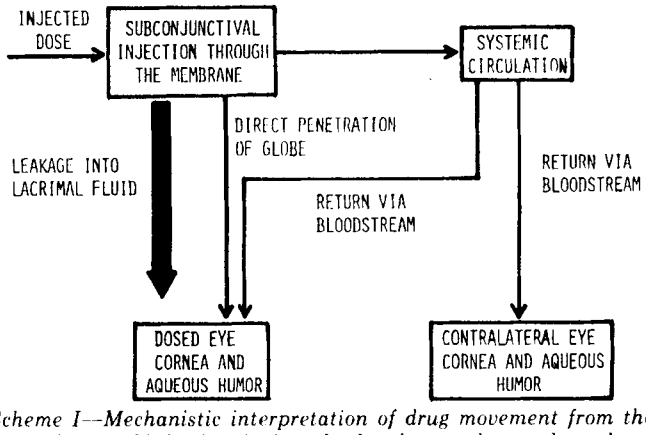

Scheme I—Mechanistic interpretation of drug movement from the subconjunctival injection site into the dosed eye and contralateral eye. At large injection volumes, leakage is the predominant mechanism, illustrated by the thick arrow. At low injection volumes, all mechanisms contribute to the process.

water-soluble drug pilocarpine did not penetrate, but apparently the more oil-soluble hydrocortisone did (5). Additional studies with other drug entities and formulation changes will clarify this picture.

The relationship of the results in rabbits to expected behavior in humans is not as clear. Maurice and Ota (6) injected small volumes of fluorescein subconjunctivally into rabbits and humans. They observed leakage of the dye in the rabbit but not in humans; however, higher levels of fluorescein in the human aqueous humor compared to the rabbit were obtained. Based on these findings, the question of the suitability of the rabbit as a model for subconjunctival injections was raised.

There has been controversy over the behavior of fluorescein in these two species (27), and the differences may be due to the dye itself. Moreover, while the small volume interpretation of these investigators may be accurate, it probably bears little relationship to what occurs at higher volumes. It is probable, based on the work of Maurice and Ota (6), that human and rabbit eyes differ in the importance of one mechanism over another, especially at low volumes. Intuitively, however, since leakage depends on pressure and large volumes are used clinically, it is not unreasonable to assume that humans and rabbits will behave similarly insofar as major mechanisms of drug availability are concerned.

CONCLUSIONS

The study was initiated to provide mechanistic insight into the movement of drug from the site of subconjunctival injection to the aqueous chamber. Several mechanisms apparently are involved in pilocarpine disposition in albino rabbits, depending on the volume of solution injected. At low volumes, it appears that transconjunctival permeation followed by corneal absorption, systemic absorption followed by return *via* the vascular bed, reflux out of the injection site, and, finally, direct penetration of the globe of the eye all contribute to aqueous humor drug levels. However, at larger volumes, leakage from the injection site is the overwhelming mechanism for drug availability (Scheme I).

Effects of Human Serum Albumin Concentration on Binding of [^{3}H]Amphetamine, [^{3}H]Atropine, [^{3}H]Epinephrine, and [^{14}C]Histamine

JOSEPH JUDIS

Received September 20, 1979, from the *College of Pharmacy, University of Toledo, Toledo, OH 43606.* Accepted for publication February 29, 1980.

Abstract □ The binding of [^{3}H]amphetamine, [^{3}H]atropine, [^{3}H]epinephrine, and [^{14}C]histamine to human serum albumin was examined with a constant ligand concentration and varying albumin concentrations. Two concentrations of each ligand were studied. Scatchard plots of the binding data were linear and had positive slopes; the slopes were greater at the higher ligand concentration. The lowest point was for the highest albumin level and increased in sequence to the lowest albumin concentration. The β (fraction bound) value increased with an increasing amount of albumin in the system. The change in β per change in albumin concentration [$d(\beta)/d$(albumin)] when plotted against albumin concentration yielded curves with negative slopes; the slope was greatest at the lower albumin levels and was much less at the higher albumin levels (equivalent to those encountered in human blood). In agreement with literature data for other systems, the nK value (number of binding sites times the association constant) decreased with increasing albumin concentration. In previous studies of the same ligands and protein, when the albumin concentration was kept constant and the ligand concentration was varied, the Scatchard plots had positive slopes. Positive slopes also were found in this study with constant ligand concentrations and varying albumin levels. These results suggest cooperativity in the binding of these ligands to human serum albumin.

Keyphrases □ Amphetamine—effect of human serum albumin concentration on binding □ Atropine—effect of human serum albumin concentration on binding □ Epinephrine—effect of human serum albumin concentration on binding □ Histamine—effect of human serum albumin concentration on binding □ Binding—effect of human serum albumin concentration on binding of amphetamine, atropine, epinephrine, and histamine

Previous studies on the binding of amphetamine, atropine, epinephrine, and histamine to human serum albumin showed that the Scatchard plots for all four ligands had positive slopes (1). Similar Scatchard plots were observed previously in the binding of codeine, morphine, and methadone to human serum albumin (2). In all of these experiments, the protein concentration was kept constant and the ligand concentration was varied. This approach is typical of most binding studies. In several studies of protein binding in which the ligand concentration was kept constant and the protein concentration was varied, Scatchard plots with positive slopes were reported (3–6).

Bowmer and Lindup (7) commented on the need for data on the effects of protein concentration on binding of ligands for more complete characterization of the protein binding of a ligand. In the usual studies, the protein concentration is kept constant and the ligand concentration is varied. With this concept in mind, the previously described studies of the binding of codeine, morphine, and methadone to human serum albumin were extended to provide data on the effects of varying the human serum albumin concentration. Under these conditions (8), the Scatchard plots had positive slopes, as was reported earlier (1, 2) where the protein concentration was kept constant and the ligand concentration was varied.

The present studies represent an extension of the investigations on the binding of amphetamine, atropine, epinephrine, and histamine to human serum albumin (1). In these additional experiments, the ligand concentration was kept constant and the concentration of human serum albumin was varied.

EXPERIMENTAL

Methods—Protein binding was determined using equilibrium dialysis in multiple-cell blocks, each having a volume of 1 ml on each side of the cellulose membrane, as in previous studies (1, 2). Radioactivity was determined in a liquid scintillation system using techniques described previously (1, 2).

Materials—Tritium-labeled and carbon 14-labeled derivatives of the ligands were obtained from the sources reported previously (1). Crystalline human serum albumin was obtained commercially[1]. The unlabeled forms of the ligands were the highest drug quality available, and all other chemicals were reagent grade.

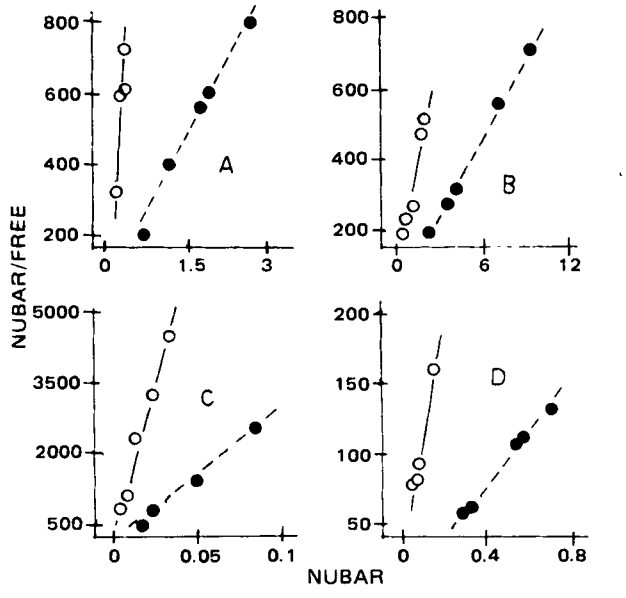

Figure 1—*Scatchard plots of data for binding of [^{3}H]atropine, [^{3}H]amphetamine, [^{3}H]epinephrine, and [^{14}C]histamine to human serum albumin. For each curve, the albumin concentrations are given for each data point starting with the lowest point on the curve. Key: A, [^{3}H]atropine at 4.5×10^{-4} M (○) and 3.43×10^{-3} M (●), with albumin concentrations of 60, 40, 10, and 6 mg/ml for the first ligand concentration and 60, 40, 20, 10, and 6 mg/ml for the second ligand concentration; B, [^{3}H]amphetamine at 3.69×10^{-3} M (○) and 1.48×10^{-2} M (●), with albumin concentrations of 60, 40, 20, 10, and 6 mg/ml for both ligand concentrations; C, [^{3}H]epinephrine at 1.14×10^{-5} M (○) and 4.56×10^{-5} M (●), with albumin concentrations of 60, 40, 20, 10, and 6 mg/ml for the first ligand concentration and 60, 40, 20, and 10 mg/ml for the second ligand concentration; and D, [^{14}C]histamine at 1.15×10^{-3} M (○) and 5.36×10^{-3} M (●), with albumin concentrations of 60, 40, 20, and 10 mg/ml for the first ligand concentration and 60, 40, 20, 10, and 6 mg/ml for the second ligand concentration.*

Histamine	1.15×10^{-3}	906.4	0.999
Histamine	5.36×10^{-3}	184.5	1.000

[a] Nubar refers to the molar concentration of ligand bound divided by the molar concentration of human serum albumin in the system. [b] The *r* value refers to the coefficient of correlation of Nubar/free concentration and Nubar.

RESULTS AND DISCUSSION

The human serum albumin concentration was varied from 0.87×10^{-4} to 0.87×10^{-3} *M* (6–60 mg/ml.). Two concentrations of each ligand were used, in the general range of the concentrations used previously (1). The Scatchard plots obtained are shown in Fig. 1. All plots had positive slopes, and the curves were linear (Table I), as can be seen from the coefficients of correlation. In all four cases, a higher slope was obtained with the lower concentration, and higher Nubar (moles of ligand bound per mole of protein in the system) values were seen with the higher concentration.

In the experiments where the protein concentration was kept constant and the ligand concentration was varied, β (fraction bound) values increased with a decrease in ligand concentration (1). In the results obtained in this study, β increased as the albumin concentration increased (Fig. 2). The differences in the plots of β *versus* albumin concentration were not great for the two ligand concentrations. This result is not unexpected when ligand concentrations are not near those required to saturate the protein binding sites. The higher the protein concentration, the more binding sites are available; thus β is expected to increase. For a given ligand, the ratio of the slopes for the two concentrations never exceeded 2.1 (Table II).

Since β varied with albumin concentration for a given ligand, the extent of change of β with a change in albumin concentration was of interest. The rate of change [$d(\beta)/d$(albumin)] was calculated by fitting β values and corresponding albumin concentrations to curves by computer and calculating the first derivative for each albumin concentration for the curve giving the best statistically significant fit (coefficient of correlation of ≥0.95). Plots of these derivatives *versus* albumin concentration are presented in Fig. 3.

The rate of change of β per change in albumin concentration was not constant for all albumin concentrations; it was higher at low albumin concentrations and decreased as the albumin concentration reached that normally found in human blood. Thus, the curves consisted of two major

	5.36×10^{-3}	44.53	0.968	−93,100	−0.946

[a] The n parameter refers to the number of binding sites on the protein molecule, and K is the association constant for the binding system. [b] The r value is the coefficient of correlation for the best fit of the data points to a straight line. The slope given is that calculated for the best-fit straight line.

Table III—Comparison of Slopes of Major Sections of Curves Obtained by Plotting $d(\beta)/d$(Albumin) *versus* Albumin Concentration

Ligand	Concentration of Ligand, M	Slope of Curve Segment[a]		Slope A/Slope B
		A	B	
Amphetamine	3.69×10^{-3}	−1,028,000	−136,100	7.55
	1.48×10^{-2}	−693,000	−114,400	6.06
Atropine	4.5×10^{-4}	−1,780,000	−214,300	8.31
	3.43×10^{-3}	−1,600,000	−249,000	6.43
Epinephrine	1.14×10^{-5}	−4,930,000	−294,000	16.77
	4.56×10^{-5}	−11,960,000	−368,100	32.50
Histamine	1.15×10^{-3}	−253,100	−67,160	3.77
	5.36×10^{-3}	53.54	53.54	1.00[b]

[a] The slope for Segment A was that of the straight line fitted to the three left-hand points of the curve; for Segment B, it was that of the straight line fitted to the three right-hand points. [b] The plot of β *versus* albumin concentration (molar) was a straight line, and $d(\beta)/d$(albumin) was taken as its slope.

segments, one at lower albumin concentrations and the other at higher albumin concentrations. Slopes for the two segments were calculated, and the ratios of the two slopes were computed as a representation of the differences in different albumin concentration ranges (Table III). It appears that β changes the least in the albumin concentration range usually found in human blood. The albumin concentration ranges in which β changes greatly are not encountered clinically.

In several previous studies (7), an increase in protein concentration was accompanied by a decrease in nK[2]. The nK values were calculated using an equation that permits calculation of nK values from β and protein concentrations (9). Plots of nK *versus* albumin concentration are given in Fig. 4. For all four ligands studied, an increase in albumin concentration apparently was accompanied by a decrease in nK. The slopes of these curves are given in Table II; while there were differences in the slopes for the two concentrations of each ligand, these differences were not great (ratios of <2.0), suggesting that the relationship between nK and albumin concentration was essentially independent of ligand concentration for the two ligand concentrations used.

For these four ligands, Scatchard plots with positive slopes were obtained both when the protein concentration was kept constant and the liquid concentration was varied and when the ligand concentration was kept constant and the protein concentration was varied. According to Bowmer and Lindup (7), this result suggests that the positive Scatchard plots may be explained by cooperativity. It also appears that for the compounds examined, the change in β with respect to change in albumin concentration is minor for the albumin concentrations encountered clinically. This finding suggests that β should be similar in normal individuals and those with mild hypoalbuminemia.

[2] The parameter n refers to the number of binding sites or systems on the protein molecule, and the K parameter is the association constant for the protein-ligand system.

Abstract □ Three ketophosphonium salts containing a morpholino group were prepared and evaluated for their neuromuscular blocking effect. Solution and crystal conformations were studied. An attempt was made to explain, in structural terms, different activity levels in connection with the interatomic distances.

Keyphrases □ Ketophosphonium salts—synthesis, relationship between neuromuscular blocking activity and interatomic distances □ Structure–activity relationships—ketophosphonium salts, relationship between neuromuscular blocking activity and interatomic distances □ Neuromuscular blocking activity—ketophosphonium salts, relationship between activity and interatomic distances

The striking relationship between neuromuscular blocking potency and chain length (1–3) or spatial configuration (4–6) in a series of bis-onium salts has been recognized. Replacement of the ammonium moiety by sulfonium, arsonium, or stilbonium has been studied, but the change of one of the two electropositive sites for a phosphonium group has not been well documented (7, 8).

To determine whether it could alter such activity, a triphenylphosphonium salt was introduced on an aliphatic chain with two polar groups. These derivatives exhibit a blocking effect, and the geometric characteristics of the molecules in the crystalline state and in solution were studied to correlate their structure with their biological activity. Their conformations were studied by PMR in solution and by X-ray diffraction in the solid state, enabling evaluation of the distance between the two cations.

EXPERIMENTAL

Methods—Melting points were determined in open glass capillaries and are uncorrected. IR[1] spectra were taken on a double-beam spectrophotometer, utilizing a potassium bromide pellet for solid samples and sodium chloride windows for liquids. PMR[2] spectra were recorded on a 60-MHz instrument. Accurate cell parameters were determined on an automatic diffractometer[3] using Mo K_α radiation. Intensity data also were collected on this instrument.

The structures were solved by direct methods using the Multan program (9). The atoms were normally located by direct and difference Fourier maps, except for some hydrogen atoms. The functional analysis was carried out with the determination of the mean planes and intramolecular distances. Analytical results[4] for the elements were within ±0.4% of theoretical values.

Syntheses—*4-Morpholino-2-butanone (I)*—Concentrated hydrochloric acid (50 ml, 0.5 mole) was added dropwise to a stirred suspension of *s*-trioxane (22.2 g, 0.75 mole) in a cold mixture (5°) of morpholine (43.5 g, 0.5 mole), acetone (200 ml, 2.7 moles), and methanol (30 ml). The mixture was refluxed for 12 hr, cooled, and evaporated to dryness *in vacuo*. A solution of the residue in water (50 ml) was made slightly basic with 10% NaOH and extracted with ether; the combined ethereal solutions were dried over sodium sulfate, evaporated, and distilled under reduced pressure to give 63 g (83% yield) of a colorless liquid, bp 68–74° (0.01 mm).

1-Bromo-4-morpholino-2-butanone Hydrobromide (II)—A solution of bromine (5.1 ml, 0.1 mole) in acetic acid (6 ml) was added dropwise at room temperature to a solution of I (15.7 g, 0.1 mole) in a mixture of hydrobromic acid (20 ml, 0.3 mole) and acetic acid (25 ml). The resulting solution was heated at 40° for 2 hr and then evaporated; crystallization occurred after trituration of the pasty residue with ethanol. Recrystallization from ethanol gave 23.8 g (75% yield) of II, mp 179°.

Anal.—Calc. for $C_8H_{15}Br_2NO_2$: C, 30.31; H, 4.77; N, 4.42. Found: C, 30.39; H, 4.73; N, 4.44.

(2-Oxo-4-morpholino)butyltriphenylphosphonium Bromide Hydrobromide (III)—A mixture of 31.7 g (0.1 mole) of II and 26.2 g (0.1 mole) of triphenylphosphine in 100 ml of anhydrous chloroform was heated to reflux for 12 hr under nitrogen. The solvent was evaporated, and the residue was triturated with an anhydrous ethanol–ether mixture. The resulting solid was recrystallized from ethanol to give 37 g (65% yield) of III, mp 209°.

Anal.—Calc. for $C_{26}H_{30}Br_2NO_2P$: C, 53.91; H, 5.22; N, 2.42. Found: C, 53.61; H, 5.21; N, 2.59.

(2-Oxo-3-chloro)propyltriphenylphosphonium Chloride (IV)—A mixture of 1,3-dichloroacetone (2.5 g, 0.02 mole) and triphenylphosphine (5.2 g, 0.02 mole) in benzene was heated under reflux for 2 hr. The precipitate was collected and crystallized from 95% ethanol to yield 6.9 g (85% yield) of IV·H_2O, mp 173°.

Anal.—Calc. for $C_{21}H_{19}Cl_2OP \cdot H_2O$: C, 61.93; H, 5.20. Found: C, 62.04; H, 5.25.

(2-Oxo-3-morpholino)propyltriphenylphosphonium Chloride Hydrochloride (V)—To a solution of IV (4.1 g, 0.01 mole) and morpholine hydrochloride (1.2 g, 0.01 mole) was added sodium (0.7 g, 0.03 mole) in ethanol. The reaction mixture was refluxed for 3 hr. Sodium chloride was filtered, and ethanolic hydrochloric acid was added to the filtrate. After evaporation of the solvent, the crude product was recrystallized from ethanol to yield 3.5 g (74% yield) of V, mp 165°.

Anal.—Calc. for $C_{25}H_{28}Cl_2NO_2P$: C, 63.03; H, 5.92; N, 2.94. Found: C, 62.92; H, 5.80; N, 2.87.

N-(Chloroacetyl)morpholine (VI) (10)—To a cold solution (−10°) containing 13 g (0.15 mole) of morpholine in a mixture of ethylene dichloride (50 ml) and 20% NaOH (20 ml) was added dropwise 11.3 g (0.1 mole) of chloroacetyl chloride. After stirring at 20° for 1 hr, the reaction mixture was left at 5° overnight. The organic layer was separated, and the aqueous phase was extracted with ethylene dichloride. The organic extracts were washed (10% HCl, 5% $NaHCO_3$, and water), dried (sodium

sulfate), and concentrated *in vacuo*. Distillation afforded 12 g (73% yield) of VI, bp 106° (0.01 mm).

(2-Oxo-2-morpholino)ethyltriphenylphosphonium Chloride (VII)—A solution of 16.3 g (0.1 mole) of VI and 26.2 g (0.1 mole) of triphenylphosphine in dry benzene (50 ml) was refluxed for 5 hr under nitrogen. The hot mixture was filtered, and the precipitate was washed with anhydrous ether. Recrystallization from isopropanol yielded 30.6 g (72% yield) of VII, mp 225°; IR (KBr): 1630 (C=O) cm^{-1}; PMR (acetonitrile-d_3): δ 3.47 (m, 4H, CH_2NCH_2), 3.72 (s, 4H, CH_2OCH_2), 5.71 (d, 2H, P^+CH_2, $J_{P,H}$ = 13 Hz), and 7.73 (m, 15H, phenyl).

(2-Oxo-4-morpholino)butyltriphenylphosphorane (IIIc)—A 10% K_2CO_3 solution (25 ml, 0.017 mole) was added slowly to III (5.8 g, 0.01 mole) dissolved in a minimum of water in a nitrogen atmosphere at 20°. The crude precipitate was filtered after 2 hr and recrystallized from ethyl acetate to afford 3.7 g (88% yield) of IIIc, mp 135°.

Anal.—Calc. for $C_{26}H_{28}NO_2P$: C, 74.81; H, 6.76; N, 3.36. Found: C, 74.70; H, 6.60; N, 3.29.

Pharmacology—*Neuromuscular Blocking Potency*—The gastrocnemius muscle-sciatic nerve preparation was obtained from anesthetized rats (average weight 350 g) by intravenous injection of 0.4 ml of 6% pentobarbital sodium[5]. Contractions were produced by stimulating the nerve within the muscle at a frequency of 1 Hz with rectangular pulses of 1 msec in duration and 30 mv in amplitude and were recorded together with the arterial blood pressure. Animals were placed under artificial respiration.

Tested drugs were compared with gallamine triethiodide[6], with the effects being considered equal when a test concentration produced a 50% inhibition of the action potential (ED_{50}).

LD_{50} Determination—The acute, single-dose toxicity of III, V, and VII in mice following intraperitoneal administration is shown in Table I in terms of the quantitative lethal potency determined by the Miller and Tainter method (11).

RESULTS

Chemistry and Spectral Studies—Schemes I–III illustrate the syntheses of the phosphonium salts. 4-Morpholino-2-butanone (I) was prepared from acetone *via* the Mannich reaction as described previously (12). The corresponding 1-bromo derivative (the hydrobromide salt, II) subsequently was obtained in a good yield from the acetic acid-catalyzed

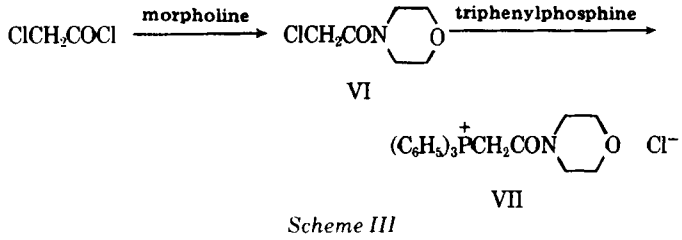

Scheme III

bromination. Direct substitution of II with 1 equivalent of triphenylphosphine in anhydrous chloroform under an inert atmosphere yielded the phosphonium salt (III).

Preparation of (2-oxo-3-morpholino)propyltriphenylphosphonium chloride hydrochloride (V) was achieved by reacting 1,3-dichloroacetone with triphenylphosphine, yielding IV, which then was converted into V with morpholine. Treatment of chloroacetyl chloride with morpholine afforded the amide (VI), and further condensation with triphenylphosphine gave (2-oxo-2-morpholino)ethyltriphenylphosphonium chloride (VII).

The structures of V and VII in the solid state as well as in solution require no special discussion; examination of the X-ray diffraction data and the NMR spectra confirmed the observations revealed by IR spectroscopy, which evidenced their ketonic and amide functions, respectively.

Compound III demands more precise investigation. An X-ray diffraction analysis (Figs. 1 and 2) indicated that the molecule shows an expanded position, probably due to better, stronger packing. Phosphonium and ketone groups are *gauche* with respect to the C_1–C_2 bond, and the C=O does not deviate far from the P–C_1–C_2 plane. The electronic perturbations found here and, in particular, the effect of an α-carbonyl group on the length of the P–C_1 bond confirm previous studies about alkyltriphenylphosphonium salts (13–27). Moreover, the presence of a morpholinyl nitrogen, protonated or not, is apt to bring modifications in the geometry of the PC_1C_2O moiety and to induce a preferential conformation for III in solution. Evidence that III is a mixture of the keto and enol species (Scheme IV) with predominance of the former is given by the presence in the IR spectrum (Table II) of two absorptions at 1720 and 1615 cm^{-1}, the latter being assigned to the C=C stretching of an enolic function. The establishment of the III⇌IIIa equilibrium is confirmed further by the PMR spectral data, which, when obtained in a chloroform medium, included a singlet at a lower field attributable to the hydroxyl hydrogen.

Because the structure of IIIa may give rise to possible *cis–trans* isomers (22), the related phosphorane (IIIc), which presents the same particu-

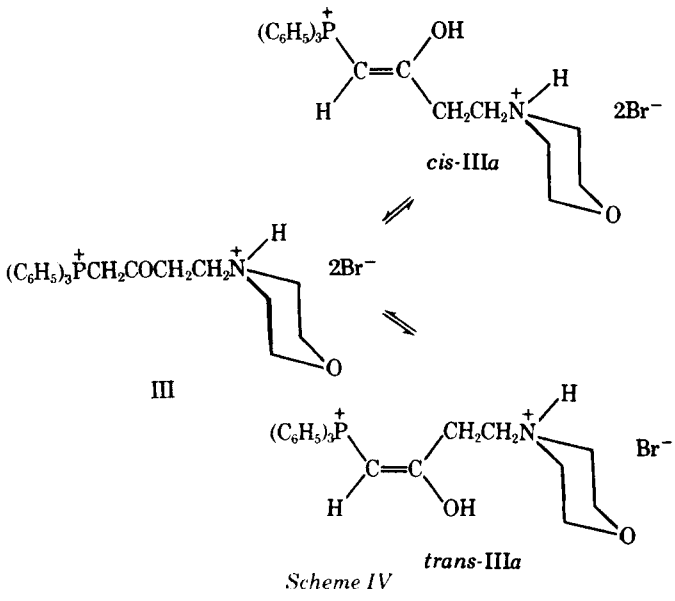

Scheme IV

larity, was studied; its geometry is easier to establish and allows the determination of the respective positions of phosphorus and oxygen in the parent compound (III*a*).

The phosphorane (III*c*) was obtained by addition of a basic reagent in a calculated amount. A first dehydrohalogenation led to the phosphonium bromide (III*b*), whose enolic form is stabilized by hydrogen bonding; its stereochemistry cannot be ascertained from routine experiments. However, further dehydrohalogenation gave the phosphorane (III*c*), and IR data (28–36) revealed the presence of only one rotation isomer (*cis*-III*c*) with the cyclic enolic structure strongly favored by the P^+O^- interaction and by the H···N hydrogen bonding (Scheme V). This latter bonding (37) is confirmed by the dihedral angle ($0 < \alpha < 30°$) determined from $^3J_{b,c}$ = 6 Hz (38–40). Furthermore, the rotation about the C_1–C_2 double bond was observed by NMR at 48° in chloroform, but this phenomenon did not occur up to 150° in dimethyl sulfoxide.

The *cis*-structure of III*c* suggests that its precursor (III*a*) presents the

same configuration in solution and thereby renders the *gauche*-conformation more likely (at the dihedral PC_1C_2O site) for the corresponding ketonic form (III) in solution, as proved by X-ray diffraction (Figs. 1 and 2 and Table III).

Biological Testing—The neuromuscular blocking potencies were tested on the gastrocnemius muscle–sciatic nerve preparation of the anesthetized rat and compared with effects of gallamine triethiodide. The results in Table I are expressed in terms of variations in the amplitude of the action potential. Arterial blood pressure and the frequency of respiration also were recorded. A significant blood pressure decrease was concomitant with the respiratory arrest. Under further artificial respiration, the arterial blood pressure increased to normal values.

DISCUSSION

The levels of neuromuscular blocking activity of the three compounds were not directly related to the P···N distance. The correlation between the curare-like potency and the relative dispositions of the onium groups in bis-onium derivatives has been questioned (41–44). It appears that the activity of some pentamethonium iodides (41) or hexa- and decamethonium bromides (42) may arise from the number of van der Waals contacts between the extreme methyl groups and the receptor sites. In addition, it has been postulated that the ether linkages of the tubocurarines are involved in the interaction with the receptor (43, 45–47).

Similarly, for III, V, and VII, the electronic interaction of the phosphonium cation and the formation of hydrogen bonding between the oxygen atom of the morpholine group and the receptor site can be suggested. Thus, the observed P···O distance for the more potent VII is 6.8 Å, in accordance with the known value found for the cholinergic receptors (48–50).

General Method for Calculation of Hydrogen-Ion Concentration in Multicomponent Acid–Base Mixtures

D. A. VENTURA and H. Y. ANDO ˣ

Received November 29, 1978, from the *Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.* Accepted for publication March 6, 1980.

Abstract □ A generalized method for the rapid evaluation of complicated ionic equilibria in terms of the hydrogen-ion concentration was developed. The method was based on the derivation of a single general equation that could be used to evaluate any mixture. A tableau method also was developed which allowed calculation of the numerical solution to the general equation without computer analysis or graphical or intuitive approximations. Examples illustrating the utility of the method are presented. These examples include a mixture of barbital, citric acid, boric acid, monobasic sodium phosphate, and sodium hydroxide. Calculated hydrogen-ion concentrations showed good agreement with experimental values for simple and complex solutions. The major advantages of the method are its simplicity and the obtainment of numerical solutions without initial approximations in the calculations. However, activity corrections are not included in the calculations.

Keyphrases □ Hydrogen-ion concentration—general calculation method for multicomponent acid–base mixtures, calculated results compared with experimental results □ Model, mathematical—calculation of hydrogen-ion concentration in multicomponent acid–base mixtures, comparison with experimental results □ Acid–base mixtures—calculation of hydrogen-ion concentration in multicomponent acid–base mixtures, comparison with experimental results

The calculation of pH values for multicomponent mixtures of weak acids and bases, strong acids and bases, and ampholytes often requires solving a formidable set of simultaneous equations. Although intuitive reasoning may lead to simplifications, it also may lead to erroneous results (1). Although graphical procedures (2) have shown didactic and practical utility, they can become complex and the evaluation may be difficult.

A general method for rapid evaluation of complicated equilibria in terms of the hydrogen-ion concentration is

General Method for Calculation of Hydrogen-Ion Concentration in Multicomponent Acid–Base Mixtures

D. A. VENTURA and H. Y. ANDO ˣ

Received November 29, 1978, from the *Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.* Accepted for publication March 6, 1980.

Abstract □ A generalized method for the rapid evaluation of complicated ionic equilibria in terms of the hydrogen-ion concentration was developed. The method was based on the derivation of a single general equation that could be used to evaluate any mixture. A tableau method also was developed which allowed calculation of the numerical solution to the general equation without computer analysis or graphical or intuitive approximations. Examples illustrating the utility of the method are presented. These examples include a mixture of barbital, citric acid, boric acid, monobasic sodium phosphate, and sodium hydroxide. Calculated hydrogen-ion concentrations showed good agreement with experimental values for simple and complex solutions. The major advantages of the method are its simplicity and the obtainment of numerical solutions without initial approximations in the calculations. However, activity corrections are not included in the calculations.

Keyphrases □ Hydrogen-ion concentration—general calculation method for multicomponent acid–base mixtures, calculated results compared with experimental results □ Model, mathematical—calculation of hydrogen-ion concentration in multicomponent acid–base mixtures, comparison with experimental results □ Acid–base mixtures—calculation of hydrogen-ion concentration in multicomponent acid–base mixtures, comparison with experimental results

The calculation of pH values for multicomponent mixtures of weak acids and bases, strong acids and bases, and ampholytes often requires solving a formidable set of simultaneous equations. Although intuitive reasoning may lead to simplifications, it also may lead to erroneous results (1). Although graphical procedures (2) have shown didactic and practical utility, they can become complex and the evaluation may be difficult.

A general method for rapid evaluation of complicated equilibria in terms of the hydrogen-ion concentration is

described in this paper. A tableau method for the numerical solution also is described. This method eliminates the need for computer analysis.

Activity coefficients were omitted in the following sections to simplify the treatment of the equilibria presented. These corrections may be needed in many pharmaceutical situations.

THEORETICAL

Mixture of Weak Polybasic Acids—Let the mixture contain a concentration TP of a weak polyprotic acid ($H_\alpha P$) with α dissociable hydrogen ions and a concentration TQ of a weak polyprotic acid ($H_\beta Q$) with β dissociable hydrogen ions. The equilibrium expressions for $H_\alpha P$ are:

$$H_\alpha P \overset{KP_1}{\rightleftharpoons} H_{\alpha-1}P^{-1} + H^+$$
Scheme I

$$H_{\alpha-1}P^{-1} \overset{KP_2}{\rightleftharpoons} H_{\alpha-2}P^{-2} + H^+$$
Scheme II

$$\vdots \qquad \vdots$$

$$H_1P^{-(\alpha-1)} \overset{KP_\alpha}{\rightleftharpoons} P^{-\alpha} + H^+$$
Scheme III

and for $H_\beta Q$ are:

$$H_\beta Q \overset{KQ_1}{\rightleftharpoons} H_{\beta-1}Q^{-1} + H^+$$
Scheme IV

$$H_{\beta-1}Q^{-1} \overset{KQ_2}{\rightleftharpoons} H_{\beta-2}Q^{-2} + H^+$$
Scheme V

$$\vdots \qquad \vdots$$

$$H_1Q^{-(\beta-1)} \overset{KQ_\beta}{\rightleftharpoons} Q^{-\beta} + H^+$$
Scheme VI

Let:

$$P_0 = H_\alpha P \qquad \text{(Eq. 1)}$$

$$P_1 = H_{\alpha-1}P^{-1} \qquad \text{(Eq. 2)}$$

$$\vdots \qquad \vdots$$

$$P_\alpha = P^{-\alpha} \qquad \text{(Eq. 3)}$$

and:

$$Q_0 = H_\beta Q \qquad \text{(Eq. 4)}$$

$$Q_1 = H_{\beta-1}Q^{-1} \qquad \text{(Eq. 5)}$$

$$\vdots \qquad \vdots$$

$$Q_\beta = Q^{-\beta} \qquad \text{(Eq. 6)}$$

The individual species for each acid can be expressed as functions of P_0 or Q_0, the respective ionization constants, and the hydrogen-ion concentration. By using Schemes I–VI and Eqs. 1–6, the following equations can be derived:

$$P_0 = P_0 \qquad \text{(Eq. 7)}$$

$$P_1 = KP_1H^{-1}P_0 \qquad \text{(Eq. 8)}$$

$$P_2 = KP_1KP_2H^{-2}P_0 \qquad \text{(Eq. 9)}$$

$$\vdots \qquad \vdots$$

$$P_\alpha = KP_1KP_2 \ldots KP_\alpha H^{-\alpha}P_0 \qquad \text{(Eq. 10)}$$

and:

$$Q_0 = Q_0 \qquad \text{(Eq. 11)}$$

$$Q_1 = KQ_1H^{-1}Q_0 \qquad \text{(Eq. 12)}$$

$$Q_2 = KQ_1KQ_2H^{-2}Q_0 \qquad \text{(Eq. 13)}$$

$$\vdots \qquad \vdots$$

$$Q_\beta = KQ_1KQ_2 \ldots KQ_\beta H^{-\beta}Q_0 \qquad \text{(Eq. 14)}$$

Note that $H^{-1} = 1/H$. Let the charge balance be expressed as:

$$D = \sum_{p=0}^{\alpha} pP_p + \sum_{q=0}^{\beta} qQ_q \qquad \text{(Eq. 15a)}$$

where (1):

$$D = H - OH = H - \frac{K_w}{H} \qquad \text{(Eq. 15b)}$$

Let the mass balance for each acid be expressed as:

$$TP = \sum_{p=0}^{\alpha} P_p \qquad \text{(Eq. 16)}$$

and:

$$TQ = \sum_{q=0}^{\beta} Q_q \qquad \text{(Eq. 17)}$$

Equations 7–10 and Eqs. 11–14, respectively, can be written in general form as:

$$P_p = \prod_{\pi=0}^{p} KP_\pi H^{-p}P_0 \qquad \text{(Eq. 18)}$$

and:

$$Q_q = \prod_{\pi=0}^{q} KQ_\pi H^{-q}Q_0 \qquad \text{(Eq. 19)}$$

where $KP_0 = KQ_0 = 1$.

Substitution of Eq. 18 into Eq. 16 and of Eq. 19 into Eq. 17 yields, respectively:

$$TP = \sum_{p=0}^{\alpha} \prod_{\pi=0}^{p} KP_\pi H^{-p}P_0 \qquad \text{(Eq. 20)}$$

and:

$$TQ = \sum_{q=0}^{\beta} \prod_{\pi=0}^{q} KQ_\pi H^{-q}Q_0 \qquad \text{(Eq. 21)}$$

Rearrangement of Eqs. 20 and 21 yields, respectively:

$$P_0 = \frac{TP}{\sum_{p=0}^{\alpha} \prod_{\pi=0}^{p} KP_\pi H^{-p}} \qquad \text{(Eq. 22)}$$

and:

$$Q_0 = \frac{TQ}{\sum_{q=0}^{\beta} \prod_{\pi=0}^{q} KQ_\pi H^{-q}} \qquad \text{(Eq. 23)}$$

Substitution of Eq. 22 into Eq. 18 and of Eq. 23 into Eq. 19 yields, respectively:

$$P_p = \frac{\prod_{\pi=0}^{p} KP_\pi H^{-p}TP}{\sum_{p=0}^{\alpha} \prod_{\pi=0}^{p} KP_\pi H^{-p}} \qquad \text{(Eq. 24)}$$

and:

$$Q_q = \frac{\prod_{\pi=0}^{q} KQ_\pi H^{-q}TQ}{\sum_{q=0}^{\beta} \prod_{\pi=0}^{q} KP_\pi H^{-q}} \qquad \text{(Eq. 25)}$$

Substitution of Eqs. 24 and 25 into Eq. 15a yields:

$$D = \frac{\sum_{p=0}^{\alpha} p \prod_{\pi=0}^{p} KP_\pi H^{-p}TP}{\sum_{p=0}^{\alpha} \prod_{\pi=0}^{p} KP_\pi H^{-p}} + \frac{\sum_{q=0}^{\beta} q \prod_{\pi=0}^{q} KQ_\pi H^{-q}TQ}{\sum_{q=0}^{\beta} \prod_{\pi=0}^{q} KQ_\pi H^{-q}} \qquad \text{(Eq. 26)}$$

Rearrangement of Eq. 26 followed by multiplication by $H^{(\alpha+\beta)}$ yields:

$$D \sum_{p=0}^{\alpha} \sum_{q=0}^{\beta} \prod_{\pi=0}^{p} KP_\pi \prod_{\pi=0}^{q} KQ_\pi H^{(\alpha+\beta-p-q)} = \sum_{p=0}^{\alpha} \sum_{q=0}^{\beta} \prod_{\pi=0}^{p} KP_\pi \prod_{\pi=0}^{q} KQ_\pi H^{(\alpha+\beta-p-q)}pTP + \sum_{p=0}^{\alpha} \sum_{q=0}^{\beta} \prod_{\pi=0}^{p} KP_\pi \prod_{\pi=0}^{q} KQ_\pi H^{(\alpha+\beta-p-q)}qTQ \qquad \text{(Eq. 27)}$$

Define tensors:

$$H_{pq} = H^{(\alpha+\beta-p-q)} \quad \text{(Eq. 28)}$$

and:

$$K_{pq} = \prod_{\pi=0}^{p} KP_\pi \prod_{\pi=0}^{q} KQ_\pi \quad \text{(Eq. 29)}$$

Substitution of Eqs. 28 and 29 into Eq. 27 yields:

$$D \sum_{p=0}^{\alpha} \sum_{q=0}^{\beta} K_{pq}H_{pq} = \sum_{p=0}^{\alpha} \sum_{q=0}^{\beta} K_{pq}H_{pq}pTP + \sum_{p=0}^{\alpha} \sum_{q=0}^{\beta} K_{pq}H_{pq}qTQ \quad \text{(Eq. 30)}$$

Equation 30 can be simplified by noting that the indexes p and q are repeated in the multiplication of the tensors K_{pq} and H_{pq}. Following the convention proposed by Jeffreys (3), the summation signs will be omitted and the summation will be implied (the indexes are given all possible values of p and q and the terms are added). Equation 30 can be written using this convention as:

$$DK_{pq}H_{pq} = K_{p'q}H_{pq}TP + K_{pq'}H_{pq}TQ \quad \text{(Eq. 31)}$$

where $K_{p'q} = K_{pq}p$ and $K_{pq'} = K_{pq}q$.

The derivation of Eq. 31 can be extended to yield an equation for any number of acids. The resulting equation is:

$$DK_{pq\ldots z}H_{pq\ldots z} = K_{p'q\ldots z}H_{pq\ldots z}TP + K_{pq'\ldots z}H_{pq\ldots z}TQ + K_{pq\ldots z'}H_{pq\ldots z}TZ \quad \text{(Eq. 32)}$$

Mixture of Weak Polyacidic Bases—Let a mixture contain a concentration TR of a weak polyacidic base ($H_\gamma^{+\gamma}R$) with γ ionizations and a concentration TS of a weak polyacidic base ($H_\delta^{+\delta}S$) with δ ionizations. The equilibrium expressions for the bases are:

$$H_\gamma^{+\gamma}R \overset{KR_1}{\rightleftharpoons} H_{\gamma-1}^{+(\gamma-1)}R + H^+$$

Scheme VII

$$H_{\gamma-1}^{+(\gamma-1)}R \overset{KR_2}{\rightleftharpoons} H_{\gamma-2}^{+(\gamma-2)}R + H^+$$

Scheme VIII

$$\vdots \qquad \vdots$$

$$H^+R \overset{KR_\gamma}{\rightleftharpoons} R + H^+$$

Scheme IX

For $H_\delta^{+\delta}S$, they are:

$$H_\delta^{+\delta}S \overset{KS_1}{\rightleftharpoons} H_{\delta-1}^{+(\delta-1)}S + H^+$$

Scheme X

$$H_{\delta-1}^{+(\delta-1)}S \overset{KS_2}{\rightleftharpoons} H_{\delta-2}^{+(\delta-2)}S + H^+$$

Scheme XI

$$\vdots \qquad \vdots$$

$$H^+S \overset{KS_\delta}{\rightleftharpoons} S + H^+$$

Scheme XII

Let:

$$R_0 = H_\gamma^{+\gamma}R \quad \text{(Eq. 33)}$$

$$R_1 = H_{\gamma-1}^{+(\gamma-1)}R \quad \text{(Eq. 34)}$$

$$\vdots \qquad \vdots$$

$$R_\gamma = R \quad \text{(Eq. 35)}$$

and:

$$S_0 = H_\delta^{+\delta}S \quad \text{(Eq. 36)}$$

$$S_1 = H_{\delta-1}^{+(\delta-1)}S \quad \text{(Eq. 37)}$$

$$\vdots \qquad \vdots$$

$$S_\delta = S \quad \text{(Eq. 38)}$$

Let the charge balance be expressed as:

$$D = \sum_{r=0}^{\gamma} (r - NR)R_r + \sum_{s=0}^{\delta} (s - NS)S_s \quad \text{(Eq. 39)}$$

where NR is the number of cationic species possible from the protonation of the neutral base R and NS is the number of cationic species possible from the protonation of the neutral base S.

Let the mass balance equations be expressed as:

$$TR = \sum_{r=0}^{\gamma} R_r \quad \text{(Eq. 40)}$$

and:

$$TS = \sum_{s=0}^{\delta} S_s \quad \text{(Eq. 41)}$$

The individual species for each base can be expressed as a general equation as were the acids in the previous section. The equations for the bases are:

$$R_r = \prod_{\pi=0}^{r} KR_\pi H^{-r}R_0 \quad \text{(Eq. 42)}$$

and:

$$S_s = \prod_{\pi=0}^{s} KS_\pi H^{-s}S_0 \quad \text{(Eq. 43)}$$

A general equation for a system of two polyacidic bases can be derived in a manner analogous to Eq. 31 for the system of two polybasic acids. The equation thus derived is:

$$DK_{rs}H_{rs} = K_{r's}H_{rs}TR + K_{rs'}H_{rs}TS \quad \text{(Eq. 44}a\text{)}$$

where $K_{r's} = K_{rs}(r - NR)$ and $K_{r's} = K_{rs}(s - NS)$.

The derivation of Eq. 44*a* can be extended to a system of any number of bases analogous to the extension of Eq. 31 to Eq. 32. The general equation for any number of polyacidic bases is:

$$DK_{rs\ldots z}H_{rs\ldots z} = K_{r's\ldots z}H_{rs\ldots z}TR + K_{rs'\ldots z}H_{rs\ldots z}TS + \ldots K_{rs\ldots z'}H_{rs\ldots z}TZ \quad \text{(Eq. 44}b\text{)}$$

Mixture of Weak Acids, Weak Bases, Ampholytes, Salts, and Strong Bases—Inspection of Eqs. 31 and 44*a* reveals a mathematical similarity. If an NP term and an NQ term had been defined for the acids, as NR and NS were defined for the bases, then the equations would have been mathematically identical (NP and NQ would have been zero since no cationic species of the acids were formed). Therefore, Eq. 44*a* can be applied to mixtures of acids, mixtures of bases, and mixtures of acids and bases.

Equation 44*a* also is applicable to ampholytes, but caution must be exercised in the determination of the number of cationic species possible.

Salts can be considered as mixtures of acids and bases. Therefore, Eq. 44*a* is applicable to solutions formed from salts. Mathematically, the solution is considered to be formed from a stoichiometric mixture of the acid and base components of the salt.

The addition of a strong acid and/or strong base to any mixture requires modification of the charge balance. Let SB_t denote the total concentration of strong base and SA_t denote the the total concentration of strong acid. If one component of a salt is a strong acid or base, then its concentration must be added to the SA_t or SB_t term, respectively.

Example 1: Ammonium Acetate—This salt is treated as an equimolar mixture of ammonia (TP) and acetic acid (TQ): $TP = TQ$, $NP = 1$, and $NQ = 0$.

Example 2: Sodium Acetate—This salt is treated as an equimolar mixture of acetic acid (TP) and sodium hydroxide (SB_p): $TP = SB_t$, $NP = 0$, and $SB_t = SB_p$.

Example 3: Sodium Carbonate—This salt is treated as a mixture of sodium hydroxide (SB_p) and carbonic acid (TP): $2TP = SB_p$, $NP = 0$, $SB_t = SB_p$.

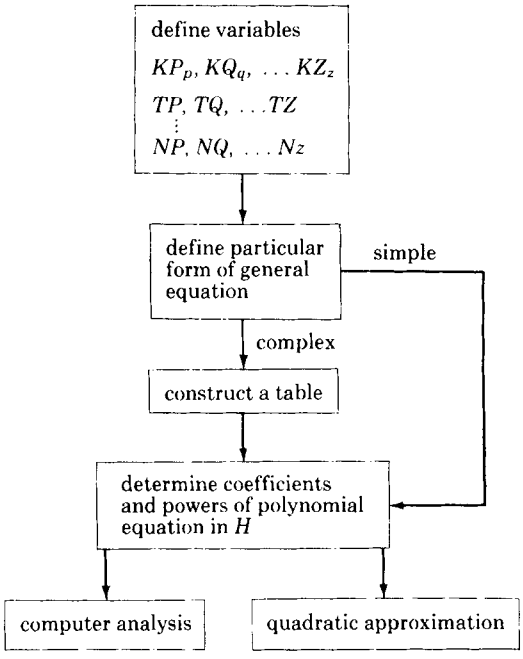
Example 4: Sodium Carbonate and Sodium Hydroxide—This solution is treated as a mixture of carbonic acid (TP) and sodium hydroxide as in Example 3; however, the additional sodium hydroxide is added to the SB_t term: $2TP = SB_p$, $NP = 0$, and $SB_t = SB_p + SB$.

Therefore, Eq. 44*b* can be extended to mixtures of weak acids, weak bases, ampholytes, salts, strong acids, strong bases, and all of their combinations. The general equation (derived analogously to Eq. 44*b*) is:

$$(SB_t - SA_t + D)K_{pq\ldots z}H_{pq\ldots z} = K_{p'q\ldots z}H_{pq\ldots z}TP + K_{pq'\ldots z}H_{pq\ldots z}TQ + K_{pq\ldots z'}H_{pq\ldots z}TZ \quad \text{(Eq. 44}c\text{)}$$

GENERAL METHOD AND APPLICATION

The substitution of known values into Eq. 44*b* for a particular mixture followed by rearrangement and collection of terms in H results in a



Scheme XIII

polynomial in H. The determination of the coefficients and the order of the polynomial can be facilitated by constructing a table for the systematic enumeration of: (*a*) all possible values of the subscripts of the tensor $K_{pq\ldots z}$, (*b*) the powers of the polynomial in H that correspond to the subscripts, (*c*) the values of the components of $K_{pq\ldots q'}$, and (*d*) the stoichiometric factors for each component.

The table also allows a numerical comparison of the contribution of each term to a particular coefficient. This comparison permits omission of insignificant terms. The advantage of this method increases with the complexity of the mixture.

The final polynomial in H obtained from the table can be solved by numerous numerical computer techniques. However, a quadratic approximation of the polynomial also can be used (1), eliminating the need of a computer.

The general procedure to calculate the hydrogen-ion concentration of a complex system is illustrated in Scheme XIII. A step-by-step approach of the general procedure with specific application to a simple and a complex mixture follows.

Consider the calculation of the hydrogen-ion concentration in a solution of 0.09 M $NaHCO_3$ and 0.01 M Na_2CO_3:

1. The number of actual components is specified. This particular mixture contains two, carbonic acid and sodium hydroxide (refer to previous section).

2. The ionization constants for each component (excluding strong acids and strong bases) are defined. The total number of ionizations for each component also is defined ($\alpha, \beta, \ldots \omega$). The values for this example are: $KP_1 = 4.20E\text{-}07$ for the equilibrium shown in Scheme XIV and $KP_2 = 4.80E\text{-}11$ for the equilibrium shown in Scheme XV, with $\alpha = 2$.

$$H_2CO_3 \overset{KP_1}{\rightleftharpoons} HCO_3^{-1} + H^+$$

Scheme XIV

$$HCO_3^{-1} \overset{KP_2}{\rightleftharpoons} CO_3^{-2} + H^+$$

Scheme XV

3. The number of cationic species formed from each actual component (excluding strong acids and strong bases) is determined. The only component to be considered in this example is carbonic acid, which does not form any cationic species. Therefore, the NP term is equal to zero.

4. The total concentration of each component is determined. The components for this example are carbonic acid and sodium hydroxide. The mass balance for the sodium hydroxide is: $SB_t = 0.09\ M + 2(0.01\ M) = 0.11\ M$ (sodium hydroxide). The mass balance for the carbonic acid is: $TP = 0.09\ M + 0.01\ M = 0.1\ M$ (carbonic acid).

5. By using the general equation (Eq. 44*c*), a particular (general) equation for the mixture is defined. The equation for this example is:

$$(D + SB_t)K_pH_p = PK_{p'}H_p \qquad \text{(Eq. 45)}$$

Table I—Data for Example 1

p	H^n	$p - NP$ ($CP = 1.00E\text{-}01M$)	K_p ($SB_t = 1.10E\text{-}01M$)
0	2	0	1
1	1	1	$4.20E\text{-}07$
2	0	2	$2.00E\text{-}17$

6. The known values (Steps 1–4) are substituted into the equation obtained from Step 5. If the equation is simple, then a direct substitution can be performed after expansion of the equation. Expanding Eq. 45 yields:

$$(D + SB_t)(H^2 + KP_1H + KP_1\,KP_2) = (KP_1H + 2KP_1KP_2)P \qquad \text{(Eq. 46)}$$

Substituting the values from Steps 1–5 and Eq. 15*b* into Eq. 46 yields the final equation for this example:

$$H^4 + (1.1E\text{-}01)H^3 + (4.2E\text{-}09)H^2 - (1.8E\text{-}18)H - 2.01E\text{-}31 = 0 \qquad \text{(Eq. 47)}$$

In more complex situations, rearranging Eq. 45 or whatever general equation results from Step 5 results in a more useful form for substitution of the variables:

$$DK_pH_p + SB_tK_pH_p - PK_{p'}H_p = 0 \qquad \text{(Eq. 48)}$$

A table can be constructed that allows the evaluation of the coefficients of Eq. 48 without expanding the general equation. The table is constructed in the following manner (Table I):

a. A column is constructed that contains each possible combination of $p, q, \ldots z$. The total number of rows (combinations) equals $(\alpha + 1)(\beta + 1)\ldots(\omega + 1)$. In Table I, the three values possible for p in this example are shown in the first column.

b. With the values obtained in the first column, a second column is calculated. This column contains the relative powers of H in the final polynomial. The power is calculated for each row in the second column by using the value of the subscripts $p, q, \ldots z$ in the corresponding row of the first column and solving:

$$(\alpha + \beta + \ldots \omega) - (p + q + \ldots z) = \text{power of } H \qquad \text{(Eq. 49)}$$

c. A column for each component (excluding strong acids and strong bases) is constructed. In Table I, only one column for component CP (carbonic acid) is required for this example. In general, the rows of the component columns are determined from the corresponding entries in the first column and by calculating $p - NP, q - NQ, \ldots, z - NZ$. Since NP is zero, the component column is equivalent to the first column for this example.

d. The last column is constructed by calculating $K_{pq\ldots z}$ from the corresponding values of the subscripts $p, q, \ldots z$ in the first column. The nature of the $K_{pq\ldots z}$ tensor allows each succeeding row after the first to be calculated from a previous row (not necessarily the last row) by multiplication with the next ionization constant corresponding to the new subscript. This column is labeled $K_{pq\ldots z}$ and subtitled with the appropriate concentration of $SB_t - SA_t$. The resultant column for this example is shown in Table I.

7. The next step is to calculate the coefficients and powers of the final polynomial equation. Starting with the highest power of H, the entry is determined under each component for the row corresponding to that power. The value obtained is multiplied by the component concentration (s). This value is subtracted from the $SB_t - SA_t$ concentration. The difference obtained then is multiplied by the corresponding value in the $K_{pq\ldots z}$ column and by the corresponding value of H^n. (In more complex systems, more than one row will be found for a given order. If the values for rows of a given power are equal in magnitude, they are added. If the values are not equal, then the minor contributing row may be ignored.) This procedure is repeated for each decreasing power of H. The values for each power then are added. The values for this example are: power 2 = $(1.10E\text{-}01)(1)H^2$, power 1 = $(1.10E\text{-}01 - 1.00E\text{-}01)(4.20E\text{-}07)H^1$, and power 0 = $(1.10E\text{-}01 - 2.00E\text{-}01)(2.01E\text{-}17)H^0$, so that:

$$\Sigma = (1.10E\text{-}01)H^2 + (4.20E\text{-}09)H^1 - (1.81E\text{-}18)H^0 \qquad \text{(Eq. 50)}$$

The summation obtained in general will equal the total equation (Eq. 48 for this example) minus the term $DK_{pq\ldots z}H_{pq\ldots z}$ (DK_pH_p for this example). This term can be expanded after substituting Eq. 15*b* to yield:

[a] The asterisk indicates the row contributing significantly to the total Eq. 55.

$$\left(\frac{H^2 - K_w}{H}\right) K_{pq\ldots z} H_{pq\ldots z} \qquad \text{(Eq. 51)}$$

The $K_{pq\ldots z}H_{pq\ldots z}$ value is computed using the table by recalling the rows used in the determination of the coefficients of the polynomial. Since all three rows were used in this example:

$$K_p H_p = H^2 + (4.20E\text{-}07)H^1 + (2.01E\text{-}17)H^0 \qquad \text{(Eq. 52)}$$

The final equation can be obtained by substituting the values obtained from the summation, the $K_{pq\ldots z}H_{pq\ldots z}$ value, and Eq. 15*b* into the general equation. The result for this example is obtained by substituting Eqs. 50, 52, and 15*b* into Eq. 48 to yield:

$$H^4 + (1.10E\text{-}01)H^3 + (4.20E\text{-}09)H^2 - (1.81E\text{-}18)H^1 - (2.01E\text{-}31)H^0 = 0 \qquad \text{(Eq. 53)}$$

8. The last step is the numerical solution of the final equation. For this example, Eq. 53 can be solved by numerical techniques. However, the quadratic equation obtained from the last three terms of Eq. 53 approximates the total equation. This approximation yields a pH of 9.37, the same as that given by Eq. 53 to this accuracy. Experimentally, a pH of 9.30 was obtained.

The second example is the calculation of the hydrogen-ion concentration of a solution of 0.0216 *M* citric acid (*P*), 0.0216 *M* monobasic sodium phosphate (*Q*), 0.0216 *M* barbital (*R*), 0.0216 *M* boric acid (*S*), and

0.0491 M NaOH, which can be solved as follows:

1. There are five components of this mixture: citric acid, phosphoric acid, barbital, boric acid, and sodium hydroxide.

2. The ionization constants, α, β, γ, and δ, for this example are defined as: $KP_1 = 8.40E\text{-}04$, $KQ_1 = 7.50E\text{-}03$, $KS_1 = 5.80E\text{-}10$, $KP_2 = 1.80E\text{-}05$, $KQ_2 = 6.20E\text{-}08$, $KR_1 = 3.70E\text{-}08$, $KP_3 = 4.00E\text{-}06$, $KQ_3 = 4.80E\text{-}13$, $\alpha = 3$, $\beta = 3$, $\gamma = 1$, and $\delta = 1$.

3. There are no cationic species formed from any of the components. Therefore, $NP = NQ = NR = NS = 0$.

4. The component concentrations are: $TP = TQ = TR = TS = 0.0216$ M and $SB_t = 0.0491$ M (sodium hydroxide) + 0.0216 M (SB_q) = 0.0707 M.

5. The general equation for this particular mixture is then defined from Eq. 44c. Equation 44c for a mixture of four components (TP, TQ, TR, and TS) and SB_t results in:

$$(D + SB_t)K_{pqrs}H_{pqrs} = K_{p'qrs}H_{pqrs}TP + K_{pq'rs}H_{pqrs}TQ + K_{pqr's}H_{pqrs}TR + K_{pqrs'}H_{pqrs}TS \quad \text{(Eq. 54)}$$

6. The tableau method for the calculation of coefficients and powers in the final polynomial is advantageous for this example because of its complexity. Rearranging Eq. 54 and substituting Eq. 15b yield:

$$\left(\frac{H^2 - K_w}{H}\right)K_{pqrs}H_{pqrs} = (SB_tK_{pqrs} - TPK_{p'qrs} - TQK_{pq'rs} - TRK_{pqr's} - TSK_{pqrs'})H_{pqrs} \quad \text{(Eq. 55)}$$

Table II was constructed using the procedure outlined in the previous example. However, in this example, not every row was used in calculating the coefficients. Only 16 rows contributed significantly to the total equation. The values in the K_{pqrs} column for a given power should be compared and the relative values noted. These contributing rows are marked with an asterisk in Table II.

7. The coefficients for each power are determined from Step 6 and summed for all powers of H. This sum equals the right side of Eq. 55. The value of $K_{pqrs}H_{pqrs}$ is calculated by recalling all of the contributing rows used in the determination of the previous summation. The values in the $K_{pqrs}H_{pqrs}$ column corresponding to these rows are added. Substituting the value obtained for the right side of Eq. 55 and the value obtained for $K_{pqrs}H_{pqrs}$ into Eq. 55 and expanding yield the final equation for this system:

$$H^{10} + (7.9E\text{-}02)H^9 + (4.2E\text{-}04)H^8 + (1.7E\text{-}07)H^7 + (6.7E\text{-}13)H^6 - (7.3E\text{-}18)H^5 - (1.72E\text{-}24)H^4 - (6.2E\text{-}32)H^3 - (4.9E\text{-}41)H^2 - (3.6E\text{-}53)H^1 - (2.9E\text{-}66)H^0 = 0 \quad \text{(Eq. 56)}$$

8. This step is performed as in the previous example. The quadratic approximation based on H^7 yields a pH of 5.37, whereas solving the entire Eq. 55 gives a pH of 5.30. The latter pH was the one obtained experimentally.

EXPERIMENTAL

The pH measurements were performed using a digital pH meter[1]. The instrument and test solutions were at 23°. Buffer solutions bracketing the approximate pH of the test solution were used to calibrate the instrument.

RESULTS AND DISCUSSION

The results for two- and five-component mixtures of acids, bases, and ampholytes showed reasonable agreement between experimental and calculated pH values. The general method presented has the advantage that approximations can be made in the final equation rather than in the derivation. This approach allows the approximation to be based on numerical comparison rather than on intuition. Additionally, the method can be used without any approximation if a computer is available (the general nature of the final equation is well suited for computer analysis). In summary, the general equation presented is simple and versatile; it can be used to calculate the hydrogen-ion concentration of simple and complex solutions. However, at high ionic strengths, the lack of activity corrections is expected to limit the accuracy of the method.

Determination of Free Methyldopa in Plasma by High-Pressure Liquid Chromatography and Electrochemical Detection

GREGORY M. KOCHAK and WILLIAM D. MASON ˣ

Received September 21, 1979, from the *Pharmacokinetics Laboratory, Schools of Pharmacy and Medicine, University of Missouri–Kansas City, Kansas City, MO 64108.* Accepted for publication March 7, 1980.

Abstract □ A quantitative method for the analysis of free methyldopa in plasma is described. The method is based on reversed-phase high-pressure liquid chromatography with electrochemical detection utilizing an ion-pairing agent. Separation of methyldopa from plasma is achieved by alumina adsorption. The parameters associated with the adsorption step are described. The lower limit of sensitivity is ~10 ng of methyldopa/ml with a corresponding retention time of 6.9 min.

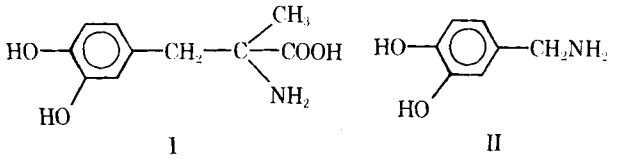
Keyphrases □ Methyldopa—high-pressure liquid chromatographic analysis using electrochemical detection, separation from plasma by alumina adsorption □ High-pressure liquid chromatography—analysis, methyldopa, plasma □ Adsorption—separation of methyldopa from plasma by alumina adsorption, high-pressure liquid chromatographic analysis

Previous measurements of small quantities of methyldopa (I) and other catechols in biological fluids have been based on separation by alumina adsorption and detection by oxidation to the fluorescent hydroxyindole derivatives. Since most catechol compounds adsorb onto alumina and form the fluorescent derivative, the approach is not specific for any one compound without additional chromatographic procedures. Kwan *et al.* (1) employed no additional chromatography and reported a mean reading for predose plasma equivalent to 280 ± 30 ng of methyldopa/ml. Subtraction of a blank value of this magnitude and variance results in considerable assay variance and severely limits sensitivity.

This paper describes a quantitative method for the determination of methyldopa in plasma that utilizes high-pressure liquid chromatography (HPLC) with electrochemical detection. Electrochemical detection previously was used successfully for detection of catecholamines (2–4). Methyldopa was separated from its metabolites and other endogenous catecholamines with reversed-phase ion-pair HPLC. 3,4-Dihydroxybenzylamine (II) was used as the internal standard.

EXPERIMENTAL

Reagents and Standards—All reagents were reagent grade or better. Water was triple glass distilled. Organic solvents were HPLC grade. The mobile phase was passed through a 0.2-μm filter[1] before introduction into the system. Pure methyldopa[2], 3,4-dihydroxybenzylamine[3], type WN-3 chromatographic alumina[3] (activity grade I), and heptanesulfonic acid[4] (sodium salt) were used. All standard solutions were made in triple glass-distilled water containing 0.005 *M* sodium metabisulfite and acidified to pH 2.6 with phosphoric acid.



I II

Instrumental Parameters—A chromatographic reciprocating pump[5], a sample injection valve[6], a 5-μm octadecylsilane column[7], a glassy carbon electrochemical detector[8], and a dual-pen recorder[9] comprised the HPLC system.

The mobile phase consisted of 0.07 *M* phosphate buffer adjusted to pH 2.6 with sodium hydroxide, 8% acetonitrile, 0.1 m*M* disodium ethylenediaminetetraacetate, and 5 m*M* heptanesulfonic acid. The anode potential was set at +0.80 v *versus* a silver–silver chloride reference electrode, and amplification was achieved with a polarographic analyzer[10]. With a mobile flow rate of 1.5 ml/min, the retention times for methyldopa (I) and 3,4-dihydroxybenzylamine (II) were 6.9 and 5.2 min, respectively.

Separation from Plasma—One milliliter of plasma was spiked with II. Then 0.1 ml of 0.05 *M* sodium metabisulfite and 0.1 ml of 5% (w/v) disodium ethylenediaminetetraacetate were added to the plasma. The plasma was adjusted to pH 7.0 by the addition of 2 ml of 0.065 *M* tris(hydroxymethyl)aminomethane buffer and then was adjusted further to pH 8.0–8.6 with 1 *M* NaOH after the batchwise addition of 135 ± 1.3 mg of acid-washed alumina (5). The sample was shaken for 15 min, and the supernate was aspirated. The alumina was washed twice with 2 ml of triple-distilled water. The methyldopa was eluted from the alumina by shaking for 15 min with 1 ml of 0.05 *M* phosphoric acid. The acid supernate was transferred immediately to a second tube from which 100 μl subsequently was injected onto the column.

DISCUSSION

Chromatography—Various parameters such as the pH and composition of the mobile phase were evaluated systematically. The ionic strength of the mobile phase greatly affected the electrode response. The effects of various ionic strengths on the bioanalytical electrodes previously were established for phosphate buffer (6) and corresponded to the present results (Fig. 1). Maximal response occurred at 0.07 *M* phosphate buffer. The effect of varying the percent composition of the organic phase in the aqueous mobile phase was described theoretically by Horvath *et al.* (7). Acetonitrile was used as the organic solvent, and the results of varying organic composition *versus* log K' (retardation factor) proved to be linear, verifying the work of Horvath *et al.* (Fig. 2).

The results of the effect of pH on K' are presented in Figs. 3 and 4. Methyldopa has a reported pKa value of 2.2 (8) for the carboxylic acid function at 25°, and K' is related directly to the ionization of the carboxylic acid functional group. The amino group with a pKa of 9.0 at 25° is ionized and is presumed to be paired with heptanesulfonic acid. Increasing the percentage of ionization of the carboxyl group decreased retention up to ~pH 3.20, where elution of methyldopa was at the solvent front. The mobile phase pH must be maintained constant since small pH fluctuations may change the chromatography significantly.

The efficiency of liquid chromatographic columns has been shown to be the greatest for compounds with K' values between 2 and 6 (9). The composition of the mobile phase was adjusted accordingly and resulted in K' values of 2.7 and 3.9 for 3,4-dihydroxybenzylamine and methyldopa, respectively.

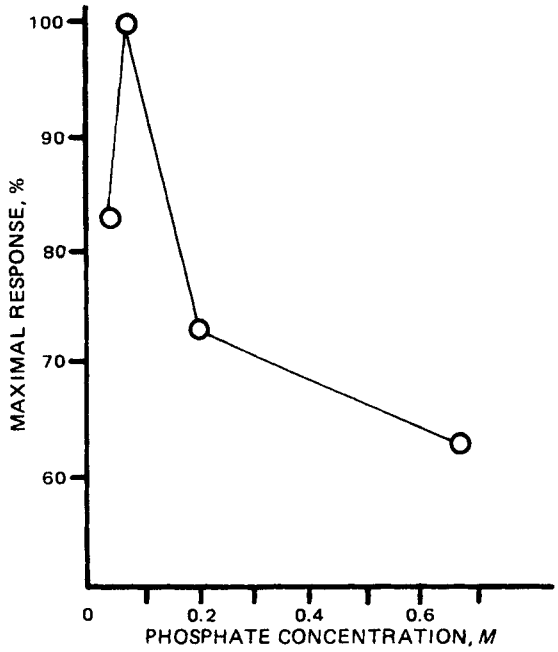

Figure 1—*Effect of ionic strength on the detector response of methyldopa. At a phosphate concentration above 0.07* M, *the current decreased in accordance with the Nernst equation for the diffusion coefficient, in which diffusion is inversely related to the ionic strength. The diminished detector response at low ionic strength is attributed to increased resistance in the electrochemical cell.*

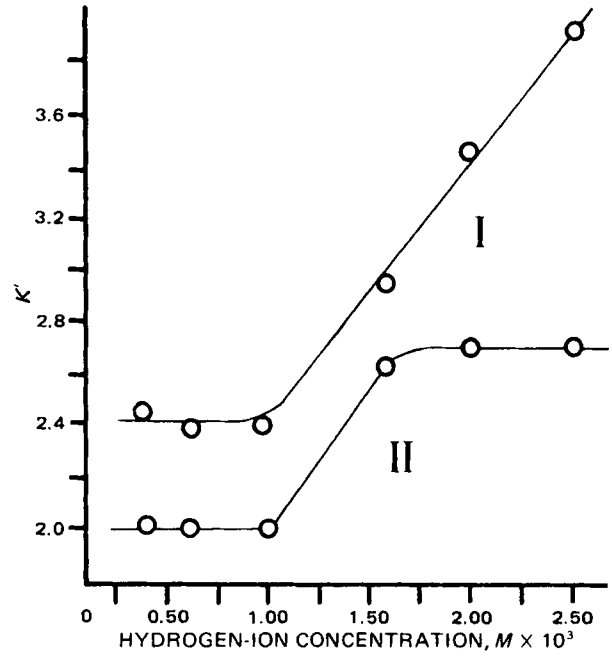

Figure 3—*Effect of hydrogen-ion concentration on the retardation factor. The mobile phase consisted of 0.1* mM *disodium ethylenediaminetetraacetate, 5* mM *heptanesulfonic acid, 0.07* M *phosphate, and 8% acetonitrile; the pH was adjusted by titration with sodium hydroxide before the organic modifier was added. The flow rate was 1.5 ml/min.*

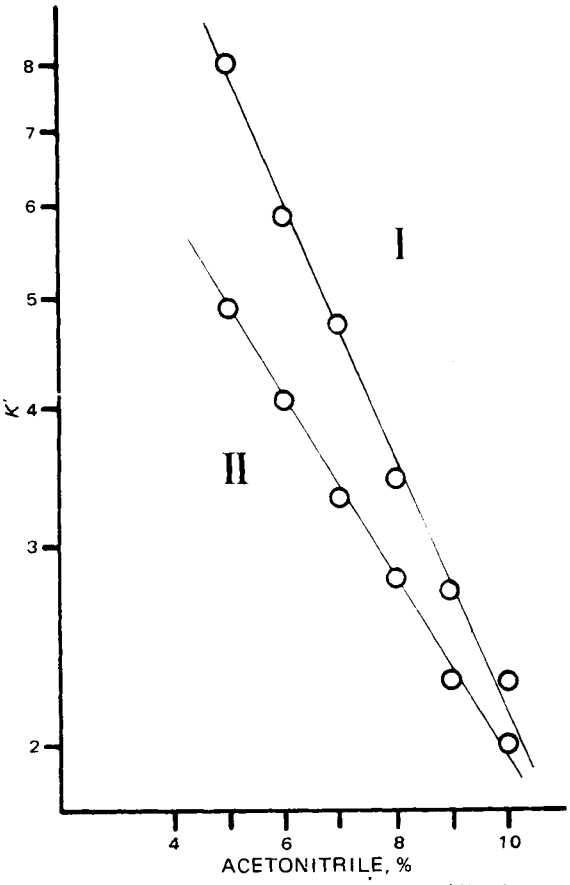

Figure 2—*Retardation factor values at varying mobile phase composition. The mobile phase consisted of 0.1* mM *disodium ethylenediaminetetraacetate, 5* mM *heptanesulfonic acid, and 0.07* M *phosphate buffer at pH 3.0 and a flow rate of 1.5 ml/min. The regression for 3,4-dihydroxybenzylamine was log y = (−0.076 ± 0.004)x + (1.066 ± 0.028), r = 0.995. The regression for methyldopa was log y = (−0.111 ± 0.044)x + (1.41 ± 0.031), r = 0.997.*

Extraction—A modified alumina adsorption method (5) was used to extract 3,4-dihydroxybenzylamine and methyldopa. The adsorption of catecholamines and methyldopa is not linear over a wide range. Both 36 and 135 mg of alumina were tried with various eluents. With 36 mg of alumina, the linear region extended to 150 ng of methyldopa/ml and saturation occurred at 600 ng/ml; 135 mg of alumina/ml produced linearity up to 400 ng/ml with saturation occurring at 750 ng/ml. Using larger

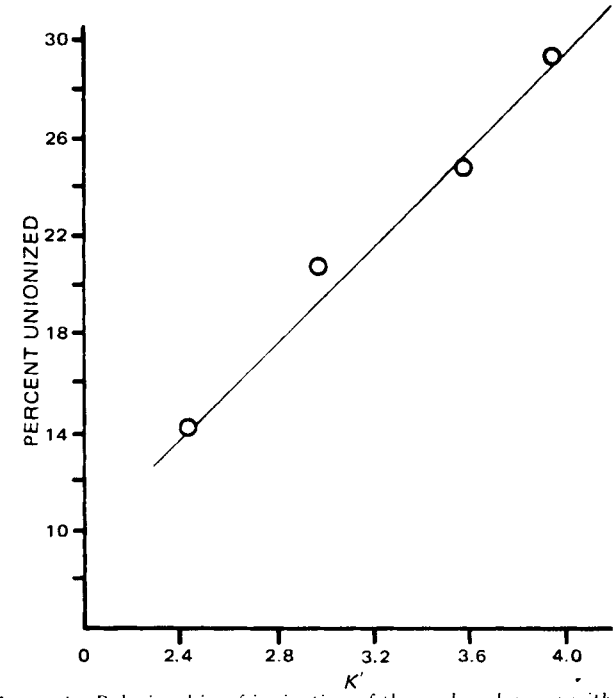

Figure 4—*Relationship of ionization of the carboxyl group with the retardation factor. The percent unionized acid function of methyldopa was calculated using literature pKa values and was not adjusted for the 8% acetonitrile in the mobile phase. The regression was* y = (9.958 ± 0.627)x + (9.490 ± 2.040), r = 0.996.

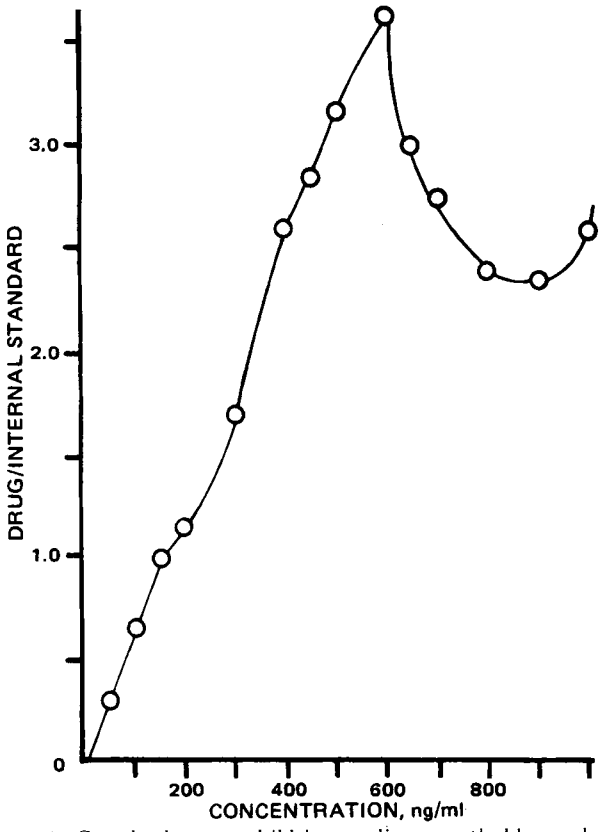

Figure 5—*Standard curve exhibiting nonlinear methyldopa adsorption. Alumina (36 mg) was used to extract methyldopa. Each value is the mean of four determinations.*

amounts of alumina was cumbersome; therefore, 1-ml plasma fractions were utilized when necessary to keep the analysis in the linear range.

The nonlinear nature of alumina adsorption was not mentioned by Kwan *et al.* (1) when measuring up to 7.5 μg of methyldopa/ml. This nonlinearity would account for substantial variation if linearity were assumed. The shape of the standard curves is typical of adsorption of drugs onto solid porous adsorbents (10) (Figs. 5 and 6).

The recovery of known quantities of methyldopa and 3,4-dihydroxybenzylamine from plasma by alumina adsorption varied for differing amounts of alumina as well as for the two drugs. The efficiency of recovery for methyldopa and 3,4-dihydroxybenzylamine was 71 and 72% with coefficients of variation of 3.8 and 3.6%, respectively, when 36 mg of alumina was used in the extraction step. The recovery efficiency changed to 84 and 56% with coefficients of variation of 2.8 and 1.8% for methyldopa and 3,4-dihydroxybenzylamine, respectively, when 135 mg of alumina was used. There were six determinations in both cases.

The linearity of the assay was demonstrated by standard curves over the 0–100- and 0–400-ng/ml ranges in which 36 and 135 mg of alumina adsorbent were used, respectively. The standard curve regressions were: $y = (0.00663 \pm 0.00011)x + (0.00520 \pm 0.00690)$, with $r = 0.999$ for 36 mg of alumina, and $y = (0.00345 \pm 0.00011)x + (0.02800 \pm 0.03100)$, with $r = 0.997$ for 135 mg of alumina, where y is the methyldopa peak height divided by the 3,4-dihydroxybenzylamine peak height and x is the concentration of methyldopa (nanograms per milliliter).

Reproducibility was demonstrated by a day-to-day coefficient of variation based on the change of the standard curve slope of 5.7% ($n = 6$) for 135 mg of alumina. The within-run coefficients of variation (drug/internal standard) were 5.4 and 1.0% ($n = 6$) for 36 and 135 mg of alumina, respectively. The lower limit of this assay with the described instrumentation and procedure (signal to noise ratio of five with no interfering peaks) is ~10 ng/ml of plasma.

Figure 7 is an example of a typical chromatogram. This assay has been applied to over 400 plasma samples and has been reliable. After ~50 assays, the electrode must be removed and the glassy carbon surface must be cleaned by mechanical polishing. Extractions are clean, and the peak resolution is very good. In the development of this assay, consideration also was given for quantitating methylnorepinephrine (III), norepinephrine (IV), and methyldopamine (V). All appeared as resolved peaks with retention times of 4.7, 4.0, and 10.6 min, respectively (Fig. 8).

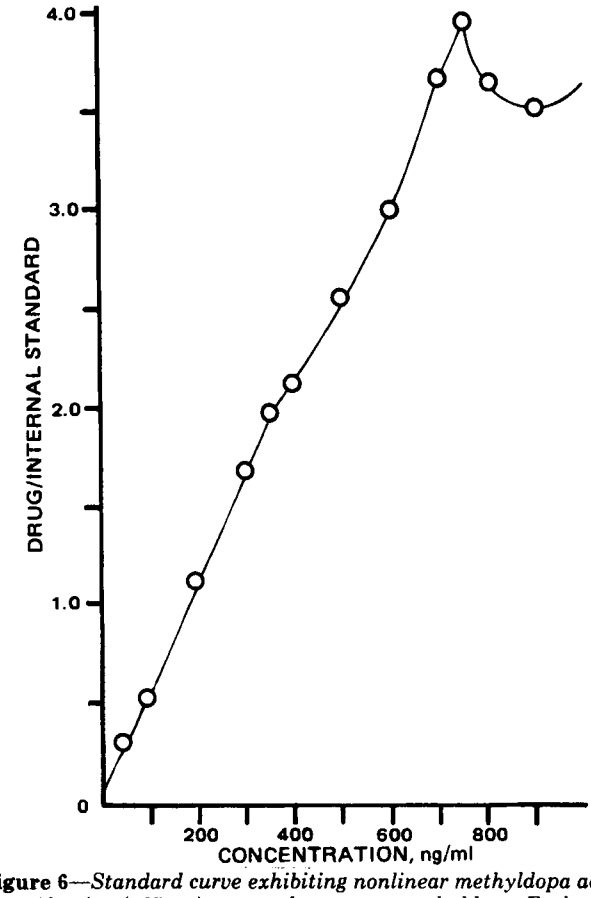

Figure 6—*Standard curve exhibiting nonlinear methyldopa adsorption. Alumina (135 mg) was used to extract methyldopa. Each value is the mean of four determinations. Note that the adsorption isotherms of both 36 and 135 mg of alumina are similar in shape, with the additional alumina shifting the curve in this figure.*

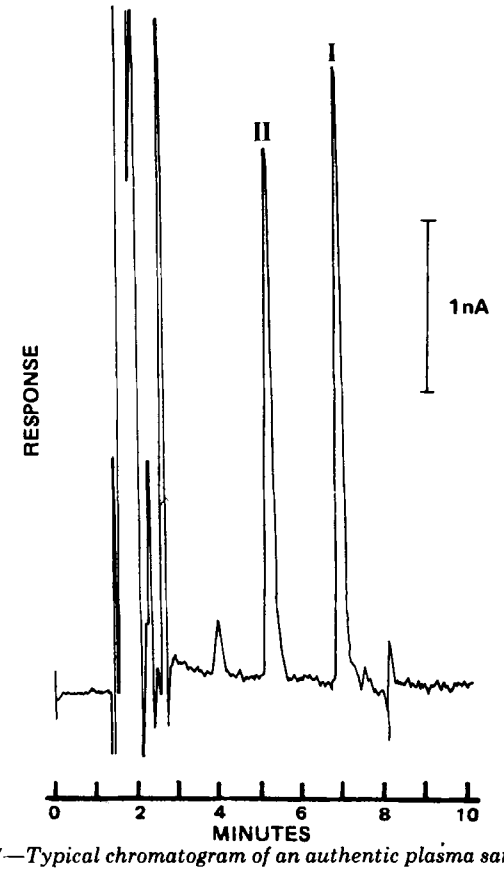

Figure 7—*Typical chromatogram of an authentic plasma sample.*

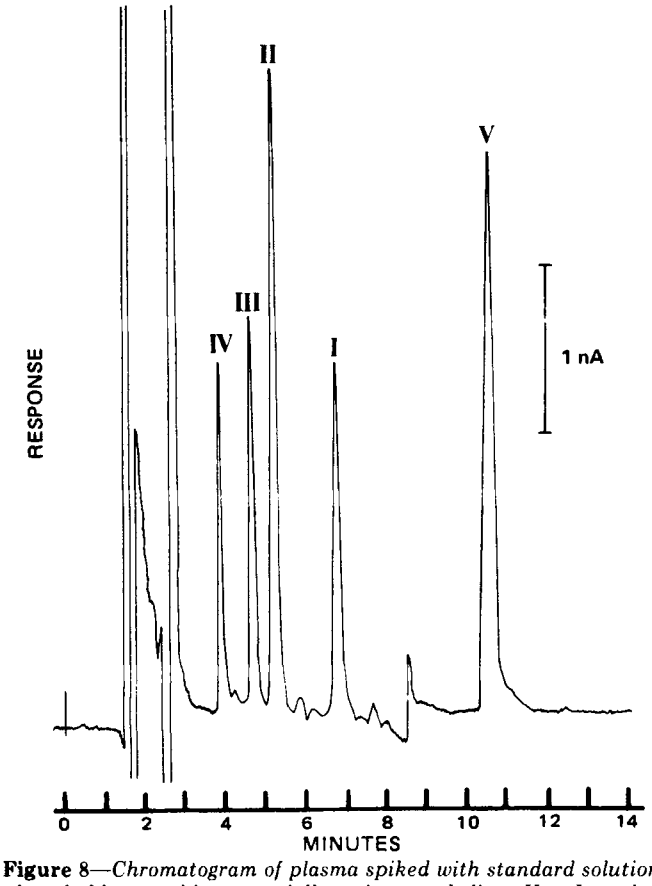

Figure 8—*Chromatogram of plasma spiked with standard solutions of methyldopa and its potentially active metabolites. Key: I, methyldopa; II, 3,4-dihydroxybenzylamine; III, methylnorepinephrine; IV, norepinephrine; and V, methyldopamine.*

Dopamine eluted with methyldopa with a retention time of 6.9 min. However, dopamine does not compromise the assay of methyldopa since normal plasma dopamine concentrations are below the sensitivity of this assay. Blank plasma samples showed no detectable interference. Changing the mobile phase to 9% acetonitrile and pH 2.40 and the ion-pair to 5 m*M* pentanesulfonic acid (sodium salt), with all other parameters remaining constant, allows complete resolution of methyldopa from dopamine. Authentic plasma samples of subjects receiving methyldopa also showed no detectable dopamine in the presence of methyldopa when resolved.

Interactions of Aspirin with Acetaminophen and Caffeine in Rat Stomach: Pharmacokinetics of Absorption and Accumulation in Gastric Mucosa

AD J. M. SEEGERS *x, MARTIN OLLING *, LOWIE P. JAGER ‡, and JACOBUS VAN NOORDWIJK *

Received December 3, 1979, from the **National Institute of Public Health, P.O. Box 1, 3720 BA Bilthoven, The Netherlands*, and the ‡*Department of Pharmacology, Faculty of Pharmacy, State University of Utrecht, Utrecht, The Netherlands.* Accepted for publication February 27, 1980.

Abstract □ To study the pharmacokinetic interactions between aspirin (250 mg/kg) and simultaneously administered oral acetaminophen (125 mg/kg) or caffeine (50 mg/kg) in male adult rats, noninterfering GLC assays for these drugs were developed. Acetaminophen and caffeine both retarded the appearance of salicylate in plasma. During the elimination phase, acetaminophen enhanced plasma salicylate levels whereas caffeine did not. Aspirin reduced the plasma levels of both acetaminophen and caffeine during absorption and elimination. Regardless of whether the drugs had been administered separately or in combination, higher concentrations of salicylate, acetaminophen, and caffeine were found in the glandular part of the stomach compared to the nonglandular part (rumen). In both parts, the absorption of acetaminophen increased in the presence of aspirin. Simultaneous administration of aspirin with caffeine did not influence the absorption of either drug in the glandular and ruminal parts. The inhibitory action of acetaminophen and the potentiating action of caffeine on the erosive activity of aspirin are not due to any effects of these drugs on salicylate accumulation in glandular tissue.

Keyphrases □ Aspirin—administered alone and with acetaminophen or caffeine, absorption, distribution in gastric tissue, blood plasma levels, rats □ Acetaminophen—administered alone and with aspirin, absorption, distribution in gastric tissue, blood plasma levels, rats □ Caffeine—administered alone and with aspirin, absorption, distribution in gastric tissue, blood plasma levels, rats □ Pharmacokinetics—aspirin administered alone and with acetaminophen or caffeine, absorption, distribution in gastric tissue, blood plasma levels, rats

Irritation of the GI mucosa, production of erosions, and GI bleeding are serious side effects of aspirin and other nonsteroidal anti-inflammatory drugs (1, 2). Acidic anti-inflammatory drugs are thought to cause these side effects

following their rapid absorption to give very high intracellular concentrations, finally resulting in cell death (3–5). However, a causal relationship between the intracellular accumulation of salicylate and the decay of gastric mucosal cells has not been proven. Therefore, the present study was initiated to compare the characteristics of absorption and distribution of aspirin in the rat stomach with those of acetaminophen and caffeine, two drugs that are nonulcerogenic in rats (6).

It also was suggested (5) that the reduced gastric toxicity of slow-release and enteric-coated aspirin formulations (7–9) might be explained by the delayed absorption of aspirin and, thus, a reduction in salicylate trapping in parietal cells. In the rat, acetaminophen reduced the erosive activity of aspirin whereas caffeine potentiated this activity (6, 10). To test this hypothesis, the effects of acetaminophen and caffeine on the absorption of salicylate into the cells of the glandular (containing the parietal cells) and nonglandular parts of the rat stomach were investigated.

EXPERIMENTAL

Reagents and Materials—Aspirin[1], salicylic acid[1], acetaminophen[1], caffeine[1], phenacetin[1], and polysorbate 80[2] were obtained commercially. All other chemicals were analytical reagent grade. Ether[3] was distilled every day. Male Wistar rats of an inbred strain, 180–200 g, were purchased locally[4].

GLC—For aspirin and salicylic acid, a gas chromatograph[5] equipped with a multitemperature programmer, a flame-ionization detector, and an integrator[6] was used. The glass column, 1.00 m × 3 mm i.d., was packed with 3% OV-17[7] on 80–100-mesh Gas Chrom Q[7]. The column oven temperature was programmed for 2 min at 105°, an increase of 4°/min from 105 to 130°, an increase of 30°/min from 130 to 195°, 2 min at 195°, and then cooling down. The injector temperature was 220°, the detector temperature was 220°, the argon carrier gas flow rate was 35 ml/min, the hydrogen flow rate was 40 ml/min, the air flow rate was 400 ml/min, and the amplifier range was at 10. Under these conditions, the retention times of the trimethylsilyl ether derivatives were 3.0 min for *p*-toluic acid (internal standard), 5.0 min for salicylic acid, and 7.5 min for aspirin.

For acetaminophen, a gas chromatograph[8] equipped with a flame-ionization detector and a computing integrator[9] was used. The glass column, 1.80 m × 2 mm i.d., was packed with 3% OV-101[7] on 80–100-mesh Gas Chrom Q. The column oven temperature was 135°, the injector temperature was 200°, the detector temperature was 220°, the nitrogen carrier gas flow rate was 30 ml/min, the hydrogen flow rate was 35 ml/min, and the air flow rate was 350 ml/min. The retention times of the trimethylsilyl ether derivatives were 4.5 min for *p*-bromoacetanilide (internal standard), 7.5 min for acetaminophen, and 6.0 min for phenacetin.

For caffeine, a gas chromatograph[8] equipped with an alkali flame-ionization detector and a computing integrator[9] was used. The glass column, 1.50 × 2 mm i.d., was packed with 3% OV-101 on 80–100-mesh Gas Chrom Q. The column oven temperature was 165°, the injector temperature was 220°, the detector temperature was 220°, the nitrogen carrier gas flow rate was 30 ml/min, the hydrogen flow rate was 35 ml/min, and the air flow rate was 300 ml/min. Under these conditions, the retention times were 5.0 min for phenacetin (internal standard) and 8.0 min for caffeine.

Drug Treatment and Sample Collection—Rats were distributed randomly into groups of eight or 10 animals and were deprived of food, but not water, for 36 hr. They were kept in cages (0.32 × 0.20 × 0.20 m) with a metal grid (8 × 8 mm) to avoid coprophagy. Room temperature was maintained at 21 ± 0.5°. Aspirin, acetaminophen, and caffeine were ground before use (<110 μm). All treatments were administered orally at 5 ml/kg as suspensions in 4% polysorbate 80; control rats received a similar volume of 4% polysorbate 80 solution.

Rats were treated with aspirin (250 mg/kg), acetaminophen (125 mg/kg), caffeine (50 mg/kg), aspirin and acetaminophen (250 and 125 mg/kg), and aspirin and caffeine (250 and 50 mg/kg). Blood samples (1.0 ml) were obtained by decapitation. In the drug elimination studies, dosage groups of 10 rats were decapitated at 0.5, 1.5, 4, 8, and 17 hr after administration. In the drug absorption studies, dosage groups of eight rats were decapitated at 5, 10, 15, 20, and 30 min after administration.

In the absorption experiments, the stomachs were removed immediately after blood sampling, opened along the greater curvature, and rinsed in saline. The glandular part of the gastric tissue was scraped off, and the ruminal part was cut off. Blood was collected in polyethylene snap caps, which contained 1 drop of a solution of 250 IU of heparin[10] and 12 mmoles of sodium fluoride/ml. After centrifugation[11] at 1000×*g*, the plasma was stored at −20°. Tissue samples were weighed wet, stored at −20°, and homogenized[12] in water (1:3 w/v) just before analysis.

Assay of Aspirin and Salicylic Acid—To a 15-ml stoppered conical glass centrifuge tube were added 0.1–0.5 ml of plasma or 1 ml of tissue homogenate, 200–300 mg of sodium chloride, 0.5 ml of buffer solution (17.2 mmoles of potassium sulfate in 100 ml of 0.2 *M* H_2SO_4), and 10 ml of ether. After shaking[13] for 30 min and centrifuging for 10 min at 1000×*g*, as much ether as possible was transferred into a conical tube and evaporated to dryness on a heating block[14] at 30° under a nitrogen stream. To the dry residue was added 0.1 ml of 0.6 m*M* *p*-toluic acid in acetone.

The contents of the tube were transferred with four 0.1-ml portions of acetone to a micro reaction vessel[7]. After evaporation of the acetone, the residue was dissolved in 50 μl of bis(trimethylsilyl)trifluoroacetamide[7], and the vessel was closed with a polytetrafluoroethylene-lined rubber septum[7]. After agitation and heating at 50° for 1 hr, 1 μl was injected into the GLC column and the temperature programming was started.

Assay of Acetaminophen—To a 10-ml glass-stoppered centrifuge tube were added 0.1–1 ml of plasma or 1 ml of tissue homogenate, 2 ml of buffer solution (1 *M* dibasic potassium phosphate saturated with sodium chloride and brought to pH 7.4 with 1 *M* NaOH), and 5 ml of ether containing 24 nmoles of *p*-bromoacetanilide. After shaking for 30 min and centrifuging for 10 min at 1000×*g*, the organic layer was transferred to a conical glass tube and evaporated under a nitrogen stream at room temperature.

The residue was transferred to a micro reaction vessel with two 150-μl portions of acetone; after evaporation of the acetone, the residue was dissolved in 50 μl of bis(trimethylsilyl)trifluoroacetamide and the vessel was closed with a polytetrafluoroethylene-lined rubber septum. After agitation and heating at 50° for 2 hr, 1 μl was injected into the GLC column.

Assay of Caffeine—To a 10-ml glass-stoppered centrifuge tube was added 0.1 ml of a solution of 0.1 m*M* phenacetin in acetone. After evaporation of the acetone, 0.1–0.5 ml of plasma or 1 ml of tissue homogenate and 5 ml of dichloromethane were added. After shaking for 15 min and centrifuging for 5 min at 1000×*g*, the organic layer was dried over sodium sulfate and evaporated to dryness at 40° under a nitrogen stream. The residue was dissolved in 100 μl of methanol, and 1 μl was injected into the GLC column.

Data Analysis—The means and standard errors of the mean (*SEM*) of plasma and tissue concentrations of total salicylate (acetylsalicylate and salicylate), acetaminophen, and caffeine are presented in Figs. 1–4 (the standard error of the mean is presented only when it exceeds the dimensions of the symbol). Rankit tests (11) showed that the assumption that the concentrations within treatment groups were normally distributed was justified.

Differences between the mean concentrations of the treatment groups were tested using the Student *t* test. Because the ratio of two normally distributed variables is not normally distributed, differences in concentration ratios between treatment groups were tested using Wilcoxon's signed rank test. Differences were assumed to be real when tests indicated probability levels of <5%.

RESULTS

GLC—Linear relationships were observed between the concentrations of aspirin or salicylic acid (5–100 nmoles/ml) added to normal rat plasma and the peak area ratio measured using *p*-toluic acid as the internal standard ($r = 0.9989$ for aspirin and 0.9976 for salicylic acid). The mean recoveries of added aspirin and salicylic acid from plasma were 98.6 ± 3.5 and 99.9 ± 5.8%, respectively. The recoveries from tissue homogenates were 98.2 ± 3.4 and 99.5 ± 5.0%, respectively ($n = 8$). The detection limit for both compounds was 2 nmoles/ml of plasma; acetaminophen, caffeine, and phenacetin did not interfere with the assay.

In the concentration range of 4–100 nmoles/ml, linear relationships were observed between the concentrations of acetaminophen or phenacetin added to blood plasma and the peak area ratio measured using *p*-bromoacetanilide as the internal standard ($r = 0.9998$ for acetaminophen and 0.9993 for phenacetin). The mean recoveries of acetaminophen and phenacetin from plasma were 70.0 ± 4.0 and 99.0 ± 5.0%, respectively. The recoveries from tissue homogenates were 71.2 ± 4.2 and 99.3 ± 5.3%, respectively ($n = 15$). The detection limit for both compounds was 0.5 nmole/ml of plasma; aspirin, salicylic acid, caffeine, and *p*-aminophenol did not interfere with the assay.

A linear relationship was observed between the concentrations of caffeine (5–50 nmoles/ml) added to blood plasma and the peak area ratio measured using phenacetin as the internal standard ($r = 0.9974$). The recovery of caffeine from plasma samples in the concentration range of 1–175 nmoles/ml was 95.0 ± 4.4% ($n = 17$). The recovery from tissue homogenates in the concentration range of 20–500 nmoles/g was 94.1 ± 5.0% ($n = 8$). The detection limit was 1 nmole/ml of plasma; aspirin, salicylic acid, and acetaminophen did not interfere with the assay.

Plasma Levels during Elimination—The average plasma levels of salicylate, acetaminophen, and caffeine after administration to rats of the individual drugs alone or in combination are shown in Fig. 1.

Administration of aspirin alone or in combination with acetaminophen

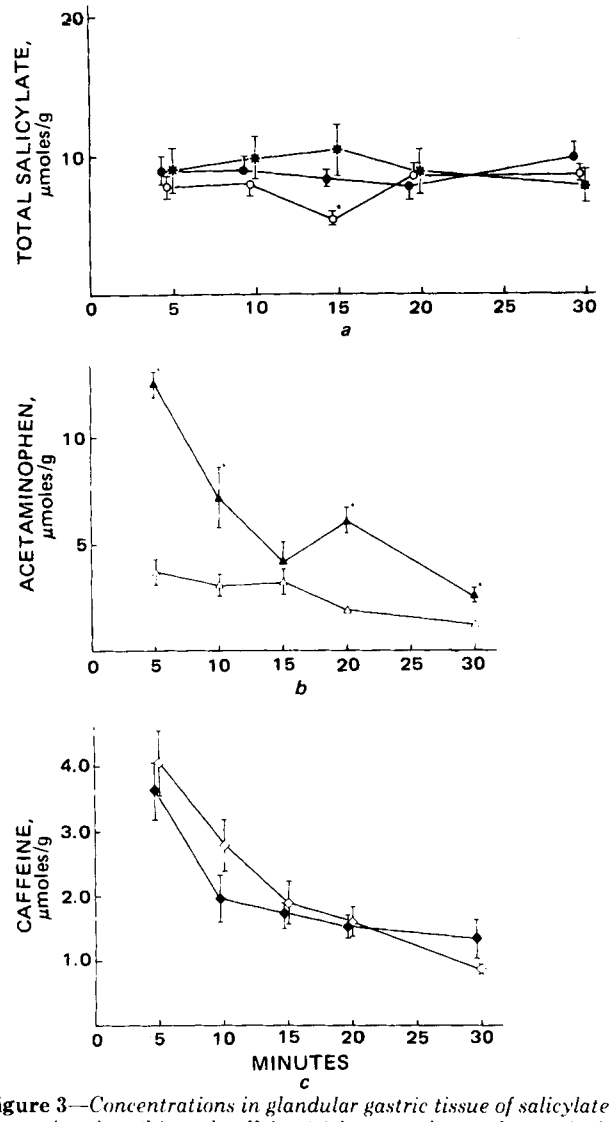

Figure 3—*Concentrations in glandular gastric tissue of salicylate* (a), *acetaminophen* (b), *and caffeine* (c) *in starved rats after oral administration of aspirin (250 mg/kg)* (*), *acetaminophen (125 mg/kg)* (△), *caffeine (50 mg/kg)* (◇), *aspirin* (○) *and acetaminophen* (▲) *(250 and 125 mg/kg, respectively), and aspirin* (●) *and caffeine* (◆) *(250 and 50 mg/kg, respectively). Values are means* ± SEM *from eight rats. An asterisk indicates* $p < 0.05$ *compared to the drugs given alone.*

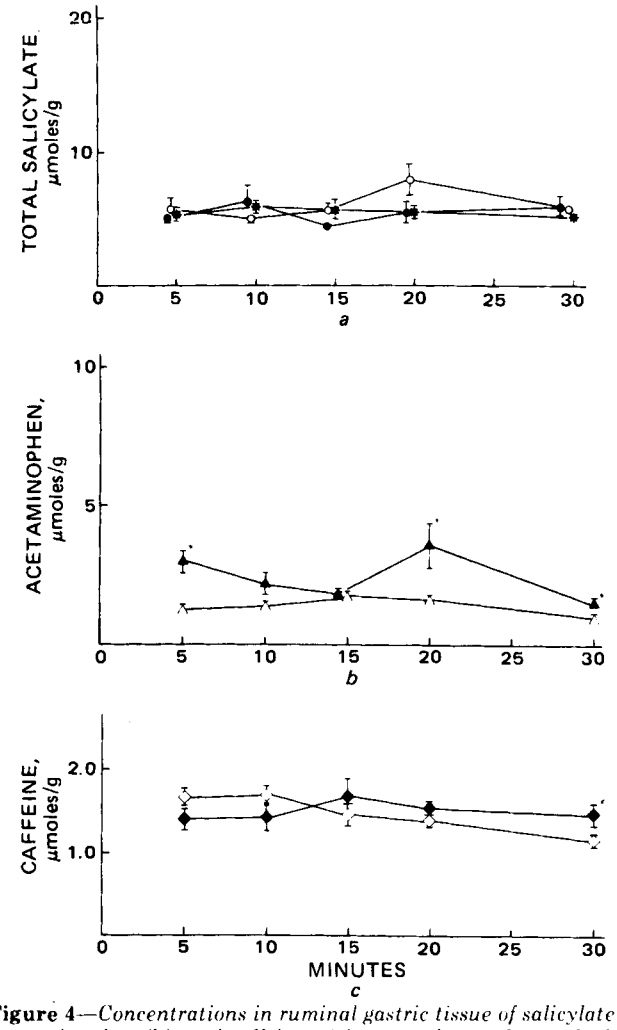

Figure 4—*Concentrations in ruminal gastric tissue of salicylate* (a), *acetaminophen* (b), *and caffeine* (c) *in starved rats after oral administration of aspirin (250 mg/kg)* (*), *acetaminophen (125 mg/kg)* (△), *caffeine (50 mg/kg)* (◇), *aspirin* (○) *and acetaminophen* (▲) *(250 and 125 mg/kg, respectively), and aspirin* (●) *and caffeine* (◆) *(250 and 50 mg/kg, respectively). Values are means* ± SEM *from eight rats. An asterisk indicates* $p < 0.05$ *compared to the drugs given alone.*

or caffeine resulted in maximal plasma salicylate levels within 1.0–1.5 hr. Coadministration of acetaminophen with aspirin significantly reduced the plasma salicylate levels at 0.5 hr, whereas the levels after 1.5 hr were enhanced significantly. Simultaneous administration of caffeine with aspirin significantly reduced plasma salicylate levels at 1.5 hr after administration (Fig. 1*a*).

In the presence of aspirin, the plasma levels of acetaminophen (Fig. 1*b*) and caffeine (Fig. 1*c*) were decreased significantly in comparison to the levels following administration of the individual drugs.

Plasma and Gastric Tissue Concentrations during Absorption—*Plasma Levels*—The average plasma levels of salicylate, acetaminophen, and caffeine during their absorption are shown in Fig. 2 after administration of the individual drugs alone or in combination to rats.

In comparison with aspirin treatment alone, administration of mixtures of aspirin and acetaminophen and aspirin and caffeine resulted in significantly lower plasma salicylate levels during the first few minutes of absorption. However, at $t = 30$ min, the salicylate levels in the presence of caffeine equaled those after aspirin treatment alone; in the presence of acetaminophen, the plasma salicylate levels were enhanced at $t = 20$ and 30 min (Fig. 2*a*). With aspirin, the plasma levels of acetaminophen (Fig. 2*b*) and caffeine (Fig. 2*c*) were reduced significantly during absorption.

Concentrations in Glandular Gastric Tissue—The average concentrations of salicylate, acetaminophen, and caffeine in the glandular tissue of the rat stomach during absorption are presented in Fig. 3 after administration of the individual drugs alone or in combination.

Maximal concentrations of salicylate in the glandular gastric tissue were observed within 5–15 min after administration of aspirin (Fig. 3*a*). Simultaneous administration of acetaminophen with the aspirin tended to retard salicylate absorption, although statistically significant differences between the glandular tissue concentrations could be demonstrated only at $t = 15$ min. Coadministration of caffeine with aspirin did not affect the absorption of salicylate into the glandular tissue.

Acetaminophen (Fig. 3*b*) and caffeine (Fig. 3*c*) were rapidly absorbed into the glandular part of the rat stomach. In the presence of aspirin, the absorption of acetaminophen into the glandular tissue increased significantly whereas the absorption of caffeine was not affected.

During the absorption phase, the ratios of the glandular tissue concentration to the plasma concentration (Table I) remained almost constant for salicylate; for acetaminophen and caffeine, this ratio gradually decreased with time. Coadministration of acetaminophen did not influence the glandular tissue to plasma salicylate concentration ratio; conversely, this ratio for the acetaminophen concentration significantly increased in the presence of aspirin (Table I). Simultaneous administration of caffeine with aspirin tended to increase the concentration ratios for both drugs, although significant differences were observed only at $t = 15$ min for salicylate and at $t = 30$ min for caffeine.

