The characteristics of the extrapolation are shown by Fig. 1 where the extrapolation plots of the 20, 45 and 70% series at 25° are shown. In the case of the 20% series, the plot through the points at the four highest concentrations is a straight line which has been continued to the intercept. The point at the lowest concentration lies somewhat below this plot. We feel justified in giving less weight to this result since the function plotted should yield a straight line at low concentrations. In the cases of the 45 and 70% series, the plots have been drawn through the points. There is a slight curvature at the higher concentrations which seems to disappear as the ionic strength decreases. The slope of the 20% curve is slightly positive, that of the 45% curve is slightly negative, while that of the 70% plot is negative. The extrapolation plots at all other temperatures were similar to these.

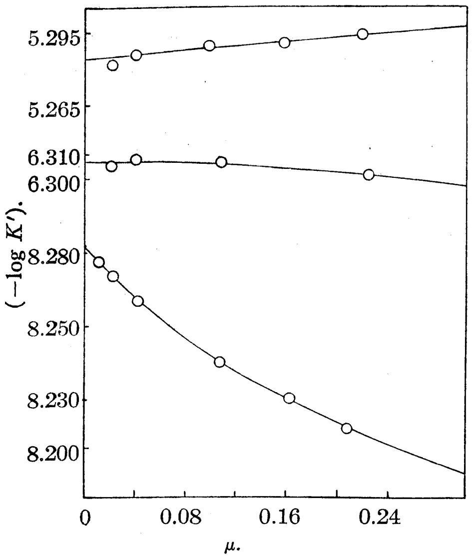

Fig. 1.—Extrapolation plots: diameters of circles correspond to 0.2 millivolt.

It is difficult to estimate the accuracy of this determination of the absolute value of $(-\log K)$. At 25°, an error corresponding to 0.1 mv. corresponds to an error of 0.002 to 0.003 in $(-\log K)$, or an uncertainty of 0.5 to 0.7% in the value of

K. The determination of K is estimated to be better than ±0.7% but not better than ±0.3%. The results in the more concentrated dioxane solutions appear to be the more consistent.

In Table II, the values of K are given at all temperatures at which measurements were made. We observe that K is in molality units. To convert to moles per liter of solution, it is only necessary to multiply by the solvent density. Thus, $K_c = Kd_0$. Examination of the values of K shows that in all solvents this quantity increases, passes through a maximum, and then decreases with increasing temperature. This fact is in accord with the behavior of weak electrolytes in aqueous solution.

IONIZATION CONSTANTS, OBSERVED AND CALCULATED BY EQUATION (5)

	$X = 20$		$X = 45$		$X = 70$	
	$D_{25} = 60.8$		$D_{25} = 38.5$		$D_{25} = 17.7$	
	$K \times 10^6$, obsd.	$K \times 10^6$, calcd.	$K \times 10^7$, obsd.	$K \times 10^7$, calcd.	$K \times 10^9$, obsd.	$K \times 10^9$ calcd.
0	4.77	4.77	4.74	4.75	5.17	5.18
5	4.88	4.89	4.83	4.84	5.25	5.25
10	4.99	4.99	4.91	4.90	5.27	5.29
15	5.07	5.05	4.93	4.94	5.31	5.29
20	5.10	5.10	4.96	4.94	5.25	5.27
25	5.13	5.11	4.93	4.92	5.22	5.21
30	5.09	5.10	4.87	4.87	5.11	5.13
35	5.04	5.05	4.80	4.79	5.04	5.02
40	4.97	4.98	4.69	4.69	4.88	4.88
45	4.89	4.87	4.54	4.56	4.70	4.72
50	4.78	4.75	4.39	4.41	4.50	4.54

Constants of Equation (4)

$X = 20$; $\Theta = 24.6$, $\log K_m = \bar{6}.7088$, $K_m = 5.12 \times 10^{-6}$
$X = 45$; $\Theta = 18.5$, $\log K_m = \bar{7}.6942$, $K_m = 4.95 \times 10^{-7}$
$X = 70$; $\Theta = 13.4$, $\log K_m = \bar{9}.7237$, $K_m = 5.29 \times 10^{-9}$

Harned and Embree[5] have shown that the equation

$$\log K - \log K_m = -p(t - \Theta)^2 \qquad (4)$$

expresses quite well the temperature variation of ionization constants of weak acids, bases and ampholytes in aqueous solution. K_m is the value of K at its maximum, Θ the characteristic temperature at which K is a maximum, and t is the centigrade temperature. p is a constant for all the electrolytes and has a value of 5.0×10^{-5}. Harned and Embree[2] also showed that the ionization constant of acetic acid in some methyl alcohol–water mixtures could be computed by this equation. They thus extended the range of applicability to a medium of dielectric constant of 70. The present results which extend to media of dielectric constant of the order of 18 are excellent for testing the further extension of the equation of Harned and Embree.