Concentrations in Ruminal Gastric Tissue—The average concentrations of salicylate, acetaminophen, and caffeine in the ruminal tissue of the rat stomach during absorption are presented in Fig. 4 after administration of the individual drugs alone or in combination.

Table I—Mean Concentration Ratios (w/v) of Glandular Gastric Tissue to Blood Plasma following Oral Administration of Drugs and Drug Mixtures to Starved Rats (n = 8)

Treatment	Substance Determined	Time after Administration, min				
		5	10	15	20	30

	Acetaminophen	11.2[a]	10.5[a]	7.9[a]	15.9[a]	8.9[a]
Aspirin and caffeine, 250 and 50 mg/kg	Salicylate	7.0	4.5	4.2	4.4	4.1
	Caffeine	15.4	11.1	11.6[b]	11.0[b]	11.1[b]

[a] $p < 0.05$ compared to acetaminophen alone. [b] $p < 0.05$ compared to caffeine alone.

Table III—Mean Concentration Ratios (w/w) of Glandular Tissue to Ruminal Tissue of the Stomach following Oral Administration of Drugs and Drug Mixtures to Starved Rats (n = 8)

Treatment	Substance Determined	Time after Administration, min				
		5	10	15	20	30
Aspirin, 250 mg/kg	Salicylate	1.6	1.5	1.6	1.6	1.6
Acetaminophen, 125 mg/kg	Acetaminophen	3.5	2.5	2.2	1.4	1.6
Caffeine, 50 mg/kg	Caffeine	2.4	1.6	1.3	1.1	0.8
Aspirin and acetaminophen, 250 and 125 mg/kg	Salicylate	1.7	1.6	1.0	1.4	1.5
	Acetaminophen	4.9	3.4	2.3	2.1	1.7
Aspirin and caffeine, 250 and 50 mg/kg	Salicylate	1.8	1.9	1.9	1.6	1.8
	Caffeine	2.6	1.4	1.1	1.0	0.9

Aspirin administration, alone as well as in combination with acetaminophen or caffeine, resulted in comparable ruminal salicylate concentrations, which remained constant during the absorption phase (Fig. 4*a*). As in the glandular tissue, the absorption of acetaminophen into the rumen (Fig. 4*b*) was increased significantly in the presence of aspirin whereas the absorption of caffeine (Fig. 4*c*) was not affected.

The ratio of the ruminal tissue concentration to the plasma concentration (Table II) remained almost constant for salicylate and acetaminophen throughout the absorption phase; for caffeine, this ratio gradually decreased with time. The concentration ratios for salicylate were not affected by coadministration of acetaminophen or caffeine; on the other hand, aspirin enhanced the concentration ratios for both acetaminophen and caffeine (Table II).

Glandular Tissue to Ruminal Tissue Concentration Ratios—Table III shows the average glandular tissue to ruminal tissue concentration ratios for salicylate, acetaminophen, and caffeine during their absorption following administration of the individual drugs alone or in combination.

Regardless of whether the drugs were administered separately or in combination, the absorption of all drugs into the glandular tissue was higher than into the rumen. In particular, acetaminophen showed marked accumulation in the glandular tissue. Administration of the drug combinations did not affect the accumulation of the individual drugs in the glandular tissue.

DISCUSSION

Analytical Procedure—The assay used for aspirin and salicylic acid was a modification of earlier methods (12–16). By making derivatives of aspirin and salicylic acid with pure bis(trimethylsilyl)trifluoroacetamide under controlled conditions, more reproducible results were obtained in comparison with methods where the derivatizing agent was diluted with carbon disulfide (12) or acetone (15). With the temperature programming used, an acceptable separation of the desired compounds was obtained from endogenous compounds in plasma and gastric tissue homogenates. Care had to be taken during evaporation of the organic solvent to prevent sublimation (76°) of the aspirin and salicylic acid.

Many stationary phases, such as FFAP (17), OV-1 (18), SP 2250 (19), and OV-17 (20), can be used for the GLC determination of acetaminophen. Because an assay was needed that also could be used in investigations with phenacetin, one assay for both compounds was developed; the use of *p*-bromoacetanilide as an internal standard (21, 22) and an OV-101 column gave the best quantitative results.

Several previous investigations (23–25) involved the determination of caffeine in plasma; none of these reports described a method suitable for tissues. In the present assay, an OV-101 column (24) was used because with an OV-17 column (25) and hexobarbital and phenacetin as internal standards, both compounds gave broad tailing peaks. Extracting caffeine with dichloromethane instead of chloroform (24, 25) rendered the procedure more convenient and less hazardous.

Glandular Accumulation—One theory explaining the gastric toxicity of aspirin assumes an association between its erosive activity and its toxic intracellular actions after absorption (3, 26). Although orally administered aspirin is absorbed mainly from the small intestine (27), considerable amounts also are absorbed *via* the stomach (28). Under the acidic conditions present in the stomach, aspirin (pKa 3.5) is mainly undissociated, which facilitates diffusion of the drug molecules across membranes. In mucosal cells, aspirin is likely to be hydrolyzed to salicylic acid (29), and this compound exists predominantly in an ionized form in the cells (pH ~7.4). Because the back-diffusion of salicylate ions across membranes is very slow, high intracellular concentrations of salicylate rapidly accumulate (30, 31). If sufficiently high concentrations are reached, mitochondrial oxidative phosphorylation is uncoupled, resulting in cessation of synthetic and transport activities in the cell and possibly leading to a reduction in transmucosal resistance (32). However, not all cell types of the gastric mucosa appear to be equally susceptible to damage since erosions induced with aspirin are found only in the glandular part of the rat stomach. Recently, Brune *et al.* (5) showed that the

parietal cells in the glandular mucosa trap salicylate to an excessive extent. It is possible that gastric mucosal damage induced with aspirin starts with the decay of these cells.

In the present study, the salicylate concentrations reached in the glandular tissue during aspirin absorption were higher than those in the rumen (Table III). The concentrations reached in the gastric mucosa depend on the presence of the drug within the stomach lumen since lower levels are obtained in the mucosa after subcutaneous administration of aspirin (33). Acetaminophen (pKa 9.5) and caffeine (pKa 13.2) also accumulated in the glandular tissue after oral administration, to an even larger extent than salicylate (Table III). The fact that acetaminophen and caffeine do not induce gastric erosions (6) might indicate that the intracellular action of these compounds differs from that of salicylate. Thus, accumulation of a drug in glandular tissue *per se* does not account for erosive activity. However, since the erosions are found only in the glandular part of the stomach, in which the highest concentrations of salicylate were reached, an involvement of salicylate accumulation in glandular tissue in the pathogenesis of aspirin-induced erosions cannot be ruled out.

Throughout the absorption period after aspirin treatment, salicylate concentrations in the glandular and ruminal areas of the stomach were not significantly affected by simultaneous administration of either acetaminophen or caffeine (Figs. 3*a* and 4*a*). Only in the group of rats killed after 15 min did salicylate levels in the glandular tissue tend to decrease in the presence of acetaminophen. However, in view of the large number of different observations made at various time points, the possibility that one mean is (significantly) lower by chance is not inconceivable. In any case, the concentrations of salicylate still achieved values of 6–10 μmoles/g in the presence of acetaminophen. Exposure of the gastric mucosa to similar concentrations of salicylate, both *in vitro* (34, 35) and *in vivo* (36, 37), is associated with changes in its electrophysiological properties and permeability characteristics. Furthermore, oral administration of aspirin (50 mg/kg), leading to salicylate concentrations in gastric tissue of 1–2 μmoles/g (33), still causes gastric erosions (6). Hence, it is unlikely that this slight reduction in salicylate accumulation in glandular tissue accounts for the inhibition of the erosive activity of aspirin by acetaminophen.

In the presence of aspirin, the absorption of acetaminophen into the gastric tissues increased (Figs. 3*b* and 4*b*), and this increased absorption might have affected prostaglandin biosynthesis in the gastric wall. According to Vane (38), inhibition of prostaglandin biosynthesis in the gastric mucosa by aspirin-like drugs at least contributes to the formation of gastric erosions. In addition, coadministration of prostaglandins protects the gastric mucosa against irritation by aspirin (39). Therefore, the observation of Robak *et al.* (40) that acetaminophen, in concentrations similar to those measured in blood plasma, stimulates prostaglandin synthetase activity *in vitro* might be important. As a result of its (increased) accumulation, acetaminophen might protect against the erosive activity of aspirin by counteracting the aspirin-induced inhibition of prostaglandin biosynthesis in the glandular part of the stomach.

Blood Plasma Concentrations—The combination of acetaminophen with aspirin retarded the appearance of salicylate in plasma (Fig. 2*a*), and the plasma salicylate levels were enhanced during elimination. A possible explanation for the latter observation might be competition of aspirin with acetaminophen for the glucuronide-forming enzyme system. Such a metabolic interaction between salicylate and acetaminophen could not be demonstrated in humans (41) or rats (42). However, in these studies, considerably lower doses of both drugs were used compared to those used in the present study. In both previous reports (41, 42), the investigators indicated that such an interaction at higher doses may be possible.

The combination of aspirin with acetaminophen appeared to reduce the acetaminophen absorption rate (Fig. 2*b*), an observation that has been reported for the rat (43), guinea pig (44), hamster (45), and mouse (46). Presumably, this retardation is related to the rate of gastric emptying. In this context, Smith and Irving (47) reported that salicylate administered to rats reduced the gastric emptying rate, and it was demonstrated recently that reduction of the gastric emptying rate reduced acetaminophen absorption (48–50). The increment in the acetaminophen concentrations in the glandular and ruminal areas of the stomach corroborates this assumption. After coadministration with aspirin, the elimination rate of acetaminophen from plasma was lower than that of acetaminophen given alone (Fig. 1*b*). This phenomenon might be due to retardation of the acetaminophen absorption and/or to an aspirin-induced decrease in the elimination rate of acetaminophen (43).

Administration of aspirin with caffeine retarded the appearance of both drugs in plasma (Figs. 2*a* and 2*c*). This effect probably is due to a delay in gastric emptying since both caffeine and aspirin relax GI smooth muscles (51, 52). Since simultaneous administration of aspirin and caffeine did not affect the concentrations of either of these drugs in the gastric wall (Figs. 3*a*, 3*c*, 4*a*, and 4*c*), the appearance of salicylate and caffeine in plasma probably depends mainly on absorption from the small intestine and not on absorption from the stomach.

In summary, neither the inhibition by acetaminophen nor the potentiation by caffeine of aspirin-induced erosions in the rat stomach can be attributed to effects of these drugs on salicylate accumulation in glandular mucosa. Furthermore, since simultaneous administration of these drugs to the rat influenced their mutual rates of absorption and elimination, the pharmacological efficacy of the mixtures cannot be predicted simply from the plasma levels of the components.

Rearrangement of Chloramphenicol-3-monosuccinate

D. A. BRENT *x, P. CHANDRASURIN *, A. RAGOUZEOS *, B. S. HURLBERT *, and J. T. BURKE ‡

Received July 19, 1979, from the **Wellcome Research Laboratories, Burroughs Wellcome Co., Research Triangle Park, NC 27709*, and the ‡*School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication March 7, 1980.

Abstract □ The equilibrium mixture of chloramphenicol-3-monosuccinate and its alternate form at neutral pH in aqueous solution was reexamined. The structure of the alternate form was shown by mass spectrometry and NMR spectroscopy to be chloramphenicol-1-monosuccinate and not the cyclic hemi-ortho ester reported previously.

Keyphrases □ Chloramphenicol-3-monosuccinate—identification of alternate form in equilibrium mixture as chloramphenicol-1-monosuccinate □ Antibacterials—chloramphenicol, identification of 1-succinate ester as alternate form in equilibrium mixture with 3-succinate ester □ Prodrugs—chloramphenicol-3-monosuccinate, identification of 1-succinate ester as alternate form in equilibrium mixture with 3-succinate ester

The sodium salt of chloramphenicol-3-monosuccinate[1] (III) is used as a prodrug, generating the broad spectrum antibiotic chloramphenicol by hydrolysis of the succinate ester in the liver (1). Sandmann *et al.* (2) reported that at neutral pH, III exists in equilibrium with a different molecular form, which they identified as a cyclic hemi-ortho ester (II) (Scheme I).

RESULTS AND DISCUSSION

By using a recently developed, sensitive, high-pressure liquid chromatographic (HPLC) assay for III, three products were detected after equilibrating III in aqueous solution at pH 7.5 for 24 hr (3). The first and third peaks (Fig. 1) were identified as chloramphenicol and III, respectively, by comparison with standards and by mass spectrometry of their trimethylsilyl ethers. The mass spectrum of the trimethylsilyl derivative of the first HPLC peak agreed with spectra published for *O*-bis(trimethylsilyl)chloramphenicol (4–6). The mass spectrum of the trimethylsilyl derivative of the third HPLC peak gave ions consistent with IV: *m/e* 551 (2.6%, M − CH_3), 483 (0.6), 377 (2.92), 225 (75.6), 224 (28.9), 173 (25.2), and 73 (100.0).

The second eluted compound exhibited an NMR spectrum identical to that reported by Sandmann *et al.* (2) for II. However, the mass spectrum of the trimethylsilyl derivative of this compound supported the structure of chloramphenicol-1-monosuccinate (I) and not the cyclic hemi-ortho ester (II). The ion having the greatest mass was *m/e* 551 (1.7%,

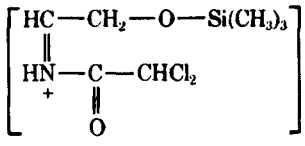
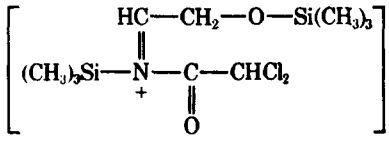
IV (mol. wt. 566)

M − CH_3). The base peak was *m/e* 73. The accurate masses of *m/e* 551 (2.7%), 242 (10.6), and 314 (4.57) were measured by peak matching at 10,000 resolution and 10% valley definition; their accurate masses were 551.0838, 131.0161, and 314.0569, respectively. The corresponding elemental compositions are $C_{20}H_{29}Cl_2N_2O_8Si_2$ (error of 0.1 millimass unit), $C_7H_{14}Cl_2NO_2Si$ (1.0), and $C_{10}H_{22}Cl_2NO_2Si_2$ (0.3). These peaks are consistent with bis- and tris(trimethylsilyl) derivatives of I. The mass spectrum supports the structure of I, but it is unclear whether the derivatizing reagent, which contains a weak base, could cause II to rearrange to I prior to silylation.



m/e 242



m/e 314

The evidence reported for the alternate form of III, having the structure denoted as II, was reexamined to determine if it really excluded the possibility of this product being I. Sandmann *et al.* (2) reported that chemical evidence indicated that the O→O migration product was incapable of existence in equilibrium under experimental conditions, but they did not describe experiments to prove this point. Within the knowledge of the present investigators, I never has been synthesized. The IR spectrum of III shows three distinct carbonyl absorptions (1690, 1718, and 1745 cm^{-1}), but only two absorptions (1690 and 1745 cm^{-1}) were shown for the alternate form (2). Sandmann *et al.* (2) concluded that this result was due to loss of the ester carbonyl. However, the band at 1718 cm^{-1} is likely the acid carbonyl, which has coalesced with one of the two remaining carbonyl bands or has shifted to 1600 cm^{-1} if it is in the form of a carboxylate anion (7). The optical rotatory dispersion curve for III shows a positive Cotton effect, while the curve for the alternate form shows a negative Cotton effect (2). The optical rotatory dispersion curves for O^1-acetylchloramphenicol-3-monosuccinate and O^1-dichloroacetylchloramphenicol-3-monosuccinate show negative Cotton effects

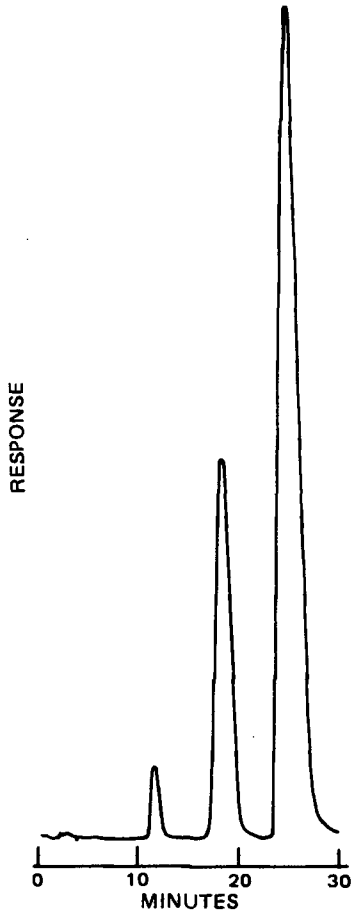


Figure 1—*High-pressure liquid chromatogram of the equilibrium mixture of I. The pH of the mobile phase was 2.5.*

(2). This evidence, used to support Structure II, also supports Structure I.

Sandmann *et al.* (2) reported that attempts to methylate the alternate form of III resulted in complex mixtures. In the present investigation, methylation of the alternate form with diazomethane in ether gave methyl esters of III and I if the reaction was allowed to stand with excess diazomethane. If the diazomethane was added and followed immediately by the addition of acetic acid, only the methyl ester of I resulted. These reactions were followed by HPLC and NMR. The NMR parameters of these products are shown in Table I.

One key factor causing Sandmann *et al.* to assign the alternate form of III as II was the absence of a hydroxylic proton in the NMR spectrum (2). As shown in Table I, this proton is visible in the NMR spectrum of the methyl ester of the alternate form taken in dimethyl sulfoxide-d_6. Furthermore, the downfield shift for H-1 of the alternate form compared with its shift in III is attributed to ester formation at C-1. Whereas ester formation at C-1 should cause such a shift, hemi-ortho esters should shift in the opposite direction, *e.g.*, HCO_2CH_3, δ CH_3 = 3.79; $HOCH_3$, δ CH_3 = 3.47; and $HC(OCH_3)_3$, δ CH_3 = 3.33 (8). None of the NMR data reported previously (2) supports arguments against Structure I as the alternate form of III. In addition, the stability of a hemi-ortho ester (9)

Table I—Proton Chemical Shift Values (Parts per Million) for the Methyl Esters of I and III

Proton	Methyl Ester of I		Methyl Ester of III	
	Chloroform	Dimethyl Sulfoxide-d_6	Chloroform	Dimethyl Sulfoxide-d_6
Phenyl C-3 and C-5 2H	8.18–8.30 m	8.175, 8.27	8.18–8.30 m	8.155–8.24
Phenyl C-2 and C-6 2H	7.54–7.60 m	7.565, 7.65	7.54–7.66 m	7.61–7.695
NH	7.00–7.20 m	8.62 d (J = 9 Hz)	(7.0–7.2)	8.55 d
C-1 H	6.29 d (J = 6.5 Hz)	6.02 d (J = 5 Hz)	5.14 br s	5.05 br s

Amide-2 ($CHCl_2$)	66.43 (d)	66.24 (d)	66.37 (d)
Succinyl C-1 (CO_2R)		171.84 (s)	171.18 (s)
Succinyl C-2 (CH_2)		28.60 (t)	28.80+ (t)
Succinyl C-3 (CH_2)		28.60 (t)	28.53+ (t)
Succinyl C-4 (CO_2H)		173.29 (s)	173.21 (s)

[a] Obtained in dimethyl sulfoxide-d_6; values are in parts per million from tetramethylsilane; letters in parentheses refer to peak character in off-resonance decoupled spectrum (s, singlet; d, doublet; and t, triplet). [b] The *, + indicate that these pairs of assignments may be reversed.

under the conditions used to isolate II by Sandmann *et al.* is questionable.

Finally, ^{13}C-NMR (a technique unavailable to Sandmann *et al.* at the time of their investigation) was used to verify the structure of I. The carbon chemical shifts of chloramphenicol and its two succinate derivatives are shown in Table II. The peaks near 163.5 and 66.3 ppm are consistent through the three spectra and are assigned as the carbonyl and methine carbons of the dichloroacetamide moiety, respectively. These shifts are quite consistent with shifts reported by Stothers (10) of 169.7 and 63.8 ppm for dichloroacetic acid and 165.0 and 69.7 ppm for dichloroacetyl chloride.

The assignment of the phenyl carbon shifts for the compounds of this study is based on the shifts of the equivalent carbons of *p*-nitrostyrene (C-1 = 143.6, C-2 and C-6 = 126.0, C-3 and C-5 = 123.1, and C-4 = 146.5 ppm) reported by Dhami and Stothers (11). The upfield shift of C-1 of the phenyl group of I relative to the other two compounds is due to the greater substitution at C-1 of the side chain in I. The assignments of C-1, C-2, and C-3 of the side chain are based on chemical shift and off-resonance decoupling results. The 2-carbon is at the highest field and shows a slight upfield shift on acylation (γ-substitution) at either C-1 or C-3. The 3-carbon is a triplet under off-resonance decoupling conditions. The 1- and 3-carbons show the expected downfield shifts on acylation. The succinyl moiety is assigned on the basis of the succinic acid shifts (CH_2 = 30.0 and CO_2H = 176.4 ppm) reported by Stothers (10). The carboxyl carbons are assigned at a lower field than the ester carbons, as is normally the case.

Most pertinent to the central argument of this paper are the shifts of the succinyl ester carbons at 171.84 and 171.18 ppm. The great similarity of these shifts argues that I is a normal ester, as is III. Furthermore, although reports of chemical shifts for hemi-ortho esters such as II are very rare due to their chemical instability, two such compounds are reported (12) as having shifts of a hemi-orthoacetate carbon at 77.1 ppm. This field shift is surprisingly high and may not be typical, but the ortho ester carbon of ethyl orthoformate absorbs at 112 ppm and those of two orthoacetates absorb at 118.1 and 119.5 ppm (12). It is unreasonable to suppose that the hemi-ortho ester carbon of II absorbs at 171 ppm, which is typical of a normal ester carbonyl carbon.

EXPERIMENTAL

Materials—The equilibrium mixture of III and its alternate form was obtained by dissolving 600 mg of chloramphenicol-3-monosuccinate[2] in 3 ml of water, adjusting the pH to 7.5 with 0.1 *N* NaOH, and allowing the resulting solution to stand at ambient temperature overnight.

Equipment—HPLC was carried out using a reversed-phase column[3] coupled to a UV detector[4] set at 254 nm.

Both the double-focusing mass spectrometer[5] and the NMR spectrometer[6] were coupled to data systems.

Procedures—One hundred microliters of the equilibrium mixture was injected onto the preparative reversed-phase column[5]. The components of the mixture were separated by isocratic elution using 0.01 *M* NaH_2PO_4–40% acetonitrile (final pH adjusted to 2.5 with phosphoric acid) as the mobile phase. A flow rate of 1 ml/min was used for analytical runs, and a rate of 2 ml/min was used for preparative runs. The eluate for each component was extracted with ethyl acetate and dried with magnesium sulfate. The volume of ethyl acetate was reduced by rotary evaporation, and the products were stored at −10° under a nitrogen atmosphere until they were analyzed.

Methylations were carried out by reaction with excess diazomethane[7] in ether. Trimethylsilylation was accomplished by adding 200 μl of *N,O*-bis(trimethylsilyl)acetamide in dimethylformamide[8] (2.5 mg/ml) to a solution of the target compound in acetonitrile.

High-Pressure Liquid Chromatographic Assay for Chloramphenicol, Chloramphenicol-3-monosuccinate, and Chloramphenicol-1-monosuccinate

J. T. BURKE *, W. A. WARGIN *x, and M. R. BLUM ‡

Received July 19, 1979, from the **School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514*, and the ‡*Wellcome Research Laboratories, Burroughs Wellcome Co., Research Triangle Park, NC 27709.* Accepted for publication November 30, 1979.

Abstract □ A high-pressure liquid chromatographic method for the sensitive and rapid determination of chloramphenicol, chloramphenicol-3-monosuccinate, and chloramphenicol-1-monosuccinate is presented. The procedure utilizes a reversed-phase chromatographic column with UV absorption detection. The assay is useful for monitoring patients receiving chloramphenicol, determining the pharmacokinetics of parenteral chloramphenicol sodium succinate, and certifying sterile chloramphenicol sodium succinate.

Keyphrases □ Chloramphenicol—simultaneous high-pressure liquid chromatographic assay with chloramphenicol-3-monosuccinate and chloramphenicol-1-monosuccinate □ High-pressure liquid chromatography—analysis, chloramphenicol, chloramphenicol-3-monosuccinate, and chloramphenicol-1-monosuccinate □ Antibiotics—chloramphenicol, simultaneous high-pressure liquid chromatographic assay with chloramphenicol-3-monosuccinate and chloramphenicol-1-monosuccinate

Chloramphenicol, a broad spectrum antibiotic, is available for parenteral administration as the sodium salt of the 3-monosuccinate ester[1]. This prodrug is biologically inactive and must be converted to chloramphenicol base by hydrolysis of the ester in the liver (1). Glazko *et al.* (2) reported that ~30% of a dose administered to normal adults is excreted unhydrolyzed in the urine. Consequently, impaired renal and/or hepatic function may affect the bioavailability of active chloramphenicol when administered parenterally as the sodium succinate salt.

Chloramphenicol-3-monosuccinate (III) exists in equilibrium with chloramphenicol-1-monosuccinate (I) at pH values near neutrality (3) (Scheme I). A colorimetric assay (4) for the simultaneous measurement of chloramphenicol and chloramphenicol succinate is tedious and lacks specificity. Numerous chromatographic methods have been developed for determining chloramphenicol in biological fluids (5–14), but none included the quantification of chloramphenicol succinate. The current Food and Drug Administration spectrophotometric assay for certifying chloramphenicol sodium succinate for injection (15) does not differentiate among chloramphenicol, III, and I. This paper presents a high-pressure liquid chromatographic (HPLC) method that allows the simultaneous quantification of these compounds.

EXPERIMENTAL

Materials—Reagent grade acetic acid[2], sodium acetate[3], deionized water, and HPLC grade acetonitrile[3] were used to prepare the mobile phase. Pure chloramphenicol[4] and chloramphenicol-3-monosuccinate[5] (III) were dissolved in ethyl acetate[3] to prepare the standard solutions. The internal standard solution was benzocaine[6] in methanol[3] (0.06 mg/ml). Trichloroacetic acid[3] (30%) was used for protein precipitation.

Instrument Conditions—The liquid chromatograph[7] was equipped with a variable-wavelength UV detector. The effluent was monitored at 275 nm with 0.05 aufs. An integrator[8] and a recorder[9] were used to monitor the detector output. A reversed-phase column[10] (25 cm long × 4 mm i.d.) was maintained at 50°. The mobile phase consisted of a 22% solution (v/v) of acetonitrile in 0.05 *M* sodium acetate. The pH of the final solution was adjusted to 5.7 with acetic acid. The flow rate was 1.25 ml/min.

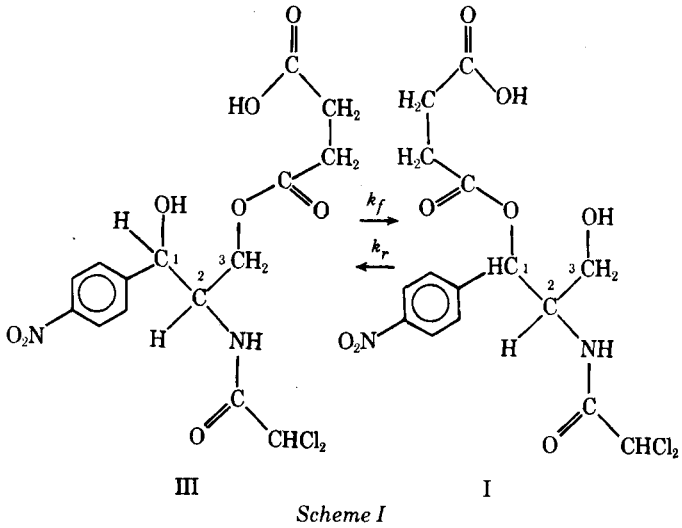
Determination of Equivalence of Molar Absorbance of I and III—A 0.05 *M* phosphate buffer adjusted to pH 7.4 was used to prepare 13 1.0-ml samples of 9.08×10^{-5} *M* III. Immediately after preparation, the samples were incubated at 37° for various periods. The internal standard (50 μl) was added to the sample at the end of the incubation, and a 90-μl portion was injected immediately onto the high-pressure liquid chromatograph.

A standard curve for III and chloramphenicol was prepared in a 0.05 *M* phosphate buffer at pH 4.0. The concentrations of III, I, and chloramphenicol were determined by relating the peak area ratios of the unknowns to the internal standard and comparing them to the standard curves. The standard curve for III was used to quantitate III and I. The apparent first-order forward, k_f, and reverse, k_r, rate constants describing the equilibrium between III and I (Scheme I) were estimated using the NONLIN program (16) with the following equations and unweighted data:

$$A = \frac{A_0 k_r}{k_f + k_r} + \frac{A_0 k_f}{k_f + k_r} e^{-(k_f + k_r)t} \qquad \text{(Eq. 1)}$$

$$B = \frac{A_0 k_f}{k_f + k_r} - \frac{A_0 k_f}{k_f + k_r} e^{-(k_f + k_r)t} \qquad \text{(Eq. 2)}$$

$$K_{eq} = \frac{k_f}{k_r} \qquad \text{(Eq. 3)}$$



III ⇌ I

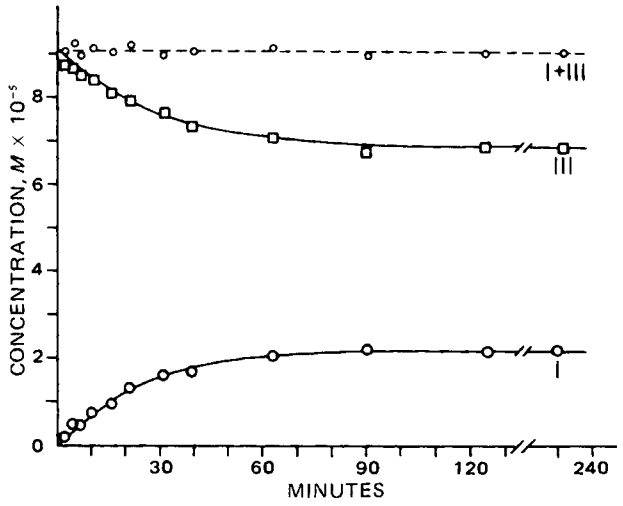

Figure 1—*Rearrangement of III to I in pH 7.4 phosphate buffer at 37°*

where A is the concentration of III, B is the concentration of I, and A_0 is the concentration of III at $t = 0$.

Quantitation of III, I, and Chloramphenicol in Biological Fluids—Blood samples treated with ethylenediaminetetraacetic acid were placed immediately in an ice bath. The plasma was separated and adjusted to pH ~4 by the addition of 20 μl of 4 *N* HCl/ml of plasma. A 250-μl sample was transferred to a 15-ml conical glass tube. The internal standard (25 μl) was added immediately before precipitation with 50 μl of a 30% solution of trichloroacetic acid. The sample was vortexed for 10 sec and then centrifuged for 10 min at 2500 rpm. A portion of the supernate (90 μl) was injected.

Urine samples were centrifuged to remove the sediment and diluted to concentrations of 1:100–1:500. The internal standard (25 μl) was added to 250 μl of the diluted urine sample, and 90 μl then was injected. Plasma standards containing III and chloramphenicol were prepared for each patient using a quantity of his own acidified plasma (pH 4.0). Phosphate buffer (pH 4.0) was used to prepare standards for urine assays.

Stability of III in Plasma—Two portions of fresh human plasma were adjusted to pH 4.0 and 7.4, respectively, and were used to prepare 250-μl samples containing 61.1 μg of III/ml[11]. Sets of plasma samples adjusted to pH 7.4 were incubated at 37, 25, and 0°. The pH 4.0 plasma samples were incubated at 25 and 0°. The concentrations of I, III, and chloramphenicol were determined at 0.5, 1.0, 2.0, 6.0, 12.0, and 24.0 hr.

Effect of Plasma Protein Concentration on Drug Recovery for Assay—Plasma samples from three normal volunteers were each diluted with normal saline to prepare 1:0, 3:1, 1:1, 1:3, and 0:1 dilutions (plasma to normal saline). The pH of each solution was adjusted to 4.0 with 4 *N* HCl and then spiked with 25 μg of chloramphenicol/ml and 19.1 μg of III/ml. Then 100 μl of trichloracetic acid (30%) was added to 0.5-ml samples of each solution. The samples were vortexed for 10 sec and centrifuged for 10 min at 2500 rpm.

A portion of the supernate (250 μl) was transferred to a 15-ml conical glass tube. The internal standard (25 μl) was added to the supernate, the sample was vortexed for 10 sec, and a portion of the supernate (90 μl) was injected. The absolute recoveries of both drugs at the 1:0, 3:1, 1:1, and 1:3 dilutions were determined by relating the peak area ratios of the drugs to the internal standard at these plasma dilutions to the peak area ratios obtained from the 0:1 dilution.

Rearrangement of III to I in Plasma—Citrated human plasma adjusted to pH 7.4 was used to prepare 250-μl samples of 30.5 μg of III/ml. Immediately after preparation, the samples were incubated for various periods at 37°. At the end of the incubation, 50 μl of 30% trichloroacetic acid was added to the sample. The sample then was vortexed for 10 sec and centrifuged for 10 min at 2500 rpm. A portion of the supernate (90 μl) was injected onto the high-pressure liquid chromatograph. The peak area ratio of III to the sum of III and I was determined at the various time intervals. The rate constants for the equilibrium between III and I were estimated by the NONLIN program employing Eq. 1 with unweighted data.

[11] The concentrations of I and III are expressed as chloramphenicol equivalents. The relationship is such that 1.0 mg of the acid form of either ester will yield 0.7635 mg of chloramphenicol upon hydrolysis.

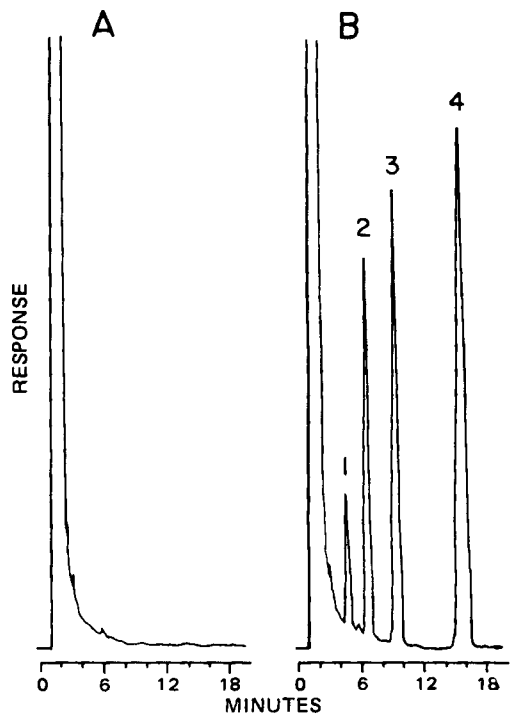

Figure 2—*Sample chromatogram for the assay in plasma. Key: A, blank plasma; B, spiked plasma; 1, I (4.4 μg/ml); 2, III (14.2 μg/ml); 3, chloramphenicol (13.7 μg/ml); and 4, benzocaine internal standard.*

RESULTS AND DISCUSSION

Determination of Equivalence of Molar Absorbance of I and III—The standard curve for the quantification of III also was used to quantitate I. Compound III is commercially available and is stable in crystalline form. Compound I, a pale-yellow oil at room temperature, is difficult to weigh accurately and transfer, rearranges to III under ambient conditions, and can be isolated only by preparative liquid chromatography or other suitable chromatographic methods. Although the technique of utilizing the standard curve for III to quantitate I and III offers numerous advantages, it is valid only if the molar absorptivities for I and III are equivalent for the specified instrument conditions.

The validity of this assumption was tested by measuring the concentrations of III and I as III rearranged to I. If the sum of the concentrations of I and III are constant utilizing a standard curve prepared from III to quantitate both I and III, then the molar absorptivities are equivalent. Figure 1 illustrates the rearrangement of III to I and the resulting equilibrium between the two compounds. The mean sum of the concentrations of I and III was $9.08 \pm 0.10 \times 10^{-5}$ *M* ($\pm SD$, $CV = 1.1\%$) for the 13 determinations. Since this value was constant within very narrow limits and showed no trend as the ratio of the concentration of the two compounds changed, no difference was detected in the molar absorptivities of I and III.

The assumption that the molar absorptivities of I and III are equivalent may not be valid for a different mobile phase or if the effluent is monitored at a different wavelength, although studies demonstrated that the molar absorptivities also were equivalent when the mobile phase pH was adjusted to 4.0 or 7.0. The technique also assumes that neither I nor III forms any other compounds during the sampling interval. The only other compound that could be detected was chloramphenicol, which formed slowly and amounted to only 0.19×10^{-5} *M* at the 230-min sample. This process was considered negligible for the purpose of evaluating the equivalence of the molar absorptivities of III and I.

Quantification in Biological Fluids—A typical chromatogram for the assay in plasma is presented in Fig. 2. Changes in the mobile phase pH had a dramatic effect on the retention times of III and I. Both I and III eluted before chloramphenicol when the mobile phase pH was 5.7 and after chloramphenicol when the mobile phase pH was 4.0. A summary of sample standard curves for chloramphenicol and III in plasma is presented in Table I. Three determinations were performed at each concentration. The intercepts for both standard curves were not significantly different from zero. Linear regression analysis of four-point standard curves for 14 patients demonstrated excellent correlation ($r^2 = 0.991$–1.000 for chloramphenicol and $r^2 = 0.998$–1.000 for III).

[a] (I)/[(I) + (III)].

Potential assay interference was investigated by adding the following drugs to plasma: phenytoin, aspirin, penicillin, ampicillin, cefazolin, cimetidine, oxacillin, theophylline, phenobarbital, isoniazid, gentamicin, ethambutol, probenecid, sulfamethoxazole, and trimethoprim. These compounds did not produce a chromatographic peak or did not have the same retention time as chloramphenicol. Trimethoprim interfered with the quantification of I.

Stability of III in Plasma—Tables II and III illustrate the effects of pH and temperature on the stability of III in plasma. The recovery was 61.3 ± 1.8 μg/ml (±*SD*) for these determinations. The results at physiological conditions confirm findings by previous investigators (1) that chloramphenicol succinate is not rapidly hydrolyzed by plasma esterases to chloramphenicol.

Since rearrangement of III to I proceeded rapidly at pH 7.4 and 25°, it was necessary to acidify plasma to pH 4.0 before preparing a standard curve for III. Optimal conditions to prevent the rearrangement involve placing plasma in an ice bath and acidifying the plasma to pH 4.0. The addition of 20 μl of 4 *N* HCl/ml of plasma is sufficient to lower the pH of plasma to ~4.0.

Both III and I were isolated from the plasma and urine of human subjects. Preparing biological samples to study the rearrangement of III *in vivo* or to study independently the pharmacokinetics of I and III poses certain problems. The best method of plasma preparation involves immediately placing blood samples on ice and separating the plasma in a refrigerated centrifuge. The samples then should be acidified as described previously while the plasma is still cooled to 0°.

Although I and III possess different chemical structures, the usefulness of studying the pharmacokinetics of these compounds independently is mitigated by the fact that the two compounds are in rapid equilibrium. Doses of chloramphenicol succinate contain approximately the same fraction of I that appears in human urine and plasma. An analysis of 13 doses of chloramphenicol succinate[12] prepared in a hospital pharmacy by dilution in 50 ml of 5% dextrose injection revealed that 20.0 ± 1.7% (±*SD*) of the dose existed as I immediately prior to administration. Doses were administered between 1 and 24 hr after preparation.

Effect of Plasma Concentration on Drug Recovery for Assay—The absolute recoveries for chloramphenicol and III were 63.0 ± 2.4 and 49.2 ± 2.3% (±*SD*), respectively, when the samples were prepared with 30% trichloroacetic acid. These relatively low recoveries were the result of drug binding to the denatured protein. The effect of protein concentration on the absolute recovery of chloramphenicol and III is illustrated in Fig. 3.

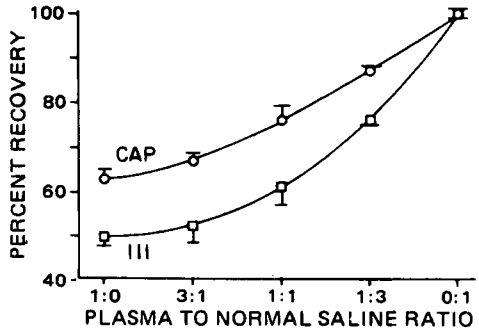

Figure 3—*Effect of protein concentration on drug recovery for assay for various ratios of plasma to normal saline (CAP = chloramphenicol).*

Table IV—Kinetic Parameters for the Rearrangement of III to I

Medium	k_f, min^{-1}	k_r, min^{-1}	$\frac{0.693}{k_f + k_r}$, min	K_{eq}	r^2
Buffer	0.0097	0.0297	17.6	0.327	0.990
Plasma	0.0285	0.0681	7.2	0.418	0.996

Although the absolute recovery for the trichloroacetic acid method is less than optimal, it is adequate for assaying chloramphenicol in the therapeutic range. It offers the advantage of minimal sample preparation time and produces cleaner solutions for injection than does organic solvent extraction. The major disadvantage to the trichloroacetic acid method is that the standard curve should be prepared from the plasma of the individual patient. This approach is preferable because quantitative and qualitative differences in the plasma protein composition might affect the absolute recovery of the compounds assayed.

Kinetics of Rearrangement of III to I—The kinetics of the rearrangement of III to I were studied *in vitro* in a phosphate buffer and plasma at physiological pH and temperature (Table IV). The apparent K_{eq} in the buffer was different from that in plasma (Fig. 4).

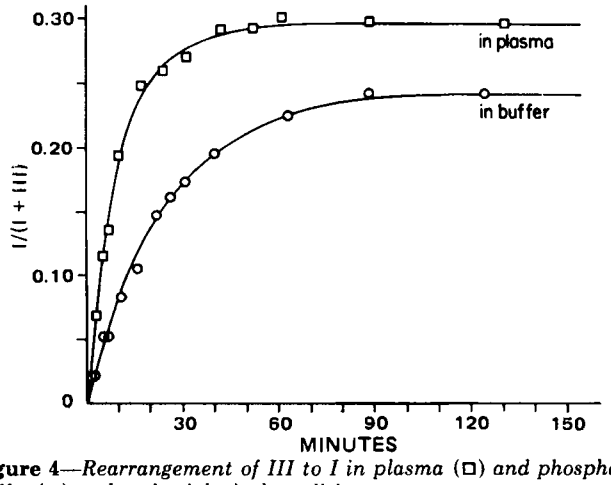

Figure 4—*Rearrangement of III to I in plasma (□) and phosphate buffer (○) under physiological conditions.*

[12] Chloromycetin Sodium Succinate, Parke-Davis Co.

The apparent K_{eq} in plasma may be greater because I is more extensively protein bound. It also may result from the use of trichloroacetic acid as a protein precipitant.

CONCLUSIONS

Chloramphenicol-3-monosuccinate (III) exists in rapid equilibrium with chloramphenicol-1-monosuccinate (I) under physiological conditions and in intravenous solutions prepared for administration. The analytical technique developed permits the quantification of chloramphenicol, I, and III in biological fluids and reconstituted commercial preparations. The methodology may be adapted for certifying chloramphenicol sodium succinate and offers advantages over the current FDA spectrophotometric method, which does not differentiate between these compounds. The analysis of I was simplified by demonstrating that I and III have similar molar absorptivities.

The results of previous investigators who reported that chloramphenicol succinate is not rapidly hydrolyzed by plasma esterases were confirmed. A rapid analytical technique is offered that will allow future studies of the effects of renal and hepatic disease on the pharmacokinetics and bioavailability of chloramphenicol sodium succinate.

Solubility and Partitioning I: Solubility of Nonelectrolytes in Water

SAMUEL H. YALKOWSKY ˣ **and SHRI C. VALVANI**

Received July 6, 1979, from the *Pharmacy Research Unit, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication March 17, 1980.

Abstract □ On the basis of a semiempirical analysis, an equation was obtained that enables the estimation of the aqueous solubility of either liquid or crystalline organic nonelectrolytes:

$$\log S_w \approx -1.00 \log PC - 1.11 \frac{\Delta S_f(MP - 25)}{1364} + 0.54$$

where log PC and ΔS_f are estimated from the chemical structure and MP is either known or experimentally determined. Analysis of this equation provides a means of assessing the role of crystal structure [as reflected by the melting point (MP) and the entropy of fusion (ΔS_f)] and of the activity coefficient [as reflected by the octanol–water partition coefficient (PC)] in controlling the aqueous solubility of a drug. Techniques are also provided for estimating the entropy of fusion of organic compounds.

Keyphrases □ Solubility—nonelectrolytes in water, estimation techniques □ Nonelectrolytes—estimation of solubility in water □ Aqueous solubility—nonelectrolytes, estimation techniques

Aqueous solubility has long been recognized as a key factor in controlling drug efficacy. Before an orally administered drug can become available to its receptor, it first must dissolve in the GI fluid. Both the dissolution rate and the maximum amount of drug that can be dissolved are governed by the solubility of the drug in the medium (1).

The design of orally active drugs must account for the effects of structural modifications on solubility. The lack of sufficient aqueous solubility often causes a drug to appear inactive or less active than some reference compound of a series. Aqueous solubility is a key factor in the design of parenteral and ophthalmic formulations, and it also is important in controlling taste. For these reasons, some appreciation of the relationship between aqueous solubility and chemical structure is needed.

THEORETICAL

In spite of the tremendous importance of aqueous solubility in pharmacy and other applied chemical disciplines, it is a poorly understood phenomenon. There are no generally useful guidelines for estimating the solubility of a substance in water from a consideration of its structure and physical properties. One reason that solubility of crystalline compounds has successfully defied attempts to make it predictable is that it is not a simple equilibrium but rather a combination of equilibria.

This report attempts to provide some guidelines for understanding the factors that govern aqueous solubility and for estimating the aqueous solubility of nonelectrolytes. Subsequent reports will deal with the estimation of the solubility of weak electrolytes.

Factors Influencing Aqueous Solubility—The aqueous solubility of a drug is governed by three major factors: (*a*) the entropy of mixing; (*b*) the difference between the drug–water (DW) adhesive interactions and the sum of the drug–drug (DD) and water–water (WW) cohesive interactions; and (*c*) the additional drug–drug interactions associated with the lattice energy of crystalline drugs, which are designated $\overline{DD}$ and are not applicable to liquids.

The entropy of mixing can be thought of as a force that favors complete

Keyphrases □ Solubility—nonelectrolytes in water, estimation techniques □ Nonelectrolytes—estimation of solubility in water □ Aqueous solubility—nonelectrolytes, estimation techniques

Aqueous solubility has long been recognized as a key factor in controlling drug efficacy. Before an orally administered drug can become available to its receptor, it first must dissolve in the GI fluid. Both the dissolution rate and the maximum amount of drug that can be dissolved are governed by the solubility of the drug in the medium (1).

The design of orally active drugs must account for the effects of structural modifications on solubility. The lack of sufficient aqueous solubility often causes a drug to appear inactive or less active than some reference compound of a series. Aqueous solubility is a key factor in the design of parenteral and ophthalmic formulations, and it also is important in controlling taste. For these reasons, some appreciation of the relationship between aqueous solubility and chemical structure is needed.

THEORETICAL

In spite of the tremendous importance of aqueous solubility in pharmacy and other applied chemical disciplines, it is a poorly understood phenomenon. There are no generally useful guidelines for estimating the solubility of a substance in water from a consideration of its structure and physical properties. One reason that solubility of crystalline compounds has successfully defied attempts to make it predictable is that it is not a simple equilibrium but rather a combination of equilibria.

This report attempts to provide some guidelines for understanding the factors that govern aqueous solubility and for estimating the aqueous solubility of nonelectrolytes. Subsequent reports will deal with the estimation of the solubility of weak electrolytes.

Factors Influencing Aqueous Solubility—The aqueous solubility of a drug is governed by three major factors: (*a*) the entropy of mixing; (*b*) the difference between the drug–water (DW) adhesive interactions and the sum of the drug–drug (DD) and water–water (WW) cohesive interactions; and (*c*) the additional drug–drug interactions associated with the lattice energy of crystalline drugs, which are designated $\overline{DD}$ and are not applicable to liquids.

The entropy of mixing can be thought of as a force that favors complete

0022-3549/80/0800-0912$01.00/0

© 1980, American Pharmaceutical Association

miscibility of all components. If $DD + WW - 2DW = 0$ for a liquid solute (*i.e.*, $\overline{DD} = 0$), the solubility is governed only by the entropy of mixing, which is assumed to be ideal. On a mole fraction scale, the ideal solubility of a liquid, X_i^l, is equal to unity and $\log X_i^l = 0$.

In general, the liquid interaction term and the crystal interaction term combine to reduce the aqueous solubility of most drugs by:

$$2.303RT \log X = -(DD + WW - 2DW) - \overline{DD} \qquad \text{(Eq. 1)}$$

If the material is crystalline, the crystalline interactions reduce the solubility by $\overline{DD} = -2.303RT \log X_i^c$, where X_i^c is the ideal solubility of a crystalline compound.

The difference between the adhesive and cohesive forces usually is described (2) by an activity coefficient for the drug in water, γ_w, by:

$$(DD + WW - 2DW) = 2.303RT \log \gamma_w \qquad \text{(Eq. 2)}$$

If the left side is equal to zero, γ_w must equal unity. If $DD + WW - 2DW > 0$, the solubility will be less than ideal. If $DD + WW - 2DW \gg 0$ (as usually is the case for nonelectrolytes in water), there usually will be less than total miscibility and the drug will have a finite solubility in water, X_w. These equations assume that there is no significant mutual miscibility of the drug and water phases. Therefore, *DD* and *WW* refer to the pure phases. A more sophisticated treatment would account for the fact that each phase contains some of the other phase. This treatment would have the effect of increasing *DD* and decreasing *WW*. Mathematically, X_w, X_i, and γ_w are related by:

$$\log X_w = \log X_i - \log \gamma_w \qquad \text{(Eq. 3)}$$

The greater the difference between the adhesive and cohesive forces, the greater is the deviation from ideality and, in general, the lower is the solubility.

If $DD + WW - 2DW = 0$ and the drug is crystalline, $\overline{DD}$ will cause the ideal mole fractional solubility to be less than unity. In most instances, both $DD + WW - 2DW$ and $\overline{DD}$ are greater than zero, so solubility is inhibited by a combination of the liquid interaction term, $\log \gamma_w$, and the crystal interaction term, $\log X_i$. To understand the aqueous solubility of crystalline drugs, it is necessary to consider these terms separately. This report will attempt to provide some insight into the dependence of these terms on chemical structure and, thereby, to present a means for their estimation and thus the estimation of the aqueous solubility of a variety of nonelectrolytes.

Ideal Solubility of Crystals—As already stated, the ideal solubility of a crystalline drug (*i.e.*, its solubility in an ideal solvent) is dependent only on the nature of the crystal. According to Hildebrand and Scott (2), the ideal solubility of a crystalline substance expressed as its mole fraction, X_i^c, is:

$$\log X_i^c = \frac{-\Delta H_f}{2.303R}\left[\frac{T_m - T}{T_m T}\right] + \frac{\Delta C_p}{2.303R}\left[\frac{(T_m - T)}{T} - \log \frac{T_m}{T}\right] \qquad \text{(Eq. 4)}$$

where ΔH_f is the molar heat of fusion of the solid; R is the gas constant; T_m and T are the absolute melting point and temperature of interest, respectively; and ΔC_p is the difference in heat capacity of the crystalline and molten forms of the drug. Since ΔC_p usually is quite small, and since $(T_m - T)/T$ is approximately equal to $\ln(T_m/T)$, the last term in Eq. 4 usually can be ignored without any significant loss in accuracy. Therefore, as a reasonable approximation, X_i^c can be approximated from T_m (°K), T (°K), and ΔH_f by:

$$\log X_i^c \simeq -\frac{\Delta H_f}{2.303RT_m}\frac{(T_m - T)}{T} \qquad \text{(Eq. 5)}$$

Both ΔH_f and T_m depend on the chemical structure of the solute, and both of these parameters tend to increase with increasing molecular weight and increasing polarity. However, these relationships have not proven to be amenable to estimation with any degree of reliability.

Since the free energy of fusion, ΔG, is equal to zero at the melting point, $\Delta H_f/T_m$ can be replaced with ΔS_f, where ΔS_f is the entropy of fusion. At 25 °C, Eq. 5 becomes:

$$\log X_i^c = -\frac{\Delta S_f}{1364}(T_m - 298) \qquad \text{(Eq. 6)}$$

For convenience, the difference in absolute temperatures can be replaced with the difference in centigrade temperatures:

$$\log X_i^c = -\frac{\Delta S_f}{1364}(MP - 25) \qquad \text{(Eq. 7)}$$

where *MP* is the melting point of the drug on the conventional centigrade scale.

The advantage of Eq. 7 over Eq. 5, in addition to its greater simplicity, is that ΔS_f is more understandable and more predictable than ΔH_f (1).

The real aqueous solubility of a crystalline drug, X_w^c, differs from the ideal solubility in the same manner as described for liquids. Thus:

$$\log X_w^c = -\frac{\Delta S_f}{1364}(MP - 25) - \log \gamma_w \qquad \text{(Eq. 8)}$$

From Eq. 8, it is apparent that the estimation of aqueous solubility requires the estimation of two parameters, ΔS_f and $\log \gamma_w$. The remainder of this report deals with the estimation of these parameters for nonelectrolytes and their application to the estimation of aqueous solubility.

EXPERIMENTAL

Entropies of Fusion—All entropies of fusion were calculated from the heats of fusion and melting points. These quantities were either obtained from the literature (3) or were determined experimentally on a differential thermal analyzer with a high-pressure differential scanning calorimeter cell[1]. The literature values were obtained at atmospheric pressure. The experimentally determined values were obtained at 500 psi as described by Martin *et al.* (4) to inhibit sublimation of the more volatile compounds. It was determined that this pressure had little or no effect on the entropy of fusion of nonvolatile compounds; thus, it was assumed that it had no effect on the entropy of fusion of the volatile crystals studied.

Reliable values for the entropy of fusion of three solids could not be determined experimentally. *p*-Aminophenol decomposed before melting, even under 1000 psi of nitrogen. Phthalic acid dehydrated upon melting to form phthalic anhydride. Terephthalic acid sublimed, even under 1000 psi of nitrogen, as evidenced by a coating of the compound around the inside of the calorimeter cell. However, this coating was insoluble in dilute sodium hydroxide and had the texture of a polymer, suggesting that some chemical change (possibly to a linear anhydride) occurred as well. Therefore, the data were excluded from the analysis.

Partition Coefficients—Octanol–water partition coefficients were calculated from the fragment constants, *f*, developed by Nys and Rekker (5) with the following modifications. Secondary and tertiary hydroxyl groups were given *f* values of −1.14 and −0.71, respectively. For the steroids, the experimentally determined values of Tomida *et al.* (6) were used. These values (which were determined under the same conditions as were used to determine the aqueous solubilities) were used because current methods of estimating partition coefficients are unreliable when applied to steroids.

Aqueous Solubilities—The aqueous solubilities of the various classes of compounds were obtained as follows.

The solubilities of halobenzenes were determined spectrophotometrically after equilibration for 24 hr and filtration through sintered glass as described by Yalkowsky *et al.* (7).

Alkyl *p*-aminobenzoate solubilities were determined in the manner described by Yalkowsky *et al.* (8).

The solubilities of polycyclic aromatic compounds were determined as described by MacKay and Shiu (9).

Steroid solubilities were determined as described by Tomida *et al.* (6).

The alcohol solubility data were obtained by averaging data from over 30 sources taken from a compilation[2] of solubility data.

Statistical Analysis of Data—Multiple regression analysis of the data was performed using standard statistical procedures.

RESULTS AND DISCUSSION

Estimation of Entropy of Fusion—In this section, a strictly geometric interpretation of the melting process will be utilized to provide a simple and easily understood means of estimating entropy. Since entropy is a state function, consideration of how the process occurs is not required. Only the initial and final states, *i.e.*, the crystal and the melt, are important. On a molecular level, the most obvious difference between these states is their relative degree of geometric order. The intermolecular distance, the packing arrangement, the orientation, and the conformation of crystalline molecules are held within a much narrower range in the crystal than for the liquid.

[1] DuPont model 910.

[2] S. H. Yalkowsky and S. C. Valvani, unpublished data.

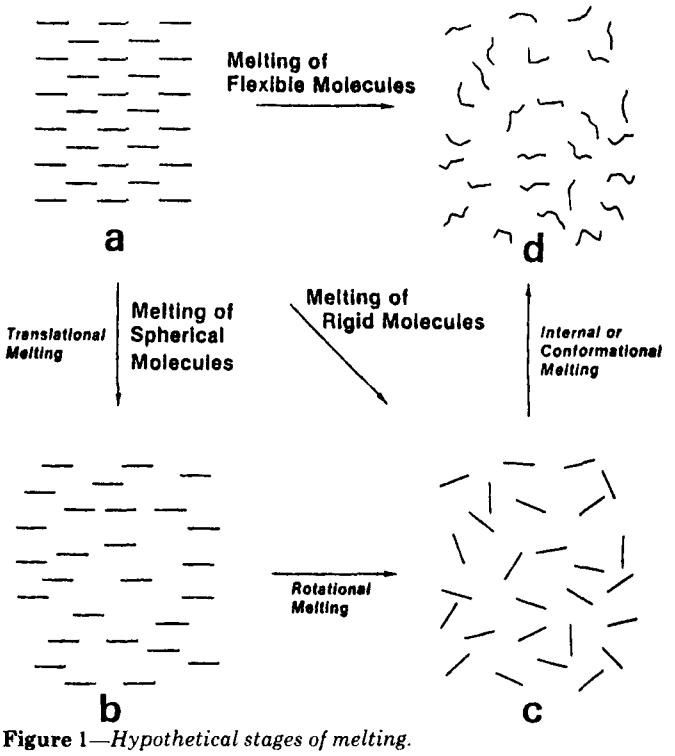

Figure 1—*Hypothetical stages of melting.*

For conceptualization, the melting process can be divided into three subprocesses (4):

1. Translational melting—the change from the ordered arrangement of the molecular centers of gravity in the crystal to the expanded and more randomized arrangement in the liquid.

2. Rotational melting—the change from the ordered arrangement of the major axes of crystalline molecules to the randomly oriented arrangement in the liquid. (This process is not applicable to spherical molecules.)

3. Internal melting—the change from the uniform conformation of flexible molecules of the crystal to the random conformation of such molecules in the liquid. (This process is not applicable to rigid molecules and, thus, to most drugs. However, it does become important for long chain molecules.)

These subprocesses are illustrated in Fig. 1. Since the total entropy is dependent only on the initial and final states, these processes can be treated for convenience as occurring sequentially. For spherical molecules, only translational melting can occur. For rigid nonspherical molecules, both translational and rotational melting exist. All three steps are applicable to the melting of flexible molecules, *i.e.*, those that can undergo conformational changes to an appreciable extent.

The geometrical entropy of a liquid, S_L, is related to the number of ways, W_L, in which its molecules can be arranged that would be consistent with the liquid state by $S_L = R \ln W_L$. Similarly, the geometrical entropy of a crystalline solid, S_c, is related to the number of ways, W_c, of arranging the molecules in the crystal by $S_c = R \ln W_c$. It is assumed that W_c is a subset of W_L; *i.e.*, the crystal arrangement is a special case of the more general, less constrained liquid arrangement.

The molar entropy of fusion, ΔS_f, is equal to the entropy of the liquid minus the entropy of the crystal:

$$\Delta S_f = S_L - S_c = -R \ln \left(\frac{W_c}{W_L}\right) = -R \ln P_f \qquad \text{(Eq. 9)}$$

where P_f is the ratio of the number of ways of achieving the crystal to the number of ways of achieving the liquid. It is equal to the probability (above the melting point) of a collection of 1 mole of liquid molecules spontaneously arranging themselves in such a way as to fulfill the geometrical requirements of the crystal. This quantity will be referred to as the total geometrical probability of fusion and is assumed to be equal to the product of the subprocess probabilities:

$$P_f = P_{trans} P_{rot} P_{int} \qquad \text{(Eq. 10)}$$

Since the entropies of the subprocesses are related to their probability of occurrence by equations analogous to Eq. 9, and since the probabilities are assumed to be multiplicative, the entropies must be additive:

$$\Delta S_f = \Delta S_{trans} + \Delta S_{rot} + \Delta S_{int} \qquad \text{(Eq. 11)}$$

Thus, the total entropy of fusion can be estimated from the probabilities of the component processes of fusion.

Translational Entropy of Fusion—The translational entropy of fusion can be visualized by a two-dimensional analogy. Consider a field of disks or checkers that have been trapped into a nearly closest packed arrangement (Fig. 1*a*) as representing a two-dimensional crystal. When this crystal melts, a slight expansion and a randomization of the positions of the disks occur (Fig. 1*b*). The probability of two-dimensional fusion taking place is equal to the number of arrangements of the disks that are possible within the area allotted for the solid divided by the much greater number of arrangements that are possible within the area allowed for the liquid. This, in turn, is related to the ratio of the areas available within each phase for the disks to occupy, *i.e.*, to the ratio of free areas. In a three-dimensional arrangement of molecules, the ratio of free volumes rather than free areas would be of concern.

As already stated, spherical molecules can gain only translational entropy when they melt. The entropies of fusion for spherical molecules such as the inert gases and for pseudospherical molecules such as methane and carbon tetrachloride usually fall within the range of 3–4 eu. A value of 3.5 eu can be considered as a reasonable approximation for the translational entropy of fusion of all molecules (although nonspherical molecules tend to have a somewhat larger volume change associated with fusion).

Rotational Entropy of Fusion—The rotational entropy of fusion is a component of the total entropy of fusion of all nonspherical molecules. For rigid molecules, it is the only term in addition to the translational entropy that needs to be considered. From the data in Tables I and II, it appears that most rigid aromatic molecules have entropies of fusion between 11 and 16 eu. This constancy of the entropy of fusion has been noted repeatedly in the literature (10–13) but has not been explained.

If it is assumed that the translational contribution to the entropy of fusion is ~3.5 eu, as noted earlier, then the rotational entropy of rigid aromatic molecules must be ~10 ± 3 eu.

An intuitive justification of the nearly constant rotational entropy of fusion is based on the following two assumptions:

1. In the crystal, the molecules (with their centers of mass fixed and accounted for by ΔS_{int}) can wobble or vibrate (~10° in the spherical coordinates ϕ and θ from their most stable position after averaging over all axes).

2. In the liquid, the individual molecules have much greater orientational freedom and can rotate over a much wider range of ϕ and θ.

The probability difference between the two degrees of rotational freedom can be evaluated easily by comparing the areas available to a point on the molecular surface in each phase, provided that the range of ϕ and θ in the two phases is known. If it is assumed for simplicity that a liquid molecule can rotate freely, any reference point will trace out a sphere about the center of gravity of the molecule. If the molecule is restricted orientationally, as it is in the crystal, the reference point will trace out only a spherical segment.

For example, the area of a spherical segment obtained by a ±10° variation in θ and ϕ is 0.00754 times that of a sphere of the same radius. Thus, the probability of n molecules being oriented within the allowed limits for crystallinity is 0.00754^n and the entropy contribution is $-k \ln 0.00754^n$ or ~10 eu. Similarly, the entropy associated with $\theta = \phi = 20°$ is 7 eu. Although the actual values of θ and ϕ probably will depend on the overall geometry of the molecules and their degree of interaction, the relative constancy of ΔS_f for rigid molecules suggests that the variation is not too large or, more likely, that factors inhibiting rotation in the liquid also inhibit rotation in the crystal.

The assumption of free rotation in the liquid is used only for mathematical convenience and probably is physically inappropriate in many cases. However, the entropy estimate is based on the ratio of areas available to the reference point in the two phases. If the liquid rotation is restricted, as it would be in highly elongated or hydrogen-bonded molecules, then the rotation in the solid also is more restricted for the same reasons. The constancy of the entropy of fusion of rigid molecules suggests that, in these cases, the ratio of the rotational freedom in the liquid to the solid is the same.

Pirsch (14, 15) suggested that elongated molecules have higher entropies of fusion; Bondi (10) postulated that, because of their restricted motion in the liquid, hydrogen-bonded molecules have lower entropies of fusion than their hydrocarbon homomorphs. These postulates are not supported by the data available for rigid molecules.

As can be seen in Table I, there is no systematic effect of hydrogen bonding on entropy of fusion. Specifically, the isomeric xylenes and their

corresponding dihydroxybenzenes have nearly identical entropies of fusion. The degree of substitution of the benzene ring does not have any systematic effect, as is evidenced by the data for the halobenzenes. Molecular size and shape also appear to have no effect on the entropy of fusion (for compounds larger than benzene).

Surprisingly, there is no systematic difference in entropy with respect to the position of substitution (Table I). The decreased rotational entropy of the more symmetrical compounds evidently is offset by the increased translational entropy that results from their greater packing efficiency. Highly prolate ellipsoids such as diphenyl, anthracene, and naphthacene and highly oblate ellipsoids such as hexamethylbenzene, hexachlorobenzene, and coronene all have entropies of fusion in the range discussed.

Internal Entropy of Fusion—The internal or conformational entropy of fusion results from the fact that molecular configuration is fixed invariably in the crystal but not in the liquid. For example, a molecule of stearic acid is likely to be found only in the *anti*-conformation in a crystal, whereas many bonds are likely to be *gauche* in the liquid.

If twist angles of only 60° (*gauche*), 180° (*anti*), and 300° (*gauche*) are possible and if these three angles are equally probable, then the probability of finding a long chain molecule in the completely outstretched conformation is equal to $(1/3)^{n-3}$, where n is the number of carbon and heteroatoms in the chain and $n - 3$ is the number of twist angles. The entropy associated with this probability is:

$$\Delta S_{int} = -R(n - 3) \ln (1/3) = 2.2(n - 3) \quad \text{(Eq. 12)}$$

For reasons discussed previously (16), the internal entropy of fusion is better approximated by $2.5(n - 5)$. Molecules having less than five units in a flexible chain can be treated as rigid molecules as a first approximation.

Total Entropy of Fusion—On the basis of the preceding discussion, the entropy of fusion is dependent primarily on molecular geometry. For spherical or nearly spherical molecules:

$$\Delta S_f = \Delta S_{trans} = 3.5 \text{ eu} \quad \text{(Eq. 13)}$$

For rigid molecules:

$$\Delta S_f = \Delta S_{trans} + \Delta S_{rot} = 13.5 \text{ eu} \quad \text{(Eq. 14)}$$

For molecules having $n > 5$ nonhydrogen atoms in a flexible chain:

$$\Delta S_f = \Delta S_{trans} + \Delta S_{rot} + \Delta S_{int} = 13.5 + 2.5(n - 5) \text{ eu} \quad \text{(Eq. 15)}$$

Some small nonspherical molecules have very small rotational entropies and thus have entropies of fusion falling between 3.5 and 13 eu. Fortuitously, these compounds, like spherical molecules, melt below room temperature and thus have ideal mole fractional solubilities of unity. In other words, the term involving ΔS_f is equal to zero.

Estimation of Ideal Solubility—The ideal room temperature solubility of the various classes of molecules can be calculated by simply inserting the entropy of fusion approximation into Eq. 7 to give:

$$-\log X_i = 0.01(MP - 25) \quad \text{(Eq. 16)}$$

for rigid nonspherical molecules and:

$$-\log X_i = [0.01 + 0.0018(n - 5)](MP - 25) \quad \text{(Eq. 17)}$$

for partially flexible molecules. The logarithms of the ideal solubilities of a wide variety of compounds calculated from experimentally measured entropies of fusion and from these approximations are listed in Table II. The two values rarely differ by more than 0.3 log unit (*i.e.*, by a factor of two). In fact, the solubility estimates frequently are better than the entropy estimates from which they were generated.

The high accuracy of this approach results in part because compounds that are more spherical or that are highly flexible and thus are likely to have the greatest error in ΔS_f estimation are compounds that tend to have low melting points, so the product $(MP - 25)\ \Delta S_f$ is small and thus does not contribute greatly to the calculation, *i.e.*, $\log X_i$ is near zero.

Statistical analysis of the calculated (from Eq. 7) and approximated (from Eq. 16 or 17) ideal solubilities of the compounds in Table II gives the following:

$$\log X_{calc} = 0.962 \log X_{estim} - 0.020 \quad \text{(Eq. 18)}$$

$$r = 0.96 \quad s = 0.16$$

Since the compounds considered were chosen previously (3) (*i.e.*, there was no subjective selection by the present investigators), this analysis probably can be regarded as an objective test of the relationships dis-

[a] All entropy values are expressed in entropy units.

cussed in this report. If so, Eq. 16 offers a 95% probability of estimating the ideal solubility of a substance to within a factor of two.

The contribution of increasing chain length to the internal entropy of fusion and to the ideal solubility is illustrated specifically for the alkyl *p*-aminobenzoates in Table III.

Experimentally, ideal solubilities can be demonstrated only for solutes in solvents of very similar polarity. The most convenient system for demonstrating the ideal solubility for solids is the aromatic and haloaromatic hydrocarbons in benzene. The observed solubilities of a number of polycyclic aromatics and substituted benzenes in benzene are listed in Table IV along with the ideal solubilities estimated by Eq. 7. The estimated values are in excellent agreement with the experimentally determined values.

Because this treatment is based on many assumptions and approximations, it cannot be expected to provide highly accurate ideal solubility estimates for all compounds. However, it does provide a simple means of obtaining a reasonable estimate of ideal solubility from nothing more than the structure and melting point of the compound in question.

From a pharmaceutical point of view, the value of being able to estimate ideal solubility is not that it enables calculation of the solubility of compounds in ideal solvents but rather that the ideal solubility of a substance is a factor which partially determines its solubility in water and other pharmaceutically important solvents.

Estimation of Aqueous Activity Coefficient—The estimation of the activity coefficient is somewhat more difficult than estimation of the entropy of fusion. The former value is dependent on the nature of two

Table IV—Mole Fraction Solubility of Aromatic Compounds in Benzene

species, the solute and the solvent (in this case, water), whereas the latter quantity is dependent only on the nature of the solute. Most theoretical treatments of activity coefficients apply to nonpolar solutes in nonpolar solvents [*cf.*, the Scatchard–Hildebrand approach (2)] or to electrolytes in water (*cf.*, Ref. 17).

This report will attempt to develop a practical and easily used semiempirical approach. This approach relates the aqueous activity coefficient to the octanol–water partition coefficient, *PC*, which can in turn be estimated from the chemical structure by established techniques. Some of the more useful schemes used to estimate log *PC* were summarized previously (4).

The aqueous activity coefficient of a drug and its octanol–water partition coefficient are related by:

$$PC_x = \frac{\gamma_w}{\gamma_0} \qquad \text{(Eq. 19)}$$

where γ_0 is the activity coefficient of the drug in octanol. All three terms are expressed in mole fractions. (In its strictest sense, the partition coefficient is the ratio of the activity coefficients of the solute in water-saturated octanol to octanol-saturated water. Since it was shown that the effects of mutual saturation usually are quite small[3], they will be ignored in this report.)

By analogy to the aqueous activity coefficient, the activity coefficient of the drug in octanol can be described by:

$$2.303RT \log \gamma_0 = DD + OO - 2DO \qquad \text{(Eq. 20)}$$

where *OO* represents the octanol cohesive interactions and *DO* is the drug–octanol adhesive interaction term. By combining Eqs. 19 and 20, the following relationship is obtained:

$$2.303RT \log \gamma_w = \log PC_x + DD + OO - 2DO \qquad \text{(Eq. 21)}$$

If the drug has a molar cohesive energy that is similar to that of octanol, the adhesive interactions can be assumed to be equal to the average of the drug and octanol adhesive interactions, so that:

$$DD + OO \cong 2DO \qquad \text{(Eq. 22)}$$

and thus:

$$\log \gamma_w \approx \log PC_x \qquad \text{(Eq. 23)}$$

This treatment is somewhat similar in concept to the Hildebrand and Scott (2) treatment of regular solution theory, with an arithmetic mean being used instead of a geometric mean.

[3] T. J. Roseman and S. H. Yalkowsky, unpublished data.

The fact that most available partition coefficient data are for the octanol–water system is fortuitous. Octanol is a solvent of moderate polarity and is not very different in polarity from most drugs. Octanol has a solubility parameter (δ) of 10.3; for most drugs, this value is $8 \leq \delta \leq 12$. Extremely nonpolar compounds such as hexane have a δ value of >7, and very polar compounds such as ethanol have a δ value of <13. This similarity of polarities is responsible for the near equivalence of *DD* and *OO* and thus for the success of Eqs. 22 and 23. Additional support for the applicability of Eq. 22 is provided by the fact that most organic liquids are miscible in all proportions with octanol[3], indicating that γ_0 is near unity and thus that log γ_0 in Eq. 20 is near zero.

The requirement described by Eq. 22 is important in that it restricts this treatment to nonelectrolytes. If ionized, weak electrolytes can self-interact much more strongly than octanol, the sum of the cohesive forces will be greater than the adhesive forces and the calculated solubility will be erroneous.

Estimation of Aqueous Solubility of Liquids—Equation 23 can be tested on organic liquids that do not self-associate. For these liquids, the activity coefficient can be approximated by the reciprocal of the mole fraction solubility in water, X_w^l:

$$\log \gamma_w \approx -\log X_w^l \qquad \text{(Eq. 24)}$$

By merging the aqueous solubility file of Yalkowsky and Valvani[2] with the octanol–water partition coefficient data of Hansch and Leo (18), over 100 liquids have been found[2] for which apparently reliable solubility and partition coefficient data have been published. The result of regression analysis on these data (which include multiple values for most of the liquids) is:

$$-\log \gamma_w = \log X_w^l = -1.08 \log PC - 1.04 \qquad \text{(Eq. 25)}$$

$$n = 417 \quad r = 0.946 \quad s = 0.356$$

which is in good agreement with Eq. 24.

The slight deviation of the slope from unity is believed to be due to a systematic decrease in *DD* with increasing values of log *PC*, *i.e.*, with decreasing polarity. The intercept of 1.04 is due to the fact that Eq. 23 refers to the mole fractional partition coefficient, which is equal to the conventionally defined partition coefficient minus 0.94 (the logarithm of the ratio of the molarity of pure octanol to that of pure water). This distinction has been discussed more fully (19).

Although verified in this case for liquids, Eq. 25 is not restricted to liquid solutes. It can be expected to hold equally well for crystalline compounds. Therefore, a method has been obtained for estimating log γ_w for all organic nonelectrolytes that do not self-associate.

The reason for the exercise that equated log γ with log *PC* is that the

latter value can be estimated by linear free energy (*i.e.*, group contribution) approaches. Due to the efforts of Hansch and coworkers (20, 21) and Nys and Rekker (5), it is possible to estimate, with reasonable accuracy, the value of log *PC* for most organic compounds. The fragment contributions to log *PC* (*f* values) developed by Nys and Rekker for the most common functional groups are summarized in Ref. 5. These *f* values can be used to obtain an approximate log *PC* value for most compounds.

Estimation of Aqueous Solubility of Organic Nonelectrolytes—If the estimations of ΔS_f and γ_w are valid for drugs, they can be inserted into Eq. 8 to give:

$$\log X_w^c \approx -\log PC - \left(\frac{\Delta S_f}{1364}\right)(MP - 25) - 0.94 \qquad \text{(Eq. 26)}$$

which simplifies to:

$$\log X_w \approx -\log PC - 0.01MP - 0.69 \qquad \text{(Eq. 27)}$$

for rigid molecules.

Equations 26 and 27 can be made applicable to liquids simply by replacing the melting point by 25° for compounds that melt below this temperature. This process effectively eliminates the crystal interaction term and causes the equations to revert back to Eq. 25.

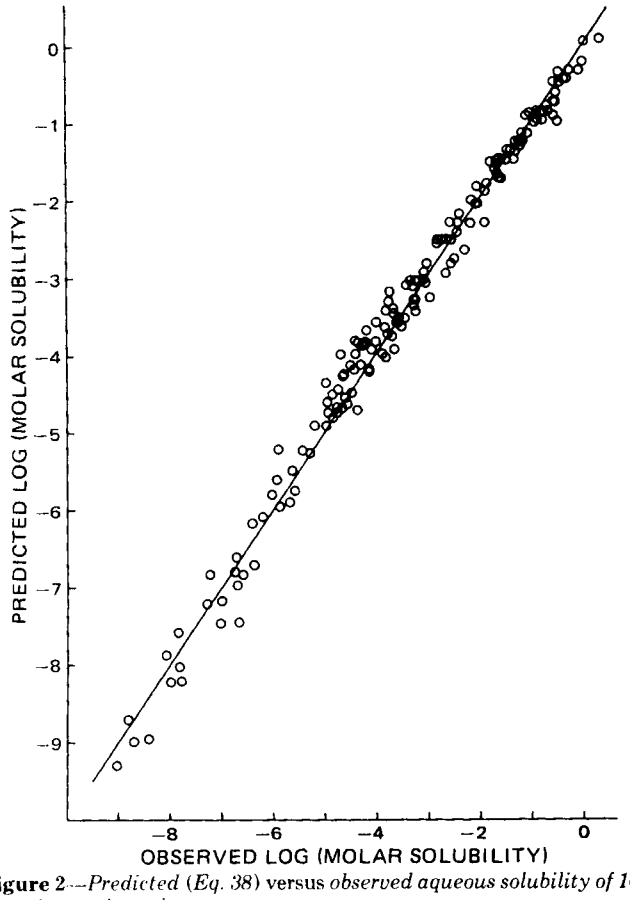

Figure 2—*Predicted (Eq. 38)* versus *observed aqueous solubility of 167 organic nonelectrolytes.*

The aqueous solubility of drugs by convention is reported on a molar rather than a mole fraction scale. For poorly soluble compounds, the molar solubility is simply the mole fraction solubility multiplied by 55.5 (the molarity of water) so that:

$$\log S_m = \log X + 1.74 \qquad \text{(Eq. 28)}$$

where S_m is the solubility in moles per liter. Thus, on a molar scale, Eqs. 26 and 27 become:

$$\log S_m^c \approx -\log PC - \frac{\Delta S_f(MP - 25)}{1364} + 0.80 \qquad \text{(Eq. 29)}$$

in general for nonelectrolytes and:

$$\log S_m^c \approx -\log PC - 0.01MP + 1.05 \qquad \text{(Eq. 30)}$$

for rigid and short chain molecules.

For the more soluble solutes, it is necessary to account for the volume of water displaced by the dissolved solute. The more precise relationship between molar and mole fraction solubilities is:

$$S_w = \frac{1000\rho X_w}{18 + (MW - 18)X_w} \qquad \text{(Eq. 31)}$$

where ρ is the density of the saturated solution and MW is the molecular weight of the solute. Note that as X_w approaches zero and as ρ approaches unity, Eq. 31 approaches Eq. 28. Since S_w is not a truly linear function of X_w, it is not a strictly linear function of MP and log PC, especially at high values of S_w. However, it can be approximated by a linear function with slightly altered coefficients. As long as very soluble solutes are avoided, no serious errors will be encountered as a result of this approximation.

Applications—To test the ability of Eqs. 29 and 30 to estimate the aqueous solubilities of organic nonelectrolytes, several series of compounds will be considered: polycyclic aromatic hydrocarbons; mono- and multihalobenzenes; steroid hormones; normal, branched, and cyclic alcohols; and alkyl *p*-hydroxybenzoates and alkyl *p*-aminobenzoates. These series enable coverage of a wide variety of melting points, partition coefficients, and solubilities. The regression equations of the estimated and observed solubilities for each series and for the combination of all compounds will be given.

Tables V and VI contain the aqueous solubility data for two classes of compounds containing only rigid molecules (the polycyclic aromatic compounds and the halobenzenes). Tables V and VI also contain the estimated partition coefficients and the melting points. In the case of liquids, 25° is used in place of the melting point. For the polycyclic aromatic compounds, the results of regression analysis between the observed and estimated solubilities are:

$$\log S_{obs} = 0.944 \log S_{estim} - 0.785 \qquad \text{(Eq. 32)}$$

$$n = 32 \quad r = 0.989 \quad s = 0.252$$

and for the halobenzenes:

$$\log S_{obs} = 0.980 \log S_{estim} - 0.32 \qquad \text{(Eq. 33)}$$

$$n = 35 \quad r = 0.995 \quad s = 0.136$$

Table VII contains the same type of data for the alkyl *p*-substituted benzoates, a series of both rigid and flexible molecules, all of which are

crystalline. The statistics for this series are:

$$\log S_{obs} = 1.008 \log S_{estim} - 0.270 \qquad \text{(Eq. 34)}$$

$$n = 14 \quad r = 0.990 \quad s = 0.264$$

Table VIII concerns the aliphatic alcohols. The series contains rigid and flexible molecules, most of which are liquids at room temperature. For this series, the observed and estimated solubilities are related by:

$$\log S_{obs} = 0.989 \log S_{estim} - 0.203 \qquad \text{(Eq. 35)}$$

$$n = 67 \quad r = 0.994 \quad s = 0.178$$

Table IX lists the data for some steroid hormones. The data for this group of rigid solids were taken from a study by Tomida *et al.* (6) in which both aqueous solubilities and octanol–water partition coefficients were determined. The experimental data for these cases were used because the group contribution approaches (20, 21) worked poorly for steroids (1). The regression equation for this series is:

$$\log S_{obs} = 0.879 \log S_{estim} - 0.863 \qquad \text{(Eq. 36)}$$

$$n = 19 \quad r = 0.847 \quad s = 0.309$$

In each of the five classes of compounds, there is a definite relationship

Table IX—Solubility Estimates for Some Steroids

Triamcinolone	270°	1.03	−3.68	−3.31	−0.374
Triamcinolone acetonide	293°	2.31	−4.31	−4.63	0.323
Triamcinolone diacetate	235°	1.92	−4.13	−3.78	−0.349
Dexamethasone	266°	1.83	−3.59	−3.97	0.384
Betamethasone	230°	1.94	−3.77	−3.75	−0.016
Dexamethasone acetate	230°	2.91	−4.90	−4.61	−0.293
Betamethasone-17-valerate	183°	3.49	−4.71	−4.70	−0.006

between the observed and estimated values of log S. In four of the five groups, the coefficient of log S_{estim} is close to 0.96. For the steroids, a lower value is observed. The major variation is observed in the value of the intercept, which varies from −0.863 to −0.203. The reason for the variation (which would be equal to zero if Eqs. 29 and 30 were absolutely correct) is not clear. However, it is clear that the average of Eqs. 32–36:

$$\log S_{obs} \approx \log S_{estim} - 0.5 \qquad \text{(Eq. 37)}$$

can be used as a means of estimating the solubility of nearly any rigid nonelectrolyte regardless of whether it is liquid or solid.

In each of the five classes of compounds, there is a similar relationship between the observed and predicted solubilities. Whether the differences observed are real or are due to systematic errors in calculating log *PC* is not clear.

The complete data set was fitted by multiple linear regression to a function of log *PC* and $\Delta S_f(MP - 25)$. This analysis yielded the following semiempirical equation:

$$\log S_w \sim -1.00 \log PC - 1.11 \frac{\Delta S_f(MP - 25)}{1364} + 0.54 \qquad \text{(Eq. 38)}$$

$$n = 167 \quad r = 0.994 \quad r^2 = 0.988 \quad s = 0.242$$

Equation 38 estimates the solubilities of all but eight of the solutes listed in Tables V–IX to within 0.5 log unit. The agreement between the observed solubilities and the solubilities estimated by Eq. 38 is illustrated in Fig. 2. Although the solubility values span nine orders of magnitude, the error in no case reached a factor of 10.

The pooled data for the rigid molecules gave:

$$\log S_w = -1.05 \log PC - 0.012MP + 0.87 \qquad \text{(Eq. 39)}$$

$$n = 155 \quad r = 0.989 \quad r^2 = 0.979 \quad s = 0.308$$

These equations are believed to be useful because they enable the estimation of aqueous solubility on the basis of a single physical measurement, the melting point. They also enable the chemist to appreciate the likely effect of a structural modification on aqueous solubility.

Although this study was restricted to nonelectrolytes, it appears that Eqs. 38 and 39 can be extended to cover weak electrolytes with only slight modification (22).

Influence of Various Anions on Intestinal Disappearance of Hexamethonium Chloride and Pralidoxime Chloride in Rats

SURYAKANT I. BHUTA *x, EDWIN T. SUGITA, PAUL J. NIEBERGALL ‡, and ROGER L. SCHNAARE

Received May 21, 1979, from the *Department of Pharmacy, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.* Accepted for publication March 11, 1980. *Present address: Sandoz Pharmaceuticals, East Hanover, NJ 07936. ‡Present address: Marion Laboratories, Inc., Kansas City, MO 64137.

Abstract □ The intestinal transfer of two poorly absorbed quaternary ammonium drugs, hexamethonium chloride (I) and pralidoxime chloride (II), in the presence of various organic and inorganic anions was investigated in the rat using a modified *in situ* gut technique. The results were in agreement with those of the conventional *in situ* loop and plasma drug level techniques. Of the anions investigated, cholate, desoxycholate, taurocholate, phoscholate, dehydrocholate, and hyodesoxycholate had the greatest effect on increasing the amount and rate of disappearance of I. Similarly, the amount and rate of disappearance of II were enhanced markedly in the presence of phoscholate and trichloroacetate. The effect of cholate and phoscholate was investigated in detail. The membrane permeability and histological studies indicated that these anions may compromise the structural integrity of the membrane tissue, thus enhancing drug transfer.

Keyphrases □ Hexamethonium chloride—influence of various anions on intestinal disappearance in rats □ Pralidoxime chloride—influence of various anions on intestinal disappearance in rats □ Quaternary ammonium drugs—hexamethonium chloride and pralidoxime chloride, influence of various anions on intestinal disappearance in rats □ Absorption—hexamethonium chloride and pralidoxime chloride, influence of various anions on intestinal disappearance in rats

Quaternary ammonium drugs may have limited therapeutic usefulness following oral administration since they are poorly and erratically absorbed. These compounds are ionized completely at all physiological pH values and thus tend to have high aqueous and low lipid solubilities. According to the pH–partition theory of passive absorption, these ionized moieties should be only insignificantly absorbed since they are transported slowly across lipid membranes.

The poor GI absorption of quaternary ammonium drugs can be illustrated by noting the difference in therapeutically effective oral and parenteral doses. For example, much larger doses of the antihypertensive drug hexamethonium and the cholinesterase reactivator pralidoxime chloride must be given by mouth as compared to parenteral administration to achieve a pharmacological response (1–3).

Various attempts have been made to improve the GI absorption of quaternary ammonium drugs. Isolated studies have shown that, in some cases, the amount and rate of absorption of hexamethonium (4), benzomethamine (5), and isopropamide (6) are increased by the addition of anionic substances. For example, Harington (4) showed that the various salts of hexamethonium are absorbed to different extents. These studies imply that the anionic portion of the salt plays a part in the absorption process since the other moiety always was the positively charged quaternary ion.

Although the existence of ion-pair complexes has been speculated, no conclusive evidence has been found. Furthermore, no data are available showing the effect of these anions on *in vivo* membrane permeability. Further work in this area is warranted to elucidate the mechanism of the enhancing action effected by anions.

The purposes of this study were to investigate techniques for increasing GI transfer of two model quaternary ammonium drugs, hexamethonium chloride (I) and pralidoxime chloride (II), and to study the mechanisms involved in this enhancement.

EXPERIMENTAL

Test Animals—Male Sprague–Dawley rats[1], ~140 g, were housed two per cage and had access to food and water until they attained a weight of 180–200 g. Animals were fasted for 24 hr prior to use but had free access to water.

Chemicals—Hexamethonium chloride[2], hexamethonium iodide[2], pralidoxime chloride[3], and pralidoxime iodide[3] were used as purchased. Chemicals used as anions were purchased from various sources.

The concentration of hexamethonium chloride (I) was 2.6×10^{-3} *M*, while that of pralidoxime chloride (II) was 8.7×10^{-3} *M*. The anions were administered as their sodium salts. When a sodium salt was not available, the desired acid was dissolved in deionized, distilled water with an equivalent quantity of sodium hydroxide. All solutions were prepared fresh on the day of the experiment.

Anesthesia—Each rat was anesthetized with urethan[4] (ethyl carbamate), 1 mg/g ip.

Experimental Design—To determine the number of experimental animals required to evaluate each drug–anion combination, preliminary studies were conducted with I and II in four animals on 4 consecutive days. An analysis of variance indicated that there was no statistical difference between the results from the different animals. This finding suggested that each drug–anion combination studied in four animals would give satisfactory results that could differentiate the effects of different anions on drug disappearance. Therefore, each I–anion and II–anion combination to be studied on any particular day was selected randomly.

The results were analyzed statistically using Duncan's new multiple range procedure (7). This procedure groups the ranked means that do not differ statistically ($p = 0.05$) and is suitable for the interpretation of the results since it distinguishes between a single anion and a group of anions that have similar effects on drug absorption.

Methods of Analysis—A slight modification (4% instead of 1.5% washed isopentanol) of the ion-pair technique described by Auerbach (8) and Mitchell and Clark (9) was used for the determination of hexamethonium in aqueous solutions and plasma. The pralidoxime content in biological fluids was analyzed utilizing the method of May *et al.* (10) and Ellin and coworkers (11, 12). The analytical procedure of Roe *et al.* (13) as modified by Schreiner (14) was employed for determining the inulin content in the aqueous solution. In all cases, the standard curves obeyed the Beer–Lambert law.

***In Situ* Gut Technique**—The experimental technique used to study drug transfer kinetics was a modification of a method described previously (15). The earlier technique did not account for intestinal volume changes. To overcome this difficulty, the ilial syringe was replaced with

Sulfide	1:5	0.99 ± 0.14

[a] Statistical results of Duncan's new multiple range procedure.

a 10.0-ml graduated pipet. At various times, the drug solution from the intestine was emptied gently into the pipet, the volume was measured accurately, a 0.1-ml aliquot was withdrawn for analysis, and the solution was returned to the intestine.

***In Situ* Loop Technique**—This method was an adaptation of the *in situ* gut technique. The experimental procedure and setup were identical up to the point where the drug solution was to be introduced into the washed intestine. At this stage, the syringe was disconnected from the duodenal cannula and replaced with a 5.0-ml pipet containing exactly 5.0 ml of drug solution. This solution was allowed to flow into the intestinal lumen, and the intestine was ligated at the tip of the duodenal cannula. Similarly, the intestine at the ilial cannula was ligated, with care taken to ensure that no drug solution was in the receiving pipet. The pipet and cannulas then were removed.

After 3 hr, the entire section of small intestine was removed and placed in a beaker containing ~50 ml of distilled water. After the intestine was cut into thin rings, the contents in the beaker were stirred vigorously for 30 min. The mixture was filtered, and the solution was diluted to a desired volume. An aliquot of this solution was analyzed for drug content as described previously. The difference between the amount of drug introduced and the amount remaining at the completion of the experiment yielded the drug lost from the intestinal segment.

At the completion of the experiment, a blood sample was obtained *via* heart puncture from the same animal in which the loop technique was studied. The drug concentration in the plasma was determined as described. The blood volume of the rat was estimated from its body weight using the chart published previously for blood volume *versus* the body weight of male rats (16). The product of the plasma drug concentration and the plasma volume yielded a measure of the amount of drug in the plasma of the rat.

Table II—Intestinal Disappearance of Pralidoxime Chloride (II) in the Presence of Different Anions for the *In Situ* Gut Technique [a]

Anion	Molar Ratio of II to Anion	$k^* \times 10^3$, min^{-1}
Phoscholate	1:3	7.37 ± 0.30
Trichloroacetate	1:2	6.56 ± 0.14
Taurocholate	1:2	5.64 ± 0.10
Glycotaurocholate	1:1	5.49 ± 0.21
Hyodesoxycholate	1:2	5.42 ± 0.15
Iodide	1:2	5.25 ± 0.12
Cholate	1:2	5.23 ± 0.27
Dehydrocholate	1:1	5.18 ± 0.51
Glycocholate	1:1	5.19 ± 0.14
Bromide	1:2	4.75 ± 0.71
Chloride	1:2	4.58 ± 0.11
Acetate	1:2	3.73 ± 0.72
Desoxycholate	1:2	3.51 ± 0.13
Tartrate	1:2	3.32 ± 0.12
Propionate	1:2	3.29 ± 0.33
Lactate	1:2	3.24 ± 0.06
Sulfate	1:2	3.16 ± 0.15
Phosphate	1:2	3.07 ± 0.21
Citrate	1:2	2.57 ± 0.38

[a] Statistical results of Duncan's new multiple range procedure.

Membrane Permeability Study—The experimental setup was the same as that used in the *in situ* gut technique. The drug solution was introduced into the intestine; simultaneously, a sterile solution of 20 mg of inulin was injected into the femoral vein. At the end of 3 hr, the volume of the intestinal solution was measured accurately, and an aliquot was taken for inulin analysis.

The amount of inulin determined in the sample aliquot and the volume of the intestinal contents yielded the amount of inulin transferred from the blood to the intestinal lumen.

Histological Study—The *in situ* gut technique was utilized to obtain the intestinal tissue samples. The drug solution was introduced into the intestine; after 3 hr, segments from different intestinal areas were removed, gently flushed out with distilled water, and then fixed for at least 24 hr in a 10% formalin and 1% $CaCl_2$ solution. These sections were fixed permanently for later use.

RESULTS AND DISCUSSION

Intestinal Disappearance—The kinetics of intestinal disappearance of the two quaternary ammonium drugs, hexamethonium chloride (I) and pralidoxime chloride (II), in the presence of various anions were observed for 3 hr. The kinetics between 30 and 180 min followed apparent first-order disappearance and, therefore, could be represented mathematically by:

$$m = m_0 e^{-kt} \qquad \text{(Eq. 1)}$$

where m is the amount of drug in the intestine at any time t, m_0 is the initial amount of drug in the intestine, and k is the disappearance rate constant.

Preliminary studies indicated that the intestinal disappearance rate of the drugs and their combinations with various anions for the initial 30 min did not follow simple first-order kinetics. For this reason, the constant was redefined as an apparent disappearance rate constant and designated as k^*. The behavior during the initial period was studied in detail and will be discussed later. The k^* values for I and II were estimated using linear regression to be $3.05 \pm 0.07 \times 10^{-3}$ and $4.58 \pm 0.11 \times 10^{-3}$ min^{-1}, respectively.

The influence of an excess of chloride ions while utilizing hexamethonium iodide and pralidoxime iodide also was investigated. The disappearance rates of these iodide salts in the presence of an excess of chloride anions were identical to those of the chloride salts of the drugs. Similarly, another study showed that the apparent rates of I and II in the presence of an excess of iodide ions were not different from the rates for the iodide salts of these drugs. The results indicate strongly that the intestinal disappearance kinetics of I and II are affected by the presence of foreign anions and that the drugs behave as the salt of the excess anion present. A possible reason for such behavior is that the quaternary ammonium salts are ionized completely at all physiological pH values to their corresponding cations and anions, and an excess of foreign anion will swamp the anion of the salt.

All anions, except bromide, when used in the molar ratios of drug to anion of 1:2 to 1:5 had the same effect on I and II. With bromide, a progressive increase in the anion concentration caused a corresponding increase in the disappearance rate of I but not of II. The molar ratio of drug to anion was maintained within the range of 1:2 to 1:5; in a few instances, it was necessary to change (±10%) the anion concentration to achieve an isotonic solution to prevent drastic intestinal volume changes. The pH of the solutions during this investigation ranged from 7.5 to 8.3; only the desoxycholate and taurocholate systems gave slightly lower values.

The results for hexamethonium chloride and pralidoxime chloride in the presence of various anions are presented in Tables I and II, respectively. The brackets enclosing the anion or anions in the first column indicate the results of the statistical analysis by Duncan's new multiple range procedure. The effects on the apparent disappearance rate constant of the drug for the anions included in the same bracket do not differ statistically at $p = 0.05$; however, the effects of the anions grouped in different brackets are significantly different at $p = 0.05$.

The simple ion, bromide, increased the disappearance of I but had no effect on the rate constant of II. Iodide increased the value of II and had no significant effect on the value of I. The results of the hexamethonium studies agree with Harington's findings (4); however, the results of the

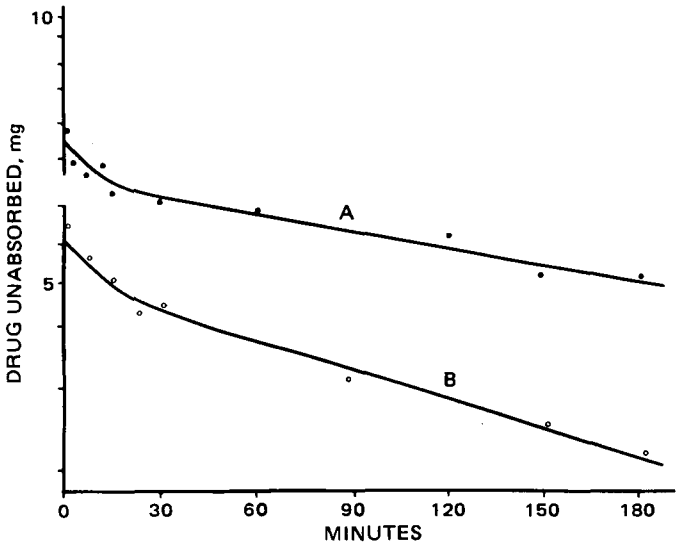

Figure 1—*Intestinal disappearance of hexamethonium chloride (A, ●) and pralidoxime chloride (B, ○) in rats.*

pralidoxime experiments differ from those of Levine and Steinberg (17).

Another anion that had opposing effects on the drug transfer rate was phosphate. It increased the disappearance constant of I while it decreased the value of II appreciably.

Citrate, sulfate, lactate, propionate, tartrate, and acetate had similar effects; they all decreased or had no effect on the disappearance rate constants of I and II. These findings parallel those in the literature, although one investigator (18) reported increased intestinal absorption of the quaternary ammonium compound benzomethamine in the presence of acetate and propionate anions. However, this effect occurred only at high acid concentrations (0.2 *M*) and at relatively low pH values (pH 3–4).

Trichloroacetate had no influence on the results of I while it increased the corresponding value of II. This anion increased the pharmacological response of isopropamide iodide (6).

The most dramatic changes were caused by the bile salt anions. For example, cholate caused an approximately threefold increase in the rate constant for I but only a slight increase for II. Of the bile anions studied, cholate, taurocholate, dehydrocholate, hyodesoxycholate, and glycocholate increased the disappearance rates of I and II. Desoxycholate increased the rate constant of I but was ineffective with II, while glycotaurocholate had an opposite effect.

The most promising of the anions studied was phoscholate. This anion, which is the conjugate base of phoscholic acid (2,2′-phosphinicodilactic acid), significantly increased the disappearance rate constants of both I and II. For example, the rate constant for I in the presence of chloride ions was 3.05×10^{-3} min^{-1}, while its value in the presence of phoscholate was 5.35×10^{-3} min^{-1}. Similarly, the k^* value of II in the presence of chloride ions was 4.58×10^{-3} min^{-1}, which increased to 7.37×10^{-3} min^{-1} when the drug was present with phoscholate.

It was stated previously that the intestinal disappearance of I and II and their combinations with various anions followed a definite pattern; their initial disappearance rate was rapid and was followed by a slower phase. Similar results for other quaternary ammonium drugs (5, 19–21) and other drugs such as phenothiazines (22), haloperidol (22), and steroids (23) also were reported. This pattern may be indicative of the mechanism by which these quaternary ammonium drugs are absorbed through the intestinal barrier.

Figure 1 illustrates the typical kinetic patterns of the intestinal disappearance of I and II. The rate was rapid in the initial period and was followed by a slower phase between 30 and 180 min. An attempt was made to describe mathematically the kinetics of I and II. Of the kinetic models considered, the model shown in Scheme I gave the best fit to the experimental data.

$$A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B \xrightarrow{k_3} C$$

Scheme I

In Scheme I, A is the drug in the intestinal lumen, k_1 and k_2 are the constants that are part of the equilibrium step, and k_3 is the constant responsible for the disappearance of the drug from the lumen. Assuming that k_1, k_2, and k_3 are first-order rate constants and solving the differential equation for A yield (22, 24, 25):

$$A = A_0 \left[\frac{(k_2 + k_3 - \alpha)e^{-\alpha t} - (k_2 + k_3 - \beta)e^{-\beta t}}{\beta - \alpha}\right] \quad \text{(Eq. 2)}$$

where α and β are given by:

$$\alpha = \tfrac{1}{2}[(k_1 + k_2 + k_3) + \sqrt{(k_1 + k_2 + k_3)^2 - 4k_1k_3}] \quad \text{(Eq. 3)}$$

and:

$$\beta = \tfrac{1}{2}[(k_1 + k_2 + k_3) - \sqrt{(k_1 + k_2 + k_3)^2 - 4k_1k_3}] \quad \text{(Eq. 4)}$$

This derivation gives a mathematical relationship between the defined microconstants k_1, k_2, and k_3 and the disappearance of the drug from the intestine. The β value obtained from the 0–180-min data is identical to the k^* constant determined previously.

The presence of excess chloride did not affect the rate constants of I and II. This finding is in agreement with the results of earlier studies. The presence of cholate and phoscholate increased the disappearance rate constant, k_3, of I and II. They also caused a corresponding increase in the apparent disappearance rate constants of I and II in the *in situ* gut study. For comparison purposes, the k^* values are listed in Tables III and IV in parentheses.

Therefore, it is possible that the quaternary ammonium drugs I and II may be absorbed in the manner described by the proposed mathematical model. Nakamura *et al.* (26–28) investigated the mechanism of intestinal absorption of four highly ionized, poorly lipid-soluble dyes and noted that these compounds must bind to mucus as the first step in absorption. Mucus, which coats the epithelial surface, is secreted by the goblet cells of the small intestine.

Martin *et al.* (29) found that the bile salts sodium deoxycholate, sodium taurodeoxycholate, and sodium glycocholate cause breakdown of the mucus structure. In addition to possibly causing membrane changes, the anions also may elicit their effect in this manner.

The investigation so far indicated that the intestinal disappearance of quaternary ammonium drugs can be influenced by the presence of a suitable anion and also that the *in situ* gut technique can be used to study such enhancement. Since this method determines only the disappearance of drugs from the intestinal lumen, several possibilities could produce misleading results. These possibilities are drug degradation, binding of the drug to the membrane or intestinal contents, intramembrane storage, and mechanical error during sampling. Therefore, before any definite conclusion could be drawn from the study, further investigation of the method was warranted.

To determine the stability of I and II in solution, different drug–anion solutions were prepared and kept at room temperature for 1 week. Almost 100% recovery of each drug from these solutions indicated that the drugs were stable in aqueous solutions containing the different anions. Similar experiments were conducted using the membrane and intestinal contents. Again, almost 100% recovery indicated that the drugs were stable over the experimental period. These results agree with previous reports (4, 17).

Table III—Intestinal Disappearance Rate Constants of Hexamethonium Chloride (I) in the Presence of Different Anions

Anion	Molar Ratio of I to Anion	$k_1 \times 10^2$, min^{-1}	$k_2 \times 10^2$, min^{-1}	$k_3 \times 10^2$, min^{-1}
Chloride	1:3	3.3	11.9	1.1 (0.305)[a]
Cholate	1:5	4.4	12.8	4.1 (0.833)[a]
Phoscholate	1:5	3.0	6.5	1.7 (0.535)[a]

[a] Apparent disappearance rate constant, k^*, in the *in situ* gut technique.

Table IV—Intestinal Disappearance Rate Constants of Pralidoxime Chloride (II) in the Presence of Different Anions

Anion	Molar Ratio of II to Anion	$k_1 \times 10^2$, min^{-1}	$k_2 \times 10^2$, min^{-1}	$k_3 \times 10^2$, min^{-1}
Chloride	1:2	4.2	9.5	1.7 (0.458)[a]
Cholate	1:2	3.1	5.5	1.7 (0.523)[a]
Phoscholate	1:2	1.9	3.6	2.9 (0.730)[a]

Table V—Intestinal Disappearance and Appearance in Plasma of Hexamethonium Chloride (I) and Pralidoxime Chloride (II) in the Presence of Different Anions for the *In Situ* Loop Technique

Anion	I		II	
	Intestinal Loss after 3 hr, mg	Amount in Plasma at 3 hr, mg	Intestinal Loss after 3 hr, mg	Amount in Plasma at 3 hr, mg
Chloride	1.6 ± 0.1	0.46 ± 0.03	3.6 ± 0.1	0.038 ± 0.006
Cholate	2.4 ± 0.2	0.74 ± 0.10	5.4 ± 0.4	0.068 ± 0.007
Phoscholate	2.3 ± 0.1	0.81 ± 0.07	6.3 ± 0.3	0.110 ± 0.004

To determine whether the loss of drug from the intestine was a result of absorption, two experiments were conducted. The first experiment was a study of the effects of selected anions on the intestinal absorption of I and II using a conventional *in situ* loop technique; the second experiment was a study of the amount of drug transferred from the intestine into the blood at the end of 3 hr. Chloride, cholate, and phoscholate were the three anions studied in combination with I and II. The chloride anion was selected because it is the most commonly used anion in the synthesis of quaternary ammonium drugs. Furthermore, the chloride salts of hexamethonium and pralidoxime frequently are used as therapeutically active agents. Cholate was representative of the bile salts, while phoscholate was the most promising anion, and both enhanced the disappearance rates of I and II.

The results for I and II in the presence of cholate and phoscholate as determined by the loop technique are presented in Table V. Both cholate and phoscholate increased the amount of I and II absorbed as compared to the standard, chloride. These findings are in agreement with those of the *in situ* gut technique.

The plasma samples obtained at the completion of the loop experiments indicated the presence of drug, thereby qualitatively substantiating that both I and II were absorbed to some degree. As seen in Table V, both cholate and phoscholate caused increased intestinal loss of I and II (as compared to chloride), and this loss, in turn, increased the quantity of drug in plasma.

The amount of drug lost could be calculated from the *in situ* gut technique data. This value was the difference between the amount of drug known to be present in the intestine at time zero and the amount remaining in the intestine after 180 min. The amount of drug lost was converted to a percentage, and this value then was compared to the results of the *in situ* loop technique. The gut and loop techniques yielded similar values for the percent of drug lost (Table VI). Both cholate and phoscholate enhanced the disappearance of I and II.

During the *in situ* gut technique experiments, if the drug had adhered to or been bound to the intestinal membrane or contents, then the sample aliquot obtained at any time would not have truly represented the actual amount of drug in the lumen. This possibility cannot be fully discounted since no recovery experiments were conducted. However, the results of the two methods were in close agreement. In the *in situ* loop technique, the entire intestine and contents are assayed, so the drug not accounted for must be located in areas other than the intestine. Finally, since no samples are removed until the conclusion of the experiment, mechanical errors such as frequent sampling cannot account for the different kinetic results.

Membrane Permeability—Quaternary ammonium drugs are completely ionized at all physiological pH values, and these drug solutions always contained their corresponding anions. It seemed reasonable that these anions may have affected membrane permeability. This assumption was investigated in a study with a sodium chloride solution as the control. The molar ratios of drug to anion were the same as those of the *in situ* gut technique for all test solutions. Again, the anions selected were chloride, cholate, and phoscholate.

Table VI—Comparison of *In Situ* and Loop Techniques for the Intestinal Disappearance of Hexamethonium Chloride (I) and Pralidoxime Chloride (II) in the Presence of Different Anions

Anion	Drug Lost, %			
	I		II	
	Gut Technique	Loop Technique after 3 hr	Gut Technique	Loop Technique after 3 hr
Chloride	44	46	54	48
Cholate	68	69	67	72
Phoscholate	60	66	79	84

Table VII—Effect of Different Drug–Anion Combinations on Membrane Permeability in the Rat Intestine in the Membrane Permeability Study

Drug–Anion Combination	Molar Ratio of Drug to Anion	Inulin in Intestine after 3 hr, mg × 10^2	Percentage Change[a]
Chloride	—	61 ± 8	Control
I + chloride	1:3	62 ± 5	No change
I + cholate	1:5	84 ± 10	35
I + phoscholate	1:5	90 ± 12	38
I + sulfate	1:5	48 ± 9	−26[b]
II + chloride	1:2	64 ± 8	No change
II + cholate	1:2	86 ± 12	38
II + phoscholate	1:2	83 ± 10	35
II + citrate	1:2	38 ± 5	−39

[a] Percentage change as compared to control. [b] Negative number indicates less than control.

The drug–anion combinations tested for their possible effects on membrane permeability are listed in Table VII. Table VII also shows the percentages of inulin in the intestine after an intravenous dose of 20 mg. The percentages of inulin reported in Table VII are in terms of the control.

The drug–chloride combinations and the chloride alone (control) gave similar results. However, the presence of cholate and phoscholate in the drug solutions increased the amount of inulin in the intestine by ~35%. These results indicate that there were changes in the intestinal membrane permeability when the drug solutions containing cholate and phoscholate were in the intestine for 3 hr.

The control solution containing chloride ion apparently affected the membrane permeability because ~3% of the inulin was found in the intestine when this solution was tested. However, this anion in combination with the drugs gave the same effect as the chloride ion alone. Furthermore, the changes in permeability with phoscholate and cholate in the presence of both drugs were similar. These findings seem to indicate that the anionic components of the solutions were responsible for the permeability changes of the intestinal membrane and not the drug molecules.

Feldman and coworkers (30–34) studied the enhancement of drug absorption by bile salts; in all cases, the increases were attributed to permeability changes. Other investigators (35, 36) demonstrated a similar effect by the bile salts, resulting in better drug absorption. These results suggest that the enhancement of the transfer of I and II caused by cholate and phoscholate is the result of permeability changes in the rat intestine. Also, it is suggested that the anionic components and not the drug molecules are responsible for these effects.

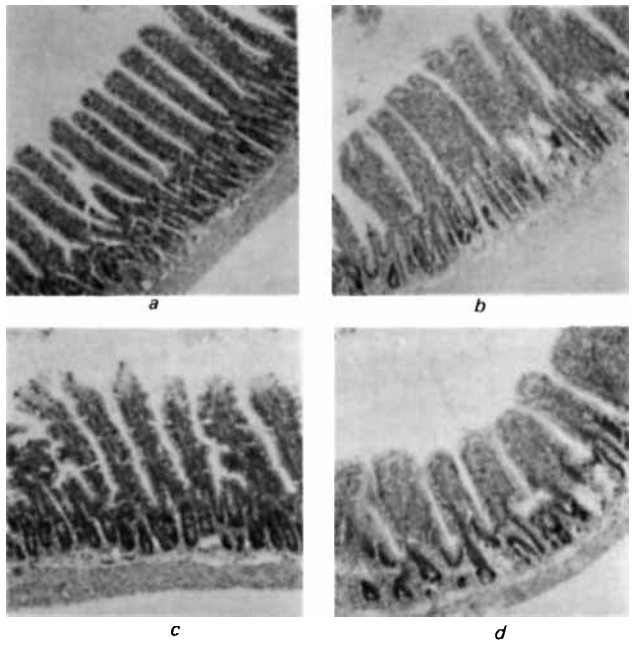

Figure 2—*Examples of intestinal morphological changes. Key:* a, *control;* b, *fusion of villi;* c, *loss of epithelial cells; and* d, *edema of the lamina propria.*

Table VIII—Histological Study of Effect of Drugs and Anions on the Structural Integrity of the Intestinal Membrane [a]

Anion, Drug, or Drug–Anion Combination	Loss of Epithelial Cells	Loss of Goblet Cells	Fusion of Villi	Edema of Lamina Propria	Changes in Mucous Membrane
Control	0	0	0	0	0
I	1	1	2	0	1
II	0	1	1	0	0
Chloride	1	3	1	1	1
Bromide	4	4	3	0	4
Cholate	2	3	2	0	3
Phoscholate	2	2	2	0	2
I + chloride	1	2	1	0	1
I + cholate	2	1	1	0	1
I + phoscholate	1	2	2	0	2
II + chloride	0	3	1	0	2
II + bromide	4	3	3	0	4
II + cholate	2	1	2	0	2
II + phoscholate	3	3	2	0	2

[a] Key: 0 = normal, 1 = slight, 2 = moderate, 3 = severe, and 4 = very severe.

Histological Study—This study was undertaken to investigate the effect of I and II, selected anions, and their combinations on the morphology of the intestine. Since the mucous membrane of the intestine comes in direct contact with the drug, the changes in its structure were of concern. The three layers of importance in absorption are the epithelial lining, lamina propria, and muscularis mucosa. The gross morphological changes in these layers were studied by the following observations:

1. Loss of epithelial cells—These cells form the innermost layer of the intestine, lining the villi of the intestinal mucosa. The epithelium consists of columnar cells and the basement membrane. Since absorption occurs through the columnar cells, any damage or loss of these cells could easily affect the transfer process.

2. Loss of goblet cells—Intermingled with the absorptive cells in the mucous membrane are goblet cells. These cells secrete mucus, which protects the epithelial lining from injury by the materials in the intestine.

3. Fusion of villi—The mucosal surface provides a large surface from which absorption occurs. Since the fusion of the villi means a reduction in the surface area, this fusion possibly could affect the absorption of materials from the intestines.

4. *Edema of lamina propria*—The lamina propria supports the epithelium and connects it to the muscularis mucosa. It carries both the blood and the lymphatic capillaries close to the epithelial surface, and diffusing materials therefore travel only a short distance through the tissue fluid of the lamina propria before gaining entrance into either type of capillary. Damage to the lamina propria could affect the transfer of drugs and their subsequent entrance into the blood.

5. Changes in mucous membrane—These changes did not concern any particular tissue of the mucous membrane but were overall changes in the absorptive surface.

The results of the morphological changes were classified as: 0 = normal, 1 = slight, 2 = moderate, 3 = severe, and 4 = very severe. Examples of these changes are presented in Fig. 2, and the results of this study are shown in Table VIII.

Compound I alone caused only minimal intestinal morphological changes; II caused even milder changes. These results can be correlated with those of the permeability study where the drugs did not affect the permeability of the intestinal membrane.

The responses elicited by the anions were varied. Chloride ions caused considerable loss of goblet cells; however, the overall effect on the mucous membrane was slight. This anion, as well as cholate and phoscholate, earlier was shown to affect membrane permeability. This study demonstrated that these anions had a moderate effect on the morphological structure of the membrane. The most dramatic changes were caused by bromide ions. Bromide was included since it was found previously that increasing the bromide concentration increased the loss of I.

The effects of drugs in combination with anions on the intestinal membrane morphology were similar to the effect of the specific anion alone. This finding supports the view that the drug molecule did not cause any further morphological changes.

None of the drugs or the anions or their combinations caused edema of the lamina propria, while all caused fusion of the villi to varying degrees. Moreover, some goblet cells were lost in all cases. The phoscholate ion and its combination with a drug caused moderate damage to epithelial cells. These findings are in agreement with those of Low-Beer *et al.* (37), who demonstrated a similar morphological change in the presence of foreign materials in the intestine. Cholate ions had a similar effect on the membrane.

The anions that enhanced the absorption of I and II also caused permeability and histological changes in the intestinal membrane. Although these results seem to indicate that the permeability change may have been caused by histological changes, which then led to enhanced drug absorption, they should be viewed cautiously since histological results are not available for the anions that actually decreased drug transfer.

Separation and Quantitation of Chlortetracycline, 4-Epitetracycline, 4-Epianhydrotetracycline, and Anhydrotetracycline in Tetracycline by High-Performance Liquid Chromatography

NASEEM MUHAMMAD ˣ **and JOY A. BODNAR**

Received September 7, 1979, from *Bristol Laboratories, Division of Bristol-Myers Co., Syracuse, NY 13201.* Accepted for publication March 12, 1980.

Abstract □ The analysis of tetracycline epimers in tetracycline preparations by high-performance liquid chromatography is described. The method uses a microparticulate phenyl column (3.9 mm i.d. × 30 cm) with a step gradient of 12–22% acetonitrile in 0.2 *M* phosphate buffer at pH 2.2. The analysis takes 22 min. The relative standard deviations of the method (2σ, $n = 6$) for the analysis of chlortetracycline, 4-epitetracycline, 4-epianhydrotetracycline, and anhydrotetracycline in tetracycline were ±3.68, ±4.47, ±7.60, and ±2.77%, respectively.

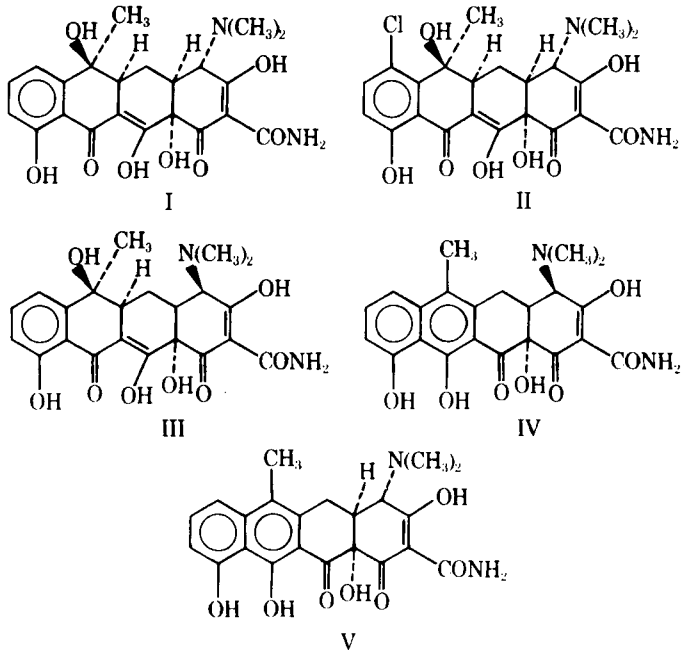
Keyphrases □ Tetracycline—simultaneous high-performance liquid chromatographic analysis of tetracycline epimers in tetracycline preparations □ High-performance liquid chromatography—analysis, tetracycline epimers in tetracycline preparations □ Antibacterials—tetracycline, high-performance liquid chromatographic analysis of tetracycline epimers in tetracycline preparations

Pharmaceutical preparations of tetracycline (I) contain small quantities of related compounds as impurities. The most important compounds are chlortetracycline (II), 4-epitetracycline (quatrimycin, III), 4-epianhydrotetracycline (IV), and anhydrotetracycline (V). Their permitted concentrations are listed in the Federal Register (1) for tetracycline dosage forms marketed in the United States and in the British Pharmacopoeia (2) and European Pharmacopoeia (3) for the European markets. The need for a simple assay prompted this investigation of the conditions under which these compounds could be separated and quantitated by high-performance liquid chromatography (HPLC) without a solvent gradient system.

BACKGROUND

TLC (4, 5), paper chromatography (6), and column chromatography followed by UV spectrophotometry (7, 8) have proved laborious and generally are not sufficiently sensitive or precise. A GLC method (9) requires prior formation of the trimethylsilyl derivative under carefully controlled conditions.

Several HPLC methods have been applied to separate III–V from I using a cation-exchange column with an ethylenediaminetetraacetic acid buffer (10), a C_{18} column (5–7% loading) with phosphate buffer and a linear gradient of 10–60% acetonitrile (11), a C_{18} column (10–18% loading) with a linear gradient of methanol–water–0.2 *M* phosphate buffer at pH 2.5 (30:60:10) and methanol–acetonitrile–water–0.2 *M* phosphate buffer at pH 2.5 (50:30:20:10) (12), and a C_{18} column with water–acetonitrile–perchloric acid in two steps (13).



In the present study, a microparticulate phenyl column with a step gradient of 12–22% acetonitrile in 0.2 *M* phosphate buffer at pH 2.2 (using an automatic switching valve) at a flow rate of 2.6 ml/min was used to separate II–V from I in 22 min. The method did not require a solvent gradient system and needed only one pump. It was tested for the analysis of several different tetracycline formulations.

EXPERIMENTAL

Apparatus—The liquid chromatographic apparatus shown in Fig. 1 was used[1].

Reagents and Materials—Ammonium 4-epitetracycline[2], 4-epianhydrotetracycline hydrochloride[2], anhydrotetracycline hydrochloride[2], chlortetracycline hydrochloride[3], acetonitrile[4], phosphoric acid[5], potassium hydroxide[5], and ammonium hydroxide[5] were used.

[1] A Valcor series SV-72 automatic switching valve, a Waters Associates model 6000 A pump, a Valco loop injector, a Waters Associates μBondapak phenyl column, and a Waters Associates model 440 absorbance detector were used.

Separation and Quantitation of Chlortetracycline, 4-Epitetracycline, 4-Epianhydrotetracycline, and Anhydrotetracycline in Tetracycline by High-Performance Liquid Chromatography

NASEEM MUHAMMAD ˣ **and JOY A. BODNAR**

Received September 7, 1979, from *Bristol Laboratories, Division of Bristol-Myers Co., Syracuse, NY 13201.* Accepted for publication March 12, 1980.

Abstract □ The analysis of tetracycline epimers in tetracycline preparations by high-performance liquid chromatography is described. The method uses a microparticulate phenyl column (3.9 mm i.d. × 30 cm) with a step gradient of 12–22% acetonitrile in 0.2 *M* phosphate buffer at pH 2.2. The analysis takes 22 min. The relative standard deviations of the method (2σ, $n = 6$) for the analysis of chlortetracycline, 4-epitetracycline, 4-epianhydrotetracycline, and anhydrotetracycline in tetracycline were ±3.68, ±4.47, ±7.60, and ±2.77%, respectively.

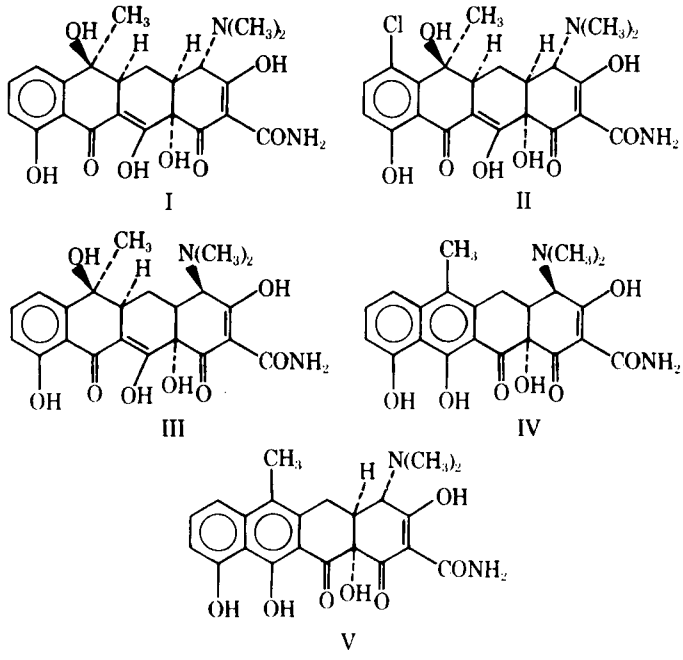
Keyphrases □ Tetracycline—simultaneous high-performance liquid chromatographic analysis of tetracycline epimers in tetracycline preparations □ High-performance liquid chromatography—analysis, tetracycline epimers in tetracycline preparations □ Antibacterials—tetracycline, high-performance liquid chromatographic analysis of tetracycline epimers in tetracycline preparations

Pharmaceutical preparations of tetracycline (I) contain small quantities of related compounds as impurities. The most important compounds are chlortetracycline (II), 4-epitetracycline (quatrimycin, III), 4-epianhydrotetracycline (IV), and anhydrotetracycline (V). Their permitted concentrations are listed in the Federal Register (1) for tetracycline dosage forms marketed in the United States and in the British Pharmacopoeia (2) and European Pharmacopoeia (3) for the European markets. The need for a simple assay prompted this investigation of the conditions under which these compounds could be separated and quantitated by high-performance liquid chromatography (HPLC) without a solvent gradient system.

BACKGROUND

TLC (4, 5), paper chromatography (6), and column chromatography followed by UV spectrophotometry (7, 8) have proved laborious and generally are not sufficiently sensitive or precise. A GLC method (9) requires prior formation of the trimethylsilyl derivative under carefully controlled conditions.

Several HPLC methods have been applied to separate III–V from I using a cation-exchange column with an ethylenediaminetetraacetic acid buffer (10), a C_{18} column (5–7% loading) with phosphate buffer and a linear gradient of 10–60% acetonitrile (11), a C_{18} column (10–18% loading) with a linear gradient of methanol–water–0.2 *M* phosphate buffer at pH 2.5 (30:60:10) and methanol–acetonitrile–water–0.2 *M* phosphate buffer at pH 2.5 (50:30:20:10) (12), and a C_{18} column with water–acetonitrile–perchloric acid in two steps (13).



In the present study, a microparticulate phenyl column with a step gradient of 12–22% acetonitrile in 0.2 *M* phosphate buffer at pH 2.2 (using an automatic switching valve) at a flow rate of 2.6 ml/min was used to separate II–V from I in 22 min. The method did not require a solvent gradient system and needed only one pump. It was tested for the analysis of several different tetracycline formulations.

EXPERIMENTAL

Apparatus—The liquid chromatographic apparatus shown in Fig. 1 was used[1].

Reagents and Materials—Ammonium 4-epitetracycline[2], 4-epianhydrotetracycline hydrochloride[2], anhydrotetracycline hydrochloride[2], chlortetracycline hydrochloride[3], acetonitrile[4], phosphoric acid[5], potassium hydroxide[5], and ammonium hydroxide[5] were used.

[1] A Valcor series SV-72 automatic switching valve, a Waters Associates model 6000 A pump, a Valco loop injector, a Waters Associates μBondapak phenyl column, and a Waters Associates model 440 absorbance detector were used.
[2] Bristol reference standards, Bristol Laboratories, Syracuse, N.Y.
[3] USP reference standard.

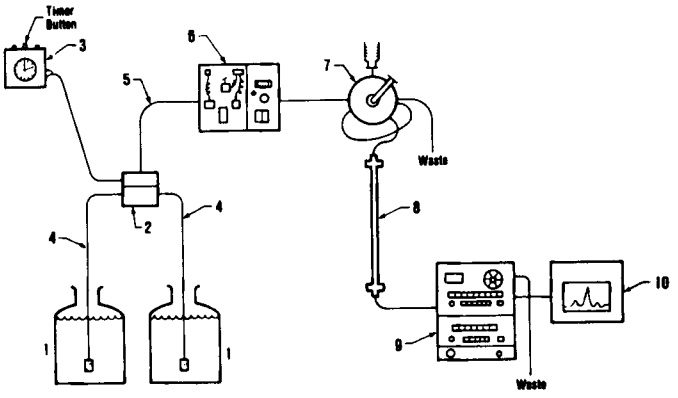

Figure 1—*HPLC step-gradient system for determination of tetracycline epimers. Key: 1, 2-liter reservoirs containing Eluents 1 and 2; 2, automatic switching valve (miniature three-way solenoid); 3, delay timer; 4, polytef tubing (3.2 mm i.d.) used to transfer the eluent from the reservoirs to the switching valve; 5, polytef tubing (16 cm long × 3.2 mm i.d.) used to transfer the eluent from the valve to the pump; 6, pump; 7, 20-μl loop injector operated at 7000 psi; 8, μBondapak phenyl 3.9 mm i.d. × 30-cm column; 9, absorbance detector; and 10, recorder.*

Mobile Phase—Eluent 1 was prepared by adding 240 ml of degassed acetonitrile and 27 ml of phosphoric acid to 1650 ml of degassed, distilled, deionized water. The pH was adjusted to 2.2 with 45% aqueous KOH, and the solution was diluted to 2 liters. The solution was degassed for only 15 sec prior to use.

Eluent 2 was prepared by adding 440 ml of degassed acetonitrile and 27 ml of phosphoric acid to 1500 ml of degassed, distilled, deionized water. The pH was adjusted to 2.2 with 25% aqueous KOH, and the solution was diluted to 2 liters with degassed, distilled, deionized water. The solution was degassed for only 15 sec prior to use.

Standard Solution Preparation—About 20 mg of ammonium 4-epitetracycline, 3 mg of epianhydrotetracycline hydrochloride, 3 mg of anhydrotetracycline hydrochloride, and 10 mg of chlortetracycline hydrochloride reference standards were weighed accurately into a 50-ml volumetric flask, dissolved, and diluted to volume with distilled water. Sonication sometimes was necessary for dissolution.

Sample Preparation—Bulk tetracycline hydrochloride samples were prepared by weighing accurately 500 mg of the sample into a 50-ml volumetric flask. The sample was dissolved and diluted to volume with distilled water.

Tetracycline base samples were prepared by weighing accurately 500 mg of the sample into a 50-ml volumetric flask. The sample was dissolved and diluted to volume with 0.1 *N* aqueous HCl.

Samples of hard, filled capsules containing sodium polymetaphosphate, phenazopyridine hydrochloride, sulfamethizole, and tetracycline phosphate were prepared by weighing accurately 500 mg of capsule blend into a 50-ml volumetric flask. To the flask were added 15 ml of distilled water and 1 ml of concentrated ammonium hydroxide. The flask was shaken until dissolution occurred. The solution was diluted to volume with pH 4.0 phosphate buffer, allowed to stand for 10 min, and filtered.

Sample Analysis—The column was conditioned with Eluent 1. The delay timer (Fig. 1) was set at 10 min. Twenty microliters of the standard solution or sample solution was injected using a loop. The timer was started, and the system was allowed to run. After 10 min, the automatic switching value opened to Eluent 2. The system was allowed to run on Eluent 2 until all peaks eluted (~15 min).

Calculations—The areas of the peaks were measured by the peak height times the half-width method or by a computer. The percentage of each compound was obtained from:

$$\text{factor for II, IV, and V: } F = \frac{\text{peak area of standard}}{\text{mg of standard}} \quad \text{(Eq. 1}a\text{)}$$

or:

$$\text{factor for III: } F = \frac{\text{peak area of standard}}{\text{mg of standard} \times 1.04} \quad \text{(Eq. 1}b\text{)}$$

and the correction factor for tetracycline based on the label claim (K):

$$K = \frac{\text{mg of sample}}{\text{label claim of tetracycline (mg)}} \quad \text{(Eq. 2)}$$

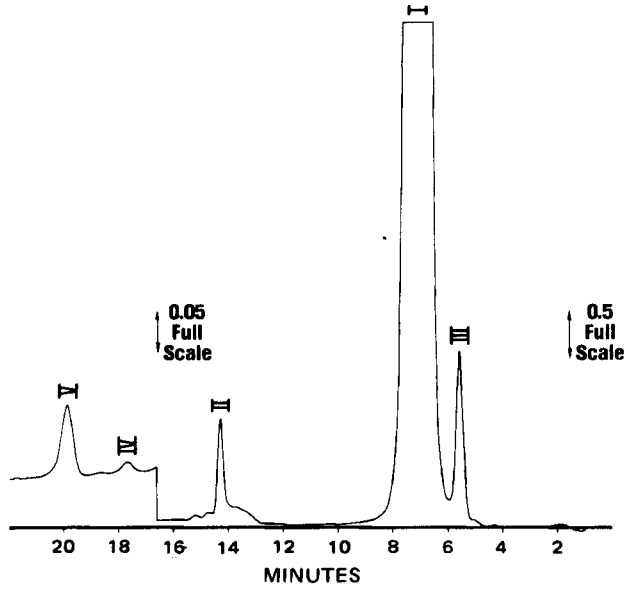

Figure 2—*Representative chromatogram of sample.*

so that:

$$\%\ \text{impurity} = \frac{\text{peak area of individual impurity} \times 100 \times K}{\text{mg of sample} \times F} \quad \text{(Eq. 3)}$$

DISCUSSION

The described HPLC method was developed for use in laboratories without a programmed solvent gradient system. The method requires one pump and an automatic switching valve. The microparticulate phenyl column produced symmetrical peaks without any tailing as compared to the C_{18} (alkyl) column (Figs. 2 and 3).

Standard linearity was checked over the ranges of 0.114–0.306 mg/ml for II, 0.286–0.620 mg/ml for III, 0.0215–0.036 mg/ml for IV, and 0.021–0.084 mg/ml for V. All four compounds responded linearly at the reported concentrations, thus providing more than an adequate range for their analysis as impurities in tetracycline (I).

Chromatographic variability was determined by six identical injections of a solution containing reference standards II–V. Standard variability was determined by a single injection of six different solutions containing reference standards II–V. Sample variability was determined by a single injection of six different preparations of the sample. Procedural variability was determined by a single injection of six individual standards and sample preparations. Standard deviations (s%) and relative standard deviations ($2s$%) for chromatographic variability, standard variability, sample variability, and procedural variability for II–V are shown in Table I.

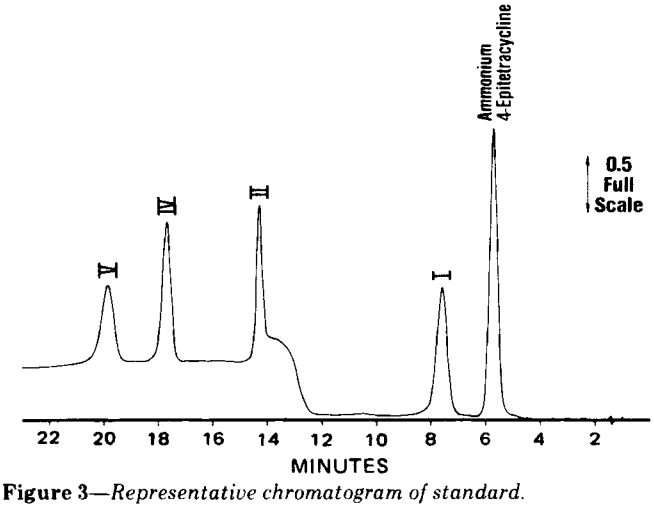

Figure 3—*Representative chromatogram of standard.*

Table I—Standard Deviations and Relative Standard Deviations

	II		III		IV		V	
	s%	$2s$%	s%	$2s$%	s%	$2s$%	s%	$2s$%
Chromatographic variability	0.0075	5.83	0.0663	2.80	0.0083	1.27	0.0183	3.39
Standard variability	0.0040	1.79	0.0081	2.34	0.0051	6.58	0.0016	2.20
Sample variability	0.029	5.44	0.049	4.92	0.0002	8.11	0.0012	4.10
Procedural variability	0.023	3.68	0.044	4.47	0.00017	7.60	0.0008	2.77

Table II—Representative Samples [a]

Sample[b]	II, %	III, %	IV, %	V, %
Capsule 1	1.95	1.13	1.30	3.19
Capsule 2	1.08	1.08	0.05	0.16
Capsule 3	1.98	1.08	0.83	4.01
Capsule 4	2.07	1.05	0.06	0.22
Capsule 5	2.05	1.12	0.02	0.13
Powder 1	1.88	1.09	0.004	0.068
Powder 2	1.99	1.05	0.005	0.054

[a] Percentages are based on the labeled claim of tetracycline. [b] Hard, filled capsules and bulk powders were used.

Accuracy of the assay was determined by spike recoveries of impurities II–V from I. Tetracycline (I) was spiked with impurities at 100% of the target value. The percent recoveries were 96, 102, 104, and 85% for II, III, IV, and V, respectively.

Several tetracycline-containing products were analyzed for impurities (II–V) (Table II).

In summary, the reversed-phase HPLC method described in this paper provides a rapid, sensitive, simple, and quantitative method for the simultaneous determination of impurities (II–V) in tetracycline (I).

Aminoalkanesulfonic Acids IV: Synthesis of Mitodepressive *N*-Nitrosoaminoalkanesulfonic Acids

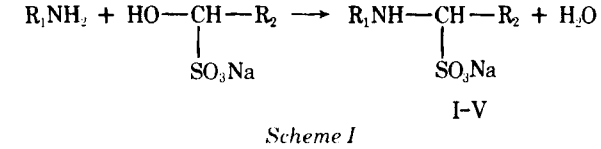
Lj. BUTULA ˣ **and Ž. BUKOVEC**

Received September 5, 1978, from the *Faculty of Pharmacy and Biochemistry, University of Zagreb, A. Kovačića 1, Zagreb, Yugoslavia.* Accepted for publication March 12, 1980.

Abstract □ Sodium aminoalkanesulfonates were synthesized from substituted amines and aldehyde sodium bisulfites at 40–60°. Nitrosation yielded the corresponding *N*-nitroso derivatives. Mitodepressive activity on cresse (*Lepidium sativum* L.) was determined, and all compounds examined possessed growth inhibition activity. The *N*-nitroso derivatives were slightly less active but also showed less toxicity than the parent aminoalkanesulfonic acids.

Keyphrases □ Aminoalkanesulfonic acids—synthesis of *N*-nitroso derivatives, evaluation for mitodepressive activity □ Mitodepressive activity—evaluation of aminoalkanesulfonic acids and *N*-nitroso derivatives □ *N*-Nitrosoaminoalkanesulfonic acids—synthesis, evaluation for mitodepressive activity

Aminoalkanesulfonic acids are known to have antiviral (1, 2) and anticancer (3, 4) activities. Some *N*-nitroso compounds, such as *N*-nitrosomethylamine, *N*-nitrosodimethylamine, and *N*-nitrosodiethylamine, showed blastogenic action when applied on Hungarian hamsters (5). Some experiments (6) showed imbalances in DNA and histone synthesis during carcinogenesis induced by nitrosamines. On the other hand, some *N*-nitroso compounds, such as 1,3-bis(2-chloroethyl)-1-nitrosourea (carmustine), are useful in the treatment of certain malignant diseases (7).



Scheme I

These findings prompted the synthesis of some new derivatives in this series (8–10) to determine their mitodepressive activity.

This report describes the synthesis of some sodium aminoalkanesulfonates (I–V) in which *m*- and *p*-chloroanilines were used with the corresponding aldehyde sodium bisulfites (Scheme I and Table I). In some cases, the desired products were obtained by the addition of sodium metabisulfite to azomethine derivatives (Scheme II).

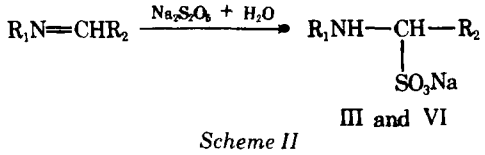
[a] Isolated in free acid form.

methane sulfonate[1] (VI) yielded the corresponding sodium *N*-nitrosoaminoalkanesulfonates (VII–XIII) (Scheme III and Table II). Compounds X and XII were isolated in the form of free sulfonic acids.

All products were tested for mitodepressive activity on cresse seeds (*Lepidium sativum* L.) by a literature method (12).

DISCUSSION

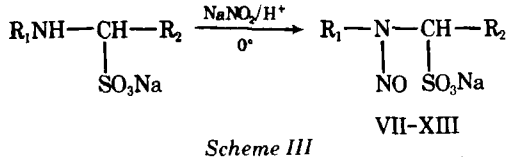
For the synthesis of the sodium salts of *m*- and *p*-chloroanilinoalkanesulfonic acids (I–VI), Method A was used at lower temperatures and shorter reaction times than those described by Neelekantan and Hartung



III and VI

Scheme II

[1] Compound VI was synthesized by Neelekantan and Hartung (11).



VII–XIII

Scheme III

(11). These conditions produced higher yields of both *m*- and *p*-chloroanilinoalkanesulfonic acids.

The method of Greco *et al.* (13) for nitrosation of α-aminocarboxylic acids was modified by employing a significantly shorter reaction time and a higher reaction pH to avoid extensive decomposition of the products.

In previous work (10), phytobiological experiments were carried out on a group of aminoalkanesulfonates in which 2-aminopyrimidine and 2-aminopyridine were incorporated. Significant inhibitory properties were observed.

The phytobiological experiments (Tables III and IV) showed that inhibitory properties of sodium alkanesulfonates (I–VI) varied between 50 and 80%. The R_1 and R_2 substituents did not influence inhibition greatly. Inhibition properties of *N*-nitroso derivatives (VII–XII) tended to be somewhat lower than those of the parent compounds. On the other hand, aminoalkanesulfonates were more toxic than the corresponding *N*-nitroso derivatives. Cresse seeds recovered their biological properties, such as growth, more readily when treated with *N*-nitroso compounds.

VI[a]	4-Chlorophenyl	Phenyl	70	53

[a] Synthesized by Neelekantan and Hartung (11).

Table IV—Inhibitory Properties of Sodium *N*-Nitrosoaminoalkanesulfonates

Compound	R_1	R_2	Inhibition, % 2 mg/ml	1 mg/ml
VII	3-Chlorophenyl	H	41	40
VIII	3-Chlorophenyl	CH_3	60	52
IX	3-Chlorophenyl	Phenyl	52	41
X[a]	4-Chlorophenyl	H	40	30
XI	4-Chlorophenyl	CH_3	46	28
XIII	4-Chlorophenyl	Phenyl	75	67

[a] Isolated in free acid form.

Mitodepressive effects of *N*-nitroso compounds probably result from a combination of the inhibitory effect of the parent sulfonic acids and the growth-stimulating activity of the incorporated *N*-nitroso group in VII–XII. Preliminary experiments with carcinoma Hep-2 cells of the nasopharynx showed that the parent compounds (I–VI) were predominantly cytotoxic while the related *N*-nitroso derivatives (VII–XIII) had mainly cytostatic activity.

EXPERIMENTAL[2]

Preparation of Sodium *m*- and *p*-Chloroanilinoalkanesulfonates—*Method A*—*m*- or *p*-Chloroaniline (6.3 g, 50 mmoles) and formaldehyde, acetaldehyde, or benzaldehyde sodium bisulfite (5.2 mmoles) were mixed in water (10 ml) for 1–2 hr at 40–50°. The reaction mixture was cooled to room temperature, and the crystals that formed were separated and recrystallized.

Method B—Benzaldehyde (5.3 g, 50 mmoles) was stirred with a solution of sodium metabisulfite (5.3 g, 2.8 mmoles) in 30 ml of water at room temperature for 1 hr. *m*- or *p*-Chloroaniline (6.3 g, 50 mmoles) was added to the reaction mixture, and the mixture was stirred and warmed to 60° for 1 hr. After cooling, the resulting crystals were removed by suction, dried in air at room temperature, and recrystallized.

Method C—Benzylidenechloroaniline (2.2 g, 10 mmoles) was warmed in a solution of sodium metabisulfite (2.7 g, 14 mmoles) in 10 ml of water for 1 hr at 40–50°. On cooling, the crystals that formed were isolated and recrystallized.

[2] Melting points were determined using a Buchi (Totoli) melting-point apparatus and are uncorrected. IR spectra were obtained on a Perkin-Elmer 457 grating instrument using potassium bromide wafers. TLC was carried out mainly on silica gel F-254 with butanol–concentrated ammonia (8:2) or benzene–methanol–acetic acid (7:2:1) as the solvent system.

Synthesis of Sodium *N*-Nitrosoaminoalkanesulfonates—A solution of sodium nitrite (7 mmoles) in 1 ml of water was added to a suspension (5 mmoles) of sodium chlorosulfonic acids (I–VI) in 10 ml of water at 0°. Dilute (5%) hydrochloric acid was added with mixing at 0–5° until pH 4 was reached. Stirring was continued for an additional 20 min at room temperature, and the solvent was removed at 30°. Colored crystals were obtained and purified by dissolution in methanol and precipitation in ether at room temperature.

The purity of all products was established chromatographically.

Phytobiological Experiments—Chromatographically pure products were tested for mitodepressive activity on germinating seeds of cresse[3] (*L. sativum* L.) in concentrations of 1 and 2 mg/ml. The values for inhibitory properties are calculated according to:

$$\% I = \frac{L_B - L_X}{L_B} \times 100 \qquad \text{(Eq. 1)}$$

where L_B is the mean value of the length of the cresse radicles formed by germination at 25 ± 1° in water and L_X is the mean value of cresse radicles formed in aqueous solutions of the tested compounds.

The experiments were carried out in the following manner. Twenty to 30 cresse seeds were placed on filter paper in a petri dish and covered with 15 ml of water. After the seeds were incubated for 24 hr at 25 ± 1°, water was decanted and an aqueous solution of the experimental compounds was added. One seed sample left in the water was used as a blank.

After further incubation for 24 hr at the same temperature, test solutions were decanted. The seeds were washed several times with water and fixed with a solution containing 2 g of salicylic acid, 2 g of zinc sulfate, and 15 drops of freshly prepared concentrated sodium phenoxide in 100 ml of distilled water. After fixation, radicles from 20 seeds were measured by using millimetric paper and a lens. A mean value of the measured radicle length was found for each sample, and the inhibitory properties were calculated (Tables III and IV).

4,5-Disubstituted Primaquine Analogs as Potential Antiprotozoan Agents

HANNS BURGHARD and C. DeWITT BLANTON, Jr. ˣ

Received January 7, 1980, from the *Department of Medicinal Chemistry, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication March 12, 1980.

Abstract □ 4,5-Dimethylprimaquine and 5-fluoro-4-methylprimaquine were synthesized and evaluated against *Plasmodium berghei* in the mouse. Significant blood schizonticidal activity was observed. The 5-fluoro-4-methylprimaquine analog also was active as a tissue schizonticidal agent when evaluated against *P. cynomolgi* in the rhesus monkey, as an antileishmanial agent when evaluated against *Leishmania donovani* in the hamster, and as a causal prophylactic agent when evaluated against *P. berghei yoelii.*

Keyphrases □ Primaquine analogs—synthesis and evaluation for antiprotozoan activity □ Antiprotozoan agents, potential—primaquine analogs, synthesis and evaluation for activity □ 8-Aminoquinolines, substituted—synthesis and evaluation for antiprotozoan activity

Although generally quite toxic, 8-aminoquinoline derivatives related to primaquine (I*a*) are of interest as potential radical curative and causal prophylactic antimalarial agents (1). Primaquine, the tissue schizonticidal drug of choice, is used mainly with a strong blood schizonticide as a radical cure of relapsing malaria and for chemoprophylaxis or the interruption of transmission (2). A major drawback of primaquine is its relatively low therapeutic index, and modification of the side chain of the molecule exclusively has not resulted in any marked improvement of antimalarial activity combined with reduced toxicity (3, 4).

Substitution of a methyl group onto the 8-amino-6-methoxyquinoline nucleus offers potential for obtaining agents with high antimalarial activity and reduced toxicity relative to the unsubstituted nucleus. For example, 4-methylprimaquine (I*b*) was reported (5, 6) to possess enhanced antimalarial activity and somewhat lower toxicity when evaluated against *Plasmodium cynomolgi* in the rhesus monkey (7, 8) and *P. berghei* in mice (9). Similar trends were reported when 8-aminoquinoline derivatives were screened against *P. gallinaceum* (10). Thus, 8-[(2-diethylaminoethyl)amino]-6-methoxyquinoline (II*a*) had a therapeutic index of 1.8 (10) while the 4-methyl (II*b*) and 5-methyl (II*c*) analogs possessed therapeutic indexes of 20 and 9.1, respectively. Nuclear substitution and modification of the side chain at position 8 led to further improvement in the therapeutic index, as seen with II*d* and II*e*, which had therapeutic indexes of 59 and 33.5 (10). Based on these considerations, a program was initiated to synthesize and evaluate the potential antimalarial activity of 4,5-dimethylprimaquine (I*c*).

II*c*: R = H, R_1 = CH_3, n = 2
II*d*: R = CH_3, R_1 = H, n = 6
II*e*: R = H, R_1 = CH_3, n = 6

DISCUSSION

Chemistry—The synthesis of the key intermediate (VII) required for the preparation of 4,5-dimethylprimaquine (I*c*) is outlined in Scheme I. 4-Amino-2-fluoro-5-nitroanisole (III) was prepared by the procedure of Elderfield *et al.* (11). Reaction of III with methyl vinyl ketone under modified Skraup conditions (12) gave 4-methyl-5-fluoro-6-methoxy-8-nitroquinoline (IV). Attempts to displace the activated fluorine atom at position 5 with a methyl nucleophile [*e.g.*, methylenetriphenylphosphorane (13)] failed. Similarly, attempts to displace the fluorine atom with a cyanide ion (14) for subsequent reduction (15, 16) to a methyl group failed.

The use of 18-crown-6 ether (17) did not facilitate cyanide-ion displacement of the fluorine atom. However, by reaction of the anion of ethyl malonate and IV in the presence of copper(I) bromide (18) and 18-crown-6 ether, it was possible to displace the fluorine atom with formation of a carbon–carbon bond (V). Acid hydrolysis of the substituted malonate (V) led directly to the desired intermediate (VII). If the hydrolysis step was terminated too soon, the substituted acetic acid derivative (VI) could be isolated. Reduction of 4,5-dimethyl-6-methoxy-8-nitroquinoline (VII) with stannous chloride and alkylation of the amine (VIII) by 4-bromo-1-phthalimidopentane (19) in triethylamine (20, 21) followed by hydrazinolysis gave the desired analog (I*c*).

Since IV then was readily available, 4-methyl-5-fluoroprimaquine (I*d*) also was prepared. Standard reduction of IV and alkylation of the amine (X) followed by hydrazinolysis gave the desired product (I*d*).

Direct synthesis of VII by the Skraup reaction of 2-nitro-4-methoxy-5-methylaniline (XI) (22) and methyl vinyl ketone (Scheme II) was attempted, but the expected intermediate (XII) was the only isolated product; various alterations in experimental conditions or reagents did not change the course of the reaction. (Several of these alterations are summarized in Scheme II, and the uncyclized intermediates XIII and XIV were isolated as in the case of XII.) Steric effects, as well as electronic effects, may prevent direct cyclization to VII. Therefore, Skraup cyclization of III and methyl vinyl ketone, although in low yield, was possible since the fluoro compound (III) presented less of a steric problem than XI.

Antiprotozoan Activity[1]—The blood schizonticidal activity of the potential antimalarials I*c* and I*d* was assessed against *P. berghei* in mice by the method of Osdene *et al.* (9). 4,5-Dimethylprimaquine (I*c*) was active[2] in the Rane test: ΔMST = 7.6 at 160 mg/kg, 9.1 (1C, 2T) at 320 mg/kg, and 0.0 (3C, 2T) and 10.8 (1C, 3T) at 640 mg/kg. 5-Fluoro-4-methylprimaquine (I*d*) showed good activity against *P. berghei* at 10 mg/kg (ΔMST = 6.7). Doses higher than 40 mg/kg produced toxic deaths in all animals (5T). Primaquine diphosphate was active at 80 mg/kg (ΔMST = 9.4) with drug-related toxic deaths at 160 (ΔMST = 10.8, 2T) and 320 (ΔMST = 0.0, 5T) mg/kg.

The tissue schizonticidal potential[1] of I*d* was evaluated in rhesus monkeys by a literature procedure (7, 8). Compound I*d* showed 3/3 cures[3]

[1] Antiprotozoan test results were provided by the Walter Reed Army Institute of Research. Tests for blood schizonticidal and causal prophylactic activity were carried out by the Rane Laboratory, University of Miami, Miami, Fla. Tests for tissue schizonticidal activity were carried out by Dr. L. H. Schmidt, Southern Research Institute, Birmingham, Ala. Tests for antileishmanial activity were carried out by Dr. W. L. Hanson, University of Georgia, Athens, Ga.

[2] The mean survival time (MST) of untreated mice is 6.1 days. A compound is active if ΔMST exceeds 6.1 days. Animals that survive 60 days postinfection are considered cured (C). Deaths on Days 2–5 after drug administration are attributed to drug toxicity (T).

[3] Monkeys that do not relapse in 90 days are considered cured.

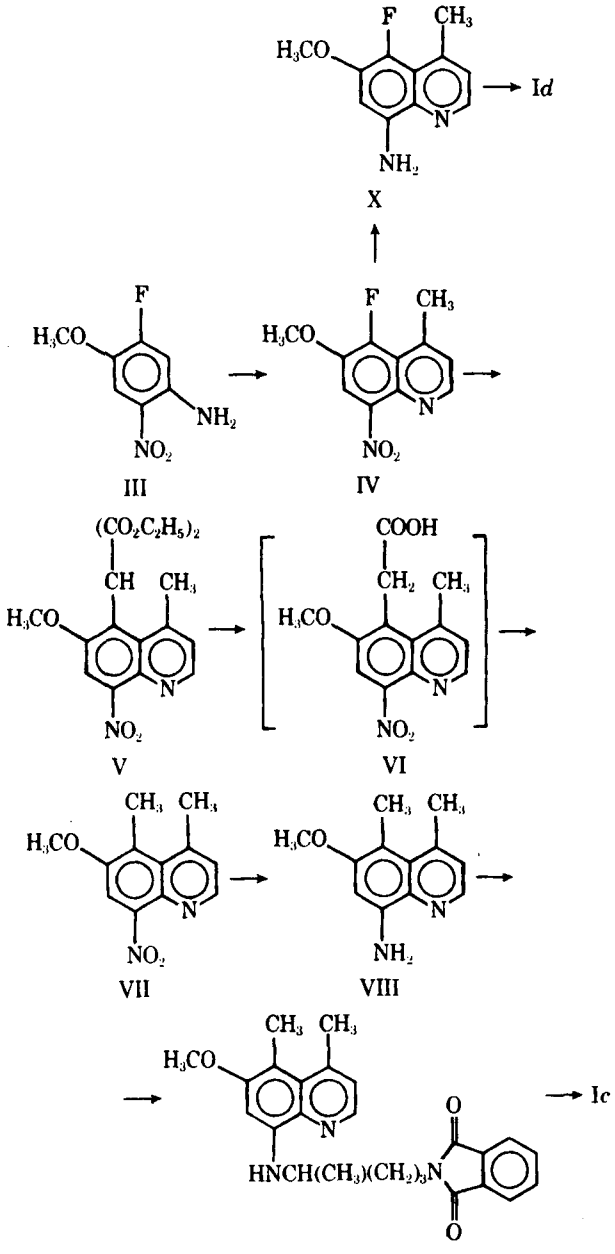


Scheme I

at 0.5 mg/kg. Primaquine diphosphate cured 90% of the monkeys in this test system when administered at a dose of 1.3 mg/kg for 7 days in combination with 5 mg of chloroquine/kg/day.

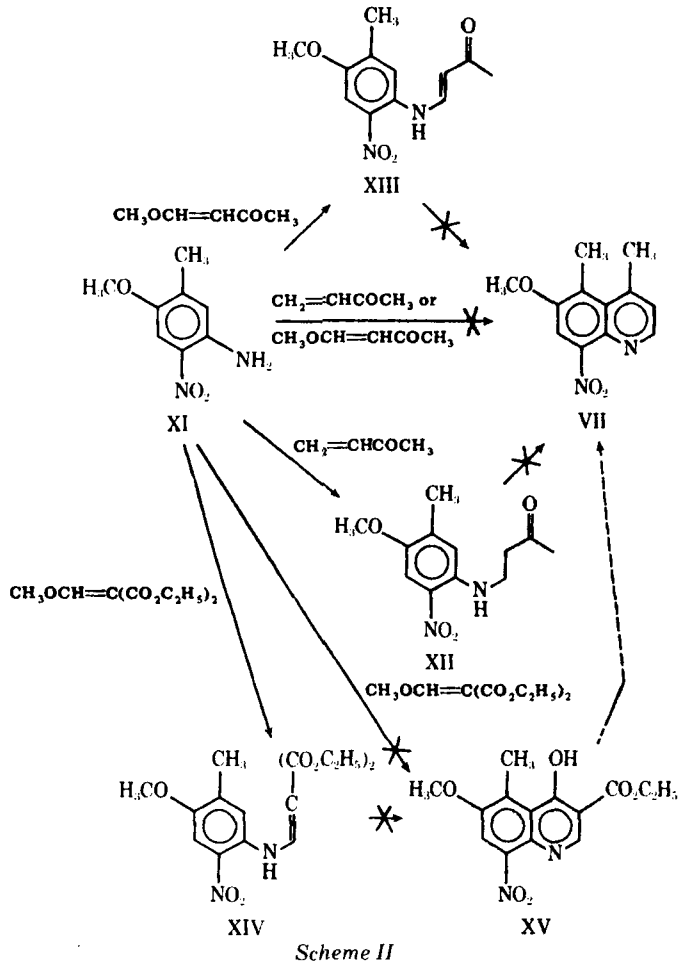
The antileishmanial activity[1] of Id against *Leishmania donovani* was determined in golden hamsters by the method of Hanson *et al.* (23). The suppressive effects of the test compound were compared to those of the reference compound, *N*-methylglucamine antimoniate[4], and a G index[5] was calculated (4, 23). 5-Fluoro-4-methylprimaquine (Id) showed significant activity in the antileishmanial screen with a G index of 10.98 at 3.25 mg/kg/day. Primaquine possessed a G index of 0.96 at the SD_{90} level, whereas some 8-aminoquinolines with a methyl group at position 4 were reported to have enhanced antileishmanial properties (24); *e.g.*, 8-[(6-diethylaminohexyl)amino]-6-methoxy-4-methylquinoline had a G index of 472 at the SD_{90} level (4).

Compound Id was tested for causal prophylactic activity[1,6] against sporozoite-induced *P. berghei yoelii* in rodents (25, 26). This agent was active at 10 mg/kg when administered subcutaneously (5/5 cures).

[4] Glucantime.

[5] The glucantime index, G, was calculated using G = dose (SD_x) of glucantime/dose (SD_x) of test drug.

[6] Prophylactic activity is evidenced by survival of drug-treated mice for 30 days. Survival of 40% or more of the treated mice indicates activity.



Scheme II

Compound Id given orally was active at 10 and 40 mg/kg (5/5 cures).

Although Ic was not tested for tissue schizonticidal, antileishmanial, or causal prophylactic activity, the data presented confirm that appropriate substituents at the 4- and 5-positions can alter significantly the antiprotozoan activity of 8-aminoquinolines. In the blood schizonticidal test (9), Id was more active at lower doses than primaquine, but it also was more toxic. Compound Ic was not as active as primaquine in this test system, but it was significantly less toxic.

EXPERIMENTAL[7]

4-Methyl-5-fluoro-6-methoxy-8-nitroquinoline (IV)—4-Amino-2-fluoro-5-nitroanisole (III) was prepared by the method of Elderfield *et al.* (11). Compound III (37.23 g, 0.2 mole), 34.96 g of arsenic pentoxide (0.15 mole), and 45 ml of 85% phosphoric acid were mixed to form a viscous slurry. This slurry was stirred vigorously until a homogeneous paste formed. Then 200 ml of 85% phosphoric acid was added gradually while stirring. The suspension was heated to 90°. This mixture was treated with 16.8 g (0.24 mole) of methyl vinyl ketone at such a rate as to maintain the temperature at 90°; the addition required 0.5 hr.

The resulting mixture was kept at 85–95° for 1.5 hr and then was poured into 800 ml of ice-cold water and slowly made basic with 450 ml of concentrated ammonium hydroxide. The dark solid was collected, washed with water, and dried at 50° overnight. The product was dissolved in chloroform (200 ml), but some tar and by-products remained undissolved. A volume of silica gel approximately equal to the volume of crude product was added, and the chloroform mixture was removed *in vacuo*. The brown silica gel complex was transferred onto a short column containing approximately a double volume of fresh silica gel. This column

[7] Melting points were determined on a Thomas-Hoover apparatus (capillary method) and are uncorrected. NMR spectra were determined on a Hitachi Perkin-Elmer R20A high-resolution NMR spectrometer using tetramethylsilane as the internal reference. IR spectra were determined on a Perkin-Elmer 467 grating spectrophotometer using the potassium bromide technique. Elemental analyses were determined by Atlantic Microlab, Atlanta, Ga. Mass spectra were determined on a DuPont 21-490 low-resolution mass spectrometer.

was eluted with chloroform, and the solvent was evaporated *in vacuo* to give a red impure product.

Recrystallization from ethyl acetate gave 11.8 g (25% yield) of product, mp 142°; NMR[8]: δ 2.81 (d, 3H, CH_3 at C-4, J = 7 Hz), 3.90 (s, 3H, CH_3O at C-6), 7.26 (d, H at C-3, J = 5 Hz), 8.67 (d, H at C-2, J = 5 Hz), and 8.95 (*d*, H at C-7, J = 8 Hz). Concentration of the mother liquor gave another 4.3 g (9% yield) for an overall yield of 34%. If the quantity of methyl vinyl ketone is doubled, the yield can be raised to 60–70%.

Anal.—Calc. for $C_{11}H_9FN_2O_3$: C, 55.93; H, 3.84; N, 11.85. Found: C, 55.97; H, 3.88; N, 11.80, 11.82.

Diethyl α-(4-Methyl-6-methoxy-8-nitroquinolyl)malonate (V)—Sodium hydride (0.7 g of 50% dispersion in paraffin oil) was added over 10 min to a stirred mixture of IV (2.95 g, 12.5 mmoles) and copper(I) bromide (0.1 g, 0.7 mmole) in 25 ml of ethyl malonate. The mixture was maintained in an oil bath at 40–45° during the addition of sodium hydride. Ten drops of 18-crown-6 ether were added to the mixture, and the temperature was raised to 80°. Stirring and heating (60–80°) under a nitrogen atmosphere was continued for 6 hr.

The red solution was cooled and diluted with 600 ml of water, and the pH of the aqueous mixture was adjusted to 10 with 10% NaOH. After standing for 48 hr at room temperature, a fluffy yellow solid (5.1 g) was collected by filtration. The material was recrystallized from benzene–petroleum ether (30–60°), mp 162–163° (4.1 g, 87% yield); NMR ($CDCl_3$): δ 1.28 (t, 6H, CH_3 groups of esters), 2.88 (s, 3H, CH_3 at C-4), 3.98 (s, 3H, CH_3O at C-6), 4.25 (q, 4H, CH_2 groups of esters), 5.7 (s, 1H, CH at C-5), 7.28 (broad s, 1H, H at C-3), 7.75 (s, 1H, H at C-7), and 8.65 (broad s, 1H, H at C-2); mol. wt. (mass spectra): calc., 376, and found, 376.

Anal.—Calc. for $C_{18}H_{20}N_2O_7$: C, 57.44; H, 5.36; N, 7.44. Found: C, 57.42; H, 5.38; N, 7.39.

4,5-Dimethyl-6-methoxy-8-nitroquinoline (VII)—Compound V (2.9 g, 7.7 mmoles) was suspended in 50 ml of water and treated with 10 ml of acetic acid and 5 ml of concentrated sulfuric acid. The temperature of the mixture was raised slowly to reflux. The dark mixture was stirred and refluxed for 4 hr (oil bath temperature was maintained between 130 and 150°), cooled, and poured into 250 ml of water containing sufficient 10% NaOH to give a pH of 10. A greenish-gray product separated.

The product was collected by filtration and recrystallized from aqueous dimethylformamide after treatment with charcoal to yield fine yellow needles, mp 177–179° (1.5 g, 83.7% yield); NMR (dimethyl sulfoxide-d_6): δ 2.66 (s, 3H, CH_3 at C-5), 2.85 (s, 3H, CH_3 at C-4), 3.98 (s, 3H, CH_3O at C-6), 7.35 (d, 1H, H at C-3, J = 4.5 Hz), 8.15 (s, 1H, H at C-7), and 8.60 (d, 1H, H at C-2, J = 4.5 Hz).

Anal.—Calc. for $C_{12}H_{12}N_2O_3$: C, 62.06; H, 5.21; N, 12.06. Found: C, 62.12; H, 5.26; N, 12.04.

α-(4-Methyl-6-methoxy-8-nitroquinolyl)acetic Acid (VI)—When the oil bath temperature was not maintained above 130°, hydrolysis and decarboxylation of V was incomplete, and VI was obtained in near quantitative yield, mp 115–117°; NMR (dimethyl sulfoxide-d_6): δ 2.90 (s, 3H, CH_3 at C-4), 4.00 (s, 3H, CH_3O at C-6), 4.30 (s, 2H, CH_2 at C-5), 7.45 (broad s, 1H, H at C-3), 8.3 (s, 1H, H at C-7), and 8.7 (broad s, 1H, H at C-2).

When VI was refluxed with the aqueous acetic acid–sulfuric acid mixture at 130–150° for 4 hr, VII was obtained in a 97.6% yield.

8-Amino-4,5-dimethyl-6-methoxyquinoline (VIII)—A solution of stannous chloride hydrate (31.6 g, 0.14 mole) and 15 ml of concentrated hydrochloric acid was cooled to −5–0°. After the addition of 0.5 g of mossy tin, the mixture was stirred as a precooled solution of VII (8.2 g, 0.035 mole) in 25 ml of concentrated hydrochloric acid was added at a rate such that the temperature remained below 6°. The addition required ~45 min. The brown suspension was stirred for an additional 15 min at 0°, and the ice bath was removed.

After stirring at room temperature for 5 hr, the brown suspension was poured into 200 ml of water. The yellow solid which precipitated became gray when the acidic mixture was made basic with 9 *N* NaOH. The basic solution was covered with 200 ml of ether–ethyl acetate (1:1) and filtered through diatomaceous earth[9] to remove some black insoluble material. The organic layer was separated from the water layer, and the filter cake was washed with ethyl acetate (200 ml) and acetone (200 ml). The aqueous layer was extracted with ethyl acetate (2 × 100 ml). All organic layers were combined and dried (magnesium sulfate).

Removal of the solvents *in vacuo* gave a gold-colored solid. The analytical sample was obtained from aqueous ethanol (4.5 g, 63.6% yield), mp 127–128°; NMR ($CDCl_3$): δ 2.6 (s, 3H, CH_3 at C-4), 2.8 (s, 3H, CH_3 at C-5), 3.80 (s, 3H, CH_3O at C-6), 4.8 (broad s, 2H, NH_2, exchanged by deuterium oxide), 6.7 (s, 1H, H at C-7), 7.05 (d, 1H, H at C-3, J = 4.5 Hz), and 8.39 (d, 1H, H at C-2, J = 4.5 Hz).

Anal.—Calc. for $C_{12}H_{14}N_2O$: C, 71.26; H, 6.98; N, 13.85. Found: C, 70.99; H, 6.98; N, 13.85.

4,5-Dimethyl-6-methoxy -8- [(4-amino-1-methylbutyl)amino]-quinoline (Ic) Maleate—A mixture of VIII (4 g, 0.0198 mole), 4-bromo-1-phthalimidopentane (8.79 g, 0.0297 mole), and triethylamine (3 g, 0.0297 mole) was stirred and heated at 110–135° for 5 hr. Additional 4-bromo-1-phthalimidopentane (2.93 g, 0.0099 mole) and triethylamine (1 g) were added, and heating was continued for 6 hr. The dark reaction mixture was digested in 200 ml of benzene and filtered hot to remove triethylamine hydrobromide. The benzene was removed *in vacuo* to give a dark blood-red oil. This oil was treated with ethanol (150 ml) and 15 ml of 85% hydrazine hydrate.

The mixture was refluxed for 3 hr, cooled to room temperature, and concentrated *in vacuo*. The residue was treated with methylene chloride (200 ml) and filtered to remove phthalhydrazide. The methylene chloride filtrate was dried (magnesium sulfate) and concentrated to an oil. The residual oil was treated with 50 ml of ethanol and 3 g of maleic acid. Addition of ether precipitated a voluminous yellow solid. After recrystallization from ethanol–ether, 1.9 g of the maleate of Ic was obtained (23.8% yield), mp 135–137°.

Anal.—Calc. for $C_{21}H_{29}N_3O_5$: C, 62.51; H, 7.24; N, 10.41. Found: C, 62.49; H, 7.27; N, 10.41.

4-Methyl-5-fluoro-6-methoxy-8-aminoquinoline (X)—Compound IV was reduced by the procedure described for the preparation of VIII. Compound X was obtained in a 91% yield (ethanol) as greenish-white crystals, mp 129°; NMR (dimethyl sulfoxide-d_6): δ 2.64 (d, 3H, CH_3 at C-4, J = 7.0 Hz), 3.9 (s, 3H, CH_3O at C-6), 6.8 (d, H at C-7, J = 8.0 Hz), 7.18 (d, H at C-3, J = 5.0 Hz), and 8.39 (d, H at C-2, J = 5.0 Hz).

Anal.—Calc. for $C_{11}H_{11}FN_2O$: C, 64.06; H, 5.37; N, 13.58. Found: C, 64.22; H, 5.40; N, 13.56.

4-Methyl-5-fluoro-6-methoxy-8-[(4-amino-1-methylbutyl)amino]quinoline (Id) Maleate—The maleate of Id was prepared in a 59% yield (ethanol) by the procedure described for Ic, mp 131°.

Anal.—Calc. for $C_{20}H_{26}FN_3O_5$: C, 58.95; H, 6.43; N, 10.31. Found: C, 58.70; H, 6.48; N, 10.25.

2-Nitro-4-methoxy-5-methyl-*N*-(3-oxobutyl)aniline (XII)—2-Nitro-4-methoxy-5-methylaniline (1.82 g, 0.01 mole), prepared by the procedure of Carmack *et al.* (22), and 40 g of 85% phosphoric acid were heated at 85° while 1.05 g (0.015 mole) of methyl vinyl ketone was added dropwise with vigorous stirring. After 30 min, the addition was completed and the mixture was stirred for an additional 30 min. The brown solution was poured into ice–water and filtered, and the orange product was dried. After recrystallization from ethanol (1.84 g, 73% yield), XII melted at 138°. [This material was identical to that isolated from the Skraup reaction, and no evidence for quinoline (VII) formation was observed.]

Anal.—Calc. for $C_{12}H_{16}N_2O_4$: C, 57.13; H, 6.39; N, 11.10. Found: C, 57.11; H, 6.43; N, 11.12.

4-(2-Nitro-4-methoxy-5-methylanilino)but-3-en-2-one (XIII)—2-Nitro-4-methoxy-5-methylaniline (3.64 0.02 mole) (22) was mixed with 4.0 g (0.04 mole) of 4-methoxybut-3-en-2-one and fused at 150° for 3 hr. The flask was fitted with a condenser to remove methanol. Red crystals were collected when the reaction mixture was cooled and the residue recrystallized from ethanol (71% yield), mp 177°. [This product was identical to that obtained when Skraup reaction conditions were employed, and no evidence of quinoline (VII) formation was obtained.]

Anal.—Calc. for $C_{12}H_{14}N_2O_4$: C, 57.59; H, 5.63; N, 11.19. Found: C, 57.55; H, 5.66; N, 11.22.

Diethyl (3-Methyl-4-methoxy-6-nitroanilino)methylenemalonate (XIV)—2-Nitro-4-methoxy-5-methylaniline (0.91 g, 0.005 mole) (22) and 1.08 g (0.005 mole) of diethyl methoxymethylenemalonic ester were fused (27) and kept at 150° for 45 min. The crude product (XIV) was recrystallized from ethanol (1.61 g, 92% yield, mp 127–128°. [No evidence for quinoline (XV) formation was obtained.]

Anal.—Calc. for $C_{16}H_{20}N_2O_7$: C, 54.54; H, 5.72; N, 7.95. Found: C, 54.41; H, 5.72; N, 7.96.

[8] The solvent was Unisol-D, a blended mixture of deuterated chloroform and deuterated dimethyl sulfoxide, Norell Chemical Co., Landisville, N.J.

Aporphines XXVI: GLC and Mass Spectrometric Properties of Trifluoroacetyl Derivatives of *N*-Methyl-, *N*-Propyl-, and Noraporphines

J. F. GREEN *, G. N. JHAM ‡, J. L. NEUMEYER *, and PAUL VOUROS ‡x

Received December 4, 1979, from the **Department of Medicinal Chemistry and the* ‡*Institute of Chemical Analysis, Applications and Forensic Science, Northeastern University, Boston, MA 02115.* Accepted for publication March 12, 1980.

Abstract □ The *O*-trifluoroacetyl and *N,O*-trifluoroacetyl derivatives of a series of aporphine and noraporphine alkaloids were prepared, and their GLC and mass spectrometric characteristics were determined. The positional isomers apocodeine and isoapocodeine were resolved chromatographically as their trifluoroacetyl derivatives, and their mass spectra were distinctly different. Mass spectrometric fragmentation processes apparently unique to *N*-trifluoroacetyl derivatives of noraporphines were observed. Plausible mechanisms for the formation of the major ions in the mass spectra of the various compounds are given.

Keyphrases □ Aporphines—trifluoroacetyl derivatives, GLC and mass spectrometry □ Noraporphines—trifluoroacetyl derivatives, GLC and mass spectrometry □ GLC—trifluoroacetyl derivatives of aporphines and noraporphines

The need for sensitive and quantitative methods for elaborating the metabolism of apomorphine (I*a*) (Scheme I) has increased due to the biological activity of apomorphine and related alkaloids (1–3). Although conjugation was reported as a primary route for the metabolism of I*a* in the rat (4), apocodeine (I*d*) and isoapocodeine (I*e*) formed from *O*-methylation have been reported as possible metabolites in rat liver preparations (5). *N*-Dealkylation also was reported to give an *in vitro* metabolite of several naturally occurring aporphine alkaloids (6). More recent studies in liver microsomal preparations indicated that several aporphine analogs could be converted metabolically to their *O*-demethylated derivatives (*i.e.*, I*d* → I*a* and I*e* → I*a*) (7).

BACKGROUND

N-n-Propylnorapomorphine (I*b*) was reported to be several times more potent than I*a* in several biological systems (3). Monohydroxyaporphines substituted in either the 10- or 11-position were found to be active dopamine agonists, although they were less potent than I*b* (8, 9). It is generally accepted that catechol analogs of apomorphine are more potent dopamine agonists than are the monohydroxy analogs (10). However, the possibility that monohydroxy analogs such as I*j* and I*k* are converted *in vivo* into a catechol-like compound (*e.g.*, I*b*) cannot be excluded (11). Preliminary studies showed no evidence for the microsomal hydroxylation of the monohydroxy aporphines I*j* and I*k* to the corresponding catechol, I*b*, using TLC to distinguish monophenols from catecholic metabolites (7).

To develop more definitive techniques, specifically GLC–mass spectrometric methods for the detection, identification, and quantitation of aporphines, the *O*-trifluoroacetyl derivatives of a series of *N*-methyl- and *N*-propylaporphines were prepared. Since *N*-dealkylation is a common metabolic process, the mass spectra of a series of trifluoroacetyl noraporphine derivatives also were considered. It was hoped that this examination might reveal unique fragmentation processes which could aid in the recognition of noraporphine metabolites or natural products in general.

Paper chromatography, GLC, and TLC were used previously to define

Ia Ie Ic Id

Scheme I—Possible metabolic pathways of apomorphine

the metabolism of such compounds *in vitro* (5, 7) and *in vivo* (12). These techniques *per se* do not necessarily define specificity for such studies. Findings obtained in these laboratories indicated that GLC–mass spectrometry permitted unambiguous analysis of a series of hydroxynoraporphines as their *N*-heptafluorobutyryl-*O*-trimethylsilyl derivatives (13), as well as the trimethylsilyl derivatives for *N*-methyl- and *N*-propylaporphines (14). GLC–mass spectrometry of the trifluoroacetyl derivatives described in this report offers specific advantages over the use of both their trimethylsilyl and heptafluorobutyryl-*O*-trimethylsilyl counterparts.

EXPERIMENTAL

The compounds were available in these laboratories as their hydrochloride or hydroiodide salts. A solution of 1 mg/ml or less of the aporphine and noraporphine in trifluoroacetic anhydride was prepared and heated for 10 min at 60°. The excess reagent was evaporated under a nitrogen stream, and the derivative was dissolved in methylene chloride to yield a 1-mg/ml solution. An aliquot (1–2 μl) was injected into the gas–liquid chromatograph–mass spectrometer system[1] for analysis.

A 183-cm × 2-mm i.d. glass column packed with 1% OV-17 on 100–120-mesh Supelcoport and temperature programmed for 6°/min from 200° was used. The gas chromatograph injection port, detector, and transfer line were maintained at 250, 250, and 200°, respectively. The mass spectrometer ion source was heated to 225°. Mass spectra were recorded in the electron-impact mode (70 ev) at an accelerating voltage of 4.5 kv and a trap current of 50 μamp.

If	29.52	27.67
Ij	29.08	25.80
Ik	27.07	24.33

[a] Values are in methylene units.

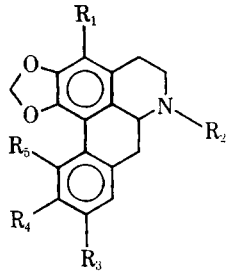
The following compounds were prepared as their *O*-trifluoroacetyl derivatives and studied by GLC–mass spectrometry: apomorphine (Ia), *N*-*n*-propylnorapomorphine (Ib), apocodeine (Id), isoapocodeine (Ie), *N*-*n*-propylnorapocodeine (If), 2,10,11-trihydroxyaporphine (Ig), morphothebaine (Ih), 11-hydroxy-2,10-dimethoxyaporphine (Ii), 10-hydroxy-*N*-*n*-propylnoraporphine (Ij), and 11-hydroxy-*N*-*n*-propylnoraporphine (Ik).

Mass spectrometric data also were acquired on the following noraporphines as their *N*-trifluoroacetyl or *N*,*O*-bis(trifluoroacetyl) derivatives: 11-hydroxy-2,10-dimethoxynoraporphine (Il), 10-methoxy-2,11-dimethoxynoraporphine (Im), and 2,10,11-trihydroxynoraporphine (In). The naturally occurring aporphine alkaloids sparsiflorine (Io), asimilobine (Ip), tuduranine (Iq), bulbocapnine (IIa), nandigerine (IIb), cassyfiline (IIc), xylopine (IId), anolobine (IIe), and actinodaphnine (IIf) also were examined[2].

RESULTS AND DISCUSSION

GLC—N-*Propyl- and* N-*Methylaporphines*—The GLC retention data of the *O*-trifluoroacetyl derivatives of *N*-propyl- and *N*-methylaporphines are given in Table I. For comparison, the methylene unit values for the corresponding trimethylsilyl derivatives reported previously (13) have been included.

In general, the *O*-trifluoroacetyl derivatives of these compounds exhibited good GLC characteristics. The retention data indicate a marked increase in volatility for the *O*-trifluoroacetyl derivatives compared to the corresponding *O*-trimethylsilyl derivatives. For example, this increase in volatility for apomorphine represents a 40° difference in the elution temperature (280 *versus* 240°). This difference not only decreases analysis time but also eliminates the problems of thermal sensitivity associated with these compounds (14).



II

IIb: $R_1 = R_2 = R_3 = H, R_4 = OH, R_5 = OCH_3$
IIc: $R_1 = R_4 = OCH_3, R_2 = R_5 = H, R_3 = OH$
IId: $R_1 = R_2 = R_4 = R_5 = H, R_3 = OCH_3$
IIe: $R_1 = R_2 = R_4 = R_5 = H, R_3 = OH$
IIf: $R_1 = R_2 = R_4 = H, R_3 = OH, R_5 = OCH_3$

[2] The aporphine alkaloids Io–Iq and IIb–IIf were kindly supplied by Dr. M. Shamma, Pennsylvania State University.

Table II—GLC Retention Data of Noraporphine Derivatives [a]

Compound	Mixed Derivative[b]	Trifluoroacetyl Derivative
Im	30.48	30.60
In	30.00	28.90
Io	28.96	26.30

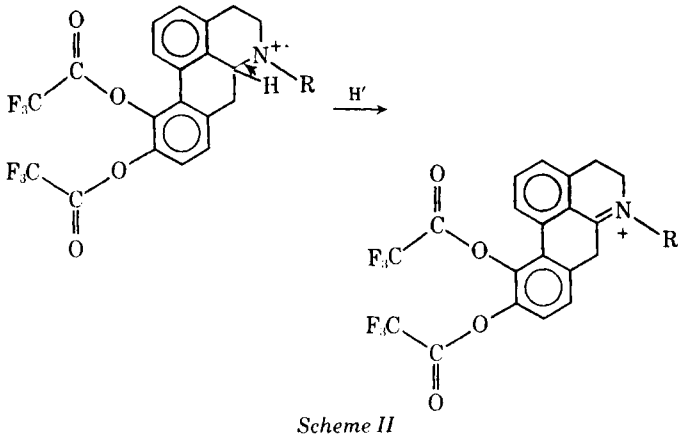
[a] Values are in methylene units. [b] *N*-Heptafluorobutyryl-*O*-trimethylsilyl derivative.

Of even greater importance is the ability to separate chromatographically, with baseline resolution, the *O*-trifluoroacetyl derivatives of apocodeine (Id) and isoapocodeine (Ie), as substantiated by the retention data in Table I. By contrast, the *O*-trimethylsilyl derivatives of these compounds coelute, a phenomenon that was observed previously (7). Because these two compounds were suggested as possible metabolites of apomorphine, it is essential to identify and to distinguish these products in a biological medium.

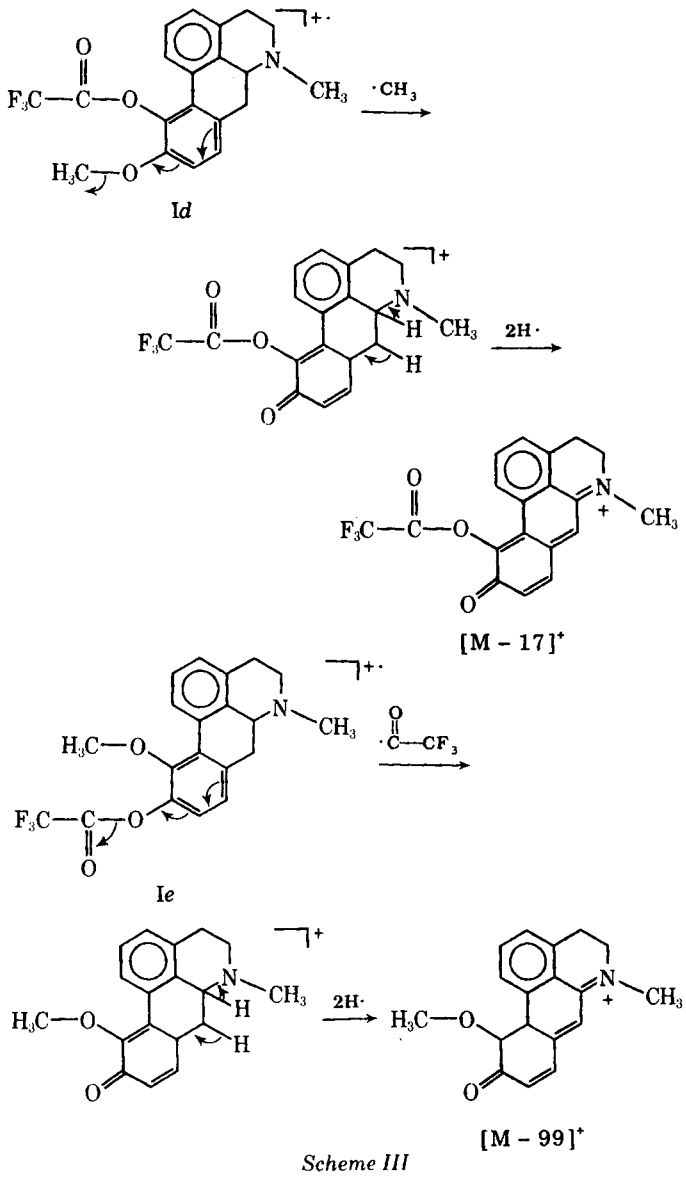
Noraporphines—The retention data for the trifluoroacetyl derivatives of noraporphines (Il–In) are given in Table II. These data can be compared to the methylene units of the corresponding mixed derivatives (*O*-trimethylsilyl-*N*-heptafluorobutyryl) reported previously (13). The general improvement in volatility when trifluoroacetyl derivatives are used is apparent. Moreover, temperature variation of the injection port, column, detector, and gas chromatograph–mass spectrometer transfer line over a wide range gave no indication of thermal sensitivity for the trifluoroacetyl derivatives as opposed to their trimethylsilyl counterparts.

Mass Spectrometry—*N-Methyl- and N-Propylaporphines*—The complete mass spectra of the trifluoroacetyl derivatives of apomorphine (Ia), *N*-*n*-propylnorapomorphine (Ib), apocodeine (Id), and isoapocodeine (Ie) are shown in Figs. 1–4, respectively. Partial mass spectra of the compounds in the series are summarized in Tables III and IV.

$M^{+\cdot}$ and $[M-1]^+$ Ions—The mass spectra of the *O*-trifluoroacetyl derivatives of *N*-methyl- and *N*-propylaporphines were noted for the high intensity of the molecular ion peaks or those corresponding to the loss of a hydrogen at $[M-1]^+$. The $[M-1]^+$ ion presumably is formed by the loss of the 6α-hydrogen to yield a quaternary nitrogen (Scheme II). In general, there were few other ions of any significance in the spectra of the



Scheme II



Scheme III

N-methylaporphines. The only peak of any significant intensity in most cases was $[M-97]^+$, arising from the loss of $CF_3C(=O)\cdot$ from $M^{+\cdot}$.

Apocodeine and Isoapocodeine—Two significant differences may be noted (Figs. 3 and 4 and Table III) when the mass spectra of these positional isomers are compared. The spectrum of apocodeine shows a peak at $[M-17]^+$, which was not detected in the spectrum of the trifluoroacetyl derivative of isoapocodeine. In addition, the relative intensities of the peaks at $[M-99]^+$ in the spectra of these two compounds are significantly different, the $[M-99]^+$ ion being much more (10 times)

abundant in the spectrum of the isoapocodeine derivative. These differences can be explained by the formation of a quinone-type ion structure (Scheme III). The *O*-trimethylsilyl derivatives of these compounds have virtually identical spectra.

N-n-*Propyl Compounds*—In addition to the $[M - 1]^+$ and $[M - 99]^+$ ions, there are fragmentation pathways specific for compounds containing an *N-n*-propyl substituent. The base peak in the spectra of the *N-n*-propyl compounds studied occurred at $[M - 29]^+$, which results from

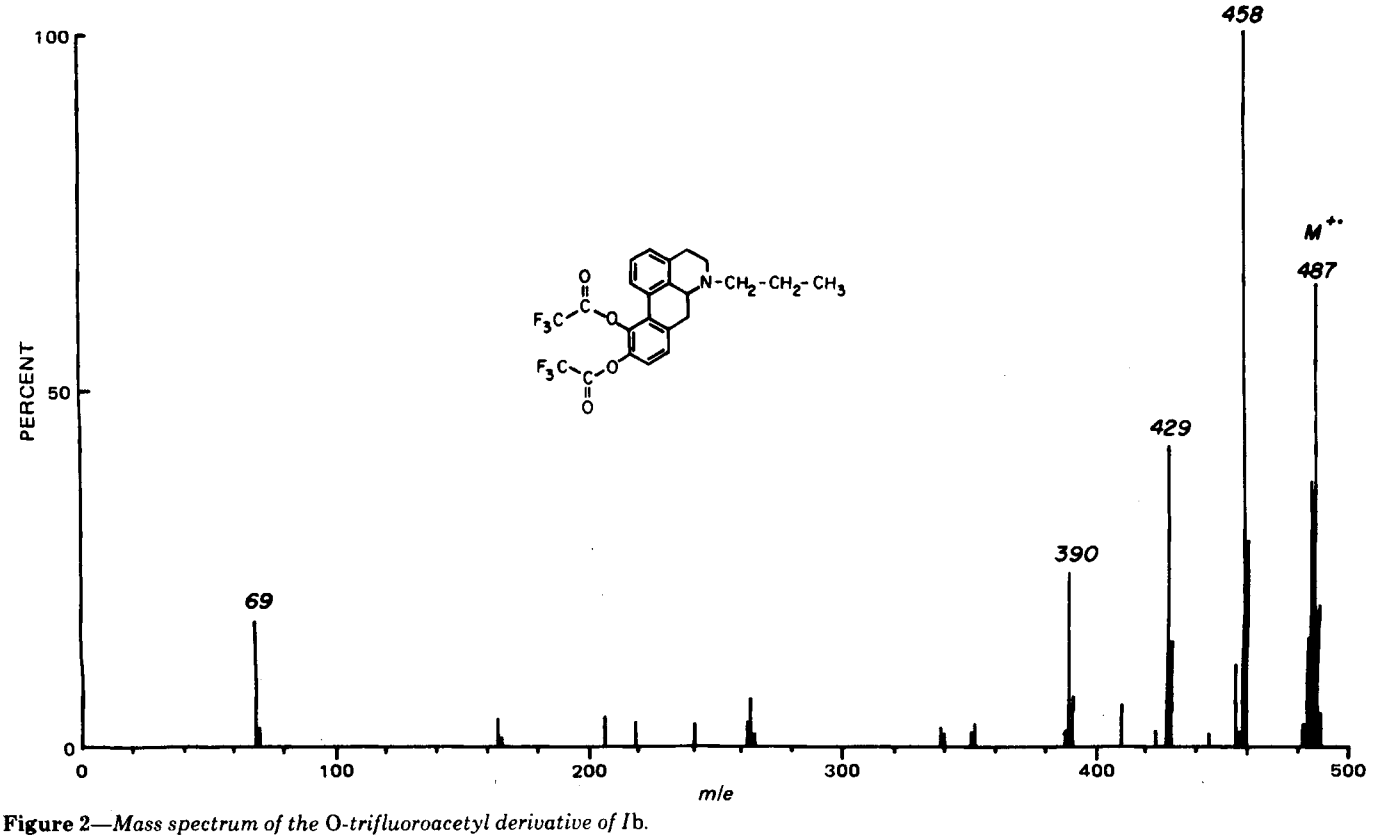

Figure 2—*Mass spectrum of the* O-*trifluoroacetyl derivative of I*b.

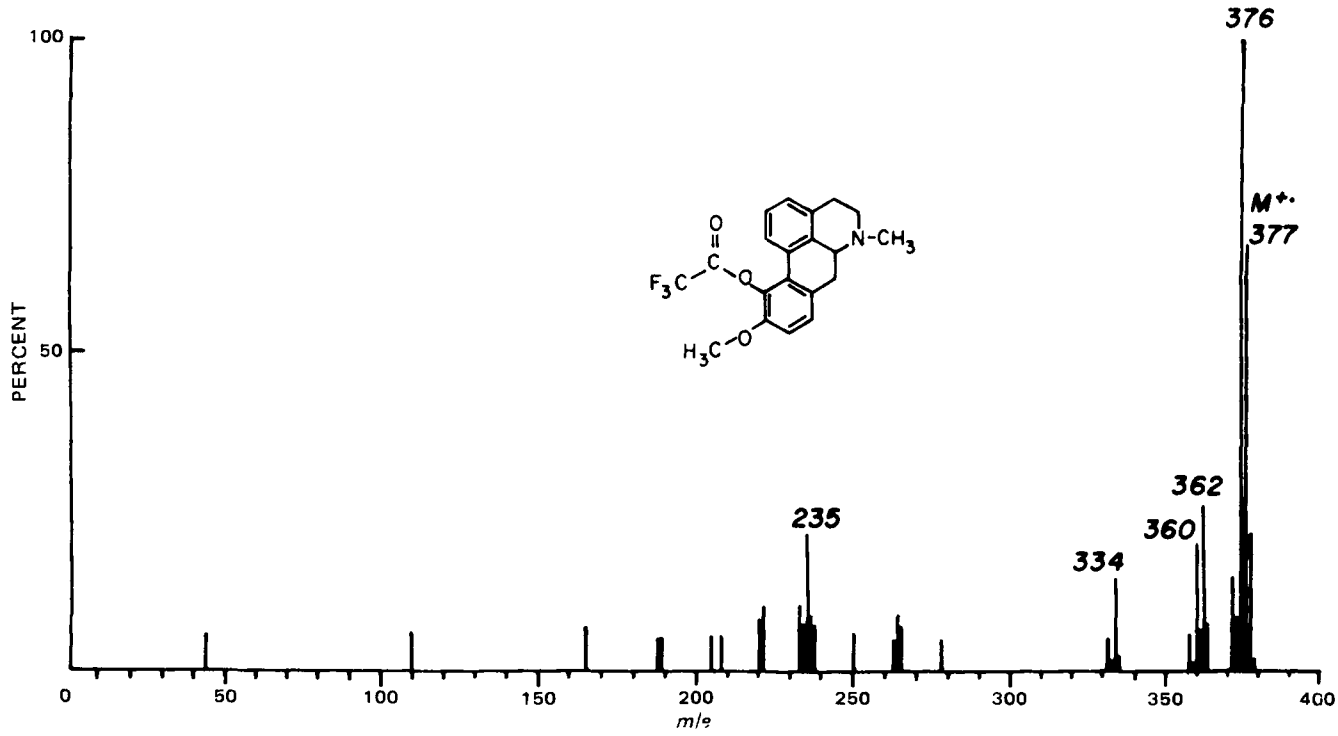

Figure 3—*Mass spectrum of the* O-*trifluoroacetyl derivative of* Id.

cleavage of the carbon–carbon bond beta to the nitrogen. Subsequent fragmentation of this ion gave rise to a peak at $[M - 58]^+$ (Scheme IV).

Noraporphines—The partial mass spectra of the trifluoroacetyl derivatives of the noraporphines (*Il–In*) are listed in Table V. A complete mass spectrum of the *N,O*-bis(trifluoroacetyl) derivative of anolobine (IIe) is shown in Fig. 5. The mass spectrum consists of only a few major ions associated with the fragmentation of the trifluoroacetyl group. This pattern typifies the general spectral characteristics of the trifluoroacetyl derivatives of the noraporphines studied. The ion peaks at $[M - 69]^+$ and $[M - 97]^+$ correspond to the loss of $CF_3\cdot$ and $CF_3C(=O)\cdot$ from $M^{+\cdot}$.

The $[M - 126]^+$ ion is unique to the noraporphine derivatives, and a plausible mechanism for its formation is given in Scheme V. It is suggested that its formation is initiated by a six-membered ring hydrogen transfer (McLafferty rearrangement) from C-7 to the carbonyl oxygen, followed by cleavage of a carbon–carbon bond beta to the heteroatom. The proposed γ-hydrogen transfer is consistent with the general behavior of the structurally related *N*-acetates of biogenic amines (14). Alternatively, the possibility of formation of the $[M - 126]^+$ ion by the loss of a hydrogen from the ion formed by a retro-Diels–Alder fragmentation of $M^{+\cdot}$ cannot *a priori* be ruled out.

In a previous publication, Green *et al.* (15) reported on the GLC–mass spectrometry of mixed *N*-heptafluorobutyryl-*O*-trimethylsilyl derivatives of noraporphines. By comparison, the mass spectra of the trifluoroacetyl derivatives reported here are noted for their overall simplicity. The intensity of the peak at $[M - 126]^+$ is rather striking, and this peak usually dominates the spectra of these derivatives. The analogous peak is of significantly lower relative intensity in the spectra of the *N*-heptafluorobutyryl-*O*-trimethylsilyl derivatives.

In view of the apparent uniqueness of the $[M - 126]^+$ ion, determina-

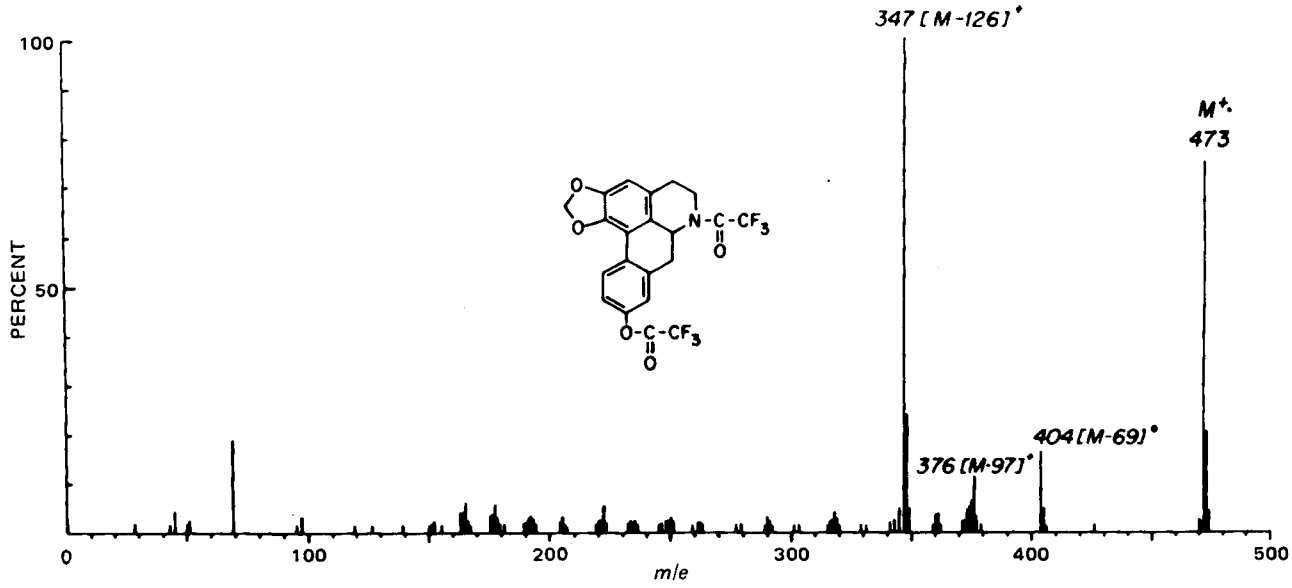

Figure 5—*Mass spectrum of the* N,O-*bis(trifluoroacetyl) derivative of IIe.*

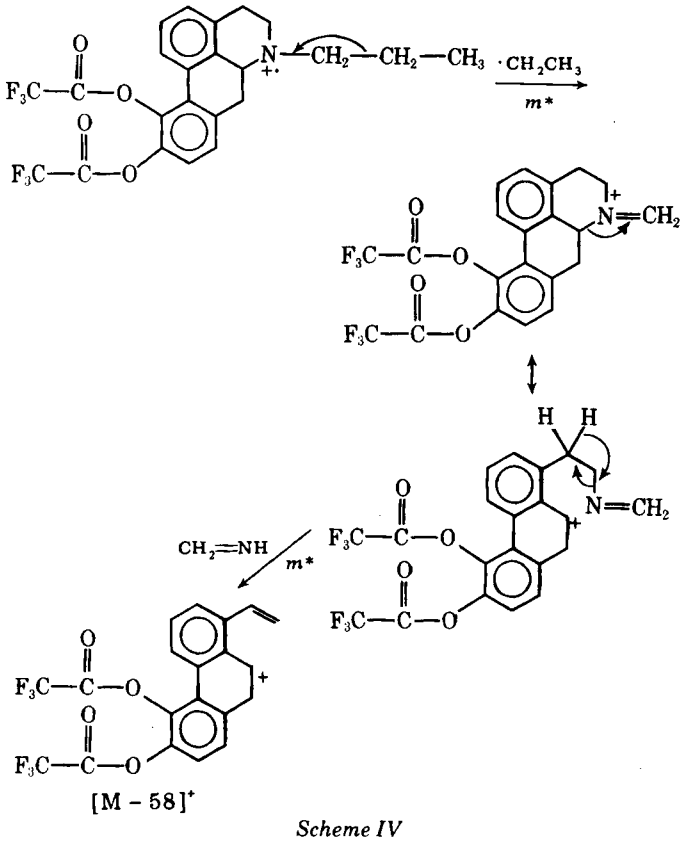
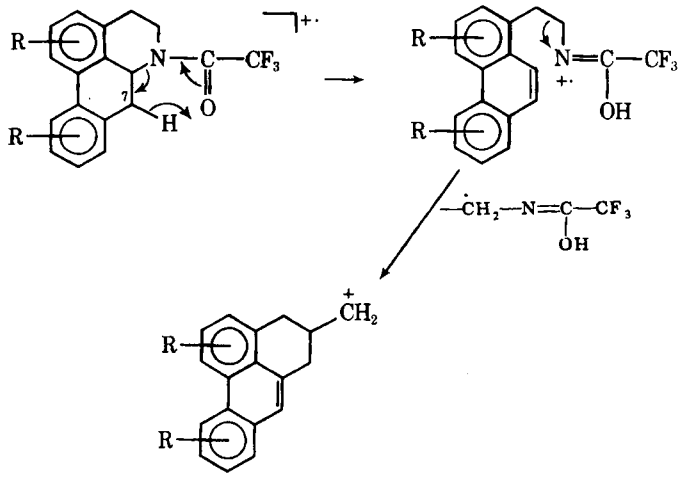
tion of whether this fragmentation could be used diagnostically to recognize the presence of a noraporphine was desired. The type of substitution on the secondary nitrogen of the underivatized aporphine generally is determined on the basis of the retro-Diels–Alder fragmentation. However, in noraporphines, this fragmentation is of reduced intensity (10% relative intensity) compared to that of the *N*-alkyl-substituted alkaloids. Accordingly, the mass spectra of the trifluoroacetyl derivatives of the following naturally occurring noraporphines were studied: sparsiflorine (Io), asimilobine (Ip), tuduranine (Iq), nandigerine (IIb), cassyfiline (IIc), xylopine (IId), anolobine (IIe), and actinodaphnine (IIf).

The partial mass spectra of these derivatives are listed in Table V, and the complete mass spectrum of anolobine is shown in Fig. 5. As with the other noraporphines, the mass spectra again were characterized by few major ions, of which the $[M - 126]^+$ ion was the most prominent. These findings support the earlier supposition that this fragmentation can be used as a diagnostic tool to determine the degree of substitution on the nitrogen of aporphine alkaloids isolated from natural products or as possible metabolites in biological fluids.



Scheme IV



Scheme V

CONCLUSIONS

The trifluoroacetyl derivative formation for aporphine and noraporphine alkaloids represents a reliable technique which has application in the analysis of biological fluids in drug metabolism studies, as well as in the characterization of naturally occurring aporphine alkaloids.

The trifluoroacetyl derivative offers the following advantages over the corresponding trimethylsilyl derivative:

Decomposition of Aminophylline in Suppository Formulations

JAMES F. BROWER ˣ, ERIC C. JUENGE, DONALD P. PAGE, and MATTHEW L. DOW

Received January 21, 1980, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication March 13, 1980.

Abstract □ An aminophylline suppository product, when stored at room temperature, was found to be deficient in ethylenediamine content by the USP XIX assay and by a specific method for primary amines. The product also had a melting point that was considerably higher than body temperature. An accelerated decomposition experiment, conducted on normal suppositories of identical original composition, yielded a product refractory at steam bath temperatures and containing no ethylenediamine measurable by the USP assay. The suppositories from both the original sample and the decomposition experiment contained considerable amounts of a white material, which melted at ~150° and which consisted of the diamide products formed by the reaction of ethylenediamine and the fatty acids present in coconut and palm kernel oils. The results, which confirmed the work of Cieszynski, showed that the ethylenediamine constituent of aminophylline can react with suppository base materials to produce insoluble amide decomposition products.

Keyphrases □ Aminophylline—decomposition in suppository formulations □ Suppositories—aminophylline, decomposition in suppository formulations □ Decomposition—aminophylline in suppository formulations

During a study by the Food and Drug Administration which required the analysis of various dosage forms of xanthine derivative drugs, an aminophylline suppository formulation was encountered that unexpectedly failed to melt when heated in a beaker on a steam bath. In fact, the suppositories barely softened, and a composite was prepared for assay only with great difficulty. Analysis by the USP XIX method (1) showed that the suppository contained approximately the labeled amount of theophylline but considerably less than the compendial requirement for ethylenediamine. The suppository sample had been stored at room temperature for a month before analysis, so the original condition of the product was unknown.

An accelerated decomposition experiment was devised to study the phenomenon of hardening and to elucidate the decomposition that apparently had occurred. Ci-

eszynski (2) had isolated the decomposition products from aged aminophylline suppositories and identified them as the amide reaction products of ethylenediamine with glyceryl esters of the fatty acids in cocoa butter and a suppository base composed of the triglycerides of C_{12}–C_{18} fatty acids[1]. Identification was based on extensive TLC, GLC, and IR spectral analyses of the isolated amides and of products synthesized from authentic materials.

Cieszynski (2) also conducted an accelerated decomposition experiment in which the decomposition reaction described was duplicated. He (2) did not give the melting characteristics of the decomposed suppositories or elemental analyses for the impurities found, but this information may be in one of his earlier papers, which was not available for translation.

The work of Cieszynski allowed this laboratory to concentrate its attention on a small group of possible decomposition compounds. The isolation and identification of the agents responsible for the hardening observed in the aminophylline suppositories are described here.

EXPERIMENTAL

Accelerated Decomposition Study—Fifty 500-mg aminophylline suppositories from another commercial sample of an identical formulation, which originally met all USP XIX requirements, were used. These samples had been stored at room temperature but melted readily on a steam bath and showed only a small loss of ethylenediamine by the USP XIX assay (1). One package of suppositories was stored at 0° during the experiment, and the remaining units were placed in a 40° convection oven. At intervals, four suppository units were removed from the oven. Two were placed in a refrigerator (0°), and the other two were assayed for theophylline (1) and ethylenediamine[2] content.

Isolation of Amide Decomposition Products—The suppository was dispersed in a beaker with 20–30 ml of isooctane[3] to dissolve the fatty base. The undissolved residue was collected on filter paper[4], and the residue was washed with two additional portions of isooctane. The residue on the filter was air dried and washed with two 20-ml portions of hot water to remove the aminophylline and any ethylenediamine or theophylline present. The washed residue was transferred to a beaker, 10 ml of chloroform[3] was added, and the mixture was heated to boiling. Ethanol (95%) was added dropwise until a clear solution was obtained.

The solution was placed in a refrigerator or freezer until crystallization occurred. The precipitate was collected on filter paper and washed with methanol[3]. The material was recrystallized successively from hot methanol and methanol–chloroform (1:1), and the crystals were air dried. Drying was completed in a 105° oven before the melting-point determination or IR scan.

Preparation of Authentic Individual or Mixed Fatty Acid Amides—*Method I (3): Synthesis from Fatty Acids*—Approximately 0.5 g of authentic fatty acid or the fatty acid mixture from saponified base was dissolved in 5 ml of chloroform, 0.2 ml of thionyl chloride was added, and the reaction mixture was cooled. Then 5 ml of chloroform containing 0.5 ml of ethylenediamine[5] (98%) was added slowly, and the mixture was refluxed for an additional 0.5 hr. The mixture was cooled and the precipitated product was collected by filtration. The residue was washed on the filter with methanol and allowed to air dry for ~0.5 hr.

Method II: Preparation from Glyceryl Esters of Fatty Acids—This reaction requires a 2:3 molar ratio of glyceryl ester to ethylenediamine. Approximately 7 g of suppository base was melted in a side-arm test tube and cooled until the onset of crystallization. One milliliter of ethylenediamine was added, and the reactants were mixed thoroughly with a magnetic stirrer. The test tube was fitted with a cold-finger condenser, and the tube was flushed with nitrogen.

The tube was heated in an oil bath, and the reaction mixture was stirred continuously under a nitrogen atmosphere as long as the magnetic bar was operable. The melt gradually became cloudy, and a semisolid appeared as a floating mass. The reaction was allowed to continue until complete solidification occurred. The amide was extracted and the reaction product was recrystallized as described for the isolation of amide decomposition products.

Saponification of Amides—The appropriate amide, 100–500 mg, was placed in a 50-ml round-bottom boiling flask, 10 ml of 20% KOH in propylene glycol was added, and the mixture was refluxed for 3 hr. Then the mixture was cooled, 10 ml of water was added, concentrated hydrochloric acid was added to acidify the solution, and the solution was cooled again. The solution was extracted with methylene chloride in a separator, and the organic phase was evaporated to dryness on a steam bath.

IR Spectra[6]—Sample spectra were prepared neat or as the trifluorovinyl chloride polymer[7] mull of the substance examined.

GLC (4)—The gas chromatograph[8] was equipped with a flame-ionization detector and a 3.05-mm i.d. nickel column[9]. The carrier gas was helium at a flow rate of 28 ml/min. The temperature was 250° for the column, injector, and detector.

Derivatization Procedure (Methylation)—(*m*-Trifluoromethylphenyl)trimethylammonium hydroxide[10], 200 μl, was added to 10 mg of the test substance, and the mixture was allowed to stand for 30 min in a covered vial.

Spectrophotometric Determination of Ethylenediamine in Suppositories[2]—The suppository, or a composite mixture equivalent to one unit, was dispersed in 95% ethanol, and the solution was carried through the automated procedure. The standard may be prepared from a previously analyzed aminophylline drug substance or the USP XIX reference standard. The method is specific for primary aliphatic and secondary cyclic amines.

TLC Identification of Amide Reaction Products—A portion of the reacted mixture was washed with three portions of cold isooctane. The residue was dissolved in boiling chloroform–methanol (1:1) and spotted on 75-mm silica gel plates[11]. Solutions of authentic aminophylline and of the diamide reaction product were spotted adjacent to the sample spots. The chromatogram was developed with chloroform–methanol (9:1) and viewed directly under UV light or by daylight after treatment with iodine vapor. Typical R_f values for aminophylline and the diamide are 0.45 and 0.60, respectively.

The isolation of the high-melting substance from the hardened suppositories was based on consideration of the solubility properties of aminophylline, theophylline, ethylenediamine, and the suppository base[12] used in this product.

The fatty base in the formulation was derived from coconut and palm kernel oils (5), which are rich in the glycerides of lauric and myristic acids, along with smaller amounts of the glycerides of oleic, palmitic, capric, and stearic acids (6). Myristic and palmitic acids were selected as representative of the group, and the pure substances were used for the preparation of authentic amide products by reaction with ethylenediamine after their conversion to acid chlorides.

Authentic suppository base also was used to prepare the amide product by direct reaction with ethylenediamine at 40 and 100°. The higher temperature was used to expedite the reaction and to increase the yield of amide. This experiment was repeated using aminophylline. In all experiments, IR spectrophotometry and TLC were used to monitor the final stages of the amide syntheses.

A portion of the purified high-melting substance isolated from the original, decomposed suppositories and a portion of the synthetic amide mixture prepared from the authentic suppository base were saponified to obtain the free acid mixture from each. These mixtures, another portion of suppository base, and individual lauric, myristic, palmitic, stearic, and oleic acid samples were derivatized and chromatographed by GLC for comparison of acid content.