Equation (4) may be transposed to

$$\log K = [\log K_m - p\Theta^2] + 2p\Theta t - pt^2 \qquad (5)$$

($\log K + pt^2$) was plotted against t using the values of K given in Table II. Straight lines were obtained for the results in all the dioxane–water mixtures which proved the validity of the equation. From these graphs K_m and Θ were evaluated. Values of these quantities are given at the bottom of the table, and values of K computed by means of equation (5) are also given for purposes of comparison. The numerical equations for K in the three mixtures, obtained from equation (5) are

$$X = 20;\ \log K = \bar{6}.6785 + 0.00246\, t - 5 \times 10^{-5} t^2 \qquad (6)$$
$$X = 45;\ \log K = \bar{7}.6771 + 0.00185\, t - 5 \times 10^{-5} t^2 \qquad (7)$$
$$X = 70;\ \log K = \bar{9}.7147 + 0.00134\, t - 5 \times 10^{-5} t^2 \qquad (8)$$

respectively. The agreement between observed and calculated values is excellent. The maximum deviation is 0.6% for the 20% series and 0.5% for the 45% series. In the case of the 70% series, the maximum deviation is 0.4% except for the value at 50° where a 0.9% deviation is observed.

We have not tabulated the heat of ionization, ΔH. According to equation (4), this quantity is given by

$$\Delta H = 4.575 \times 10^{-4}\, T^2 (t - \Theta) \qquad (9)$$

The accuracy of the evaluation of ΔH depends on the accuracy with which Θ can be determined. An error in Θ of 1° will cause an error of 32 cal. at 0° and 48 cal. at 50°.

Summary

1. Measurements of the cells

$$H_2\ (1\ \text{atm.})\ |\ HAc(m_1),\ NaAc(m_2),\ NaCl(m_3),\ X\%\ \text{dioxane},\ Y\%\ H_2O\ |\ AgCl\text{–}Ag$$

have been made at 5° intervals from 0 to 50° in dioxane–water mixtures containing 20, 45 and 70% by weight of dioxane. The dielectric constants of these solvents at 25° are 60.8, 38.5 and 17.9, respectively.

2. From these data, the ionization constant of acetic acid, in each of the three solvents, has been computed at 5° intervals from 0 to 50° by the method of Harned and Ehlers.[3]

3. These values have been employed to test the empirical equation found by Harned and Embree[5] to express the variation of the dissociation constants of all weak electrolytes with the temperature.

---

[5] Harned and Embree, THIS JOURNAL, **56**, 1050 (1934).

The results of this investigation indicate that this general equation without any modification may be valid in non-aqueous solutions. It may at least be said that the Harned and Embree equation is able to reproduce the experimental results in solutions covering a wide range of dielectric constant, extending from 80 in aqueous solutions to 15.4 in a solvent containing 70% dioxane by weight at 50°.

A Redetermination of the Protium–Deuterium Ratio in Water[1]

BY NORRIS F. HALL AND THOMAS O. JONES

Since Bleakney and Gould[2] gave 5000 as the H/D ratio in rain water, several attempts[3] have been made to check this value by preparing water free from deuterium and comparing its density with that of ordinary water. Most of these fall roughly into two groups, resulting in values either near 5500 or near 9000.

Lewis in 1933[4] calculated the value 6500 on the basis of his first electrolytic fractionations. Recently Applebey and Ogden[5] have suggested an upper limit of 7000 on the basis of electrolyses and the assumption of "reasonable" values of the electrolytic separation factor. The opinion has been expressed[6] that Applebey's results definitely discredit values of the H/D ratio in the neighborhood of 9000. By most workers[7] Johnston's recent value ($-18.3\ \gamma$ in density, equivalent to a ratio of 5800) appears to be accepted as the most probable. We have now redetermined this ratio by a method which involves no extrapolation, and in which the final value is approached from both the light and heavy side.