RESULTS AND DISCUSSION

The results accumulated after storage of the samples at 40° for 3 months showed a progressive diminution of the ethylenediamine content, as measured by both colorimetric amine[2] and USP XIX titration (1)

Table I—Assay Results on Individual Suppository Units after Incubation at 40°

Elapsed Time, months	Ethylenediamine, % of aminophylline	Aminophylline, % of declared
0 (original analysis)	12.6	100.2[a]
1.0 (start of study)	11.8	100.0
1.5	11.9	102.0
2.0	8.9	95.8
3.5	0	99.2
4.0	0	93.2

[a] Average of six individual suppository assays; results ranged from 97.8 to 106.9%.

methods. The theophylline content showed little or no loss until late in the study (Table I).

The suppositories hardened during the accelerated decomposition experiment, but the increase in their melting point was not readily discernible until the melting point exceeded the steam bath temperature. The accelerated decomposition study had been in progress for 10 weeks by this time, and the ethylenediamine assay results were zero.

A large amount of a white, waxy substance, mp 145–147°, was isolated from the original sample of hardened suppositories. The high melting point of this substance could easily account for the refractory behavior of the suppositories at steam bath temperatures.

The IR spectrum of the trifluorovinyl chloride polymer mull of the dried, extracted material exhibited the following absorption bands: 3290 (NH stretch, amide), 3120 (NH stretch, purine from theophylline), 2930, 2850 (CH_2 symmetrical and unsymmetrical stretch), 1740 (C=O stretch, ester from fatty base), and 1640 (C=O stretch, amide) cm^{-1}. The interpretation was made with the aid of additional IR spectra of the neat suppository base[12], neat ethylenediamine, and the trifluorovinyl chloride polymer mulls of a refrigerated suppository fragment, trimyristin, and the reaction product of myristic acid and ethylenediamine *via* myristoil chloride.

The IR spectrum of the isolated high-melting product is consistent with that of a mixture of an alkyl amide and an alkyl ester (7) and includes all of the principal bands found by Cieszynski (2) in his spectra of amide decomposition products. An alkyl ester band found at 1750 cm^{-1} in the spectrum is believed to be due to unreacted suppository base since the band was absent in the spectrum obtained from the substance recrystallized from hot methanol. A minor NH amide band at 3290 cm^{-1} was found in the spectrum of the refrigerated suppository, which indicates that a small amount of decomposition may have occurred during storage after the original analysis; this observation accounts for the small reduction in the ethylenediamine content of the suppositories between the time of the original analysis and the start of the study.

The recrystallized *N,N'*-(1,2-ethanediyl)bisamides, synthesized from myristic and palmitic acids, had melting points of 150–152° and 147.5–148.0°, respectively, and gave IR spectra that showed the same prominent bands at 3290 and 1640 cm^{-1} that had been obtained from the high-melting substance previously isolated from the suppository.

The purified substance, obtained by direct reaction of myristin and ethylenediamine, melted at 148.5–150° and showed the same prominent IR bands at 3290 and 1640 cm^{-1}.

The spectra of the amide products that had been synthesized directly from aminophylline exhibited strong bands at 3290 and 1640 cm^{-1}, confirming the generation of an amide product by a reaction between aminophylline and the suppository base.

The distribution of fatty acid peaks found by GLC of the substance isolated from the suppositories was the same in kind and rank order as that of the authentic suppository base, confirming the source of the acyl components of the amides (Table II). It was not expected that the ratio percentage of each acid would be the same in both, because the suppository base material is derivatized directly whereas the amide must be saponified and the acids must be extracted before derivatization and GLC.

Table II—Fatty Acid Composition (Percent) of Products Analyzed by GLC

Product	Lauric	Myristic	Palmitic	Stearic	Oleic
Synthetic diamide mixture	45.0	18.2	10.6	26.0	0.2
Suppository base	43.8	17.9	11.1	24.7	2.3
High-melting substance	37.0	18.2	13.4	31.2	0.2

Table III—Elemental Composition of Analyzed Products[a]

Product	C	H	N	Melting Point
Isolated diamide mixture	74.49	12.67	5.84	148.5–149.5°
Synthetic diamide mixture	74.05	12.33	5.73	148.5–150.0°
Calculated for diamide mixture	74.93	12.55	5.79	
Synthetic bispalmitamide	76.21	13.41	5.04	147.5–148.0°
Calculated for *N,N'*-(1,2-ethanediyl)bis-palmitamide	76.06	12.77	5.21	

[a] Based on ratio percent distribution of fatty acids found in suppository base by GLC, expressed as bisamides.

The amide decomposition products isolated from the suppositories are believed to be the 1,2-ethanediamides based on the following experimental evidence. A single stretching band was found at 3290 cm^{-1}. If any primary amide were present, a doublet would have been seen in the region of 3300–3500 cm^{-1} in the IR spectrum. No color reaction was seen with the 2,3-dichloro-1,4-naphthoquinone reagent (8). No monoamide precipitated upon neutralization of the hydrochloric acid extract of the solid material. There was no blue color change when the spot separated by TLC was sprayed with bromcresol green.

Additional confirmation of the presence of diamides was obtained by quantitative elemental microanalyses[13] (Table III).

The results obtained in this study confirm the finding of Cieszynski (2) that the ethylenediamine moiety of aminophylline is capable of reacting with the glyceryl esters of some suppository bases to form insoluble, high-melting amide decomposition products. In a concurrent study conducted in this laboratory, a chemically similar decomposition occurred in rectal theophylline ethanolamine solutions preserved with parabens[14].

The reactions were carried out with authentic materials under conditions likely to exist during the commercial manufacture of suppositories. The reaction between the suppository base and free ethylenediamine at 40° began within 1 hr under an atmosphere of nitrogen, which also showed that prior rancidity was not a necessary condition for the formation of amide products. The reaction of the suppository base with aminophylline at 40° was much slower. Conditions that initiate the reaction, other than heat, have not been determined.

The significance of these results becomes apparent when the manufacturing process for suppositories (3) is examined. Aminophylline is stirred into molten suppository base; the melt is poured into heated molds and slowly cooled to minimize the formation of an unwanted α-state of the base. The maximum batch temperature exceeds 50° for a short time before the addition of drug substance and is kept just above the melting point of the base during pouring. The total elapsed heating time may last up to 1 day, depending on the size of the batch.

The manufacturing process could result in the formation of amide reaction products if temperature and process times are not controlled carefully, especially for the units poured at the end of a large batch run. The same reaction takes place slowly if the finished suppositories are not kept refrigerated, especially under summer temperatures.

A limited number of current commercial products was examined by IR spectrophotometry, which showed the presence of small quantities of amide reaction products. These products were indicated by a weak amide band at 3290 cm^{-1} and a shoulder at 1640 cm^{-1} in most of these spectra. The formulations containing hydrogenated coconut and palm kernel oil mixtures appear to be the most susceptible to decomposition. This observation may be due to the manufacturing process or it may be inherent in the product.

An IR limit test for 1,2-ethanediamides or a melting-point test is recommended for inclusion in the USP monograph for aminophylline suppositories.

Oxidative Degradation of Hydrocortisone in Presence of Attapulgite

JUAN CORNEJO *, MARIA C. HERMOSIN *, JOE L. WHITE *, GARNET E. PECK ‡, and STANLEY L. HEM ‡x

Received November 1, 1979, from the **Department of Agronomy and the* ‡*Department of Industrial and Physical Pharmacy, Purdue University, West Lafayette, IN 47907.* Accepted for publication March 12, 1980.

Abstract □ Degradation of hydrocortisone in attapulgite suspensions was monitored by high-pressure liquid chromatography and UV spectrophotometry. The rate of oxidative degradation of hydrocortisone was accelerated significantly in the presence of attapulgite. In addition, degradation appeared to be composed of two apparent first-order reactions rather than the single apparent first-order degradation reaction observed for hydrocortisone solutions. However, the same degradation products were obtained in both hydrocortisone solutions and attapulgite suspensions, indicating that interaction with attapulgite did not alter the degradation pathway. Kinetic and adsorption studies suggested that hydrocortisone is adsorbed weakly by attapulgite and undergoes oxidative degradation, which is catalyzed by adsorbed iron oxides or hydroxides as well as by structural ferric iron at the clay surface. Since clay minerals generally contain surface ferric iron, the potential for accelerating the oxidative degradation of drugs should be considered whenever clays and drugs are combined.

Keyphrases □ Attapulgite—effect on hydrocortisone degradation, kinetic and adsorption studies □ Hydrocortisone—oxidative degradation in attapulgite suspensions □ High-pressure liquid chromatography—monitoring of degradation of hydrocortisone in attapulgite suspensions □ Adsorption—hydrocortisone onto attapulgite, oxidative degradation of hydrocortisone

A recent study of the interaction of montmorillonite with digoxin revealed that the clay surface, through its ability to concentrate both digoxin and protons, accelerated the acid-catalyzed hydrolysis of digoxin and suggested that other neutral drugs which are degraded by acid-catalyzed hydrolysis may be affected similarly by interaction with a clay (1). Since oxidation also is a major mechanism of drug degradation, a study was undertaken to determine if interaction with a clay surface could result in accelerated oxidative degradation.

BACKGROUND

Montmorillonite, a member of the smectite group of clays, promotes the oxidation of a number of organic compounds, including the conversion of pyrogallol to quinones of poorly defined structure (2), of dihydroxyquinones to *p*-benzoquinone (3), and of benzidine to a blue monovalent semiquinone (4). In addition, hectorite, a clay belonging to the same structural group as montmorillonite, catalyzes the oxidation of benzidine (5, 6). Surface-adsorbed contaminants or structural ferric iron at the clay surface have been suggested as being responsible for the oxidation of organic materials by these clays.

Attapulgite was chosen for this study because: (*a*) it belongs to the fibrous group of minerals whose effect on oxidative degradation has not been studied extensively, (*b*) the oxidizing action of Fe^{3+} in attapulgite has been demonstrated (7), and (*c*) it is used in pharmaceuticals as a GI adsorbent (8) or excipient. Hydrocortisone was chosen as the model drug because it is known to degrade by oxidation, it may be coadministered orally with a clay-containing pharmaceutical, and it is used in topical dosage forms that also may contain a clay.

Degradation of the C-17 dihydroxyacetone side chain of corticosteroids has been studied extensively (9–13). Transformations and elimination of the side chain occur in both the presence and the absence of oxygen (12). However, autoxidation appears to be the major mechanism of degradation of corticosteroids in pharmaceutical dosage forms (12).

Factors influencing the degradation of prednisolone in aqueous solution were investigated, and trace metals present as contaminants in the buffer reagents were indicated as the cause of accelerated degradation (11).

EXPERIMENTAL

Materials—All chemicals were official or reagent grade. Attapulgite was obtained commercially[1]. X-ray diffraction of the clay sample confirmed that attapulgite was the major mineral but that a small amount of quartz also was present.

The effect of surface ferric iron was studied by treating the attapulgite by the citrate–dithionite procedure (14), which extracts nonstructural iron from the clay surface. The iron extracted was quantified by the *o*-phenanthroline method (15), and the total iron content was determined by the hydrofluoric acid dissolution procedure (16).

Hydrocortisone Assay—A high-pressure liquid chromatographic (HPLC) method, which was recommended for the analysis of hydrocortisone tablets (17), was modified slightly for this study. The liquid chromatograph[2] was equipped with a UV detector operating at 254 nm and a 20-μl injector loop[3]. A commercially packed octadecylsilane[4] column was used with acetonitrile–water (35:65) as the mobile phase. The operating parameters were: flow rate, 1 ml/min; pressure, 1000–1200 psi; temperature, ambient; and UV attenuator, 0.02 aufs. Linear calibration curves were used to quantify hydrocortisone, while the relative concentration of the observed degradation products was characterized by peak heights.

Changes in the A-ring of hydrocortisone were monitored by UV spectrometry at 254 nm.

Self-supporting films were prepared for IR analysis[5] by pipetting appropriate volumes of either the attapulgite or the hydrocortisone–atta-

Table I—Stability of Hydrocortisone in Presence of Attapulgite

Temperature	Aqueous Solution at pH 8.4, k_1, hr^{-1}	Attapulgite Suspension[a] at pH 8.4		Dithionite-Citrate-Treated Attapulgite Suspension[a] at pH 8.4	
		k_1, hr^{-1}	k_2, hr^{-1}	k_1, hr^{-1}	k_2, hr^{-1}
23°	—[b]	20.2×10^{-3}	4.4×10^{-3}	8.10×10^{-3}	2.3×10^{-3}
38°	—[b]	25.7×10^{-3}	8.3×10^{-3}	—	—
50°	0.8×10^{-3}	67.0×10^{-3}	14.3×10^{-3}	—	—
69°	1.5×10^{-3}	93.6×10^{-3}	22.2×10^{-3}	—	—

[a] For comparative purposes, the complex degradation pattern of hydrocortisone in attapulgite suspension was treated as consisting of an initial first-order phase characterized by k_1, which was followed by a slower, first-order phase characterized by k_2. [b] No measurable degradation of hydrocortisone occurred in 180 hr.

pulgite suspension onto polyethylene terephthalate[6] and air drying them at room temperature (18).

Hydrocortisone was prepared for IR analysis as a potassium bromide pellet.

Kinetic Studies—The attapulgite concentration was selected as representative of the range of clay usually used in pharmaceuticals; the hydrocortisone concentration was below the solubility limit, 280 μg/ml at 25° (19), to ensure complete solubility during the kinetic studies. Thus, 360 mg of attapulgite was mixed with 30 ml of an aqueous solution of hydrocortisone (200 μg/ml) in a 50-ml stoppered centrifuge tube. The samples were aged in a constant-temperature shaker bath at 23, 38, 50, or 69°. At appropriate intervals, aliquots were centrifuged at 6000 rpm, and the supernate was filtered[7] and analyzed by HPLC.

The pH of each suspension was measured and found to be 8.4 at each sampling interval.

Aqueous solutions of hydrocortisone (200 μg/ml), adjusted to pH 8.4 with sodium hydroxide, were aged with the drug–clay suspensions and served as controls.

The supernate from a suspension of 360 mg of attapulgite in 30 ml of water was filtered and used to prepare a hydrocortisone solution (200 μg/ml). The stability of hydrocortisone in this solution was monitored during aging at 23°.

A hydrocortisone–attapulgite suspension was monitored for 1 week while aging at 23°. After 1 week, the solid phase (attapulgite) was separated by centrifugation and washed three times with distilled water. The washed attapulgite was used to prepare a fresh hydrocortisone–attapulgite suspension whose stability at 23° was monitored as described.

RESULTS AND DISCUSSION

Hydrocortisone exhibited very slow degradation in aqueous solution at pH 8.4, which is consistent with previously reported stability results (20). A hydrocortisone solution at pH 8.4 was monitored every 2 days for 42 days while aging at 69°. During this time, the hydrocortisone concentration decreased from 200 to 33 μg/ml. A plot of log hydrocortisone concentration *versus* time gave a straight line ($r = 0.981$), indicating that degradation of hydrocortisone in solution at pH 8.4 occurs by apparent first-order kinetics (Table I). Earlier reports (9–12) suggested that hydrocortisone degrades by apparent first-order kinetics, although Pitman *et al.* (20) used the tetrazolium assay and observed complex kinetics for the degradation of hydrocortisone in 0.05 *M* NaOH.

Hydrocortisone degraded rapidly in the presence of attapulgite at pH 8.4. For example, the hydrocortisone content of an attapulgite suspension at pH 8.4 decreased from 200 to 100 μg/ml after aging at 23° for ~2 days (Fig. 1). During the same period, the hydrocortisone content of an aqueous solution at pH 8.4 and 23° remained at 200 μg/ml (Table I). The relationship between the hydrocortisone concentration or the logarithm of the hydrocortisone concentration and time was not linear at any temperature studied. To characterize the hydrocortisone degradation rate for comparative purposes, the degradation profile (Fig. 1) was treated as consisting of an initial first-order phase, characterized by k_1 which was followed by a slower, first-order phase characterized by k_2 (Table I).

This approach appears to be justified since both k_1 and k_2 followed the Arrhenius equation and the activation energy for the degradation of hydrocortisone was the same regardless of whether it was calculated from k_1 or k_2 (*i.e.*, 7.13 and 7.16 kcal/mole, respectively).

When the solubility of hydrocortisone was monitored by UV spectrophotometry, no change in absorbance at 254 nm was observed in the control solutions. Similarly, except for a small initial decrease, no change in absorbance at 254 nm was observed when the hydrocortisone–attapulgite suspensions were aged at 23, 38, 50, and 69° (Fig. 1). These results indicate that the degradation of hydrocortisone in the control solutions and the attapulgite suspensions occurred by oxidation of the 17-dihydroxyacetone side chain rather than by photolytic decomposition of the A-ring. The initial decrease in UV absorbance at 254 nm in the presence of attapulgite may be due to a small degree of adsorption of hydrocortisone by the clay.

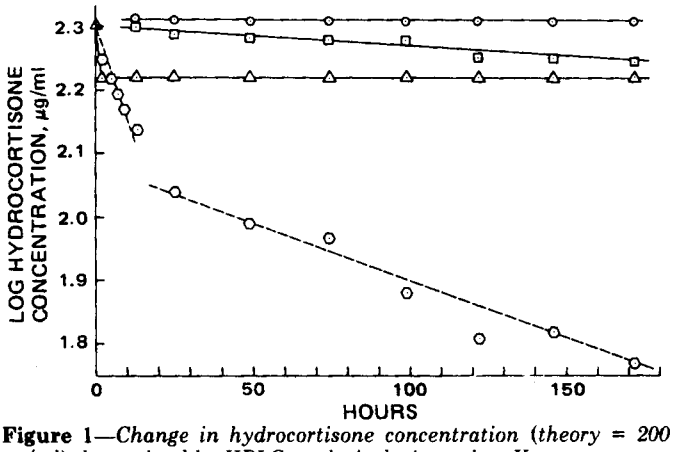

Figure 1—*Change in hydrocortisone concentration (theory = 200 μg/ml) determined by HPLC analysis during aging. Key: □, aqueous solution at pH 8.4 and 50°; ○, solution in supernate from attapulgite suspension at 38°; ○, attapulgite suspension at pH 8.4 and 23°; and △, hydrocortisone concentration of attapulgite suspension at pH 8.4 and 23° determined by UV absorbance at 254 nm.*

The same degradation pathway of hydrocortisone was observed in both the presence and the absence of attapulgite. Other investigators (9, 12) reported two degradation products for prednisolone: a small amount of a neutral keto product and a larger quantity of acidic material. Olson (21) also reported two peaks in addition to hydrocortisone during the HPLC analysis of hydrocortisone in alkaline media.

Figure 2A shows the three peaks observed in the high-pressure liquid chromatograms at 23, 38, and 50°. The peak having a retention time of

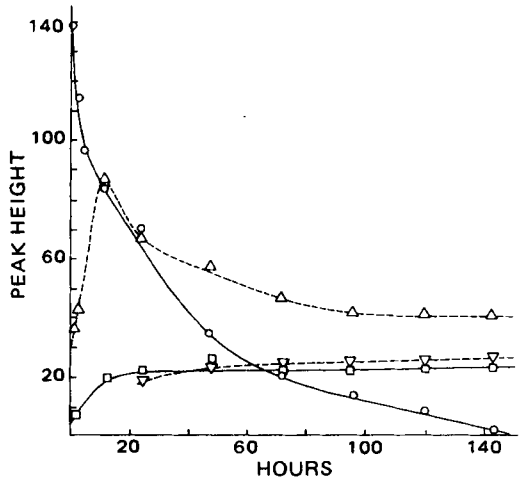

Figure 4—*Relative concentration of hydrocortisone and its degradation products during aging in an attapulgite suspension at pH 8.4 and 69°. Key: ○, hydrocortisone; △, acidic degradation product with retention time of 2.5 min; □, neutral degradation product with retention time of 11 min; and ▽, unknown degradation product with retention time of 7 min.*

8 min corresponded to the hydrocortisone reference standard. No attempt was made to identify the other two peaks. However, the degradation profile seen in Fig. 3 suggests that compounds with retention times of 2.5 and 11 min arise directly from hydrocortisone and that the former compound is the acidic product while the latter compound is the neutral product noted in previous studies. Similar degradation profiles were obtained at 38 and 50°.

A third degradation product having a retention time of 7 min was observed at 69° (Fig. 2B). This compound did not appear until the hydrocortisone was substantially degraded. The third degradation product began to appear after the degradation product with a retention time of 2.5 min (acidic product) reached its maximum concentration (Fig. 4). This type of degradation profile suggests that the third degradation product arises from further decomposition of the acidic product.

The increased degradation rate of hydrocortisone in an attapulgite suspension is not due to any soluble impurity or extractable component of attapulgite since virtually no degradation of hydrocortisone occurred in a solution prepared using the supernate from an attapulgite suspension (Fig. 1). Thus, the accelerated degradation of hydrocortisone in attapulgite suspensions requires contact with the clay surface.

It was hypothesized that oxidation of the C-17 side chain was the mechanism responsible for the accelerated degradation and that the source of the oxidizing action occurring at the surface of attapulgite was ferric iron. Surface ferric iron in attapulgite, as in other clay minerals, may exist either as surface-adsorbed iron oxides or hydroxides or as structural ferric iron, which is located mainly in the octahedral sites of attapulgite. To verify this hypothesis, a portion of attapulgite was treated by the citrate–dithionite method to extract nonstructural ferric iron. The amount of ferric iron extracted was 0.62 mg/g, which represents 2.3% of the total iron (26.6 mg/g) in the sample. Hydrocortisone was much more stable in a suspension of the treated attapulgite, although the degradation was substantially greater than that occurring in aqueous hydrocortisone solutions. The degradation profile did not fit either zero- or first-order kinetics; for comparison, it also was treated as consisting of two first-order phases (Table I). The twofold reduction in the degradation rate of hydrocortisone when surface ferric iron was removed from the attapulgite indicates that nonstructural ferric iron catalyzes the degradation of hydrocortisone. However, structural ferric iron probably also is involved in the catalysis since accelerated degradation occurred in the presence of treated attapulgite.

The IR spectrum of the hydrocortisone–attapulgite suspension did not show any evidence of adsorption of hydrocortisone. However, the small initial decrease in the hydrocortisone content of the supernate of a hydrocortisone–attapulgite suspension (Fig. 1) suggests that hydrocortisone is adsorbed weakly by attapulgite and undergoes oxidative degradation, which is catalyzed by both nonstructural and structural ferric iron at the clay surface.

The catalytic potential of attapulgite appears to be readily regenerated. The degradation rate of hydrocortisone in an attapulgite suspension was determined at 23° (Table I). The attapulgite was recovered and, after washing, was used to prepare a fresh hydrocortisone–attapulgite suspension. The rate profile and k_1 and k_2 values were identical to the results obtained for the original suspension.

It is hypothesized that the two-phase degradation reaction of hydrocortisone observed in the presence of attapulgite may be an indication that two kinds of sites for iron exist in attapulgite. As the oxidizing potential of the more accessible sites is exhausted, the degradation rate decreases.

The rate of diffusion of oxygen to the iron sites may be the rate-limiting factor. In this case, the rapid, initial degradation of hydrocortisone causes the oxidative potential of the iron sites to be exhausted. The regeneration of the sites is limited by the diffusion of oxygen to the sites, and a slower second phase is observed.

A third possible mechanism that may produce the two-phase degradation profile could occur if the hydrocortisone degradation products are adsorbed more strongly by attapulgite than hydrocortisone and preempt the catalytic sites on attapulgite. The two phases also may arise if both an oxidative and a nonoxidative degradation reaction occurs at the C-17 side chain.

Since clay minerals generally contain surface ferric iron, the potential for accelerating the oxidative degradation of drugs should be considered whenever clays and drugs are combined.

Quantitative Semiautomated Colorimetric Determination of Thyroid (Iodine) in Thyroid Tablets

E. D. McGARY

Received October 1, 1979, from the *Food and Drug Administration, Department of Health, Education, and Welfare, Kansas City, MO 64106.* Accepted for publication March 21, 1980.

Abstract □ A faster, simpler, more sensitive, and semiautomated method was developed for the analysis of thyroid in individual thyroid tablets and composite samples. The sample is combusted in a Schoniger flask in an oxygen atmosphere, and the liberated iodine is trapped in a dilute sodium hydroxide solution. The solution is acidified with sulfuric acid (1:1), and the iodine is determined colorimetrically using a suitable spectrophotometer equipped with an automated analyzer. The proposed methodology was applied to tablets containing 32.4–324 mg of thyroid. Recoveries ranged from 90.0 to 125.0% of the amount of iodine added as potassium iodide. The proposed method is sensitive to 2.5 ng of iodine/ml.

Keyphrases □ Thyroid—semiautomated colorimetric analysis in individual tablets □ Iodine—semiautomated colorimetric analysis in individual thyroid tablets □ Colorimetry—analysis, thyroid in individual thyroid tablets

This paper describes a simple method for the determination of thyroid in individual thyroid tablets and composite samples. The method is fast and reliable. It permits more samples to be analyzed in an equivalent amount of time than previously reported methodology (1–3) and gives comparable results when applied to individual thyroid tablets and composite samples.

BACKGROUND

The USP XIX procedure for content uniformity (1) employs an empty sample wrapper, which is combusted and used as the blank preparation. When these sample wrappers are used for the oxygen flask combustion in the developed procedure, high and erratic blanks are recorded. Experiments (4) indicated that the high blanks are due to the black dye incorporated in the sample wrappers and can be minimized by washing the sample wrappers several times with distilled water and drying before use. For reliable results, the blank must have <3 ng of iodine/ml for this procedure.

In the procedure developed by Graham (2), iodine is determined spectrophotometrically as the triiodide ion, following the oxygen flask ignition of Moody *et al.* (3), from a sample equivalent to 30 mg of thyroid. The USP assay (1) utilizes essentially the same chemical transformation but requires a sample equivalent to 1 g of thyroid and a final thiosulfate titration. Both procedures give comparable results.

Luchtefeld (5) developed a semiautomated procedure, which was based on the kinetic procedure of Sandell and Kolthoff (6, 7) for the determination of iodine in the Total Diet market basket. By combining the procedures and making selected modifications, a method has been developed that is faster, simpler, more sensitive, and capable of being automated.

EXPERIMENTAL

Apparatus—The automated analyzer[1] system consisted of a water bath maintained at 40°, heating coils [6.1-m (20-ft) inner coil and 12.2-m (40-ft) outer coil of 1.6-mm i.d. glass tubing], tubing S[2] and T[3], a spectrophotometer[4] (gears must be adjusted to permit chart scan with stationary wavelength at 405 nm), and 10-mm flowcells. The schematic diagram in Fig. 1 shows the coils, tubing, and fittings.

The combustion system utilizes sample wrappers[5] (which must be washed prior to use), sample carriers[6], stoppers[7], 1-liter Schoniger oxygen combustion flasks[8], clamps[9], and an oxygen flask igniter[10].

Sample Wrapper Preparation—The sample wrappers were placed in a beaker and covered with distilled water. The beaker was placed in a sonic vibrator for 10–15 min, and the water was discarded. The procedure was repeated five times to decrease the amount of iodides present in the sample wrappers. Then the wrappers were placed on a paper towel and allowed to dry at room temperature.

Reagents—*Ceric Ammonium Nitrate Solution*—Ceric ammonium nitrate, 8.66 g, was dissolved in 100 ml of water in a 2-liter flask, 56.8 ml of sulfuric acid (1:1) was added, and the solution was cooled and diluted to 2 liters with water.

Arsenous Acid Solution—Arsenic trioxide, 15 g, was dissolved in 500 ml of water (made basic with 10 ml of 50% NaOH) by heating on a steam bath. The solution was cooled, 56.8 ml of sulfuric acid (1:1) was added, and the solution was cooled and diluted to 2 liters with water.

Sodium Sulfate Solution—To prepare the sodium sulfate solution, 60 ml of 50% NaOH was transferred to a 2-liter flask with 1 liter of water. Sulfuric acid (1:1), 100 ml, was added cautiously. The solution was cooled and diluted to 2 liters with water.

Sodium Chloride Solution—The sodium chloride solution was a 0.5% aqueous solution.

Standard Preparation—To prepare the standards, 0.1308 g of certified ACS grade potassium iodide[11] was dissolved in water, and the solution was diluted to 1 liter to give a concentration of 0.1 mg of iodine/ml. This solution was diluted with the sodium sulfate solution to give a concentration of 0.1 μg of iodine/ml. Standards containing 2.5, 5.0, 10.0, 15.0, 20.0, and 25 ng of iodine/ml were prepared from the resulting solution and the sodium sulfate solution. These solutions are used for the standard curve and should be prepared fresh daily.

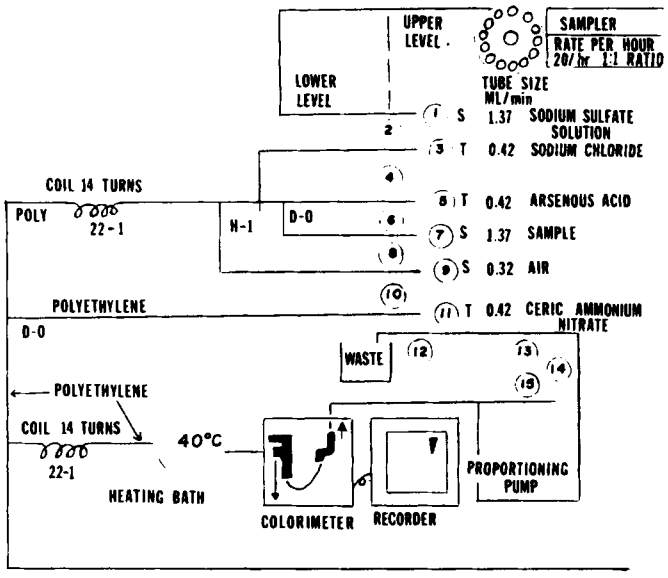

Figure 1—*Flow diagram of semiautomated system for determination of iodine in thyroid tablets.*

Sample Preparation—An amount of tablet or composite sample equivalent to 12–40 mg of thyroid was weighed accurately on a washed sample wrapper. The wrapper was folded, and the sample was transferred to the sample carrier. Thirty milliliters of 0.5 *N* NaOH was placed in a 1-liter Schoniger combustion flask, and the flask was deaerated with a rapid oxygen stream for 4 min with shaking. The mouth of the flask was moistened with water, and the stopper containing the sample was placed immediately in the flask and clamped securely. The joint of the flask around the stopper was moistened with water, and the sample was ignited with the igniter.

After combustion was completed, the flask was shaken vigorously for 1 min and then was allowed to stand for a minimum of 15 min with intermittent shaking. The solution in the flask was transferred quantitatively with water to a 200-ml volumetric flask containing 1 ml of sulfuric acid (1:1), and the solution was diluted to volume with water. Then a 4-ml aliquot was transferred to a 100-ml volumetric flask, and the solution was diluted to volume with the sodium sulfate solution.

Blank Preparation—An empty sample wrapper was subjected to the same procedure as described for sample preparation.

Determinative Step—The automated analyzer pump manifold was set up as shown in Fig. 1. From the water bath, which was maintained at 40 ± 1°, the solution passed through a 10-mm flowcell in a suitable spectrophotometer adjusted to maintain a constant wavelength at ~405 nm and to scan the chart at or near the slowest speed. The reference beam contained an empty 10-mm flowcell.

The instrument was zeroed by placing Tubes 1, 3, 5, and 11 (Fig. 1) in a container of distilled water. The water was pumped through the automated analyzer pump manifold through a 10-mm flowcell in the sample compartment of the spectrophotometer for 30 min. Then the tubes were removed from the water and placed in the following solutions: Tube 1, sodium sulfate solution; Tube 3, sodium chloride solution; Tube 5, arsenous acid solution; and Tube 11, ceric ammonium nitrate solution. The solutions were pumped through the automated analyzer as in zeroing the instrument to establish a baseline (usually from 0.7 to 0.9 absorbance unit). A standard curve (Fig. 2) was obtained by placing the iodine standard solutions in successive cups using a rate of 20/hr. The sample blank and the samples were run in the same manner as the standards.

The iodine content of the samples was determined from the standard curve. Figure 3 shows typical signal peaks used to construct the iodine standard curve.

The percent of iodine per tablet based on the label declaration of thyroid was calculated from:

$$\% \text{ iodine} = \frac{\frac{(S - B)}{1{,}000{,}000} \times DF \times ATW \times 100}{SW \times D} \qquad \text{(Eq. 1)}$$

where S is the nanograms of iodine found in the sample from the standard curve, B is the nanograms of iodine found in the blank from the standard curve, DF is the dilution factor of the sample (5000), ATW is the average tablet weight (grams), 1,000,000 is the factor converting nanograms of iodine to milligrams, SW is the sample weight (grams), and D is the label declaration of thyroid per tablet (milligrams). If the label declaration of thyroid is given in grams per tablet instead of milligrams per tablet, 64.8 mg should be taken as equal to 1 gr.

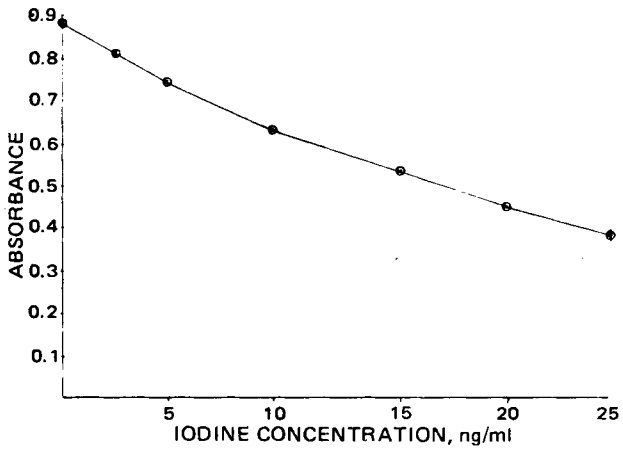

Figure 2—*Standard curve for semiautomated determination of iodine.*

RESULTS

The efficiency of the method was determined by adding known amounts of iodine to the 0.5 *N* NaOH in the combustion flask before the sample combustion and calculating the percent recoveries (Table I).

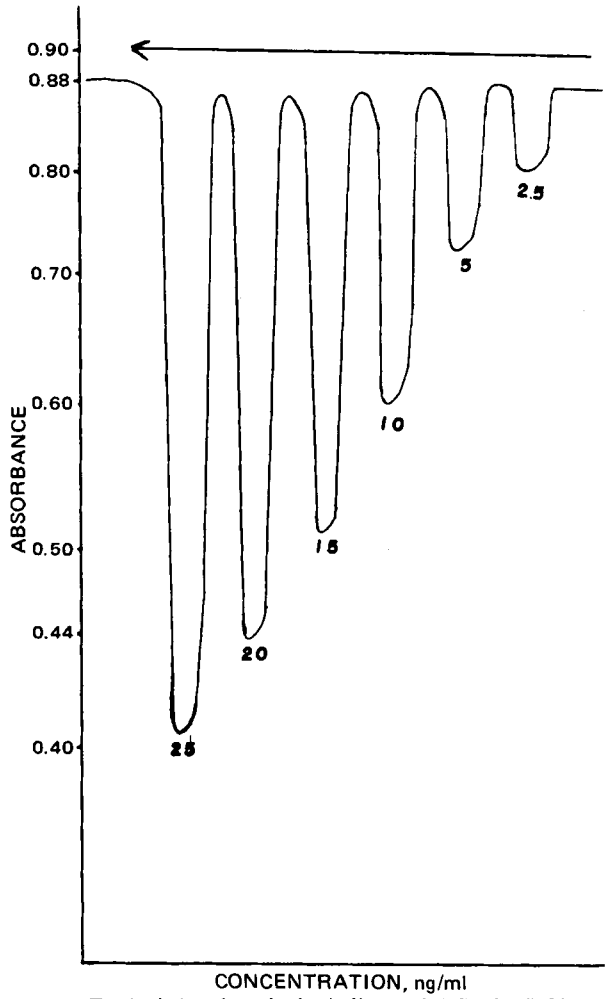

Figure 3—*Typical signal peaks for iodine at 2.5, 5, 10, 15, 20, and 25 ng/ml. Peaks are scanned from right to left.*

Table I—Recovery of Iodine Added to Composite Samples

Sample	Composite	Added, ppm	Found, ppm	Recovery, %
A, 32.4 mg/tablet	1	200	230	115
	2	400	410	102
	3	400	410	102
	4	400	490	122
	5	500	570	114
	6	600	550	92
Average				108
B, 64.8 mg/tablet	1	200	210	105
	2	200	190	95
	3	200	250	125
	4	400	460	115
	5	600	590	98
Average				108
A-1, 64.8 mg/tablet	1	400	360	90
B-1, 120 mg/tablet	1	500	460	92
C-1, 180 mg/tablet	1	222.2	244.5	110
D-1, 240 mg/tablet	1	425.5	468	110
E-1, 300 mg/tablet	1	375	400	107

Four concentrations of uncoated thyroid tablets labeled in milligrams (32.4, 64.8, 130, and 180 mg) and five concentrations of uncoated thyroid tablets labeled in grains (1, 2, 3, 4, and 5 gr) were assayed by the proposed procedure for individual tablets and composite samples. The results were compared to those obtained from the USP assay (1) on the composite samples and are in close agreement (Table II).

DISCUSSION

The primary considerations in developing this semiautomated procedure for content uniformity of individual tablets were its reliability, sensitivity, speed, and simplicity. The proposed procedure addresses all of these concerns.

While this procedure was being developed, much experimentation was required to determine the cause of high blanks. Blanks obtained by using the sample wrappers as received were high, inconsistent, and erratic. In some instances, the absorbance of the blanks indicated that more iodine was present than in the samples; therefore, the quantity of thyroid in the thyroid tablets could not be determined with any accuracy.

Table II—Comparison of Individual Thyroid Tablets and Composite Samples Assayed by the Proposed Procedure and USP (1) Assay for Percent of Labeled Amount of Thyroid

Sample	Composite Sample, %	Individual Tablet Assay[a], %	USP Composite Assay, %

[a] Assay of 10 individual tablets. [b] $n = 6$. [c] One determination of composite samples A-1, B-1, C-1, D-1, and E-1 was performed using the proposed methodology. [d] $n = 3$.

Table III—Comparison of Analytical Data with and without Solvents Used to Reduce the Amount of Iodine in the Sample Wrappers

Sample	Solvent	Absorbance	Iodine Found, μg
1	Water	0.765	0.1
2	Acetic Acid	0.410	20.8
3	Ethanol	0.382	22.6
4	Methanol	0.351	25.0
5	None		
	Control (1)	0.535	12.4
	(2)	0.515	13.7

A series of four experiments (4) was designed to check experimentally the apparatus as well as the solutions and sample wrappers. The analysis of these results indicated that the high iodine blanks were caused by the black dye incorporated in the paper used to wrap the samples.

The sample wrappers were washed with distilled water, alcohol, methanol, acetic acid, chloroform, acetone, benzene, and heptane in glass beakers of convenient size. The solvents were decanted from the wrappers, and all wrappers were dried first on a steam bath under a current of air and then in a convection oven at 105° (except the wrappers from the water wash, which were allowed to dry at room temperature).

The wrappers from the chloroform, acetone, benzene, and heptane washes were brittle after drying and were discarded. The remaining wrappers (one from each of the water, acetic acid, ethanol, and methanol washes) and two unwashed sample wrappers (controls) were assayed by the proposed procedure, and the amount of iodine remaining in the wrappers was calculated from a standard iodine curve. The results of the analysis (Table III) indicate that the methanol, ethanol, and acetic acid were contaminated with iodine; distilled water was the solvent of choice for decreasing the amount of iodine in the sample wrappers to give negligible iodine blanks.

Several factors influence the determination of iodine in thyroid tablets. One is the increase in absorbance as the temperature is increased. This phenomenon implies that the standards and the sample should be run at the same temperature. This effect also was observed and demonstrated by Moran (8). Another factor is the ionic strengths of the cerium(IV) and arsenic(III) solutions. These solutions should be prepared and maintained as proposed in this procedure if the analysis is to be valid and useful. A previous study (9) supported these views. The final factor is the tubing (S and T); it should be changed when the absorbances of the standard iodine solutions change significantly while the other parameters remain the same.

The reaction rate is not directly proportional to the iodine concentration; therefore, a calibration curve with a slight curvature is obtained (Fig. 2).

In developing this procedure for the analysis of thyroid in thyroid tablets, 0.25 *N* NaOH was used first as the absorbing solution to trap the liberated iodine after the oxygen flask combustion. Low recoveries of iodine were obtained. The next attempt was with 0.5 *N* NaOH, and the recoveries were much improved (Table IV). This contrast in recoveries probably is due to the lower sodium hydroxide concentration not ab-

Table IV—Comparison of Percent Recovery of Iodine Added to Composite Samples Using Two Concentrations of Sodium Hydroxide

sorbing all of the iodine released from the oxygen flask combustion of the tablets.

The combustion apparatus and glassware must be scrupulously cleaned before and after use with distilled water, dilute sodium hydroxide (0.1–0.5 *N*), and again with distilled water to prevent contamination of iodine adsorbed onto these surfaces.

The proposed procedure was not used on coated thyroid tablets, but it should work if a homogeneous sample is obtained.

Semiautomated Method for Analysis of Enteric-Coated and Plain Coated Diethylstilbestrol Tablets

RICHARD E. KOLINSKI *x, JAMES W. MYRICK *, and ELAINE A. BUNCH ‡

Received December 13, 1979, from the **National Center for Drug Analysis, Food and Drug Administration, 1114 Market Street, St. Louis, MO 63101*, and the ‡*Food and Drug Administration, Seattle, WA 98174.* Accepted for publication March 19, 1980.

Abstract □ A semiautomated fluorometric method for the analysis of enteric-coated and plain coated diethylstilbestrol tablets is presented. To eliminate interferences from tablet excipients, diethylstilbestrol is extracted into an organic solvent and then into a basic aqueous solution. After UV irradiation, a product of diethylstilbestrol is formed from which a fluorophore is produced chemically. The fluorescence is measured at an excitation wavelength of 335 nm and an emission wavelength of 410 nm. The coefficient of variation measured for the semiautomated procedure was 0.59%. Assay results agreed well with the USP procedure for tablets containing >1 mg of diethylstilbestrol. Tablet dyes and excipients interfered in the USP procedure, which yielded low results for tablets containing <1 mg of diethylstilbestrol. Standard recovery data and assays of tablet composites showed that dyes and other excipients do not interfere with the semiautomated procedure.

Keyphrases □ Diethylstilbestrol—semiautomated fluorometric analysis of enteric-coated and plain coated tablets □ Fluorometry—semiautomated analysis of enteric-coated and plain coated diethylstilbestrol tablets □ Estrogens—diethylstilbestrol, semiautomated fluorometric analysis of enteric-coated and plain coated tablets

Diethylstilbestrol is one of several synthetic estrogens whose use has been the subject of many clinical studies. The estrogenic activity of this stilbenediol derivative was discovered in 1938 (1). In recent years, diethylstilbestrol has been administered for estrogen replacement therapy and treatment of mammary carcinoma and as a contraceptive.

BACKGROUND

The USP (2) content uniformity requirement for diethylstilbestrol tablets increased the analytical workload of many pharmaceutical laboratories. The individual tablet assay described in the monograph is tedious and, because of excipient interference, cannot be used to assay enteric-coated tablets containing <1 mg of diethylstilbestrol. The semiautomated method developed by Hussey *et al.* (3) is similar in principle to the USP XIX procedure (2) but is limited to the analysis of plain tablets and the cores of enteric-coated tablets of dosage levels of >0.25 mg.

The semiautomated method described in this report utilizes a fluorometric determinative step to achieve greater sensitivity for the analysis of low dosage tablets. After UV irradiation of diethylstilbestrol, a fluorophore is produced quantitatively by reducing the irradiation product (4) with an alcoholic hydrochloric acid solution containing 2% pyrocatechol and heating to form a phenanthrenediol. The pyrocatechol increases the fluorescence intensity slightly, which adds to the overall stability of the automated system.

Use of the irradiation product itself as the fluorophore for analysis was investigated by Goodyear and Jenkinson (5). Excipients in enteric coatings were reported to cause some interference, and the fluorescence intensity of the irradiation product without the addition of acid and without heating was not sufficient for quantitation of low dosage tablets in the automated system. However, an intense fluorophore, 3,6-dihydroxy-9,10-diethylphenanthrene, is produced when the UV irradiation product is heated with an alcoholic hydrochloric acid solution containing 2% pyrocatechol. Umberger *et al.* (6) performed a similar reduction by heating the UV irradiation product with acid and bisulfite in alcohol solution to form the phenanthrenediol.

The need to analyze low dosage, enteric-coated diethylstilbestrol tablets from various manufacturers prompted the development of this semiautomated system. The method utilizes the principles and materials of the methods cited, and an extraction step was added to eliminate interferences from tablet excipients.

EXPERIMENTAL

Principles—A solution of diethylstilbestrol in 0.05 *M* alcoholic dibasic potassium phosphate was acidified with 1 *N* HCl and extracted with isooctane–butanol. The drug in the organic phase then was extracted with 1 *N* NaOH. The extract was mixed with phosphoric acid and dibasic potassium phosphate, and the mixture was irradiated with UV light. The irradiation product was reacted with a 2% solution of pyrocatechol in 2 *N* HCl at 70°. The fluorophore thus produced was measured at an excitation wavelength of 335 nm and an emission wavelength of 410 nm.

Apparatus—The automated analyzer[1] system consisted of a sampler, two proportioning pumps, a heating bath at 70°, a fluorometer with a primary[2] and a secondary[3] filter, and a recorder utilizing linear chart paper to record the relative fluorescence intensity. Typical fluorometer

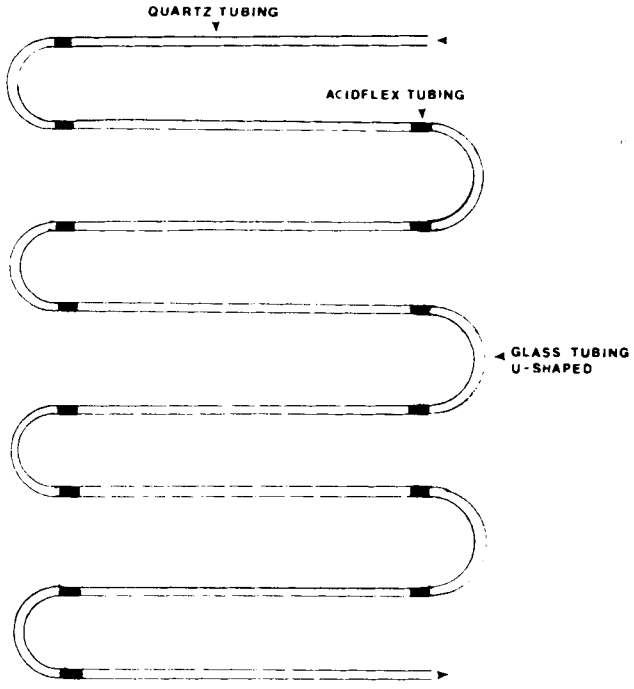

Figure 1—*Section of quartz irradiation coil. The coil consists of 22 37-cm lengths of quartz tubing, 2 mm i.d. × 3 mm o.d., connected by tubing and glass U-tubes. The coil is formed into top and bottom grids, each having 11 lengths of quartz tubing. The grids are shifted out of line to maximize exposure to UV light.*

parameters were: sample aperture, 3; reference aperture, 2; and full-scale recording, 110.

The UV irradiation assembly consisted of clear quartz tubing[4], 2 mm i.d. × 3 mm o.d. and ~9 m long, made into a coil as described by Hussey *et al.* (3) and connected by tubing[5] and glass U-tubes[6] (Fig. 1), and a 15-w germicidal lamp[7] mounted ~10 cm above the quartz coil. Aluminum foil was placed under the coil to provide a reflective background. The entire UV irradiation assembly was covered with aluminum foil for maximum internal reflectance and to prevent leakage of harmful UV radiation.

Reagents—The alcohol used was 95% ethanol.

To prepare 0.05 *M* alcoholic dibasic potassium phosphate, 8.7 g of anhydrous dibasic potassium phosphate was dissolved in 500 ml of water, and the solution was diluted to 1 liter with alcohol.

The 1 *N* HCl was prepared by diluting 83 ml of concentrated hydrochloric acid to 1 liter with water.

For the alcoholic hydrochloric acid, 83 ml of concentrated hydrochloric acid was diluted to 500 ml with water, and the mixture was diluted to 1 liter with alcohol.

The 1 *N* NaOH was prepared by diluting 50 ml of 50% (w/v) NaOH to 1 liter with water.

For the alcoholic phosphoric acid solution, 250 ml of alcohol was added to 60 g of 85% H_3PO_4, and the mixture was diluted to 1 liter with water. The strength of this reagent was adjusted, if necessary, to obtain the correct pH after irradiation.

To prepare the pyrocatechol solution, 20 g of pyrocatechol was dissolved in 500 ml of water, and 178 ml of hydrochloric acid and 250 ml of alcohol were added. The solution was mixed and diluted to 1 liter with water.

The organic solvent was prepared by adding 200 ml of *n*-butanol to 1 liter of isooctane with mixing. *n*-Butanol and distilled-in-glass isooctane that are suitable for spectrophotometry and chromatography were used.

Diethylstilbestrol Standard Solution—Approximately 25 mg of diethylstilbestrol USP reference standard was weighed into a 250-ml volumetric flask. The standard was dissolved and diluted to volume with the alcoholic dibasic potassium phosphate. A 10.0-ml aliquot of the stock standard solution was transferred to a 100-ml volumetric flask and diluted to volume with the alcoholic dibasic potassium phosphate; this solution was stable for at least 10 days. To assay tablets containing <1 mg of diethylstilbestrol, a 10.0-ml aliquot of the stock standard solution was placed in a 100-ml volumetric flask, 40 ml of the alcoholic dibasic potassium phosphate reagent was added, and the mixture was diluted to volume with the alcoholic hydrochloric acid.

Sample Preparation—For tablets containing 1 mg or more of diethylstilbestrol, individual tablets were disintegrated or weighed composites were dispersed in an accurately measured volume of the alcoholic dibasic potassium phosphate reagent to give a concentration of 0.01 mg/ml. Samples were placed in an ultrasonic generator for ~15 min with intermittent swirling to ensure tablet disintegration. Enteric-coated tablets were sonicated until visual examination indicated no trace of intact tablet particles when the sample was swirled. Up to 30 min was required for some products, depending on the enteric-coating formulation. The alcoholic dibasic potassium phosphate reagent was used as the wash solution for the automatic analyzer.

For tablets containing <1 mg of diethylstilbestrol, individual tablets were disintegrated or weighed composites were dispersed in an accurately measured volume of the alcoholic dibasic potassium phosphate reagent to give half of the final volume of the sample solution. The diethylstilbestrol from the tablet material was dissolved by ultrasonic treatment as described. An accurately measured equal volume of the alcoholic hydrochloric acid reagent was added to give a final diethylstilbestrol concentration of 0.01 mg/ml. The solution was allowed to stand until the precipitate had settled. For the automatic analyzer, a wash solution of dibasic potassium phosphate reagent–alcoholic hydrochloric acid reagent (1:1) was used.

Procedure—The automated system was assembled as shown in Fig. 2. The first manifold (Pump A) is the extraction manifold. The second manifold (Pump B) is the irradiation and fluorescence manifold.

The automated system was equilibrated as follows. With the fluorescence manifold pump turned off, the proper reagents were pumped through the extraction manifold. When the B4 fitting on the fluorescence manifold was filled with aqueous and organic layers, the fluorescence manifold pump was turned on and all of the reagents were pumped through the system. Approximately 30 min was allowed for system equilibration. The pH of the phosphate solution was checked after irradiation by collecting, on pH paper, a few drops from the waste line off the C3 resample fitting. A pH of 7–8 was desired.

Portions of the prepared sample and standard solutions were placed in 8.5-ml polystyrene cups on the sampler, which was set to a rate of 20 samples/hr and a sample-to-wash ratio of 2:1. The sampling pattern was three cups of standard, five cups of sample, one cup of standard, five cups of sample, *etc.* Two cups of standard were placed at the end of each run. In the calculations, the first two and the last standard peaks were disregarded.

In the automatic analyzer, the sample was withdrawn, segmented with air, and acidified with 1 *N* HCl. Isooctane–butanol was added and mixed, and the aqueous and organic phases were separated. The organic phase, which contained the drug, was resampled, segmented with air, and mixed with 1 *N* NaOH. The aqueous phase, which then contained the diethylstilbestrol, was separated and mixed with alcoholic dibasic potassium phosphate and phosphoric acid. The solution was irradiated in a quartz coil under a germicidal lamp. The solution was resampled, mixed with 2% pyrocatechol in 2 *N* HCl and alcohol, and heated at 70°. The solution, which then contained a fluorophore of the diethylstilbestrol irradiation product, was cooled and passed through the fluorometer. The fluorescence was measured at an excitation wavelength of 335 nm and an emission wavelength of 410 nm. Typical peaks from the analyzer are shown in Fig. 3.

RESULTS AND DISCUSSION

Four diethylstilbestrol standard solutions having concentrations of 50, 100, 150, and 200 μg/ml were passed through the analyzer. A graph of the fluorescence intensities of these solutions *versus* concentration resulted in a straight line that passed through the origin.

A sampling rate of 25 cups/hr was tested with standard solutions. However, the coefficient of variation for the system increased to 2.00% at 25 cups/hr from 0.60% at 20 cups/hr. Moreover, the percentage of steady state (defined as 100 times the ratio of the sample peak intensity to the steady-state signal intensity) achieved by the peaks decreased from 94.4 to 84.0%.

A composite sample of enteric-coated, 1-mg tablets was prepared from a commercial product. Twenty weighed portions of this composite, each equivalent to a single tablet, were assayed by the semiautomated method. The coefficient of variation obtained was 1.09% (Table I). In addition,

a single determination on each of 10 days was performed on the same composite to test the day-to-day reproducibility of the system, and the coefficient of variation obtained was 0.59%. The individual standard solutions used in the tests were assayed by comparison to freshly prepared standard solutions. All of the standard solutions were stoppered and stored on a bench top, exposed to room light and to changes in temperature and humidity. These solutions were reexamined after 8 days, and no decomposition was observed.

[a] Results are reported as percent of label declaration.

Seventy-six cups of a solution prepared from a composite of plain coated tablets were passed through the system. No serious evaporation effects were observed. However, since the samples were dissolved in a 50% alcoholic solution and the sampler was set at 20 cups/hr, the cups were filled and the trays were loaded just before analysis.

Enteric-coated tablets usually are difficult to disintegrate. Normally, an enteric-coated tablet must be crushed or the outer shell must be cracked before the solvent is added; otherwise, tablet disintegration with an ultrasonic generator proceeds slowly and a uniform dispersion of tablet material is not obtained. Use of alcoholic dibasic potassium phosphate as a solvent proved successful for the disintegration of enteric-coated diethylstilbestrol tablets. With the aid of an ultrasonic generator, this solvent disintegrated the tablets into a fine dispersion; the outer shell disintegrated, the tablet core slowly disintegrated, and complete tablet disintegration occurred in a reasonable period. The task of cracking the outer shell of each tablet before solvent addition thus was eliminated.

[a] Results are reported in percent of label declaration. Numbers of samples analyzed are given in parentheses.

A white precipitate formed in the coils when the enteric-coated tablets from one manufacturer, which contained <1.0 mg of diethylstilbestrol, were assayed. The inner coating of the tablet contained a plasticizer that precipitated when treated with acid on the extraction manifold. The problem was solved by addition of the alcoholic hydrochloric acid reagent to the sample, which previously had been treated with the alcoholic dibasic potassium phosphate reagent, *before* sampling on the automatic analyzer. The precipitate formed and was allowed to settle, and a portion of the supernate then was placed in a cup and sampled.

The extraction manifold was designed to eliminate excipient interference. A mixture of isooctane and butanol was selected as the organic solvent; butanol was added to isooctane to achieve increased polarity for complete extraction of diethylstilbestrol. Dyes present in the outer shells of the enteric-coated tablets remained in the aqueous layer and proceeded to the waste reservoir.

In initial experiments, a coil made from polytetrafluoroethylene[8] tubing was used in the irradiation assembly. However, this tubing was unsuitable; pulsing occurred in the coil because of the presence of air between sample and wash segments. A quartz irradiation coil similar to that described by Hussey *et al.* (3) resulted in a more even flow and more complete irradiation. The extraction step provided a cleaner solution for irradiation and decreased the possibility of interferences in the fluorometric measurement. A 70° temperature in the heating bath for the reaction with pyrocatechol produced the maximal fluorescence.

Results from the semiautomated method compared closely with results from the USP XIX content uniformity method (2) when ground composites of enteric-coated and plain coated 1-mg diethylstilbestrol tablets were analyzed. Ten determinations by the semiautomated method on a ground composite of enteric-coated tablets resulted in a mean of 102.1% of the label declaration and a coefficient of variation of 0.59%. Five determinations on the same composite by the USP method gave a mean of 102.5% of the label declaration and a coefficient of variation of 1.31%. Twenty determinations of a ground composite of plain coated tablets by the semiautomated method resulted in a mean of 95.4% of the label declaration and a coefficient of variation of 0.66%. Five determinations on the same composite by the USP method resulted in a mean of 96.0% of the label declaration and a coefficient of variation of 0.91%.

Composites of enteric-coated and plain coated tablets, obtained from four manufacturers and labeled as containing 0.1–5 mg of diethylstilbestrol, were analyzed by the semiautomated and USP assay methods. Results agreed closely for plain coated and enteric-coated tablets containing 1 mg or more of diethylstilbestrol (Table II) but were low when enteric-coated tablets containing <1 mg of diethylstilbestrol were assayed by the USP method. The large amount of tablet material required for the assay of low dosage, enteric-coated tablets interfered with the USP extraction procedures. Two major problems were encountered: emulsions occurred in the extraction step, and tablet dyes interfered with the color produced by irradiation. These problems were not encountered in the semiautomated method.

A recovery experiment was performed on solutions containing diethylstilbestrol reference standard plus tablet dye and excipients using the semiautomated and manual assay procedures. Two standard solutions, each containing dye to simulate a sample solution of a 0.1-mg diethylstilbestrol tablet, were analyzed by the semiautomated method, and a standard recovery of 100.7% was obtained from each. Two similar standard solutions, containing both dye and excipients, were analyzed by the semiautomated method and gave standard recoveries of 100.8 and 100.6%. The automated analysis of two additional standard solutions of diethylstilbestrol and dye, each equivalent to a sample solution of a 0.25-mg diethylstilbestrol tablet, yielded standard recoveries of 100.1 and 100.3%. A standard solution of diethylstilbestrol, assayed by the USP method, gave a 100.8% standard recovery at a level of 0.1 mg of diethylstilbestrol/tablet. However, a standard solution corresponding to the same diethylstilbestrol level but containing dye and excipients resulted in recovery of only 92.4%. These results indicated that tablet excipients that gave problems in the USP method did not interfere in the semiautomated procedure.

The addition of an extraction and a fluorometric determination to a previously published automated method has made it possible to assay low dosage, enteric-coated tablets without interference from tablet dyes and other excipients. The semiautomated method is reproducible, accurate, and precise and was used to analyze 1500 enteric-coated and 800 plain coated diethylstilbestrol tablets in a survey for content uniformity.

Physical Stability of Semisynthetic Suppository Bases

LARRY J. COBEN ˣ **and NICHOLAS G. LORDI** *

Received January 19, 1979, from the *Pharmaceutical Technical Services Department, Parke-Davis Division, Warner-Lambert Company, Morris Plains, NJ 07950.* Accepted for publication March 31, 1980. *College of Pharmacy, Rutgers—The State University, Piscataway, NJ 08854.

Abstract □ Changes in the melting range of several semisynthetic suppository bases were studied over time. X-ray diffraction studies characterized the changes as amorphous to crystalline transitions, with likely polymorphic effects occurring concurrently. Use of a modified Krowczynski apparatus to test pure base and single-ingredient suppositories showed dramatic hardening of the materials over periods as short as 6 weeks. Data were obtained by differential scanning calorimetry on freshly solidified, incrementally aged, and equilibrated samples. These methods may be used as both predictive and ongoing physical stability tests in the evaluation of suppository bases and formulas.

Keyphrases □ Suppositories—physical stability of semisynthetic suppository bases □ Physical stability—semisynthetic suppository bases

Krowczynski (1) noted changes in the deformation time of suppositories during storage using an apparatus of his own design (2). He also noted hardening in polyethylene glycol suppositories (3) but pointed out that plasticizers prevented the phenomenon. Ritschel-Beurlin (4) reported aging in suppository bases by studying the change in "spreading." Torrado-Valeiras (5) studied the stability of suppositories using a hardness tester as well as the Krowczynski device and found that certain excipients could stabilize the "melting point" by a "lubricant action" and stabilization of the metastable form. Mezey *et al.* (6), using a cone flow device, had results similar to those of Torrado-Valeiras. Other studies (7, 8) showed that suppository aging affects the *in vitro* and *in vivo* drug release rates.

Whittam and Rosano (9) studied short-term physical aging in pure monoacid triglycerides using X-ray diffraction analysis, differential thermal analysis, and polarizing microscopy. Lovegren *et al.* (10, 11) utilized differential scanning calorimetry to investigate the polymorphic nature of cocoa butter. Differential scanning calorimetry was employed by Rossell (12) to study cooling phenomena in palm kernel oil products. Correlation to dilatometric means of studying the solids content of fats was shown in a differential scanning calorimetric procedure developed by Miller *et al.* (13).

The aim of this research was to elucidate the aging or hardening phenomena observed in suppositories prepared from semisynthetic suppository bases. The hardening effect, resulting in little or no suppository melting, can cause local irritation, a defecatory reflex, or bowel obstruction. Development of procedures as both predictive and ongoing physical stability tests for both bases and formulated products was undertaken. It was thought that studying the changes through thermal analysis and comparing these results with physical hardening data would allow predictions of shelflife hardening from the initial thermal data. Pure bases and bases with ingredients added were studied.

The combination of the modified Krowczynski procedure, X-ray diffraction analysis, and differential scanning calorimetry gave this study specificity, reproducibility, versatility, and direct application to the dosage form.

EXPERIMENTAL

Materials—Five semisynthetic, commercially available bases were chosen. Table I summarizes their chemical properties and the processes by which they were produced, and Fig. 1 compares their solid fat indexes.

Three excipients were chosen to study the ingredient addition effect. Zinc oxide[1] was selected because of its insolubility, its amorphous nature, and its thickening property in oils. Resorcinol[2] was studied for its crystalline nature and its miscibility with fats. A neutral oil[3], consisting of triglycerides with fatty acid moieties between C-8 and C-12, was used because of its fatty nature and because it was claimed by Mezey *et al.* (6) to inhibit hardening.

Softening Time—The apparatus was a slight modification of Krowczynski's device (2). The original device has a constricted glass tube, with a stoppered bottom, in a glass mantle with an inlet and outlet for thermoregulated water. The suppository sits on the constriction, and a glass rod (29–31 g) is placed on the suppository. When the rod reaches the constriction, the melting time is read. Modifications (Fig. 2) included the use of a constricted U tube to avoid possible back pressure on melting past the constriction, use of a water bath[4] with both refrigeration and heating units (accuracy of ±0.05°), and reduction of the weight of the glass rod from 30 to 14 g.

The first experiment was a screening study of the five bases at 37, 36.5, 36, and 35.5°. Freshly molded suppositories and incrementally aged samples were tested in triplicate. Following Krowczynski's approach, the test was expanded to additional samples if a significant variation was noted. Softening times in excess of 90 min were not continued to the end-point during the screening trials but were noted as such.

Two bases, Bases 1 and 3, were chosen for continuing study because of their stability and instability, respectively, at 37.0°.

The second study tested the effect of several parameters on the hardening characteristics of Base 3 since this base was the least stable at 37°. The parameters studied were storage temperature after molding, cooling rate during molding, and ingredient addition. The storage temperatures used were room temperature (22°), refrigeration (4°), and freezer (−5°). For cooling variation, the suppositories were molded using dry ice, refrigeration, and standing at room temperature, varying the molding time (cooling from 50 to 20°) from 5 to 15 to 30 min, respectively. The ingredient addition studies were carried out using 5, 10, and 20% zinc oxide USP, 5% neutral oil, and 0.2, 0.5, 1, and 2% resorcinol USP. Samples were tested at the beginning of the study and after 1-, 2-, 4-, and 6-week periods.

All suppositories were molded in 50-cavity brass molds. All masses were prepared in a 2-liter beaker nested in a 4-liter beaker containing water on a hot plate. Zinc oxide USP was passed through a comminuting machine[5] at high speed with hammers forward before incorporation. Dispersion was accomplished by a laboratory homogenizing mixer[6].

Differential Scanning Calorimetry—A thermal analyzer[7] was used with the differential scanning calorimeter cell attachment. Samples between 7.0 and 10.0 mg were prepared in tightly covered aluminum cups and were tested against an empty, covered cup blank. Sample weight was determined by subtracting the tare weight of the container. The cell containing the blank and sample cups was chilled to −20° using liquid nitrogen. The test runs then were carried out at a heating rate of 2.0°/min over the range of −10–+45°.

Three samples of each base were tested as individual continuous experiments. The experimental design allowed the same samples to be tested at all incremental age periods (initial, 1, 2, 4, and 6 weeks and 6 months or equilibrium).

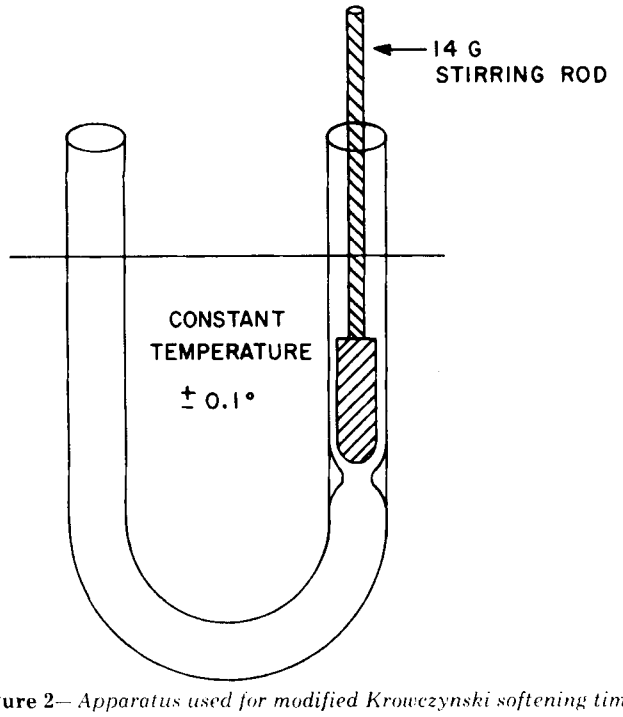

Figure 2— *Apparatus used for modified Krowczynski softening time test.*

[6] Arde-Barinco model CJ-3.
[7] Dupont model 900.

After the equilibrium testing of a sample (*e.g.*, 6 months old), the melted sample was held at 45° for 5 min and then cooled back to room temperature using compressed air or nitrogen through the cell over ~20 min. The test then was repeated immediately, with freezing to −20° and running as outlined to establish the initial endotherm. After holding and cooling to room temperature a second time, the sample was stored at the desired temperature for 1, 2, 4, or 6 weeks. Retesting and continued storage were repeated, resolidifying the sample each time, so that full testing of all time periods took 13 weeks. If any test periods were missed, a longer period was measured, and the desired period was repeated that many weeks later.

Bases 1 and 3 then were retested in triplicate at equilibrium, at the initial point, and at 6 weeks, but they were stored at 4, 20, and 30°. Base 3 then was tested with 5% neutral oil (duplicate), 10% zinc oxide USP (duplicate), and 2% resorcinol USP (duplicate as well as single samples with 1, 0.5, and 0.2% resorcinol USP). As before, these samples were tested only at equilibrium, at the initial point, and at 6 weeks.

The recorded endotherms were examined for the position and height of the major peak. This height was measured vertically from the peak tip to a horizontal line drawn between the two equilibrium points at the beginning and end of the run. The height in centimeters was converted to degrees, divided by the sample weight, and recorded as degrees per gram. Heats of fusion, ΔH_f, for the samples were determined by cutting and weighing sample endotherms *versus* a gallium standard.

X-Ray Diffraction—An X-ray diffractometer[8] was used. Samples of each base were prepared by melting the base and molding it in a 0.2-mm thick aluminum frame backed by masking tape. The frame opening created a sample surface measuring 2.0 × 1.0 cm. All five bases were studied initially upon molding and after 1, 2, 4, and 6 weeks. Since this test is nondestructive to the sample, a study could be run in 6 weeks. A second study was done on Bases 1 and 3 stored at 4, 20, and 30° *versus* a polypropylene control since variability was seen in the amplifier from week to week.

RESULTS AND DISCUSSION

Softening Time Testing—Table II summarizes the results of the base screening study performed with the modified Krowczynski apparatus. Observed softening times were noted as a function of temperature for suppositories stored for up to 54 days. Bases 2 and 5 showed no increases in softening time throughout the range of rectal temperature. While Bases 1 (Fig. 3) and 4 showed only slight hardening at 37°, the softening times were increased significantly at lower body temperatures. Base 3 (Fig. 4) showed drastic hardening at all temperatures studied.

Table III summarizes the results of the effects of cooling time, storage temperature, and adjuvant addition on the rise in softening time of Bases 1 and 3 at 37°. Cooling time had no effect on the degree of hardening noted at the test periods, whereas storage temperature had an initial separating effect on the samples but not a lasting one. This finding suggested a discrete, point-to-point process that occurred more slowly as the temperature was lowered as opposed to an ongoing, continuous process. As a control, Base 1 showed little change.

Ingredient addition studies showed the effect on the hardening rate of the three additives: neutral oil, resorcinol USP, and zinc oxide USP. The two oil-soluble materials yielded more dramatic results than the insoluble zinc oxide due to the viscosity-imparting property of this dispersed powder in the melted base. Therefore, the smallest addition of zinc oxide was the most effective in reducing hardening.

Conversely, reducing the concentration of soluble resorcinol reduced its effect on prevention of hardening.

X-Ray Diffraction Studies—In the initial study, all five bases showed similar results both upon molding and after storage.

33	9	11	13.5	30
48	9	11.5	15	22

All bases, upon molding, exhibited a broad peak (~2.2° wide at mid-height) at a 2θ value centering at 20.3–20.6°. A sharper peak (~0.6° wide at half-height) also was seen at a 2θ value of 22.7–23.0°. In the initial samples, the low point between the two peaks was at ~37% of the height of the peak at 20.5°.

After storage, no new major peaks were seen. However, the peak at 20.3° grew sharper and more distinct from the peak at 22.7°, eventually having a smaller width similar to the other peak. The low point between the peaks after 6 weeks approached the baseline (Fig. 5). In Bases 3 and 4, peaks that appeared initially as shoulders on the major peak at 20.5° became more distinct, but in no case did any shift occur to a new position nor did any peak evolve that was not observed initially.

These observations suggest an amorphous to crystalline shift in the materials studied rather than polymorphic changes. Figure 5 shows a typical initial and aged sample scan made on Base 3.

In interpreting these data, it must be kept in mind that all commercial fat products, including semisynthetic suppository bases, are mixtures of many fatty molecules. Thus, these data may not be examined in the same depth as the data for a pure compound or a single crystal. Never-

measured is a crystallization phenomenon. This result reinforces the observation made on comparisons of softening times that a discrete process characterized by a temperature-dependent rate of hardening was taking place.

The hardening rate dependence on temperature was reinforced by the second X-ray study, which showed more rapid peak sharpening at higher storage temperatures in samples aged for 6 weeks at 4, 20, and 30°.

Differential Scanning Calorimetry—Accuracy in melting-range determinations was gained by utilizing a heating rate of 2°/min. The poor heat transfer characteristics of fats (14) prevented the use of faster speeds due to the lag time in the return to a ΔT equilibrium. Speeds of 5°/min and higher totally washed out and shifted the sharp peaks observed at 2°/min. In an experiment where changes in the peak positions of 1° were being sought and metastable transformations were not, this choice was mandatory since slower heating rates yielded sharper endo- or exotherms and located an equilibrium transformation temperature more accurately (10).

Figures 6 and 7 show the general trend observed for Bases 1 and 3 in the initial study conducted with samples stored at room temperature. In all bases, regardless of the initial peak position, a 2.5–3.0° shift upward in the peak positon, a sharpening of the peak, and an increase in peak height were observed over the test period. Tables IV and V summarize the data collected to quantify the measurable parameters of the endotherms in the initial study. Table IV lists the changes in temperature positions of the major peak. Table V lists the ratio of the major peak

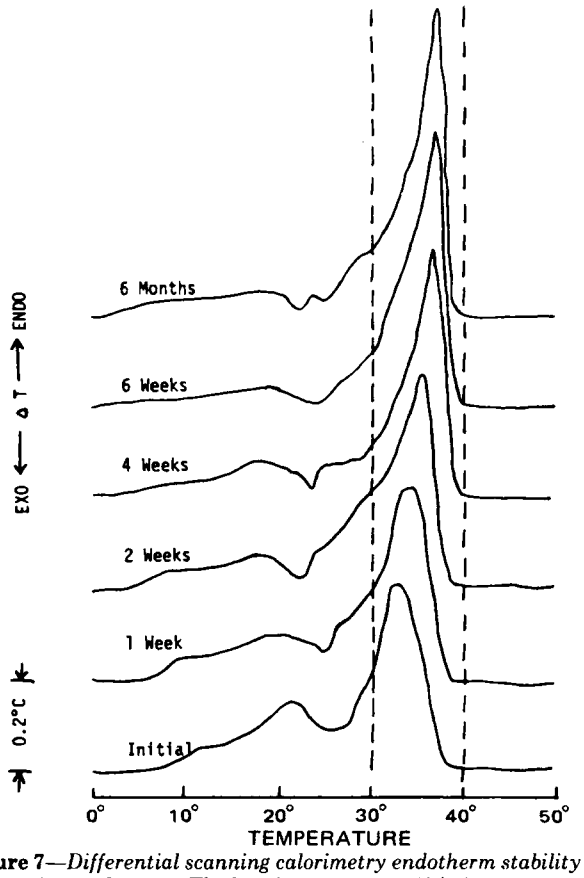

Figure 7—*Differential scanning calorimetry endotherm stability scan of Base 3 stored at 22°. The heating rate was 2.0°/min.*

height to the sample weight and the changes in this parameter over time.

The changes in sample endotherms over the 6-week period correlated perfectly with the observations of Krowczynski softening times and X-ray diffraction patterns. In all cases, a gradual change was seen. As seen in the X-ray diffraction data, changes were observed in all five bases, regardless of the production method or chemical composition.

The differential scanning calorimetry data explain the base to base variation observed in Krowczynski softening times through a correlation to the solid fat index. The solid fat index is determined dilatometrically[9] on samples immediately after solidification and may be considered only as an initial collection of data subject to change upon aging. A correlation between initial differential scanning calorimetry data and the solid fat index was shown by Miller *et al.* (13). Therefore, it is a reasonable assumption that an upward shift in the differential scanning calorimetry endotherm represents a similar upward shift in the solid fat index, *i.e.*, a higher solids content at any measured temperature. A higher solids content at any given temperature would raise the viscosity of the suppository melt at that point and, in turn, increase its softening time in the Krowczynski test.

A correlation between the degree of hardening of the five bases and their solid fat indexes at ~33° was seen (Fig. 1). Base 3, which hardened the most at 37°, had the highest solid fat index at 33° (42%). Bases 1 and 4 were next in hardening and next in decreasing solid fat index values at this temperature (37 and 35%). Base 5 at 33% and Base 2 at 17% hardened the least and were the lowest in the solid fat index at 33°.

While this correlation assumes a total shift of the curves by 4°, this shift is not necessarily the case since the shape of the curve could be changing. Until a method to measure the solid fat index of an aged sample is readily available, the procedure used for this study provides adequate correlation for prediction of hardening effects, rationalized through an upward shift in the solid fat index. In comparison, initial chemical and process information provides only the most general clues as to the melting behavior of the finished base at any age after resolidification. No useful conclusions could be drawn from the heat of fusion data collected or the peak height to sample weight ratios measured.

[9] American Oil Chemists' Society Test Method 113a.

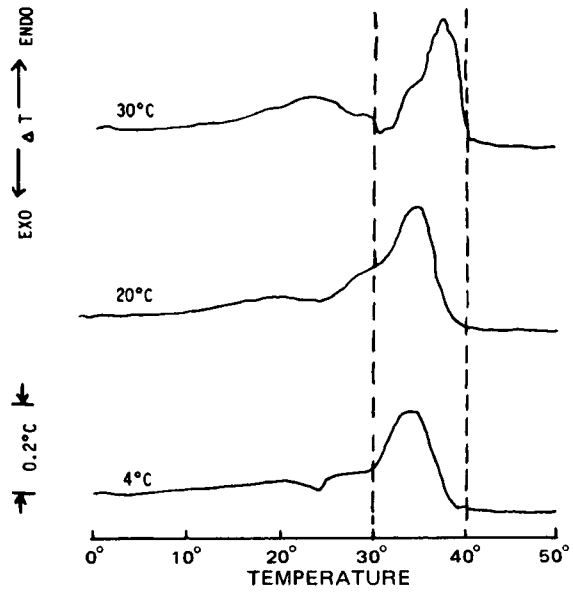

Figure 8—*Effect of storage temperature on differential scanning calorimetry endotherm stability for 6-week-old samples of Base 3. The heating rate was 2.0°/min.*

The effect of the storage temperature on the hardening rate was confirmed by measurements of the endotherms of Bases 1 and 3 stored for 6 weeks at 4, 20, and 30°. The comparative endotherms for Base 3 are shown in Fig. 8. The samples stored at temperatures closer to, but below, their melting ranges reached equilibrium crystallinity more rapidly. This phenomenon is similar to the annealing or tempering process used in metal alloy and glass preparation.

The ingredient addition trial endotherms of Base 3 showed no variation from the endotherms of Base 3 tested without additives either initially or after storage. Thus, it can be concluded that not only is there no significant freezing-point depression but that the mechanism involved in slowing the hardening rate, as evidenced by changes in softening time, is not involved with the phenomenon itself. Since the endotherm still is changing, the amorphous to crystalline shift is still occurring and, likewise, so is the shift in the solid fat index. The explanation lies in the fact that the overall phenomenon being prevented is an increase in the viscosity of the melting suppository since that is what the softening time is measuring. Addition of ingredients provides numerous pockets of discontinuity in the gross crystalline structure of the fatty solids present, lowering the gross viscosity of the semisolid suppository under testing.

This explains the effect seen from different concentrations of resorcinol. As less resorcinol was employed, there was less of a decrease of hardening. With zinc oxide, which is not soluble in the base, diminished hardening was noted at smaller concentrations, but this trend began to reverse when the powders began to add to the viscosity of the melt at higher concentrations.

CONCLUSIONS

The hardening phenomenon has been characterized by multiple test methods to be a finite amorphous to crystalline transition. The rate of this transition is storage temperature dependent but is independent of cooling time during solidification within the bounds of suppository molding rates. This transition is manifested in an upward shift in the solid fat index in the range of body temperatures. This rise in the percent solids in the melt at the temperature under examination results in a rise in viscosity at that temperature, which is perceived as hardening. In other words, there are less meltable solids at body temperature in a suppository that has hardened. Ingredients added to the base do not hinder the transition but may have one of two effects. Base-soluble ingredients disturb the gross crystalline structure of the fatty solids, lowering the achieved viscosity upon melting. Base-insoluble ingredients, in higher concentrations, may raise the viscosity of the melt simply by providing a higher solids content.

Suppository base selection may be simplified in two ways. First, examination of the solid fat index for potential problems upon shifting is an easy investigative early-warning device to narrow the field of choice. Second, differential scanning calorimetric examination of an aged base

sample (as received from a potential supplier) and an instantaneous rerun yield initial *versus* aged data on melting-range shifting after an investment in testing time of <1 hr. Even though the formula ingredients may retard the rate of transition, this test produces a best and worst case melting range to evaluate.

The results of this study in no way reflect on the quality of any base tested or on the ability of any of the manufacturers to supply a range of bases suitable to individual needs.

Kinetic Study of USP Blue Tetrazolium Assay with Methylprednisolone, Hydrocortisone, and Their Hemisuccinate Esters by High-Pressure Liquid Chromatography

MARILYN DIX SMITH

Received December 7, 1979, from *Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication March 25, 1980. Present address: American Critical Care, McGaw Park, IL 60085.

Abstract □ The reactions of blue tetrazolium (I) with methylprednisolone and hydrocortisone and their hemisuccinate esters at ambient temperature under USP assay conditions in alcohol USP and in absolute alcohol were followed by high-pressure liquid chromatography (HPLC) and spectrophotometry. The disappearance of the ester and the increase and then decrease in the alcohol, as well as the formation of several reaction products with time, were observed by HPLC analysis. The reduction of I was observed spectrophotometrically. A sequential kinetic model was used to describe the overall reaction. The rate constants for the hydrolysis of the hemiester (k_1), the reaction with I (k_2), and the degradation of the parent steroid (k_3) were determined by discrete kinetic experiments using HPLC. The following observations were made: (*a*) k_1 is proportional to $[H_2O]$ and is the rate-limiting step, (*b*) k_2 is about 100 times the value of k_3, and (*c*) k_2 for methylprednisolone is about the same as for hydrocortisone and appears to be independent of the concentration of water. With these rate constants, simulated time–concentration profiles for the reaction of the esters with I favorably compared with experimental data in alcohol USP and absolute alcohol. This study shows that the USP blue tetrazolium assay with these esters has potential for variability and is not stability indicating.

Keyphrases □ Methylprednisolone—and hemisuccinate ester, high-pressure liquid chromatographic and spectrophotometric monitoring of USP assay with blue tetrazolium □ Hydrocortisone—and hemisuccinate ester, high-pressure liquid chromatographic and spectrophotometric monitoring of USP assay with blue tetrazolium □ High-pressure liquid chromatography—kinetic study of USP blue tetrazolium assay with methylprednisolone and hydrocortisone and their hemisuccinate esters

The official USP assay for the corticosteroids, including their esters, is the blue tetrazolium (I) reaction (1). The base-catalyzed reduction of I by the C-17 side chain of corticosteroids is a classical reaction in steroid analysis (2). Meyer and Lindberg (3) established that the α-ketol moiety in corticosteroids is responsible for the reduction of I. However, the reaction mechanism for the C-21 esters of corticosteroids is unknown.

BACKGROUND

Johnson *et al.* (4) reported that color development was unusually slow with hydrocortisone hemisuccinate compared to other steroids. In a study of the reaction of I with cortisone acetate, a C-21 ester, Guttman (5) showed that as the concentration of base catalyst was decreased, the lag time increased and the sigmoid shape of the curve was emphasized. He concluded that hydrolysis of the ester was a prerequisite to a reaction resulting in the generation of formazan. Graham *et al.* (6) also suggested that ester hydrolysis occurs prior to and during formazan development. Their conclusions were derived from graphical kinetic treatment of the spectrophotometric data.

The hydrolysis of the hemiester of corticosteroids in aqueous media has been studied by several investigators. Mauger *et al.* (7) reported that the degradation of its hemisuccinate ester to hydrocortisone was first order. Further degradation to a species devoid of the 17-dihydroxyacetone also was observed. This degradation was followed by separation of the alcohol and ester and subsequent reaction with I. Garrett (8) studied the alkaline hydrolysis of hydrocortisone hemisuccinate by constant pH titration.

High-pressure liquid chromatography (HPLC) has been used recently to study the degradation of hydrocortisone (9). An HPLC method was described (10) that determined simultaneously hydrocortisone (II*a*) and its hemisuccinate ester (III*a*) or methylprednisolone (II*b*) and its hemisuccinate ester (III*b*).

This paper reports a kinetic study of the reaction of I with II and III using this HPLC method. The hydrolysis rates of III to II under compendial blue tetrazolium assay conditions also are reported.

The effect of water in the final reaction mixture of I has been studied. The percentage of water in the official USP method [due to the use of alcohol USP and 10% aqueous tetramethylammonium hydroxide (IV) in the preparation of reagents and samples] is 5.8 (11). Rechnagel and

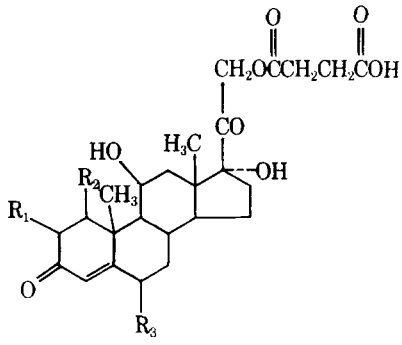
II

IIa: $R_1 = R_2 = R_3 = H$
IIb: $R_1 = R_2$ = missing (unsaturated), $R_3 = CH_3$



III

IIIa: $R_1 = R_2 = R_3 = H$
IIIb: $R_1 = R_2$ = missing (unsaturated), $R_3 = CH_3$

Litteria (12) found that water inhibits the reaction of I and that the extent of inhibition increases as the concentration of water in the final reaction increases. However, Graham and Kenner (11) showed that the effect of water is essentially negligible if it is present at <6%. This paper reports the effect of the water content of the reaction mixture on the rate constants involved in the reaction of I with II and III.

EXPERIMENTAL

Reagents—Acetonitrile[1], acetic acid[2], anhydrous methanol[3], blue tetrazolium[3] (I), and tetramethylammonium hydroxide[3] (IV) were reagent grade. Alcohol and absolute alcohol were USP grade. Compounds IIa, IIIa, and IIIb were USP reference standards. Compound IIb was an NF reference standard.

Apparatus—A high-pressure liquid chromatograph[4] equipped with a 100-μl injector[5], a fixed-wavelength detector[6] (λ = 254 nm) or a variable-wavelength detector[7], a digital integrator[8], a strip-chart recorder[9], and a scanning spectrophotometer[10] were used.

HPLC Conditions—A microparticulate (5-μm) octadecylsilane column[11] was used. The mobile phase was acetonitrile–water–acetic acid (35:65:2) at a flow rate of 1 ml/min.

Sample Preparation—Fifty milligrams of IIIa or IIIb and 39 mg of IIa and IIb were dissolved separately in 100 ml of alcohol (absolute or USP). Then 12 ml of these solutions was diluted to 500 ml with alcohol (absolute or USP) to a final concentration of ~20 μM for each sample.

Reagent Preparation—Compound I, 500 mg, was dissolved in 100 ml of anhydrous methanol. A 10% solution of IV in water was diluted 1:10 with alcohol USP. A 5% acetic acid solution was prepared by diluting acetic acid 1:20 with water.

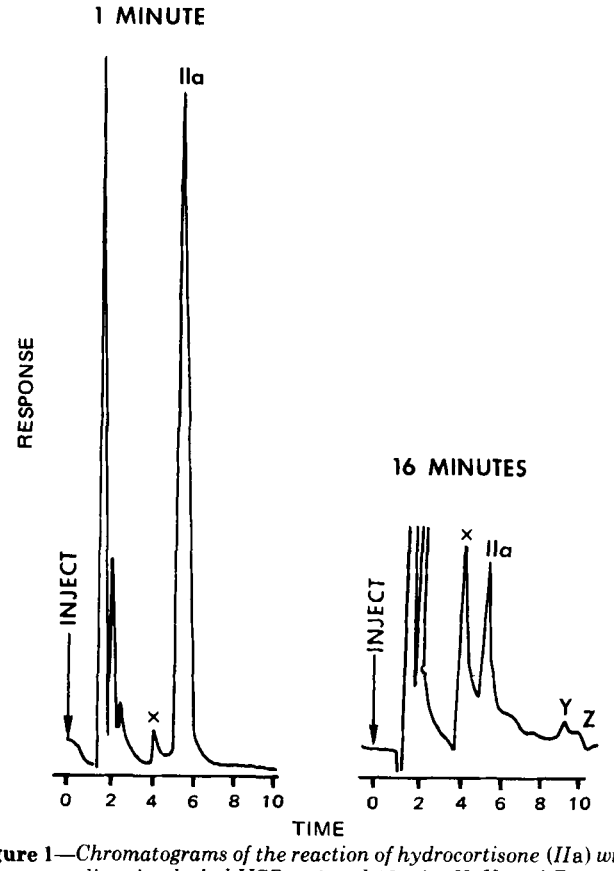

Figure 1—*Chromatograms of the reaction of hydrocortisone (IIa) with blue tetrazolium in alcohol USP at 1 and 16 min; X, Y, and Z are the products of the reaction.*

Kinetic Experiments—*Experiments with I*—Twenty milliliters of the solution of I and 40 ml of diluted IV were added to 200 ml of each sample preparation. The solution was mixed and stored in the dark. At timed intervals, 15 ml of solution was withdrawn and 0.6 ml of acetic acid was added. The absorbance of this solution at 525 nm *versus* a blank preparation was recorded. A portion of the withdrawn solution also was diluted 1:1 with 5% acetic acid and injected onto the HPLC column, and the chromatograms were recorded.

Experiments without I—Twenty milliliters of anhydrous methanol and 40 ml of diluted IV were added to 200 ml of each sample preparation. The solution was mixed. At timed intervals, 15 ml was withdrawn and 0.6 ml of acetic acid was added. This withdrawn solution then was diluted 1:1 with 5% acetic acid and injected onto the HPLC column.

RESULTS AND DISCUSSION

The reactions of I with IIa, IIb, IIIa, and IIIb at ambient temperature under USP assay conditions for III (13) in alcohol USP as well as in absolute alcohol were followed by HPLC and spectrophotometry. The identity and quantitation of each peak were made with respect to standard solutions of IIa, IIb, IIIa, and IIIb.

The percent of water, as determined by the Karl Fischer reaction, was 6.0% in alcohol USP and 0.04% in absolute alcohol. Based on these values, the percent of water in the reaction mixture was calculated to be 6.9% when alcohol USP was used in the sample preparation and 2.3% when absolute alcohol was used.

Chromatograms of these reaction mixtures in alcohol USP at various times are given in Figs. 1–4. Figures 1 and 3 (the reaction of I with IIa and IIb) show a decrease in II with a subsequent increase in peaks X, Y, and Z (possible oxidation products of II) with time. Figures 2 and 4 (the reaction of I with IIIa and IIIb) show a decrease in III with a subsequent increase and then decrease in II and an increase in peaks X and Y with time. These observations suggest that the reaction of the esters of corticosteroids with I is sequential. The intermediate in the reaction sequence is II. Since Gupta (9) showed that IIa is degraded under strongly basic conditions, the decomposition of IIa and IIb under USP assay conditions with alcohol USP and absolute alcohol also was studied.

A kinetic model to describe the overall reaction sequence is given here;

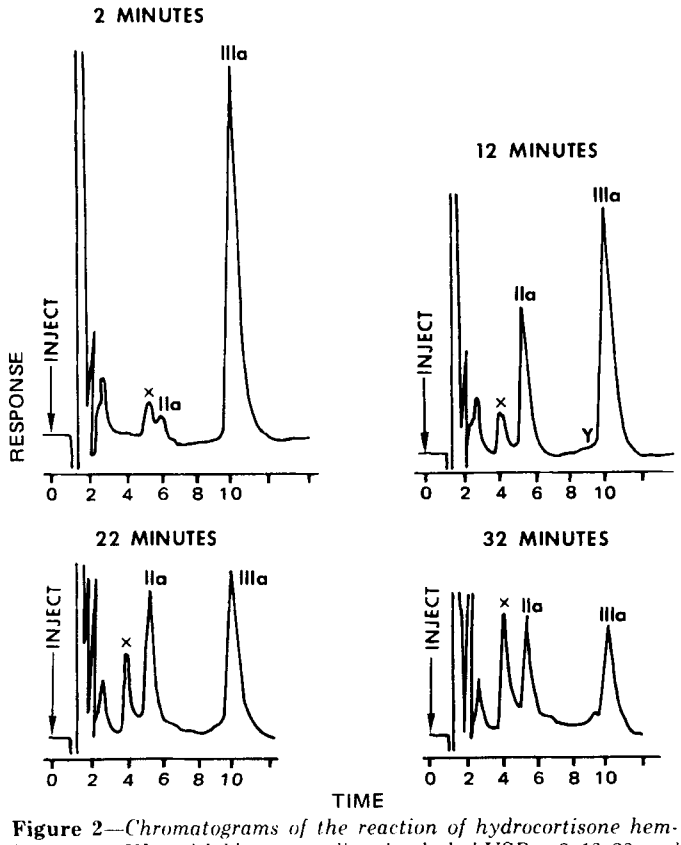

Figure 2—*Chromatograms of the reaction of hydrocortisone hemisuccinate (IIIa) with blue tetrazolium in alcohol USP at 2, 12, 22, and 32 min; X and Z are the reaction products and IIa is hydrocortisone.*

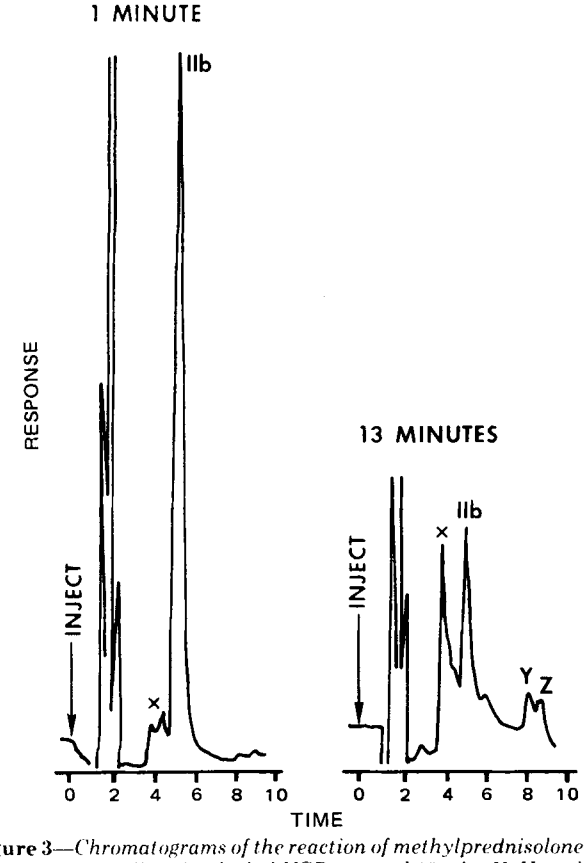

Figure 3—*Chromatograms of the reaction of methylprednisolone (IIb) with blue tetrazolium in alcohol USP at 1 and 13 min; X, Y, and Z are the reaction products.*

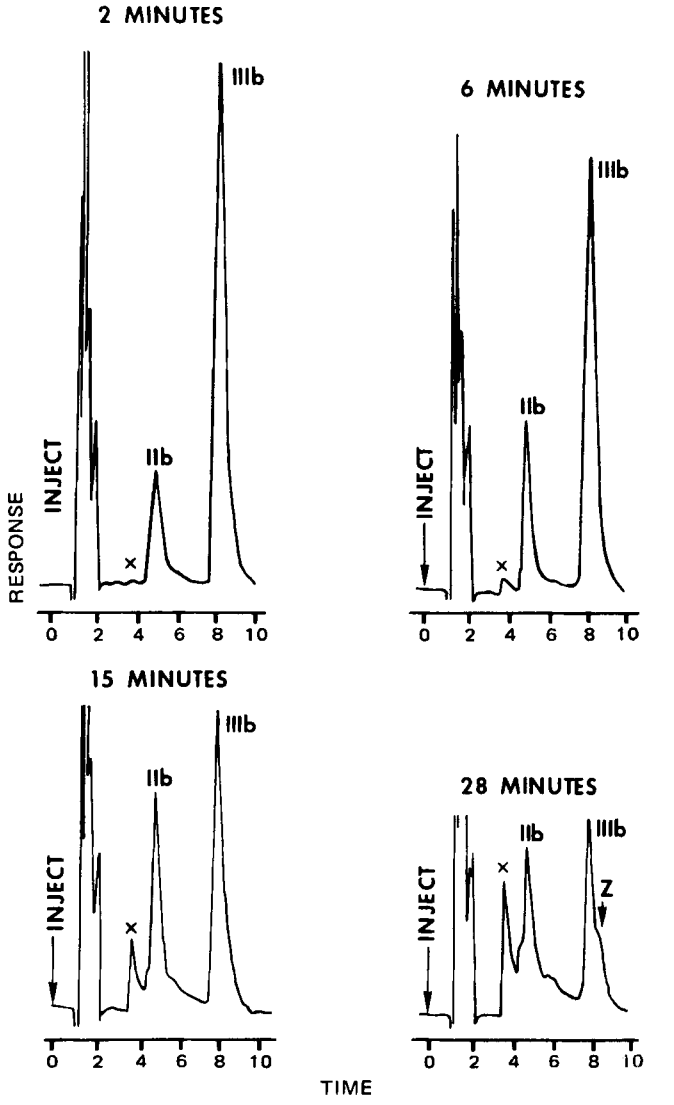

Figure 4—*Chromatograms of the reaction of methylprednisolone hemisuccinate (IIIb) with blue tetrazolium in alcohol USP at 2, 6, 15, and 28 min; X and Z are the reaction products and IIb is methylprednisolone.*

the reformation of I from formazan as postulated by Graham *et al.* (14) is not included. Experimental data of the reaction of II*a* and II*b* with I in 95% alcohol or absolute alcohol suggested that the rate of reformation of I is much slower than the rate of reaction of II with I (Scheme I). Therefore, the loss of formazan (within 100 min of reaction time) would be negligible.

$$\text{III} \xrightarrow[[OH^-]]{k_1} \text{II} \xrightarrow[[I]]{k_2} C + P$$
$$\text{II} \xrightarrow[[OH^-]]{k_3} D$$

Scheme I

P is reduced I; *C* and *D* are decomposition products of II; $[OH^-] = [IV]$, and k_1, k_2, and k_3 are pseudo-first-order rate-constants.

The disappearance of III and the appearance of II and *P* can be described by:

$$\frac{d\text{III}}{dt} = -k_1\text{III} \qquad \text{(Eq. 1)}$$

$$\frac{d\text{II}}{dt} = k_1\text{III} - (k_2 + k_3)\text{II} \qquad \text{(Eq. 2)}$$

$$\frac{dP}{dt} = k_2\text{II} \qquad \text{(Eq. 3)}$$

Table I—Rate Constants of the Blue Tetrazolium–Corticosteroid Reaction

Corticosteroid and Its Ester	Rate Constant, min^{-1}	
	Alcohol USP	Absolute Alcohol
IIa + IIIa		
k_1	0.036	0.014
k_2	0.10	0.10
k_3	0.0015	0.0007
IIb + IIIb		
k_1	0.041	0.018
k_2	0.12	0.13
k_3	0.0021	0.0018

Solutions for these differential equations are:

$$III_t = III_0 e^{-k_1 t} \quad \text{(Eq. 4)}$$

$$II_t = \frac{III_0 k_1}{(k_2 + k_3) - k_1}\left[e^{-k_1 t} - e^{-(k_2+k_3)t}\right] \quad \text{(Eq. 5)}$$

$$P_t = \frac{III_0 k_1 k_2}{k_1 - (k_2 + k_3)}\left[\frac{e^{-k_1 t}}{k_1} - \frac{e^{-(k_2+k_3)t}}{k_2 + k_3}\right] \quad \text{(Eq. 6)}$$

The rate constants k_1, k_2, and k_3 were determined experimentally by following each discrete reaction under USP conditions using either alcohol USP or absolute alcohol as the solvent. The hydrolysis of III, the decomposition of II in IV, and the reaction of II with I were followed independently by HPLC. The results of these kinetic experiments are given in Table I.

These rate constants were used to generate time–concentration profiles for II, III, and *P* to simulate the reaction of III with I under specified solvent conditions. Normalized experimental data obtained by HPLC for the reaction of IIIa and IIIb with I were superimposed on these generated time–concentration profiles (Figs. 5–8). The colorimetric data (*P*) were normalized by dividing each observed absorbance by the absorbance after the reaction was complete (>3 hr). For each ester of II in alcohol USP and absolute alcohol, the predicted concentrations of II, III, and *P* closely agreed with the experimental values. Some estimation of the experimental data (III) occurred since the decomposition products of II (Y and Z) were not totally resolved from III. These observations of the reaction of the hemiester with I corroborate conclusions (5, 6) that hydrolysis of the ester is a prerequisite to the reaction with I.

The following observations can be made about the rate constants for each pseudo-first-order reaction:

1. The rate of decomposition of II in a base (k_3) is ~1% of the rate of reaction with I (k_2) and can be ignored.
2. The rate constants (k_2) under USP assay conditions are about the same for IIa and IIb and are in agreement with the results reported by Graham *et al.* (15) (*i.e.*, k_2 [IIa] = 0.090 and k_2 [IIb] = 0.096).
3. In the ester reaction sequence, ester hydrolysis is the rate-determining step.

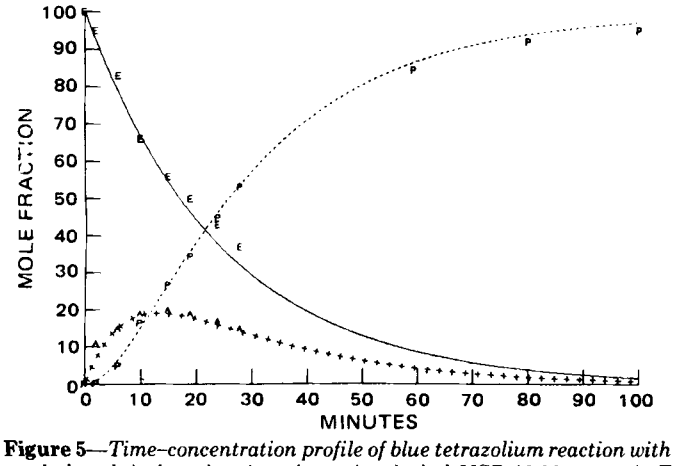

Figure 5—*Time–concentration profile of blue tetrazolium reaction with methylprednisolone hemisuccinate in alcohol USP (6.9% water); E represents the normalized data for methylprednisolone hemisuccinate (IIIb), A represents the normalized data for methylprednisolone (IIb), P represents the normalized data for reduced blue tetrazolium (formazan), and —, +, and . . . are computer-generated curves for E, A, and P, respectively, using rate constants determined independently.*

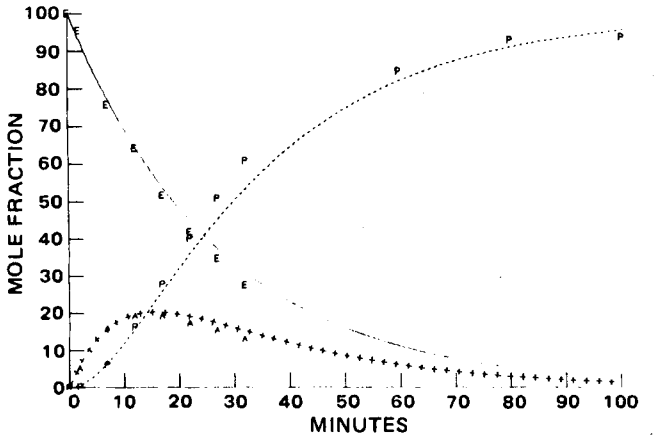

Figure 6—*Time–concentration profile of blue tetrazolium reaction with hydrocortisone hemisuccinate in alcohol USP (6.9% water); E represents the normalized data for hydrocortisone hemisuccinate (IIIa), A represents the normalized data for hydrocortisone (IIa), P represents the normalized data for reduced blue tetrazolium (formazan), and —, +, and . . . are computer-generated curves for E, A, and P, respectively, using rate constants determined independently.*

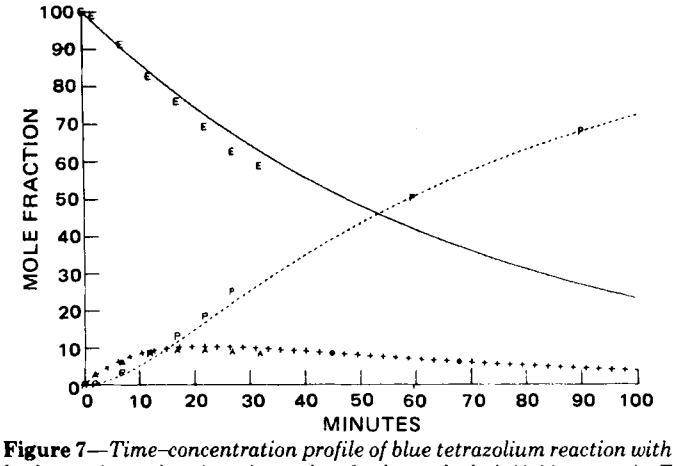

Figure 7—*Time–concentration profile of blue tetrazolium reaction with hydrocortisone hemisuccinate in absolute alcohol (2.3% water); E represents the normalized data for hydrocortisone hemisuccinate (IIIa), A represents the normalized data for hydrocortisone (IIa), P represents the normalized data for reduced blue tetrazolium (formazan), and —, +, and . . . are computer-generated curves for E, A, and P, respectively, using rate constants determined independently.*

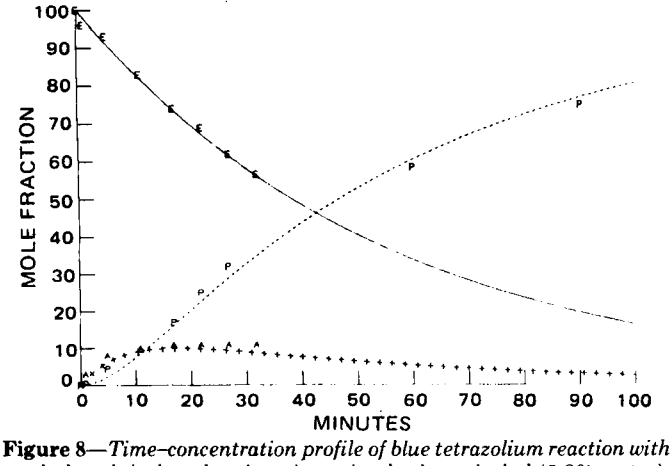

Figure 8—*Time–concentration profile of blue tetrazolium reaction with methylprednisolone hemisuccinate in absolute alcohol (2.3% water); E represents the normalized data for methylprednisolone hemisuccinate (IIIb), A represents the normalized data for methylprednisolone (IIb), P represents the normalized data for reduced blue tetrazolium (formazan), and —, +, and . . . are computer-generated curves for E, A, and P, respectively, using rate constants determined independently.*

4. The water content of the reaction mixture has little effect on the rate of reaction of the corticosteroid (II) with I within the range studied.

5. The hydrolysis rate of the ester (III → II) and subsequently the overall reaction rate appear to be proportional to the water content of the reaction mixture.

These kinetic results imply that the USP blue tetrazolium assay for these corticosteroid hemisuccinate esters has a high variability potential since it is a timed measurement (90 min). These results show that III does not react directly with I and that II must be formed. Therefore, the USP blue tetrazolium assay cannot differentiate between the corticosteroid (II) and its ester (III) and thus is not a stability-indicating assay of III. In fact, if hydrolysis of the ester of these corticosteroids occurred, the results might show an increase in corticosteroid since the reaction rate of the corticosteroid is about three times as fast as the hemiester in alcohol USP.

CONCLUSIONS

1. The reaction of corticosteroid esters (III) with I is sequential. The ester is hydrolyzed first, and the resulting corticosteroid (II) reacts with I. The hydrolysis step is the rate-determining step.

2. The USP blue tetrazolium assay is not stability indicating for the esters of these corticosteroids.

3. As the percent of water in the reaction mixture decreases, the time for complete reaction increases for the USP blue tetrazolium assay of C-21 hemisuccinate esters of corticosteroids.

New Evaluation of Potential Methylmercury Scavengers

LESLIE R. ROBERTS *§x, LARRY K. STEINRAUF *‡, and ROBERT T. BLICKENSTAFF *§

Received November 5, 1979, from the **Department of Biochemistry and the* ‡*Department of Biophysics, Indiana University School of Medicine*, and the §*Veterans Administration Medical Center, Indianapolis, IN 46202.* Accepted for publication March 24, 1980.

Abstract □ A biological assay was developed to evaluate rapidly the relative efficacy of marketed and experimental mercurial scavengers. Rat liver mitochondrial protein (1.0 mg) was titrated against methylmercuric chloride to the inhibitory level of mitochondrial respiration. Respiration induced by adenosine 5′-diphosphate with succinate (plus rotenone) as the substrate was inhibited consistently by 20.7 ± 3.9 nmoles of methylmercury/mg of protein. Adenosine 5′-diphosphate-stimulated respiration (State 3) was restored with dimercaprol, penicillamine, and cysteine but not with serine. The antagonists glutathione, 3-mercaptopropionic acid, 2-mercaptoethanol, dithiothreitol, thioglucose, mercaptosuccinic acid, and thiosalicylic acid were effective. Glutathione was significantly superior to thiosalicylic acid and mercaptosuccinic acid. Sodium sulfide, thioacetamide, and ethylenediaminetetraacetic acid were completely inactive. Substitution of glutamate (plus malate) for succinate (plus rotenone) as the substrate did not alter the responses significantly. The rat liver mitochondrial assay provides preliminary information about the efficacy and toxicity of water-soluble thiols. Investigations utilizing encapsulated water- and lipid-soluble mercaptans are in progress.

Keyphrases □ Mercurial scavengers—thiol-containing compounds, evaluation of efficacy and toxicity using rat liver mitochondrial assay □ Mercaptans—evaluation of efficacy and toxicity as mercurial scavengers using rat liver mitochondrial assay

Agents currently used to alleviate clinical symptoms and to facilitate the rapid removal of methylmercury include chelators such as dimercaprol, penicillamine, and ethylenediaminetetraacetic acid (1–3). Unfortunately, the effectiveness of these antidotes is limited by their toxicity, chemical instability, and relatively short circulation time. Polythiol resins, thioacetylated steroids, mercaptosteroids, and lipid encapsulation of ethylenediaminetetraacetic acid have been proposed to improve on these mercurial scavengers (4–9).

BACKGROUND

Reports on the analysis of subcellular distribution of labeled mercury indicate significant accumulation of mercury by mitochondria (10). Furthermore, dose and time dependence of the mercurial in relation to the extent of damage incurred by isolated mitochondria has been documented (11–13). In addition, the technique for isolation of viable rat liver mitochondria is well known.

Early reports demonstrating reversal of mercurial inhibition by mercaptans dealt with isolated enzymes (14, 15). Thompson and Whittaker (14) showed significant protection of pigeon brain pyruvate oxidase activity against mercuric chloride inhibition by the addition of dimercaprol and glutathione. Barron and Kalnitsky (15) demonstrated 75% reactivation of mercuric chloride-inhibited succinoxidase by the addition of various dithiols. Sone *et al.* (11) recently studied the effects of methylmercuric chloride on mitochondrial respiration and found nearly complete restoration of succinate oxidation with thiol-containing reagents such as 2-mercaptoethanol, glutathione, cysteine, and dithiothreitol. The concentration required for reversal was not given. Less than 10% recovery of nicotinamide-adenine dinucleotide oxidation was restored by these reagents (11).

In summary, direct effects of mercurials on rat liver mitochondria have been demonstrated (10–13). Furthermore, reactivation of mercurial-inhibited enzymes by thiols has been shown (14, 15). In addition, relief of mercurial intoxication in mitochondria by thiols has been shown but has not been quantified (15). This report describes the use of mito-

4. The water content of the reaction mixture has little effect on the rate of reaction of the corticosteroid (II) with I within the range studied.

5. The hydrolysis rate of the ester (III → II) and subsequently the overall reaction rate appear to be proportional to the water content of the reaction mixture.

These kinetic results imply that the USP blue tetrazolium assay for these corticosteroid hemisuccinate esters has a high variability potential since it is a timed measurement (90 min). These results show that III does not react directly with I and that II must be formed. Therefore, the USP blue tetrazolium assay cannot differentiate between the corticosteroid (II) and its ester (III) and thus is not a stability-indicating assay of III. In fact, if hydrolysis of the ester of these corticosteroids occurred, the results might show an increase in corticosteroid since the reaction rate of the corticosteroid is about three times as fast as the hemiester in alcohol USP.

CONCLUSIONS

1. The reaction of corticosteroid esters (III) with I is sequential. The ester is hydrolyzed first, and the resulting corticosteroid (II) reacts with I. The hydrolysis step is the rate-determining step.

2. The USP blue tetrazolium assay is not stability indicating for the esters of these corticosteroids.

3. As the percent of water in the reaction mixture decreases, the time for complete reaction increases for the USP blue tetrazolium assay of C-21 hemisuccinate esters of corticosteroids.

New Evaluation of Potential Methylmercury Scavengers

LESLIE R. ROBERTS *§x, LARRY K. STEINRAUF *‡, and ROBERT T. BLICKENSTAFF *§

Received November 5, 1979, from the **Department of Biochemistry and the* ‡*Department of Biophysics, Indiana University School of Medicine*, and the §*Veterans Administration Medical Center, Indianapolis, IN 46202.* Accepted for publication March 24, 1980.

Abstract □ A biological assay was developed to evaluate rapidly the relative efficacy of marketed and experimental mercurial scavengers. Rat liver mitochondrial protein (1.0 mg) was titrated against methylmercuric chloride to the inhibitory level of mitochondrial respiration. Respiration induced by adenosine 5′-diphosphate with succinate (plus rotenone) as the substrate was inhibited consistently by 20.7 ± 3.9 nmoles of methylmercury/mg of protein. Adenosine 5′-diphosphate-stimulated respiration (State 3) was restored with dimercaprol, penicillamine, and cysteine but not with serine. The antagonists glutathione, 3-mercaptopropionic acid, 2-mercaptoethanol, dithiothreitol, thioglucose, mercaptosuccinic acid, and thiosalicylic acid were effective. Glutathione was significantly superior to thiosalicylic acid and mercaptosuccinic acid. Sodium sulfide, thioacetamide, and ethylenediaminetetraacetic acid were completely inactive. Substitution of glutamate (plus malate) for succinate (plus rotenone) as the substrate did not alter the responses significantly. The rat liver mitochondrial assay provides preliminary information about the efficacy and toxicity of water-soluble thiols. Investigations utilizing encapsulated water- and lipid-soluble mercaptans are in progress.

chondria in the evaluation of mercaptans as scavengers of methylmercuric chloride.

EXPERIMENTAL[1]

All mercaptans were dissolved in deionized, distilled water just prior to use. These reagents, as well as methylmercury, exhibit chemical instability and volatility. For example, a dilute solution of methylmercuric chloride loses 20% of its capacity to inhibit mitochondrial respiration after standing for 5 hr at room temperature.

Preparation of Mitochondria—Mitochondria were prepared by decapitation of rats (Sprague–Dawley strain) and rapid transfer of the liver to 0.25 *M* sucrose plus 1 m*M* ethylenediaminetetraacetic acid (pH 7.2) at 4°, followed by washing, homogenization, and centrifugation according to the method of Blair (16). The final pellet was resuspended in sucrose–ethylenediaminetetraacetic acid and assayed for total protein by the biuret method (17). The total amount of protein, the volume of material, and the final protein concentration were recorded for each experiment.

Measurement of Redox Reactions—The intactness of isolated mitochondria was determined by incubation of 1.0 mg of mitochondrial protein first with 15 m*M* glutamate plus 0.15 m*M* malate and then with 20 m*M* succinate plus rotenone (500 ng/ml) in a medium containing 250 m*M* sucrose, 5.0 m*M* monobasic sodium phosphate, and 3.0 m*M* $MgCl_2$ (Medium 1). State 3 respiration[2] was initiated by the addition of 1.5 μmoles of adenosine 5′-diphosphate and recorded on an oxygraph[3] equipped with a test platinum electrode and a 2.0-ml partially enclosed reaction vessel maintained at 30° by a circulating water bath. A respiratory control ratio of 5.0 for succinate (plus rotenone) as the substrate was used as a minimum standard. All mitochondria batches were subjected to control runs at the beginning of each experiment.

Inhibition of Mitochondrial Oxidative Metabolism—The minimum level of methylmercury required to inhibit State 3 respiration to the level of State 4 respiration[4] was determined by incubating 1.0 mg of rat liver mitochondrial protein with succinate (20 m*M*) plus rotenone (500 ng/ml) in Medium 1 to which an excess of adenosine 5′-diphosphate (3.0 μmoles) had been added. Approximately 1 min after the initiation of State 3 respiration, methylmercury was pipetted into the reaction vessel. Observations were terminated after several minutes of State 4 respiration or when the rate of State 3 respiration was indistinguishable from State 4 respiration. Titrations were conducted at the beginning of each experiment to evaluate interbatch variation.

The relative efficacy of the water-soluble thiols was examined using succinate plus rotenone as the substrate, adenosine 5′-diphosphate to initiate State 3 respiration, and a constant level of methylmercury in Medium 1. Thiols were titrated to a concentration sufficient to reinstate State 3 respiration. Values reported in Table I represent 50% recovery. These values were calculated by subtracting the State 4 rate from the recovery scavenger rate and dividing by the State 3 rate minus the State 4 rate of respiration, with subsequent matching of the scavenger concentration used to the appropriate percentage recovery. All agents were tested on several preparations of mitochondria.

RESULTS AND DISCUSSION

Inhibition of mitochondrial metabolism as a function of the amount of methylmercury added was reported previously (11, 12). No change in respiration was observed below 0.10 nmole of methylmercury/mg of rat liver mitochondrial protein. Above 11.0 nmoles of methylmercury, >91% inhibition of State 3 minus State 4 respiration was obtained.

Sone *et al.* (11) reported that dimercaprol reverses methylmercury-induced inhibition of rat liver mitochondrial metabolism. To quantify the proposed reversal, a series of experiments was conducted as described. Figure 1 displays actual tracings obtained when appropriate incubations were carried out. Addition of rat liver mitochondria to a reaction medium containing the substrate initiated State 2 respiration[5]. When adenosine 5′-diphosphate was added, State 3 respiration began. Without further additions, State 3 respiration terminated to give State 4 respiration (curve A). If 1.0 μmole of dimercaprol/mg of rat liver mitochondrial protein was mixed with actively respiring mitochondria, no change was observed (curve B). Introduction of a predetermined level of methylmercury slowed the State 3 rate to a pseudo-State 4 rate. Finally, a sufficient quantity of dimercaprol added to the medium immediately relieved mercurial inhibition (curves C–E). With levels of >50 nmoles of dimercaprol/mg of rat liver mitochondrial protein, >60% recovery routinely was obtained.

Table I—Titration of Methylmercury Scavengers [a]

Mercaptan	With Methylmercury: 50% Recovery Concentration, nmoles/mg of rat liver mitochondria	Ratio of Mercaptan to Methylmercury	Without Methylmercury: Control Run Concentration, μmoles/mg of rat liver mitochondria	Effect on State 3 Respiration
Glutathione	14.5[b]	0.54	0.70	None
Thiosalicylic acid	30.4	1.15	2.40	Inhibition
3-Mercaptopropionic acid	41.5	1.76	0.40	None
2-Mercaptoethanol	58.9	2.85	2.40	None
Dithiothreitol	65.1	2.48	4.50	None
Mercaptosuccinic acid	69.2	2.80	2.52	Inhibition
Thioglucose	126[b]	4.81	2.20	None
Sodium sulfide	—	—	1.17	Inhibition
Thioacetamide	—	—	33.2	None

[a] Results are given for the assay of mitochondrial incubations with mercaptans in the presence and absence of methylmercury. Titrations of mercaptans were carried out according to procedures outlined for penicillamine and dimercaprol. Results are reported as 50% recovery levels because of the greater sensitivity in this region of the titration curve to small changes in the concentration of the scavenger. Control runs were conducted in the absence of methylmercury using higher levels of the scavenger than required to produce recovery. Qualitative effects on State 3 respiration are included in the last column. [b] $p < 0.05$ (standard t test); individual 50% recovery concentrations were compared to the mean of all 50% recovery levels.

Since penicillamine has been an alternative therapy for acute mercurial intoxication (18), the efficacy of this compound was compared to dimercaprol with the mitochondrial assay procedure. Cysteine was included as a test reagent because of its close structural similarity to penicillamine and its qualitative scavenger capacity (11, 14). Serine also was selected because it structurally resembles penicillamine but contains a hydroxyl group instead of a sulfhydryl group.

Results of several experiments are shown in Fig. 2. Titration with penicillamine and cysteine produced similar results, although a slightly higher scavenger capacity was demonstrated by penicillamine. The optimal concentration of penicillamine and cysteine required to elicit a given percentage recovery of respiration was significantly higher than the dimercaprol concentration required to produce the same response. Serine has no capacity to reverse mercurial inhibition, thereby substantiating the requirement for sulfhydryl groups on scavenger molecules.

Compounds such as 3-mercaptopropionic acid and glutathione were able to relieve mercuric chloride inhibition of isolated enzyme systems. The scavenger efficacy of these mercaptans, as well as others selected for their variation in carbon chain length, extent of ionization, and location of sulfhydryl groups, was examined (Table I). To verify the requirement of reduced thiols for activity against methylmercury, sodium sulfide and thioacetamide were tested. Because ethylenediaminetetraacetic acid has been used in the treatment of heavy metal poisoning, it was tested also.

Glutathione, a tripeptide containing one sulfhydryl group, exhibited the greatest efficiency in relieving 50% of the mercurial-induced inhibition. Thiosalicylic acid showed 50% recovery with an average of 30.4 nmoles/mg of rat liver mitochondrial protein, making it nearly as effective as glutathione, although it inhibited State 3 respiration during the control run. 3-Mercaptopropionic acid exhibited a slightly superior mercaptan

[1] Methylmercuric chloride was obtained from ICN K and K Laboratories. Sucrose, succinate, rotenone, glutamate, malate, ethylenediaminetetraacetic acid, adenosine 5′-diphosphate, 2-mercaptoethanol, thioglucose, thiosalicylic acid, glutathione, and dithiothreitol were purchased from Sigma Chemical Co. Dimercaprol, penicillamine, and serine were products of Aldrich Chemical Co. Cysteine and mercaptosuccinic acid were supplied by Eastman Organic Chemicals. 3-Mercaptopropionic acid was obtained from Evans Chemetics. Thioacetic acid and thioacetamide were products of Matheson, Coleman and Bell.

[2] Active respiration of mitochondria in the presence of excess added substrate and adenosine 5′-diphosphate.

[4] Respiration of mitochondria after added adenosine 5′-diphosphate has been phosphorylated but in the presence of exogenous substrate.

[5] Mitochondrial respiration in the presence of added substrate and phosphate.

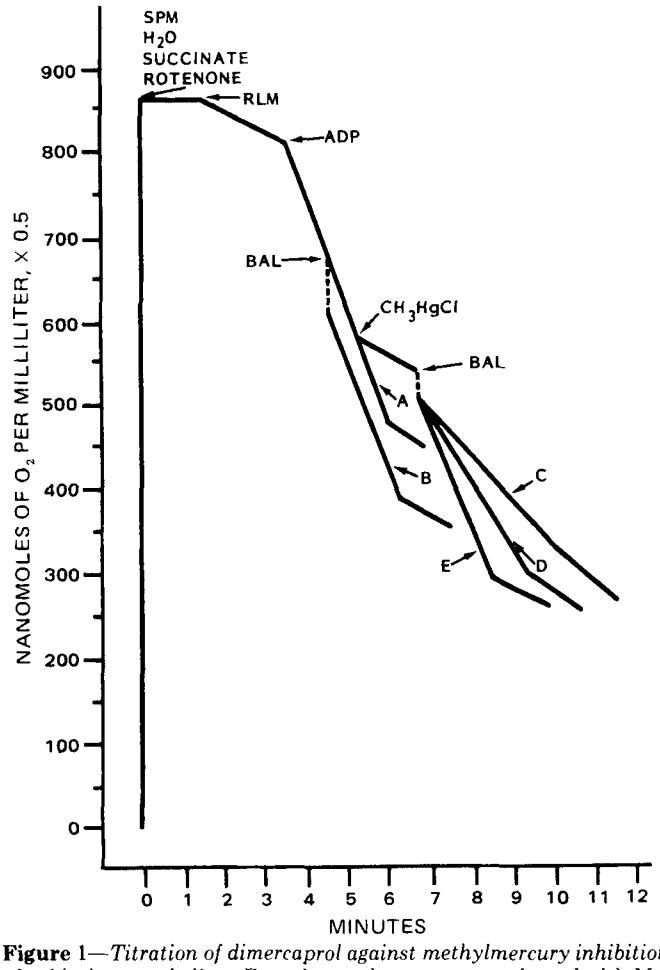

Figure 1—*Titration of dimercaprol against methylmercury inhibition of oxidative metabolism. Experimental runs were conducted with Medium 1 (20 mM succinate, 500 ng of rotenone/ml, 20 mg of mitochondria/ml, and 3.0 μmoles of adenosine 5′-diphosphate). Key: A, control run without methylmercury or dimercaprol; B, scavenger control run of 1.0 μmole of dimercaprol/mg of protein added to mitochondria after the initiation of State 3 respiration; and C–E, inhibitory effect of methylmercury (200 μg/ml) and the level of recovery using 0.05 (C), 0.10 (D), and 10 (E) μmoles of dimercaprol/mg of rat liver mitochondrial protein. Each run required ~10 min. SPM = 250 mM sucrose, 5.0 mM monobasic sodium phosphate, and 3.0 mM $MgCl_2$; RLM = rat liver mitochondria; ADP = adenosine 5′-diphosphate; and BAL = British anti-Lewisite.*

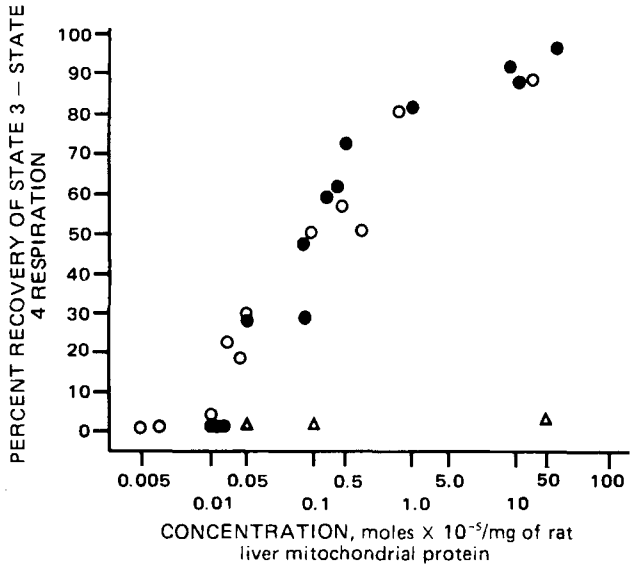

Figure 2—*Titration of penicillamine, cysteine, and serine against methylmercury. Mitochondria (20 mg/ml) were incubated in the presence of Medium 1 (20 mM succinate and 500 ng of rotenone/ml). State 3 respiration was initiated with excess adenosine 5′-diphosphate (3.0 μmoles). Inhibition of State 3 respiration to the level of State 4 respiration was obtained using 200 μg of methylmercury/ml. Aliquots of cysteine (○), penicillamine (●), and serine (△) were added to the reaction vessel, which was observed for reestablishment of State 3 respiration. The calculation of the percent recovery is described under* Experimental.

to methylmercury ratio to those of 2-mercaptoethanol and dithiothreitol, but the concentrations required were not statistically different. Mercaptosuccinic acid relieved 50% of the observed inhibition, although the scavenger capacity was reduced by a progressive increase of State 3 inhibition. Thioglucose was markedly less efficient as a mercurial scavenger. Sodium sulfate and thioacetamide proved to be ineffective scavengers and inhibitory at sufficient levels. Ethylenediaminetetraacetic acid was neither effective as a mercurial scavenger nor toxic at a concentration of 168 nmoles/mg of rat liver mitochondrial protein.

To compare the effect of an alternative substrate on mercurial scavenger efficacy, glutamate plus malate was substituted for succinate plus rotenone and several experiments were conducted as outlined. The test compounds were 3-mercaptopropionic acid, 2-mercaptoethanol, mercaptosuccinic acid, and thioacetamide. In each case, the assay responded as observed when succinate plus rotenone was used as the substrate. Furthermore, levels required for 50% recovery were statistically indistinguishable from those reported here. Thioacetamide was ineffective, as expected.

Dimercaprol proved to be a significantly superior methylmercury scavenger to penicillamine in the assay. The improved efficacy of dimercaprol compared to penicillamine also was observed in whole animal studies (8). Because dimercaprol has a relatively greater lipid solubility than penicillamine and contains an additional thiol group, the differences observed are reasonable. Nevertheless, doubling the number of sulfhydryl groups per molecule does not strictly increase its effectiveness by a factor of two. Thus, the potential of dimercaprol to bind heavy metals perhaps is antagonized by its characteristic tendency to form intermolecular disulfide bridges (18).

In this assay, glutathione was a significantly better mercurial scavenger than are the other mercaptans. Glutathione contains some ionized groups at physiological pH, so ease of transport through the inner mitochondrial membrane is not an applicable explanation. Furthermore, no damage to respiratory components was observed when glutathione was incubated with mitochondria (Table I). The explanation for the enhanced scavenger capacity of glutathione remains undetermined but is under investigation.

With the exception of glutathione and thioglucose, the mercaptans tested were not statistically different, indicating no minimal requirement for structural design beyond the availability of a free sulfhydryl group and water solubility. The inactivity of thioacetamide and sodium sulfide against methylmercury was predictable (14).

The assay is a new approach for preliminary testing of mercurial antidotes. Information is obtained not only about the efficiency of the mercurial scavenger but also about its behavior under control conditions. Although mercaptans such as thiosalicylic acid and mercaptosuccinic acid are effective scavengers, they also inhibit respiration in this system (Table I). The advantages of time and the number of animals involved make this assay attractive for first approximations of scavenger capacity. These studies are being extended to encapsulation of water-soluble mercaptans and lipid-soluble thiols.

Aspirin—A National Survey IV: *In Vitro* Dissolution of Aspirin Formulations

WILLIAM E. JUHL ˣ and ROSS D. KIRCHHOEFER

Received October 29, 1979, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication March 26, 1980.

Abstract □ The results of a national survey of the *in vitro* dissolution rates of aspirin tablets are presented. Dissolution profiles by both the proposed USP XX basket method and a paddle method are compared. The methods were used to analyze 59 tablet formulations representing 38 manufacturers. Each tablet was subjected to the dissolution procedure in 500 ml of pH 4.5 buffer solution, and an aliquot was sampled automatically and analyzed by an automated system. In 30 min, 22% of the samples tested using the basket method failed the proposed USP XX dissolution requirement. Seventy-five percent of the samples tested by the paddle method also failed the proposed dissolution requirement.

Keyphrases □ Aspirin—*in vitro* dissolution, comparison of basket and paddle methods □ Analgesics—*in vitro* dissolution of aspirin formulations □ Dissolution—aspirin formulations, *in vitro*, basket and paddle methods compared

A national survey (1) of aspirin tablet products was conducted at the National Center for Drug Analysis during the summer and fall of 1978. The purpose of the survey was to ascertain the quality of these products and the adequacy of the USP monograph (2). The USP presented a dissolution test in the *Pharmaceutical Forum* (3) that specifies use of a basket and requires 80% dissolution in 30 min.

During the survey, selected aspirin samples representing each manufacturer and dosage level were assayed for their dissolution rates *in vitro* using both a basket and a paddle and the dissolution medium (pH 4.5 buffer) and speed of rotation (50 rpm) specified in Ref. 3. The guidelines (4) for the dissolution testing were followed. The dissolution rate for each sample was determined by taking aliquots automatically (5) every 10 min over 60 min and analyzing the dissolution medium for aspirin by an automated procedure. The purpose of this experiment was to compare the dissolution characteristics of the selected marketed samples by the proposed USP XX dissolution test using the proposed basket method and the paddle method. The paddle method also was used because it has been a more discriminating test for differentiating drug products than the basket method in this laboratory.

EXPERIMENTAL

Apparatus—A dissolution apparatus[1] and a 76-liter aquarium tank with a constant-temperature water bath maintained at 37° were used.

For the sampling[2], an automatic analyzer with a sampler[3], three pumps[4], a manifold, and a timer[5] was used together with a cycle timer[6] for the sampling interval timer. Six sampling probes with filters[7] were required.

For the determinative step, an automatic analyzer with a sampler[3], pumps[8], a manifold, and a timer[5] was connected to a spectrophotometer[9] equipped with a quartz flowcell[10]. A 100-mv recorder[11] was connected to the spectrophotometer.

Reagents—ACS grade chloroform was washed with water and filtered through paper on the day of use. The pH 2.2 buffer solution was prepared by diluting 250.0 ml of 0.2 *M* KCl and 39.0 ml of 0.2 *M* HCl to 1 liter with water. The 0.2 *M* KCl was prepared by dissolving 14.911 g of potassium chloride in water and diluting it with water to 1 liter. The 0.2 *M* HCl was prepared by diluting 17.0 ml of concentrated hydrochloric acid to 1 liter with water. The pH 4.5 buffer solution was prepared by adding 2.99 g of sodium acetate to 1.66 ml of acetic acid and diluting to 1 liter with water. The buffer solution used for the dissolution medium was boiled to remove air bubbles.

Standard Preparation (324-mg Tablets)—Approximately 325 mg of USP reference standard aspirin was weighed accurately and dissolved in 5.0 ml of 95% ethanol. This solution was diluted to 1 liter with the pH 4.5 buffer solution. The standard was prepared fresh daily and was used immediately.

Sample Preparation (324-mg Tablets)—One tablet was placed in each dissolution vessel or basket. For 60 min, samples were withdrawn

Aspirin—A National Survey IV: *In Vitro* Dissolution of Aspirin Formulations

WILLIAM E. JUHL ˣ and ROSS D. KIRCHHOEFER

Received October 29, 1979, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication March 26, 1980.

Abstract □ The results of a national survey of the *in vitro* dissolution rates of aspirin tablets are presented. Dissolution profiles by both the proposed USP XX basket method and a paddle method are compared. The methods were used to analyze 59 tablet formulations representing 38 manufacturers. Each tablet was subjected to the dissolution procedure in 500 ml of pH 4.5 buffer solution, and an aliquot was sampled automatically and analyzed by an automated system. In 30 min, 22% of the samples tested using the basket method failed the proposed USP XX dissolution requirement. Seventy-five percent of the samples tested by the paddle method also failed the proposed dissolution requirement.

Keyphrases □ Aspirin—*in vitro* dissolution, comparison of basket and paddle methods □ Analgesics—*in vitro* dissolution of aspirin formulations □ Dissolution—aspirin formulations, *in vitro*, basket and paddle methods compared

A national survey (1) of aspirin tablet products was conducted at the National Center for Drug Analysis during the summer and fall of 1978. The purpose of the survey was to ascertain the quality of these products and the adequacy of the USP monograph (2). The USP presented a dissolution test in the *Pharmaceutical Forum* (3) that specifies use of a basket and requires 80% dissolution in 30 min.

During the survey, selected aspirin samples representing each manufacturer and dosage level were assayed for their dissolution rates *in vitro* using both a basket and a paddle and the dissolution medium (pH 4.5 buffer) and speed of rotation (50 rpm) specified in Ref. 3. The guidelines (4) for the dissolution testing were followed. The dissolution rate for each sample was determined by taking aliquots automatically (5) every 10 min over 60 min and analyzing the dissolution medium for aspirin by an automated procedure. The purpose of this experiment was to compare the dissolution characteristics of the selected marketed samples by the proposed USP XX dissolution test using the proposed basket method and the paddle method. The paddle method also was used because it has been a more discriminating test for differentiating drug products than the basket method in this laboratory.

EXPERIMENTAL

Apparatus—A dissolution apparatus[1] and a 76-liter aquarium tank with a constant-temperature water bath maintained at 37° were used.

For the sampling[2], an automatic analyzer with a sampler[3], three pumps[4], a manifold, and a timer[5] was used together with a cycle timer[6] for the sampling interval timer. Six sampling probes with filters[7] were required.

For the determinative step, an automatic analyzer with a sampler[3], pumps[8], a manifold, and a timer[5] was connected to a spectrophotometer[9] equipped with a quartz flowcell[10]. A 100-mv recorder[11] was connected to the spectrophotometer.

Reagents—ACS grade chloroform was washed with water and filtered through paper on the day of use. The pH 2.2 buffer solution was prepared by diluting 250.0 ml of 0.2 *M* KCl and 39.0 ml of 0.2 *M* HCl to 1 liter with water. The 0.2 *M* KCl was prepared by dissolving 14.911 g of potassium chloride in water and diluting it with water to 1 liter. The 0.2 *M* HCl was prepared by diluting 17.0 ml of concentrated hydrochloric acid to 1 liter with water. The pH 4.5 buffer solution was prepared by adding 2.99 g of sodium acetate to 1.66 ml of acetic acid and diluting to 1 liter with water. The buffer solution used for the dissolution medium was boiled to remove air bubbles.

Standard Preparation (324-mg Tablets)—Approximately 325 mg of USP reference standard aspirin was weighed accurately and dissolved in 5.0 ml of 95% ethanol. This solution was diluted to 1 liter with the pH 4.5 buffer solution. The standard was prepared fresh daily and was used immediately.

Sample Preparation (324-mg Tablets)—One tablet was placed in each dissolution vessel or basket. For 60 min, samples were withdrawn

at 10-min intervals using the automated sampling system.

Semiautomated Determination—The automated system was assembled as shown in Fig. 1. The solutions were sampled at a rate of 30 cups per hour with a sample-to-wash ratio of 2:1. A sampling pattern of three standards, six samples, one standard, six samples, *etc.*, was used. Two cups of standard were placed at the end. The first two standards and the last standard were not used in the calculations. A polytetrafluoroethylene strip was inserted into the BO fitting to direct the organic phase downward.

To start the system, ethanol was pumped through the chloroform pump tube for 5 min, and the tube then was pumped dry. The chloroform line was placed in the solution and pumped until the solution reached the spectrophotometer cell. The pH 2.2 buffer line was placed in the solution, and the system was allowed to equilibrate.

The sample stream was diluted with pH 2.2 buffer, and chloroform was added. The chloroform containing the extracted drug was pumped through a flowcell, and the absorbance of the drug was read at 280 nm.

RESULTS AND DISCUSSION

Validation Tests—A series of validation tests was performed on the automated system. A linear response was obtained from four standard solutions containing 0.3–1.3 mg of aspirin/ml (corresponding to 50–200% of the label declaration). The results of an assay of 30 individual cups exhibited a relative standard deviation of 0.9%. A standard solution containing 0.65 mg of aspirin/ml gave reproducible peaks whose height reached ~97.0% of the steady state.

Composite Assays—Portions of tablet composites equivalent to single tablets were analyzed by the paddle method and the proposed USP XX (3) method. The ground tablet composites were prepared from available commercial samples. When four samples were analyzed by the USP and the automated methods, the results obtained were (percentage of label declaration): 97.9, 98.2, 101.0, and 100.9 and 99.3, 98.2, 101.5, and 101.2, respectively. Four individual assays of one composite gave an average of 101.2% of the label declaration with a relative standard deviation of 0.27%.

Effect of Alcohol in Standard—Since aspirin is not very soluble in pH 4.5 buffer solution, the aspirin standard was dissolved in ethanol and then diluted with the buffer solution. To test the effect of the alcohol, solutions containing 1% alcohol and no alcohol were analyzed. There was no difference in absorptivity between the two solutions.

Effect of Boiling pH 4.5 Buffer Solution—Deaerated water usually is recommended for dissolution of tablets. In the proposed method, if the water is deaerated first and the buffer solution then is prepared using this

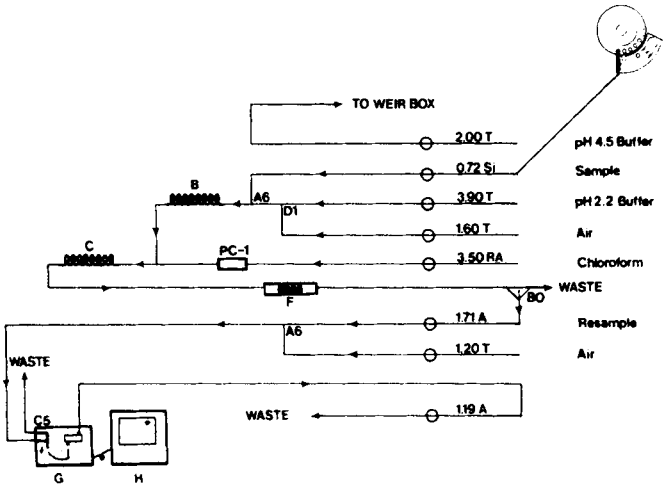

Figure 1—*Flow of automated system for aspirin dissolution. Key: Si, silicon pump tube; T, Tygon tube; A, Acidflex pump tube; RA, red Acidflex pump tube; B, 28-turn × 2.4-mm i.d. mixing coil; C, 28-turn × 2.4-mm i.d. mixing coil with one double end; F, 5.5-turn settling coil; G, UV spectrophotometer; and H, recorder. Pump tube sizes are in milliliters per minute.*

water, air can be introduced into the solution. A test was performed to determine if boiling the pH 4.5 buffer solution affects the pH of the solution. The pH of the freshly prepared solution and the boiled solution was the same.

Survey Results—The automated method was employed to analyze 59 tablet formulations representing 37 manufacturers using both the basket and the paddle techniques (Table I). Of the total samples tested, 22% failed the proposed USP XX dissolution requirement using the basket method and 75% failed using the paddle technique.

Of the 59 formulations tested, 49 were plain aspirin tablets and 10 were buffered tablets. None of the buffered tablets and 26.5% of the plain tablets failed the proposed USP XX requirements by the basket method. Eighty-six percent of the plain tablets and 20% of the buffered tablets failed the proposed USP XX requirements by the paddle method.

During this survey, the basket method gave higher results than the paddle method for ~75% of the samples. For some samples, the basket method results were twice as high as those for the paddle method. Therefore, if the basket method is used as the USP XX requirement, all buffered and most plain tablets would pass the test; but if the paddle method is used, some buffered tablets and most plain tablets would fail the proposed requirement. These results pose the question of which method will predict bioavailability more accurately.

Abstract □ The significant occurrence of thrombophlebitis in patients administered diazepam intravenously was described recently. This side effect has been attributed to the crystallization of diazepam and its subsequent precipitation upon contact with blood or intravenous fluids. The current study was designed to reveal whether the solubilizing capability of poloxamer 188 reduces the incidence of thrombotic and inflammatory effects of diazepam in rabbits. The incidence of early (3-hr) ear vein necrosis was 72% in the diazepam-treated ears, while the incidence of necrosis in the ears that received poloxamer 188 as a vehicle for diazepam was 25%. The occurrence of thrombosis and loss of vessel integrity also was higher in diazepam-treated ears than in those treated with diazepam plus poloxamer 188. Solubilization of diazepam with poloxamer 188 may decrease the incidence of the tested side effects.

Keyphrases □ Diazepam—reduction of thrombosis and inflammation using poloxamer 188 as vehicle, rabbits □ Poloxamer 188—use as vehicle for reduction of thrombosis and inflammation induced by injectable diazepam, rabbits □ Sedatives—diazepam, reduction of thrombosis and inflammation using poloxamer 188 as vehicle, rabbits

Diazepam[1] is generally accepted as an intravenous sedative/anesthetic with usefulness in dentistry and medicine (1–6). Its increased use over the past decade has resulted in support for its benefits in various procedures, but the literature also contains references to side effects.

Pain upon injection is a frequent side effect of diazepam use (3, 7–9), and there have been many reports of thrombophlebitis following diazepam injection (1–3, 9). These side effects have been associated with precipitation of di-

Table I—Effect of Poloxamer 188 on the Incidence of Diazepam-Related Rabbit Ear Vein Alterations [a]

	Thrombosis			Necrosis			Loss of Vascular Integrity		
	I[b]	II	III	I	II	III	I	II	III
Morrhuate sodium[c]	0	0	5	1	4	2	4	0	0
Saline	0	0	0	0	0	0	0	0	0
Diazepam	0	0	3	4	1	1	4	0	1
Diazepam plus poloxamer 188	0	0	1	2	0	0	0	0	0

[a] The values are the number of ears, within each group of eight ears injected, that showed the side effect. [b] Key: I = mild, II = moderate, and III = severe. [c] Known inflammatory agent.

azepam from the injectable solution in the presence of an aqueous medium, including blood (10).

The present study was designed to reveal whether the solubilizing capability of poloxamer 188[2] reduces the incidence of thrombotic and inflammatory effects of diazepam in rabbit ear veins.

EXPERIMENTAL

Sixteen male, adult, albino New Zealand rabbits[3], 2–3 kg, received an injection of a control or test solution in the marginal ear vein. After 180 min, the animals were sacrificed with ether. Vein cross-section samples, beginning 2 cm proximal to the injection site, were taken for pathological evaluation of vasculitis, necrosis, hemorrhage, thrombosis, edema, and vessel integrity. Standard staining and tissue handling techniques were used.

The animals were divided into two test groups. Group A (n = 8) animals received 0.9% saline (0.6 ml/kg) in one ear and morrhuate sodium (10 mg/kg), a known inflammatory agent, in the opposite ear. Group B (n = 8) animals received injectable diazepam[4] diluted (2×) with vehicle (diazepam, 1.5 mg/kg) in one ear and injectable diazepam diluted with water containing 5% poloxamer 188[5] (diazepam, 1.5 mg/kg) in the opposite ear. The diazepam vehicle contained 40% propylene glycol, 10% ethanol, 5% sodium benzoate, and 1.5% benzyl alcohol.

RESULTS AND DISCUSSION

Necrosis was more prevalent in diazepam-treated ear veins than in ear veins treated with diazepam plus poloxamer 188 (Table I). Necrosis also was closely associated with diazepam injection in other studies. Schneider and Mace (11) described an episode of necrosis associated with thrombosis that was related to a diazepam injection in a patient. Knill and Evans (12) injected diazepam into the central artery of rabbit ears and observed consistent necrosis and gangrene.

Antemortem thrombosis was observed in three of eight ear veins biopsied 3 hr after diazepam injection, while one ear vein contained a thrombus following diazepam plus poloxamer 188 (Table I). In ears treated with diazepam, two demonstrated hemorrhage and five showed a loss of vessel integrity. These changes were not seen in the ears treated with diazepam plus poloxamer 188.

Thrombosis after diazepam injection also was a frequent finding in previous studies. Graham *et al.* (13) found that thrombosis developed in the vein used for drug infusion within 48 hr in rats that received at least 0.25 mg of diazepam. Baker (1) reported a 15% incidence of superficial venous thrombosis in 400 patients receiving diazepam anesthesia. Three patient case reports of thrombosis following injection of diazepam also were described (14). Brown (15) observed a 15% incidence of thrombophlebitis or thrombosis following intravenous injection of 35 mg of diazepam and a 30% incidence with 50 mg of diazepam administered intravenously to patients. A 39% incidence of thrombosis was reported in patients 7–10 days after intravenous administration of 10 mg of diazepam (16).

The occurrence of thrombophlebitis probably is related to the insolubility of diazepam in aqueous media. Langdon (17) decreased the incidence of phlebitis from 7 to 2% by using 150–250 ml of saline flush. Jusko *et al.* (10) concluded that the thrombophlebitis associated with diazepam injection probably is due to precipitation of diazepam from solution when injected into a slow intravenous drip or a slow venous stream. Their calculations indicate that only a high flow rate allows the diazepam to stay in solution in an aqueous medium, where it is relatively insoluble.

This flow-related factor may be the reason that some investigators experienced fewer problems with diazepam when it was injected into a large vein (2) and may explain the lower incidence of thrombophlebitis when diazepam was followed by a large volume of saline flush (17). Graham *et al.* (7) reduced the incidence of thrombophlebitis after injection of 10 mg of diazepam in patients from 16 to 3% by diluting the drug in 20 ml of 5% dextrose–Ringer's lactate solution.

Ecanow and coworkers[6] found that a milky precipitate appeared upon introduction of injectable diazepam into whole blood and serum samples *in vitro*. The mixtures were centrifuged, and the precipitate was collected and observed under a light microscope; amorphous and needle-shaped crystalline particles were seen. A similar type of precipitate was obtained by adding the injectable diazepam to distilled water. Reformulation of the injectable diazepam was accomplished by adding poloxamer 188 (5% and more) to the commercial formulation. When the reformulated diazepam was introduced to the *in vitro* serum and whole blood solutions, no precipitation was apparent.

Poloxamer 188[7] [poly(oxypropylene) poly(oxyethylene) condensate], a surface-active agent with low toxicity, is used intravenously in humans. The present data indicate that poloxamer 188-solubilized diazepam causes fewer thrombotic and inflammatory effects in rabbit ear veins than does the injectable form of diazepam. Further studies are indicated to determine if this compound will effectively reduce diazepam side effects in patients.

Effect of Edetate Disodium on Goldfish Membrane

PETER J. CASCELLA ˣ **and PAUL D. KINDELSPIRE**

Received May 21, 1979, from the *Pharmacy Department, South Dakota State University, Brookings, SD 57007.* Accepted for publication February 13, 1980.

Abstract □ The effect of edetate disodium on the absorption of secobarbital sodium was examined in goldfish. An inverse relationship was observed between the concentration of edetate disodium to which fish were exposed and the time of death induced by secobarbital sodium. This inverse relationship is postulated to be due to an enhanced absorption of the ionized form of secobarbital in goldfish. There appears to be a period of time after exposure of the fish to the chelating agent in which the enhanced permeability of the membrane is absent in most studies. However, once the enhanced permeability effect is obtained, it is present 24 hr after exposure.

Keyphrases □ Edetate disodium—effect on absorption of secobarbital sodium in goldfish □ Secobarbital sodium—absorption in goldfish, effect of edetate disodium □ Permeability—effect of edetate disodium on goldfish membrane

Edetic acid is a sequestering agent capable of forming chelates with alkaline earth and heavy metal ions. Tidball (1) reported a 10-fold increase in the absorption of phenolsulfonphthalein (phenol red) in rats in the presence of edetic acid. Enhanced absorption of heparin and synthetic heparinoids from the GI tract of rats and dogs in the presence of edetic acid was observed (2). Feldman and Gibaldi (3) reported an ~20% increase in the transfer rate of salicylate across the everted rat intestine after exposure to edetic acid but found no apparent change in the transfer rate of salicylamide. They suggested that edetic acid may alter the rate-limiting barrier for water-soluble compounds but not for lipid-soluble compounds.

The purpose of this investigation was to examine the effect of edetate disodium on the permeability of the goldfish membrane. Levy and coworkers (4, 5) utilized goldfish to study the effects of surfactants on the absorption of alcohols and barbiturates. Nightingale *et al.* (6) used goldfish to assess structure–toxicity relationships of some substituted phenothiazines. Feldman *et al.* (7) used goldfish to study various local anesthetic agents and found an apparent relationship between the minimum effective concentration of drug to produce a response in goldfish and the minimum blocking concentration of these agents in isolated nerve or muscle fibers (8).

Therefore, it was of interest to examine the effects of edetate disodium on the goldfish membrane to determine if the permeability effects were similar to those reported previously (1–3) in other biological models.

EXPERIMENTAL

Concentration and Recovery Time Studies—Goldfish (*Carassius auratus*) (1–3 g) were placed in groups of five in tanks containing 2 liters of a solution of edetate disodium[1] at 0.1, 0.2, and 0.4 mg/ml. The solutions were made with glass-distilled[2] water and were adjusted to pH[3] 7.4 using 0.1 *N* NaOH or HCl. The fish were left in the solutions for 24 hr and then were placed for 30 min or 24 hr in recovery tanks containing 2 liters of glass-distilled water. Individual fish then were placed into beakers containing 200 ml of 0.1 m*M* secobarbital sodium[4] in 0.05 *M* phosphate buffer (pH 7.4). Cessation of gill and mouth movements was noted, and the time to death was computed.

Controls were run for each group following the procedure for the edetate disodium-treated fish, except that the chelating agent was omitted from the treatment tank. All investigations were performed at 20 ± 2°.

pH Study—Five fish were placed in tanks containing 2 liters of 0.2 mg/ml edetate disodium in glass-distilled water. The solutions were adjusted to pH 7.4 using 0.1 *N* NaOH or 0.1 *N* HCl. The fish were left in the tanks for 24 hr and then were placed for 30 min or 24 hr in a recovery tank containing 2 liters of glass-distilled water. Individual fish were placed in 200 ml of a 0.1 m*M* secobarbital sodium solution buffered to pH 6.4, 7.4, or 8.4 with 0.05 *M* phosphate buffer. Cessation of gill and mouth movements was noted, and the time to death was computed.

Controls were run in the same manner as described previously. All experiments were performed at 20 ± 2°.

RESULTS AND DISCUSSION

The results of the concentration and recovery time study are summarized in Table I. Comparisons were made within each block using a Student *t* test. There was no significant difference between the treated animals and the controls for the 24-hr treatment, 30-min recovery study, except at the highest concentration of the chelating agent. In the 24-hr treatment, 24-hr recovery study, there was a significant difference between the treated and control fish at all concentrations of edetate disodium. If it is assumed that the amount of secobarbital necessary to produce death is the same for treated and control animals, edetate disodium apparently increases membrane permeability to the barbiturate, as indicated by the shorter times until death for the treated animals.

Although the reason is unknown, there appears to be a time period after exposure in which the enhanced permeability of the membrane is absent, except at the highest concentration (0.4 mg/ml) of the chelating agent. This conclusion is suggested by the fact that there was no significant difference between treated and control animals in the 24-hr treatment, 30-min recovery study for edetate disodium at 0.1 and 0.2 mg/ml, while a significant difference was found for the 24-hr treatment, 24-hr recovery study. The fact that the apparent increased permeability of the membrane, once established, exists 24 hr after exposure suggests that the effect on membrane permeability is relatively long, at least in the system investigated.

It was of interest to determine whether a relationship exists between the concentration of the chelating agent and the increased membrane permeability. Since the condition of the fish employed may have varied, an analysis of variance was performed on the control fish for each concentration of the chelating agent used in the 24-hr treatment, 24-hr recovery study. The results indicated that a significant difference existed between the three control groups ($p < 0.05$). An analysis of the means using the least significant difference method indicated that the control run with the fish treated with 0.2-mg/ml edetate disodium was significantly different ($p < 0.05$) from the controls run with the fish treated with 0.1- and 0.4-mg/ml edetate disodium. A comparison of the means for the fish treated with 0.1- and 0.4-mg/ml edetate disodium using a Student *t* test showed a significant difference ($p < 0.05$) between the two means. Therefore, the higher the concentration of chelating agent to which the fish are exposed, the greater is the apparent increase in permeability.

Studies also were performed in which the fish were treated with 0.2-mg/ml edetate disodium solutions and then exposed to secobarbital sodium solutions buffered to pH 6.4, 7.4, and 8.4 (Table II). There again appeared to be a period of time after exposure of the fish to the chelating agent in which the enhanced permeability of the membrane was absent. This effect was evident in the 24-hr treatment, 30-min recovery study, in which no significant difference was observed between the treated and the control groups. With the 24-hr treatment, 24-hr control, there was

a significant difference between the treated fish and the controls for secobarbital sodium at pH 7.4 and 8.4. However, there was no difference between the treated fish and the controls for the secobarbital sodium solution buffered at pH 6.4.

Since secobarbital is a weak acid with a pKa of 7.9, it exists ~3, ~24, and ~76% ionized at pH 6.4, 7.4, and 8.4, respectively. Thus, the chelating agent apparently affected the transport of the ionized barbiturate form. However, the increase in the transport rate of the ionized form apparently was not enough to compensate for the decrease in the unionized concentration as the pH of the secobarbital sodium solutions increased. This result was evident from the apparent increase in time necessary to produce death as the pH of the secobarbital sodium solutions increased.

With a model proposed by Levy and Gucinski (9) (see *Appendix*) for the absorption of both the unionized and ionized drug forms in goldfish, a plot of the reciprocal of the response time ($1/t$) as a function of the fraction of drug unionized should be linear with a slope equal to $K_b(K_u - K_i)$ and an intercept equal to K_bK_i:

$$1/t = K_bK_i + K_b(K_u - K_i)f \qquad \text{(Eq. 1)}$$

where K_b is a constant equal to the quotient of the secobarbital concentration to which the fish were exposed divided by the amount of barbiturate in the fish at death and K_i and K_u are the first-order rate constants for the ionized and unionized forms of the drug. Figure 1 is the least-squares regression of the reciprocal of the response time *versus* the fraction of drug unionized for the 24-hr treatment, 24-hr recovery and the 24-hr treatment, 30-min recovery studies. The regression lines are $1/t = 0.0050 + 0.0500f$ ($r = 0.9999$) and $1/t = 0.0029 + 0.0644f$ ($r = 0.9960$), respectively.

Dividing the slope by the intercept yields:

$$\frac{\text{slope}}{\text{intercept}} = \frac{K_b(K_u - K_i)}{K_bK_i} = \frac{K_u}{K_i} - 1 \qquad \text{(Eq. 2)}$$

For the 24-hr treatment, 24-hr recovery study, Eq. 2 yields:

$$11 = K_u/K_i \qquad \text{(Eq. 3)}$$

For the 24-hr treatment, 30-min recovery, it yields:

$$23.3 = K_u/K_i \qquad \text{(Eq. 4)}$$

A rather dramatic change in the magnitude of the unionized to ionized ratio is observed between the two studies. With the assumption that the amount of drug in the fish is the same at the end-point:

$$\frac{\text{intercept 1}}{\text{intercept 2}} = \frac{\frac{C}{\text{amount}}K_i}{\frac{C}{\text{amount}}K_i} = \frac{K_{i1}}{K_{i2}} = 1.7 \qquad \text{(Eq. 5)}$$

Thus, there appears to be an ~70% increase in the rate constant for the ionized drug in the 24-hr treatment, 24-hr recovery study as compared to the 24-hr treatment, 30-min recovery study. Substituting the apparent increase in the rate constant for the absorption of the ionized form into Eq. 2 for the 24-hr treatment, 24-hr recovery study yields $11 = K_u/1.7K_i$ or $18.7 = K_u/K_i$. Although the apparent increase of the ionized rate constant obtained from the intercept values does not explain completely the observed ratio for the 24-hr treatment, 30-min recovery study ($K_u/K_i = 23.3$), it does account for ~80% of the value.

Unfortunately, the controls for both recovery time studies do not appear to fit the model. Although the exact reason for this result is unknown,

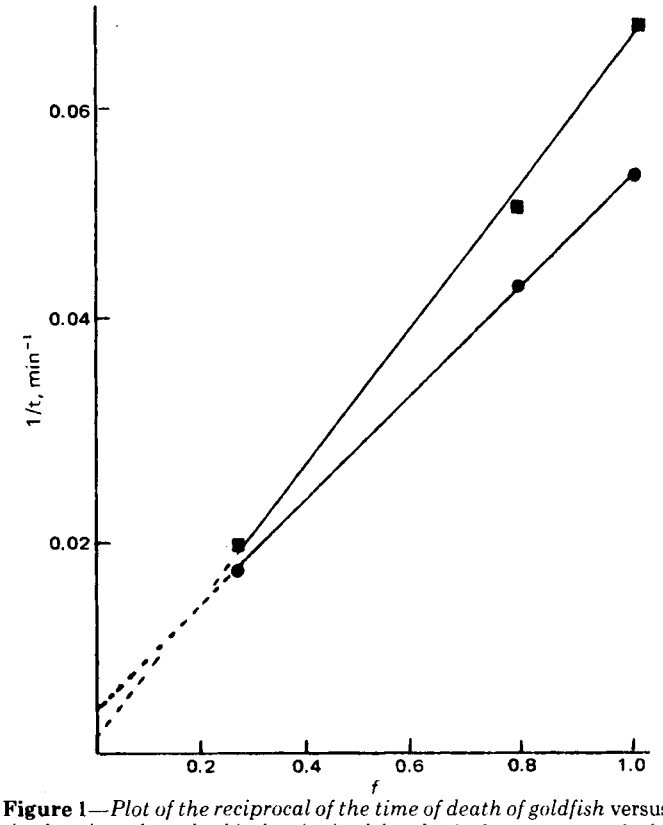

Figure 1—*Plot of the reciprocal of the time of death of goldfish* versus *the fraction of secobarbital unionized for the 24-hr treatment, 24-hr recovery study (●) and the 24-hr treatment, 30-min recovery study (■).*

in the experiment by Levy and Gucinski (9) the fish exposed to secobarbital apparently did fit the model, which led these investigators to conclude that secobarbital was absorbed in both the unionized and ionized forms. For the most part, that experiment was similar to the controls in this experiment.

In summary, there appears to be a period of time after exposure of fish to the chelating agent in which the enhanced permeability of the membrane to the barbiturate is absent. However, once the effect is obtained, it is present 24 hr after exposure. The chelating agent appears to affect the transport of the ionized drug species, but the increase in the transport of the ionized form is not enough to compensate for the reduction of the unionized concentration in the pH study. There also appears to be a direct relationship between the change in permeability and the concentration of chelating agent to which the fish are exposed. Further studies are underway concerning the effects of edetate disodium on the goldfish membrane.

APPENDIX

The model proposed by Levy and Gucinski (9) concerning the absorption of both the unionized and ionized drug forms in the goldfish is:

$$R = K_i C_i + K_u C_u \qquad \text{(Eq. A1)}$$

where R is the absorption rate, K_i and K_u are the first-order rate constants, and C_i and C_u are the concentrations of the ionized and unionized species, respectively. The amount of drug in the fish is equal to the product of the absorption rate and the time the fish is exposed to the bathing solution:

$$\text{amount} = Rt \qquad \text{(Eq. A2)}$$

Substituting Eq. A1 for R in Eq. A2 yields:

$$\text{amount} = (K_i C_i + K_u C_u)t \qquad \text{(Eq. A3)}$$

which is equivalent to:

$$1/t = \frac{K_i C_i + K_u C_u}{\text{amount}} \qquad \text{(Eq. A4)}$$

Since the sum of C_i and C_u represents the total drug concentration, which was constant for these experiments, then:

$$1/t = \frac{C}{\text{amount}}[K_i(1 - f) + K_u f] \qquad \text{(Eq. A5)}$$

where C represents the total concentration of drug and f and $1 - f$ represent the fraction of the drug present in the unionized and ionized forms, respectively. Therefore:

$$1/t = \frac{C}{\text{amount}}(K_i - K_i f + K_u f) \qquad \text{(Eq. A6)}$$

and:

$$1/t = \frac{CK_i}{\text{amount}} + \frac{C(K_u - K_i)f}{\text{amount}} \qquad \text{(Eq. A7)}$$

If it is assumed that the amount of drug necessary to produce death is constant regardless of the pH employed:

$$1/t = K_b K_i + K_b(K_u - K_i)f \qquad \text{(Eq. A8)}$$

where K_b is a constant and equals C/amount. Therefore, a plot of the reciprocal of the response time ($1/t$) as a function of the fraction of drug unionized should be linear with a slope equal to $K_b(K_u - K_i)$ and an intercept equal to $K_b K_i$.

Stability of Apomorphine in Solutions Containing Ascorbic Acid and Bisulfite and Effects of Antioxidants on Apomorphine-Induced Cage Climbing and Hypothermia in Mice

RICHARD E. WILCOX *, DAVID W. HUMPHREY ‡, WILLIAM H. RIFFEE *, and ROBERT V. SMITH ‡x

Received December 10, 1979, from the **Department of Pharmacology and* ‡*Drug Dynamics Institute, College of Pharmacy, University of Texas at Austin, Austin, TX 78712.* Accepted for publication February 29, 1980.

Abstract □ Ascorbic acid (100 mg/ml) and sodium bisulfite (0.5 and 20 mg/ml) prevented more than 10% oxidation of apomorphine hydrochloride in water maintained at room temperature over 1–3 days. Refrigeration at 5° prevented oxidation of apomorphine hydrochloride in aqueous solutions for 1 week. Neither ascorbic acid nor sodium bisulfite affected murine stereotyped cage climbing or hypothermia induced by apomorphine.

Keyphrases □ Apomorphine—stability in solutions containing ascorbic acid and sodium bisulfite, effects of antioxidants on apomorphine-induced cage climbing and hypothermia in mice □ Antioxidants—ascorbic acid and sodium bisulfite, stability of apomorphine in solutions containing antioxidants, effects of antioxidants on apomorphine-induced cage climbing and hypothermia in mice □ Stability—apomorphine in solutions containing ascorbic acid and sodium bisulfite

Current interest in apomorphine (I) stems from its activity as a dopaminergic agonist and its consequent antiparkinsonian activity (1–3). Its clinical unity has been demonstrated when used alone and in combination with other agents such as levodopa (4). In addition to parkinsonism, recent studies indicated potential new uses for I

in the experiment by Levy and Gucinski (9) the fish exposed to secobarbital apparently did fit the model, which led these investigators to conclude that secobarbital was absorbed in both the unionized and ionized forms. For the most part, that experiment was similar to the controls in this experiment.

In summary, there appears to be a period of time after exposure of fish to the chelating agent in which the enhanced permeability of the membrane to the barbiturate is absent. However, once the effect is obtained, it is present 24 hr after exposure. The chelating agent appears to affect the transport of the ionized drug species, but the increase in the transport of the ionized form is not enough to compensate for the reduction of the unionized concentration in the pH study. There also appears to be a direct relationship between the change in permeability and the concentration of chelating agent to which the fish are exposed. Further studies are underway concerning the effects of edetate disodium on the goldfish membrane.

APPENDIX

The model proposed by Levy and Gucinski (9) concerning the absorption of both the unionized and ionized drug forms in the goldfish is:

$$R = K_i C_i + K_u C_u \qquad \text{(Eq. A1)}$$

where R is the absorption rate, K_i and K_u are the first-order rate constants, and C_i and C_u are the concentrations of the ionized and unionized species, respectively. The amount of drug in the fish is equal to the product of the absorption rate and the time the fish is exposed to the bathing solution:

$$\text{amount} = Rt \qquad \text{(Eq. A2)}$$

Substituting Eq. A1 for R in Eq. A2 yields:

$$\text{amount} = (K_i C_i + K_u C_u)t \qquad \text{(Eq. A3)}$$

which is equivalent to:

$$1/t = \frac{K_i C_i + K_u C_u}{\text{amount}} \qquad \text{(Eq. A4)}$$

Since the sum of C_i and C_u represents the total drug concentration, which was constant for these experiments, then:

$$1/t = \frac{C}{\text{amount}}[K_i(1 - f) + K_u f] \qquad \text{(Eq. A5)}$$

where C represents the total concentration of drug and f and $1 - f$ represent the fraction of the drug present in the unionized and ionized forms, respectively. Therefore:

$$1/t = \frac{C}{\text{amount}}(K_i - K_i f + K_u f) \qquad \text{(Eq. A6)}$$

and:

$$1/t = \frac{CK_i}{\text{amount}} + \frac{C(K_u - K_i)f}{\text{amount}} \qquad \text{(Eq. A7)}$$

If it is assumed that the amount of drug necessary to produce death is constant regardless of the pH employed:

$$1/t = K_b K_i + K_b(K_u - K_i)f \qquad \text{(Eq. A8)}$$

where K_b is a constant and equals C/amount. Therefore, a plot of the reciprocal of the response time ($1/t$) as a function of the fraction of drug unionized should be linear with a slope equal to $K_b(K_u - K_i)$ and an intercept equal to $K_b K_i$.

II

in treating Huntington's chorea (5), tardive dyskinesia (6, 7), Gilles de la Tourette's syndrome (8), and schizophrenia (9, 10).

BACKGROUND

Recent efforts have focused on extending the pharmacokinetic studies of I in mice. The disposition of I following parenteral administration to mice was reported (11–14). Study of the plasma levels of I in mice following intraperitoneal, intravenous, and oral administrations (15) and preliminary investigations (15, 16) suggested a correlation between circulating levels of I and stereotyped cage climbing (16). Continued work is aimed at extensive comparisons between circulating levels of I and the stereotyped cage climbing and hypothermia induced by I in mice. These studies are being conducted to develop pharmacological models that might be useful in evaluating the efficacy of apomorphine prodrugs, some of which already have been synthesized (17) and evaluated pharmacologically in rats (18).

A problem complicating work with apomorphine is its tendency to undergo air oxidation. Aqueous solutions of I·HCl rapidly become green to blue green due to the accumulation of oxidation products (19). The oxidation process in neutral and acidic media is relatively uncomplicated, leading principally to the orthoquinone, II (20, 21). However, at alkaline pH values, the degradation is considerably more complex and yields four or more products (22, 23).

Burkman (24, 25) studied the oxidation kinetics of I from pH 5.2 to 6.8. The half-lives of I in buffered solutions were 11–166 hr with the more acidic solutions being more stable. An unbuffered 1.2% solution of I·HCl (pH 5.5) was considerably more stable than its buffered counterpart. Various investigators recommended the use of citrate (26), bisulfite (27), ascorbic acid (28), thiourea (29), and edetic acid (26) to stabilize aqueous solutions of apomorphine.

The purpose of this investigation was to reevaluate the use of bisulfite and ascorbate in stabilizing I solutions maintained at room temperature and under refrigerated conditions. The use of a specific high-performance liquid chromatographic (HPLC) assay, developed recently in these laboratories (30), was expected to facilitate this work. Furthermore, studies of the effect of ascorbate and bisulfite on apomorphine-induced stereotyped cage climbing and hypothermia in mice were conducted to determine if the antioxidants interfered in these test systems.

EXPERIMENTAL

Reagents—(*R*)-(−)-Apomorphine hydrochloride hemihydrate[1] [98% pure as determined by UV spectrophotometry (31)], ascorbic acid[2], and sodium bisulfite[2] were used as purchased. Apomorphine orthoquinone (6-methyl-5,6-dihydro-4*H*-dibenzo[*de,g*]quinone-10,11-dione) (II) was prepared according to a literature method (20). The methanol and acetonitrile used in the HPLC studies were distilled in glass[3]. All other solvents and reagents were analytical reagent grade. Water was double distilled in glass.

HPLC Analyses—The apomorphine content of solutions was analyzed using a previously described HPLC method (30). For this application, a UV detector[4] was used at 273 nm with a setting of 1.28 aufs. Under the analytical conditions, authentic II, ascorbic acid, and sodium bisulfite showed no interference in the region of the developed apomorphine peak.

Stability Studies—Samples of I·HCl were prepared at a concentration of 0.2 mg/ml in water, in a 1-mg/ml aqueous ascorbic acid solution, in a 100-mg/ml aqueous ascorbic acid solution, in a 0.52-mg/ml aqueous sodium bisulfite solution, and in a 20-mg/ml aqueous sodium bisulfite solution. Blank and sample solutions were prepared in clear 10-ml glass-stoppered containers and maintained at room temperature (22–25°) under typical laboratory conditions of light exposure. Samples were analyzed in triplicate at time zero and 1, 3, 7, and 8 days following preparation by direct injection of 100-μl portions into the HPLC column. Quantitation was performed by comparison of peak heights to a calibration curve obtained (r = 0.999) from chromatographic development of five freshly prepared solutions of apomorphine (in 1-mg/ml ascorbic acid solution) containing 0.02–0.2 mg of I·HCl/ml.

Refrigerator Stability—This experiment was performed as was the previous study, except that three apomorphine solutions (in water alone, in a 100-mg/ml ascorbic acid solution, and in a 20-mg/ml sodium bisulfite solution) were kept in a laboratory refrigerator (5°) until sampling.

Pharmacological Studies—Experimentally naive CD-1 male mice[5] weighed 20–36 g at the time of testing. Access to food and water was provided *ad libitum*, and the animals were maintained in a 12-hr light–dark cycle (lights on from 6 am to 6 pm); all testing was done between 8 am and 5 pm.

The cage climbing and hypothermia experiments were designed similarly. Each experiment consisted of one between-subject factor, the solution (4.7 mg of I·HCl·1/2H_2O/kg in water, in 100-mg/ml ascorbate, or in 0.52-mg/ml sodium bisulfite), and one within-subject factor, the response (cage climb scores or body temperature changes after one of the three solutions of I).

Cage Climbing Behavior—A modification of the procedure of Protais *et al.* (32) was used. Animals were placed individually into cylindrical cages (12 cm diameter × 14 cm high with walls of vertical bars 2 mm in

[5] Charles River Laboratories, Wilmington, Mass.

diameter and 1 cm apart) surmounted by fine wire mesh for a 20-min habituation period. Animals then received a pretreatment consisting of isotonic saline (0.1 ml/10 g of body weight ip). One hour later, the behavior of the animals was recorded on videotape as described previously (33) to establish a baseline of activity for each subject. The mice then were injected immediately with I·HCl hemihydrate (4.7 mg/kg) in water, ascorbate, or bisulfite. The behavior of each animal was recorded on videotape for 30 sec every 5 min for 1 hr and later rated "blind" using a rating scale with 0 = four paws on cage floor, 1 = two paws holding the vertical bars of the cage, and 2 = four paws holding the vertical bars of the cage.

Hypothermia—Rectal temperatures were taken immediately prior to administration of I·HCl by insertion of a rectal probe (1.5 cm) connected to a telethermometer[6]. The mice were injected with one of the three I·HCl solutions, and temperatures were taken 60 min later.

RESULTS AND DISCUSSION

As shown in Table I, both antioxidants tested were effective in delaying apomorphine decomposition. The higher levels of each antioxidant were most effective, although neither antioxidant could delay significant degradation for more than 1–3 days when solutions were stored at room temperature. Refrigeration of apomorphine samples at 5° was effective in preventing decomposition for 0–7 days, and the addition of antioxidants was unnecessary under these conditions (Table II).

Table III shows the lack of influence of the antioxidants, ascorbic acid and sodium bisulfite, on apomorphine-induced hypothermia and stereotyping of cage climbing. Neither ascorbate nor sodium bisulfite displayed any significant effects on these *in vivo* responses to I.

In summary, ascorbic acid (100 mg/ml) and sodium bisulfite (0.52 and 20 mg/ml) prevented more than 10% oxidation of apomorphine hydrochloride in water maintained at room temperature for 1–3 days. Refrigeration at 5° prevented oxidation of I·HCl in aqueous solutions for over 1 week. Neither ascorbic acid nor sodium bisulfite affected murine stereotyped cage climbing or hypothermia induced by apomorphine.

Serum Protein Binding of Prednisolone in Four Species

MARIO L. ROCCI, Jr., NOREEN F. JOHNSON, and WILLIAM J. JUSKO ˣ

Received August 10, 1979, from the *Clinical Pharmacokinetics Laboratory, Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo and the Millard Fillmore Hospital, Buffalo, NY 14209.* Accepted for publication March 6, 1980.

Abstract □ The protein binding of prednisolone in serum from humans, rabbits, dogs, and rats was determined by equilibrium dialysis. Two nonlinear least-squares regression programs were used to characterize transcortin and albumin binding of the steroid. The animal species differed markedly in their ability to bind prednisolone, but the rabbit was most similar to humans in transcortin concentration and affinity constant.

Keyphrases □ Prednisolone—serum protein binding in humans, rabbits, dogs, and rats □ Serum protein binding—prednisolone in humans, rabbits, dogs, and rats □ Binding, serum protein—prednisolone in humans, rabbits, dogs, and rats

The serum protein binding of prednisolone is nonlinear in humans due to saturation of the high affinity binding sites on the α_1-glycoprotein, transcortin (1). As serum concentrations of the steroid increase, the limited capacity of transcortin for binding is exceeded and the fraction of free drug in serum increases. This nonlinear serum protein binding is partially responsible for the dose-dependent disposition of prednisolone observed in humans (2). To examine its pharmacokinetics further, an animal model was sought that would exhibit protein binding characteristics for prednisolone similar to those observed in humans.

EXPERIMENTAL

The serum protein binding of prednisolone was examined in Sprague–Dawley rats, New Zealand White rabbits, a mongrel dog, and a normal man. Serum was spiked with prednisolone in concentrations ranging from 0.024 to 25 μM. The tritiated prednisolone was purified by high-pressure liquid chromatography (HPLC). A 10-μl aliquot (10,000 dpm) of [^{3}H]prednisolone (specific activity of 53 Ci/mmole) was added to 0.8 ml of the serum samples. The samples then were dialyzed against an equal volume of isotonic phosphate buffer (pH 7.4) using plexiglass cells maintained in a water bath at 37°. After dialysis, the counts per minute of the buffer and serum samples were converted to disintegrations per minute using the sample channel ratio technique. The percent of prednisolone bound and the molar concentrations of free (D_F) and bound (D_b) drug then were calculated for each serum sample.

The relationship that governs the protein binding of prednisolone is:

$$D_b = \frac{N_T K_T P_T D_F}{1 + K_T D_F} + \frac{N_A K_A P_A D_F}{1 + K_A D_F} \qquad \text{(Eq. 1)}$$

where N_T and N_A are the number of binding sites on the transcortin and albumin molecules, K_T and K_A are the affinity constants for transcortin and albumin, and P_T and P_A are the molar serum concentrations of transcortin and albumin (3). Albumin binding apparently was nonspecific; *i.e.*, the product of K_A and D_F for the albumin–prednisolone interaction was negligible when compared to unity, permitting simplification of Eq. 1 to yield:

$$D_b = \frac{N_T K_T P_T D_F}{1 + K_T D_F} + N_A K_A P_A D_F \qquad \text{(Eq. 2)}$$

The nonlinear least-squares regression computer program, NONLIN (4), was employed to fit the binding data to Eq. 2. The D_b and D_F variables for each serum sample served as the dependent and independent variables. Least-squares estimates of K_T, $N_T K_T P_T$, and $N_A K_A P_A$ then were computed. The N_T and N_A values were assumed to be equal to one. Albumin concentration (P_A) was measured chemically[1] in all serum samples, making solution of Eq. 2 for all binding parameters possible. The three computer-generated binding parameters (P_T, K_T, and K_A) are apparent values since endogenous corticosteroids present in the serum are likely to compete with prednisolone for protein binding sites.

Least-squares estimates of K_T, $N_T K_T P_T$, and $N_A K_A P_A$ also were obtained by the statistical method of Priore and Rosenthal (5). This method employs the total drug concentration and the fraction bound as the independent and dependent variables. The use of these variables minimizes the effects of experimental error on the magnitude of the generated binding parameters through the use of the most error-free independent variable (total drug concentration). An even distribution of the experimentally determined values around the fitted fraction bound *versus* the total drug concentration binding curve is produced.

[1] Technicon autoanalyzer.

RESULTS AND DISCUSSION

Figure 1 illustrates the protein binding profile for each species as a function of the postdialysis serum prednisolone concentration. All profiles exhibited nonlinearity consistent with saturation in transcortin binding and linear binding to albumin. Dog and rat serum demonstrated the least concentration dependence in the protein binding of prednisolone. The therapeutic range of the serum prednisolone concentration extended up to ~7 μM.

The binding parameters obtained using the modified NONLIN computer program (Method I) and using the MACMOL program of Priore and Rosenthal (Method II) are presented in Table I. The two methods yielded binding parameters in the same general range. There was excellent agreement for all binding parameters in the rabbit and in the K_A values obtained for each species. Differences between the methods existed in the P_T and K_T values obtained in the dog, rats, and human. At low serum prednisolone concentrations, where the protein binding of the steroid exhibits concentration dependence, small errors in the determination of either the fraction bound or the total drug concentration can introduce rather large errors in the calculated values of D_f (total drug concentration × free fraction). Such errors will affect most profoundly the binding parameters obtained using Method I, where D_f is the independent variable. Since this problem is avoided using Method II, it probably generates the closer estimates of the true binding parameters for transcortin.

At high prednisolone concentrations, where albumin is the major binding protein, the values of the prednisolone free fraction are larger and do not vary appreciably in any one species. As a result, the errors incurred in quantitation of the binding systems at high serum concen-

Human	6.19	3.26	0.499	1.63	6.43	1.21	1.400

[a] Method I is from Ref. 4, and Method II is from Ref. 5. [b] Determined by an automatic analyzer.

trations are of less significance, accounting for the good agreement in the K_A values between the two methods.

The binding profile of the rabbit appears most like humans in the degree of nonlinearity in prednisolone binding (Fig. 1). The binding constants in Table I (Method II) confirm this observation. The P_T and K_T values in the rabbit are closest to those values determined in humans, producing similar decreases in binding as the serum prednisolone concentration increases. The binding parameters confirm the presence of high affinity, low capacity transcortin binding and low affinity, high capacity albumin binding in each species.

The transcortin concentrations and affinity constants for all of the species examined are in the general range of values reported by other investigators for cortisol. Westphal (6) obtained P_T and K_T values in the rabbit of 3.6×10^{-7} M and 4×10^7 M^{-1}, which agree well with the present estimates. In contrast, the P_T and K_T values determined by Westphal in the rat were 6.9×10^{-7} M and 1×10^7 M^{-1}. These discrepancies may reflect inherent differences in the interactions of prednisolone and hydrocortisone with transcortin. The use of different strains of the same animal species and physiological factors such as age, sex, and endogenous corticosteroid level might affect the transcortin–steroid interaction and contribute to variability in the binding parameters (7).

In summary, the animal species studied differed markedly in their ability to bind prednisolone. The rabbit was the most similar to humans in transcortin concentration and affinity constant for prednisolone and in the range of free drug fractions at increasing steroid concentrations.

Effect of Sodium Bicarbonate on *In Vitro* Conversion of Fibrinogen to Fibrin

DENNIS W. WONG

Received November 8, 1979, from the *Division of Nuclear Medicine, Department of Radiology, Martin Luther King Jr. General Hospital and Charles R. Drew Postgraduate Medical School, Los Angeles, CA 90059.* Accepted for publication March 12, 1980.

Abstract □ The effect of sodium bicarbonate on the conversion of fibrinogen to fibrin clot was investigated using fresh human whole blood and pure human fibrinogen. *In vitro* experimental data demonstrated that sodium bicarbonate interfered with fibrin clot formation during clotting. This study assessed the possibility of synergistic action of sodium bicarbonate with sodium citrate. As expected, sodium citrate potentiated the anticoagulant action of sodium bicarbonate.

Keyphrases □ Sodium bicarbonate—effect on conversion of fibrinogen to fibrin, synergistic action with sodium citrate □ Sodium citrate—effect on fibrin clot formation, synergistic action with sodium bicarbonate □ Fibrin—effect of sodium bicarbonate and sodium citrate on *in vitro* conversion of fibrinogen

In vitro experimental results and clinical patient data demonstrate that sodium and potassium bicarbonate can interfere with the clotting process, as evidenced by prolongation in prothrombin time and thrombin clotting time (1). The anticoagulant effect appears to be caused primarily by the specific anion species and an increase in ionic strength and to a lesser extent by the effect of pH. Thrombin clotting time analyses on citrated whole blood samples containing sodium bicarbonate indicate that the unavailability of calcium ions is not the direct cause of clot inhibition.

Since previous work contained no information dealing directly with the effect of bicarbonate on clotting (2–9), the present study was undertaken to determine the effect of sodium bicarbonate on the conversion of pure human fibrinogen to fibrin clot. The possibility of synergistic action of sodium bicarbonate with sodium citrate on clot inhibition also was investigated.

EXPERIMENTAL

Lyophilized human fibrinogen[1] was reconstituted with water for injection USP to a concentration of 20 mg/ml at pH 6. Prior to the addition of fibrinogen, a predetermined amount of sodium bicarbonate solution[2] (pH 7.8, 7.5%), ranging from 1 to 25 mg in a volume of <0.1 ml, was added to each test tube containing 3.0 ml of 7 mM pH 7.4 Sorensen's phosphate buffer (ionic strength 0.017) and 0.4 ml of a 3.8% sodium citrate solution (pH 9.85, 0.13 M, ionic strength 0.078). The resulting mixture contained one part of citrate solution to nine parts of test sample. The amount of citrate solution used was equivalent to the quantity of anticoagulant present in the blood-collecting test tube. When the required amount of sodium bicarbonate solution to be added to the test samples exceeded 0.1 ml, a weighed amount of reagent grade powder[3] was dissolved in the

The P_T and K_T values in the rabbit are closest to those values determined in humans, producing similar decreases in binding as the serum prednisolone concentration increases. The binding parameters confirm the presence of high affinity, low capacity transcortin binding and low affinity, high capacity albumin binding in each species.

The transcortin concentrations and affinity constants for all of the species examined are in the general range of values reported by other investigators for cortisol. Westphal (6) obtained P_T and K_T values in the rabbit of 3.6×10^{-7} M and 4×10^7 M^{-1}, which agree well with the present estimates. In contrast, the P_T and K_T values determined by Westphal in the rat were 6.9×10^{-7} M and 1×10^7 M^{-1}. These discrepancies may reflect inherent differences in the interactions of prednisolone and hydrocortisone with transcortin. The use of different strains of the same animal species and physiological factors such as age, sex, and endogenous corticosteroid level might affect the transcortin–steroid interaction and contribute to variability in the binding parameters (7).

In summary, the animal species studied differed markedly in their ability to bind prednisolone. The rabbit was the most similar to humans in transcortin concentration and affinity constant for prednisolone and in the range of free drug fractions at increasing steroid concentrations.

Effect of Sodium Bicarbonate on *In Vitro* Conversion of Fibrinogen to Fibrin

DENNIS W. WONG

Received November 8, 1979, from the *Division of Nuclear Medicine, Department of Radiology, Martin Luther King Jr. General Hospital and Charles R. Drew Postgraduate Medical School, Los Angeles, CA 90059.* Accepted for publication March 12, 1980.

Abstract □ The effect of sodium bicarbonate on the conversion of fibrinogen to fibrin clot was investigated using fresh human whole blood and pure human fibrinogen. *In vitro* experimental data demonstrated that sodium bicarbonate interfered with fibrin clot formation during clotting. This study assessed the possibility of synergistic action of sodium bicarbonate with sodium citrate. As expected, sodium citrate potentiated the anticoagulant action of sodium bicarbonate.

Keyphrases □ Sodium bicarbonate—effect on conversion of fibrinogen to fibrin, synergistic action with sodium citrate □ Sodium citrate—effect on fibrin clot formation, synergistic action with sodium bicarbonate □ Fibrin—effect of sodium bicarbonate and sodium citrate on *in vitro* conversion of fibrinogen

In vitro experimental results and clinical patient data demonstrate that sodium and potassium bicarbonate can interfere with the clotting process, as evidenced by prolongation in prothrombin time and thrombin clotting time (1). The anticoagulant effect appears to be caused primarily by the specific anion species and an increase in ionic strength and to a lesser extent by the effect of pH. Thrombin clotting time analyses on citrated whole blood samples containing sodium bicarbonate indicate that the unavailability of calcium ions is not the direct cause of clot inhibition.

Since previous work contained no information dealing directly with the effect of bicarbonate on clotting (2–9), the present study was undertaken to determine the effect of sodium bicarbonate on the conversion of pure human fibrinogen to fibrin clot. The possibility of synergistic action of sodium bicarbonate with sodium citrate on clot inhibition also was investigated.

EXPERIMENTAL

Lyophilized human fibrinogen[1] was reconstituted with water for injection USP to a concentration of 20 mg/ml at pH 6. Prior to the addition of fibrinogen, a predetermined amount of sodium bicarbonate solution[2] (pH 7.8, 7.5%), ranging from 1 to 25 mg in a volume of <0.1 ml, was added to each test tube containing 3.0 ml of 7 mM pH 7.4 Sorensen's phosphate buffer (ionic strength 0.017) and 0.4 ml of a 3.8% sodium citrate solution (pH 9.85, 0.13 M, ionic strength 0.078). The resulting mixture contained one part of citrate solution to nine parts of test sample. The amount of citrate solution used was equivalent to the quantity of anticoagulant present in the blood-collecting test tube. When the required amount of sodium bicarbonate solution to be added to the test samples exceeded 0.1 ml, a weighed amount of reagent grade powder[3] was dissolved in the

[a] The amount of sodium bicarbonate added to the samples ranged from 12.5 to 125 mEq/liter of blood, assuming an average adult blood volume of 65 ml/kg of body weight. The plasma ionic strength, μ, was 0.154. All values represent the average of three determinations from three normal healthy volunteers.

sodium citrate–phosphate buffer mixture. Exactly 0.6 ml of fibrinogen solution (12 mg of fibrinogen) was added to each test tube, yielding a final concentration of 3 mg of fibrinogen/ml of sample. (Normal blood fibrinogen concentration ranged from 150 to 350 mg %.) Similar samples but without sodium citrate were prepared to eliminate any synergistic effect of sodium citrate with sodium bicarbonate.

After thorough mixing, the pH of each sample was determined at 37° by a pH meter[4] with a combination glass and ceramic electrode. Coagulation was induced by the addition of 0.1 ml (10 units/ml, pH 6) of topical thrombin[5] in normal saline to 0.2 ml of the test sample previously incubated at 37° for 2–5 min. The thrombin clotting time (expressed in seconds) was recorded mechanically with an automatic clot timer[6]. Control samples were assessed without sodium bicarbonate. The ionic strength of the phosphate-buffered fibrinogen solution in the absence of sodium bicarbonate and sodium citrate was 0.017. With the addition of sodium citrate, the total ionic strength was 0.095.

To determine the effect of sodium bicarbonate on clotting, *in vitro* studies were performed using fresh blood samples collected from healthy volunteers by venipuncture. Prior to addition of the whole blood, a predetermined amount of sodium bicarbonate solution or powder was added to specimen test tubes used for blood collection, each containing 0.3 ml of 3.8%, 0.13 *M* sodium citrate. Exactly 2.7 ml of the fresh whole blood was added immediately to the sample test tube and mixed well. The quantity of sodium bicarbonate added to the blood samples was equivalent to administration of 1–10 mEq/kg to a 70-kg adult, assuming uniform distribution only in the blood.

The blood sample pH was determined prior to plasma separation. Plasma was separated from the whole elements by centrifugation at 2000 rpm (540×*g*) for 30 min. One-stage prothrombin time, by the addition of thromboplastin and calcium ions to 0.2 ml of plasma, was determined according to standard laboratory methods. The same plasma sample was diluted to 1:10 with Owren's pH 7.4 barbital[7] (barbital sodium–sodium chloride) buffer. Thrombin clotting time was determined by adding 0.1 ml (1 unit) of topical thrombin to 0.1 ml of a plasma sample previously incubated at 37°. Both the prothrombin time and the thrombin clotting time were recorded with an automatic clot timer. The plasma ionic strength was assumed to equal that of normal saline (0.9% NaCl), which is 0.154. Control samples were tested without the addition of sodium bicarbonate.

RESULTS

The inhibitory effect of sodium bicarbonate on the conversion of fibrinogen to fibrin clot is illustrated in Fig. 1. At the salt concentration used, the ionic strength of the bicarbonate samples increased from a control value of 0.017 to 0.317 and that of the sodium citrate–sodium bicarbonate samples rose from a control value of 0.095 to 0.395. Thrombin clotting time increased gradually from 6.9 to 8.6 sec as the bicarbonate concentration increased from 0.012 to 0.12 mEq/ml (1–10 mg/ml). The thrombin clotting time of the control sample was 6.4 sec. Increasing the bicarbonate content beyond 0.12 mEq/ml caused a sharp rise in the thrombin clotting time from 10 to 156 sec.

As seen in Fig. 1, sodium citrate potentiated the anticoagulant effect of sodium bicarbonate. While the sodium citrate concentration remained constant at 3.8 mg/ml, the addition of sodium bicarbonate to these samples markedly prolonged the thrombin clotting time.

The pH of the bicarbonate samples gradually rose from 7.2 to 7.8 with the increasing amount of salt added. A similar increase in pH, from 7.2 to 7.7, was observed with sodium citrate–sodium bicarbonate samples. However, results from the pH determination did not demonstrate a linear relationship between the rise in pH and the sharp increase in the thrombin clotting time.

Table I summarizes the *in vitro* prothrombin time and thrombin

clotting time data on fresh blood samples containing various amounts of sodium bicarbonate. The amount of sodium bicarbonate added to the samples ranged from 12.5 to 125 mEq/liter of blood, assuming an average adult blood volume of 65 ml/kg. At added bicarbonate concentrations of 1–2 mEq/kg, significant changes in clotting were observed. Both the prothrombin time and the thrombin clotting time were elevated (Samples 1 and 2, Table I). Increasing the bicarbonate concentration beyond 2 mEq/kg inhibited clotting markedly.

DISCUSSION

Sodium bicarbonate is used widely as a therapeutic agent for acid–base imbalance (10–12). The usual dose of sodium bicarbonate ranges from 1 to 2 mEq/kg and normally is administered intravenously as a 7.5% hypertonic solution or as a 1.5% isotonic solution. Sodium bicarbonate has been regarded as a safe and effective therapeutic agent and is relatively free of serious side effects. With the exception of overdose-induced seizures or tetany secondary to hypocalcemia and hyperalkalosis, no known adverse reactions have been reported (13, 14).

Results from the present investigation demonstrate that sodium bicarbonate inhibits the conversion of fibrinogen to fibrin. Although the mechanism of clot inhibition is unclear, it is well known that some neutral salts retard coagulation and that others accelerate the conversion of fibrinogen to fibrin (2–9). Both cations and anions may bind to the fibrinogen or fibrin molecules during clot formation, and, depending on the individual chemical species, they can either accelerate or inhibit coagulation. The degree of clot inhibition also is affected greatly by the concentration and ionic strength of the salt.

Although data from pH determinations do not correlate well with observed changes in the prothrombin time and the thrombin clotting time, the effect of increasing pH on clotting cannot be ignored. Previous studies revealed that the structure and properties of fibrin clots are modified greatly by variations in pH and ionic strength during coagulation. However, even at constant pH and ionic strength, certain ions and neutral molecules at low concentration greatly affect the structure of the fibrin clot and its formation rate.

Polydimethylsiloxane Pellets for Sustained Delivery of Morphine in Mice

WILLIAM H. RIFFEE ˣ, RICHARD E. WILCOX, JULIE A. ANDERSON, and JAMES W. McGINITY

Received February 11, 1980, from the *Departments of Pharmacology and Pharmaceutics, Drug Dynamics Institute, College of Pharmacy, University of Texas at Austin, Austin, TX 78712.* Accepted for publication March 13, 1980.

Abstract □ A new dosage form was designed whereby a polymeric silicone elastomer pellet provided sustained delivery of morphine to mice over 11 days. These pellets, which can be made easily and inexpensively with a standard tablet mold, gradually released morphine sulfate into the implanted mice. Maximal morphine-induced physical dependence, measured by jumping during naloxone-induced withdrawal, was observed 3–5 days after implantation. At this time, slightly less than 50% of the morphine sulfate had been released. Drug release continued through Day 11 and was accompanied by a physical dependence of decreased magnitude compared to that observed on Day 3 or 5.

Keyphrases □ Morphine—sustained release from polydimethylsiloxane pellets, mice □ Drug delivery systems—sustained release of morphine from polydimethylsiloxane pellets, mice □ Sustained-release systems—delivery of morphine from polydimethylsiloxane pellets, mice

As a representative of the narcotic analgesic drugs, morphine has been used to induce tolerance and physical dependence in experimental animals (1). Its relatively short half-life in small animals requires frequent injections of morphine to sustain drug levels over an extended period.

BACKGROUND

Attempts have been made to deliver morphine to experimental animals without these injection routines but with the production of maximum tolerance and dependence. For example, Collier *et al.* (2) used an oily sustained-release preparation. Hui and Roberts (3) adsorbed morphine sulfate onto molecular sieves. Goode (4) used an implanted silicone rubber tubing reservoir of morphine solution. Teiger (5) used continuous intraperitoneal infusion. The usefulness of several of these methods is marginal as judged by the lack of utilization by fellow researchers. According to this criterion, employment of implanted tableted pellets that slowly release their morphine content appears to be the most accepted method to date.

The most commonly used morphine implant is the microcrystalline cellulose pellet described by Gibson and Tingstad (6). However, this pellet has several disadvantages as a drug delivery system for morphine. One disadvantage is that drug delivery in the animal ceases after 3 days, with only half of the drug being released from the pellet for absorption; the pellet tends to become encapsulated by membranous tissue, thereby diminishing morphine bioavailability (7, 8). Another disadvantage is that the pellet quickly becomes soft and mushy, so complete removal of the implant from the animal is difficult. This result is due to the fact that the pellet contains ~50% microcrystalline cellulose, a tablet disintegrant. Failure to remove all of the implanted pellet gives erroneously high values

Keyphrases □ Morphine—sustained release from polydimethylsiloxane pellets, mice □ Drug delivery systems—sustained release of morphine from polydimethylsiloxane pellets, mice □ Sustained-release systems—delivery of morphine from polydimethylsiloxane pellets, mice

As a representative of the narcotic analgesic drugs, morphine has been used to induce tolerance and physical dependence in experimental animals (1). Its relatively short half-life in small animals requires frequent injections of morphine to sustain drug levels over an extended period.

BACKGROUND

Attempts have been made to deliver morphine to experimental animals without these injection routines but with the production of maximum tolerance and dependence. For example, Collier *et al.* (2) used an oily sustained-release preparation. Hui and Roberts (3) adsorbed morphine sulfate onto molecular sieves. Goode (4) used an implanted silicone rubber tubing reservoir of morphine solution. Teiger (5) used continuous intraperitoneal infusion. The usefulness of several of these methods is marginal as judged by the lack of utilization by fellow researchers. According to this criterion, employment of implanted tableted pellets that slowly release their morphine content appears to be the most accepted method to date.

The most commonly used morphine implant is the microcrystalline cellulose pellet described by Gibson and Tingstad (6). However, this pellet has several disadvantages as a drug delivery system for morphine. One disadvantage is that drug delivery in the animal ceases after 3 days, with only half of the drug being released from the pellet for absorption; the pellet tends to become encapsulated by membranous tissue, thereby diminishing morphine bioavailability (7, 8). Another disadvantage is that the pellet quickly becomes soft and mushy, so complete removal of the implant from the animal is difficult. This result is due to the fact that the pellet contains ~50% microcrystalline cellulose, a tablet disintegrant. Failure to remove all of the implanted pellet gives erroneously high values

0022-3549/80/0800-0980$01.00/0

© 1980, American Pharmaceutical Association

for the percent of morphine absorbed. However, the greatest disadvantage is the need for expensive equipment and pharmaceutical expertise to produce these tableted pellets.

McGinity and Mehta (9) recently reported a method for morphine delivery in rats utilizing a silicone rubber matrix formulated with algin, a water-soluble carrier. This method has been modified for use in mice, and the present study evaluates the ability of this pellet system to render mice physically dependent on morphine.

EXPERIMENTAL

Male experimental CD-1 albino mice[1], 20–35 g, were permitted to acclimate to the animal housing and testing facility (adjacent rooms) for at least 3 days prior to experimentation. Food and water were available *ad libitum*. The animal quarters were maintained on a 12-hr light–dark cycle (lights on at 7 am and off at 7 pm). All testing was done between 8 am and 6 pm.

The drugs and chemicals used were morphine sulfate[2], algin[3], polydimethylsiloxane[4], silicone oil[5], and stannous octate[6].

The pellets were prepared by the addition of silicone oil to the polydimethylsiloxane elastomer in a ratio of 1:1, followed by homogeneous mixing with the powders (morphine sulfate and algin). The method of preparation was described previously (10). When the pellets hardened, edges were trimmed carefully and the pellets were removed from the mold. The cylindrical pellets were 6 mm in diameter and 3 mm in height. Ten percent of the pellets were selected at random and tested for batch uniformity and morphine content. The morphine content in each pellet (both for batch uniformity and for each experimental pellet) was determined spectrophotometrically at 286 nm, and the morphine concentration was calculated using a standard curve.

Light ether anesthesia was used to permit the implantation of two morphine pellets in each mouse (pilot studies indicated two pellets would induce a satisfactory level of physical dependence). The pellets were implanted subcutaneously along the midline of the dorsal neck region posterior to the ears. Placebo pellets (pellets with lactose substituted for morphine) were implanted similarly.

Fifty mice were implanted, and groups of eight were challenged with naloxone at 5 mg/kg on Days 1, 3, 5, 7, 9, and 11 following implantation (each group was used for only one challenge). Each animal was placed in a large, clear glass (4-liter capacity) container and observed for spontaneous jumping off the floor. This behavior was videotaped and subsequently quantified by viewing of the videotapes. Counts for the number of spontaneous jumps were recorded for 5-min intervals up to 30 min after the naloxone challenge. Statistical analysis was done using analysis of variance and *post hoc* tests for differences among means.

RESULTS AND DISCUSSION

Figure 1 shows the concentration of morphine remaining in the pellet over time. Twenty-four hours after implantation, 81% of the morphine remained in the pellet, whereas 56% remained 3 and 5 days after surgery. The concentration of morphine then decreased to 35–40% 7–11 days after implantation.

The spontaneous jumping behavior also is shown in Fig. 1. Approximately 25 spontaneous jumps were shown over a 20-min period following naloxone challenge on Day 1. The peak withdrawal jumping behavior was observed at 3 and 5 days after implantation (207 and 206 jumps, respectively). After Day 5, jumping behavior decreased (Days 7 and 9) to approximately 135 jumps, falling to a level not significantly different from that of placebo-implanted mice on Day 11 (90 jumps).

A morphine-containing silicone rubber implant was reported previously for use in rats (9). This pellet was modified and reformulated for use in mice in the present study. The time course of development of physical dependence agrees well with that obtained by Way *et al.* (11) and Isom *et al.* (12). The former investigators used microcrystalline cellulose pellets, first described by Gibson and Tingstad (6), which contained 75 mg of morphine base; the latter investigators used silicone pellets containing 300 mg of morphine sulfate and mineral oil. The silicone pellet described in the present report contained 32 mg of morphine sulfate and algin, thus providing the implantation of 64 mg of drug/mouse. The major advantage in the use of these sustained-release drug

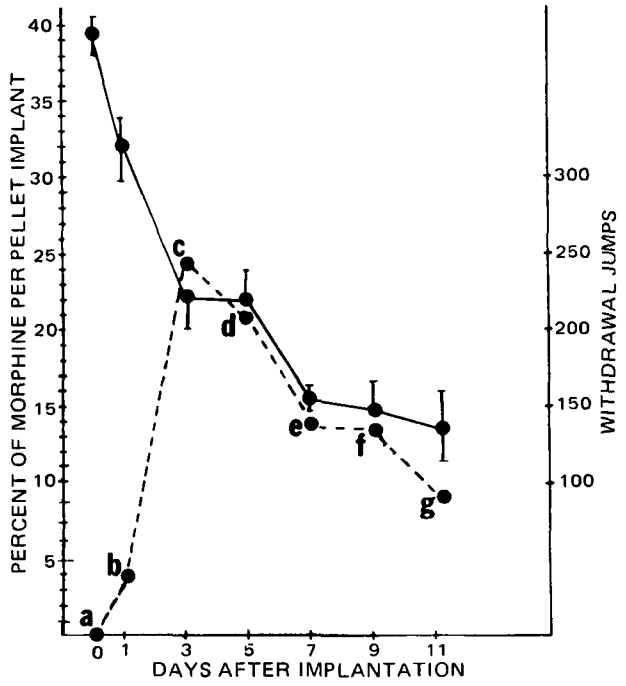

Figure 1—*Percent of morphine remaining in the polydimethylsiloxane pellet (—) (left axis) and the number of jumps observed during withdrawal induced by naloxone (- -) (right axis) plotted against the number of days the pellets were implanted. Symbols a–g represent the mean number of withdrawal jumps per 20 min after naloxone injection. The following symbols were not statistically significantly different from each other ($p < 0.05$): a and b; c and d; d, e, and f; and e, f, and g.*

delivery systems is the rapid induction of physical dependence without time-consuming repetitive injections. However, the microcrystalline cellulose pellets are manufactured *via* tablet presses available to relatively few investigators interested in this area of study.

The silicone pellet containing mineral oil (12) required approximately five times the amount of morphine used in the silicone pellet developed in these laboratories. The former pellet also produced a relatively low level of naloxone-induced jumping (*e.g.*, a peak withdrawal jumping score of 42 over 30 min compared to 247 jumps in 30 min in this study using 4 and 5 mg of naloxone/kg, respectively). The continuous intraperitoneal infusion reported by Teiger (5) allows reliable, controlled, and easily measurable quantities of morphine to be delivered to an experimental animal. However, the extensive surgery, long recovery, and the possible limitation for use in rats or larger animals are distinct disadvantages of this system.

An advantage of the polydimethylsiloxane pellets reported in this study is the use of algin, which causes the pellet to swell in the presence of tissue fluid. As the swelling occurs, the slow release of morphine sulfate within the pellet occurs. The incorporation of algin at the 10% level appears to be optimum for the incorporation and release of morphine sulfate at a concentration of 40% of the pellet weight. The manufacture of these pellets is extremely simple and inexpensive. In addition, only minor surgery and a very brief recovery period are required, thus permitting any investigator the opportunity of developing a sustained-release drug delivery system for morphine with which to study events associated with chronic morphine administration (*e.g.*, tolerance, physical dependence, and morphine-induced alterations of neurotransmitter dynamics).

The quantification of the level of physical dependence on morphine utilizing vertical jumping (as in the present study) *versus* platform jumping was studied by Takemori and Sprague (13). They reported no differences between the two methods. The vertical jumping is a simple method of assessing physical dependence induced by morphine, and the use of videotape greatly enhances the ability to quantitate this behavior accurately.

Determination of Procainamide and *N*-Acetylprocainamide in Biological Fluids by High-Pressure Liquid Chromatography

CHII-MING LAI, BURDE L. KAMATH, ZEE M. LOOK, and AVRAHAM YACOBI ˣ

Received October 10, 1979, from the *Pharmaceutical Development Department, Research and Medical Affairs, Arnar-Stone Laboratories, Inc., McGaw Park, IL 60085.* Accepted for publication March 12, 1980.

Abstract □ A modification of a high-pressure liquid chromatographic method for the simultaneous determination of procainamide and *N*-acetylprocainamide in plasma is described. The deficiencies in the specificity of the existing method were overcome by replacing the cation-exchange column and the mobile phase. The recovery and reproducibility of both procainamide and *N*-acetylprocainamide from human, dog, and rat plasma and urine spiked with either compound were excellent in the concentration range of 0.05–10 μg/ml for plasma and 0.5–20 μg/ml for urine. The comparison of this method with a specific extraction method for sets of plasma samples from human subjects and rats receiving *N*-acetylprocainamide and procainamide, respectively, showed no statistically significant difference.

Keyphrases □ Procainamide—simultaneous high-pressure liquid chromatographic determination with *N*-acetylprocainamide in biological fluids □ *N*-Acetylprocainamide—simultaneous high-pressure liquid chromatographic determination with procainamide in biological fluids □ High-pressure liquid chromatography—analysis, procainamide and *N*-acetylprocainamide in biological fluids □ Antiarrhythmic agents—procainamide, simultaneous high-pressure liquid chromatographic determination with *N*-acetylprocainamide in biological fluids

High-pressure liquid chromatographic (HPLC) procedures for the determination of procainamide and its major metabolite, *N*-acetylprocainamide, in plasma have been described (1–6). One approach requires selective extraction of the drugs from plasma with an organic solvent, followed by reextraction or evaporation of the organic solvent prior to assay (1–4). The other approach involves deproteinization of plasma with acetonitrile and direct injection of the supernate following centrifugation (5). The former procedure usually is tedious. The latter procedure, while simple and rapid, may exhibit specificity and recovery deficiencies under certain conditions.

Nation *et al.* (7) suggested that the extraction method, although tedious and time consuming, may be a prudent approach for the determination of procainamide and *N*-acetylprocainamide. The present investigators experienced similar difficulties in using the deproteinization method. The purpose of this report is to describe a modified deproteinization method which produced consistent results and eliminated the lack of specificity and recovery. This result was achieved by replacing the cation-exchange column and the mobile phase utilized previously (5, 7).

EXPERIMENTAL

Materials—*N*-Acetylprocainamide hydrochloride[1] (an investigational new drug), procainamide hydrochloride USP[2], dioxane[3], toluene[3], acetonitrile[3], TLC plates[4], heparin USP[5], and a carbonated beverage[6] were obtained from commercial sources. Dioxane, toluene, and acetonitrile were glass distilled and purchased commercially. [^{14}C]Procainamide hydrochloride (specific activity 32 μCi/mg) and [^{14}C]-*N*-acetylprocainamide hydrochloride (specific activity 23.1 μCi/mg) were obtained commercially[7]. The internal standard, *p*-amino-*N*-(2-dipropylaminoethyl)benzamide, was synthesized in these laboratories.

Apparatus and Conditions—The high-pressure liquid chromatograph[8] was equipped with a 30-cm long × 4-mm i.d. alkylphenyl column[9] and a UV detector[10] at 280 nm. The column was eluted with a mobile phase that was a 60:40 mixture of acetonitrile and phosphate buffer (0.01 *M* NaH_2PO_4 and 0.005 *M* Na_2HPO_4, pH 6.6). The final pH of the mobile phase was 7.7. The flow rate was 2.0 ml/min. The solutions containing the drugs and the internal standard were injected into the chromatograph *via* an automatic processor[11].

The TLC plates were developed in an ascending fashion in a saturated chamber containing dioxane–toluene–ammonium hydroxide (80:30:1). The radioactivity on the developed TLC plates was detected by a radiochromatographic scanner[12], and the activity was determined on a liquid scintillation counter[13].

Preparation of Standards—The stock solution of the internal standard was prepared in methanol at a concentration of 2 mg/ml. This solution was diluted with acetonitrile to give a working standard solution of 1.5 μg/ml.

The standard solutions in plasma (human, dog, and rat) were prepared by spiking known amounts of procainamide and *N*-acetylprocainamide from a stock solution containing 1 mg/ml of each drug as the

[a] Mean ± *SD*, $n = 4$. [b] Values equal 100 minus percent coefficient of variation. [c] Contaminated aqueous standards.

free base in water. The plasma standards were 0.05, 0.1, 0.25, 0.5, 0.75, 1.0, 2.5, 5.0, 7.5, and 10 μg/ml of each drug as the free base.

The standard solutions in human urine were prepared from a stock solution containing 1 mg/ml each of procainamide and *N*-acetylprocainamide as the hydrochloride salts. The concentrations of the standards were 0.5, 1.0, 2.5, 5.0, 7.5, 10, 15, and 20 μg/ml of procainamide hydrochloride and *N*-acetylprocainamide hydrochloride.

Preparation of Samples—To compare the deproteinization method with the extraction method (7), plasma samples were obtained from a clinical study in which a normal subject was given a 500-mg *N*-acetylprocainamide hydrochloride tablet every 6 hr for 54 hr and from a metabolism study in which rats received procainamide hydrochloride (1280 mg/kg/day) mixed in the diet for 6 months. The human plasma samples were collected at 30, 36, 48, 49, 50, 54.5, 55.0, 56, 58, and 60 hr following the first dose.

Procedure—To a 0.1- or 0.5-ml plasma or urine sample containing 0.05–20 μg each of *N*-acetylprocainamide and procainamide/ml was added an equal or double volume, respectively, of acetonitrile containing 1.5 μg of the internal standard [*p*-amino-*N*-(2-dipropylaminoethyl)-benzamide]/ml. The mixture was vortexed for 10 sec and then centrifuged for 5 min at 4500 rpm. The supernatant solution was decanted, and 50 μl was applied for HPLC analysis.

The solvent extraction method consisted of the following sequences. A mixture of 0.1 ml of plasma, 0.5 ml of water, and 0.1 ml of 1 *M* NaOH was vortexed for 1 min with 3 ml of ethyl acetate. After centrifugation, most of the organic layer was transferred to a test tube and vortexed for 1 min with 0.1 ml of 0.5% phosphoric acid. The tube was centrifuged, and the aqueous phase was separated, evaporated to dryness, and reconstituted in water–acetonitrile (1:2). An aliquot of this solution was injected.

The specificity of the HPLC method was examined using [^{14}C]-*N*-acetylprocainamide and [^{14}C]procainamide and TLC. Briefly, plasma samples containing both drugs were deproteinized with two volumes of acetonitrile, vortexed, and centrifuged. Fifty microliters of the supernate was spotted on TLC plates, and the chromatograms then were developed. The developed plates were examined by a radiochromatographic scanner, and the activity corresponding to *N*-acetylprocainamide and procainamide spots was determined by liquid scintillation. Additionally, 20-sec fractions of the HPLC eluate were collected for radioactivity determination to establish the entire high-pressure liquid chromatogram.

RESULTS AND DISCUSSION

The HPLC retention times of *N*-acetylprocainamide, procainamide, and the internal standard were 3.5, 4.4, and 5.6 min, respectively. Tables I and II summarize the recovery and reproducibility of the assay for human, dog, and rat plasma as well as for human urine for a wide range of procainamide and *N*-acetylprocainamide concentrations. The relationships between the peak height ratios and drug concentrations were linear over the entire range studied for both plasma and urine. The assay recovery of procainamide for human, dog, and rat plasma was 98.8, 99.1, and 95.6%, respectively; the recovery of *N*-acetylprocainamide was 95.6, 93.6, and 91.0%, respectively. The recovery of procainamide and *N*-acetylprocainamide for human urine was 99.9 and 98.9%, respectively. Both plasma and urine recoveries were concentration independent throughout the range studied.

The average reproducibility of the assay for each set of samples (n = 32–40) was ~98%. The use of an internal standard with similar physicochemical characteristics to the drugs contributed to the accuracy and high reproducibility. The TLC–HPLC comparison produced essentially the same results with respect to the specificity and recovery of the assay. Additionally, 48-hr incubation of plasma samples containing *N*-acetylprocainamide and procainamide at room temperature showed 93.5 ± 8.31 and 95.6 ± 3.76% (mean ± *SD*, n = 10) of the spiked values, respectively, indicating no significant degradation of either drug. The resolution of the column as tested by radioactivity measurement was consistent at all times, regardless of aging of the alkylphenyl column, and symmetrical peaks were produced with no indication of interfering compounds. Similarly, the radiochromatographic scanning of TLC plates showed no interfering peaks.

Although the lack of specificity of the assay may result from drug metabolites, it often may be due to the presence of endogenous and/or

exogenous compounds. Plasma samples often are heparinized, and traces of heparin can be a source of interference with the drug peaks, particularly in the deproteinization techniques. This problem was observed with at least two HPLC columns differing in their polarity and under various elution systems. Unless a suitable chromatographic system is selected for a given compound, heparin probably will be a source of error in the assay of drugs. In this method, the retention time of heparin was 2.2 min and that of components of coffee or a carbonated beverage was <2 min. Previous investigators (8, 9) noticed that chemicals contained in vacutainer stoppers may interfere with extraction procedures for lidocaine and procainamide for a GLC measurement.

The application of both methods to human and rat plasma samples produced results with no statistically significant differences (paired *t* test) between the method described in this study and the specific extraction method (7) with respect to *N*-acetylprocainamide in humans and procainamide and *N*-acetylprocainamide in rats (Table III). The concentration ratio of the deproteinization method to the extraction method averaged 95.3–97.9%.

The proposed assay offers the same simplicity of the deproteinization procedure published previously (5, 7). However, the use of the alkylphenyl column with an appropriate mobile phase produces more consistent and reliable results. This procedure was tested with numerous samples obtained from subjects or animals given *N*-acetylprocainamide, procainamide, or both without any difficulties or specificity problems.

II: R = Br

action by using suitable gamma or positron radionuclides. Since the usual techniques for incorporation of fluorine 18 into an aromatic ring result in compounds of low specific activity, the use of radiobromines (bromine 77, 76, and 75) was investigated. Substitution of bromine for hydrogen at one aromatic ring may represent a minimum structural alteration without much of a change in pharmacological activity. As an essential step in this procedure, the nonradioactive brominated analog of spiperone was prepared to determine the effect of this substitution on its biological utility as a neuroleptic compound.

This report describes the synthesis and biological testing of the brominated spiperone (II).

EXPERIMENTAL[1]

Synthesis—To a solution of spiperone (80 mg, 0.2 mmole) in methylene chloride (5 ml) was added dropwise bromine (35 mg, 0.22 mmole) in carbon tetrachloride (5 ml). The solution was stirred at 0° for 30 min. At the end of the reaction, an equal volume of an aqueous solution of 5% NH_4OH and 1% $Na_2S_2O_3$ was added. The organic phase was separated and dried over anhydrous sodium sulfate. Removal of the solvent gave a white powder. Recrystallization from a mixture of methylene chloride and carbon tetrachloride gave pure II (70 mg, 74%), mp 204–205°.

Anal.—Calc. for $C_{23}H_{25}BrFN_3O_2$: C, 58.23; H, 5.31; Br, 16.85. Found: C, 58.01; H, 5.36; Br, 16.52.

The mass spectrum of the compound showed molecular ions at *m/e* 474 (M) and 476 (M + 2) of equal intensity and other fragmentation peaks at 123, 165, 322, 324, 336, and 338; NMR ($CDCl_3$): δ 1.5–2.2 (m, 4H), 2.3–3.2 (m, 10H), 4.66 (s, 2H), 6.68 (d, 2H *ortho* to N, J = 9 Hz), 6.9–7.5 (m, 4H), 7.97 (q, 2H *ortho* to carbonyl group), and 8.89 (s, 1H); IR (KBr): ν_{max} 814, 839, 1230, 1387, 1507, 1606, and 1717 cm^{-1}; TLC [reversed-phase silica gel[2] with methanol–water (80:20)]: R_f 0.18 for II and 0.23 for I.

Receptor Binding Assay—The ability of bromospiperone to displace [^{3}H]spiperone from its specific binding sites in calf caudate and anterior pituitary homogenates was tested by methods described previously (3). The tissues were homogenized in cold 50 m*M* tris(hydroxymethyl)aminomethane hydrochloride buffer (pH 7.7) and centrifuged twice at 50,000×*g* for 10 min, with rehomogenization of the intermediate pellet in the same buffer. The final pellet was resuspended in a cold incubation medium containing 50 m*M* tris(hydroxymethyl)aminomethane hydrochloride, 10 m*M* pargyline hydrochloride, 0.1% ascorbic acid, 120 m*M* NaCl, 5 m*M* KCl, 2 m*M* $CaCl_2$, and 1 m*M* $MgCl_2$ (pH 7.1) at 25°.

The final concentration of [^{3}H]spiperone was 0.25 n*M* for pituitary and 0.13 n*M* for caudate. Each tube contained ~0.4 mg of protein and was incubated at 37° for 10 (pituitary) or 15 (caudate) min. The assay was terminated by rapid filtration through glass fiber filters[3]. The filters were washed with three 3-ml portions of cold 50 m*M* tris(hydroxymethyl)-aminomethane hydrochloride buffer (pH 7.7), and the radioactivity trapped by the filters was counted with an efficiency of 40–45%. Nonspecific binding was obtained by displacement using 1 μ*M* *d*-butaclamol (3). Specific binding was defined as the difference between the total and the nonspecific binding and ranged from 40 to 50% of the total binding.

Plasma Prolactin Levels—Male Sprague–Dawley rats (175–200 g) were housed six per cage in a temperature- (26°) and humidity- (60%) regulated room with a 12-hr light–dark cycle. The animals had free access to rat chow[4] and water at all times. Rats were decapitated 30 min following the intraperitoneal injection of a test compound or saline. Trunk blood was collected. Serum then was separated and stored at −20° until it was assayed for prolactin by the double-antibody radioimmunoassay as described previously (4).

Table I—IC_{50} Values[a] for Binding of [^{3}H]Spiperone to Calf Anterior Pituitary and Caudate

			2–3	NS

[a] Mean serum prolactin level ± *SEM* for a group of five rats. The significance of the difference was assessed using the Student *t* test.

RESULTS AND DISCUSSION

Chemistry—*p*-Bromospiperone (II) was synthesized by direct bromination of spiperone with bromine. Structural identification of II was obtained from various spectral evidence. The mass spectrum of II showed the molecular ions at *m/e* 474 (M) and 476 (M + 2) of approximately equal intensity, characteristic of the presence of a bromine atom. The brominated product was assigned a *para*-position based on the fact that the aniline-type structure favors *ortho*- or *para*-substitution in the electrophilic reaction because of the electron-donating character of nitrogen. In this case, the steric interference would render *ortho*-substitution less favorable. In addition, the NMR spectrum showed a characteristic doublet (δ 6.68) for two protons *ortho* to nitrogen.

The IR spectrum of II did not show much difference from that of I. However, careful examination revealed some information as to the structural identity of the compound. For example, the disappearance of the peak at 755 cm^{-1} is characteristic of monosubstitution due to a C–H bending vibration. This disappearance was accompanied by the appearance of the peak at 814 cm^{-1}, which is indicative of 1,4-disubstitution due to the bromination (5). The peak at 839 cm^{-1}, present in both I and II, probably is due to the CH bending from the other fluorine-substituted aromatic ring.

The similarities in the chemical behavior of spiperone and *p*-bromospiperone can be demonstrated by TLC. TLC on silica gel in several solvent systems (acetone, methanol, methylene chloride, and carbon tetrachloride–methanol) did not separate I and II. However, the separation could be accomplished by reversed-phase TLC[2] with methanol–water (80:20) as the solvent.

Biological Testing—The IC_{50} values determined by the binding assay are shown in Table I. Spiperone and *p*-bromospiperone were essentially equipotent in displacing [^{3}H]spiperone from specific binding sites in both calf caudate and pituitary. This finding indicates that bromination does not interfere with the binding of the spiperone nucleus to dopamine receptors *in vitro*.

Dopamine receptor blockers stimulate prolactin secretion *in vivo* be-

[1] Melting points were determined with an Electrothermal melting-point apparatus and are uncorrected. NMR spectra were obtained with a Varian A-60 spectrometer using tetramethylsilane as the internal standard and deuterochloroform as the solvent. IR spectra were recorded on a Beckman IR 12 spectrophotometer. TLC was performed on silica gel with a fluorescence indicator (Eastman) on plastic sheets or on reversed-phase silica gel with a fluorescence indicator (Whatman KC_{18}); visualization was with either UV light or iodine vapor. The mass spectrum was obtained with a Bendix time-of-flight mass spectrometer. Elemental analyses were performed by Galbraith Laboratory, Knoxville, Tenn. [^{3}H]Spiperone was obtained from New England Nuclear with a specific activity of 25.64 Ci/mmole. Spiperone was a gift of Janssen Pharmaceuticals, Belgium, and Dr. P. Seeman, Toronto, Canada, and *d*-butaclamol was a gift of Ayerst Laboratories.

cause they interfere with tonic dopaminergic inhibition of prolactin release (6). Previous work showed that spiperone, one of the most potent dopamine receptor antagonists, elevates plasma prolactin levels in rats (3). In the present study, prolactin levels were elevated significantly 30 min after the administration of a low dose of this neuroleptic to male rats (Table II). As shown in Table II, the same low dose of *p*-bromospiperone resulted in a comparable rise in serum prolactin levels. These results indicate that the bromination of the spiperone molecule does not significantly affect its ability to act as a dopamine receptor blocker in pituitary receptors *in vivo*, a finding consistent with results from the *in vitro* binding study. This brominated analog thus has potential as a neuroleptic drug. In addition, the radiobrominated compound may prove to be an extremely useful pharmacological tool for dopamine receptor studies in humans using positron emission tomography.

New Compounds: N^1,N^8-Bis(2,3-dihydroxybenzoyl)spermidine and Analogs as Potential Iron-Chelating Drugs

K. K. BHARGAVA, R. W. GRADY ˣ, and A. CERAMI

Received May 3, 1979, from the *Department of Medical Biochemistry, Rockefeller University, New York, NY 10021.* Accepted for publication March 18, 1980.

Abstract □ N^1,N^8-Bis(2,3-dihydroxybenzoyl)spermidine was synthesized and evaluated as an iron-chelating drug. Homologs were prepared and evaluated together with a series of *N,N'*-bis(2,3-dihydroxybenzoyl)-α,ω-diaminoalkanes. Analogous 2-hydroxybenzoyl compounds also were synthesized and evaluated.

Keyphrases □ N^1,N^8-Bis(2,3-dihydroxybenzoyl)spermidine—synthesis and evaluation as iron-chelating drug □ Chelating agents—N^1,N^8-bis(2,3-dihydroxybenzoyl)spermidine and analogs, synthesis and evaluation as iron-sequestering agents

An orally effective, iron-chelating drug is needed to treat patients with Cooley's anemia. Patients suffering from this genetic disease must be transfused every 2–4 weeks. Since the body lacks a physiological means of excreting the iron present in transfused erythrocytes, these patients develop a secondary iron overload, which leads to damage of vital organs and eventually to death. It was suggested that 2,3-dihydroxybenzoic acid might be an orally effective, iron-chelating drug (1). Although subsequent clinical evaluation confirmed this report (2–4), it was not possible to maintain patients in iron balance.

A chelating agent with a greater affinity for iron presumably would be more effective. Several iron-sequestering agents produced by microbes are conjugates of 2,3-dihydroxybenzoic acid (5–9). These compounds all possess affinities for iron that are many orders of magnitude greater than the affinity of the parent compound. One of these compounds, N^1,N^8-bis(2,3-dihydroxybenzoyl)spermidine (8), removes iron from the ferritin of cultured Chang cells and from transferrin, the principal iron-binding protein of serum (10).

The synthesis of N^1,N^8-bis(2,3-dihydroxybenzoyl)-spermidine hydrochloride (XVII) together with a series of simpler analogs is presented in this report. Preliminary evidence suggests that this type of compound may be useful in iron-chelation therapy whereas the corresponding 2-hydroxybenzoyl derivatives are inactive. The *in vitro* and *in vivo* evaluation of these compounds will be presented later.

DISCUSSION

Prior to the synthesis of XVII, a series of simpler analogs, *i.e.*, *N,N'*-bis(2,3-dihydroxybenzoyl)-α,ω-diaminoalkanes, was prepared. Like the spermidine derivative, these compounds would be expected to bind iron strongly, their affinities for iron and perhaps their biological activities being related to the separation of the 2,3-dihydroxybenzoyl moieties. The compounds were obtained readily in a 40–50% yield *via* the reaction of 2,3-dioxosulfinylbenzoyl chloride (11) with the appropriate α,ω-diaminoalkane in tetrahydrofuran (Procedure A). Since the goal of this program was to obtain enough pure material for biological testing, no attempt was made to optimize the yield of this or subsequent reactions.

All compounds were obtained as solids which were purified by recrystallization. The ethane (I) and propane (II) derivatives were somewhat unique in that they were crystallized from aqueous methanol as their hydrates. Compound I was obtained as a monohydrate, with the water of crystallization being lost upon drying under vacuum at 78° for 4 hr. Compound II was obtained from aqueous methanol as the dihydrate. Drying caused the loss of both moles of water, as evidenced by elemental analysis.

The identity of I, II, and V was confirmed *via* independent synthesis. Two moles of 2,3-diacetoxybenzoic acid were condensed with ethylenediamine, 1,3-diaminopropane, or 1,6-diaminohexane *via* activation with *N,N'*-dicyclohexylcarbodiimide (Procedure B). Subsequent hydrolysis of the protecting groups yielded products (40%) identical to those obtained by Procedure A. Compound II also was prepared by fusing methyl 2,3-dihydroxybenzoate and 1,3-diaminopropane at 130° under nitrogen (Procedure C). The latter procedure was used to prepare an analogous series of *N,N'*-bis(2-hydroxybenzoyl)-α,ω-diaminoalkanes (X–XIV).

One of these compounds, N^1,N^8-bis(2,3-dihydroxybenzoyl)spermidine (8), removes iron from the ferritin of cultured Chang cells and from transferrin, the principal iron-binding protein of serum (10).

The synthesis of N^1,N^8-bis(2,3-dihydroxybenzoyl)-spermidine hydrochloride (XVII) together with a series of simpler analogs is presented in this report. Preliminary evidence suggests that this type of compound may be useful in iron-chelation therapy whereas the corresponding 2-hydroxybenzoyl derivatives are inactive. The *in vitro* and *in vivo* evaluation of these compounds will be presented later.

DISCUSSION

Prior to the synthesis of XVII, a series of simpler analogs, *i.e.*, *N,N'*-bis(2,3-dihydroxybenzoyl)-α,ω-diaminoalkanes, was prepared. Like the spermidine derivative, these compounds would be expected to bind iron strongly, their affinities for iron and perhaps their biological activities being related to the separation of the 2,3-dihydroxybenzoyl moieties. The compounds were obtained readily in a 40–50% yield *via* the reaction of 2,3-dioxosulfinylbenzoyl chloride (11) with the appropriate α,ω-diaminoalkane in tetrahydrofuran (Procedure A). Since the goal of this program was to obtain enough pure material for biological testing, no attempt was made to optimize the yield of this or subsequent reactions.

All compounds were obtained as solids which were purified by recrystallization. The ethane (I) and propane (II) derivatives were somewhat unique in that they were crystallized from aqueous methanol as their hydrates. Compound I was obtained as a monohydrate, with the water of crystallization being lost upon drying under vacuum at 78° for 4 hr. Compound II was obtained from aqueous methanol as the dihydrate. Drying caused the loss of both moles of water, as evidenced by elemental analysis.

The identity of I, II, and V was confirmed *via* independent synthesis. Two moles of 2,3-diacetoxybenzoic acid were condensed with ethylenediamine, 1,3-diaminopropane, or 1,6-diaminohexane *via* activation with *N,N'*-dicyclohexylcarbodiimide (Procedure B). Subsequent hydrolysis of the protecting groups yielded products (40%) identical to those obtained by Procedure A. Compound II also was prepared by fusing methyl 2,3-dihydroxybenzoate and 1,3-diaminopropane at 130° under nitrogen (Procedure C). The latter procedure was used to prepare an analogous series of *N,N'*-bis(2-hydroxybenzoyl)-α,ω-diaminoalkanes (X–XIV).

These compounds chelated iron but failed to induce significant amounts of iron excretion when given intraperitoneally to hypertransfused rats.

Attempts to prepare N^1,N^8-bis(2,3-dihydroxybenzoyl)spermidine *via* Procedure A met with little success. Mixtures were obtained from which the desired compound could not be isolated. The hydrochloride salt (XVII) ultimately was prepared in low yield (14%) *via* treatment of the fusion products of spermidine and methyl 2,3-dihydroxybenzoate with hydrogen chloride (Procedure D). While purification of the free amine proved difficult, the hydrochloride could be purified readily by recrystallization from water. In similar fashion, the corresponding derivatives of diethylenetriamine and 3,3'-diaminodipropylamine were prepared. These hydrochlorides were obtained as the hydrates from which the water was removed upon drying *in vacuo*. N^1,N^5-Bis(2-hydroxybenzoyl)diethylenetriamine (XVIII) also was prepared. This compound was readily obtained as the free amine using Procedure C.

EXPERIMENTAL[1]

Methyl salicylate, 2,3-dihydroxybenzoic acid, *N,N'*-dicyclohexylcarbodiimide, and all of the diamines and triamines were obtained commercially. Methyl 2,3-dihydroxybenzoate was prepared according to the method of Clinton and Laskowski (12), whereas 2,3-diacetoxybenzoic acid was synthesized as described by Simokoriyama (13).

Preparation of Conjugated Derivatives—The general procedures for synthesis of *N,N'*-bis(aroyl)-α,ω-diaminoalkanes and *N,N'*-bis(aroyl)-ω,ω'-diaminodialkylamines are described as follows. The physical constants observed together with the analytical data are summarized in Tables I and II.

Procedure A—A mixture of 15.4 g (0.1 mole) of 2,3-dihydroxybenzoic acid and 35 ml (0.5 mole) of thionyl chloride was heated under reflux for 8 hr. Upon cooling, the residual thionyl chloride was removed under vacuum. To the residue was added ~10 ml of anhydrous benzene, which was evaporated under vacuum. This process was repeated three times.

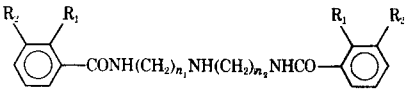
The solid residue containing 2,3-dioxosulfinylbenzoyl chloride (11) then was dissolved in 200 ml of tetrahydrofuran. To this solution were added 0.04 mole of the diamine and 30 g (0.22 mole) of anhydrous potassium carbonate. The reaction mixture was heated under reflux for 12 hr, cooled, and filtered to remove potassium salts. After evaporation of the solvent, 250 ml of water was added and the mixture was allowed to stand at room temperature for 5–6 hr. After the water was decanted, the residue was recrystallized from aqueous methanol.

Procedure B—A solution of 2.1 g (0.01 mole) of *N,N'*-dicyclohexylcarbodiimide and 4.76 g (0.02 mole) of 2,3-diacetoxybenzoic acid in 200 ml of acetonitrile containing 2 ml of pyridine was stirred at room temperature for 2 hr. The precipitated dicyclohexylurea was removed by filtration, and 0.005 mole of the diamine and 1.75 ml (0.0125 mole) of triethylamine were added. The reaction mixture was allowed to stir overnight at room temperature under nitrogen.

The solvent was evaporated under reduced pressure, and the residue

[1] Melting points were determined with a capillary melting-point apparatus and are uncorrected. TLC was carried out on silica gel with benzene–methanol–acetic acid (45:8:1) as the eluent. Compounds were visualized by spraying first with 0.5% ferric chloride and then with either 1% basic permanganate reagent or 50% H_2SO_4 (charred). For identification, NMR spectra were determined at 60 MHz in acetone-d_6 or dimethyl sulfoxide-d_6 containing a few drops of deuterium oxide. In all cases, the integrals and chemical shifts were in agreement with those expected. The spectra of representative compounds (V, XIII, and XVII) were determined at 220 MHz in dimethyl sulfoxide-d_6 containing deuterium oxide. Values are reported in parts per million (δ) downfield from tetramethylsilane (the internal standard).

Table II—Physical Constants of *N,N'*-Bis(aroyl)-ω,ω'-diaminodialkylamines



Compound	n_1	n_2	R_1	R_2	Method	Yield, %	Melting Point	Recrystallization Solvent	Formula	Analysis, %	Calc.	Found

was taken up in ethyl acetate. This solution was washed with 10% HCl (two times), 10% $NaHCO_3$, and water. The solvent was evaporated, leaving a residual semisolid, which then was dissolved in methanol (30 ml) to which was added 10 ml of 4 *N* NaOH. This solution was stirred under nitrogen at room temperature for 1 hr, after which it was acidified with 10% HCl. The solvent was evaporated, and the residue was crystallized from aqueous methanol.

Procedure C—To a 50-ml, round-bottom flask were added 21 g (17.9 ml, 0.138 mole) of methyl salicylate and 0.067 mole of the diamine (or triamine). An immediate reaction took place with generation of heat. Precipitation often ensued. The reaction mixture then was heated under nitrogen at 130° for 3 hr. Upon cooling, the residue was recrystallized from 95% ethanol.

Procedure D—To a 100-ml, round-bottom flask were added 0.03 mole of the triamine and 0.06 mole of methyl 2,3-dihydroxybenzoate. This mixture was heated under nitrogen at 130–140° for 3 hr. Upon cooling, the viscous residue was dissolved in 200 ml of methanol. The resulting solution was concentrated to ~50 ml and poured into 200 ml of anhydrous ether.

After stirring at room temperature for 30 min, the precipitate was collected by suction filtration and dissolved in 200 ml of methanol. This solution was saturated with hydrogen chloride, concentrated to ~50 ml, and poured into 200 ml of anhydrous ether. After stirring for 30 min, the ether was decanted and the residue was recrystallized from water.

***N,N'*-Bis(2,3-dihydroxybenzoyl)ethylenediamine (I)**—Compound I was prepared according to Procedure A. The solid obtained was recrystallized twice from aqueous methanol to yield 7.6 g (43%) of I as tiny tan needles, which were pure as evidenced by TLC. Elemental analysis revealed that the material was a monohydrate. Drying *in vacuo* at 78° for 8 hr caused loss of the water of crystallization.

Compound I also was prepared according to Procedure B. The synthesis was carried out as described, except that pyridine was used in place of triethylamine. The semisolid obtained was recrystallized from aqueous methanol to yield 0.72 g (41%) of light-tan needles, mp 220–221°. The melting point was not depressed upon admixture with the sample prepared according to Procedure A. TLC and the NMR spectra showed that the two samples were identical. Elemental analysis of a sample dried at 78° for 8 hr verified it as $C_{16}H_{16}N_2O_6$.

***N,N'*-Bis(2,3-dihydroxybenzoyl)-1,3-diaminopropane (II)**—Compound II was prepared by Procedure C. Upon cooling, the reaction mixture was dissolved in ethanol (50 ml). This solution was poured into 50 ml of water containing a few drops of acetic acid. After stirring at room temperature for 30 min, the solid (6.3 g) was collected by filtration. TLC showed that this solid was nearly pure; it was contaminated with a small amount of methyl 2,3-dihydroxybenzoate together with traces of the mono adduct. Addition of more water to the filtrate gave additional product, but it was very impure.

The solid (6.3 g) was dissolved in 25 ml of ethanol and decolorized with charcoal. Addition of 25 ml of water to the pale-orange solution yielded the desired compound upon cooling. The pink needles (4.8 g, 42%) melted over a wide range, depending on the rate of heating. Elemental analysis revealed that the compound contained 2 moles of water. After drying at 78° for 6 hr, the compound melted at 168–169°. Both moles of water were lost after drying, as evidenced by elemental analysis.

A second sample of II was prepared by Procedure A. The semisolid obtained was recrystallized twice from aqueous methanol to yield 9.0 g (59%) of II. TLC revealed that the material was pure and that it cochromatographed with a sample of the material prepared by Procedure C.

This compound also was synthesized from 2,3-diacetoxybenzoic acid according to Procedure B. The semisolid obtained was recrystallized twice from aqueous methanol to yield 0.85 g (44%) of tiny pink needles. TLC revealed that the material was pure and that it cochromatographed with the product obtained *via* Procedure C. The melting point of a sample dried *in vacuo* at 78° for 4 hr and admixed with a similar sample prepared according to Procedure C was not depressed. Likewise, the NMR spectrum was identical to that of a sample prepared according to Procedure C.

***N,N'*-Bis(2,3-dihydroxybenzoyl)-1,4-diaminobutane (III)**—Compound III was prepared according to Procedure A. The semisolid obtained was crystallized from aqueous ethanol and then was recrystallized from aqueous methanol to yield 5.8 g (45%) of III as an amorphous tan solid, mp 210–212°. The NMR spectrum and elemental analysis were in agreement with those expected.

***N,N'*-Bis(2,3-dihydroxybenzoyl)-1,5-diaminopentane (IV)**—Compound IV was prepared according to Procedure A. The semisolid residue was dissolved in ethyl acetate and then extracted with 10% $NaHCO_3$, water, and saturated sodium chloride. After drying over anhydrous magnesium sulfate, the ethyl acetate was removed *in vacuo*. The residual solid was recrystallized from aqueous methanol to give 5.8 g (40%) of IV as an amorphous tan solid, mp 174–176°.

***N,N'*-Bis(2,3-dihydroxybenzoyl)-1,6-diaminohexane (V)**—Compound V was synthesized *via* Procedure A. The reaction product was recrystallized twice from aqueous ethanol, yielding 8.3 g (55%) of a cream-colored amorphous solid, mp 184–186°; NMR (dimethyl sulfoxide-d_6–deuterium oxide): δ 7.26 [dd, 2H, $^3J(H^6\text{–}H^5) \simeq 8.1$, $^4J(H^6\text{–}H^4) \simeq 1.2$, aromatic C_6-H], 6.93 [dd, 2H, $^3J(H^5\text{–}H^6) \simeq 7.9$, $^4J(H^4\text{–}H^6) \simeq 1.2$, aromatic C_4-H], 6.69 [m, 2H, $^3J(H^5\text{–}H^4) \simeq {}^3J(H^5\text{–}H^6) \simeq 7.9$, $^4J(H^4\text{–}H^6) \simeq 1.2$, aromatic C_5-H], 3.28 (m, 4H, $J \simeq 6.8$, $NHCH_2$), 1.54 (m, 4H, $NHCH_2CH_2$), and 1.34 (m, 4H, $NHCH_2CH_2CH_2$).

Compound V also was synthesized by Procedure B. Pyridine was employed rather than triethylamine. The product obtained was recrystallized twice from aqueous methanol, yielding 0.73 g (38%) of a light-tan solid, mp 184–186°. The mixed melting point of this product with that obtained *via* Procedure A was not depressed. TLC and NMR spectroscopy revealed that the two compounds were identical.

***N,N'*-Bis(2,3-dihydroxybenzoyl)-1,8-diaminooctane (VI)**—Compound VI was prepared according to Procedure A. The reaction product was taken up in ethyl acetate and washed successively with 10% $NaHCO_3$ (twice), water, and saturated sodium chloride. Recrystallization (twice) from ethyl acetate–petroleum ether (60–90°) gave 6.4 g (38%) of tan crystals, mp 172–174°.

***N,N'*-Bis(2,3-dihydroxybenzoyl)-1,9-diaminononane (VII)**—Compound VII was prepared exactly as was VI using Procedure A. The compound was isolated (9.2 g, 53%) as tiny cream-colored needles after recrystallization (twice) from ethyl acetate–petroleum ether (60–90°). The NMR spectrum and elemental analysis were in agreement with the theory.

***N,N'*-Bis(2,3-dihydroxybenzoyl)-1,10-diaminodecane (VIII)**—Compound VIII was prepared exactly as was VI using Procedure A. The product was obtained (9.1 g, 51%) as a tan powder, mp 148–150°. TLC revealed that the material was pure. The elemental analysis and the NMR spectrum were in agreement.

***N,N'*-Bis(2,3-dihydroxybenzoyl)-1,12-diaminododecane (IX)**—Compound IX was prepared as was VI using Procedure A. The product

(10.2 g, 54%) was obtained as a cream-colored powder, mp 130–131°. The NMR spectrum agreed with that expected.

***N,N'*-Bis(2-hydroxybenzoyl)ethylenediamine (X)**—Compound X was prepared according to Procedure C. The reaction mixture was dissolved in methanol, and this solution then was poured into ether. After stirring at room temperature for 1 hr, the solid was collected by filtration. This solid was recrystallized from ethanol to give 8.3 g (46%) of cream-colored crystals, mp 187–189°.

***N,N'*-Bis(2-hydroxybenzoyl)-1,3-diaminopropane (XI)**—Compound XI was prepared according to Procedure C. Upon cooling, the reaction mixture was dissolved in 50 ml of methanol. To this solution was added 50 ml of water containing a few drops of acetic acid. Upon stirring at room temperature, the oily precipitate solidified. The solid (13.5 g) was recrystallized twice from ethanol (100 ml) to yield 7.2 g (38%) of white crystals, which were pure by TLC, mp 181–182.5°.

***N,N'*-Bis(2-hydroxybenzoyl)-1,4-diaminobutane (XII)**—Compound XII was prepared according to Procedure C. The solid reaction mixture was dissolved in methanol, and the product was precipitated *via* the addition of water. The product (15.9 g) was recrystallized from ethanol (75 ml) to yield 8.2 g (42%) of shiny white plates, which were pure by TLC, mp 180–181°.

***N,N'*-Bis(2-hydroxybenzoyl)-1,6-diaminohexane (XIII)**—Compound XIII was prepared according to Procedure C. The waxy solid residue was crystallized from 35 ml of ethanol, yielding 10.9 g of product. TLC showed that this product contained some of the mono adduct. Recrystallization from ethanol gave 9.7 g (45%) of pure product as waxy white plates, mp 141–142.5°; NMR (dimethyl sulfoxide-d_6–deuterium oxide): δ 7.82 [dd, 2H, $^3J(H^6\text{–}H^5) \simeq 8.1$, $^4J(H^6\text{–}H^4) \simeq 1.3$, aromatic C_6-H], 7.41 [m, 2H, $^3J(H^4\text{–}H^3) \simeq {}^3J(H^4\text{–}H^5) \simeq 7.7$, aromatic C_4-H], 6.90 [m, 4H, $^3J(H^3\text{–}H^4) \simeq {}^3J(H^5\text{–}H^4) \simeq {}^3J(H^5\text{–}H^6) \simeq 7.9$, aromatic C_5-H and C_3-H], 3.31 (m, 4H, $J \simeq 6.8$, $NHCH_2$), 1.57 (m, 4H, $NHCH_2CH_2$), and 1.36 (m, 4H, $NHCH_2CH_2CH_2$).

***N,N'*-Bis(2-hydroxybenzoyl)-1,8-diaminooctane (XIV)**—Compound XIV was prepared according to Procedure C. The solid reaction mixture was crystallized from ethanol (50 ml), yielding 12.5 g of product. TLC revealed that this product contained a small amount of the mono adduct. Recrystallization from ethanol gave 11.4 g (49%) of product as waxy white plates, mp 139–140.5°.

***N*^{1},*N*^{5}-Bis(2,3-dihydroxybenzoyl)diethylenetriamine Hydrochloride (XV)**—Compound XV was prepared *via* Procedure D from 5.2 g (0.05 mole) of diethylenetriamine and 16.0 g (0.10 mole) of methyl 2,3-dihydroxybenzoate. The hydrochloride was obtained as a cream-colored powder (3.8 g, 18%), mp 163–165°.

***N*^{1},*N*^{7}-Bis(2,3-dihydroxybenzoyl) -3,3'- diaminodipropylamine Hydrochloride (XVI)**—Compound XVI was prepared according to Procedure D exactly as was XV. The hydrochloride was isolated as a cream-colored powder (2.6 g, 16%). After drying at 78° for 4 hr, the elemental analysis confirmed its formula as $C_{19}H_{25}N_3O_6$·HCl. This material failed to melt sharply; a phase transition occurred at 85–87°, after which it melted with decomposition at 115–117°.

***N*^{1},*N*^{8}-Bis(2,3-dihydroxybenzoyl)spermidine Hydrochloride (XVII)**—Compound XVII was prepared by Procedure D from 5 g (0.034 mole) of spermidine and 11.6 g (0.07 mole) of methyl 2,3-dihydroxybenzoate. The product was obtained as a light-tan powder (2.2 g, 14%), mp 205–207°. TLC revealed that the compound was pure. After drying at 78° for 6 hr, the compound was free from the water of crystallization as evidenced by elemental analysis. The NMR spectrum of the hydrochloride (dimethyl sulfoxide-d_6–deuterium oxide) gave the following values: δ 7.31 [m, 2H, $^3J(H^6\text{–}H^5) \simeq 7.7$, $^4J(H^6\text{–}H^4) < 1.0$, aromatic C_6-H], 6.95 [d, 2H, $^3J(H^4\text{–}H^5) \simeq 7.9$, $^4J(H^4\text{–}H^6) < 1.0$, aromatic C_4-H], 6.70 [m, 2H, $^3J(H^5\text{–}H^4) \simeq {}^3J(H^5\text{–}H^6) \simeq 7.9$, aromatic C_5-H], 3.36 (m, 4H, $CONHCH_2$), 2.93 (m, 4H, CH_2NHCH_2), 1.91 (m, 2H, $NHCH_2CH_2CH_2NH$), and 1.64 (m, 4H, $NHCH_2CH_2CH_2CH_2NH$).

***N*^{1},*N*^{5}-Bis(2-hydroxybenzoyl)diethylenetriamine (XVIII)**—Compound XVIII was prepared according to Procedure C. Upon cooling, the reaction mixture solidified as a glass. This solid was triturated with methanol from which 14.3 g of solid separated. The solid was recrystallized from ethanol to yield 8.4 g (37%) of slightly orange crystals, mp 151.5–153°. The NMR spectrum and elemental analysis were in agreement with those expected.

Indole–Catechol Charge Transfer Complexes I

Keyphrases □ Catechol—charge transfer complex with indoles □ Indoles—charge transfer complex with catechol □ Charge transfer complexes—interaction of catechol and indoles

To the Editor:

The involvement of charge transfer phenomena, based on UV absorption measurements, was hypothesized between catechol-containing substances and the nucleic acid bases in the mechanism of action of biogenic amines as well as in their storage in the adrenal medulla and other nerve endings (1, 2). In continuing efforts to elucidate this effect in nerve conduction, the interaction between (−)-tryptophan and catechol was studied by UV absorption and emission techniques in aqueous solutions.

Figure 1 shows that the mixture containing (−)-tryptophan and catechol is shifted toward longer wavelengths and is accompanied by an increase in absorbance from that representing the sum of the absorbances of the single pure substances, indicating complex formation[1]. The increase in absorbance is attributed to the (−)-tryptophan–catechol complex and is used to calculate the equilibrium constant by applying the Benesi–Hildebrand equation:

$$\frac{[A_0]}{A_\lambda^{AD}} = \frac{1}{\epsilon_\lambda^{AD}} + \frac{1}{K_{abs}\epsilon_\lambda^{AD}[D_0]} \qquad \text{(Eq. 1)}$$

where $[A_0]$ and $[D_0]$ represent the total concentrations of the reactants, A_λ^{AD} and ϵ_λ^{AD} are the absorbance and molar absorptivity at a given wavelength, and K_{abs} is the equilibrium constant. Equation 1 is based on the assumptions that a 1:1 complex is formed and that $[A_0] \ll [D_0]$. A plot of $[A_0]/A_\lambda^{AD}$ *versus* $1/[D_0]$, with $[A_0]$ kept constant, gave a straight line (Fig. 2). The equilibrium constant calculated from the slope and intercept of the plot, when treated by the least-squares method, was 0.178 ± 10% M^{-1} in 10^{-3} M cacodylate buffer at pH 5 and 15° while the molar absorptivity at the wavelength of the measurement (306 nm) was 99.2 ± 2%.

Fluorescence measurements frequently are used to study complex formation (3). To allow meaningful comparison, the system was studied by this method under similar conditions in neutral solutions. When (−)-tryptophan was excited at 275 nm, the maximum emission wavelength observed was 365 nm. The fluorescence of (−)-tryptophan was quenched upon addition of catechol[2] (Fig. 3). The fraction of the fluorescence intensity remaining is a function of the concentrations of both components.

The equilibrium constant obtained from the fluorescence measurements, K_{fluo}, is calculated from:

$$\frac{1-\beta}{\beta} = K_{fluo}\{[D_0] - [A_0](1-\beta)\} \qquad \text{(Eq. 2)}$$

where β represents the relative fluorescence intensity

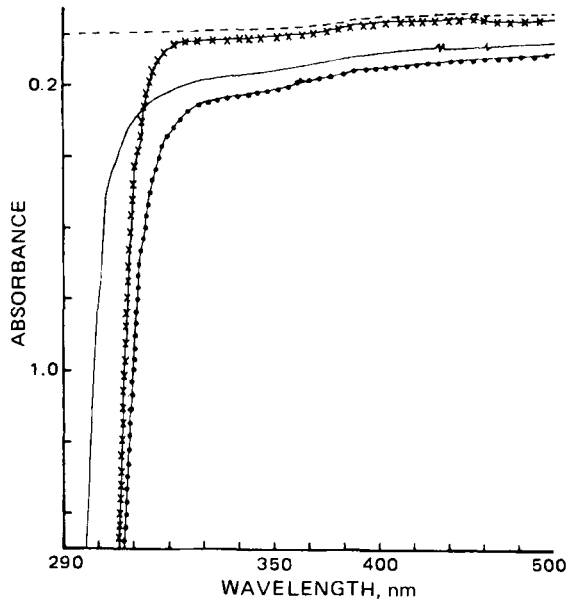

Figure 1—*Absorption spectra of 2 × 10^{-2} M (−)-tryptophan (-×-×), 1 M catechol (—), and 2 × 10^{-2} M (−)-tryptophan with 1 M catechol (-●-●); the broken line (- - -) represents the baseline. All solutions were in 10^{-3} M cacodylate buffer at pH 5. Measurements were made in 0.5-cm path length cells at 15°.*

observed. Equation 2 is based on the assumption that a 1:1 complex is formed; the complex does not fluoresce, and the fluorescence intensity is related linearly to concentration. Nearly equal K_{fluo} values (6.152 × 10^3 ± 17% M^{-1}) were found when fixed concentrations of (−)-tryptophan (10^{-5} and 10^{-4} M) and varying concentrations of catechol (up

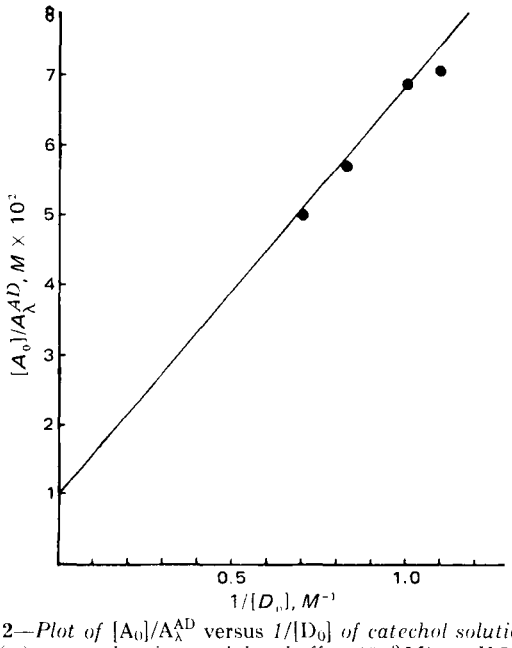

Figure 2—*Plot of $[A_0]/A_\lambda^{AD}$ versus $1/[D_0]$ of catechol solutions containing (−)-tryptophan in cacodylate buffer (10^{-3} M) at pH 5 and 15°. The total concentration of (−)-tryptophan, $[A_0]$, was 2 × 10^{-2} M; the total concentration of catechol, $[D_0]$, was 0.9–1.4 M; A_λ^{AD} represents the absorbance of the complex in a 1-cm path length cell at 306 nm.*

[1] Absorbances were measured with a Perkin-Elmer model 402 UV–visible spectrophotometer.

[2] Fluorescence measurements were made with an Aminco-Bowman model J4-8203G spectrophotofluorometer.

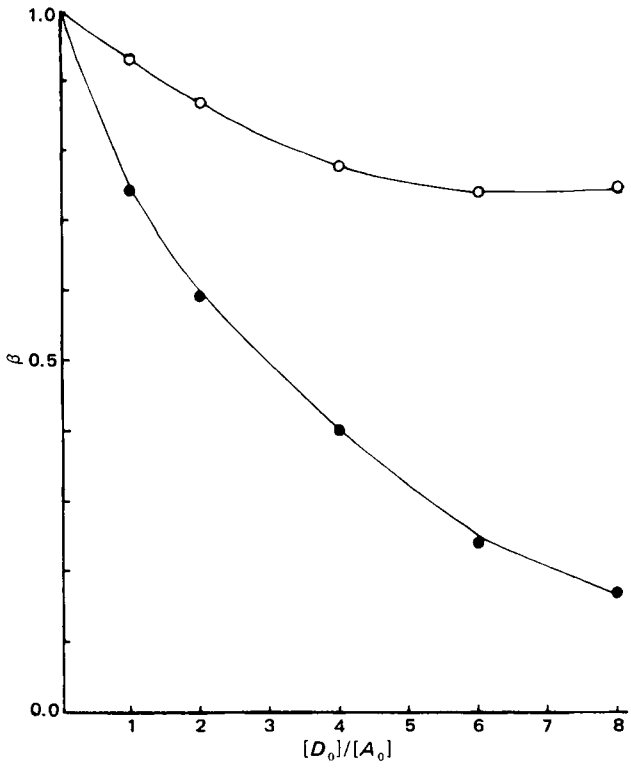

Figure 3—*Change in the relative fluorescence intensity of (−)-tryptophan, β, versus the molar ratio of catechol to (−)-tryptophan, $[D_0]/[A_0]$, at 10^{-5} M (-O-O) and 10^{-4} M (-●-●) (−)-tryptophan in cacodylate buffer (10^{-3} M) at pH 7 and 15°. The excitation wavelength was 275 nm. Fluorescence intensity was measured at 365 nm.*

to eightfold) were used. Furthermore, catechol did not have appreciable fluorescence at the highest concentration used (~5% from the total fluorescence intensity at the wavelength used).

In correlating the equilibrium constants obtained by the methods, a quenching coefficient, γ, is introduced in calculating the true (thermodynamic) equilibrium constant, K_t, from the simple mathematical model proposed:

$$K_{fluo} = \frac{[AD]\gamma_{AD}}{[A]\gamma_A[D]\gamma_D} = \frac{[AD]}{[A][D]}\left(\frac{\gamma_{AD}}{\gamma_A\gamma_D}\right) = K_t K_{quen} \qquad \text{(Eq. 3)}$$

$$K_{quen} = \frac{\gamma_{AD}}{\gamma_A\gamma_D} \qquad \text{(Eq. 4)}$$

where K_{quen} is the quenching constant. When K_{quen} was calculated by assuming $K_t \simeq K_{abs}$, it had a value of 3.4562×10^4.

Fluorescence quenching of tryptophan and some other fluorescing compounds was attributed to charge transfer interactions (4). In those studies, tryptophan was considered as an electron donor. It was suggested that the catechol-containing compounds act as electron donors when forming charge transfer complexes with nucleic acid bases in aqueous acidic solutions (1, 2). It may be reasonably concluded that the results presented in this work can be interpreted on the basis of charge transfer effects. It is difficult to assign the donor or acceptor species of the present molecules since precise theoretical data involving molecular orbital calculations of the highest occupied or lowest empty molecular orbitals are either inconsistent or unavailable and the values usually are expressed in terms of resonance units (uncertain quantities). However, it is assumed tentatively that catechol acts as an electron donor while (−)-tryptophan acts as an electron acceptor.

To explain the differences between the equilibrium constants obtained from the two methods as well as the appearance of the quenching constant, it is proposed that one pair of (−)-tryptophan–catechol out of several thousand pairs of molecules, within the concentration limits used, exists in close proximity in the form of a real complex while the rest remain isolated in solution.

On the other hand, to justify the charge transfer mechanism for the observed quenching, we propose a hypothesis of an electron pump through water. Experimental results indicated an observable quenching at concentrations as low as 10^{-5} *M* each (5.5%). Simple calculations revealed that the distance between molecules at 2×10^{-5} *M* is 436.26 Å; the distance between two molecules of water is 3.1 Å. Therefore, under this proposal, an electron can be pumped through ~140 molecules of water.

It is hoped that the results presented here and the theory advanced may help in understanding many important biological processes such as conduction through nerves and other excitable membranes.

Table I—Relative Abundances of the Peaks at *m/e* 315 and 343 in the Mass Spectra of Betamethasone and Dexamethasone

Compound	*m/e*	Relative Abundance[a], %
I	315	3 ± 2[b], 3, ~10
	343	3 ± 2[b], 5, ~12
II	315	40 ± 5[b], 12, ~15
	343	4 ± 2[b], 5, ~76

[a] Refers to the base peak at *m/e* 122. The first value was determined by the present investigator, the second value was taken from Ref. 5, and the third value was obtained from Ref. 2.

thermal decomposition of the sample under the rather drastic conditions prevailing in the ion source, must be given serious consideration with steroids to prevent experimental artifacts.

A case in point is the mass spectral analysis of betamethasone (I) and dexamethasone (II), which are configurational isomers at C-16; their spectra were reported by Lodge and Toft (2, 3). According to these investigators, unequivocal discrimination between the epimers is allowed by the fragment (M − 49) at *m/e* 343, a major peak (actually, the second most abundant ion) in the spectrum of II whose abundance is insignificant in the spectrum of I. Formation of the fragment was traced (2, 3) to the preliminary loss of water from the D-ring followed by cleavage of the 20,21-bond, which should be favored in II according to a mechanism similar to that suggested by Zaretskii *et al.* (4) for the epimers of 17-alkyl-19-nortestosterone.

While these results and their interpretation remain unchallenged in the literature, there are indications (5) of unsuccessful attempts to corroborate the occurrence of a major peak at *m/e* 343 in the mass spectrum of II together with the suggestion that the spectrum may be affected greatly by the thermal decomposition of the sample. In view of the pharmaceutical relevance of the epimeric pair involved, a systematic investigation was undertaken to reconcile the discrepancy and to evaluate the effects of the possible instrumental artifacts.

Authentic samples of I and II from different sources, whose identity and purity had been checked by melting-point determination, IR spectroscopy, and high-pressure liquid chromatography (HPLC), were analyzed on a quadrupole spectrometer[1] and two magnetic sector spectrometers[2]. An effort was made to duplicate as closely as possible the conditions described previously (2, 3), using a direct-insertion probe temperature of 180–200° and an electron energy of 70 ev.

The results confirm that the molecular ion is barely detectable and indicate that the base peak in the spectra of both I and II is the ion at *m/e* 122. However, other significant features of the spectra, including the peaks at *m/e* 315 and 343, differ significantly from previously reported values (Table I).

The discrepancies clearly are too large to be explained by instrumental factors and suggest that thermal decomposition of the sample plays a significant role. This view is supported by the correspondingly large scatter (~22°) of the melting points reported in the literature and their dependence on the heating rate (5).

To gather additional evidence on this point, further experiments were carried out using thermogravimetric analysis and mass spectrometry. A sample of II was heated in a thermoanalyzer[3], both in a self-induced atmosphere and in dry nitrogen, from 25 to 220° at rate of 4°/min and then maintained at 220°. A significant (8.1 ± 0.1%) weight loss occurred above 200°, peaking at ~205°.

In a separate experiment, samples of II were heated at 205° in a glass tube under high vacuum (1.5×10^{-6} torr), and a white sublimate was observed immediately above the heated portion of the tube. The composition of the sublimate could be taken as representative of the composition of the vapors above the heated sample under conditions that closely approach those in the ion source. Accordingly, the mass spectrum of the sublimate was recorded and was significantly different from that of pure II. In particular, the relative abundances of the peaks at *m/e* 315 and 343 were 13 and 7%, respectively, which are very close to the values reported in Ref. 5.

These experiments provide compelling evidence that thermal decomposition plays a significant role in the mass spectrum of II, affecting in particular the relative abundances of the peaks at *m/e* 315 and 343. Consequently, the diagnostic value of the fragment at *m/e* 343 in unequivocally distinguishing between I and II is questionable.

If discrimination between the two epimers has to be achieved by mass spectrometry rather than by more suitable techniques, *e.g.*, HPLC, it appears that the most significant diagnostic peak is the one at *m/e* 315. In fact, not only the present data but also those reported in Ref. 5 show that the fragment at *m/e* 315 is consistently and significantly more abundant in the mass spectrum of II than of I.

Any mechanistic interpretation of the electron-induced fragmentation pattern of complicated molecules, especially in those cases where heat-sensitive substances are involved, should be made cautiously.

REVIEWS

Index Nominum 1980. 10th ed. The Swiss Pharmaceutical Society. 1979. xiv + 913 pp. 21 x 29.5 cm. (Available from Drug Intelligence Publications, Dept. C78, Hamilton, IL 62341.) (*Introduction in French, German, and English; text in French.*)

Index Nominum 1980 is an alphabetical list of generic and trade names of internationally available drug products containing one active substance. Information is given on International Nonproprietary Names (INN) and other generic names, trade names and manufacturers, chemical names and structures, pharmacopeial monographs on each drug, and main therapeutic uses. The 1980 edition lists approximately 3800 compounds and derivatives, approximately 200 of which are new. More than 26,000 references are given.

As with the previous edition, Index Nominum 1980 is a single volume with a single alphabet; readers never have to look up more than one cross-reference to find the main entry. Among the other convenient features retained in this edition are the listing of monograph titles from pharmacopeias of international importance and the distinction of new substances published for the first time by a point preceding the name or synonym.

Staff Review

Selective Toxicity: The Physico-Chemical Basis of Therapy, 6th ed. By ADRIEN ALBERT. Wiley, One Wiley Drive, Somerset, NJ 08873. 1979. 662 pp. 15 × 23 cm. Price $42.50.

The first edition of this book appeared in 1951, and the sixth edition, published recently, is approximately 10% larger than the fifth edition, which was published in 1973.

The book is divided into two parts. The first part is entitled Topics of General Interest and consists of seven chapters (269 pages). The first chapter briefly discusses the principle of selectivity, and the second chapter outlines various steps in correlating chemical structure with biological activity. This account deals mainly with the concept of receptors followed by a discussion of how minor molecular modifications by methyl or methylene groups may affect biological properties. Chapters 3–5 (129 pages) deal with three general principles of selectivity: differences in the distribution of compounds between "economic and uneconomic cells," a comparison of the biochemistry between the same metabolic routes in different biological systems, and comparisons between the structures of different cells and cellular components. Chapter 6 describes some principles of chemotherapy, including a succinct account of drug resistance. This chapter is prefaced by a short but interesting account of various aspects of the history of chemotherapy. The first section of this book concludes with a chapter on pharmacodynamics (70 pages), in which the theme of selective toxicity of a compound in one organism is amplified.

The second section, Studies, in Depth, of Topics from Part I (285 pages), commences with a chapter on the nature of chemical bonding and absorption followed by a chapter on metabolites and antimetabolites. Chapters 10 and 11 are particularly valuable and emphasize the importance of ionization and chelation of compounds in eliciting biological responses. They are followed by two chapters on the covalent bond and stereochemistry. Chapter 14 discusses surface activity. The next chapter deals with biological activity that is not related to chemical structure. A chapter not appearing in previous editions, entitled The Perfection of a Discovery (approximately 5 pages), emphasizes multiple regression analyses, molecular orbital calculations, and molecular conductivity. Four appendixes follow the second section.

On the positive side, many medicinal chemists, pharmacologists, biochemists, and toxicologists will derive some benefit from portions of this book. A number of recent developments in medicinal chemistry are incorporated into this monograph, including certain aspects of cancer, opioid receptors, and robust metal complexes. The bibliography is excellent, and many recent references are included.

On the negative side, although it is difficult to deal adequately with every facet of selective toxicity, there are areas where the present work is lacking. While the author states that regression analysis and other mathematical models are much used, he gives only a brief account of them. Thus, although he deals with this subject on pages 70–75 and 557–562, this account will be considered by some to be a somewhat cursory treatment. Furthermore, a somewhat truncated summary of information is available on prodrugs. Another criticism is the fragmentation of information throughout the book; although it is understood that the classification of the vast amount of information recorded in this book is a difficult art, the value of dividing the book into two parts is not clear to this reviewer. Why go back in Part II and resurrect a theme that was started in Part I? For example, the subject of receptors is introduced on pages 23–39, mentioned briefly again on pages 250–261, and outlined again in Chapter 13. The same approach is used not only for stereochemistry, which is described initially on pages 39–46 and then becomes the subject of an entire chapter, but also for regression analyses, as noted earlier. Presumably, the author would maintain that it is an unreasonably large jump, and, thus, the book may be regarded as too undergraduate oriented for those who are experienced in the chemical–biological interface.

In summary, this book is valuable reading to those interested in chemicals producing biological responses, but medicinal chemists and others will have to delve into other monographs in many cases to obtain a fuller treatment of the subject.

Atlas of the Three-Dimensional Structure of Drugs, Vol. 1. By J. P. TOLLENAERE, H. MOEREELS, and L. A. RAYMAEKERS. Elsevier/North-Holland Inc., 52 Vanderbilt Ave., New York, NY 10017. 1979. 322 pp. 17 × 24.5 cm. Price $36.50.

Medicinal chemists should welcome this volume since it is a successful effort to relate appropriate crystallography to the representation of the molecular architecture of compounds from a variety of pharmacological classes.

Representative compounds from the following categories are included: muscarinic agonists and antagonists; nicotinic agonists and antagonists; phenethylamines, catecholamines, and related compounds; H_1- and H_2-histamine receptor agonists and antagonists; opiate receptor agonists and antagonists; serotonin and related compounds; hallucinogens; local anesthetics; antiarrhythmic agents; Ca^{2+}-antagonists; anticonvulsants and sedative hypnotics; diuretics; nonsteroidal anti-inflammatory agents; and anthelmintic, antifungal, and antiprotozoal agents.

The primary objective was to compare and classify the compounds within each class with respect to geometric and conformational characteristics by using crystallographic data, but it was necessary to visualize molecular structures rather than merely rely on interpretations of numerical data in terms of distances and torsion angles. To determine the optimal orientation of so many molecules, interactive computer techniques were used; an APL (A Programming Language) function PROJ was developed to generate numerous orientations from which the final selection was made. Rotation angles around defined x, y, and z axes, the scale, and viewing distance then were transferred and used in the ORTEP (Oak Ridge Thermal Ellipsoid Program), which draws the picture on a CALCOMP plotter. The ORTEP drawings of the molecular structures then were retouched slightly and thus appear very artistically in the book.

The authors emphasize the idea of pharmacological class relationship by representing molecular structure in space in such a manner that common moieties within each class can be recognized. In many cases, a compromise had to be made between strictly analogous orientation of key moieties and clarity of the representation and the authors' attempt to show the intrinsic beauty of molecular architecture. Due to this compromise, not only medicinal chemists who have expertise in crystallography and three-dimensional structural studies, but also most connoisseurs of fine art and fine science will appreciate the beauty of the struc-

tural representations, with one structure per page covering most of the page.

The introduction includes very helpful, brief explanations regarding the structural data bearing on groups, classes, and subclasses of the compounds. Although these comments are not intended to provide complete explanations, they strengthen the perception of intra- and interclass relationships and differences which are reflected by the pictorial representations.

The authors' intent was for this book "to serve as a bridge between crystallographers and structural chemists and those engaged in drug research." This reviewer concludes that the book does in fact provide such an effective bridge. This book therefore is recommended not only to medicinal chemists but also to graduate and undergraduate students in medicinal chemistry and pharmacology.

Computer-Assisted Drug Design. Edited by E. C. OLSON and R. E. CHRISTOFFERSEN. (ACS Symposium Series 112.) American Chemical Society, 1155 16th St., N.W., Washington, DC 20036. 1979. 619 pp. 15 × 23 cm. Price $40.00.

This book is a collection of 26 presentations made at a recent American Chemical Society symposium entitled "Computer-Assisted Drug Design." The articles cover a few of the theoretical structure–activity relationship methods in use for drug design. The book is divided into four sections covering the assessment of several techniques, drug receptor modeling, examples of some techniques, and applications. A 15-page index completes the book.

A number of articles stand out and deserve comment. In the first section, a review of a few of the general structure–activity relationship methods is attempted. Unfortunately, it is incomplete in its coverage. An article by Topliss *et al.* is a useful description of chance factors in dealing with structure–activity relationship statistics.

In the second section on drug receptor modeling, Andrews briefly discusses transition state analogs. Articles by *Cole et al.*, Marshall *et al.*, and Humber *et al.* on mapping and modeling are of interest. An article by Loew *et al.* on interaction studies on the opiate receptor is well written and of quality. Rohrer *et al.* describe the use of PROPHET in the same section.

In the third section on examples of techniques, articles by Magee, Bersohn, Weintraub, and Stuper *et al.* present useful descriptions of computer-assisted methods of analysis.

The fourth section on applications in drug design contains a refreshingly thorough and accurate review of theoretical structure–activity relationship contributions over the past 15 years by Grunewald *et al.* Articles by Gund *et al.*, Petit *et al.*, and Hodes reveal computer-based applications of theoretical structure—activity relationships.

A number of problems apparent with this book are common to similar efforts to publish quickly everything presented at a symposium. Because of the requirement for speed, there is little opportunity for screening or review, leading to a wide range of scholarship and quality. Since every presentation is published, the amount of background material that can accompany each article is restricted. As a result, a reader outside of the area is not sufficiently informed. In contrast, an investigator in the field probably would turn to the original journal articles of the authors.

The book should be examined by anyone involved or interested in theoretical structure–activity relationship studies in medicinal chemistry.

Index Nominum 1980. 10th ed. The Swiss Pharmaceutical Society. 1979. xiv + 913 pp. 21 x 29.5 cm. (Available from Drug Intelligence Publications, Dept. C78, Hamilton, IL 62341.) (*Introduction in French, German, and English; text in French.*)

Index Nominum 1980 is an alphabetical list of generic and trade names of internationally available drug products containing one active substance. Information is given on International Nonproprietary Names (INN) and other generic names, trade names and manufacturers, chemical names and structures, pharmacopeial monographs on each drug, and main therapeutic uses. The 1980 edition lists approximately 3800 compounds and derivatives, approximately 200 of which are new. More than 26,000 references are given.

As with the previous edition, Index Nominum 1980 is a single volume with a single alphabet; readers never have to look up more than one cross-reference to find the main entry. Among the other convenient features retained in this edition are the listing of monograph titles from pharmacopeias of international importance and the distinction of new substances published for the first time by a point preceding the name or synonym.

Staff Review

Selective Toxicity: The Physico-Chemical Basis of Therapy, 6th ed. By ADRIEN ALBERT. Wiley, One Wiley Drive, Somerset, NJ 08873. 1979. 662 pp. 15 × 23 cm. Price $42.50.

The first edition of this book appeared in 1951, and the sixth edition, published recently, is approximately 10% larger than the fifth edition, which was published in 1973.

The book is divided into two parts. The first part is entitled Topics of General Interest and consists of seven chapters (269 pages). The first chapter briefly discusses the principle of selectivity, and the second chapter outlines various steps in correlating chemical structure with biological activity. This account deals mainly with the concept of receptors followed by a discussion of how minor molecular modifications by methyl or methylene groups may affect biological properties. Chapters 3–5 (129 pages) deal with three general principles of selectivity: differences in the distribution of compounds between "economic and uneconomic cells," a comparison of the biochemistry between the same metabolic routes in different biological systems, and comparisons between the structures of different cells and cellular components. Chapter 6 describes some principles of chemotherapy, including a succinct account of drug resistance. This chapter is prefaced by a short but interesting account of various aspects of the history of chemotherapy. The first section of this book concludes with a chapter on pharmacodynamics (70 pages), in which the theme of selective toxicity of a compound in one organism is amplified.

The second section, Studies, in Depth, of Topics from Part I (285 pages), commences with a chapter on the nature of chemical bonding and absorption followed by a chapter on metabolites and antimetabolites. Chapters 10 and 11 are particularly valuable and emphasize the importance of ionization and chelation of compounds in eliciting biological responses. They are followed by two chapters on the covalent bond and stereochemistry. Chapter 14 discusses surface activity. The next chapter deals with biological activity that is not related to chemical structure. A chapter not appearing in previous editions, entitled The Perfection of a Discovery (approximately 5 pages), emphasizes multiple regression analyses, molecular orbital calculations, and molecular conductivity. Four appendixes follow the second section.

On the positive side, many medicinal chemists, pharmacologists, biochemists, and toxicologists will derive some benefit from portions of this book. A number of recent developments in medicinal chemistry are incorporated into this monograph, including certain aspects of cancer, opioid receptors, and robust metal complexes. The bibliography is excellent, and many recent references are included.

On the negative side, although it is difficult to deal adequately with every facet of selective toxicity, there are areas where the present work is lacking. While the author states that regression analysis and other mathematical models are much used, he gives only a brief account of them. Thus, although he deals with this subject on pages 70–75 and 557–562, this account will be considered by some to be a somewhat cursory treatment. Furthermore, a somewhat truncated summary of information is available on prodrugs. Another criticism is the fragmentation of information throughout the book; although it is understood that the classification of the vast amount of information recorded in this book is a difficult art, the value of dividing the book into two parts is not clear to this reviewer. Why go back in Part II and resurrect a theme that was started in Part I? For example, the subject of receptors is introduced on pages 23–39, mentioned briefly again on pages 250–261, and outlined again in Chapter 13. The same approach is used not only for stereochemistry, which is described initially on pages 39–46 and then becomes the subject of an entire chapter, but also for regression analyses, as noted earlier. Presumably, the author would maintain that it is an unreasonably large jump, and, thus, the book may be regarded as too undergraduate oriented for those who are experienced in the chemical–biological interface.

In summary, this book is valuable reading to those interested in chemicals producing biological responses, but medicinal chemists and others will have to delve into other monographs in many cases to obtain a fuller treatment of the subject.

Atlas of the Three-Dimensional Structure of Drugs, Vol. 1. By J. P. TOLLENAERE, H. MOEREELS, and L. A. RAYMAEKERS. Elsevier/North-Holland Inc., 52 Vanderbilt Ave., New York, NY 10017. 1979. 322 pp. 17 × 24.5 cm. Price $36.50.

Medicinal chemists should welcome this volume since it is a successful effort to relate appropriate crystallography to the representation of the molecular architecture of compounds from a variety of pharmacological classes.

Representative compounds from the following categories are included: muscarinic agonists and antagonists; nicotinic agonists and antagonists; phenethylamines, catecholamines, and related compounds; H_1- and H_2-histamine receptor agonists and antagonists; opiate receptor agonists and antagonists; serotonin and related compounds; hallucinogens; local anesthetics; antiarrhythmic agents; Ca^{2+}-antagonists; anticonvulsants and sedative hypnotics; diuretics; nonsteroidal anti-inflammatory agents; and anthelmintic, antifungal, and antiprotozoal agents.

The primary objective was to compare and classify the compounds within each class with respect to geometric and conformational characteristics by using crystallographic data, but it was necessary to visualize molecular structures rather than merely rely on interpretations of numerical data in terms of distances and torsion angles. To determine the optimal orientation of so many molecules, interactive computer techniques were used; an APL (A Programming Language) function PROJ was developed to generate numerous orientations from which the final selection was made. Rotation angles around defined x, y, and z axes, the scale, and viewing distance then were transferred and used in the ORTEP (Oak Ridge Thermal Ellipsoid Program), which draws the picture on a CALCOMP plotter. The ORTEP drawings of the molecular structures then were retouched slightly and thus appear very artistically in the book.

The authors emphasize the idea of pharmacological class relationship by representing molecular structure in space in such a manner that common moieties within each class can be recognized. In many cases, a compromise had to be made between strictly analogous orientation of key moieties and clarity of the representation and the authors' attempt to show the intrinsic beauty of molecular architecture. Due to this compromise, not only medicinal chemists who have expertise in crystallography and three-dimensional structural studies, but also most connoisseurs of fine art and fine science will appreciate the beauty of the struc-

The ORTEP drawings of the molecular structures then were retouched slightly and thus appear very artistically in the book.

The authors emphasize the idea of pharmacological class relationship by representing molecular structure in space in such a manner that common moieties within each class can be recognized. In many cases, a compromise had to be made between strictly analogous orientation of key moieties and clarity of the representation and the authors' attempt to show the intrinsic beauty of molecular architecture. Due to this compromise, not only medicinal chemists who have expertise in crystallography and three-dimensional structural studies, but also most connoisseurs of fine art and fine science will appreciate the beauty of the struc-

tural representations, with one structure per page covering most of the page.

The introduction includes very helpful, brief explanations regarding the structural data bearing on groups, classes, and subclasses of the compounds. Although these comments are not intended to provide complete explanations, they strengthen the perception of intra- and interclass relationships and differences which are reflected by the pictorial representations.

The authors' intent was for this book "to serve as a bridge between crystallographers and structural chemists and those engaged in drug research." This reviewer concludes that the book does in fact provide such an effective bridge. This book therefore is recommended not only to medicinal chemists but also to graduate and undergraduate students in medicinal chemistry and pharmacology.

Computer-Assisted Drug Design. Edited by E. C. OLSON and R. E. CHRISTOFFERSEN. (ACS Symposium Series 112.) American Chemical Society, 1155 16th St., N.W., Washington, DC 20036. 1979. 619 pp. 15 × 23 cm. Price $40.00.

This book is a collection of 26 presentations made at a recent American Chemical Society symposium entitled "Computer-Assisted Drug Design." The articles cover a few of the theoretical structure–activity relationship methods in use for drug design. The book is divided into four sections covering the assessment of several techniques, drug receptor modeling, examples of some techniques, and applications. A 15-page index completes the book.

A number of articles stand out and deserve comment. In the first section, a review of a few of the general structure–activity relationship methods is attempted. Unfortunately, it is incomplete in its coverage. An article by Topliss *et al.* is a useful description of chance factors in dealing with structure–activity relationship statistics.

In the second section on drug receptor modeling, Andrews briefly discusses transition state analogs. Articles by *Cole et al.*, Marshall *et al.*, and Humber *et al.* on mapping and modeling are of interest. An article by Loew *et al.* on interaction studies on the opiate receptor is well written and of quality. Rohrer *et al.* describe the use of PROPHET in the same section.

In the third section on examples of techniques, articles by Magee, Bersohn, Weintraub, and Stuper *et al.* present useful descriptions of computer-assisted methods of analysis.

The fourth section on applications in drug design contains a refreshingly thorough and accurate review of theoretical structure–activity relationship contributions over the past 15 years by Grunewald *et al.* Articles by Gund *et al.*, Petit *et al.*, and Hodes reveal computer-based applications of theoretical structure—activity relationships.

A number of problems apparent with this book are common to similar efforts to publish quickly everything presented at a symposium. Because of the requirement for speed, there is little opportunity for screening or review, leading to a wide range of scholarship and quality. Since every presentation is published, the amount of background material that can accompany each article is restricted. As a result, a reader outside of the area is not sufficiently informed. In contrast, an investigator in the field probably would turn to the original journal articles of the authors.

The book should be examined by anyone involved or interested in theoretical structure–activity relationship studies in medicinal chemistry.

TAKING ANIMALS OUT OF THE LAB

If we were to ask our readers whether they favor "research modernization," undoubtedly the response would be one of overwhelming approval.

If we likewise polled them as to whether or not they favor the elimination of animals in pharmaceutical research, we expect that the response would be equally overwhelming in opposition.

Interestingly enough, however, these two apparently different concepts currently bear a very close relationship. Specifically, legislation is now being seriously and actively considered within the U.S. Congress that bears the title "Research Modernization Act" (H.R. 4805), and which has the specific purpose of working toward significant reduction or complete elimination of the use of animals in research.

In itself, legislation of this general nature is not novel, because many bills affecting the use of animals in research have been introduced on numerous occasions in the past; in fact, there are at least three other bills in the present Congress which also have as their objective the reduction or elimination of the use of animals in biomedical research (H.R. 282, H.R. 4479, and H.R. 6847).

What makes H.R. 4805 relatively novel is the appealing approach embodied in the preamble of the bill which states that a national center is to be established to develop and coordinate "alternative methods of research and testing" which do not involve the use of live animals.

Those of our readers who have occasion to see *Science*, the weekly publication of the American Association for the Advancement of Science, may have noted an article which appeared in the May 9, 1980 issue. The article was entitled "Legislating an End to Animals in the Lab," and it carried the subtitle "A bill backed by animal-rights activists could all but outlaw federally funded research using cats, rats, dogs, rabbits . . . ." This article brought into sharp focus the potential impact of the legislation should it be successfully enacted. Moreover, the article likewise revealed the intense support being given the legislation by antivivisectionists and other animal-rights activists.

On the other hand, from our perception we have seen relatively little discussion of this legislation in the scientific or technical press, nor have we heard much mention of it at scientific or technical meetings. Yet, as brought out in the article in *Science*, "Those in the scientific establishment (who have studied the bill) say the impact of such legislation would be catastrophic, ..."

Certainly, the basic nature of pharmaceutical research is such that any abrupt action to diminish the availability and use of animals for research and testing purposes would have a dramatic impact on both drug research and production—animals being widely used not only as precursors to human clinical testing in drug research but also, in many instances, as test subjects in quality control monitoring of drug products in production.

There is no question but that appropriate care, humane treatment, good housing, and a healthy environment must be accorded all research animals. Any noncompliance calls for stringent measures of regulatory enforcement against the violators. Happily, extensive progress had been made in these areas fully a generation ago, and present conditions of animal treatment in virtually all research centers are at a high level and generally in compliance with current legislation dealing with humane care and housing.

Furthermore, simple economic considerations have provided the scientific community with a strong incentive to devise and adopt *in vitro* methods to replace *in vivo* procedures wherever possible. *In vitro* methods are generally less expensive to conduct; they are more consistent and uniform; and their results are generally considerably more accurate. Hence, even in the absence of animal-rights considerations, there is strong motivation for science to replace animal test procedures with alternative methodology wherever possible.

The primary purpose of this editorial is not to serve as a defense for the use of animals in pharmaceutical research and testing. Our readers are fully cognizant of the importance of the use of animals for such purposes. Indeed, many of our readers are personally engaged in activities which involve their directly working with animals on a regular basis.

What we do wish to achieve by this editorial is the alerting of the pharmaceutical scientific community to the existence of this major legislative threat and the probable severity of the results if this innocent-sounding legislation were to be enacted.

It has only been within the last few months that regulatory measures were finalized to eliminate the use of prisoners in drug research as of June 1, 1981. This development is already having severe impact on human clinical research in the United States. If legislation of the sort now before the Congress were enacted relative to ending the use of animals in the laboratory, the ultimate impact would even dwarf that resulting from the regulatory action eliminating the use of prisoners.

Those of our readers who have occasion to see *Science*, the weekly publication of the American Association for the Advancement of Science, may have noted an article which appeared in the May 9, 1980 issue. The article was entitled "Legislating an End to Animals in the Lab," and it carried the subtitle "A bill backed by animal-rights activists could all but outlaw federally funded research using cats, rats, dogs, rabbits . . . ." This article brought into sharp focus the potential impact of the legislation should it be successfully enacted. Moreover, the article likewise revealed the intense support being given the legislation by antivivisectionists and other animal-rights activists.

On the other hand, from our perception we have seen relatively little discussion of this legislation in the scientific or technical press, nor have we heard much mention of it at scientific or technical meetings. Yet, as brought out in the article in *Science*, "Those in the scientific establishment (who have studied the bill) say the impact of such legislation would be catastrophic, ..."

Certainly, the basic nature of pharmaceutical research is such that any abrupt action to diminish the availability and use of animals for research and testing purposes would have a dramatic impact on both drug research and production—animals being widely used not only as precursors to human clinical testing in drug research but also, in many instances, as test subjects in quality control monitoring of drug products in production.

There is no question but that appropriate care, humane treatment, good housing, and a healthy environment must be accorded all research animals. Any noncompliance calls for stringent measures of regulatory enforcement against the violators. Happily, extensive progress had been made in these areas fully a generation ago, and present conditions of animal treatment in virtually all research centers are at a high level and generally in compliance with current legislation dealing with humane care and housing.

Furthermore, simple economic considerations have provided the scientific community with a strong incentive to devise and adopt *in vitro* methods to replace *in vivo* procedures wherever possible. *In vitro* methods are generally less expensive to conduct; they are more consistent and uniform; and their results are generally considerably more accurate. Hence, even in the absence of animal-rights considerations, there is strong motivation for science to replace animal test procedures with alternative methodology wherever possible.

The primary purpose of this editorial is not to serve as a defense for the use of animals in pharmaceutical research and testing. Our readers are fully cognizant of the importance of the use of animals for such purposes. Indeed, many of our readers are personally engaged in activities which involve their directly working with animals on a regular basis.

What we do wish to achieve by this editorial is the alerting of the pharmaceutical scientific community to the existence of this major legislative threat and the probable severity of the results if this innocent-sounding legislation were to be enacted.

It has only been within the last few months that regulatory measures were finalized to eliminate the use of prisoners in drug research as of June 1, 1981. This development is already having severe impact on human clinical research in the United States. If legislation of the sort now before the Congress were enacted relative to ending the use of animals in the laboratory, the ultimate impact would even dwarf that resulting from the regulatory action eliminating the use of prisoners.

Synthesis, Stereochemical Analysis, and Neuromuscular Blocking Activity of Selected *E,E*- and *Z,Z*-Isomeric *O*-Ethers of 4-Androstene-3,17-dione Dioximes

DAVID B. GARCIA *§, ROBERT G. BROWN ‡, and JAIME N. DELGADO ‡x

Received March 29, 1979, from the **College of Pharmacy, Idaho State University, Pocatello, ID 83209,* and the ‡*College of Pharmacy, University of Texas at Austin, Austin, TX 78712.* Accepted for publication December 28, 1979. §Present address: Alcon Laboratories, Product Services Chemistry, Fort Worth, TX 76134.

Abstract □ A number of selected geometric oxime ethers were synthesized as potential neuromuscular blocking agents. The study consisted of the synthesis, separation, and stereochemical analysis of selected compounds followed by a preliminary pharmacological evaluation for neuromuscular blockade. Synthesis of the compounds began with the double oximination of 4-androstene-3,17-dione followed by TLC, column chromatography, and fractional crystallization as the purification methods. These procedures yielded two of the possible four isomers. Configurational assignments on the isolated pair were based on experiments using IR, UV, and NMR spectroscopy. Isomerically pure diethers were prepared by two methods: (*a*) *O*-alkylation of the stereochemically pure dioximes with the appropriate aminoalkyl halide, and (*b*) *O*-alkylation of the dioxime mixture followed by quaternization and subsequent isolation of configurationally pure salts *via* fractional crystallization. A preliminary pharmacological evaluation was conducted by using mice on a treadmill apparatus. Some structure–activity relationships are discussed.

Keyphrases □ 4-Androstene-3,17-dione dioximes—*E,E*- and *Z,Z*-isomeric *O*-ethers, synthesis, stereochemical analysis, and evaluation for neuromuscular blocking activity □ Neuromuscular blocking agents, potential—*E,E*- and *Z,Z*-isomeric *O*-ethers of 4-androstene-3,17-dione dioximes, synthesis, stereochemical analysis, and pharmacological testing

Recent reports from these laboratories discussed oxime derivatives possessing significant anticholinergic activity (1–4). Furthermore, some of the studies (3, 4) supported the idea that the isomeric character of the oxime function results in potency differences among isomeric pairs that could characterize further the cholinergic receptor. On the basis of these findings, this investigation was initiated to study the neuromuscular blockage and receptor activity of oxime ethers.

The oximino ethers chosen were derived from 4-androstene-3,17-dione dioxime and are bisquaternary ammonium compounds (I). These compounds differ from the more classical neuromuscular blocking agents in that their quaternary nitrogens are bridged by 17 or 19 atoms instead of the usual nine to 11 atoms. This feature places the series in the second peak of potency reported by Barlow and Zoller (5).

DISCUSSION

Synthesis and Resolution—The dioximes of 4-androstene-3,17-dione were prepared in good yield using a reported method (6). This method was applied on the assumption that four geometrical isomers would result (II–V). However, numerous attempts by several methods failed to produce four compounds. TLC, column chromatography, and fractional crystallization proved to be suitable and yielded apparently two isomerically pure compounds (fast and slow[1]). NMR spectroscopy (PMR and ^{13}C-NMR) was utilized to verify their isolation.

[1] Fast and slow designate the relative migration rates of the two compounds on the TLC plates.

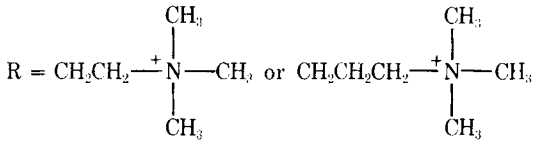
I

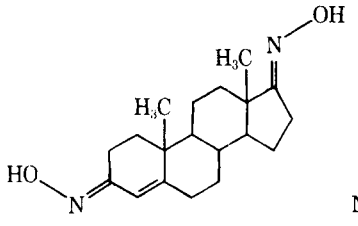


The isolation (and the apparent existence of only two of the possible four isomers) is perplexing since the dioximes that were isolated and stereochemically characterized possess all possible configurations at each oxime site. Furthermore, earlier studies (7–10) involving steroid monooximes showed that the isomeric pairs are separable and distinguishable using available methods. At present, the possibility of specific stereochemical conversion of the *Z,E*- and *E,Z*-isomers to the *E,E*- and *Z,Z*-isomers, respectively, is under consideration. This conversion may be a consequence of the isolation or purification procedures. Indirect evidence for this hypothesis comes from PMR data, which clearly show that the two zones obtained from a dry silica gel column represent configurationally pure compounds. The dioxime mixture is readily distinguishable, with respect to all configurations at both oxime sites, when subjected to PMR analysis.

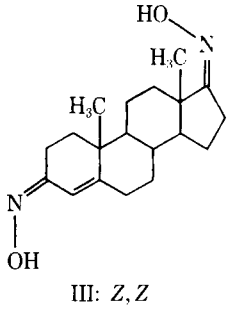
Two general methods were used in the preparation of isomerically pure oxime ethers. Method A utilized isomerically pure dioximes followed by *O*-alkylation with the appropriate aminoalkyl halide. Method B generated a mixture of ethers from *O*-alkylation of isomerically mixed dioximes. Stereochemically pure material in Method B was obtained by exhaustive quaternization of the free base followed by fractional crystallization.

Stereochemical Analysis—Because of the importance of the stereochemical features of the oxime ethers to the research objectives, several methods were used to identify the configurations at each oxime site. Configurational characterization was restricted mainly to the dioximes and was based on NMR, IR, and UV spectroscopy.

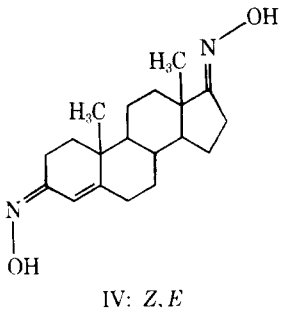
Preliminary NMR Data—There is evidence that, in some cases, proximity of an electronegative atom such as oxygen causes deshielding of protons on adjacent groups (11, 12). Karabotsos *et al.* (13) noted that the α-methylene protons and the imino proton experience greater deshielding as a consequence of the oxime hydroxyl group being in closer proximity; the β-methylene protons are reported to experience a shielding effect under the same conditions (Fragment A). These effects on the α- and β-protons have been verified for this system in carbon tetrachloride,



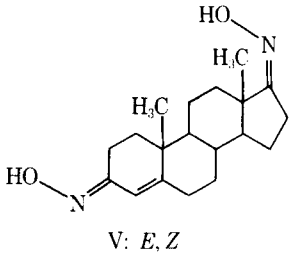
II: *E,E*



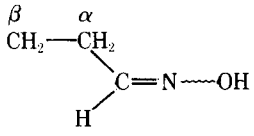
III: *Z,Z*



IV: *Z,E*



V: *E,Z*



Fragment A

benzene, methylene bromide, and nitrobenzene. The effect on the imino proton appears to be independent of the solvent and the structure. Whereas the imino proton can be used confidently to determine *E*- and *Z*-configurations, assignments based on α- and β-protons are complicated because the structure as well as the solvent reverses the resonance of *E*- and *Z*-hydrogens.

In the present study, preliminary NMR data on the dioximes were generated in dimethyl sulfoxide. A previous study on the oximes of isophorone (compounds resembling the A-ring of the dioximes) supports the suggestion that closer proximity of the oxime hydroxyl group causes deshielding of protons on adjacent groups of the dioximes (11).

For the fast isomer, the chemical shifts were δ 5.63 and 0.94 for the olefinic and 18-methyl protons, respectively. For the slow isomer, the chemical shifts were δ 6.26 and 0.98, respectively.

With the assumption that closer proximity of the oxygen to a group causes deshielding of protons on that group, tentative configurational assignments of *E,E* and *Z,Z* were made for the fast and slow isomers, respectively.

Aromatic Solvent-Induced Shifts—To support the tentative configurational assignments, the two compounds were analyzed *via* the technique of aromatic solvent-induced shifts. Wolkowski *et al.* (14) reported data derived from this technique that allowed identification of the oximes of isophorone.

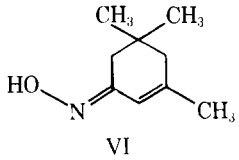
Using the formula $\Delta\delta = \nu CCl_4 - \nu C_6D_6$, Wolkowski *et al.* (14) obtained $\Delta\delta$ values of −21 and −14 Hz for the olefinic proton of the *Z*-(VII) and *E*-(VI) isomers, respectively. By utilization of the same formula, with the substitution of deuterochloroform for the aliphatic solvent and pyridine (*d*-5) for the aromatic solvent[2], similar calculations were conducted on data derived from the isolated oximes. The fast isomer demonstrated $\Delta\delta$ values of −24 and −3.4 Hz for the olefinic and 18-methyl protons, respectively. The slow isomer showed $\Delta\delta$ values of −32 and −4.4 Hz for the same parameters. Since Wolkowski *et al.* obtained greater negative values for the *Z*-isomer of isophorone oxime, the data indicate that the fast isomer has the *E,E*-configuration and the slow isomer must possess the *Z,Z*-configuration.

NMR Shift Studies—Earlier investigations (15) involving the oximes of isophorone and the shift reagent tris(dipivalomethanato)europium revealed that a greater shift of the olefinic proton is found in the *Z*-isomer. Wolkowski *et al.* (14) extrapolated to an equimolar concentration of the shift reagent and obtained shifts of 27.0 and 22.0 ppm for the *Z*- and *E*-isomers, respectively. However, in the present study, in which the shift reagent tris(1,1,1,1,1,2,2-heptafluoro-7,7-dimethyloctanedione)-europium and the oximes of isophorone were used, the opposite effect was observed (*i.e.*, a greater shift of the olefinic proton in the *E*-isomer). No attempt was made to investigate this apparent anomaly.

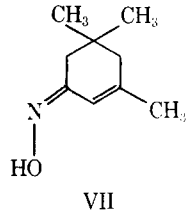
Subjecting the dioximes of 4-androstene-3,17-dione to a similar study using the shift reagent tris(1,1,1,1,1,2,2-heptafluoro-7,7-dimethyloctanedione)europium resulted in a greater shift of the olefinic and 18-methyl protons in the fast isomer compared to the shifts in the slow isomer. Since the olefinic proton of the *E*-isomer in isophorone oxime also exhibited greater movement using the same shift reagent, it was concluded that the fast isomer also must possess the *E*-configuration on the A-ring.

The assignments of *E*- and *Z*-configurations at the D-ring to the fast and slow isomers, respectively, unfortunately were not substantiated with a model shift study; consequently, the evidence is not as strong.

IR Data—Several factors have been cited as affecting the stretching



VI



VII

[2] The equation $\Delta\delta = \nu_{aliphatic} - \nu_{aromatic}$ also applies to the substitution of chloroform for carbon tetrachloride and of pyridine for benzene.

frequency of the carbonyl group (16). The position of this particular band in the IR spectrum can be affected by the physical state, electrical and mass effect, conjugation, hydrogen bonding, and ring strain. Since the same factors also are expected to affect the oximino function (C=N) in the same qualitative manner, generalities that apply to a carbonyl system were extrapolated to the oximino systems of the dioximes.

Since ring strain tends to raise the frequency of the C=N group, the higher frequencies in the region of the C=N frequency were assigned to the C=N group of the D-ring. Configurational assignments on the D-ring were made on the basis of data reported by Göndös *et al.* (9). After establishing the configuration of some 17-oximino steroids *via* the Beckman rearrangement reaction, these investigators assigned the higher frequency to the *E*-isomer. Thus, the slow isomer in the present work, which exhibited a frequency of 1681 cm^{-1}, was assigned the *Z*-configuration; the fast isomer, which displayed a frequency of 1704 cm^{-1}, was assigned the *E*-configuration.

By inspection of the oxime function on the A-ring using Dreiding stereomodels, it was noted that more steric hindrance would be realized if the oxime hydroxyl group were in the *Z*-configuration. Since steric hindrance tends to interfere with the coplanarity of the conjugated system, a higher frequency was expected for the isomer with the *Z*-configuration at this site. For the fast isomer, a singlet was recorded at 1634 cm^{-1}; for the slow isomer, a doublet was found at 1642 and 1618 cm^{-1}.

Of significance in these recordings is the fact that the slow isomer did show one elevated frequency (1642 cm^{-1}), but perhaps more informative is the observation that a distinct doublet was detected. This observation possibly could indicate a hybrid situation where perfect overlap between the C=N and C=C groups is not allowed because of the *peri-peri* interactions encounted by the oxime hydroxyl group and the olefinic hydrogen. Thus, on this basis, the slow isomer must be assigned the *Z*-configuration and the fast isomer must have the *E*-configuration.

UV Data—Since oximes show no absorption in the UV spectrum for the C=N group unless it is involved in conjugation (17), the UV analysis was restricted to the oxime function on the A-ring. In this connection, certain α,β-unsaturated carbonyl compounds have been known to possess lower absorptivities when the coplanarity is affected unfavorably (18). Therefore, a lower absorptivity for the *Z*-isomer is expected since, in this isomer, the oxime hydroxyl group would interact significantly with the olefinic hydrogen. Experimentally, the faster isomer demonstrated an absorptivity of 26,898; the slow isomer registered an absorptivity of 22,943. Therefore, the fast isomer was assigned the *E*-configuration and the slow isomer must have the *Z*-configuration at the C-3 oxime site. These assignments are in complete agreement with NMR and IR data.

Conclusion—Based on the evidence, it is concluded that the fast and slow isomers must possess *E,E*- and *Z,Z*-configurations, respectively. These assignments are substantiated by the rule predicting the isomeric ratio (19). The rule predicts that the more nearly equal in bulk the substituent groups attached to the oxime function are, the more nearly equal will be the isomeric ratio.

Oxime Ethers—Studies in these laboratories (3, 4) showed that oximes in general are relatively configurationally stable to the etherification reaction. Thus, in the systems investigated, starting with a configurationally pure oxime will yield a configurationally enriched oxime ether. In the present study, etherification of configurationally enriched dioximes did not produce detectable levels of alternate configurations, as evidenced by PMR spectroscopy. For example, the *Z,Z*- and *E,E*-isomers of the *N,N*-dimethylaminopropyl ethers (free bases) are readily distinguishable by comparison of the chemical shifts for the olefinic protons and the 18-methyl protons. In the *Z,Z*-isomer, the δ values were 5.56 and 1.03, respectively; for the *E,E*-isomer, the same groups had δ values of 6.22 and 1.01.

NMR analysis also was conducted on the quaternary ammonium salts to ensure the configurational purity of the final compounds.

EXPERIMENTAL[3]

Synthesis—4-Androstene-3,17-dione dioximes were prepared according to the method of Crabbé *et al.* (6).

Oxime Ethers—Two general methods were employed for the preparation of isomerically pure oxime ethers. The first method consisted of reacting isomerically pure dioximes (as determined by TLC and NMR spectroscopy) with the appropriate aminoalkyl halide. No problems with configurational conversion were encountered. The second method involved etherification of the mixture of the two dioximes with the appropriate aminoalkyl halide followed by quaternization and fractional crystallization of the mixture produced. Both methods were reliable.

All ethers were prepared by first dissolving the appropriate dioxime in absolute ethanol followed by the addition of the base, potassium *tert*-butoxide. The proper aminoalkyl halide hydrochloride then was added in one portion. All solutions were refluxed and stirred for the prescribed time in a three-necked flask. Subsequent to the reaction interval, the solutions were filtered by suction and evaporated on a rotary evaporator *in vacuo*. This general procedure afforded an oily residue. Variations in reactant quantities and specific procedures, as applicable to the individual ethers, will be given; physical data also are included.

Quaternization of the free bases was effected by dissolving the oily material in absolute ethanol in the presence of excess methyl bromide. The salts were purified by crystallization from a mixture of absolute ethanol and isopropyl ether.

E,E-*4-Androstene-3,17-di*(N,N-*dimethylaminoethyl oximino ether*) *Dimethobromide* (*VIII*)—*E,E*-4-Androstene-3,17-dione dioxime (1.65 g, 0.0052 mole) was dissolved in 90 ml of absolute ethanol. Potassium *tert*-butoxide (2.33 g, 0.021 mole) and 2-dimethylaminoethyl chloride (1.5 g, 0.0104 mole) then were added with constant stirring. After 4.5 hr, the solvent was evaporated, giving an oily residue that was treated with two 25-ml portions of isopropyl ether. Separation of the isopropyl ether layers and evaporation gave a material that subsequently was treated with 20 ml of petroleum ether. The petroleum ether extract was cooled in an acetone–dry ice bath and then removed and allowed to warm to room temperature. Decanting and subsequent evaporation of the warmed petroleum ether extract yielded the first crop of the dioximino ether.

All of the material that was not soluble in the petroleum ether or isopropyl ether was solubilized in ~20 ml of dimethyl sulfoxide and extracted with five 20-ml portions of petroleum ether. Small amounts of water were added between each extraction to reduce the solubility of the ether in the dimethyl sulfoxide. The petroleum ether extracts were combined and treated as before using the acetone–dry ice bath. Evaporation of the petroleum ether yielded a second crop. This procedure yielded a total of 0.7 g of the dioximino ether (29.3% yield); IR: λ_{max} (neat) 1619 (C=N, conjugated), 1667 (C=N, unconjugated), and 1035 (O—C) cm^{-1}; NMR[4]: δ 1.04 (s, 3H, 18-methyl), 2.19 (s, 12H, *N*-methyl protons), ~2.50 (β-methylene protons from both side chains; two almost overlapping A_2X_2 systems), and 5.58 (s, 1H, HC=).

The methobromide salt melted at 221° dec. and was analyzed for carbon, hydrogen, and nitrogen.

Anal.—Calc. for $C_{29}H_{52}Br_2N_4O_2$: C, 53.70; H, 8.08; N, 8.64. Found: C, 53.79; H, 8.13; N, 8.38.

Z,Z-*4-Androstene-3,17-di*(N,N-*dimethylaminoethyl oximino ether*) *Dimethobromide* (*IX*)—A mixture of *Z,Z*- and *E,E*-4-androstene-3,17-dione dioximes (3.0 g, 0.0095 mole) was dissolved in 80 ml of absolute ethanol. While stirring, potassium *tert*-butoxide (4.32 g, 0.039 mole) and 2-dimethylaminoethyl chloride (2.77 g, 0.019 mole) were added. The reaction was allowed to proceed for 8 hr, giving an oily residue upon evaporation of the solvent. The crude product was extracted with several portions of petroleum ether, and the extracts were combined and chilled in an acetone–dry ice bath to precipitate impurities. After the petroleum ether extracts warmed to room temperature, the solvent was decanted and evaporated. This procedure yielded 2.3 g of the ether (40.0% yield).

The oil obtained was dissolved in ~80 ml of absolute ethanol. Excess methyl bromide was added to the alcoholic solution followed by standing for several hours in a stoppered flask. Isopropyl ether was added to the solution of the methobromide salt until cloudiness persisted, and the milky solution was placed on a hot plate until the cloudiness dissipated. Allowing the solution to cool slowly over ~10 hr gave the first crop (0.65 g) of crystals, characterized (*via* NMR) as a mixture of *Z,Z*- and *E,E*-isomers in a 2:1 ratio.

A second crystallization in the same manner afforded a material in which no *E,E*-isomer was detectable. This material was recrystallized four times to ensure the isomeric purity of the product, mp 251° dec.; IR: λ_{max}[3] 1619 (C=N, conjugated), 1646 (C=N, unconjugated), and 1084 (C—O) cm^{-1}; NMR[5]: δ 1.09 (s, 3H, 18-methyl), 3.10 (s, 18H, *N*-methyl protons), and 6.26 (s, 1H, HC=).

[3] Melting points are uncorrected; a Thomas-Hoover Uni-Melt apparatus was used. Elemental analysis were conducted by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y. IR spectra were obtained with a Beckman IR-8 spectrophotometer; spectra of oils were obtained using sodium chloride windows; spectra of salts utilized potassium bromide dispersion pellets. PMR spectra were produced on Varian A-60, Varian 100-MHz, and Jeol C-60hl spectrometers. ^{13}C-NMR spectra were taken on a Bruker WH 90 spectrometer. Optical rotations were obtained with a Perkin-Elmer 141 polarimeter.

[4] Chloroform-*d*; tetramethylsilane was the reference.

[5] Dimethyl sulfoxide-*d* was the solvent; the pentet for dimethyl sulfoxide-*d* at δ 2.5 was used as the reference.

Anal.—Calc. for $C_{29}H_{52}Br_2N_4O_2$: C, 53.70; H, 8.08; N, 8.64. Found: C, 53.63; H, 8.20; N, 8.47.

E,E-*4-Androstene-3,17-di*(N,N-*dimethylaminopropyl oximino ether*) *Dimethobromide* (*X*)—*E,E*-4-Androstene-3,17-dione dioxime (3.0 g, 0.0095 mole) was reacted with potassium *tert*-butoxide (4.3 g, 0.0383 mole) and 3-dimethylaminopropyl chloride (3.0 g, 0.019 mole). A reaction time of ~18 hr was allowed. After filtration and evaporation of the solvent, the resulting material was extracted with 150 ml of petroleum ether. The extract was cooled in an acetone–dry ice bath, allowed to come to room temperature, and decanted; the solvent was evaporated to yield a viscous yellow oil. Further purification was effected by redissolving the material in 40 ml of petroleum ether followed by a second cooling in the acetone–dry ice bath, decantation, and evaporation as already described.

A second crop of the desired material was obtained by dissolving all of the material that was not soluble in the petroleum ether in 17 ml of dimethyl sulfoxide. Several extractions of the dimethyl sulfoxide with petroleum ether afforded additional material, which was purified by employing the acetone–dry ice bath as described. Small amounts of water were added between extractions. The total yield was 2.1 g (35.0% yield); IR: λ_{max} (neat) 1634 (C=N, conjugated), 1730 (C=N, unconjugated), and 1044 (C—O) cm^{-1}; NMR[6]: δ 1.03 (s, 3H, 18-methyl), 2.11 (s, 12H, *N*-methyl), 3.88 (γ-methylene protons from both side chains; two overlapping A_2X_2 systems), and 5.56 (s, 1H, HC=).

Quaternization of the free base followed by crystallization from a mixture of absolute ethanol and isopropyl ether gave a salt that melted at 244° dec.

Anal.—Calc. for $C_{31}H_{56}Br_2N_4O_2$: C, 55.02; H, 8.34; N, 8.29. Found: C, 55.39; H, 8.36; N, 8.28.

Z,Z-*4-Androstene-3,17-di*(N,N-*dimethylaminopropyl oximino ether*) *Dimethobromide* (*XI*)—The *Z,Z*-dioxime of 4-androstene-3,17-dione (2.0 g, 0.0063 mole) was dissolved in 80 ml of absolute ethanol. Potassium *tert*-butoxide (2.85 g, 0.0254 mole) and 3-dimethylaminopropyl chloride (2.0 g, 0.0127 mole) were added, and the mixture was allowed to reflux for 23 hr. The oily residue that resulted after evaporation of the alcohol was extracted several times with petroleum ether. The petroleum ether extracts were combined, and the solvent was evaporated, yielding an oily residue.

The residue was purified further by retreating it with petroleum ether followed by separation of the ether layer and evaporation. This procedure was continued until only petroleum ether-soluble material remained. The procedure yielded 1.4 g of a viscous yellow oil (35% yield), mp 236° dec.; IR: λ_{max} (neat) 1634 (C=N, conjugated), 1734 (C=N, unconjugated), and 1044 (C—O) cm^{-1}; NMR[6]: δ 1.01 (s, 3H, 18-methyl), 2.11 (s, 12H, *N*-methyl protons), 4.08 (γ-methylene protons from both side chains; two overlapping A_2X_2 systems), and 6.22 (s, 1H, HC=).

Crystallization of the methobromide salt from absolute alcohol and isopropyl ether yielded an analytically pure sample.

Anal.—Calc. for $C_{31}H_{56}Br_2N_4O_2$: C, 55.03; H, 8.34; N, 8.28. Found: C, 54.82; H, 8.63; N, 7.98.

Separation Procedures (Dioximes)—*Method I* (*TLC*)—Separation by TLC was accomplished using a cylindrical developing chamber (25 × 5.5 cm) lined with filter paper to enhance saturation. The developing solvent consisted of benzene–ethyl acetate (10:3). Silica gel strips[7] (20 cm) were activated for 30 min at 110° and allowed to cool in a desiccator. After the system reached equilibrium (1 hr), the plates were developed to a distance of 15 cm, resulting in two distinct zones. The fast isomer was at R_f 0.17, and the slow isomer was at R_f 0.11.

Method II (*Dry Column Chromatography*)—With the same solvent system described for TLC and silica gel[8] as the support, column chromatography afforded semipreparative amounts of isomerically pure dioximes.

Method III (*Fractional Crystallization*)—4-Androstene-3,17-dione dioxime (mixture) (10.7 g) was dissolved in 425 ml of hot acetone and filtered. The solution was placed in a 500-ml beaker and covered with aluminum foil. Several small holes were provided near the center of the foil to allow slow and controlled evaporation of the acetone. When the solvent had reached the 350-ml level, the acetone was decanted and the crystals that had formed were washed with 5 ml of fresh acetone.

This first crop amounted to 2.2 g of the fast isomer with traces of the slow isomer. A second crystallization from the same solvent afforded 1.7 g of the fast isomer. The mother liquor was allowed to evaporate further in the manner described until the solvent level reached 250 ml. A second crop was obtained and identified as the slow isomer (0.8 g). Further evaporation yielded crystals that were a mixture of both isomers. This procedure gave two analytically pure samples.

The fast isomer had a melting point of 223° dec.; $[\alpha]_D^{25}$ +231° (methanol, 0.32%); UV: λ_{max} (methanol) 241 (ϵ 26,898) nm; IR[3]: λ_{max} 1634 (C=N, conjugated) and 1704 (C=N, unconjugated) cm^{-1}; NMR[5]: δ 0.780 (s, 3H, 19-methyl), 0.940 (s, 3H, 18-methyl), 5.626 (s, 1H, CH=), 9.930 [s, 1H, HO—N=C (D-ring)], and 10.326 [s, 1H, HO—N=C (A-ring)].

Anal.—Calc. for $C_{19}H_{28}N_2O_2$: C, 72.11; H, 8.92; N, 8.86. Found: C, 72.02; H, 8.89; N, 8.59.

The slow isomer melted at 223–226° dec.; $[\alpha]_D^{25}$ +132° (methanol, 0.23%); UV: λ_{max} (methanol) 243 (ϵ 22,943) nm; IR[3]: λ_{max} 1642 and 1618 (C=N, conjugated) and 1681 (C=N, unconjugated) cm^{-1}; NMR[5]: δ 0.780 (s, 3H, 19-methyl), 0.976 (s, 3H, 18-methyl), 6.259 (s, 1H, CH=), 9.930 [s, 1H, HO—N=C (D-ring)], and 10.026 [s, 1H, HO—N=C (A-ring)].

Anal.—Calc. for $C_{19}H_{28}N_2O_2$: C, 72.11; H, 8.92; N, 8.86. Found: C, 72.29; H, 9.09; N, 8.79.

NMR Shift Studies (Dioximes)—Five milligrams of each dioxime was weighed accurately and dissolved separately in 0.5 ml of deuterochloroform. To each sample was added accurately 0.007 ml of a 10% methanol solution in carbon tetrachloride using a microsyringe[9]. Minimal tetramethylsilane was added to avoid precipitation of the sample. Seven spectra were obtained on each sample, with increasing amounts of tris(1,1,1,1,1,2,2-heptafluoro-7,7-dimethyloctanedione)europium added to effect shifts on the signals[10] of the olefinic proton and C-18 methyl protons.

PHARMACOLOGY

Method—The rolling (rotarod) apparatus was used to evaluate neuromuscular blockade. This device was first described by Dunham and Miya (20), who mentioned the possibility of using such an apparatus to detect muscular relaxation. Subsequent reports (21–24) discussed the use of this method to quantify motor incoordination in laboratory animals under the influence of various drugs. Although this method is not specific for the evaluation of neuromuscular blocking agents, it does provide a reliable and simple screening avenue for such agents.

Female albino mice [Sprague–Dawley SH:ARA (ICR) f], 17–29 g, were used to evaluate the neuromuscular blocking activity of the synthesized compounds. The mice were injected intraperitoneally with solutions of the methyl bromide salts of the compounds in double-distilled water. Approximately 0.1 ml of the solution was used to deliver each dose. Immediately after injection, the mice were placed on a rotating motorized drum (7.150 rpm) and the time was recorded.

To eliminate a prolonged training period for each animal, the drum design included a screen wire walking surface with a diameter of 11.4 cm and partitions (17.8 cm in diameter) isolating each animal. A maximum of 30 min was allowed to record observations. If the animal was unable to remain on the rotating drum for the allotted time, a positive response was recorded; no response was noted if the animal remained the full time. No positive responses were observed with the control group that had been injected previously with double-distilled water.

Because the stock solutions lost significant potency over 24 hr, all stock solutions were used within 8 hr; dilutions from the stock solution were used immediately. All stock solutions were made by weighing at least 30 mg of each compound followed by dissolution with an appropriate volume of double-distilled water. Four doses (10 animals per dose) were used for all compounds tested.

The Litchfield–Wilcoxon method (24) was employed for the statistical evaluation of the data and the fitting of curves.

Results—The pharmacological data provided the following information.

1. The slopes of all curves, including the one for decamethonium, were not significantly different (95% confidence limits).
2. The *Z,Z*-isomers were significantly more potent than the *E,E*-isomers.
3. With respect to potency, the molecular modification from the ethylamino side chains to the propylamino side chains was more significant in *Z,Z*-isomerism (the propylamino homolog was more potent).
4. All of the compounds were considerably more potent than decamethonium.
5. The oxime ethers had a slower onset of action compared to decamethonium.

[6] Carbon tetrachloride; tetramethylsilane was the reference.

Table I—Summary of Pharmacological Data

Compound[a]	ED_{50}, μM/kg	95% Confidence Limit, μM/kg	Average Response Time, min
Decamethonium[b]	1.38	1.21–1.57	5.63
VIII: *E,E*-isomer	10.0×10^{-2}	$8.2–12.2 \times 10^{-2}$	11.5
IX: *Z,Z*-isomer	7.05×10^{-2}	$6.47–7.69 \times 10^{-2}$	9.59
X: *E,E*-isomer	9.80×10^{-2}	$9.30–10.3 \times 10^{-2}$	11.1
XI: *Z,Z*-isomer	5.10×10^{-2}	$4.81–5.41 \times 10^{-2}$	15.7

[a] As the methyl bromide salts. [b] Syncurine, Burroughs Wellcome.

Additionally, from gross observations, it appears that the compounds of this study act primarily *via* a depolarizing type of mechanism. Table I summarizes the pharmacological data.

Discussion—Since the slopes of the dose–effect curves of the synthesized compounds and of decamethonium were not significantly different, the mechanism of action must be mainly depolarizing. This conclusion was supported by gross observation of the similarity in behavioral patterns when the animals were under the influence of decamethonium or the synthesized compounds. Both decamethonium and the test compounds resulted in twitching, some piloerection, pronounced heavy deep breathing, bulging eyes, and apparent convulsions subsequent to injection with an overdose. Death always followed the convulsive episode. The behavioral pattern was readily distinguishable from that produced by the antidepolarizing agent (+)-tubocurarine.

Two observations can be made with respect to possible structure–activity relationships implying drug–receptor interactions. First, in both the ethylamino and propylamino series, the *Z,Z*-isomers were significantly more potent than the *E,E*-isomers. However, the distance between the two quaternary nitrogens in the extended conformation was not significantly altered by the isomerism in question. Given the ethylamino side chain, the intercationic distance was not significantly different between the *Z,Z*- and *E,E*-isomers. Furthermore, conformational analysis using Dreiding molecular models revealed significant conformational bulky differences among the side chains of the two isomeric pairs. In the extended conformation, the side chains in the *Z,Z*-isomers could assume an almost parallel alignment (with themselves); however, *E,E*-isomerism directed the side chains at an angle of ~90°.

Second, the molecular modification from ethylamino to propylamino side chains was more significant in *Z,Z*-isomerism. In this respect, the *Z,Z*-dipropylamino congener was significantly more potent than the *Z,Z*-diethylamino compound; the *E,E*-dipropylamino compound was equipotent with the *E,E*-diethylamino congener.

At least two factors may account for the fact that the synthesized compounds were significantly more potent than decamethonium (one compound was ~27 times more potent). Because of the greater hydrophobic to hydrophilic ratio, the steroidal compounds may interact more favorably with the proposed hydrophobic area within or in close proximity to the receptor. Moreover, the steroidal oxime ethers also have the advantage of interacting with the proposed esterophilic portions of the receptor *via* the polarized oximino function; decamethonium obviously is not able to interact by a similar mechanism.

With respect to the onset of action, these compounds were significantly slower than decamethonium, probably because their greater lipid character leads to poorer transfer in the aqueous medium of the biological system.

Inhibitors of Polyamine Biosynthesis VII: Evaluation of Pyruvate Derivatives as Inhibitors of *S*-Adenosyl-L-methionine Decarboxylase

M. PANKASKIE and M. M. ABDEL-MONEM ˣ

Received April 20, 1979, from the *College of Pharmacy, University of Minnesota, Minneapolis, MN 55455.* Accepted for publication August 6, 1979.

Abstract □ The mechanism of the enzymatic decarboxylation of *S*-adenosyl-L-methionine catalyzed by *S*-adenosyl-L-methionine decarboxylase and its inhibition by methylglyoxal bis(guanylhydrazone) were investigated. The results indicate that the carbonyl group of the pyruvate cofactor does not form an azomethine bond with an amino group of the enzyme protein. The substrate and/or product forms an azomethine bond with the pyruvate cofactor, which can be reduced efficiently with sodium cyanoborohydride. Methylglyoxal bis(guanylhydrazone) appears to interfere with the formation of the enzyme–substrate complex by competing with the substrate for binding with the active enzyme site. The dimethylaminoethylhydrazone, semicarbazone, and guanylhydrazone derivatives of pyruvic acid, ethyl pyruvate, pyruvic acid amide, and pyruvyl glycineamide were synthesized. None of these compounds had significant inhibitory activity on the enzymatic decarboxylation of *S*-adenosyl-L-methionine by *S*-adenosyl-L-methionine decarboxylase from rat liver *in vitro*. These results indicate that the structural requirements for binding of methylglyoxal bis(guanylhydrazone) to the enzyme are strict and that structural modifications of this compound result in a dramatic loss of activity.

Keyphrases □ *S*-Adenosyl-L-methionine decarboxylase—inhibition by pyruvate derivatives □ Enzyme inhibition—effects of pyruvate derivatives on *S*-adenosyl-L-methionine decarboxylase

The polyamines appear to play an essential role in cellular metabolism and cell proliferation (1). Selective inhibitors of polyamine biosynthesis have produced antiproliferative activity in cell culture (2) and *in vivo* (3). Most of the compounds studied have been inhibitors of L-ornithine decarboxylase, the rate-controlling enzyme in the biosynthesis of the polyamines (4). Only a few inhibitors of *S*-adenosyl-L-methionine decarboxylase, the second enzyme in the synthetic pathway of polyamines, have been studied (5, 6). Therefore, studies to develop specific inhibitors of mammalian, putrescine-activated *S*-adenosyl-L-methionine decarboxylase were initiated.

This report presents a tentative scheme for catalysis by *S*-adenosyl-L-methionine decarboxylase and a possible mechanism of its inhibition by methylglyoxal bis(guanylhydrazone) (I*a*). The synthesis of some pyruvate derivatives structurally similar to I*a* and evaluation of them as inhibitors of enzymatic decarboxylation of *S*-adenosyl-L-methionine by the decarboxylase from rat liver also are reported.

BACKGROUND

The identification of covalently bound pyruvate in rat liver *S*-adenosyl-L-methionine decarboxylase was reported recently in two studies (7, 8). The pyruvate group appears to be essential for the catalytic activity of the enzyme and probably is involved in the formation of an azomethine bond with the amino group of the substrate, *S*-adenosyl-L-methionine, to form an intermediate (IV) (Scheme I). Previous studies with pyridoxal phosphate-dependent decarboxylases showed that the pyridoxal phosphate is linked to the ε-amino group of a specific lysyl residue by an azomethine bond and that the enzyme–substrate complex is formed by transaldimination between the enzyme–pyridoxal phosphate complex and the substrate. Unlike pyridoxal-dependent decarboxylases, the carbonyl group of the pyruvate cofactor does not form an azomethine bond with an amino group from the enzyme protein since sodium borohydride reduction of the purified enzyme results in the formation of lactic acid and not an *N*-substituted alanine.

Since studies with model systems indicated that transaldimination proceeds more rapidly than *de novo* Schiff base formation (9), the possibility of *S*-adenosyl-L-methionine decarboxylase activation by putrescine, due to the formation of the ketimine (III) between the pyruvate residue and putrescine, was explored. Transketimination between III and the substrate (II) would result in the more rapid formation of the intermediate (IV). The decarboxylation product (V) of II also may be bound to the enzyme by an azomethine bond.

Imminium compounds such as III–V could be trapped in the presence of free pyruvate residues by selective reduction with cyanoborohydride (10). Thus, the presence of such intermediates in an incubation medium containing *S*-adenosyl-L-methionine decarboxylase and the appropriate ligand could be demonstrated if a loss of enzymatic activity were observed on treatment of the mixture with sodium cyanoborohydride. This approach was used by Satre and Kennedy (11) to demonstrate the formation of a Schiff base between the amino group of phosphatidyl serine and the pyruvate residue of the enzyme as an essential step in the action of phosphatidylserine decarboxylase. Therefore, experiments were carried out to determine the effects on enzyme activity of the addition of sodium cyanoborohydride to *S*-adenosyl-L-methionine decarboxylase preparations containing the activator putrescine and/or the substrate.

EXPERIMENTAL[1]

Melting points were determined in open capillary tubes and are uncorrected. NMR spectra were taken in deuterochloroform or deuterium oxide with tetramethylsilane or sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the internal standard, respectively. Mass spectral analyses were performed at 20–70 ev and chamber temperatures of 25–200°.

Methylglyoxal Disemicarbazone (I*b*)—Methylglyoxal (2.5 g of a 40% aqueous solution) was added to a solution of semicarbazide hydrochloride (1.0 g) and sodium acetate (1.5 g) in water (25 ml). The mixture was heated on a steam bath for 30 min. The precipitate was collected by filtration, washed with warm water, and dried *in vacuo* to give I*b* (2.4 g, 95% yield), mp 252° dec. [lit. (12) mp 254°].

Anal.—Calc. for $C_5H_{10}N_6O_2$: C, 32.25; H, 5.41; N, 45.14. Found: C, 32.47; H, 5.43; N, 45.10.

Methylglyoxal Dithiosemicarbazone (I*c*)—A solution of sodium acetate (2.0 g in 10 ml of water) was added to a solution of methylglyoxal (2.5 g of a 40% aqueous solution) and thiosemicarbazide (1.0 g) in water (25 ml). The mixture was heated on a steam bath for 30 min. A heavy orange precipitate was formed and then collected by filtration. The precipitate was washed with boiling water and dried *in vacuo* overnight to give Ic (2.8 g, 93% yield), mp 250° dec. [lit. (12) mp 253°].

Anal.—Calc. for $C_5H_{10}N_6S_2$: C, 27.51; H, 4.62; N, 38.50. Found: C, 27.77; H, 4.46; N, 38.47.

Pyruvyl Glycineamide Diethyl Ketal (XI)—Ethyl pyruvate diethyl ketal was prepared from ethyl pyruvate and ethyl orthoformate according to the procedure of Wermuth and Marx (13). Ethyl pyruvate diethyl ketal (5.0 g, 26 mmoles) was treated with a 3% aqueous potassium hydroxide solution (50 ml, 30 mmoles) and stirred overnight at room temperature. The aqueous solution was made acidic by the addition of 5% HCl and extracted with ether (2 × 150 ml). The ether extract was concentrated *in vacuo* to give pyruvic acid diethyl ketal (3.5 g, 88% yield); IR (neat):

[1] Instruments used were a Thomas-Hoover melting-point apparatus, a Perkin-Elmer 281 spectrophotometer, Varian A-60D and T-60 NMR spectrophotometers, an AEI MS-30 mass spectrometer, and a Beckman LS-100C liquid scintillation counter. Elemental analyses were performed by M-H-W Laboratories, Phoenix, Ariz.

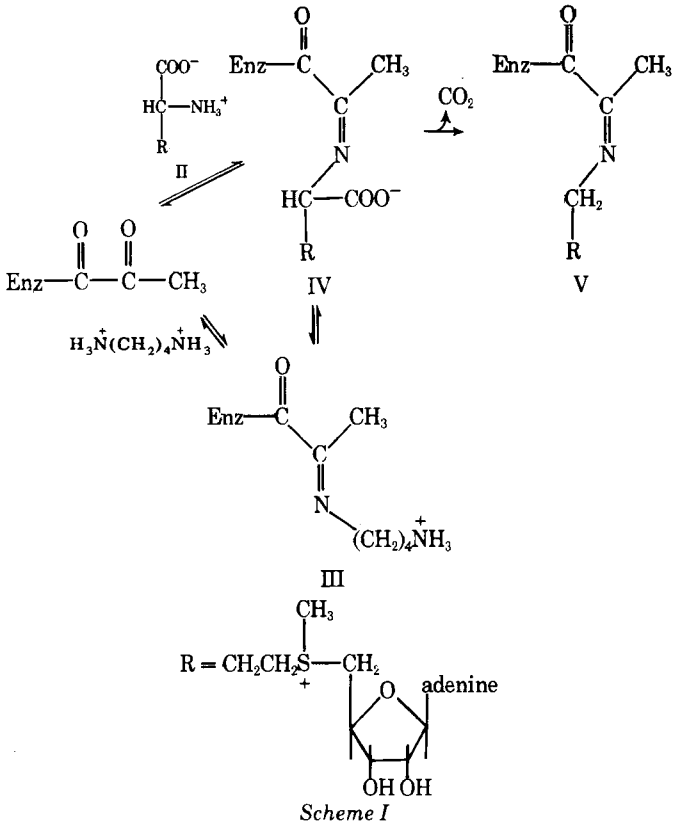

Scheme I

3200 (broad), 2985, 2930, 2895, 1740, 1450, 1370, 1150, 1040, 950, 855, and 740 cm^{-1}; NMR (deuterochloroform): δ 3.6 (m, 4H), 1.6 (s, 3H), and 1.2 (t, 6H) ppm.

A cooled (ice–salt bath) solution of pyruvic acid diethyl ketal (2.0 g, 12 mmoles) in chloroform (100 ml) was treated with triethylamine (1.25 g, 12 mmoles) and ethyl chloroformate (1.35 g, 12 mmoles), and the mixture was stirred for 20 min. The ice–salt bath was removed, and a solution of glycineamide (1.0 g, 15 mmoles) in chloroform (100 ml) was added slowly over 30 min. The reaction mixture was stirred for 4 hr at room temperature, and the chloroform solution was washed with successive portions of 10% $NaHCO_3$ and brine. The chloroform solution was dried over anhydrous sodium sulfate and evaporated to dryness *in vacuo*. The semisolid residue obtained was crystallized from boiling ether to give XI (1.6 g, 60% yield), mp 95–96°; IR (melt): 3320, 2995, 2940, 1670, 1620, 1525, 1450, 1365, 1300, 1200, 1160, 1050, and 950 cm^{-1}; NMR (deuterochloroform): δ 7.6, 6.9, and 6.2 (broad s, 3H, exchangeable with deuterium oxide), 4.0 (d, 2H), 3.5 (q, 4H), 1.5 (s, 3H), and 1.3 (t, 6H) ppm; mass spectrum: *m/e* 219 ($M^+ + 1$), 217 ($M^+ - 1$), 173, 156, 128, 117, 100, 89, 75, 61 (100%), 59, 43, and 30.

Anal.—Calc. for $C_9H_{18}N_2O_4$: C, 49.53; H, 8.31; N, 12.84. Found: C, 49.25; H, 8.49; N, 12.89.

Monoacetyl Hydrazine—Monoacetyl hydrazine was prepared according to the procedure described by Rabini and Vita (14), mp 64–65° [lit. (14) mp 62°]. This compound is hygroscopic and was stored in a vacuum desiccator over anhydrous calcium chloride granules.

***N*-Acetyl-*N*-(dimethylaminoethyl)hydrazine Dihydrochloride (XIV)**—A solution of dimethylaminoacetaldehyde diethyl acetal (XII) (5.0 g, 31 mmoles) in concentrated hydrochloric acid (10 ml) was allowed to stand overnight at 4° and then was concentrated under reduced pressure at 40°. The viscous residue was dissolved in dry methanol (100 ml) and treated with acetylhydrazine (2.5 g, 35 mmoles) and sodium cyanoborohydride (1.3 g, 20 mmoles) under nitrogen. The pH of the reaction mixture was maintained at 2–3 by the addition of methanolic hydrochloric acid, using bromcresol green as an indicator, over 6 hr at room temperature.

After concentration *in vacuo* at room temperature, the residue was dissolved in cold absolute ethanol and filtered. The filtrate was treated with ethanolic hydrochloric acid and stored at 4° overnight. The precipitated solid was filtered and dried *in vacuo* to give XIV (2.8 g, 42% yield), mp 126–128°. An analytical sample was recrystallized from 95% ethanol; IR (KBr): 3400 (broad), 300 (broad), 2040, 1715, 1630, 1460, 1380, 1230, 1000, and 800 cm^{-1}; NMR (deuterium oxide): δ 3.2 (s, 4H), 2.8 (s, 6H), and 2.0 (s, 3H) ppm; mass spectrum: *m/e* 145 ($M^+ - 2HCl$), 87, 71, 59, 58 (100%), 44, and 36.

Anal.—Calc. for $C_6H_{17}Cl_2N_3O$: C, 33.03; H, 7.86; N, 19.26. Found: C, 33.17; H, 8.07; N, 19.20.

Dimethylaminoethylhydrazine Dihydrochloride (XV)—A solution of XIV (2.0 g, 9 mmoles) was dissolved in ethanolic hydrogen chloride solution (20 ml) and warmed gently on a steam bath for 45 min. The mixture was stored at 4° overnight to give a quantitative yield of XV, mp 120–121°. The product was hygroscopic; IR (KBr): 3400 (broad), 3000, 2700, 2050, 1620, 1470, 1150, and 800 cm^{-1}; NMR (deuterium oxide): δ 3.2 (s, 4H) and 2.8 (s, 6H) ppm; mass spectrum: *m/e* 103 ($M^+ - 2HCl$), 58 (100%), 42, and 36.

Anal.—Calc. for $C_4H_{15}Cl_2N_3$: C, 27.28; H, 8.59; N, 23.86. Found: C, 27.47; H, 8.56; N, 23.96.

Dimethylaminoethylhydrazone Derivatives (VI*a*–VI*d*)—The ketone (IX*a*, IX*b*, or IX*c*) or XI (3 mmoles) was added to a solution of XV (0.5 g, 3 mmoles) in ethanol (20 ml) and allowed to stand overnight at room temperature. Ether was added dropwise to the clear solution until turbidity was observed. The mixture was stored at 4°. The precipitated solid was filtered and crystallized to give the desired products (VI*a*–VI*d*) (Table I).

Semicarbazone Derivatives (VII*a*–VII*d*)—One gram of the ketone (IX*a*, IX*b*, or IX*c*) or XI was added to a solution of semicarbazide hydrochloride (1.0 g) and sodium acetate (1.5 g) in water (25 ml). The mixture was heated on a steam bath for 15 min and allowed to stand overnight. The formed solids were filtered, recrystallized from water, and dried *in vacuo* for 12 hr to give the desired products (VII*a*–VII*d*) (Table I).

Guanylhydrazone Derivatives (VIII*a*–VIII*c*)—A suspension of aminoguanidine bicarbonate (50 mmoles) in water (50 ml) was adjusted to pH 5–6 with concentrated hydrochloric acid. Compound IX*a*, IX*b*, or IX*c* was added dropwise to the clear solution of the aminoguanidine, and the reaction mixture was stirred overnight at room temperature. The precipitated solids were filtered, crystallized, and dried overnight *in vacuo* to give the desired products (VIII*a*–VIII*c*) (Table I).

Pyruvyl Glycineamide Guanylhydrazone Hydrochloride (VIII*d*)—Aminoguanidine hydrochloride (0.25 g, 2.5 mmoles) was added to a solution of XI (0.44 g, 2 mmoles) in water (30 ml), and the mixture was heated on a steam bath for 2 hr and stored at 4° overnight. The precipitated crystalline solid was filtered and washed with ice-cold water to give VIII*d* (0.41 g, 87% yield) (Table I).

Pyruvic Acid Guanylhydrazide Guanylhydrazone Dihydrochloride (VIII*e*)—Aminoguanidine hydrochloride (6.6 g, 60 mmoles) was added to a solution of ethyl pyruvate (3.5 g, 30 mmoles) in water (25 ml), and the mixture was heated at 80° overnight. The solution was evaporated to dryness, and the residue after two crystallizations from aqueous ethanol gave VIII*e* (7.3 g, 90% yield), mp 250–251°; IR (KBr): 3200, 2950, 1670, 1590, 1490, 1440, 1420, 1370, 1300, 1150, 1120, 900, and 720 cm^{-1}; NMR (deuterium oxide): δ 1.6 (s, 3H) ppm; mass spectrum: *m/e* 182, 126, 57, 44, 43, 42, 38, and 36 (100%).

[a] Solvents used were ethanol (A), ethanol–ether (B), water (C), and ethanol–water (D). [b] Inhibition of enzymatic decarboxylation of [1-^{14}C]-*S*-adenosyl-L-methionine by partially purified *S*-adenosyl-L-methionine decarboxylase from rat liver. Compound I*a* produced 100 and 63% inhibition at 10 and 1 μ*M*, respectively. [c] See Ref. 12.

Anal.—Calc. for $C_5H_{12}N_8O$·2HCl: C, 21.99; H, 5.17; N, 41.03. Found: C, 21.73; H, 5.00; N, 40.79.

Enzyme Purification—Rat liver *S*-adenosyl-L-methionine decarboxylase was purified by the method of Pegg (15) with slight modifications. Twelve male Sprague–Dawley[2] rats (250 g) were injected intraperitoneally with methylglyoxal bis(guanylhydrazone)[3] (I*a*, 80 mg/kg) and were sacrificed by cervical dislocation 24 hr later. The livers were removed and homogenized in 200 ml of Buffer A [containing 10 m*M* tris(hydroxymethyl)aminomethane hydrochloride (pH 7.5), 2.5 m*M* putrescine, 1 m*M* dithiothreitol, and 0.1 m*M* ethylenediaminetetraacetic acid disodium] at 4°. All subsequent operations were carried out at 0–5°.

The homogenate was centrifuged at 105,000×*g* for 90 min. The supernate was treated with ammonium sulfate, and the protein fraction precipitating between 35 and 65% saturation was collected by centrifugation. The protein pellet was dissolved in the minimum amount of Buffer A, and the solution was dialyzed overnight against 4 liters of the same buffer.

A glass column (2.5 × 30 cm) was packed with Sepharose[4] linked to I*a* and washed with 200 ml of Buffer A. The dialyzed protein sample was applied to the column at a flow rate of 35–40 ml/hr, and the column was washed with 100 ml of Buffer A followed by 150 ml of Buffer A containing 0.3 *N* NaCl. The protein having *S*-adenosyl-L-methionine decarboxylase activity was eluted off the column with Buffer A containing 0.3 *N* NaCl and 1 m*M* I*a*. The column eluates were collected in 10-ml fractions, and each fraction was assayed for decarboxylase activity using 50 μl in the standard procedure.

Decarboxylase activity usually was found in fractions 4–6, with >80% of the recovered activity in fraction 5 alone. The presence of I*a* in the elution solvent greatly reduced the apparent activity of these fractions. Fractions containing decarboxylase activity were pooled, divided into 5-ml aliquots, and stored at 0–5°. The protein solution was dialyzed against two 1-liter portions of Buffer A, to remove the inhibitor (I*a*), immediately before use as a source of the decarboxylase enzyme. By using this method, an enzyme preparation having a specific activity of ~15 nmoles of carbon dioxide/min/mg of protein routinely was obtained.

Assay of *S*-Adenosyl-L-methionine Decarboxylase Activity—*S*-Adenosyl-L-methionine decarboxylase activity was determined by a modification of a literature method (16). The assay medium contained 0.1 *M* sodium phosphate buffer (pH 7.0), 2.5 m*M* dithiothreitol, 2.5 m*M* putrescine, 0.2 m*M* [1-^{14}C]-*S*-adenosyl-L-methionine (2.0 × 10^5 cpm), and the enzyme fraction[5] in a total volume of 1.0 ml. Reactions were carried out in 16 × 100-mm test tubes sealed with rubber stoppers carrying a polypropylene well[6] containing 0.3 ml of ethanolamine.

After incubation for 30 min at 37°, the reaction was terminated and [^{14}C]carbon dioxide was released by the injection of 0.5 ml of 5 *N* H_2SO_4 through the rubber stopper. The tubes were incubated for an additional 45 min at 25°, and the well and its contents were transferred into a glass scintillation vial containing 10 ml of scintillation cocktail[7]. The samples were stored in the dark overnight and then counted. All counts were corrected for the nonenzymatic production of [^{14}C]carbon dioxide, which was determined by replacing the enzyme fraction in the incubation medium with an equal volume of Buffer A. This method gave the quantitative recovery of the [^{14}C]carbon dioxide released from sodium [^{14}C]-bicarbonate.

Enzyme Inhibition—The test compounds were dissolved in water (I*a* and VI–VIII) or 5% dimethyl sulfoxide in water (I*b* and I*c*) to give 1 m*M* solutions. The incubation medium contained 0.1 *M* sodium phosphate buffer (pH 7.0), 2.5 m*M* dithiothreitol, 2.5 m*M* putrescine, 0.2 m*M* [1-^{14}C]-*S*-adenosyl-L-methionine (2.0 × 10^5 cpm), the inhibitor at concentrations of 50, 20, 10, and 1 μ*M*, and 0.1 ml of the enzyme preparation in a total volume of 1.0 ml. The amount of [^{14}C]carbon dioxide released was measured as described for the assay of *S*-adenosyl-L-methionine decarboxylase activity and corrected for the nonenzymatic release of [^{14}C]carbon dioxide. The presence of dimethyl sulfoxide in solutions of I*b* and I*c* resulted in <5% inhibition of enzymatic activity, and the final

Table II—Effects of pH and Buffer on the Recovery of *S*-Adenosyl-L-methionine Decarboxylase Activity

Buffer	Activity Remaining[a] pH 6.5	pH 7.0	pH 7.5
Tris(hydroxymethyl)aminomethane hydrochloride (10 m*M*)	69	83	58
Phosphate (100 m*M*)	86	100	75

[a] See *Experimental.*

results for these compounds were corrected for inhibition by the solvent.

Effects of pH and Buffer on Recovery of *S*-Adenosyl-L-methionine Decarboxylase Activity—The dialyzed protein fraction containing *S*-adenosyl-L-methionine decarboxylase activity was diluted with Buffer A to a concentration of 0.2 mg of protein/ml. Aliquots (0.1 ml) were diluted to 0.4 ml with one of the buffer solutions listed in Table II and incubated at 37° for 30 min. Aliquots (0.1 ml) were removed and assayed for *S*-adenosyl-L-methionine decarboxylase activity as described for the assay of *S*-adenosyl-L-methionine decarboxylase activity. The activity of the sample incubated in pH 7.0 phosphate buffer was arbitrarily assigned a value of 100, and the activities of the other samples are reported in Table II as a percentage of that activity. Incubation in pH 7.0 phosphate buffer resulted in a 10% loss of activity of the original preparation.

Effects of Different Preincubation Conditions on Recovery of *S*-Adenosyl-L-methionine Decarboxylase Activity—Protein fractions containing *S*-adenosyl-L-methionine decarboxylase activity were dialyzed against a pH 7.5 buffer containing 10 m*M* tris(hydroxymethyl)aminomethane hydrochloride, 1 m*M* dithiothreitol, and 0.1 m*M* ethylenediaminetetraacetic acid disodium. Aliquots of the dialyzed protein were diluted with buffer solution (pH 7.0) containing the additions described in Table III and incubated at 37° for 30 min.

Each sample was dialyzed against Buffer A (two 100-ml portions), and 0.1-ml aliquots of the dialyzed protein were assayed for *S*-adenosyl-L-methionine decarboxylase activity as described for the assay of *S*-adenosyl-L-methionine decarboxylase activity. The activity of the sample preincubated in the buffer with no additions was arbitrarily assigned a value of 100, and the activities of the other samples are reported in Table III as a percentage of that activity.

RESULTS

Incubation of partially purified *S*-adenosyl-L-methionine decarboxylase from rat liver at 37° in a buffer for 30 min resulted in a slight loss of activity. This result is consistent with the previously reported instability of the enzyme at elevated temperatures (16). The nature and pH of the buffer influenced the degree of activity loss (Table II), with optimum stability of the enzyme observed in pH 7.0 phosphate buffer. Addition of sodium cyanoborohydride at 5 and 50 m*M* to the incubation medium [pH 7.0 tris(hydroxymethyl)aminomethane hydrochloride buffer] did not cause additional loss of enzymatic activity (Table III).

Incubation of *S*-adenosyl-L-methionine decarboxylase in pH 7.0 tris(hydroxymethyl)aminomethane hydrochloride buffer containing various concentrations of *S*-adenosyl-L-methionine at 37° for 30 min, followed by dialysis, resulted in a loss of enzymatic activity in the recovered protein. This loss was dependent on the concentration of II in the initial incubation mixture (Table III). Addition of Ia at 1.0 μM to the original incubation mixture resulted in protection of the enzyme from the substrate-induced deactivation.

Addition of sodium cyanoborohydride at 5 and 50 m*M* to a mixture of the decarboxylase and II (0.2 m*M*) in pH 7.0 tris(hydroxymethyl)-aminomethane hydrochloride buffer, followed by incubation at 37° for 30 min, resulted in an essentially complete loss of enzymatic activity in the dialyzed protein. The use of [*S*-C^{3}H$_3$]II (10.13 Ci/mmole) in the experiment resulted in the incorporation of radioactivity in the protein fraction. Extensive dialysis of the protein did not dissociate the radioactivity from the enzyme. The addition of Ia at 0.1 μM significantly lowered the degree of inactivation of *S*-adenosyl-L-methionine by sodium cyanoborohydride treatment in the presence of the substrate and putrescine (Table III).

Addition of sodium cyanoborohydride to a mixture of *S*-adenosyl-L-methionine decarboxylase and putrescine (2.5 m*M*) in pH 7.0 tris(hydroxymethyl)aminomethane hydrochloride buffer and incubation at 37° for 30 min did not result in the loss of enzymatic activity of the dialyzed protein (Table III). The use of [^{3}H]putrescine in the experiment did not lead to the incorporation of radioactivity in the enzyme.

Table III—Effects of Different Preincubation Conditions on the Recovery of *S*-Adenosyl-L-methionine Decarboxylase Activity

Additions to Incubation Medium	Activity Remaining: No Sodium Cyanoborohydride	5 m*M* Sodium Cyanoborohydride	50 m*M* Sodium Cyanoborohydride
None	100[a]	97	96

2.5 m*M* Putrescine and 0.1 m*M* *S*-adenosyl-L-methionine	82	ND[b]	ND
2.5 m*M* Putrescine and 0.05 m*M* *S*-adenosyl-L-methionine	90	ND	ND
2.5 m*M* Putrescine, 0.2 m*M* *S*-adenosyl-L-methionine, and 1.0 μM Ia	90	43	34

[a] See *Experimental.* [b] Not determined.

DISCUSSION

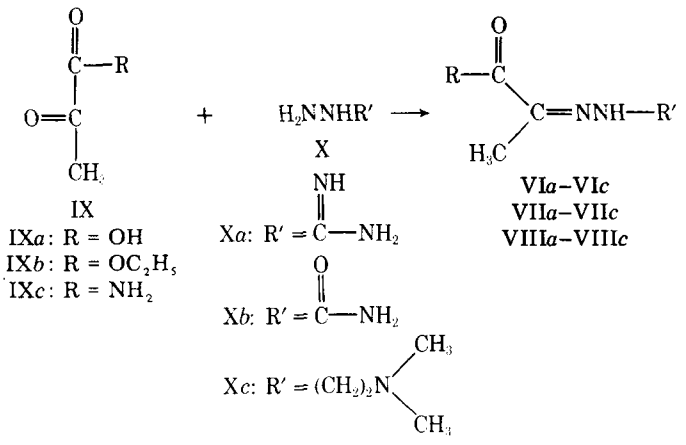
The described experiments confirm that the carbonyl group of the pyruvate cofactor does not form an azomethine bond with an amino group from the enzyme since sodium cyanoborohydride reduction of the enzyme did not result in loss of catalytic activity of the protein. It appears that putrescine does not form the intermediate III and that the mechanism of activation of *S*-adenosyl-L-methionine decarboxylase by putrescine does not involve transketimination between III and the substrate as was proposed initially. However, these experiments indicate that intermediates IV and/or V are formed during the decarboxylation of II by the enzyme.

Methylglyoxal bis(guanylhydrazone) (Ia) appears to interfere with the formation of the enzyme–substrate complex as shown by two experiments: (*a*) Ia protected the enzyme from substrate-induced inactivation, and (*b*) the degree of inactivation of the enzyme by sodium cyanoborohydride in the presence of II was much lower when Ia was added to the incubation medium. These findings and the observation that inhibition of *S*-adenosyl-L-methionine decarboxylase by I may have been competitive with respect to II indicate that Ia competes with II for binding at the enzyme active site.

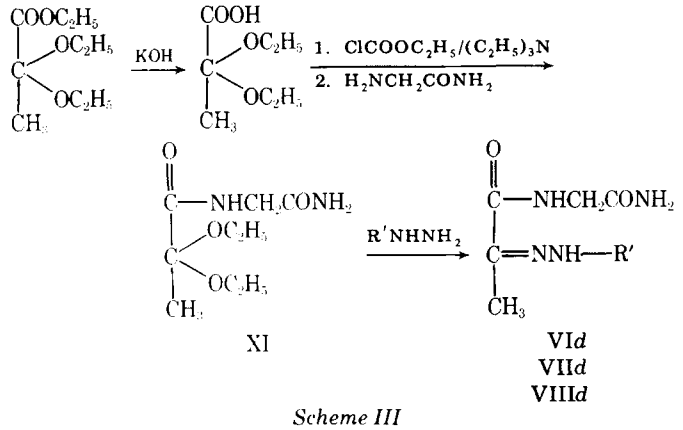
The demonstration that IV and/or V are intermediates in the enzymatic decarboxylation of II prompted the synthesis of some derivatives of pyruvic acid (VI–VIII) and their evaluation as inhibitors of *S*-adenosylmethionine decarboxylase. The structural similarities between VI–VIII and intermediates IV and V suggested that these compounds may form complexes with the enzyme and act as inhibitors of the reaction.

Two other factors suggested that VI–VIII may be inhibitors of *S*-adenosylmethionine decarboxylase. First, Ia, which has structural similarities to intermediates IV and V, inhibits *S*-adenosylmethionine decarboxylase by interfering with the formation of the enzyme–substrate complex. The very high inhibitory activity of Ia (Ia produced 100% inhibition at 10 μM in the presence of 0.2 m*M* substrate) suggested that it may be a transition-state analog rather than an analog of the substrate or product. Second, a number of pyridoxal phosphate analogs, which are structurally similar to the intermediate formed between the cofactor and the substrate, were potent inhibitors of pyridoxal-dependent decarboxylases. However, the intermediates formed between pyridoxal phosphate and substrates are not bound covalently to the enzyme, unlike intermediates IV and V, which would be bound covalently to the enzyme.

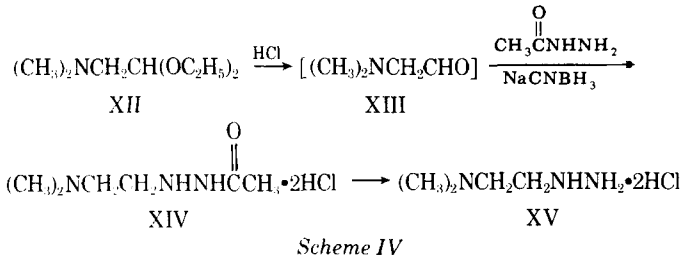
Chemistry—The target compounds (VI–VIII) were synthesized using a modification of the procedure of Podrebarac *et al.* (17) by condensing the appropriate pyruvate derivative with the corresponding hydrazine salt in aqueous alcohol (Scheme II). Pyruvyl glycineamide diethyl ketal (XI) was obtained by the condensation of pyruvic acid diethyl ketal with glycineamide using the mixed carbonic–carboxylic anhydride method (18). Condensation of XI with the appropriate hydrazine provided VId, VIId, and VIIId (Scheme III).



Scheme II

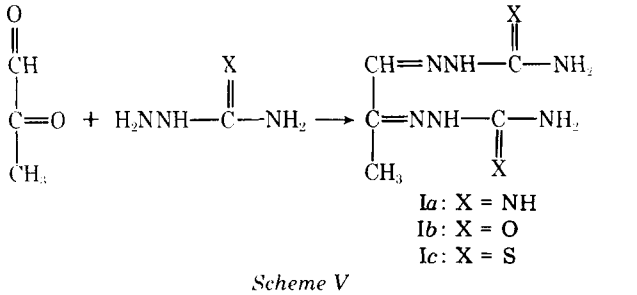


Scheme III



Scheme IV

Acid hydrolysis of dimethylaminoacetaldehyde diethyl ketal (XII) provided the free aldehyde (XIII). Treatment of XIII with acetylhydrazine and sodium cyanoborohydride provided XIV. Acid hydrolysis of XIV provided the dihydrochloride salt, dimethylaminoethylhydrazine dihydrochloride (XV) (Scheme IV). Compounds Ib and Ic were obtained by condensing methylglyoxal pyruvaldehyde with either semicarbazide or thiosemicarbazide in aqueous alcohol using the method of Shriner *et al.* (19) (Scheme V).



Scheme V

Enzyme Inhibition—The inhibition by the test compounds of the enzymatic decarboxylation of *S*-adenosyl-L-methionine was measured *in vitro*. A partially purified protein from rat liver was used as the source of the *S*-adenosyl-L-methionine decarboxylase, and the decarboxylase activity was measured by determining the amount of [^{14}C]carbon dioxide released from *S*-adenosyl-L-methionine labeled with carbon 14 on the carboxyl group. Under the assay conditions, *S*-adenosyl-L-methionine decarboxylase from rat liver had an apparent K_m value for *S*-adenosyl-L-methionine of 5.14×10^{-5} *M* and a V_{max} value of 8.72 nmoles of carbon dioxide/min/mg of protein.

The addition of Ia at 10 μM caused 100% inhibition of the enzymatic activity. However, the addition of Ib or Ic at 100 μM resulted only in 5 and 3% inhibition of enzymatic activity, respectively. Compounds VI–VIII showed little or no inhibitory activity when added to the reaction mixture in concentrations of 10 and 20 μM (Table I).

These results indicate that the structural requirements for binding of Ia to the enzyme are strict and that structural modifications of this compound result in a dramatic loss of activity. The low inhibitory activities of Ib and Ic underscore the essential role the strongly basic guanidino groups play in the binding of Ia to the enzyme. The lack of significant inhibitory activities for VI–VIII indicates that the inhibitory activity of Ia is not due to its structural similarity to intermediates IV and V in the enzymatic reaction.

N-Acetyl-DL-penicillamine and Acetaminophen Toxicity in Mice

RICHARD T. ZERA and HERBERT T. NAGASAWA ˣ

Received April 23, 1979, from the *Medical Research Laboratories, Veterans Administration Medical Center, and the Department of Medicinal Chemistry, University of Minnesota, Minneapolis, MN 55417.* Accepted for publication January 9, 1980.

Abstract □ *N*-Acetyl-DL-penicillamine (III*b*), a structural analog of *N*-acetyl-L-cysteine (III*a*), did not protect mice from lethal doses of acetaminophen (I), whereas III*a* offered protection. This lack of efficacy of III*b* probably is due to the decreased nucleophilicity of its sulfhydryl group compared to that of III*a*, the probable involvement of cysteine in any conjugate addition to the reactive intermediates of I, and the absence of metabolic conversion of III*b* to inorganic sulfate.

Keyphrases □ *N*-Acetyl-DL-penicillamine—evaluation for protection against acetaminophen toxicity in mice □ Acetaminophen—toxicity, evaluation of protection offered by *N*-acetyl-DL-penicillamine, mice □ Toxicity—acetaminophen, evaluation of protection offered by *N*-acetyl-DL-penicillamine, mice

Acetaminophen (I) is hepatotoxic in large doses (1, 2) and can be toxic even in therapeutic doses in patients with impaired liver function (3). Renal necrosis also has been associated with acetaminophen abuse (1, 2, 4).

THEORY

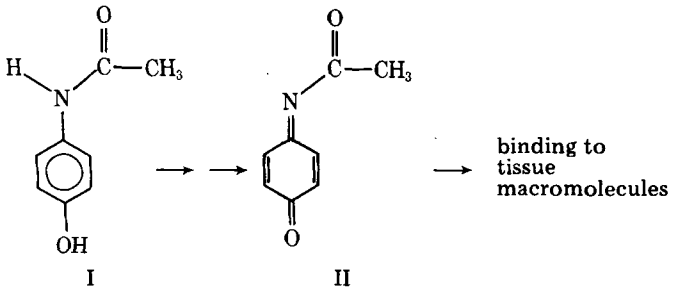
Animal studies have demonstrated that both the hepatotoxicity (5, 6) and renal toxicity (7) follow cellular glutathione depletion and subsequent covalent binding of a highly reactive metabolic product of I, presumed to be the *p*-quinoneimide (II), to tissue macromolecules (Scheme I).

Numerous sulfhydryl-containing agents, including cysteamine, L-methionine, D-penicillamine, and *N*-acetyl-L-cysteine (III*a*), have been tested and shown to ameliorate acetaminophen toxicity in varying degrees (8–15), ostensibly by covalent intervention with the reactive metabolite, II. Of these compounds, III*a* has become the currently accepted therapy (16, 17). The use of *N*-acetyl-DL-penicillamine (III*b*), a structural analog of III*a*, has not been reported. Compound III*b*, which is effective for the treatment of mercuric chloride poisoning (18, 19), is not catabolized extensively and theoretically could form a pseudomercapturic acid conjugate (IV*b*) by interaction with the quinoneimide (II) *via* its sulfhydryl group. Compound IV*b* then would be expected to be excreted as an analog of the mercapturic acid (IV*a*) (Scheme II).

Accordingly, the effectiveness of III*b* as a protective agent against the hepatotoxicity elicited by I in mice was evaluated and compared to the protection afforded by III*a*.

EXPERIMENTAL

Animals—Randomly bred male Swiss–Webster mice[1], 20–30 g, were



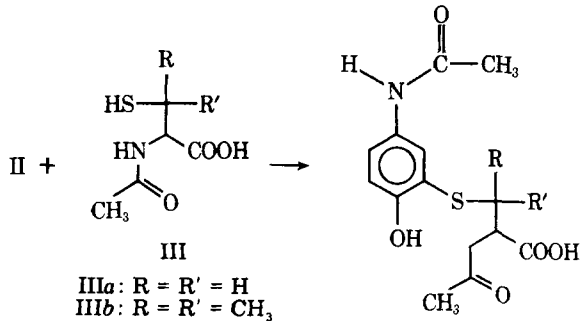
Scheme I

housed individually and fed a standard diet of rat chow and water *ad libitum*.

Chemicals—*N*-Acetyl-DL-penicillamine[2] (III*b*) was recrystallized from hot water. Injection solutions were prepared by dissolving 0.15 g in 15.0 ml of water (10 mg/ml). *N*-Acetyl-L-cysteine (III*a*) was a 20% sterile solution[3]. Solutions for injection were prepared by taking 1.0 ml of the 20% solution and diluting it to 20 ml with 0.9% sterile saline (10 mg/ml). Acetaminophen[4] (I) was recrystallized from hot water. Injection solutions were prepared by dissolving 1.25 g in 50.0 ml of sterile 0.9% saline. The solution was kept at 35–40° for injections.

Treatment Protocol and Histological Criteria—All drugs were administered intraperitoneally. Mice were treated with 750 mg of I/kg and 30 min later were given 400 mg of III*b* or III*a*/kg. Control mice received III*b*, III*a*, or 1.0 ml of sterile 0.9% saline. The mice then were observed for 48 hr with food and water allowed *ad libitum*. Mice that died during this period were examined grossly, and the liver and kidneys were excised, sliced, and fixed in 10% formalin for histological examination.

Survivors were sacrificed by cervical dislocation after the 48-hr period, and the liver and kidneys of all mice were processed as described. Paraffin sections of these tissues were stained with hematoxylin and eosin. Liver injury was graded according to the criteria described by Mitchell *et al.* (20) and quantitated as follows: 0, necrosis absent; 1+, necrosis of <6% of hepatocytes; 2+, necrosis of 6–25% of hepatocytes; 3+, necrosis of 25–50% of hepatocytes; and 4+, necrosis of >50% of hepatocytes.



Scheme II

RESULTS

The results of these experiments are summarized in Table I. Mice given 750 mg of I/kg without sulfhydryl treatment did poorly. At 48 hr, 40% had died and 40% had 3–4+ liver necrosis. Mice that were given I and treated with III*b* did not fare much better. At 48 hr, 40% of the animals had died and 50% had 3–4+ necrosis. However, mice given I and III*a* responded well to the latter treatment, as expected. No deaths were noted at 48 hr; no animal had 3–4+ necrosis, and only three of 10 animals had any evidence of liver injury characterized by mild 1+ necrosis. Although the doses of III*b* and III*a* were not exactly equimolar due to differences in their molecular weights, the results clearly indicated that III*b* was ineffective as a protective agent. Some mice in the control groups given III*a* or III*b* alone apparently sustained a low-grade liver injury, an observation noted previously with III*a* (21).

Liver necrosis was of the centrilobular hemorrhagic type in the more severe examples and of the centrilobular type in the less severe cases.

Table I—Effect of *N*-Acetyl-DL-penicillamine (III*b*) and *N*-Acetyl-L-cysteine (III*a*) Treatment on the Hepatotoxicity Induced by Acetaminophen (I) in Mice

Treatment	Number of Animals	Deaths (48 hr)	Percent of Animals with Necrosis				
			4+	3+	2+	1+	0
Saline	10	0	0	0	0	0	100
I	10	4	40	0	10	0	50
I + III*b*	10	4	50	0	10	10	30
III*b*	10	0	0	10	0	10	80
I + III*a*	10	0	0	0	0	30	70
III*a*	10	0	0	0	0	20	80

Centrilobular hemorrhagic necrosis was reported previously as a component of acetaminophen overdose in the mouse (21). The histological pattern of centrilobular hemorrhagic necrosis is more typically seen with rapidly progressive congestive heart failure (21). Centrilobular necrosis differs from centrilobular hemorrhagic necrosis only in the absence of extravasated red cells and also was observed after toxic exposure to carbon tetrachloride, chloroform, or naphthalene (22).

DISCUSSION

In a study of the relative nucleophilicities of the sulfhydryl groups in thiol amino acids, Friedman *et al.* (23) observed that the mercaptide ion of III*b* was approximately 50 times less reactive with α,β-unsaturated systems than was III*a*. Since the pK values of the two sulfhydryl groups are similar (9.90 and 9.52, respectively), it was concluded that this differential nucleophilicity was due to steric hindrance in III*b* by the presence of the *gem*-dimethyl groups adjacent to the sulfhydryl group. The failure of III*b* to protect mice against toxic doses of I may reflect this low relative nucleophilicity of its sterically hindered sulfhydryl group.

Chasseaud (24) showed that enzymatic deacetylation of III*a* occurs prior to reaction with electrophiles. This finding suggests that cysteine itself and not III*a* may be involved in any addition reactions with II *in vivo*, a premise supported by the observation that cysteine is approximately 2.5 times more nucleophilic than its acetylated derivative, III*a* (23). Moreover, III*a* is rapidly and nearly quantitatively deacetylated to cysteine in the rat (25). When [^{35}S]acetylcysteine was administered to rats, the major metabolites were cysteine and cystine at 2 hr. At 24 hr, inorganic sulfate was the major product in the urine, with minor amounts of mixed disulfide also present. Thus, III*a* may act as a prodrug form of cysteine and release the latter in the liver as a trapping agent or as a biosynthetic precursor of glutathione.

In contrast, other investigators (26–28) presented indirect evidence for the absence of deacetylation of orally administered III*b* in rats and humans. The present investigators also observed that rat liver homogenates did not deacetylate III*b* under conditions where III*a* was completely deacetylated. In any event, D-penicillamine is not a particularly effective protective agent for I (14). Since the administration of sodium sulfate itself significantly reduced the toxicity of I in mice (29), the efficacy of III*a* treatment in acetaminophen overdoses has been suggested to be due to increased sulfate generation. D-Penicillamine is not catabolized appreciably *in vivo*, and inorganic sulfate has not been demonstrated as a metabolite (30, 31). These observations and the present results with III*b* suggest that the direct formation of conjugates such as IV (as in Scheme II) may not be operative *in vivo*.

Based on metabolic (32) and pharmacokinetic considerations (33), a dual therapeutic regimen designed to (*a*) eliminate much of the excess acetaminophen represented by the overdose *via* conjugation mechanisms on the preformed phenolic hydroxyl group and (*b*) sequester the reactive metabolite(s) generated during the oxidative metabolism of I by administration of a suitable trapping agent appears to be superior to a single-treatment regimen. An obvious choice would be the combination therapy of III*a* with sodium sulfate.

Synthesis and Biological Evaluation of 2,3-Diazabicyclo[2.2.1]heptane Derivatives as Prostaglandin Endoperoxide Analogs

SHEUNG-TSAM KAM *, ROBERT N. HANSON ‡, and PHILIP S. PORTOGHESE ×

Received April 11, 1979, from the *Department of Medicinal Chemistry, College of Pharmacy, University of Minnesota, Minneapolis, MN 55455.* Accepted for publication June 26, 1979. *Present address: American Critical Care, McGaw Park, IL 60085. ‡Present address: College of Pharmacy and Allied Health Professions, Northeastern University, Boston, MA 02115.

Abstract □ Three prostaglandin endoperoxide analogs that possess the 2,3-diazabicyclo[2.2.1]heptane skeleton were synthesized and evaluated for activity in human platelets and in the rat fundus. All three compounds were inactive in inhibiting or stimulating platelet aggregation. One compound possessed weak contracting activity on the rat fundus.

Keyphrases □ Platelet aggregation—evaluation of inhibition and stimulation by prostaglandin endoperoxide analogs □ Prostaglandin endoperoxide analogs—synthesis and evaluation for inhibition and stimulation of platelet aggregation

A recent report stated that the prostaglandin endoperoxide analog 9,11-azo-13-oxa-15-hydroxyprostanoic acid (I) is a potent inhibitor of platelet aggregation (1). Some of its congeners also possessed antiaggregatory activity.

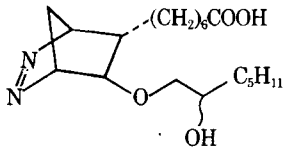
Because simple bicyclic systems, such as 2,3-dioxabicyclo[2.2.1]heptane and 2,3-diazabicyclo[2.2.1]hept-2-ene, were reported (2) to inhibit platelet aggregation in the millimolar concentration range, determination of whether less complex congeners of I containing only one side chain exhibit similar activity was of interest. The synthesis and biological evaluation of such compounds (II–IV) are described.

DISCUSSION

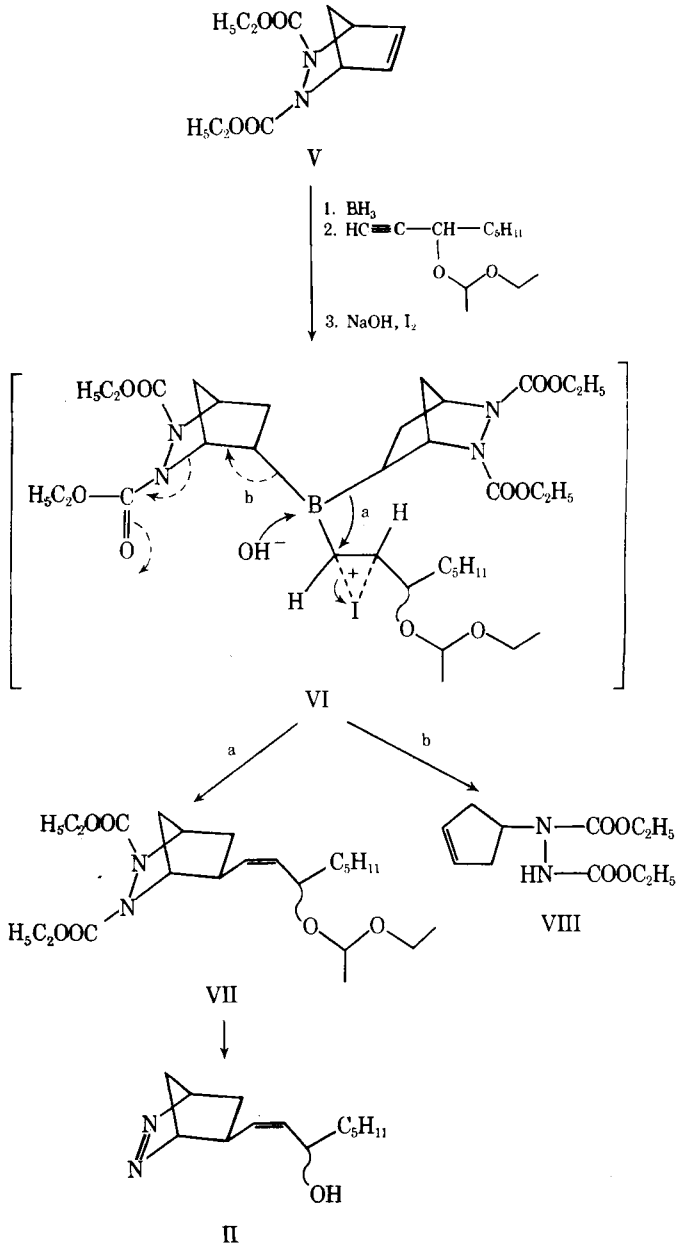
The preparation of II was accomplished *via* the olefin synthesis of Zweifel *et al.* (3) using diethyl 2,3-diazabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylate (V) (4) (Scheme I). Two products, the desired *cis*-olefin (VII) (70%) and a ring-opened product, 4-(*N,N'*-dicarboethoxyhydrazino)cyclopentene (VIII) (10%), were obtained. The isolation of VII and VIII can be rationalized by the formation of an intermediate (VI), which can rearrange through two different but competitive pathways. Path a is the dominant alkyl carbanion migration pathway and yields VII; path b leads to rupture of the bicyclic system to give VIII[1]. Treatment of VII with base followed by air oxidation with cupric acetate as a catalyst (6) and acidolysis gave the target compound, II.

The coupling constant of the olefinic protons in II is ~10 Hz, which is within the range of the coupling constant for a *cis*-double bond (7). The *exo*-orientation of the side chain at C-5 is assigned by virtue of the reaction mechanism since hydroboration of bicyclic olefins proceeds by *cis*-addition (8) from the *exo*-face (8) and migration of an alkyl group from the boron atom to an electron-deficient carbon (path a in VI) occurs (9) with the retention of configuration.

Compounds III and IV were synthesized from the *exo*-mesylate (X)



I



V, VI, VII, VIII, II

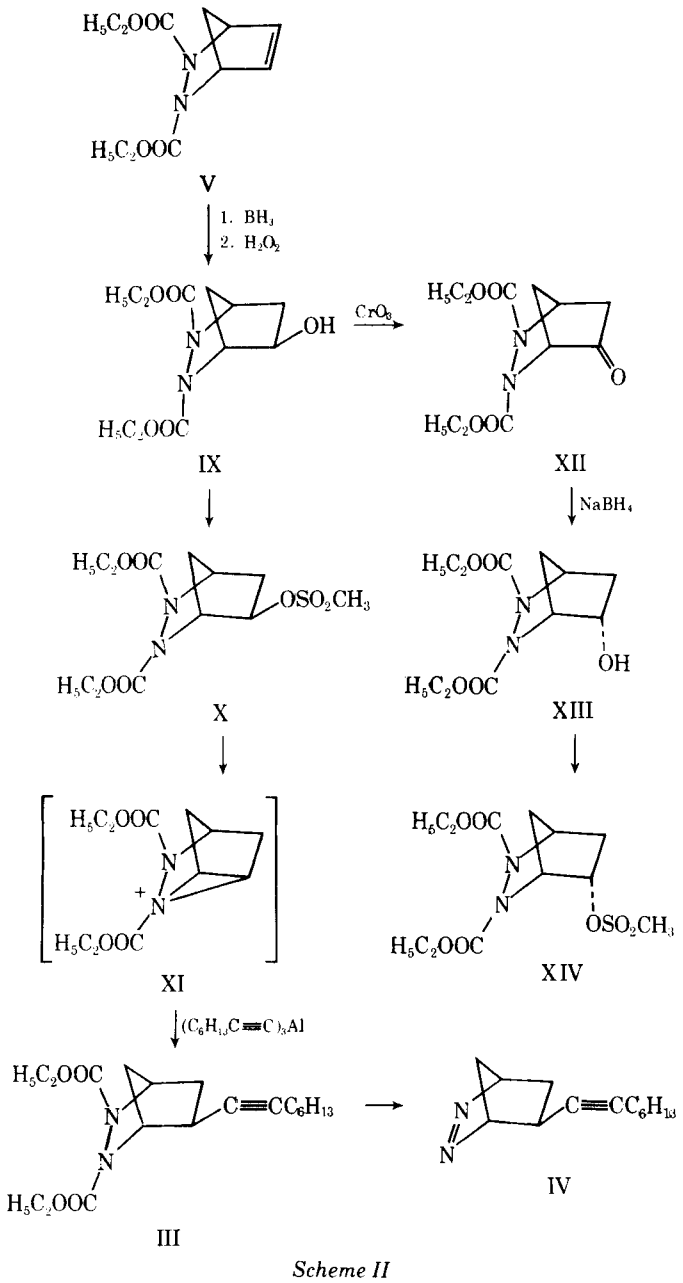
Scheme I

(Scheme II) using the aluminum-mediated condensation developed by Nagishi and Baba (10). Compound X, which was prepared from the corresponding alcohol (IX), was reacted with tri-1-octynylalane to yield III (46%) (Scheme II). Deprotection and oxidation of III gave the azo product, IV.

The NMR spectrum of III indicates that the 1-octynyl side chain at C-5 is *exo*. After decoupling of the C-6 *exo*-proton and the C-3' methylene protons of the alkyne side chain, the C-5 methine proton appeared as a broad doublet at δ 2.65. The coupling constant (J = 7 Hz) of this doublet

[1] A similar ring-opened product was reported in the hydroboration–oxidation of dimethyl 2,3-diazabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylate (5).

0022-3549/80/0900-1007$01.00/0
© 1980, American Pharmaceutical Association



Scheme II

is in the range of *endo-endo* coupling (J = 6–7 Hz) in the norbornane system (11) and is identical to that reported (12) for a related compound.

The *endo*-mesylate isomer (XIV) (Scheme II) did not react with tri-1-octynylalane under identical conditions. This isomer was prepared by a similar procedure (5) and included oxidation of the alcohol (IX) followed by hydride reduction of the resulting ketone (XII) to the *endo*-alcohol (XIII) (Scheme II).

The fact that only the *exo*-mesylate underwent this reaction can be explained by a carbonium-ion mechanism (10) with the assumption that departure of the *exo*-mesylate group is assisted by the electrons of the neighboring carbamate nitrogen. This action would give a symmetrical aziridinium-ion intermediate (XI), which opens on reaction with the alkyne. A similar type of ring opening was reported (12) with a structurally related aziridinium ion to give an *exo*-substituted product. Therefore, the predictable stereochemical consequence of the aziridinium-ion (XI) mechanism is that the newly introduced group at C-5 in III and IV is *exo*. In contrast, the stereochemistry of the *endo*-methanesulfonate group in XIV makes it difficult or impossible to form an aziridinium ion because departure of the *endo*-methanesulfonate function receives no assistance from the neighboring nitrogen.

At 10^{-4} M, none of the compounds (II–IV) induced aggregation of human platelets or inhibited the aggregation induced by 8.2×10^{-4} M arachidonic acid or by 8.5×10^{-7} M of 9,11-methanoepoxy prostaglandin H_2[2] (13). In view of the finding (1) that all analogs of I that possess the carboxyhexyl side chain showed inhibition of the aggregation induced by 9,11-methanoepoxy prostaglandin H_2, the carboxyhexyl side chain might be more important in receptor or enzyme binding relative to the other side chain. The activity of II–IV on the rat fundus also was evaluated. Compound III showed contracting activity at 10^{-4} M but was much less potent ($\sim 3 \times 10^5$-fold) than prostaglandin E_2. The other two compounds were inactive in this test.

EXPERIMENTAL[3]

Diethyl 5-*exo*-[3-[(1-Ethoxy)ethoxy]-*cis*-1-octenyl]-2,3-diazabicyclo[2.2.1]heptane-2,3-dicarboxylate (VII)—To 9.5 ml of diborane–tetrahydrofuran (1.09 M, 10 mmoles) at 0° under nitrogen was added 4.8 g (20 mmoles) of V (4) in tetrahydrofuran (10 ml). After the mixture was stirred at 0° for 6 hr, 1.98 g (10 mmoles) of 3-[(1-ethoxy)-ethoxy]oct-1-yne (14) was added dropwise. Stirring was continued for 1 hr at 0° followed by 1.5 hr at 25°. The mixture then was cooled to 0°, and migration of the diazabicyclic system was induced by addition of sodium hydroxide (6 N, 6 ml) followed by iodine (2.54 g, 10 mmoles) in 15 ml of tetrahydrofuran.

The mixture was maintained at ice temperature for 5 hr and at 25° for an additional 3 hr. Excess iodine in the mixture was destroyed by addition of an aqueous solution of sodium thiosulfate. The organic layer was separated, and the aqueous phase was extracted three times with ether (50 ml). The organic layers were combined and dried (anhydrous magnesium sulfate), and the solvent was removed *in vacuo*. The crude product was chromatographed on silica gel (100 g, 3 × 35 cm) using (*a*) 20% ethyl acetate in petroleum ether (30–60°) (300 ml), (*b*) ethyl acetate in petroleum ether (30–60°) (200 ml), (*c*) ethyl acetate (300 ml), and (*d*) 2% methanol in ethyl acetate (300 ml).

The major product, VII, was eluted with ethyl acetate fractions (3.08 g, 70%). Rechromatography of VII on silica gel (100 g, 3 × 35 cm) using 3% isopropanol in chloroform afforded analytically pure VII; IR (liquid film): 1700 and 1750 (C=O) cm^{-1}; NMR (carbon tetrachloride): δ 0.7–1.57 (m, 25H, C_5H_{11}, 2 $COOCH_2CH_3$, $CHCH_3$, OCH_2CH_3, and 2 methylene protons at C-6), 1.65 (broad s, 3H, 2 bridge protons at C-7 and 1 methine proton at C-5), 3.2–3.7 (m, 2H, OCH_2CH_3), 3.98–4.8 (m, 8H, 2 $COOCH_2CH_3$, bridgehead protons at C-1 and C-4, C=CCH, and O–CH–O), and 5.0–5.65 (m, 2H, olefinic protons); mass spectrum (70 ev): m/e 440 (M^+).

Anal.—Calc. for $C_{23}H_{40}N_2O_6$: C, 62.70; H, 9.15; N, 6.36. Found: C, 62.53; H, 9.28; N, 6.18.

The ring-opened product (VIII) (0.48 g, 10%) was isolated from the 2% methanol in ethyl acetate eluent; IR (liquid film): 3300 (NH) and 1510 (CON) cm^{-1}; NMR (chloroform-d_6): δ 1.13 (t, 6H, 2 $COOCH_2CH_3$), 2.39 (d, 4H, $CH_2C{=}CH_2$), 4.05 (q, 4H, 2 $COOCH_2CH_3$), 4.8 (m, 1H, >CHN), 5.5 (s, 2H, $CH{=}CH$), and 6.8 (s, 1H, NH); mass spectrum (70 ev): m/e 242 (M^+).

Anal.—Calc. for $C_{11}H_{18}N_2O_4$: C, 54.53, H, 7.49; N, 11.57. Found: C, 54.73; H, 7.63; N, 11.32.

5-*exo*-(3-Hydroxy-*cis*-1-octenyl) -2,3- diazabicyclo[2.2.1]hept-2-ene (II)—Compound VII (0.44 g, 1 mmole) was dissolved in ethylene glycol (1 ml) and mixed with a solution of potassium hydroxide (0.336 g, 6 mmoles) in ethylene glycol (6 ml). The mixture was heated at 115° for 4.5 hr followed by the addition of water (50 ml). The aqueous solution was extracted with two 100-ml portions of ether. The volume of the ether was reduced to ~10 ml and mixed with methanol (10 ml) containing a catalytic amount (0.01 g) of cupric acetate. Air was bubbled into the mixture at 0° for 2 hr.

The resulting mixture was partitioned between water (50 ml) and ether (2 × 200 ml). The ether layer was separated and removed *in vacuo* to give an oil, which was chromatographed on silica gel (10 g, 1.3 × 30 cm) with ether to afford 5-*exo*-[3-(1-ethoxy)ethoxy-*cis*-1-octenyl]-2,3-diazabicyclo[2.2.1]hept-2-ene (0.183 g, 65%); IR (liquid film): 1490 (N=N) cm^{-1}; mass spectrum (70 ev): m/e 294 (M^+). Deprotection of the alcohol was achieved by dissolving this product in ethyl acetate–water–tetrahydrofuran (3:1:1) (10 ml) and heating to 45° for 3 hr.

[2] U46619.

[3] Melting points were determined with a Thomas-Hoover melting-point apparatus and are uncorrected. Elemental analyses were performed by M-H-W Laboratories, Phoenix, Ariz. IR spectra were obtained with a Perkin-Elmer model 237B grating spectrophotometer. NMR data (δ) were recorded with Varian models A-60D and T-60 spectrometers. Mass spectral analyses were performed with a Hitachi Perkin-Elmer model RMU-6D spectrometer by the Mass Spectrometry Service Laboratory, School of Chemistry, University of Minnesota.

The solvents were removed *in vacuo* at 25° to leave an oily residue, which was chromatographed on silica gel (10 g, 1.3 × 30 cm) with ether to give II (0.13 g, 59%). This product was a mixture of two racemates; IR (liquid film): 3400 (OH), 1700 (*cis*-C=C), and 1490 (N=N) cm^{-1}; NMR (carbon tetrachloride): δ 1.95–2.2 (broad d, 1H, methine proton at C-5), 3.9–4.5 (m, 1H, C*H*OH), 4.75, 4.9 (2 broad s, 1H, bridgehead proton assigned to the two diastereomers at C-4), 4.95–5.6 (m, 2H, *cis*-C*H*=C*H*, J = 10 Hz), and 5.13 (broad s, 1H, bridgehead proton at C-1); mass spectrum (70 ev): m/e 176 ($M^+ - N_2 - H_2O$); UV: λ_{max} 338 (N=N) nm.

Anal.—Calc. for $C_{13}H_{22}N_2O$: C, 70.22; H, 9.98; N, 12.60. Found: C, 70.07; H, 9.87; N, 12.54.

Diethyl 5-*exo*-Hydroxy-2,3-diazabicyclo[2.2.1]heptane-2,3-dicarboxylate (IX)—Compound IX was obtained from diethyl 2,3-diazabicyclo[2.2.1]hept-5-ene-2,3-dicarboxylate (V) (4) (1 g, 3.7 mmoles) by hydroboration and oxidation *via* a procedure similar to that described by Allred and Smith (5). The oily product was chromatographed on silica gel and eluted with ethyl acetate–ether (3:2) to give 0.7 g (75%) of the *exo*-alcohol (IX) as a colorless oil, R_f 0.31 (silica gel, 10% ethanol in ether); IR (liquid film): 3475 (OH), 1720, and 1750 (C=O) cm^{-1}; NMR (carbon tetrachloride): δ 1.27 (t, 6H, 2 $COOCH_2CH_3$), 1.58 (m, 2H, bridge protons at C-7), 1.78–2.2 (m, 2H, CHOH-CH_2), 4.1 (broad s, 1H, bridgehead proton at C-1), and 4.47 (broad s, 1H, bridgehead proton at C-4); mass spectrum (70 ev): m/e 258 (M^+).

Anal.—Calc. for $C_{11}H_{18}N_2O_5$: C, 51.15; H, 7.02; N, 10.85. Found: C, 50.96; H, 7.24; N, 10.69.

Diethyl 5-*exo*-Methanesulfonyl-2,3-diazabicyclo[2.2.1]heptane-2,3-dicarboxylate (X)—To a solution of IX (3.64 g, 14.1 mmoles) in pyridine–toluene (1:1) (40 ml) was added 1.78 g (15.5 mmoles) of methanesulfonyl chloride in pyridine (20 ml) at 0°. The mixture was allowed to stir at 25° for 12 hr, and the pyridinium hydrochloride salt which precipitated was removed by filtration. The filtrate was concentrated *in vacuo*, and the residue was partitioned between water (50 ml) and methylene chloride (2 × 100 ml). Removal of the methylene chloride afforded an oil, which was chromatographed on silica gel (50 g, 2.3 × 35 cm) using benzene–ether (8:2) to give X.

Compound X was crystallized from carbon tetrachloride–ether to afford a white solid (3.8 g, 80%), R_f 0.52 (silica gel, ether), mp 87.5–88°; NMR (chloroform-d_6): δ 1.26 (2 t, 6H, 2 $COOCH_2CH_3$), 1.5–2.6 (m, 4H, methylene protons at C-6 and bridge protons at C-7), 3.02 (s, 3H, OSO_2CH_3), 4.16 (2 q, 4H, 2 $COOCH_2CH_3$), and 4.45–4.9 (m, 3H, bridgehead protons at C-1 and C-5 and methine proton at C-5); mass spectrum (70 ev): m/e 336 (M^+).

Anal.—Calc. for $C_{12}H_{20}N_2O_7S$: C, 42.85; H, 5.99; N, 8.33. Found: C, 42.58; H, 5.86; N, 8.16.

Diethyl 5-*exo*-(1-Octynyl)-2,3-diazabicyclo[2.2.1]heptane-2,3-dicarboxylate (III)—To a solution of *n*-oct-1-yne (0.9 g, 9.6 mmoles, purified by distillation over anhydrous sodium sulfate) in dry *n*-hexane (15.4 ml) was added, under nitrogen, 3.84 ml of *n*-butyl lithium (2.5 *M*, 9.6 mmoles) in hexane at 0°. The suspension was stirred at 0° for 0.5 hr, and 0.43 g (3.2 mmoles) of aluminium chloride was added. The resulting mixture was stirred at 0° for 0.5 hr, and the solvent was removed *in vacuo* at 25° to give a residue of trioctylalane; this residue was dissolved in 25 ml of dry dichloroethane (dried over phosphorus pentoxide and distilled) under nitrogen.

The trioctylalane solution was cooled to 0°, and a solution of 1.0 g (3 mmoles) of X in 5 ml of dichloroethane was added. After stirring at 25° for 24 hr, the mixture was added to another batch of freshly prepared trioctylalane (9.6 mmoles). Stirring was continued at 25° for another 24 hr, and the mixture then was partitioned between 2% HCl (50 ml) and chloroform (2 × 100 ml). The organic layer was separated, dried (anhydrous sodium sulfate), and filtered, and the solvent was removed *in vacuo* to give an oil; this oil was chromatographed on silica gel (10 g, 1.3 × 30 cm) with ether–pentane (4:1) to afford III (0.43 g, 46%).

Compound III showed a single peak on GLC (3% OV-1, 1.8 m; 200°; nitrogen flow rate, 10 ml/min; retention time, 5 min); NMR (carbon tetrachloride): δ 0.66–1.06 (m, 3H, CH_2CH_3), 1.65 (broad s, 2H, protons at C-7), 1.83 (broad s, 1H, *endo*-proton at C-6), 2.06 (broad s, 3H, 2 C=C-CH_2 and C-6 *exo*-proton), and 2.65 (broad s, 1H, >CH-C≡C-; after decoupling of the δ 2.06 peak, J = 7 Hz); mass spectrum (68 ev, high resolution): calc. M^+ for $C_{19}H_{30}N_2O_4$, m/e 350.2205; found, 350.2212.

Anal.—Calc. for $C_{19}H_{30}N_2O_4$: C, 65.16; H, 8.64; N, 8.00. Found: C, 65.47; H, 8.82; N, 7.97.

5-*exo*-(1-Octynyl)-2,3-diazabicyclo[2.2.1]hept-2-ene (IV)—Compound IV was prepared from III (0.7 g, 2 mmoles) by base hydrolysis and oxidation according to the procedure employed for the preparation of II. The product was extracted with ether after oxidation. The ether was removed *in vacuo*, and the residue was chromatographed on silica gel (10 g, 1.3 × 30 cm) with 10% isopropanol in petroleum ether (30–60°) to give IV (0.37 g, 90%); IR (liquid film): 1590 (N=N) cm^{-1}; NMR (carbon tetrachloride): δ 1.7–2.3 (m, 3H, C*H*-C≡C-CH_2) and 4.9–5.15 (m, 2H, bridgehead protons at C-1 and C-4); mass spectrum (70 ev): m/e 204 (M^+).

Anal.—Calc. for $C_{13}H_{20}N_2$: C, 76.42; H, 9.87; N, 13.72. Found: C, 76.64; H, 9.96; N, 13.75.

Diethyl 2,3-Diazabicyclo[2.2.1]heptane-5-one-2,3-dicarboxylate (XII)—A mixture of chromium trioxide (8.92 g, 88.2 mmoles), 200 ml of methylene chloride (dried over a 3-Å molecule sieve), and 7.0 g (88.2 mmoles) of pyridine (dried over potassium hydroxide pellets) was allowed to stir at 25° for 15 min. A solution containing 3.93 g (14.7 mmoles) of IX in methylene chloride (10 ml) was added to this mixture and stirred for 15 min. The reaction mixture then was filtered, and the methylene chloride was removed *in vacuo*. The residue was dissolved in ether (100 ml) and filtered again to obtain a clear filtrate.

Removal of the ether afforded an oily product (XII) (7.2 g, 82%), which was relatively pure as judged by NMR analysis. This product was used without further purification for the synthesis of XIII because of its instability. A small quantity of pure XII was isolated by using a Florisil column (50 g, 2.3 × 35 cm) with methylene chloride; IR (liquid film): 1775 (C=O) cm^{-1}; NMR (carbon tetrachloride): δ 1.3 (2 t, 6H, 2 $COOCH_2CH_3$), 1.98 (s, 2H, bridge protons at C-7), 2.22 (s, 2H, CH_2C=O), 4.15 (2 q, 4H, 2 $COOCH_2CH_3$), 4.22 (broad s, 1H, bridgehead proton at C-1), and 4.8 (s, 1H, bridgehead proton at C-4); mass spectrum (70 ev): m/e 256 (M^+).

Anal.—Calc. for $C_{11}H_{16}N_2O_5$: C, 52.30; H, 6.29; N, 10.93. Found: C, 52.17; H, 6.50; N, 10.80.

Diethyl 5-*endo*-Hydroxy-2,3-diazabicyclo[2.2.1]heptane-2,3-dicarboxylate (XIII)—To a solution of bicyclic ketone (XII) (4.1 g, 1.6 mmoles) in methanol (46 ml) maintained at −25° were added divided portions of sodium borohydride (0.6 g, 16 mmoles) in methanol–water (80:20) (49 ml). After stirring at −25° for 15 min, the reaction was quenched by addition of dilute hydrochloric acid to pH 7. The methanol was removed *in vacuo*, and the remaining aqueous solution was extracted with methylene chloride (2 × 50 ml). Removal of the methylene chloride *in vacuo* afforded an oily product (XIII), which was purified by column chromatography using silica gel (60 g, 2.3 × 3.5 cm) and eluted first with 250 ml of ether and then with 10% ethanol in ether to obtain the pure alcohol (XIII) (2.26 g, 55%), R_f 0.51 (silica gel, 10% ethanol in ether); IR (liquid film): 3475 (OH) cm^{-1}; NMR (carbon tetrachloride): δ 1.25 (t, 6H, 2 $COOCH_2CH_3$), 1.66 (s, 2H, bridge protons at C-7), 1.5–2.4 (m, 4H, 2 bridge protons at C-6 and 2 bridge protons at C-7), 4.15 (2 q, 4H, 2 $COOCH_2CH_3$), 4.2 (m, 1H, methine proton at C-5 observed after decoupling of the δ 1.25 triplet), 4.28 (s, 1H, bridgehead proton at C-1), and 4.44 (s, 1H, bridgehead proton at C-4); mass spectrum (20 ev): m/e 258 (M^+).

Anal.—Calc. for $C_{11}H_{18}N_2O_5$: C, 51.15; H, 7.02; N, 10.85. Found: C, 51.14; H, 6.99; N, 10.88.

Diethyl 5-*endo*-Methanesulfonyl-2,3-diazabicyclo[2.2.1]heptane-2,3-dicarboxylate (XIV)—Compound XIV was prepared from XIII (0.85 g, 3.3 mmoles) in the manner described for the preparation of X. The crude product was purified on silica gel (10 g, 1.3 × 30 cm) with 20% ethyl acetate in ether to afford an oil. This oil was crystallized from carbon tetrachloride to give pure XIV (10 g, 92%), R_f 0.37 (silica gel, ether), mp 120–120.5°; NMR (chloroform-d_6): δ 3.05 (s, 3H, OSO_2CH_3), 4.48 (broad s, 1H, bridgehead proton at C-1), and 4.92–5.2 (m, 2H, bridgehead proton at C-4 and methine proton at C-5); mass spectrum (70 ev): m/e 336 (M^+).

Anal.—Calc. for $C_{12}H_{20}N_2O_7S$: C, 42.85; H, 5.99; N, 8.33. Found: C, 42.72; H, 6.02; N, 8.28.

Platelet Aggregation Studies—Platelet-rich plasma was prepared according to the method of Gerrard *et al.* (15) and was incubated with II–IV (10^{-4} *M*) at 37.5° for 1.5 min. It then was added to a cell containing a standard quantity of arachidonic acid or 9,11-methanoepoxy prostaglandin H_2. Aggregation (or inhibition of aggregation) was monitored for 5 min on a dual-channel aggregometer[4].

Rat Fundus Studies—A 0.2 × 2.5-cm section of the fundus was cut from the outer curvature of the stomach from male Sprague–Dawley rats and suspended in a tissue bath. The tissue bath was perfused continuously with Krebs solution, and one end of the stomach was tied to an isotonic heart–smooth muscle transducer connected to a recorder[5].

[4] Payton.
[5] Beckman R411 Dynograph.

Compounds II–IV were added to the bath, and muscle contraction was monitored for 1.5 min. Prostaglandin E_2 was used to obtain standard contraction.

Potential Organ- or Tumor-Imaging Agents XIX: Radioiodinated Antiarrhythmic Drugs as Potential Myocardial Imaging Agents

N. KORN, J. K. GIBSON, F. J. KNIFFEN, B. R. LUCCHESI, V. V. RANADE, M. MIMNAUGH, T. YU, and R. E. COUNSELL ˣ

Received April 16, 1979, from the *Department of Pharmacology, Medical School, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication August 22, 1979.

Abstract □ Iodinated and radioiodinated analogs of propranolol and *N,N*-dimethylpropranolol were synthesized wherein an iodophenyl moiety replaced the naphthalene ring of the parent drug. These new compounds were evaluated not only for their β-adrenergic blocking and antiarrhythmic activities but also for their ability to accumulate selectively in myocardial tissue. Like propranolol, the iodinated analogs displayed comparable β-blocking and antiarrhythmic activity, and the order of potency was *ortho-* > *meta-* > *para*-iodophenyl. Quaternization of propranolol and the iodinated analogs eliminated the β-adrenergic blocking activity but retained the antiarrhythmic property of the secondary amine precursors. Among the quaternary salts, the antiarrhythmic potency was *meta-* > *ortho-* > *para*-iodophenyl. Tissue distribution of the radioiodinated derivatives revealed that only the quaternary derivatives were selectively accumulated in myocardial tissue. These results demonstrate that an iodophenyl ring can substitute for the naphthalene ring in propranolol and its quaternary salt without significant alteration of pharmacological properties. The radioiodinated quaternary derivatives may be useful pharmacological tools in experiments aimed at relating antiarrhythmic activity to myocardial uptake.

Keyphrases □ Antiarrhythmic agents—iodinated and radioiodinated analogs of propranolol and *N,N*-dimethylpropranolol, synthesis and evaluation of activity, tissue distribution of radioiodinated analogs, potential as myocardial imaging agents □ Propranolol—iodinated and radioiodinated analogs, synthesis and testing for β-adrenergic blocking and antiarrhythmic activity, tissue distribution of radioiodinated analogs, potential as myocardial imaging agents □ Radionuclide imaging—radioiodinated analogs of propranolol and *N,N*-dimethylpropranolol, tissue distribution, potential as myocardial imaging agents

The synthesis of a compound that selectively concentrates in the myocardium and that also can act as a carrier molecule for a γ-emitting nuclide has been a goal of this laboratory for several years (1–3). The approach has been to select a compound with known or suspected propensity for the target organ and then to modify the structure to allow incorporation of a γ-emitting nuclide while retaining the localizing properties of the parent compound.

BACKGROUND

One possible carrier molecule for myocardial localization is the β-adrenergic blocking agent propranolol (I). Its antiarrhythmic actions were demonstrated in a wide variety of experimentally induced arrhythmias (4, 5) as well as in clinically occurring arrhythmias (6, 7). Tissue distribution studies with [^{14}C]propranolol (8, 9) demonstrated its uptake by the heart, but not to the degree expected in view of the potent action of propranolol in blocking the cardiac effects of catecholamines (8). Instead, other tissues such as the lungs and brain contained higher levels of radioactivity (8, 9).

Previous studies in this laboratory showed that quaternization of propranolol produced a drug (II) that retained the antiarrhythmic activity but eliminated the β-adrenergic blocking property of propranolol (10). Subcutaneous administration of ^{14}C-labeled II to rats revealed a rapid and selective localization of radioactivity in the heart (23 times the blood

concentration at 2 hr postinjection) with no marked concentration of radioactivity in the lungs and brain[1]. Similar results were obtained in dogs (11).

Since II and other quaternary antiarrhythmic drugs, such as bretylium, persist in the myocardium long after blood levels have declined, it is believed that the uptake and retention of these drugs by the myocardium account for their antiarrhythmic action (11, 12). In any event, it is clear that plasma levels of these drugs cannot be used to guide individualization of dosage. As a consequence, the purpose of the present study was to synthesize not only a myocardial imaging agent but also an antiarrhythmic drug whose pharmacokinetic properties could be monitored in intact animals by external counting equipment.

Most rectilinear scanners and cameras currently available are used in conjunction with γ-emitting nuclides with an energy of <500 kev. Iodine has two radionuclides, iodine 123 and iodine 131, that fulfill this requirement and that are widely used in nuclear medicine. Accordingly, the present research focused on the synthesis and biological evaluation of iodinated analogs of propranolol and *N,N*-dimethylpropranolol. Since completion of this study, two reports (13, 14) appeared concerning propranolol as a carrier for γ-emitting radionuclides for myocardial imaging.

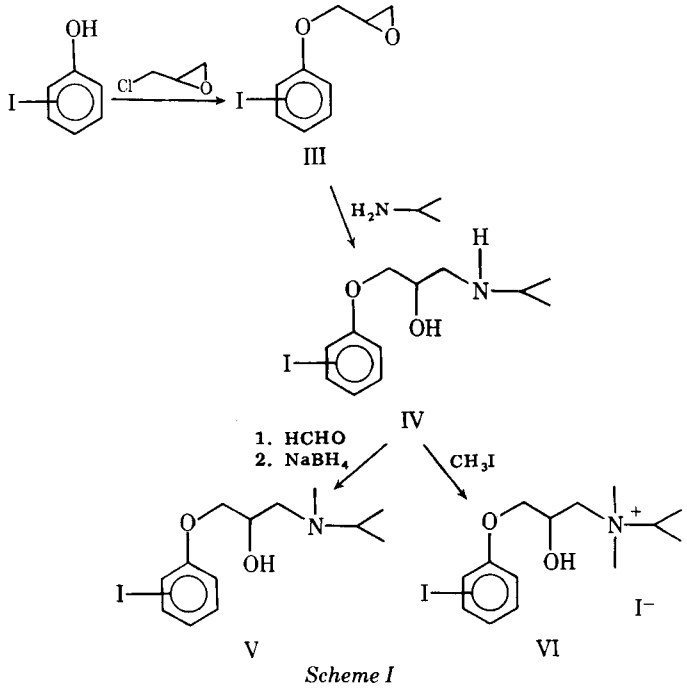
RESULTS AND DISCUSSION

Chemistry—The synthesis of the iodinated analogs of propranolol (*IV*) and their methylated congeners (V and VI) followed conventional paths as outlined in Scheme I (*a* = *ortho*, *b* = *meta*, and *c* = *para*). For synthesis of the corresponding radioiodinated derivatives, iodine 125 was selected for the initial studies because its longer half-life (60 days) and weak γ-radiation (35 kev) minimized handling and storage problems. In addition, a subsequent switch to iodine 123 or iodine 131 would represent no major change in methodology.

Radioactive iodine was introduced by the isotope-exchange method and involved refluxing an aqueous or ammonium hydroxide solution of IV or V to which the appropriate amount of sodium [^{125}I]iodide had been added. Higher yields of radioisotope incorporation usually were achieved when the exchange reactions were performed in ammonium hydroxide solution. The radioiodinated quaternary salts were obtained by treating the radioiodinated tertiary amine with methyl iodide in methanol at room temperature.

Pharmacology—The results of the pharmacological studies are summarized in Table I.

β-Adrenergic Receptor Blockade—Five of the synthesized compounds were tested for β-adrenergic receptor blocking activity against isoproterenol in isolated rabbit right atrial strips. The iodinated propranolol analogs (IV*a*–IV*c*) all showed β-adrenergic blocking activity. The order of activity was *ortho* > *meta* > *para*. The pA_2 value of 8.7 reported for propranolol by Blinks (15) was comparable to that observed for the *meta*-isomer (IV*b*). Accordingly, the *ortho*-isomer (IV*a*) was somewhat more active than propranolol as a β-adrenergic blocker. *N,N*-Dimethylpropranolol, as well as both of the iodinated analogs tested, lacked significant β-adrenergic receptor blocking activity.



Scheme I

Table I—Pharmacological Activity of Radioiodinated Analogs of Propranolol (I) and *N,N*-Dimethylpropranolol (II)

Compound	β-Adrenergic Receptor Blocking Activity, pA_2	Antiarrhythmic Activity	
		n	Dose, mg/kg
I	8.7[a]		6.1[b]
II	I(4.4)[c]		2–3[c]
IV*a*	10.0	5/5	4.8
IV*b*	8.5	5/5	5.7
IV*c*	6.6	3/3	10.0
VI*a*	I[d]	5/5	7.5
VI*b*	I	5/5	5.0
VI*c*	NT[e]	3/3	9.0

[a] Data from Ref. 15. [b] Data from Ref. 4. [c] Data from Ref. 10. [d] Inactive under conditions described under *Experimental*. [e] Not tested.

Antiarrhythmic Activity—All of the compounds tested were effective in converting the ouabain-induced ventricular tachycardia to normal sinus rhythm. Propranolol analogs IV*a*–IV*c* required doses of 4.8–10.0 mg/kg for conversion compared to 6.1 mg/kg required for propranolol (4). The iodinated analogs of *N,N*-dimethylpropranolol converted the ouabain-induced arrhythmias at doses of 5.0–9.0 mg/kg as compared to 2–3 mg/kg for the parent compound (10). In these preliminary studies, the *meta*-isomer (VI*b*) was the most potent antiarrhythmic agent among the iodinated analogs, followed in turn by the *ortho*-isomer (VI*a*) and the *para*-isomer (VI*c*).

Tissue Distribution—Based on the pharmacological results, the *meta*-iodinated analogs of propranolol and *N,N*-dimethylpropranolol were radioiodinated. The results of tissue distribution studies with these compounds are summarized in Table II. Administration of propranolol analog IV*b* resulted in no selective accumulation of radioactivity in myocardial tissue. On the other hand, there was marked uptake of activity in the lungs and liver. However, administration of the quaternary ammonium salt (VI*b*) resulted in selective concentration of radioactivity in rat myocardial tissue. Adrenal, lung, and thyroid tissues also showed high levels of uptake. The high levels of activity seen in the thyroid were believed to be due to *in vivo* deiodination of the compounds.

These results indicate that replacement of the naphthalene ring system in propranolol and *N,N*-dimethylpropranolol with an iodophenyl moiety does not markedly modify the pharmacological properties of the parent compounds. The iodinated analogs of propranolol all possessed β-adrenergic receptor blocking activity. However, the position of the iodine on the phenyl ring altered the potency of this activity. The β-blocking activities of propranolol and the *meta*-iodinated analog (IV*b*) were about equal and intermediate between the activities noted for the *ortho*-isomer (IV*a*) and the *para*-isomer (IV*c*).

This relationship also was observed for the antiarrhythmic activity of the three propranolol analogs. The doses needed to convert the ouabain-induced arrhythmia were about equal for propranolol (6.1 mg/kg) and the *meta*-iodinated analog, whereas lower and higher doses were required for the *ortho*- and *para*-isomers, respectively. Thus, the antiarrhythmic activity of these compounds paralleled their β-adrenergic receptor blocking activity. Since other drugs without β-adrenergic activity have antiarrhythmic properties, there may be no relationship between these two effects in the propanolol series; the antiarrhythmic action may be due to a direct membrane effect (5).

The absence of any significant localization of radioactivity in the heart following injection of radioiodinated IV*b* also paralleled the absence of marked localization of radioactivity in the myocardium reported after injection of ^{14}C-labeled propranolol (8). Similarly, other radioiodinated analogs of β-adrenergic antagonists have failed to demonstrate appreciable myocardial uptake and retention of radioactivity (13, 14).

Similar to the parent compound, the iodinated analogs of *N,N*-dimethylpropranolol (VI) were devoid of β-adrenergic receptor blocking activity. However, these analogs retained the antiarrhythmic activity of *N,N*-dimethylpropranolol, although larger doses of the analogs were

required to convert the ventricular tachycardia to normal sinus rhythm. The tissue distribution profile of radioiodinated VI*b* was comparable to that of II. At 2 hr after administration to rats, the heart to lung ratio of VI*b* was 3.6 whereas the ratio for the parent drug was 2.7. Studies are in progress using VI*b* labeled with iodine 131 as a probe for relating the antiarrhythmic activity of these quaternary drugs to their uptake and retention in the myocardium.

EXPERIMENTAL[2]

General procedures are described for the synthesis of III–VI, and experimental data are furnished in Table III.

1-(*o*-Iodophenoxy)-2,3-epoxypropane (III*a*)—Epichlorohydrin (2.7 g, 30 mmoles) was added dropwise at room temperature to a stirred solution of *o*-iodophenol (4.4 g, 20 mmoles) in 5% NaOH (25 ml). The reaction mixture was allowed to stir overnight. The oily layer that resulted was extracted with chloroform. This extract was washed with water and dried over anhydrous sodium sulfate. Removal of the solvent gave an oily residue which, upon distillation *in vacuo*, afforded a colorless oil (2.5 g).

1-(*o*-Iodophenoxy)-3-isopropylamino-2-propanol (IV*a*)—A solution of I*a* (5.4 g, 20 mmoles) and isopropylamine (8 ml) in isopropanol (60 ml) was stirred overnight at room temperature. The solution was evaporated to dryness, redissolved in 10% HCl, and washed with ether. The aqueous layer was made basic with sodium hydroxide and extracted with ether. The extract was washed with water, dried over anhydrous sodium sulfate, and concentrated to yield a solid. Upon recrystallization from acetone, this solid afforded a colorless solid (4.0 g).

1-(*o*-Iodophenoxy)-3-methylisopropylamino-2-propanol (V*a*)—Formaldehyde solution (37%, 0.8 ml) was added with stirring to a solution of II*a* (0.67 g, 2 mmoles) in absolute methanol (10 ml), and the reaction mixture was stirred at room temperature for 2 hr. Sodium borohydride (1.2 g) was added with stirring at ice bath temperature. The mixture was allowed to come to room temperature and then was poured into ice–water (100 ml). The mixture was extracted with ether, and the ether layer was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness *in vacuo*. The residue was dissolved in methanol–hydrochloric acid and diluted with ether. Filtration resulted in the hydrochloride salt (0.48 g), which was recrystallized from methanol–ether.

***N,N*-Dimethyl-1-(*o*-iodophenoxy)-3-isopropylamino-2-propanol Iodide (VI*a*)**—A mixture of IV*a* (3.35 g, 10 mmoles), sodium carbonate (1.1 g), and methyl iodide (5 ml) in absolute methanol (50 ml) was refluxed with stirring for 1 day. Additional methyl iodide (5 ml) was added, and refluxing was continued for 2 days. The solvent was removed under reduced pressure, and the resulting oily residue was washed with water. The residue was triturated with ethyl acetate and allowed to stand overnight. The resulting solid was filtered, washed with ethyl acetate,

[2] Melting points were taken on a Fisher-Johns melting-point apparatus and are corrected. Elemental analyses were performed by Midwest Microlab, Indianapolis, Ind., or by Spang Microanalytical Laboratory, Ann Arbor, Mich. IR spectra (Perkin-Elmer 337 spectrophotometer, either neat or as potassium bromide pellets) and NMR spectra (Varian A-60 spectrometer, taken in deuterated chloroform or dimethyl sulfoxide) were consistent with the proposed structures. TLC analyses were run on silica gel plates (Eastman Kodak), and spots were detected under UV light. Radiochemical purity of radioiodinated compounds was confirmed by TLC analysis, and they were scanned with an Atomic Associates RCS-363 radiochromatogram scanner. The corresponding authentic nonradioactive compound was cochromatographed with the radioiodinated compounds. Total radioactivities were determined with a Picker nuclear isotope calibrator.

Table IV—Isotope-Exchange Conditions and Results

Parameter	Compound IV*b*	Compound V*b*
Starting material, mg	200	200
Sodium [^{125}I]iodide, mCi	5	6
Solvent (ml)	Water (4.5)	Ammonium hydroxide (2.0)
Temperature	100°	100°
Reaction time	48 hr	5 days
Extract solvent	Chloroform	Ether
Resulting compound, mg	200	160
Total activity, μCi	600	2500
Percent exchange	12.0	41.7

and dried. Recrystallization from acetone or methanol–acetone afforded a colorless solid (3.0 g).

Isotope Exchange—Radioactive iodine was incorporated by heating a solution of the secondary (IV) or tertiary (V) amine in the presence of sodium [^{125}I]iodide. Table IV lists the experimental data. The quaternary derivative (VI) was formed by refluxing a methanolic solution of V in the presence of excess methyl iodide for 2 hr. Radiochemical purity was ascertained by TLC analysis of the compounds on silica gel plates[3] developed in ether–methanol (5:1) for IV and V or chloroform–methanol (3:1) for VI.

Pharmacology—*β-Adrenergic Receptor Blocking Activity*—Chronotropic concentration–effect curves to isoproterenol in spontaneously beating rabbit atrial strips were obtained using the procedure described by Schuster *et al.* (10). Probit analysis (16) was used to compute the median effective dose (ED_{50}) for each concentration–effect curve, and these values then were used to calculate the pA_2 values for the compounds tested according to the method described by Schild (17). The pA_2 value is defined as the negative logarithm of the antagonist concentration that doubles the agonist concentration required to achieve a given effect.

Antiarrhythmic Activity—Arrhythmias were induced in anesthetized male mongrel dogs (9–13 kg) with ouabain according to the procedure described by Schuster *et al.* (10). After establishment of ventricular tachycardia, a saline solution of the test material was administered intravenously until conversion to normal sinus rhythm was attained for at least 30 min with failure of right vagal stimulation to expose automatic ectopic ventricular activity during vagal-induced sinoatrial nodal arrest.

Tissue Distribution—Radioiodinated IV*b* and VI*b* were given by subcutaneous injection to male Sprague–Dawley rats[4], 180–330 g. The doses of radioactivity ranged from 22 to 25 μCi/rat (1.8–8.0 mg/rat) in 0.25 ml of vehicle. The vehicle was saline for VI*b* and 0.1 *N* HCl for IV*b*. At 2 and 6 hr after administration of the compounds, groups of three rats were killed by exsanguination while under ether anesthesia. Adrenal, blood, brain, heart, kidney, liver, lung, muscle, and thyroid samples were removed. Tissue samples were placed in liquid scintillation vials and weighed. Duplicate samples were taken.

The contents of each vial were digested overnight in 0.3–0.5 ml of 2.5 *N* NaOH. The vials were heated at 40–60° for 5–10 min to complete digestion. Four drops of hydrogen peroxide (30% solution) were added to each cooled vial to decolorize the samples. Enough 0.9–1.1 *M* acetic acid to neutralize the base and 10 ml of scintillation cocktail[5] were added to each sample, and the vials were shaken on a vortex mixer. The samples were assayed for radioactivity in a liquid scintillation counter[6] for 5 min or until enough counts had accumulated to reduce the counting error to 1%. Maximum counting error for samples that counted the full 5 min was 7%. Efficiency for iodine 125 was 45%.

Results are expressed as the percentage of the administered dose per gram of tissue and were calculated from:

$$\frac{\text{sample dpm} \times 1000\ \text{mg/g}}{\text{sample weight (mg)} \times 2.22 \times 10^6\ \text{dpm/}\mu\text{Ci} \times \text{dose (}\mu\text{Ci)}} \times 100$$

Potential Organ- or Tumor-Imaging Agents XX: Ovarian Imaging with 19-Radioiodinated Cholesterol

N. KORN, G. NORDBLOM, E. FLOYD, and R. E. COUNSELL ˣ

Received April 16, 1979, from the *Department of Pharmacology, Medical School, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication August 22, 1979.

Abstract □ Cholesterol is stored in the ovaries where it is a precursor in the biosynthesis of the female sex hormones progesterone and estradiol. The purpose of this study was to determine whether a radioiodinated analog of cholesterol, ^{125}I-labeled 19-iodocholesterol, would mimic cholesterol in this capacity and thus offer a means for imaging the ovaries of intact animals. Aside from the thyroid, the adrenal glands and ovaries of the female rat retained the highest levels of radioactivity at 4 days following the intravenous administration of ^{125}I-labeled 19-iodocholesterol. Moreover, the levels of radioactivity were sufficient to obtain clear images of the adrenal glands and ovaries with a small animal scanner. Folch analysis of these tissues revealed that >80% of the radioactivity was associated with the sterol ester fraction.

Keyphrases □ Cholesterol—19-radioiodinated analog, evaluation as ovarian imaging agent □ Radionuclide imaging—19-radioiodinated cholesterol, evaluation as ovarian imaging agent

19-Radioiodinated cholesterol originally was synthesized as an adrenal imaging agent (1). Since that time, this agent and its close relatives have been used in clinical diagnostic procedures for visualization of the adrenal glands and associated tumors (2).

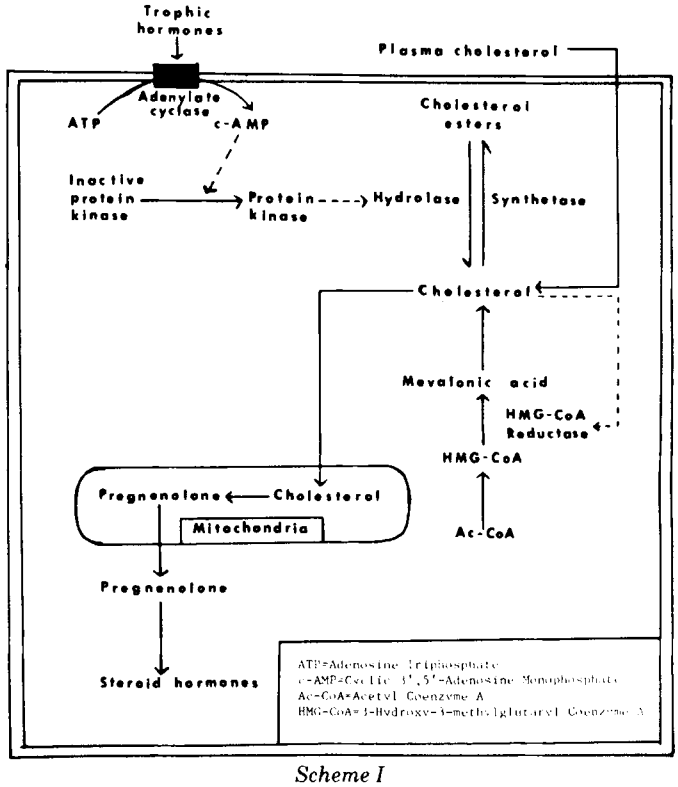
The synthesis of radioiodinated cholesterol as a radiodiagnostic agent was based on the knowledge that the adrenal cortex stores cholesterol for ultimate use in corticosteroid hormone biosynthesis. The ovary is another mammalian organ that is rich in cholesterol and that utilizes this lipid as a precursor for steroid hormone synthesis.

It is generally accepted that the synthesis of steroid hormones in the adrenal gland and ovary is controlled mainly by the trophic hormones adrenocorticotropic hormone and luteinizing hormone, respectively. While many details regarding their modes of action are unclear, they appear to influence the conversion of stored cholesterol ester to free cholesterol and the transformation of the latter compound to pregnenolone (Scheme I) (3).

This similarity between the ovary and the adrenal gland in the storage and utilization of cholesterol suggested that 19-iodocholesterol might accumulate in the ovaries and steroid-secreting ovarian tumors in addition to its predilection for adrenal cortical tissue. Thus, the purpose of this study was to compare the disposition of 19-radioiodinated cholesterol in the adrenal and ovarian tissues of the female rat.

EXPERIMENTAL

Radioiodinated Cholesterol—^{125}I-Labeled 19-iodocholesterol was prepared as described previously (1), yielding 14 mg with an estimated specific activity of 400 μCi/mg. The compound was dissolved in 5.0 ml of benzene and stored at 4° until just prior to use, at which time the material was formulated for injection as follows. An aliquot of the benzene solution was placed in a multidose vial, and the solvent was evaporated. The compound was redissolved in saline containing 1.6% polysorbate 80 and 10% ethanol. Prior to use, one aliquot of the solution was assayed for radioactivity to determine the radioactive concentration, and another aliquot was analyzed by TLC using silica gel G plates[1] developed in benzene–ethyl acetate (9:1).



Scheme I

Two solutions were prepared. Solution A, used for tissue distribution studies, was made using 1 ml of the benzene solution. The final volume of this solution was 10 ml (103 μCi/ml). Solution B, used for scanning, was prepared using 2.0 ml of the benzene solution. The final volume of this solution was 5.0 ml (350 μCi/ml). Both solutions showed only one radioactive peak when scanned with a radiochromatogram scanner[2]. The location of this peak was coincident with that of the authentic unlabeled material cochromatographed with the radioiodinated sample.

Tissue Distribution—Ten adult female Sprague–Dawley rats[3], 173–185 g, each received an intravenous injection of 25.8 μCi of ^{125}I-labeled 19-iodocholesterol in 0.25 ml of vehicle (Solution A) *via* the tail vein while under ether anesthesia. Rats were either in estrus or metestrus at the time of injection as determined by vaginal smear. Half of the rats were killed 1 day postadministration and half were killed 4 days postadministration by exsanguination from the heart while under ether anesthesia.

Tissues of the adrenal cortex and medulla, liver, ovary, blood, uterus, and thyroid were removed at sacrifice. Samples of the adrenal cortex, ovary, liver, and blood from each rat were placed on ice for subsequent extraction studies. All tissue samples were placed in tared cellulose acetate capsules and weighed. The capsules then were placed in polystyrene γ-counting tubes and assayed for radioactivity in a well scintillation counter[4] for 10 min or until 100,000 counts had accumulated. Counting efficiency for iodine 125 was 87% in all cases, except when glass culture

Table I—Distribution of Radioactivity following Intravenous Administration of ^{125}I-Labeled 19-Iodocholesterol to Female Rats

Tissue	Percent of Dose per Gram[a] 1 Day Postinjection	4 Days Postinjection
Adrenal cortex	10.195 ± 0.251	9.572 ± 0.349
Adrenal medulla	3.002 ± 0.438	1.990 ± 0.554
Blood	0.252 ± 0.010	0.021 ± 0.002
Liver	0.431 ± 0.026	0.059 ± 0.003
Ovary	5.929 ± 0.343	2.736 ± 0.437
Uterus	0.238 ± 0.010	0.055 ± 0.005
Thyroid	199.096 ± 18.263	152.042 ± 10.606

[a] Values represent the mean ± *SEM* for five rats.

tubes were used to hold samples. In the latter case, the counting efficiency was 77%.

Folch Extraction—Radioactivity was extracted from selected tissues using a variation of the procedure described by Folch *et al.* (4). The samples of the liver, adrenal cortex, and ovary were weighed and placed in a ground-glass homogenizer with sufficient distilled water to bring the combined volume of tissue and water to 0.5 ml (1 g of tissue was assumed to be equal to 1 ml). The samples were homogenized in 2–5 ml of chloroform–methanol (2:1) and filtered through filter paper[5]. The homogenizers then were rinsed twice with 2–4 ml of the solvent, and these rinses were filtered. The combined volume of the homogenizing vehicle plus the rinses for each sample was 10 ml.

Aliquots of blood (0.5 ml) were shaken with 5 ml of chloroform–methanol (2:1) in a conical centrifuge tube. The solvent was filtered, and the tube was rinsed with an additional 5 ml of solvent, which also was filtered and combined with the original filtrate. Similar to the tissue samples, the volume of the combined filtrates for each blood extract was measured and adjusted to 10 ml by addition of chloroform–methanol (2:1).

The filter paper with each precipitate was air dried, placed in a polystyrene γ-tube, and assayed as described to ascertain radioactivity associated with precipitable material. Each filtrate was placed in a 15-ml conical centrifuge tube. Distilled water (2.0 ml) was added, and the tube was shaken. The tubes then were centrifuged at low speed for 10 min to separate the phases. The upper phase of each sample was removed; the lower phase was washed with two 1.0-ml portions of Folch's upper phase solvent (chloroform–methanol–water, 3:48:47), which were combined with the upper phase from each sample. Each upper phase was adjusted to 10 ml by addition of the upper phase solvent, and a 1.0-ml aliquot of each upper phase was placed in a polyethylene microfuge tube, which then was placed in a polystyrene γ-tube and assayed for radioactivity as described.

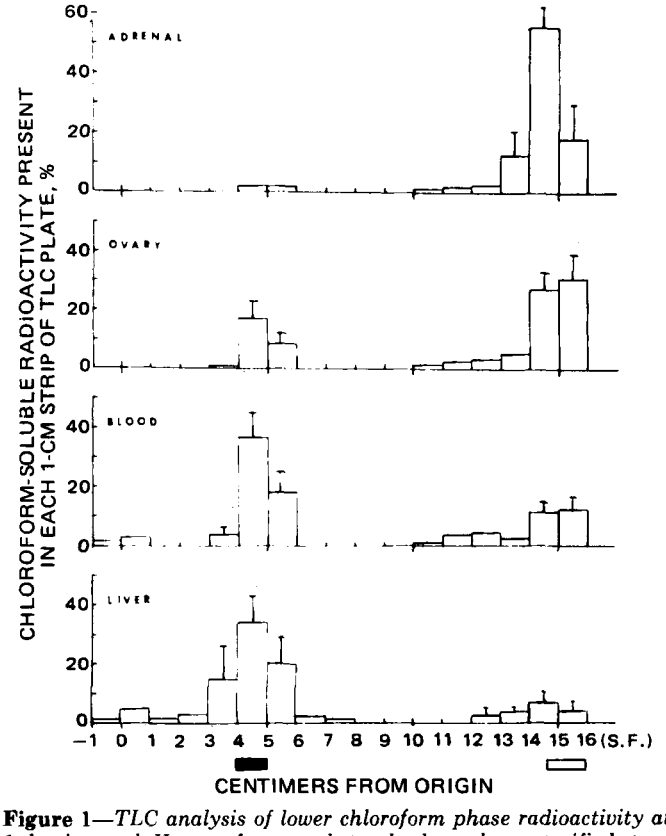

Figure 1—*TLC analysis of lower chloroform phase radioactivity at 1-day interval. Key:* ■, *free sterol standards; and* □, *esterified standards. S.F. = solvent front.*

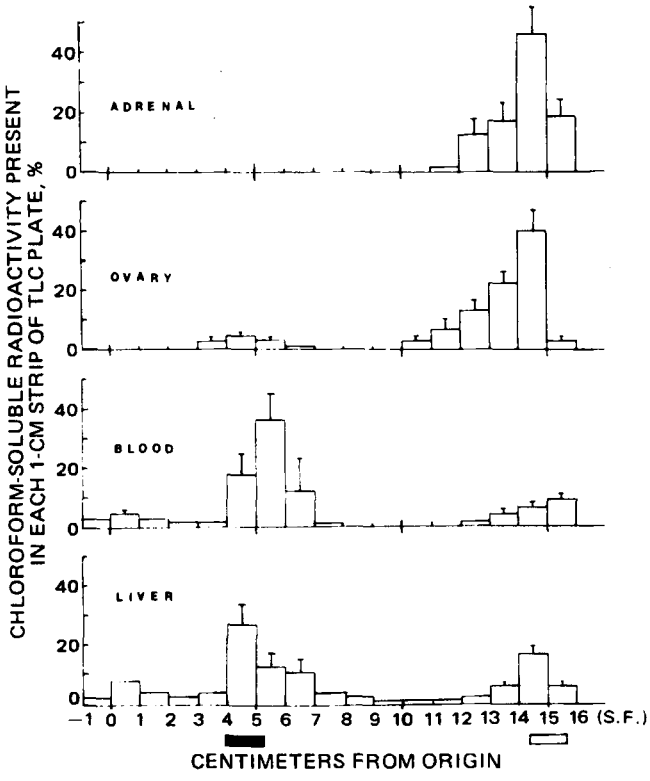

Figure 2—*TLC analysis of lower chloroform phase radioactivity at 4-day interval. Key:* ■, *free sterol standards; and* □, *esterified standards. S.F. = solvent front.*

Each lower phase was evaporated to dryness under nitrogen at 20–30°, and the residues were redissolved in 1.0 ml of benzene. An aliquot (100 μl) of each benzene fraction was placed in a glass culture tube, which then was placed in a polystyrene counting tube and assayed for radioactivity as described. The remainder of the benzene solution for each sample was stored overnight in a capped vial at 4°. The benzene then was evaporated, and the residues were redissolved in ether (10 drops) and spotted on TLC plates[6]. The vials were rinsed with another 10 drops of ether, which also was spotted on the plates. The plates then were developed once in *n*-hexane–ether–acetic acid (90:10:1) to 16 cm, air dried, and redeveloped in the same direction with *n*-hexane–ether–acetic acid (75:25:2). The plates were cut into 1-cm wide strips, starting 1 cm below the origin and continuing to the solvent front. Each strip was placed in a counting tube and assayed for radioactivity as described. Unlabeled 19-iodocholesterol, cholesterol, 19-iodocholesteryl palmitate, cholesteryl oleate, and pregnenolone were cochromatographed with the radioactive samples and visualized with iodine vapor to serve as reference standards.

Scintiscan of Female Rat—Two adult female Sprague–Dawley rats, 212 and 218 g, each received an intravenous injection of 245.4 μCi of ^{125}I-labeled 19-iodocholesterol in 0.7 ml of vehicle (Solution B) *via* the tail vein while under ether anesthesia. At 1 and 4 days postadministration, one rat was anesthetized with pentobarbital sodium by intraperitoneal injection (0.2 ml, 50 mg/ml) and scanned in the prone position using a small animal scanner. Following removal of the left ovary and adrenal gland, the rat was rescanned. The rat then was killed, and samples of the adrenal gland, ovary, and liver were assayed for radioactivity as described previously.

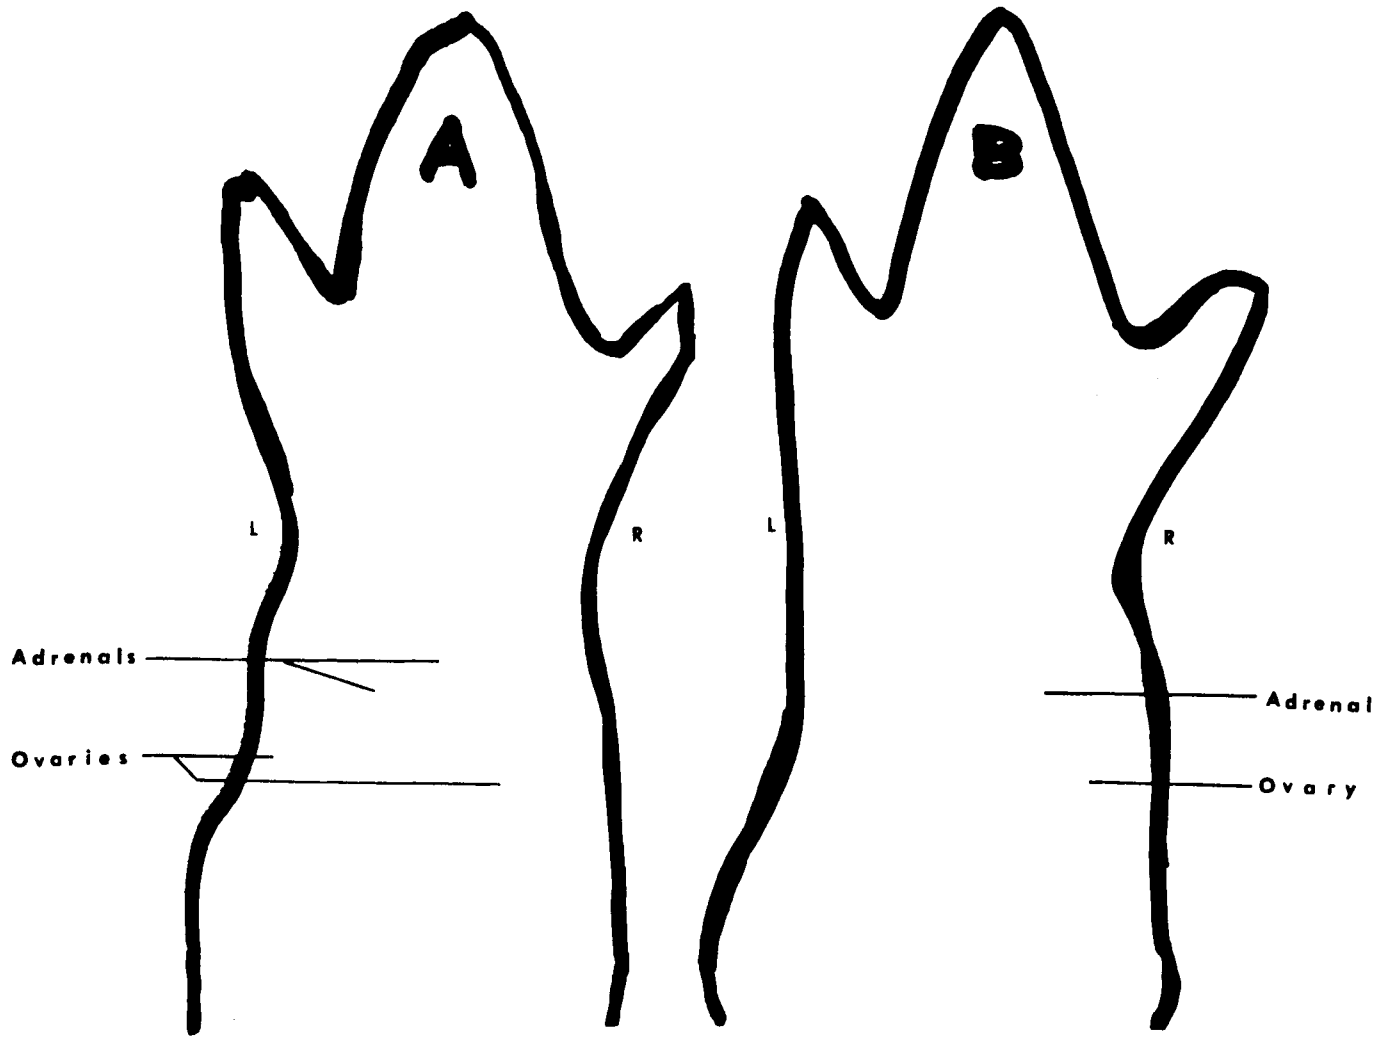

Figure 3—*Scintiscan of female rat 4 days after administration of ^{125}I-labeled 19-iodocholesterol (A) and rescan of the same rat following removal of the left ovary and left adrenal gland (B).*

RESULTS

Tissue Distribution—The distribution of radioactivity following intravenous administration of ^{125}I-labeled 19-iodocholesterol to female rats is summarized in Table I. High levels of radioactivity were noted in the adrenal cortex, ovaries, and thyroid at both times studied. The ovary to blood and ovary to liver ratios were 23 and 14 at 1 day postinjection and 138 and 47 at 4 days postinjection, respectively. The adrenal cortex to blood and adrenal cortex to liver ratios were 41 and 24 at the 1-day interval and 479 and 165 at the 4-day interval, respectively.

Folch Extraction—The results of the Folch extraction studies are summarized in Table II and Figs. 1 and 2. Greater than 90% of the radioactivity in the adrenal cortex was extractable into the lower chloroform phase at both the 1- and 4-day intervals. The remaining activity was found predominantly in the precipitated material, with only trace amounts in the upper aqueous phase. At the 1-day interval, 88% of the lower phase activity comigrated with the esterified standards; this activity increased to 95% by 4 days. While >90% of the radioactivity in the ovary also was extractable into the lower phase, only 58% of this activity comigrated with the esterified standards at the 1-day interval. Activity that comigrated with free sterol standards represented 25% of the lower phase activity. However, by 4 days, 86% of the activity was seen in the ester peak and only 10.4% was seen in the free sterol peak. Again, the remaining radioactivity was associated with the precipitated material.

For blood and liver samples, only 56–78% of the radioactivity was extractable into the lower phase. The remaining activity was found in both the precipitate and the upper phase. TLC analysis of the lower phase radioactivity showed that two distinct peaks were present; one peak corresponded to the free sterol standards, and one corresponded to the esterified sterol standards. However, unlike the adrenal gland and the ovary, most of the radioactivity was located in the free sterol peak.

Scintiscan of Female Rats—Attempts to scan the rat 1 day after administration of ^{125}I-labeled 19-iodocholesterol did not delineate the ovary or adrenal gland. Radioactivity present in the nontarget tissues of the abdominal cavity (*e.g.*, liver) as well as the adrenal glands and ovaries resulted in one large area of abdominal radioactivity. Removal of the left ovary and adrenal gland resulted in no detectable change in the image. Scintiscan of the rat 4 days after administration of ^{125}I-labeled 19-iodocholesterol (Fig. 3) resulted in the visualization of four areas of radioactivity. Removal of the left adrenal gland and ovary resulted in the corresponding disappearance of two radioactive areas when the rat was rescanned. The percent of dose per gram values for this animal were: adrenal, 10.707; ovary, 4.564; and liver, 0.062.

DISCUSSION

Results of tissue distribution and Folch extraction studies in rats showed that radioactivity was selectively accumulated and retained in an esterified form in the ovary as well as in the adrenal cortex following administration of ^{125}I-labeled 19-iodocholesterol. This finding is consistent with the reported similarities between the adrenal gland and ovary with regard to storage and utilization of cholesterol (3).

The retention of high levels of radioactivity in the adrenal gland and ovary several days after administration provides target to nontarget ratios necessary for resolution and visualization of these small organs. Although the level of radioactivity in the liver at 24 hr was considerably lower than that in either the adrenal gland or ovary, it was sufficient to interfere with imaging. However, after 4 days, the nontarget levels of radioactivity dropped significantly so that the target organs could be visualized.

The extremely high levels of radioactivity in the thyroid were noted previously (1) and are thought to be the result of *in vivo* deiodination and subsequent accumulation of free iodide in the thyroid where it becomes protein bound. Evidence for this conclusion lies in the blocking of thyroid

Table II—Percent of Radioactivity [a] Found in Each Phase following Folch Extraction of Tissue Radioactivity at 1 and 4 Days Postadministration of ^{125}I-Labeled 19-Iodocholesterol

Tissue	Day 1			Day 4		
	Precipitate	Upper	Lower	Precipitate	Upper	Lower
Adrenal	5.47 ± 2.36[b]	0.40 ± 0.42[b]	94.14 ± 2.48[b]	9.02 ± 3.54[b]	0.12 ± 0.14[b]	90.87 ± 3.65[b]
Blood	19.50 ± 4.74	13.87 ± 0.96	66.63 ± 5.21	29.00 ± 13.09	14.54 ± 4.98	56.47 ± 14.02
Liver	8.83 ± 2.00[b]	13.60 ± 2.04[b]	77.58 ± 2.29[b]	12.53 ± 1.91	11.18 ± 2.37	76.30 ± 3.87
Ovary	7.89 ± 2.21	0.92 ± 0.53	91.19 ± 1.82	8.81 ± 3.71	0.35 ± 0.10	90.84 ± 3.70

[a] Each value represents the mean ± *SD* for five rats unless noted. [b] Four rats.

uptake of radioactivity by pretreatment with potassium iodide solution (1) and in Folch extraction studies where >98% of the thyroid radioactivity was associated with the precipitated fraction[7].

The TLC systems used gave good separation of the free and esterified sterol. No further identification of radioactive products was attempted. Therefore, the esterified sterol peak could be made up of 19-iodocholesterol esterified with different saturated and unsaturated fatty acids. Similarly, slight alterations in the sterol portion of the molecule also could go undetected. Thus, [^{14}C]cholesterol and ^{125}I-labeled 19-iodocholesterol have the same R_f value in these systems.

Despite these limitations, these studies support the view that 19-iodocholesterol mimics cholesterol with regard to esterification and storage and that this property is a factor in its accumulation and retention for long periods in the adrenal cortex and ovary. In addition to its use in adrenal imaging, 19-radioiodinated cholesterol or related compounds may have clinical utility for the diagnosis of ovarian disorders.

Allyl Derivatives of Zearalenone

M. T. SHIPCHANDLER

Received May 10, 1979, from the *Research & Development Division, International Minerals & Chemical Corporation, Terre Haute, IN 47808.* Accepted for publication June 21, 1979. Present address: Diagnostics Division, Abbott Laboratories, North Chicago, IL 60064.

Abstract □ The Claisen rearrangement of 4-*O*-allylzearalenone led to only one principal product, which was identified as 3-allylzearalenone with the aid of photochemical isomerization and PMR spectroscopy. This general method is useful for distinguishing 3-substituted zearalenone isomers from 5-substituted isomers. Hydrogenation of 3-allylzearalenone gave 3-(1-propyl)zearalanone.

Keyphrases □ Zearalenone—allyl derivatives, synthesis □ Anabolic agents—zearalenone, synthesis of allyl derivatives

Zearalenone (I), a metabolite of *Gibberella zeae*, is produced *via* an industrial fermentation process (1). Several derivatives of I were synthesized to enhance its anabolic activity (2, 3). Zeranol (VI), a tetrahydro derivative, is used commercially as an anabolic agent in feedlot steers. The same fungus also produces four structurally related minor metabolites, one of which was characterized as 3-formylzearalenone (II) (4).

DISCUSSION

Isomeric 3- and 5-substituted zearalenones are not distinguished readily from each other by standard spectroscopic methods. Bolliger and Tamm (4) formylated zearalenone, and extensive PMR spectral scrutiny of the resulting 3- and 5-formylzearalenones and their corresponding dimethyl ethers led to the unequivocal assignment of Structure II to the metabolite (4). In another instance, III, the Kolbe–Schmitt reaction product of zearalenone, was subjected to extensive degradation (5).

This report describes a simple photochemical method coupled with PMR spectroscopy for a facile structural assignment. 4-*O*-Allylzearalenone (IV) was subjected to the Claisen rearrangement at 190–195°, and the principal product, V (mp 116–118°), was isolated in a 48% yield. It was isomerized to 3-allyl-*cis*-zearalenone (VIII) *via* the photochemical method of Peters (6). In the comparative PMR spectra of V and VIII, the upfield shift (13 Hz) of the aromatic proton of C-5 was very distinct, while the shifts of the allyl group protons were practically unchanged (6). Such an upfield shift of the aromatic proton of C-3 is not expected to occur in 5-substituted derivatives. The Claisen product thus was identified as 3-allylzearalenone (V). Low-pressure hydrogenation of VI gave 3-(1-propyl)zearalanone (VII).

EXPERIMENTAL[1]

4-*O*-Allylzearalenone (IV)—Compound I (15.9 g, 0.05 mole), allyl bromide (24.2 g, 0.2 mole), and potassium carbonate (10.0 g, 0.07 mole) were stirred and refluxed in acetone (200 ml) for 8 hr. The filtered inorganic salts were washed well with more solvent. The combined washings and filtrate were evaporated under reduced pressure. The residue was crystallized from 2-propanol to give 10 g of IV, mp 123–125°. In the PMR spectrum, a peak at δ 12.00 indicated the presence of the chelated hydroxyl proton at the 2-position; the absence of a peak at about δ 8.00 of the hydroxyl proton at the 4-position indicated allylation of this site. With two aromatic protons at δ 6.38 and 6.48 (J = 2.5 Hz), the rest of the spectrum was consistent with the assigned structure.

[1] Melting points (uncorrected) were measured with a Thomas-Hoover apparatus. PMR spectra were recorded on a Varian A 60-A instrument in deuterochloroform with tetramethylsilane as the internal standard. Elemental analyses were carried out by Microanalyses Inc.

uptake of radioactivity by pretreatment with potassium iodide solution (1) and in Folch extraction studies where >98% of the thyroid radioactivity was associated with the precipitated fraction[7].

The TLC systems used gave good separation of the free and esterified sterol. No further identification of radioactive products was attempted. Therefore, the esterified sterol peak could be made up of 19-iodocholesterol esterified with different saturated and unsaturated fatty acids. Similarly, slight alterations in the sterol portion of the molecule also could go undetected. Thus, [^{14}C]cholesterol and ^{125}I-labeled 19-iodocholesterol have the same R_f value in these systems.

Despite these limitations, these studies support the view that 19-iodocholesterol mimics cholesterol with regard to esterification and storage and that this property is a factor in its accumulation and retention for long periods in the adrenal cortex and ovary. In addition to its use in adrenal imaging, 19-radioiodinated cholesterol or related compounds may have clinical utility for the diagnosis of ovarian disorders.

Anal.—Calc. for $C_{21}H_{26}O_5$: C, 70.37; H, 7.31. Found: C, 70.63; H, 7.13.

3-Allylzearalenone (V)—Compound IV (5.0 g) was placed in an oil bath maintained at 190–195° for 5 hr. TLC examination revealed only one principal product. The melt was chromatographed over a silica gel column[2] (100 g, 28 × 3.3 cm) and eluted with benzene and chloroform mixtures of increasing polarity. The fractions containing the product were evaporated together, and V was crystallized from methanol–water to give 2.5 g of white crystals, mp 116–118°. In the PMR spectrum, only one aromatic proton appeared as a singlet at δ 6.48 and two peaks of phenolic proton resonances appeared at δ 12.00 and 8.64. The C-1′ olefinic proton appeared as a doublet at δ 7.12 (J = 15 Hz).

Anal.—Calc. for $C_{21}H_{26}O_5$: C, 70.37; H, 7.31. Found: C, 70.47; H, 7.33.

3-Allyl-*cis*-zearalenone (VIII)—Compound V (1.3 g) was photoisomerized[3] in methanol (100 ml) for 60 hr according to the method of Peters (6). Evaporation gave a glassy substance (1.2 g), which could not be purified by crystallization. The peak ratio of the C-5 aromatic protons in the PMR spectrum (deuterium oxide was added to remove the interfering resonance of the C-4 phenolic proton) indicated a 90–95% conversion. The singlet resonance of the C-5 aromatic proton appeared at δ 6.26, and the doublet resonance of the C-1′ olefinic proton appeared at δ 6.65 (J = 12 Hz). This observation was consistent with that of Peters (6).

3-(1-Propyl)zearalanone (VII)—Compound V (1.0 g) was hydrogenated under 50 psi in methanol (100 ml) for 3 hr in the presence of palladium-on-carbon (5%, 0.1 g). The catalyst was removed *via* filtration, and the filtrate was evaporated under reduced pressure. The residue was crystallized from methanol–water to yield 1.1 g of white crystals, mp 161–162.5°. There were no resonances of olefinic protons in the PMR spectrum. The singlet resonance of the C-5 aromatic proton appeared at δ 6.27, and the pseudotriplet resonance of the methyl protons (of the propyl group) appeared at δ 1.00 (J = 6 Hz).

Anal.—Calc. for $C_{21}H_{30}O_5$: C, 69.58; H, 8.34. Found: C, 69.70; H, 8.40.

[2] Baker No. 3404.

[3] The photoisomerization process does not need to be complete. For example, the shifts at δ 6.48 and 6.26 of the C-5 aromatic protons were distinct in the PMR spectrum of the reaction mixture containing approximately equal amounts of V and VIII.

Carbocyclic Analogs of Arabinosylpurine Nucleosides

HEEJOO LEE and ROBERT VINCE ˣ

Received March 12, 1979, from the *Department of Medicinal Chemistry, College of Pharmacy, University of Minnesota, Minneapolis, MN 55455.* Accepted for publication August 22, 1979.

Abstract □ Carbocyclic analogs of arabinofuranosylguanine (VII) and 2,6-diamino-9-β-arabinofuranosylpurine (VIII) and the corresponding 8-azapurine analogs, 5-amino-7-hydroxy-3-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]-ν-triazolo[4,5-*d*]pyrimidine (X) and 5,7-diamino-3-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]-ν-triazolo[4,5-*d*]pyrimidine (XI), were prepared. Carbocyclic nucleoside analogs VII and X exhibited significant cytotoxicity against P-388 mouse leukemia cells in culture. *In vitro* testing against herpes simplex type 1 (strain HF) indicated that only VIII exhibited significant antiviral activity.

Keyphrases □ Arabinosylpurine nucleosides—carbocyclic analogs, synthesis and evaluation for antitumor and antiviral activity □ Antitumor activity—carbocyclic analogs of arabinosylpurine nucleosides, synthesis and testing □ Antiviral activity—carbocyclic analogs of arabinosylpurine nucleosides, synthesis and testing

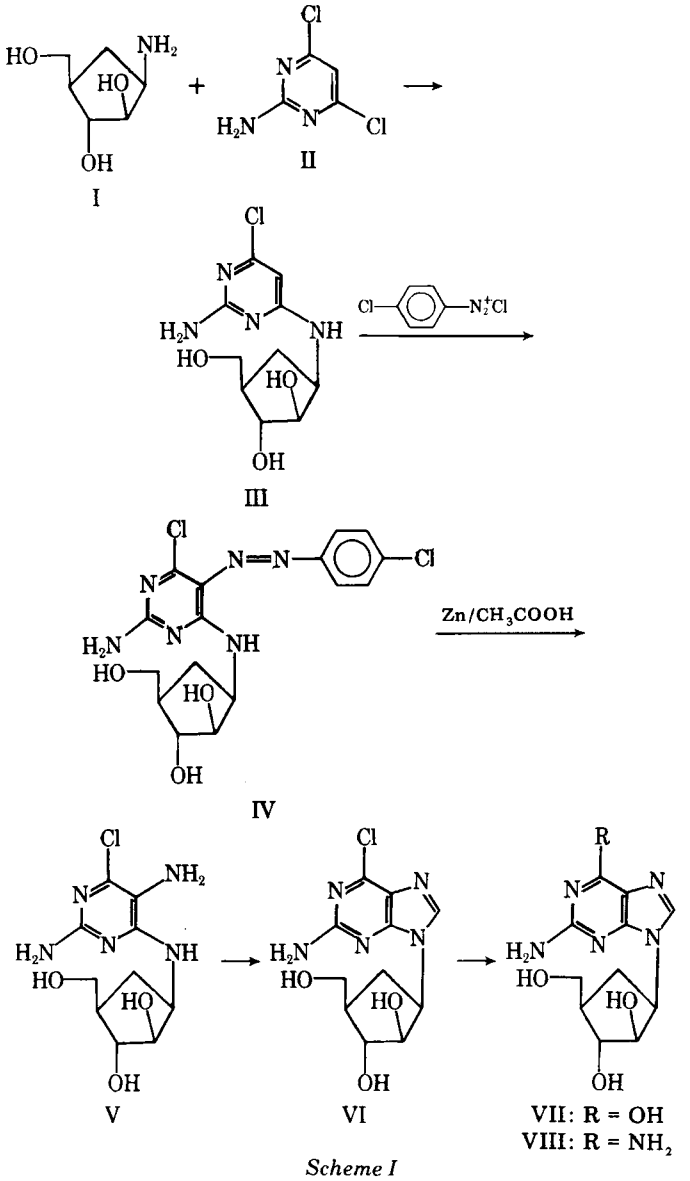
The significant antiviral and antitumor activities exhibited by the adenosine deaminase-resistant carbocyclic analog of arabinofuranosyladenine (1) prompted the synthesis of a variety of carbocyclic arabinosylpurine nucleosides. Recent studies with other antiviral nucleosides suggested that purine derivatives other than adenine should be explored in cases where an adenine nucleoside exhibits antitumor or antiviral properties (2, 3). In the case cited, the antiviral activity of the guanine analog in a series of 9-(2-hydroxyethoxymethyl)purines was two orders of magnitude greater than that of the corresponding adenine analog. In addition, Elion *et al.* (4) demonstrated high antiviral activity with 2,6-diamino-9-β-arabinofuranosylpurine. However, this analog was deaminated rapidly by adenosine deaminase. These results provide an excellent rationale for the synthesis of the guanosine and 2,6-diaminopurine derivatives of carbocyclic arabinosyl nucleosides.

RESULTS AND DISCUSSION

The synthesis of the carbocyclic purine nucleosides is outlined in Scheme I[1]. Condensation of (±)-4α-amino-2β,3α-dihydroxy-1α-cyclopentanemethanol (I) (1) with 2-amino-4,6-dichloropyrimidine (II) gave the corresponding pyrimidinylamino derivative (III). The 5-(*p*-chlorophenylazo)pyrimidine (IV) was prepared with *p*-chlorobenzenediazonium chloride by the method of Shealy and Clayton (5). Reduction of IV with zinc and acetic acid gave the pyrimidine V, which subsequently was converted to the 9-substituted 2-amino-6-chloropurine (VI) by ring closure with diethoxymethyl acetate and subsequent mild acid hydrolysis. Treatment of VI with 1 *N* HCl under reflux conditions gave carbocyclic arabinosylguanine (VII), while treatment of VI with liquid ammonia gave carbocyclic arabinosyl 2,6-diaminopurine (VIII).

The 8-azapurine analogs were obtained as illustrated in Scheme II. Ring closure of V with sodium nitrite and hydrochloric acid gave an excellent yield of (±)-5-amino-7-chloro-3-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]-ν-triazolo[4,5-*d*]pyrimidine (IX). Acid hydrolysis of IX gave the 8-aza analog (X) of carbocyclic arabinosylguanine, whereas treatment of IX with liquid ammonia gave the 8-aza analog (XI) of carbocyclic arabinosyl 2,6-diaminopurine.

The ED_{50} cytotoxicity concentrations of VI–XI in P-388 mouse leukemia cell culture are listed in Table I. Carbocyclic arabinosylguanine



Scheme I

(VII) and 8-aza carbocyclic arabinosylguanine (X) exhibited significant cytotoxicities in this assay. All purine analogs were examined for *in vitro* antiviral activity against herpes simplex virus type 1 (strain HF) by quantitating the inhibition of virus-induced cytopathogenic effects in infected cultures.

The virus was propagated and assayed for infectivity in continuous-

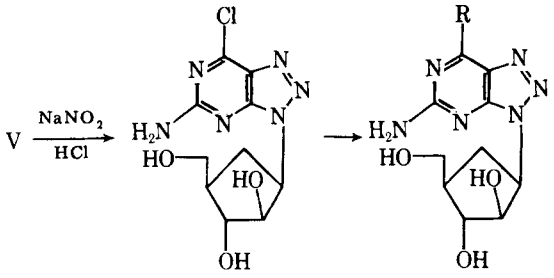

Scheme II

passage, human epidermoid carcinoma of the larynx (H. Ep.-2) cells. Virus ratings were calculated for the activity of each compound using a modification of the method of Ehrlich *et al.* (6) that was described previously (7, 8). Only the carbocyclic arabinosyl 2,6-diaminopurine analog (VIII) exhibited significant antiviral activity with a virus rating of 1.5[2].

EXPERIMENTAL[3]

TLC was performed using 0.25-mm layers of silica gel[4], and column chromatography was performed on silica gel[5]. PMR spectra were taken with a 60-MHz[6] or 100-MHz[7] spectrometer with tetramethylsilane as the internal standard. Melting points were determined in capillaries with a melting-point block[8] and are uncorrected.

(±)-2-Amino-4-*N*-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]amino-6-chloropyrimidine (III)—A mixture of aminoalcohol I [obtained from hydrolysis of 20 mmoles of (±)-4α-acetamido-2β,3α-diacetoxy-1α-cyclopentanemethyl acetate as described in Ref. 1], 2-amino-4,6-dichloropyrimidine (4.92 g, 30 mmoles), and triethylamine (20 ml) in 1-butanol (100 ml) was refluxed under nitrogen gas for 2 days (9). The solvent was removed under reduced pressure, and the residue was dissolved in water (200 ml). The aqueous solution was washed with methylene chloride (2 × 200 ml) to remove excess 2-amino-4,6-dichloropyrimidine. The aqueous solution was stirred briefly with anion-exchange resin[9] (40 ml), evaporated under reduced pressure, and azeotroped with absolute ethanol to dryness.

The liquid residue was dissolved in methanol–methylene chloride (1:4, 20 ml) and refrigerated. A pale-yellow crystalline product was collected by filtration, and recrystallization from methanol–methylene chloride (1:1) gave III as white granules (4.3 g, 78% from the acetamido acetate), mp 189–190°; UV: λ_{max} ($\epsilon \times 10^{-3}$) 310 (9.0), 274 (11.4), 238 (17.0), and 210 (28.0) in 0.1 *N* HCl, 284 (11.5), 239 (13.0), and 210 (30.0) in water, and 284 (11.3) and 236 (13.3) in 0.1 *N* NaOH; IR (KBr): 3500–3200 (NH and OH), 1640 (NH), and 1585 (C=C and C=N) cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 1.1–2.2 (m, 3H, CH and CH_2), 3.1–3.8, 4.0–5.1 (m, all other protons with water in the solvent), 5.87 (s, 1H, H at pyrimidine C-5), 6.33 (s, 2H, NH_2), and 6.74 (broad s, 1H, NH).

Anal.—Calc. for $C_{10}H_{15}ClN_4O_3$: C, 43.72; H, 5.50; Cl, 12.91; N, 20.40. Found: C, 43.51; H, 5.41; Cl, 12.94; N, 20.24.

(±)-2-Amino-4-*N*-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]amino-5-*p*-chlorophenylazo-6-chloropyrimidine (IV)—A cold (0–5°) solution of *p*-chlorobenzenediazonium chloride was prepared by adding a solution of sodium nitrite (0.65 g, 9.5 mmoles) in water (5 ml) to a solution of *p*-chloroaniline (1.15 g, 9 mmoles) dissolved in 12 *N* HCl (5 ml) and water (15 ml) and cooled in an ice–salt bath (5). The cold solution of *p*-chlorobenzenediazonium chloride was added dropwise to a mixture of III (2.15 g, 7.8 mmoles), sodium acetate trihydrate (17 g), acetic acid (40 ml), and water (40 ml) at room temperature. A yellow precipitate formed immediately, but the reaction mixture was stirred at room temperature overnight. The mixture was cooled in an ice bath; the yellow precipitate was filtered, washed with cold water, and dried.

The solid product was crystallized from methanol to yield yellow crystals (2.5 g, 77.6%, mp 243–246°), which were homogeneous by TLC and were used for the next reaction without further purification. An analytical sample of IV was obtained by recrystallization from methanol, mp 256–258°; UV: λ_{max} ($\epsilon \times 10^{-3}$) 372 (27.6), 266, and 228 (24.0) in 0.1 *N* HCl, 386 (29.8), 278 (11.6), and 226 (17.5) in water, and 386 (30.5) and 267 (13.8) in 0.1 *N* NaOH; IR (KBr): 3450–3100 (OH, NH), 1650 (NH), and 1570 (C=C and C=N) cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 1.15–2.43 (m, 3H, CH_2 and CH in cyclopentane ring), 3.29–3.92 (m, 5H, 3 CH, OH, and HOD), 4.33–4.72 (m, 2H, CH_2), 4.85 and 5.51 (2d, 2H, 2 OH), and 7.37–7.91 (m, 7H, aromatic, NH_2, and NH).

Anal.—Calc. for $C_{16}H_{18}Cl_2N_6O_3$: C, 46.50; H, 4.39; Cl, 17.16; N, 20.34. Found: C, 46.55; H, 4.38; Cl, 17.42; N, 20.23.

(±)-2,5-Diamino-4-*N*-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]amino-6-chloropyrimidine (V)—A mixture of IV (2.5 g, 6.1 mmoles), zinc dust (200 mesh, 4 g), and acetic acid (2 ml) in ethanol (100 ml) and water (100 ml) was refluxed under nitrogen until the yellow color of IV disappeared (5 hr) (5). Excess zinc was removed by filtration, and the solvent was evaporated under reduced pressure. The brown residue was dissolved in water (150 ml), and the aqueous solution was washed with methylene chloride to remove *p*-chloroaniline. After removal of water under reduced pressure, the residue was dissolved in ethanol–ethyl acetate and the solution was refrigerated overnight.

Filtration and dryness gave a crude brown product[10] (1.545 g, mp 213–215°). Repeated crystallization (three times) from water-ethanol (1:4) gave V as a slightly pink powder, mp 236–238°; UV: λ_{max} ($\epsilon \times 10^{-3}$) 298 (7.9) and 234 (18.9) in 0.1 *N* HCl, 302 (9.3), 242, 226, and 202 (19.1) in water, and 302 (9.0) and 244 in 0.1 *N* NaOH; IR (KBr): 3400–3200 (NH and OH), 1650, 1615, 1575, 1505, and 1470 cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 0.82–2.17 (m, 3H, CH_2 and CH in cyclopentane ring), 3.1–3.8 and 4.0–4.82 (m, other protons with HOD), 5.40 (broad s, 2H, NH_2), and 5.87 (d, 1H, NH).

Anal.—Calc. for $C_{10}H_{16}ClN_5O_3$: C, 41.45; H, 5.57; Cl, 12.24; N, 24.17. Found: C, 41.64; H, 5.68; Cl, 12.05; N, 24.39.

(±)-2-Amino-6-chloro-9-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]purine (VI)—Compound V (200 mg, 0.7 mmole) in diethoxymethyl acetate (20 ml) was stirred at room temperature for 1 hr, and the clear solution was heated at 80° for 24 hr with stirring. The solvent was removed under reduced pressure, and the oil residue was dissolved in 0.5 *N* HCl (10 ml) and stirred at room temperature for 30 min. The reaction solution was neutralized with anion-exchange resin[9] (pH 7–8), and the water was evaporated and azeotroped with absolute ethanol. The residue was purified by passing it through a silica gel column with methanol–methylene chloride (3:17) as the eluent.

Evaporation of the solvent of the corresponding fraction left 145 mg (69%) of a pink solid, mp 208–209°, which was homogeneous by TLC. Recrystallization from methanol–methylene chloride gave the analytically pure VI as a pink powder, mp 209–210°; UV: λ_{max} ($\epsilon \times 10^{-3}$) 312 (7.0), 242, and 218 (29.2) in 0.1 *N* HCl, 306 (8.2), 246, and 222 (28.2) in water, and 306 (8.1) and 246 in 0.1 *N* NaOH; IR (KBr): 3490, 3350 (br), 3220, 1658 (NH), 1610, 1565 (C=C and C=N), and 1035 (C–O) cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 1.65–2.35 (m, 3H, CH_2 and CH in cyclopentane ring), 3.11–4.01, 4.41–5.31 (CH_2O, 2 CHO, CHN, 3 OH, and HOD in dimethyl sulfoxide-d_6), 6.86 (s, 2H, NH_2), and 8.12 (s, 1H, H at purine C-8).

Anal.—Calc. for $C_{11}H_{14}ClN_5O_3$: C, 44.08; H, 4.71; Cl, 11.83; N, 23.37. Found: C, 44.24; H, 4.78; Cl, 11.93; N, 23.50.

(±)-9-[2α,3β-Dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]guanine (VII)—A solution of VI (146 mg, 0.49 mmole) in 1 *N* HCl (10 ml) was refluxed for 5 hr, and then the water was evaporated and azeotroped with absolute ethanol. The liquid residue was dissolved in a small amount of water, and the solution was neutralized (pH 6–7) with 6 *N* NaOH. The white precipitate formed immediately, but the solution was refrigerated for 1 hr. The solid product was collected by filtration and washed with cold water to yield 130 mg (94.3%) of a white powder, mp 290–293°.

Recrystallization from water gave VII as a white powder, mp 292–294°; UV: λ_{max} ($\epsilon \times 10^{-3}$) 227 (sh) and 252 (14.1) in 0.1 *N* HCl, 270 (sh) and 251 (13.5) in water, and 267 (12.0) and 254 (sh) in 0.1 *N* NaOH; IR (KBr): 3470, 3320, 3210, 2940–2500 (br), 1735 (C=O), 1630, and 1610 cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 1.6–2.3 (m, 3H, CH_2 and CH in cyclopentane ring), 3.31 (s, OH and HOD), 3.4–3.9 (m, 4H, CHO, CHN, and

[2] Virus rating (VR) is a weighted measurement of antiviral activity based on the *in vitro* inhibition of virus-induced cytopathogenic effects and the cytotoxicity exhibited by the drug as described in Ref. 6. A VR of >1.0 indicates definite (+) antiviral activity, and a VR of <0.5 indicates no (−) apparent antiviral activity.

CH_2O), 4.56–5.20 (m, 4H, 3 OH and CHO), 6.38 (s, 2H, NH_2), and 7.68 (s, 1H, H at purine C-8).

Anal.—Calc. for $C_{11}H_{15}N_5O_4$: C, 46.97; H, 5.38; N, 24.90. Found: C, 46.74; H, 5.42; N, 24.89.

(±)-2-Amino-9-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]adenine (VIII)—The chloropurine VI (390 mg, 1.3 mmoles) was stirred in excess liquid ammonia in a steel bomb at 75° for 42 hr. The bomb was cooled in a dry ice bath, and the reaction mixture was transferred to a beaker using methanol. The ammonia was allowed to evaporate at room temperature, and evaporation of methanol left a white powder.

Crystallization from water gave VIII as pink crystals (323 mg, 83.3%), mp 266–268°; UV: λ_{max} ($\epsilon \times 10^{-3}$) 290 (11.0), 251 (12.7), and 216 (27.0) in 0.1 *N* HCl, 280 (10.5), 254 (8.7), and 214 (273) in water, and 279 (11.5) and 254 (9.4) in 0.1 *N* NaOH; IR (KBr): 3470, 3410, 3330, 3210, 3130, 2900–2500 (br), 1670, 1630, and 1600 (NH, C=C and C=N) cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 1.71–2.31 (m, 3H, CH_2 and CH in cyclopentane ring), 3.27–3.91 (m, 8H, CHO, CNH, CH_2O, and H_2O), 4.57–5.33 (m, 4H, 3 OH and CHO), 5.77 (s, 2H, NH_2), 6.63 (s, 2H, NH_2), and 7.71 (s, 1H, H at purine C-8).

Anal.—Calc. for $C_{11}H_{16}N_6O_3 \cdot H_2O$: C, 44.28; H, 6.08; N, 28.18. Found: C, 44.04; H, 6.12; N, 28.56.

(±)-5-Amino-7-chloro-3-[2α,3β-dihydroxy-4α-(hydroxymethyl)-cyclopent-1α-yl]-ν-triazolo[4,5-*d*]pyrimidine (IX)—A solution of V (180 mg, 0.62 mmole) in 1 *N* HCl (1.3 ml) and water (4 ml) was cooled in an ice–salt bath, and sodium nitrite (45 mg, 0.65 mmole) was added with stirring. After 5 min (the solution was frozen), the ice–salt bath was removed and the solution was stirred at room temperature for 1 hr. The reaction solution was neutralized with sodium bicarbonate (109 mg, 1.3 mmoles) and then evaporated to dryness by azeotroping with absolute ethanol. The remainder was passed through a silica gel column with methanol–methylene chloride (1:4) as the eluent and gave a solid product (152 mg, 82%), mp 209–210°.

Recrystallization from methanol gave IX as a white powder, mp 210° dec.; UV: λ_{max} ($\epsilon \times 10^{-3}$) 314 (7.5) and 223 (27.0) in 0.1 *N* HCl, 314 (7.5) and 223 (22.9) in water, and 276 (12.4) in 0.1 *N* NaOH; IR (KBr): 3360, 3320, 3200 (OH and NH), 2960, 2920, 1640 (NH), 1600, 1570, 1510 (C=C and C=N), and 1110 (C—O) cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 1.80–2.46 (m, 3H, CH and CH_2 in cyclopentane ring), 3.40–4.14 (m, 4H, CHO, CHN, and CH_2O), 4.54–5.14 (m, 4H, CHO and 3 OH), and 7.56 (s, 2H, NH_2).

Anal.—Calc. for $C_{10}H_{13}ClN_6O_3$: C, 39.93; H, 4.35; Cl, 11.79; N, 27.95. Found: C, 39.66; H, 4.31; Cl, 11.79; N, 28.03.

(±)-5-Amino-7-hydroxy-3-[2α,3β-dihydroxy-4α-(hydroxymethyl)cyclopent-1α-yl]-ν-triazolo[4,5-*d*]pyrimidine (X)—A solution of IX (139 mg, 0.46 mmole) in 10 ml of 1 *N* HCl was refluxed for 5 hr, and the solvent was removed under reduced pressure and azeotroped with absolute ethanol. The solid residue was dissolved in a small amount of water, and the aqueous solution was refrigerated. Filtration afforded a fine crystalline product (pale brown, 80 mg, 62%), mp 210–215°.

Recrystallization from water gave X as pale-brown fine crystals, mp 215–217° (shrinking) and 275–277° dec.; UV: λ_{max} ($\epsilon \times 10^{-3}$) 270 (sh) and 252 (15.2) in 0.1 *N* HCl, 270 (sh), 252 (13.5), and 202 (24.0) in water, and 277 (13.0) in 0.1 *N* NaOH; IR (KBr): 3480, 3400, 3360, 3300, 3200 (OH and NH), 2940, 2880, 2800, 2740, 1700 (C=O), 1640, 1590, 1530 (C=C and C=N), and 1035 (C—O) cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 1.70–2.44 (m, 3H, CH and CH_2 in cyclopentane ring), 3.34 (s, OH and HOD), 3.40–4.10 (m, 4H, CHO, CHN, and CH_2O), 4.46–5.00 (m, 4H, 3 OH and CHO), and 6.80 (s, 2H, NH_2).

Anal.—Calc. for $C_{10}H_{14}N_6O_4$: C, 42.55; H, 5.00; N, 29.78. Found: C, 42.21; H, 5.07; N, 29.52.

(±)-5,7-Diamino-3-[2α,3β-dihydroxy - 4α - (hydroxymethyl)cyclopent-1α-yl]-ν-triazolo[4,5-*d*]pyrimidine (XI)—The chloro compound IX (202 mg, 0.67 mmole) was shaken with excess liquid ammonia in a steel bomb at room temperature for 2 days. Evaporation of ammonia left a solid residue, which was dissolved in hot water (10 ml). Refrigeration of the aqueous solution yielded a solid product (147 mg, 75.6%), mp 245–247°.

Recrystallization from water afforded XI as a white powder, mp 260–262°; UV: λ_{max} ($\epsilon \times 10^{-3}$) 282 (9.2), 252 (13.0), and 211 (32.8) in 0.1 *N* HCl, 283 (11.7), 250 (sh), and 222 (27.2) in water, and 283 (12.6) and 254 (sh) in 0.1 *N* NaOH; IR (KBr): 3500, 3400, 3320, 3140 (OH and NH), 2940, 2880, 1675 (NH), 1610, 1490 (C=C and C=N), and 1050 (C—O) cm^{-1}; PMR (100 MHz, dimethyl sulfoxide-d_6): δ 1.76–2.40 (m, 3H, CH_2 in cyclopentane ring), 3.40–4.12 (m, 4H, CHO, CNH, and CH_2O), 4.50–5.04 (m, 4H, 3 OH and CHO), 6.28 (s, 2H, NH_2), and 7.46 (s, 2H, NH_2).

Anal.—Calc. for $C_{10}H_{15}N_7O_3 \cdot 1/2H_2O$: C, 41.37; H, 5.56; N, 33.78. Found: C, 41.62; H, 5.56; N, 33.63.

Latentiated Forms of the Transport-Inhibitory α-Amino Acid Adamantanine

HERBERT T. NAGASAWA ˣ, JAMES A. ELBERLING, and FRANCES N. SHIROTA

Received March 12, 1979, from the *Medical Research Laboratories, Veterans Administration Medical Center, and the Department of Medicinal Chemistry, College of Pharmacy, University of Minnesota, Minneapolis, MN 55417.* Accepted for publication July 10, 1979.

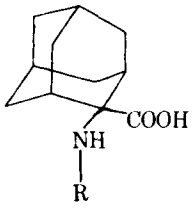
Abstract □ *N*-(γ-L-Glutamyl)adamantanine (Ic) and *N*-hydroxyadamantanine (I*b*) were synthesized as latentiated forms of the transport-inhibitory α-amino acid adamantanine (I*a*), and their biological properties were evaluated. Inhibition of the growth of P-388 tumor cells by I*b* was comparable with that of the antitumor agent *N*-hydroxycycloleucine (II*b*). *In contrast*, Ic was inactive in this system, presumably because it was not a substrate for γ-glutamyltranspeptidase. Nevertheless, the concept proposed here of using the enzyme, γ-glutamyltranspeptidase, to latentiate drugs *in vivo* by synthetic γ-glutamylation of an amino or hydroxyl group on the drug molecule appears to be worthy of further exploration.

Keyphrases □ Adamantanine—synthesis of latentiated forms and biological evaluation □ Antitumor activity—latentiated forms of adamantanine, synthesis and biological evaluation □ Transport inhibitors—latentiated forms of α-amino acid adamantanine, synthesis

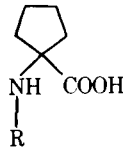
The tricyclo aliphatic α-amino acid adamantanine (2-aminoadamantane-2-carboxylic acid, I*a*), a structural analog of the transport-inhibitory and antitumor amino acid cycloleucine (II*a*), is highly effective in inhibiting the transport of L-methionine and L-leucine into Ehrlich ascites carcinoma cells *in vitro* (1). However, the bioavailability of I*a* is compromised severely by its extreme insolubility. Accordingly, methods to convert I*a* systematically to latentiated forms have been sought. The C-terminal and N-terminal glycine and leucine conjugates (dipeptides) of I*a* were inactive, reflecting the inertness of these derivatives to cleavage by leucine aminopeptidase (2).

BACKGROUND

α-Amino acids and certain natural products that are conjugated on the amino group as γ-L-glutamyl derivatives can be considered as latentiated forms of the amino acid or natural product, since the γ-glutamyl group can be cleaved *in vivo* by γ-glutamyltranspeptidase, an enzyme that is abundant in transport-active organs such as the kidneys (3). Synthetic *N*-(γ-glutamyl)-α-amino acids were shown to be substrates for γ-glutamyltranspeptidase to varying degrees (4–6). N^4-(1-Hydroxycyclopropyl)-L-glutamine, a compound found in the edible mushroom species *Coprinus atramentarius*, inhibits aldehyde dehydrogenase *in vivo* but not *in vitro* (7). *N*-(γ-L-Glutamyl)dopamine (8) and *N*-(γ-L-glutamyl)levodopa (9), both prodrugs of dopamine, have demonstrable renal vasodilator activities due to the release of the dopamine moiety *in vivo*.



I*a*: R = H
I*b*: R = OH
Ic: R = $COCH_2CH_2CHCOOH$ (NH$_2$)



II*a*: R = H
II*b*: R = OH

N-Hydroxylated α-amino acids (α-hydroxyamino acids) also can be considered as precursors of the respective amino acids since the latter compounds can be generated on reduction of the hydroxyamino function *in vivo*. The antitumor agent 1-hydroxyaminocyclopentanecarboxylic acid (*N*-hydroxycycloleucine, II*b*) is active against Ehrlich ascites carcinoma cells *in vivo* (10) and L-1210 leukemia (11); although no precise data are available to suggest the conversion of II*b* to II*a*, rat liver contains an enzyme that can reduce *N*-alkylhydroxyamines to the corresponding *N*-alkylamines (12).

Based on these considerations, several derivatives of I*a*, the γ-glutamyl derivative *N*-(γ-glutamyl)adamantanine (Ic) and the *N*-hydroxylated analog *N*-hydroxyadamantanine (I*b*), were synthesized as latentiated forms. These compounds were evaluated with respect to their ability to be released or converted to I*a* by enzymatic action.

EXPERIMENTAL[1]

Chemistry—*N*-(γ-L-Glutamyl)adamantanine (Ic) was synthesized by coupling *N*-phthaloyl-L-glutamic anhydride (III) with the *N,O*-bis(trimethylsilyl) derivative of adamantanine (IV), both prepared *in situ* (Scheme I). The procedure for the preparation of III was a modification (13) of the method of King and Kidd (14). Hydrazinolysis of the phthaloyl group of α-*N*-phthaloyl-γ-L-glutamyladamantanine (V) afforded Ic in a 74% yield. The fact that Ic was a γ-glutamyl peptide and not the isomeric α-peptide can be assessed by the method of synthesis, a procedure known to yield γ-glutamyl peptides (15), and was verified by chemical-ionization mass spectrometry[2].

N-Hydroxyadamantanine (I*b*) was prepared *via* a three-step procedure (16–18) from adamantan-2-one oxime (VI) (Scheme II). Addition of hydrogen cyanide to VI gave 2-hydroxyamino-2-cyanoadamantane (VII), which was hydrolyzed successively to the carboxamide (VIII) with cold concentrated sulfuric acid and then to the desired I*b* under more vigorous conditions.

Attempts to hydrolyze VII in one step to I*b* at elevated temperatures led to considerable decomposition and reversion (19) to adamantan-2-one. Compound I*b* was stable to acid but rapidly decomposed above pH 8, an alkaline instability typical for α-hydroxyamino acids (17). Compound I*b* also gave a strong color test for hydroxylamine with triphenyltetrazolium chloride (20) and gave a quasimolecular ion (MH^+, base peak) at the expected *m/e* 212 on chemical-ionization mass spectrometry.

α-*N*-*Phthaloyl-γ-L-glutamyladamantanine* (*V*)—To a solution of *N*-phthaloyl-L-glutamic acid (14) (19.25 g, 0.069 mole) in tetrahydrofuran (250 ml) was added dicyclohexylcarbodiimide (14.33 g, 0.070 mole), and the reaction mixture was stirred at room temperature for 2 hr. The mixture then was filtered. The filtrate was added to a solution of the trimethylsilyl derivative (IV), which was prepared *in situ* by heating I*a* (13.56 g, 0.069 mole) and *N,O*-bis(trimethylsilyl)trifluoroacetamide (17.88 g, 0.069 mole) in 300 ml of acetonitrile under reflux for 2 hr. Heating under reflux was continued for 2 hr, and the solvent was evaporated to dryness.

The residue was suspended in 300 ml of water, and the solution was brought to pH 10 with 5% Na_2CO_3 solution. Ether (200 ml) was added

[1] Melting points were determined on a Mettler FP-2 hot-stage apparatus and are corrected. All solvent evaporations were carried out *in vacuo* on a mechanical rotating evaporator using a water aspirator. Microanalyses were performed by Galbraith Laboratories, Knoxville, Tenn. IR spectra were determined on a Beckman IR-10 IR spectrophotometer, and the chemical-ionization mass spectra were provided by Dr. R. Foltz, Battelle Columbus Laboratories, Columbus, Ohio, using an AEI-MS-902 mass spectrometer equipped with an SRIC model CIS-2 combined chemical-ionization–electron-ionization ion source.

[2] R. Foltz, Battelle Columbus Laboratories, Columbus, Ohio, personal communication. The diagnostic value of chemical-ionization mass spectrometry for distinguishing γ-glutamyl dipeptides from the isomeric α-glutamyl dipeptides will be discussed in a separate report.

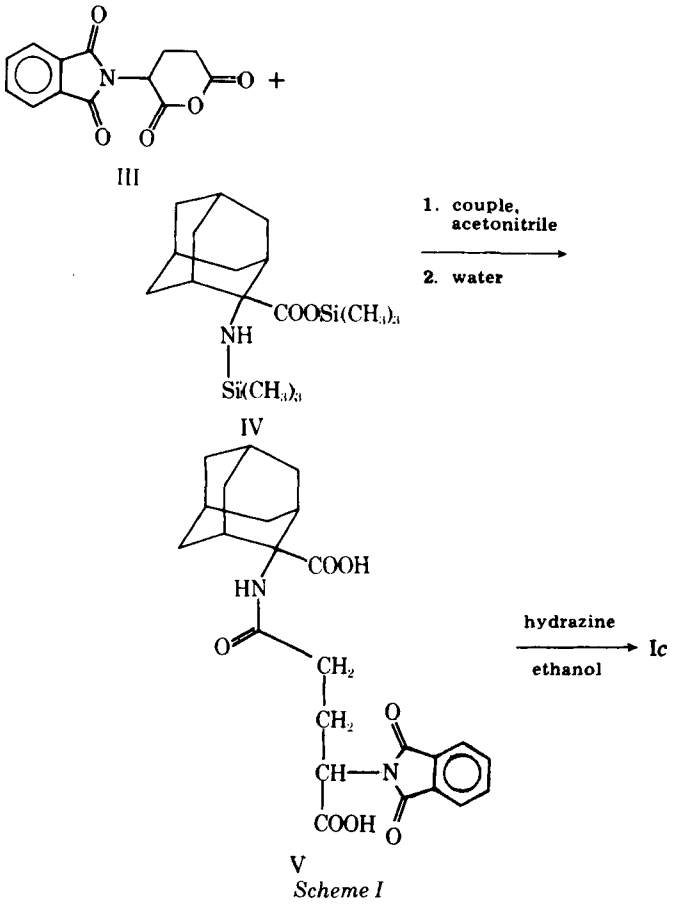


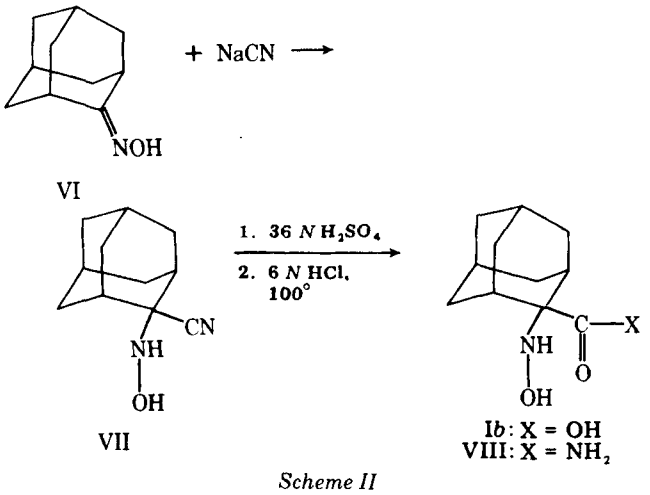
Scheme I

to the cloudy solution, and the three-phase system which contained solids was filtered. The collected solids were dissolved in fresh pH 10 aqueous sodium carbonate, and the solution was extracted with ether. The alkaline aqueous phases were combined, concentrated to remove the ether, and then acidified to pH 3 to precipitate V, which was collected and air dried to yield 23.4 g (74%), mp 135–137°.

Anal.—Calc. for $C_{24}H_{26}N_2O_7 \cdot H_2O$: C, 61.01; H, 5.97; N, 5.93. Found: C, 61.18; H, 5.80; N, 5.94.

N-(γ-*L-Glutamyl*)*adamantanine* (*Ic*)—Compound V (6.00 g, 0.013 mole) was dephthaloylated by heating it with 95% hydrazine (0.440 g, 0.013 mole) in 100 ml of ethanol for 2 hr. After evaporation of the solvent to dryness, the residue was extracted four times with 50 ml of boiling water. The aqueous extracts were combined, heated to boiling, and then filtered to remove residual solids, and the filtrate was evaporated nearly to dryness. The residue was suspended in 50 ml of hot ethanol, and the insoluble solids (1.25 g) were collected by filtration.

Concentration of the filtrate gave a total of 2.70 g of additional solids



Scheme II

Table I—Formation of γ-Glutamylhydroxamate Catalyzed by γ-Glutamyltranspeptidase

γ-Glutamyl Donor	γ-Glutamylhydroxamate Formed, μmoles/mg of protein/10 min
Ic, 10 m*M*	<0.02
Glutathione, 10 m*M*	4.62
Glutathione + Ic, both at 10 m*M*	4.79

in three successive crops. Since the latter solids were yellow, they were dissolved in 50% ethanol and decolorized with charcoal. The decolorized solution was evaporated to dryness, and the solid residue was recrystallized from ethanol–acetone. This recrystallized product was combined with the 1.25 g of product isolated earlier and once again was recrystallized from ethanol–water to give a powder. This powder was dried under vacuum at 75° to give 2.78 g (63% yield), mp 220–224°; $[\alpha]_D^{26}$ +18.3° (*c*, 1.0 mg in 1.0 *N* HCl, calculated as the monohydrate).

Anal.—Calc. for $C_{16}H_{24}N_2O_5 \cdot H_2O$: C, 56.13; H, 7.65; N, 8.18. Found: C, 56.01; H, 7.45; N, 7.87.

2-Hydroxyamino-2-cyanoadamantane (*VII*)—To a 500-ml glass pressure-reaction bottle were added adamantan-2-one oxime (VI) (21) (25.0 g, 0.15 mole), monobasic potassium phosphate (120 g, 0.88 mole), 100 ml of water, 25 ml of ethanol, and 25.0 g (0.51 mole) of sodium cyanide. The bottle was sealed with a silicone rubber stopper fitted with a dial thermometer and placed in a shaking apparatus. The reaction mixture was heated gradually with shaking to 70° over 30 min, and the temperature was maintained at 70–78° for another 30 min.

The reaction mixture then was cooled, diluted with 2 liters of water, and continuously extracted with chloroform in a liquid–liquid extractor for 4 hr. The chloroform extract was treated with charcoal, and the solvent was evaporated to dryness. The yellow residue was dissolved in methylene chloride, and the solution was treated again with charcoal and filtered. The filtrate was concentrated to ~20 ml and diluted with 40 ml of hexane to give 5.70 g (19.8% yield) of pale-yellow crystals, mp 141–142°; IR (potassium bromide): 3455 (OH), 3270 (NH), and 2210 (CN) cm^{-1}.

Anal.—Calc. for $C_{11}H_{16}N_2O$: C, 68.72; H, 8.39; N, 14.57. Found: C, 68.70; H, 8.39; N, 14.52.

2-Hydroxyaminoadamantane-2-carboxamide (*VIII*)—Compound VII (2.00 g, 0.010 mole) was added slowly to 10 ml of 36 *N* H_2SO_4 with stirring, and the mixture was allowed to stand at room temperature for 90 min. The clear solution then was poured into 100 ml of ice-cold water, and the solution was brought carefully to pH 8 with 6 *N* NaOH. The solids which precipitated were collected, air dried, and then recrystallized from tetrahydrofuran to give 1.65 g (75% yield) of colorless plates, mp 177–178°; IR (potassium bromide): 3430 (OH), 3350, 3320, 3245, 3170 (NH_2, NH), 1635 (C=O, amide I), and 1600 (NH deformation, amide II) cm^{-1}. An analytical sample was recrystallized from tetrahydrofuran and dried for 18 hr under vacuum, mp 177.5–178.5°.

Anal.—Calc. for $C_{11}H_{18}N_2O_2$: C, 62.83; H, 8.63; N, 13.32. Found: C, 62.94; H, 8.49; N, 13.34.

N-*Hydroxyadamantanine* (*Ib*)—Compound VIII (0.300 g, 1.43 mmole) and 6 *N* HCl (3 ml) were added to each of three pressure-reaction tubes. The tubes were sealed and heated for 3 hr at 110°. The cooled reaction mixtures were filtered into a common receiver, and the filtrate was evaporated to dryness *in vacuo*. The residue was dissolved in 20 ml of water and applied to a column of cation-exchange resin[3] (80 g). The column was washed with water until the eluate was chloride free (300 ml) and then eluted with 2 *N* NH_4OH (400 ml).

Evaporation of the eluate *in vacuo* gave 170 mg of crude product. This product was dissolved in 5 ml of ethanol, and the solution was decolorized with charcoal. By concentration to 2 ml, dilution with water (1 ml), and further evaporation of the solvent *in vacuo*, crystals precipitated. The crystals were collected and dried under vacuum at 65° for 18 hr to give 0.060 g (6.6% yield), mp 173.5–174.5°. The chemical-ionization mass spectrum of *Ib* exhibited peaks at *m/e* (relative intensity) 212 (MH^+, 100), 196 (16), 166 (25), and 150 (60).

Anal.—Calc. for $C_{11}H_{17}NO_3$: C, 62.54; H, 8.11; N, 6.63. Found: C, 62.54; H, 8.15; N, 6.56.

***In Vivo* Metabolism Studies**—Solutions of Ic dissolved in dilute aqueous hydrochloric acid (2.5 ml, pH 1) were administered orally at 40 and 400 mg/kg to male rats[4] weighing ~250 g, and 24-hr urine samples were collected in stainless steel metabolism cages. The 24-hr urine sam-

[3] Amberlite IRC-50 (H^+).

[4] Sprague–Dawley strain.

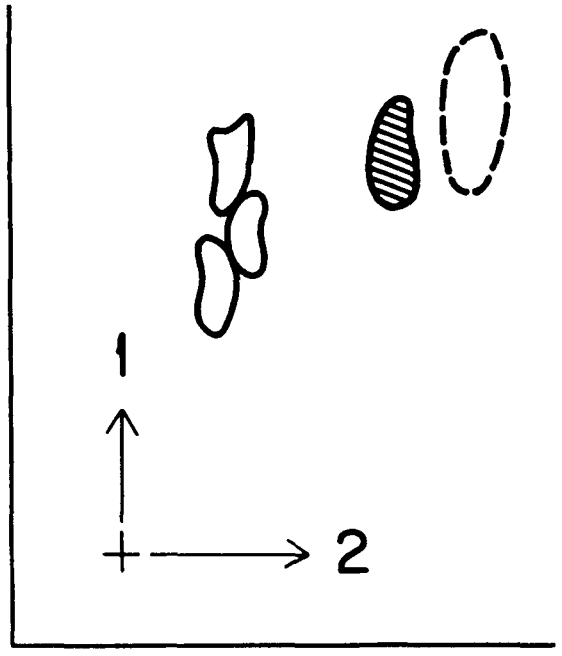


Figure 1—*Composite two-dimensional chromatogram of the urine from a rat given 400 mg of γ-glutamyladamantanine (Ic)/kg and of a control urine sample to which Ic (shaded spot) (1 mg/ml) had been added. Solvent 1 was chloroform–methanol–17% ammonia (2:2:1); Solvent 2 was 1-butanol–acetic acid–water (4:1:1). The point of application is represented by +. The shaded spot was not seen in the urine of the rat treated with Ic, the chromatograms being otherwise similar.*

ples from each rat prior to administration of the peptide served as control urine. The urine samples were spotted on 8 × 8-cm fluorescent silica gel plates and developed two dimensionally, first in chloroform–methanol–17% ammonia (2:2:1) and then in 1-butanol–acetic acid–water (4:1:1). The chromatograms were visualized with 0.3% ethanolic ninhydrin spray reagent. These chromatograms were compared to those of control urine and control urine to which the peptide was added. The results with the high dose are shown in Fig. 1.

***In Vitro* Enzyme and Growth Inhibition**—γ-Glutamyltranspeptidase was isolated from hog kidney cortex (4), and the transfer of the γ-glutamyl group of Ic to hydroxylamine was determined spectrophotometrically (22). Glutathione, the natural substrate for this enzyme, was used as the standard. The results are recorded in Table I.

Growth inhibition of P-388 lymphoid leukemia cells in tissue culture was determined as described previously (21) using varying concentrations of Ib, Ic, and IIb (Table II). Compound Ic in hydroxypropylcellulose also was administered intraperitoneally to host BDF_1 mice bearing 10^5 L-1210 lymphoid leukemia cells at doses of 400 mg/kg once daily for 9 days.

RESULTS AND DISCUSSION

Test doses of *N*-(γ-L-glutamyl)adamantanine (Ic) administered to rats at 40 and 400 mg/kg did not give rise to the excretion of the intact dipeptide (Fig. 1), in contrast to the metabolically inert dipeptides, leucyl- and glycyladamantanine, which were excreted intact in the urine (2). This result suggested that the compound was metabolized *in vivo* or else was poorly (or not at all) absorbed from the GI tract. Although Ic gives a strong ninhydrin chromophore (Fig. 1), the amino acid Ia is not chromogenic with ninhydrin or fluorescamine (23); hence, it was not possible to detect the free amino acid in the urine or plasma.

These results encouraged the evaluation of Ic for substrate activity with a partially purified preparation of γ-glutamyltranspeptidase from hog kidney cortex (22). However, Ic did not transfer its γ-glutamyl moiety to the test acceptor hydroxylamine (Table I). Under the same conditions, glutathione, the natural substrate for this enzyme, readily formed γ-glutamylhydroxamate, indicating that the enzyme preparation was active. Moreover, Ic did not inhibit the latter reaction when present at equimolar concentrations with glutathione.

As can be seen from Table II, Ic did not inhibit the growth of P-388 leukemia cells *in vitro*, nor did Ic increase the survival time of host BDF_1 mice bearing 10^5 L-1210 leukemia cells, even at daily doses of 400 mg/kg for 9 days (data not shown). However, *N*-hydroxyadamantanine (Ib) had activity comparable to *N*-hydroxycycloleucine (IIb) in the P-388 system (Table II), although these compounds were nearly 10 times less active in this system than *N*-hydroxyurea, which was the standard test compound.

Table II—Inhibition of Growth of P-388 Lymphoid Leukemia Cells *In Vitro*

Compound	I_{50} μg/ml	I_{50} m*M*
Ib	168	0.80
Ic	>1000	>3
IIb[a]	50	0.34
N-Hydroxyurea[b]	2.3	0.03

[a] Prepared according to a combination of literature procedures (17, 18), mp 196–198° dec. (corrected) [lit. (26) mp 200–202° dec.]. [b] Schwartz/Mann Division, Becton-Dickinson and Co., Orangeburg, N.Y.

The lack of substrate activity of Ic for γ-glutamyltranspeptidase probably is due to steric hindrance at the peptide bond. Various glycine and leucine dipeptides of adamantanine (both N-terminal and C-terminal) also are resistant to hydrolysis by leucine aminopeptidase (2). Meister (24) showed that γ-glutamyl derivatives of α-alkyl-substituted α-amino acids, *e.g.*, γ-glutamyl-α-aminoisobutyrate, are not good substrates for γ-glutamyltranspeptidase. Since Ia also may be considered as α-alkyl substituted, the present example provided by Ic reinforces this observation.

Although the latentiation of Ia as peptide derivatives has not yet been achieved, perhaps due to the unique structure of this amino acid, the concept of γ-glutamyltranspeptidase-mediated amino acid release should be capable of extension appropriate to the latentiation of biologically active molecules other than amino acids, *e.g.*, drugs. By utilizing this enzyme from the γ-glutamyl cycle (24), selected drugs may be transported *in vivo* as chemically conjugated synthetic γ-glutamyl derivatives with subsequent release at target organ sites. The successful use of this approach to the development of dopamine prodrugs was alluded to previously (8, 9). For the moiety attached to the γ-glutamyl end of the molecule, there is a low order of specificity. For example, whereas the natural substrate is glutathione itself, γ-L- or γ-D-glutamyl-*p*-nitroanilide (4) and *S*-substituted glutathione derivatives (25) are active substrates for the transpeptidase. Furthermore, the amide linkage is not mandatory since γ-esters of L-glutamic acid also serve as substrates (4). Since a large number of pharmacological agents possess free amino or hydroxyl groups, the applications of this concept appear to be unlimited. These possibilities are under study.

Anti-Inflammatory Activity of Amine Cyanoboranes, Amine Carboxyboranes, and Related Compounds

IRIS H. HALL *x, C. O. STARNES *, A. T. McPHAIL ‡, P. WISIAN-NEILSON ‡, M. K. DAS ‡, F. HARCHELROAD, Jr. ‡, and B. F. SPIELVOGEL ‡

Received April 10, 1979, from the **Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514,* and the ‡*Paul M. Gross Chemical Laboratory, Duke University, Durham, NC 27706.* Accepted for publication July 20, 1979.

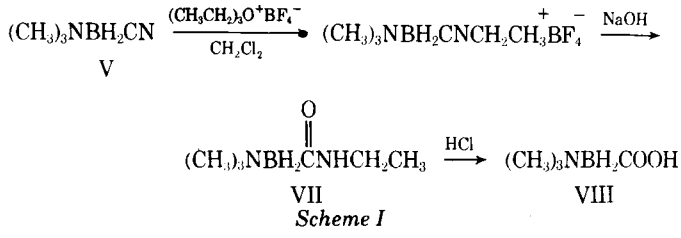
Abstract □ Amine cyanoboranes and amine carboxyboranes (boron analogs of α-amino acids) were shown to inhibit inflammation. The analogs effectively blocked general inflammation, induced arthritis, and the writhing reflex associated with inflammation pain, while the inflammation associated with pleurisy was marginally inhibited. The boron analogs were shown *in vitro* to inhibit the release of lysosomal enzymes from liver and polymorphonuclear neutrophils. Furthermore, prostaglandin synthesis was blocked by these agents at a low concentration, *i.e.*, 10^{-6} *M*. Liver oxidative phosphorylation processes also were uncoupled by these agents, but the migration of polymorphonuclear neutrophils was unaltered at 10^{-4} *M*. The elevation of cyclic adenosine monophosphate levels in polymorphonuclear neutrophils correlated positively with *in vivo* antiarthritic activity. Initial studies in rodents demonstrated that these boron analogs can be used at safe therapeutic doses.

Keyphrases □ Anti-inflammatory activity—evaluation of amine cyanoboranes, amine carboxyboranes, and related compounds □ Amine cyanoboranes and amine carboxyboranes—evaluation for anti-inflammatory activity

The antineoplastic activity of some α-amino boron analogs was reported previously (1). While studying their metabolic effects on tumor cell metabolism, it was noted that these agents interfered with oxidative phosphorylation processes of mitochondria, inhibited lysosomal enzymatic hydrolytic activities, and elevated cyclic adenosine monophosphate levels. Since commercially available anti-inflammatory agents, *e.g.*, phenylbutazone, salicylates, and indomethacin, have similar effects on cellular metabolism, testing of the boron analogs for anti-inflammatory activity in rodents was undertaken and the data are reported here.

EXPERIMENTAL

Chemistry—Consideration of the isoelectronic formalism between carbon and boron results in the prediction of boron analogs of dipolar α-amino acids, *e.g.*, glycine ammonia carboxyborane, alanine ammonia carboxymethylborane, and betaine triethylamine carboxyborane. Interest in these boron analogs lies mainly in their potential biological activity when compared with the enormous biological activity of the α-amino acids. A highly significant step toward demonstrating the existence of this class of compounds was the synthesis of trimethylamine carboxyborane, the protonated boron analog of betaine (2) (Scheme I).



Scheme I

Trimethylamine carboxyborane, a white, crystalline solid whose X-ray crystal structure was determined, is stable in air and water.

Amine Cyanoboranes—One approach to the synthesis of boron analogs of the α-amino acids involves the conversion of an amine cyanoborane to a boroamino acid according to the procedure outlined in Scheme I. To provide adequate quantities of the precursor amine cyanoboranes, a general, convenient, high-yield synthesis (3, 4) of this class of compounds was developed (Scheme II).

Scheme II

All previous syntheses (5–9) of amine cyanoboranes were limited as to the yield and reaction scale. Several synthetic procedures were developed (5, 6) following initial reports from these laboratories (10, 11) on the preparation of cyanoborane oligomers, *i.e.*, $(BH_2CN)_x$, by the addition of dry hydrogen chloride to a solution containing cyanohydroborate in ether. Thus, addition of amines to solutions of cyanoborane [which also can be prepared (8) by the reaction of cyanohydroborate and halogens] gives the amine cyanoborane. Typical yields have been ~25%, whereas yields up to 90% have been obtained with the amine hydrochloride procedure.

Following Scheme II, amine cyanoboranes were prepared where the amine was trimethylamine (V), dimethylamine (VI), pyridine (XV), 3-dimethylaminopropionitrile (XIX), or *N*-methylmorpholine (XIV). Bis(cyanoboranes) (XI and XX) were prepared (4) from ethylenediamine and tetramethylethylenediamine. However, attempts to prepare the parent ammonia cyanoborane (XVII) by this procedure were not successful. The only other report of the preparation of XVII (7) involved the reaction of trimethylamine iodoborane (IX) with sodium cyanide in liquid ammonia. Attempts to repeat this reaction in these laboratories resulted

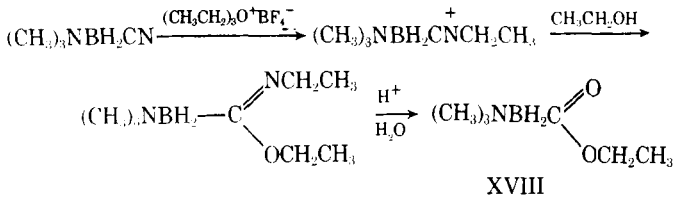
instead in the isolation of the novel complex hexakis(ammonia cyanoborane)sodium iodide (X) (12). The complex, which was characterized by X-ray crystallography, consists of six ammonia cyanoborane (XVII) molecules coordinated octahedrally around the sodium cation. However, pure ammonia cyanoborane could be obtained by dissolution of the complex in water and extraction of the ammonia cyanoborane into ether (13). The compound also was prepared (13) by base displacement (Scheme III).

$$C_6H_5NH_2{\cdot}BH_2CN \xrightarrow{H_3N} \underset{\text{XVII}}{H_3NBH_2CN} + C_6H_5NH_2$$

Scheme III

In both cases, ammonia cyanoborane as prepared in these laboratories differs from that reported previously (7), which was characterized only partially. Ammonia cyanoborane possesses considerable hydrolytic stability, suffering only an 8% loss of hydrogen in concentrated hydrochloric acid after 70 hr at room temperature. In general, the amine cyanoboranes are quite stable to air and moisture.

Amine Carboxyboranes—By using the general synthetic route illustrated in Scheme I, amine carboxyborane compounds where the amine was pyridine (XVI) or *N*-methylmorpholine were prepared (4) from the corresponding amine cyanoborane. Tetramethylethylenediamine bis(carboxyborane) (XII) and its intermediate (XIII) were synthesized (4). Trimethylamine carboxyborane (VIII) derivatives can be prepared readily by the preparation of the ethyl ester. The ethyl ester, a white solid (mp 45–47°), can be prepared in a 34% yield according to Scheme IV.



Scheme IV

The ethyl ester was obtained by allowing a solution of 95% ethanol (200 ml), concentrated aqueous hydrochloric acid (8 ml), and the *N*-ethylnitrilium salt [prepared by refluxing for 24 hr a solution of trimethylamine cyanoborane (0.2 mole) and 400 ml of 1 *N* triethyloxonium tetrafluoroborate in methylene chloride (2)] to reflux for 48 hr. After neutralization with a saturated sodium bicarbonate solution and removal of ethanol under reduced pressure, the product was extracted from the aqueous solution with methylene chloride. Drying the organic portion over magnesium sulfate and solvent removal produced a yellow liquid. Purification by recrystallization from ethanol or ether or by sublimation afforded the ester as a white crystalline solid (9.9 g). Satisfactory carbon, hydrogen, nitrogen, and boron analyses were obtained[1]. The PMR signals (deuterochloroform) were those expected for the trimethylamine (δ 2.78 singlet) and ethyl (δ 1.2 triplet and δ 4.10 quartet) functions; strong B–H (2380 cm^{-1}) and C=O (1660 cm^{-1}) stretches were present in the IR spectrum.

The structures of the boron analogs and references for their syntheses are given in Table I.

Pharmacology—*Toxicity Studies*—Acute LD_{50} toxicity studies were carried out in CF_1 male mice (~30 g) using the method of Litchfield and Wilcoxon (14).

Anti-Inflammatory Screen—CF_1 male mice (~30 g) were administered the test drugs at 10 mg/kg ip in 0.05% polysorbate 80–water 3 hr and then 30 min prior to injection of 0.05 ml of 2% carrageenan in 0.9% saline into the plantar surface of the right hindfoot. Saline injected into the left hindfoot served as a baseline. After 3 hr, both feet were excised at the tibiotarsal (ankle) joint according to the modified (15) method of Winter, resulting in a net weight increase of 87 mg in the feet of the control animals.

Antipyretic Screen—Sprague–Dawley rats (~200 g) were administered 2 ml of a 44% solution of baker's yeast subcutaneously (15) 18 hr prior to the injection of drugs at 2.5 or 5 mg/kg ip, resulting in an elevation of 3.46° F. Alternatively, rats were administered 0.25 mg of killed and dried *Mycobacterium butyricum*[2] (16) subcutaneously prior to drug administration. Rectal temperatures were taken immediately before and 2, 4, and 6 hr after drug administration.

Writhing Reflex—CF_1 male mice were administered the test drugs at 20 mg/kg ip 20 min (17) prior to the administration of 0.5 ml of 0.6% acetic acid (18). After 5 min, the number of stretches, characterized by repeated contractures of the abdominal musculature accompanied by hindlimb extension, was counted for the next 10 min. Control mice had 78 stretch reflexes/10 min.

Chronic Adjuvant Arthritic Screen—Male Sprague–Dawley rats (~160 g) were injected at the base of the tail with 0.2 ml of a solution of killed and dried *M. butyricum* and digitonin in mineral oil (19). Test drugs were administered intraperitoneally on Days 3–20 at 2.5 mg/kg/day. Animals were sacrificed on Day 21, and the feet were excised and weighed. Control animals had a net weight gain of 0.830 g.

Antipleurisy Screen—Sprague–Dawley rats were administered the test drugs at 2.5 mg/kg ip 1 hr before injection and 3 hr postinjection of 0.05 ml of a solution of 0.316% Evan's blue and carrageenan into the pleural cavity (20). After 6 hr, the rats were sacrificed and the fluid was collected from the pleural cavity. Control rats produced 2.5 ml of fluid.

[a] 0.753 mg of inorganic phosphate released/hr/g of wet tissue. [b] 2.69 mg of protein released/hr/g of wet tissue. [c] 0.26 μg of inorganic phosphate released/hr/10^7 cells. [d] 0.225 mg of protein released/hr/10^7 cells. [e] 48 pmoles of cyclic adenosine monophosphate/10^7 cells.

Polymorphonuclear neutrophil migration studies were carried out according to Nelson *et al.* (21). The analogs were tested *in vitro* at 10^{-4} *M*.

Ulcerogenic tests were carried out in Sprague–Dawley rats (~160 g); they were administered II, V, X, XIV, and XIX at 2.5 mg/kg for 3 weeks. After the rats were fasted for 18 hr, the last dose on Day 21 was administered. After 4 hr, the rats were sacrificed and the gastric and duodenum mucosa were examined for bleeding and ulcers (22). In an analogous experiment, animals were bled on Day 21 by the tail vein; the red and white blood cells were counted in a hemocytometer and expressed as the number of cells × 10^6 per cubic centimeter. Hematocrits also were obtained (23).

Biochemistry—*Lysosomal Enzymatic Assays*—Sprague–Dawley rats (~160 g) were sacrificed, the liver was excised, and a 10% homogenate (four times) in 0.25 *M* sucrose and 0.001 *M* ethylenediaminetetraacetic acid (pH 7.2) was prepared.

Polymorphonuclear neutrophils were collected from the peritoneal cavity 4 hr after injection of 35 ml of 0.5% oyster glycogen in isotonic saline (24). The polymorphonuclear neutrophils were centrifuged at 800×*g* for 20 min, washed, and resuspended in minimum essential medium with 10% fetal calf serum (pH 7.4).

Acid phosphatase activity (25) was determined by incubating 0.1 *M* β-glycerol phosphate in 0.1 *M* acetate (pH 5.0) with 5 μmoles of the test drugs in 1% carboxymethylcellulose sodium for 20 min with the liver homogenate and for 60 min with the resuspended polymorphonuclear neutrophils. Lysosome enzymes were released by 0.02% alkylphenoxy polyethoxyethanol 100[3] to obtain the total enzymatic activity. The reaction was stopped with 10% trichloroacetic acid, and the solution was centrifuged. Aliquots of the supernate were assayed for inorganic phosphate content by the method of Chen *et al.* (26). The percentage of free acid phosphatase was calculated.

Cathepsin activity was determined in an analogous manner, except that the substrate was 2% azocasein (27) and 0.1 *M* acetate buffer (pH 5.0). The supernate was assayed for acid-soluble peptide fragments at 366 nm. The percentage of free cathepsin activity was calculated.

Cyclic Adenosine 3′,5′-Monophosphate Levels—Isolated polymorphonuclear neutrophils were incubated with the test drugs at 5 μmoles for 1 hr at 37° in minimum essential medium at pH 7.4. The reaction was stopped with 6% trichloroacetic acid. The cyclic-3′,5′-adenosine monophosphate levels were determined by the radioimmunoassay of Gilman (28) using [^{3}H(G)]cyclic adenosine 3′,5′-monophosphate (39.8 Ci/mmole). Results were calculated in picomoles per 10^7 polymorphonuclear neutrophils.

Prostaglandin Synthetase Activity—The incubation medium of Tomlinson *et al.* (29) was used to determine [^{3}H]prostaglandin formation (prostaglandins E, F_α, and D) from [^{3}H(N)]arachidonic acid (86.2 Ci/mmole) and 10 mg of purified commercial prostaglandin synthetase from beef seminal vesicles[4]. After 1 hr at 37°, the reaction was stopped with 1 *N* HCl and the solution was extracted with ether and evaporated. The residue was taken up in ethyl acetate and spotted on silica gel TLC plates, which were eluted with chloroform–methanol–water–acetic acid (90:8:1:0.8) (30). The plates were dried and developed in iodine vapor; with the use of prostaglandin standards, the appropriate areas were scraped and counted for tritium content. Indomethacin was used as a standard at 10^{-4} *M*. The test drugs were used at 10^{-6} *M*.

Oxidative Phosphorylation Studies—The basal respiration and adenosine diphosphate-stimulated respiration on 10% liver homogenates were measured using succinate or α-ketoglutarate as the substrate (31). The reaction vessel contained sucrose (55 μmoles), potassium chloride (22 μmoles), dibasic potassium phosphate (22 μmoles), test compounds at 5 μmoles in 1% carboxymethylcellulose sodium and sodium succinate (90 μmoles) or α-ketoglutarate (60 μmoles) in a total volume of 1.8 ml. After the basal metabolic (State 4) level was obtained, 0.257 μmole of adenosine diphosphate was added to obtain the adenosine diphosphate-stimulated rate (State 3). The respiration rate was calculated as microliters of oxygen consumed per hour per milligram (wet weight) of liver.

RESULTS

The boron analogs afforded significant anti-inflammatory activity in rodents. Administration of I, V, and VI resulted in at least 50% inhibition of the carrageenan-induced edema in mouse footpads (Table II), while II, X, XII, and XVII resulted in at least 40% inhibition. Administration of II, V, and X caused 80% inhibition of the writhing reflex, which is similar to inflammation pain. Compounds VI–VIII caused 70% inhibition of the reflex. In the induced arthritic screen in rats, 3 weeks of dosing of III, V, X, XIV, and XIX caused >80% inhibition, with X and V causing 100 and 96% inhibition, respectively. Compound V was administered at 1.25–10 mg/kg/day ip. Doses at 1.25 mg/kg/day caused 75% inhibition, doses of 2.5 mg/kg/day caused 96% inhibition, and doses of 5 or 10 mg/kg/day resulted in 100% inhibition. Compounds VI, IX, XIII, and XVIII

[a] 6564 dpm of prostaglandin E formed/hr/mg of enzyme. [b] 9.19 μl of oxygen consumed/hr/mg of wet tissue. [c] 13.66 μl of oxygen consumed/hr/mg of wet tissue. [d] 3.38 μl of oxygen consumed/hr/mg of wet tissue. [e] 4.93 μl of oxygen consumed/hr/mg of wet tissue.

afforded >70% inhibition of the induced arthritic state, and II and XVII caused 60% inhibition.

In the antipyretic test, V at 5 or 10 mg/kg caused no inhibition of elevated body temperature. In the antipleurisy screen, inhibition of 33, 35, 49, and 39% was demonstrated for III, V, X, and XIX, respectively. Boron analogs had no effect on the chemotactic migration of polymorphonuclear neutrophils. Dosing for 3 weeks with II, V, X, XIV, and XIX intraperitoneally resulted in no alteration of the red or white blood cell count per cubic millimeter and in no gastric or duodenum mucosa irritations or bleeding.

The percentage of free lysosomal enzymatic activities in the liver and polymorphonuclear neutrophils was inhibited by the presence of boron analogs (Table III). Free acid phosphatase activity in the liver was inhibited 28–35% by III, V, IX, X, XII, XIV, and XIX; in polymorphonuclear neutrophils, inhibition of 43, 65, 50, 66, and 50% was found for III, V, VIII, X, and XIV, respectively. Free proteolytic cathepsin activity of the liver was inhibited at least 75% by III, IX, XII, XIV, and XIX, with 100% inhibition by V and 97% inhibition by X. Inhibition of polymorphonuclear neutrophil cathepsin activity of at least 82% was exhibited by III, VIII, X, XI, XVIII, and XIX, with 96% inhibition by V and 100% inhibition by X.

Cyclic adenosine monophosphate levels in polymorphonuclear neutrophils were elevated after *in vitro* incubation with drugs (Table III). The increases were 45, 145, 33, 261, 55, 65, and 99% for III, V, IX, X, XII, XIV, and XIX, respectively.

At 10^{-6} *M in vitro*, III, V, VI, IX, X, XII, XIV, XV, XVII, and XIX blocked prostaglandin synthesis by >30% (Table IV). Compound X resulted in 58% inhibition, and XIV caused 62% inhibition. The presence of boron analogs at 5 μmoles caused uncoupling of the oxidative phosphorylation processes of liver mitochondria. Several agents (*e.g.*, XX) suppressed basal (State 4) as well as adenosine diphosphate-stimulated respiration (State 3) with both substrates. Uncoupling of the electron transport chain was seen with the substrate succinate, a flavin adenine dinucleotide-linked dehydrogenase, with I–X, XIII, and XV–XVIII. This uncoupling was observed as an increase in State 4 respiration and as a decrease in State 3 respiration. With α-ketoglutarate as the substrate, a nicotinamide diphosphate-linked dehydrogenase, uncoupling was seen with I, VI–VIII, and XII–XVIII. Both States 3 and 4 respiration were inhibited with succinate in the presence of XII, XIV, XIX, and XX and with α-ketoglutarate by III–V and XX. Compounds that demonstrated potent antiarthritic activity also demonstrated potent inhibitory effects on State 3 respiration, *e.g.*, III, V, X, XII, XIV, and XIX with either succinate or α-ketoglutarate. The exception to this observation was XX.

DISCUSSION

Inflammation is a process associated with the release of chemical vasoamines, *e.g.*, histamine, serotonin, slow-reacting substance, and bradykinin, the release of lysosomal hydrolytic enzymes by leukocytes, the synthesis and release of prostaglandins, and the modulation of cyclic nucleotide levels of lymphocytes and leukocytes (32–36). These agents, in turn, cause increased vascular permeability, chemotaxis of polymorphonuclear neutrophils and macrophages, erythema, dermatitis, hypersensitivity, complement fixation, allergy reactions, and edema, and they elicit pain together with increasing the local and body temperature.

The commercially available anti-inflammatory agents are known to interfere with some of these processes, thus retarding the development of inflammation. For example, indomethacin decreases the polymorphonuclear neutrophil motility, uncouples oxidative phosphorylation processes, inhibits prostaglandin synthetase and histidine decarboxylase activities, mucopolysaccharide biosynthesis, and platelet function, stabilizes lysosomal membranes, and thus inhibits hydrolytic enzymatic activity (32). A number of agents are known to inhibit cyclic adenosine monophosphate phosphodiesterase activity (37) and increase cyclic adenosine monophosphate, which supposedly stabilizes the lysosomal membranes, blocks immunoglobulin E-dependent antigen-induced vasoamine release, and inhibits hypersensitivity (38–43).

As seen from the current studies, compounds having potent antiarthritic effects, *e.g.*, III, V, X, XII, XIV, and XIX, also were significant inhibitors of lysosomal-free hydrolytic activity both from the liver and polymorphonuclear neutrophils, indicating membrane stabilization. The inhibition of cathepsin activity was particularly high by the boron analogs. Increased levels of activity of this enzyme have been linked with a number of inflammation states. The boron analogs at the same concentration as indomethacin were more effective in inhibiting polymorphonuclear neutrophil lysosomal rupture.

Prostaglandin synthetase activity also was suppressed by III, V, X, XII, XIV, and XX at 10^{-6} *M*. Indomethacin at 10^{-6} *M* resulted in only 24% inhibition in this system; at 10^{-4} *M*, indomethacin caused 36% inhibition. Analogs V, X, XIV, XV, XVII, and XIX were more potent than indomethacin in inhibiting prostaglandin synthesis by the isolated enzyme system. Oxidative phosphorylation processes were uncoupled at 5 μmoles for the boron compounds, which demonstrated potent *in vivo* antiarthritic activity in rats. The uncoupling and suppression of energy production needed for migration and phagocytosis of polymorphonuclear neutrophils and macrophages were seen with all of the boron analogs; however, the migration of polymorphonuclear neutrophils at 10^{-4} *M* demonstrated no inhibition by boron analogs. Thus, it was more difficult to demonstrate positive correlation of uncoupling of respiration with *in vivo* antiarthritic activity. Nevertheless, excluding XX, those compounds possessing potent antiarthritic activity all suppressed adenosine diphosphate-stimulated respiration (State 3) by 40% or better.

The effects of boron analogs on respiration may be secondary to other metabolic effects. A more positive correlation with *in vivo* antiarthritic

activity is seen with the ability of the drug to elevate intracellular levels of cyclic adenosine monophosphate, which could account for the ability of these agents to block lysosomal enzyme release and prostaglandin synthesis and release. Elevated levels of cyclic adenosine monophosphate have been correlated with the ability to block the release of lysosomal enzymes (25, 41). The exact mechanism by which boron analogs cause elevations in cyclic adenosine monophosphate levels needs further study. Toxicity and side effects did not appear to be problems with boron analogs at the required therapeutic doses.

Pattern Recognition of Steroids Using Fragment Molecular Connectivity

DOUGLAS R. HENRY and JOHN H. BLOCK ˣ

Received May 18, 1979, from the *School of Pharmacy, Oregon State University, Corvallis, OR 97331.* Accepted for publication July 6, 1979.

Abstract □ The use of pattern recognition methods to classify a set of steroids into five therapeutic categories was investigated. First-order fragment molecular connectivity values were determined for 10 positions on each molecule using a template-based method of position assignment. Learning set and test set classifications were performed. Although the numbers of compounds misclassified were comparable for all of the methods, the identities of the misclassified compounds varied depending on whether the classification method assumed a local or a global view of the data. The best classification results were comparable to those obtained by linear and quadratic discriminant analyses. For this set of compounds, it was concluded that pattern recognition methods offer no advantages over traditional discriminant analysis methods if classification alone is considered, especially since most discriminant analysis procedures utilize stepwise variable selection, which is not as common in pattern recognition analyses.

Keyphrases □ Steroids—pattern recognition using fragment molecular connectivity □ Fragment molecular connectivity—pattern recognition of steroids □ Pattern recognition methods—classification of steroids in therapeutic categories using fragment molecular connectivity

The use of fragment molecular connectivity values as position descriptors in a template-based discriminant analysis has been demonstrated as a means of classifying structures according to their type of pharmacological activity (1). The use of statistical discriminant analysis in such classification problems is optimal for multivariate, normal random variables (2). For observations that are not distributed normally with respect to the descriptor variables, a discriminant analysis may not be the optimal classification method; certain distribution-free pattern recognition techniques may be more suitable (3). Although pattern recognition methods are not used as commonly in medicinal chemistry as are regression analysis and analysis of variance (4), the application of these techniques is increasing (5–9).

Accordingly, a number of classification-type pattern recognition procedures were applied to a set of steroidal compounds studied previously using linear and quadratic discriminant analysis[1]. These compounds show markedly nonnormal distributions with respect to many of the position variables used to describe them (Table I). It was felt that better classification results and greater insight into the value of molecular connectivity in classification problems possibly could be gained with pattern recognition methods.

Four such methods were selected: Andrews function curves (10), K nearest neighbor analysis (11, 12), multicategory linear learning machine analysis (13), and statistical isolinear multicomponent analysis (SIMCA)[2] (14, 15). The use of the Andrews function for representing multivariate data in statistical research is well documented (16). The remaining methods were used as part of ARTHUR, a pattern recognition program (17, 18).

[1] See D. R. Henry and J. H. Block, *Eur. J. Med. Chem.*, in press.

[2] The term SIMCA also can serve as an acronym for SIMilarity Components Analysis, SImple Modeling by Class Analogy, and other methods.

EXPERIMENTAL

A learning set of 46 steroidal compounds, classified into five therapeutic categories, was used (Table I). A test set of nine steroids also was selected (I–IX) (19). The pharmacological categories of these compounds are estrogens (E or ESTR), progestogens (P or PROG), androgens (A or ANDR), corticosteroids (C or CORT), and cardiac steroids (H or CARD). A template structure (6) was designated, and 10 positions of interest were selected. Each compound in the study was superimposed on the template

structure, and a value of the descriptor index was assigned to each of the 10 positions on the molecule.

The selected descriptor was first-order molecular connectivity ($^1\chi^v$), which was calculated as the sum of the first-order terms for each bond joining the position of interest (20). This descriptor was selected because this index, when compared to molar refraction and a number of other fragment molecular connectivity indexes, showed lower rates of misclassification when used in linear and quadratic discriminant analyses (1). Using the molecules in the learning set, each position variable was standardized to zero mean and unit variance prior to use. An observation to variable ratio of about 10 was sought. Accordingly, variable selection was performed using both the Fisher and variance weighting methods (18).

The top five variables from a variance-weighted standpoint were, in order of importance, positions *j*, *a*, *i*, *c*, and *b*. These variables were the same as those selected in the stepwise discriminant analysis of the data. Using Fisher weighting, the same variable subset was selected, except that position *f* replaced *b*, which assumed sixth place in significance. Since position *f* had a constant value for three of the groups in the analysis (estrogens, progestogens, and cardiac steroids), the five-variable subset selected by variance weighting was adopted as a basis for performing the pattern recognition analyses.

RESULTS AND DISCUSSION

Andrews Functions—Andrews (21) introduced a trigonometric series expansion with orthonormal coefficients, which is useful for representing multivariate data in two dimensions. This function takes the form:

$$F(x) = x_1\,0.707 + x_2 \sin t + x_3 \cos t + x_4 \sin 2t + x_5 \cos 2t + \cdots \quad \text{(Eq. 1)}$$

where the x values are the values of the respective variables for a given observation. For each observation, a plot of this function over the interval $t = [-\pi,\pi]$ radians gives a curve that is unique to the observation but similar in shape and amplitude to the curves of observations having similar x values (*i.e.*, observations close to each other in multidimensional space). The order of the x variables in Eq. 1 usually is determined based on the contribution of the variable to the between-group differences, with

Table II—Classification by Andrews Function [a]

True Group	Predicted Group ESTR	PROG	ANDR	CORT	CARD	Percent Correct[b]
ESTR	10	0	0	0	0	100.0
PROG	0	7	3	0	0	66.7
ANDR	0	2	5	0	2	55.6
CORT	0	4	0	6	0	60.0
CARD	0	0	1	0	6	85.7
Mean of group	−3.65	0.30	1.22	−0.07	3.33	
SD	0.98	0.67	1.29	0.24	0.90	

[a] For $t = 0.28$ rad, $F(x) = 0.707a + 0.267j + 0.964c + 0.514i + 0.858b$. Variables are ordered according to their contribution to the between-group variation. [b] Learning set results showed 74.5% correct. Compounds misclassified (predicted group) were: 11–13 (ANDR), 21 (PROG), 23 (CARD), 26 (CARD), 27 (PROG), 31 (PROG), 34 (PROG), 37 (PROG), 39 (PROG), and 45 (ANDR). Test set results showed 77.8% correct. Compounds misclassified (predicted group) were II (PROG) and III (ESTR).

the most significant variable being assigned to x_1 and the least significant variable assigned to the last term in the series.

Andrews function plots of prototypes of each therapeutic class are shown in Fig. 1. For this purpose, the group centroids (mean values) of each class were considered to be representative of the class. Other possibilities would be to use median or mode values of the variables for a given group. Each curve in Fig. 1 represents a typical member of its class. There are points along the t axis where between-group separations are large.

Figure 2 shows a plot of the total squared separation, summed over all possible pairs of groups (10 terms). The maximum in overall between-group separation occurs at 0.28 radian. By fixing t at this value, the Andrews function becomes a form of the discriminant function. A histogram of the values of this function for all of the observations is seen in Fig. 3.

Table II shows detailed classification results for the compounds. The results were obtained by determining the distance, in standard deviation units, of the Andrews function value for each observation from the mean value of each group. The observation then was classified into the group for which the absolute value of this distance was the smallest.

A comparison of the results in Table II with the corresponding results of a linear discriminant analysis (Table III) shows that the single Andrews discriminant function performed slightly worse in classifying the learning set (74% correct) compared to a discriminant analysis in which three canonical discriminant functions were used (83% correct). However, for the test set, the Andrews method correctly classified seven out of nine cases while the discriminant analysis was correct in only six cases.

Better classification results might be obtained from the Andrews function by selecting more than one value of t and generating several discriminant functions. Other values of t for which the between-group separation is large are indicated in Fig. 2. As an alternative, a separate value of t and its corresponding function could be selected for each pair of groups, and an observation could be classified based on the number of pairwise comparisons. Neither approach was tried during the present work.

***K* Nearest Neighbor Analysis**—This classification method conceptually is one of the simplest in the pattern recognition literature (22, 23). It differs from most minimum-distance classifiers in that the group centroid is not selected as the prototype of a given class. Instead, an observation is classified into the group to which a majority of its K nearest neighbors in multidimensional space belong. Values of K usually range from one to 10, but classification results suffer whenever the value of K approaches the average class size. In ties, the group showing the smallest aggregate distance is selected.

Table IV shows the results of K nearest neighbor analyses for the learning and test sets of compounds. For the learning set, the results at all levels of K were comparable to the best results obtained by discriminant analysis. For the test set, four compounds were misclassified for all values of K except the first value. This total is one misclassification more than was found with the linear and quadratic discriminant analysis methods.

Table III—Discriminant Analysis Results for Compounds in the Learning Set [a]

Variable	Discriminant Score Coefficients ESTR	PROG	ANDR	CORT	CARD
a	−9.36	2.08	−0.36	−3.36	15.67
b	−1.02	−0.73	1.16	−0.38	1.56
c	−7.09	1.06	2.87	−0.99	6.35
i	−4.24	1.19	2.29	0.50	0.71
j	−1.14	−0.14	−3.16	2.10	2.89
Constant	−13.76	−2.08	−5.60	−3.50	−21.97

[a] Linear classification results were obtained using BMDP7M (27); average results were 82.6% correct. Quadratic classification results were calculated using the University of Wisconsin MULTDIS program (28); average results were 89.1% correct. Test set classification results (both linear and quadratic classification) were 66.7% correct.

Multicategory Linear Learning Machine Analysis—In a manner similar to linear discriminant analysis, a linear learning machine seeks to define a function or boundary that will maximally separate a given group of observations from all other observations (13). However, instead of relying on a fixed statistical criterion (such as maximizing the ratio of between-group variation to within-group variation), a learning machine generates the classification function by iteration and feedback (24). A vector of weighting coefficients is derived for each group. Then, for each observation, a discriminant score is calculated for each group, and the observation is classified into the group for which the discriminant score is highest.

Table V summarizes the results of a multicategory linear learning machine analysis of the steroid data. A total of 201 iterations was performed, although the classification results ceased to improve after 186 cycles through the data. Thirty-nine of the learning set (84.8%) and six of the test set (66.7%) compounds were classified correctly by this method. In each case, the misclassified compounds and the groups into which they were placed were identical to those misclassified in a linear discriminant analysis of the data. This result occurred in spite of the fact that some notable differences existed both in the relative magnitude and in the sign between the weighting vectors derived by the learning machine (Table V) and those calculated in the discriminant analysis (Table III).

All of the misclassified compounds were placed by the learning machine

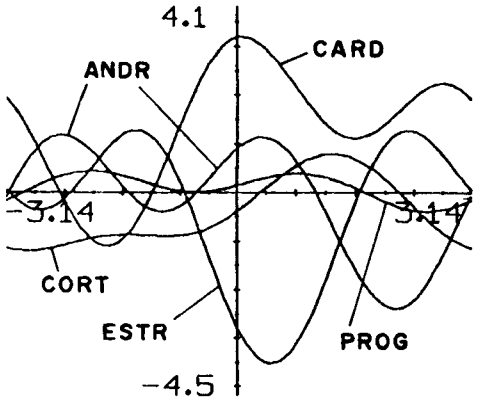

Figure 1—*Andrews function plots of the group centroids of each therapeutic category. The mean values of the position variables* a, j, c, i, *and* b *were used as coefficients in the Andrews function in the order given.*