Plan of Work

We prepared nearly deuterium-free water electrolytically by two methods. The first involved the recombination of the electrolytic gases according to the method used by Taylor, Eyring and Frost.[8] We shall refer to this method as "mixed recovery."

In one experiment 55 liters of Lake Mendota water was electrolyzed in potassium hydroxide solution with iron cathodes to about 70% of the original volume, and the 16 liters of water collected was reëlectrolyzed. This procedure was repeated five times until the volume of the last condensate was 150 ml. The amount collected at each stage was about 30% of the preceding volume. In a later experiment this process was independently repeated through four stages of electrolysis.

In the second method, called "separation recovery," we collected the hydrogen separately and burned it in ordinary air. Calculations of the equilibrium constant at high temperatures indicated that exchange effects in the flame could not introduce density differences in the burned water as great as 1 γ, and at the time this work was undertaken the results of Dole, Titani and Greene[9] were not available to us, so that we assumed that air oxygen and surface water oxygen had the same isotopic composition.

By this method two runs were made. In one run (III) through four stages using bell type cells, 30 liters of water was reduced to 150 ml. In the second (run IV), V-type cells (Fig. 1) with a loose plug of glass wool as a diaphragm were used. The initial and final volumes were 24 liters and 400 ml., respectively, and the electrolysis was carried again through four stages.

Because the results of the two types of electrolysis described did not agree, and because we expected on the basis of Johnston's work[3] a displacement of the oxygen isotope ratio during mixed recovery electrolysis, we decided to normalize the oxygen isotope content of some of our samples by equilibration against the standard

water through the medium of carbon dioxide gas. This was done as described below. As a valuable check on the density measurements, the index of refraction of many of the samples was determined.

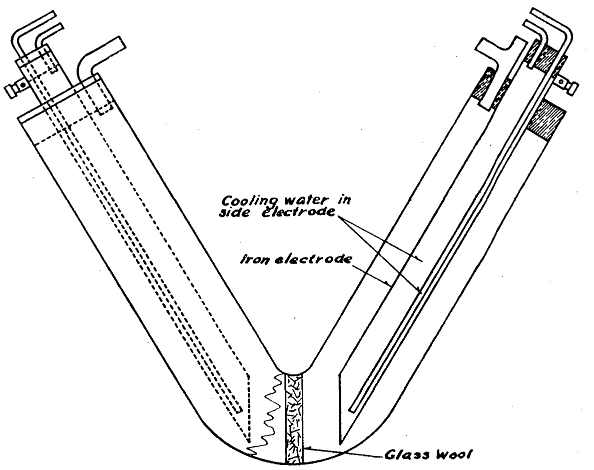

Fig. 1.—Electrolytic cell for separation recovery.

Experimental

1. Purification of Samples.—Each sample of water was distilled three times, once from alkaline permanganate in an all-glass still with a very short (1.27 cm.) Hempel column to trap spray, once from a drop of phosphoric acid through a 10-cm. Widmer column, and finally through a simple quartz still directly into the density apparatus or the interferometer cell. Small equal head and tail fractions were discarded. All the samples and the standard water were treated in exactly the same manner.

2. Density Measurements.—A magnetically controlled buoyancy apparatus (Fig. 2) was used, similar in principle to that described by Lamb and Lee.[10] The totally submerged quartz float was about 13 cm. long and had a volume of 8.2383 cc. at 25°. A cobalt–steel permanent magnet was sealed in the bottom of the float and held permanently in place with wax. The sample tube had a volume of about 60 cc. and had a bottom ground flat inside to which the magnetic float was attracted by the field of the coil beneath the sample tube. It was found that the float centered itself automatically and reproducibly in the field of the coil. The tube and connections were of Pyrex with metal parts of brass. The coil was held rigidly fixed below the tube by a brass and wax collar. By slowly reducing the current through the coil the exact voltage was found which just prevented the float from rising. The apparatus was calibrated by successively adding weighed platinum rings to the top of the float and measuring the e. m. f. required to hold the float against the bottom of the vessel. From the weight differences, the e. m. f. differences and the volume of the float and rings, it was found that one millivolt corresponded to a density change of 9.22 γ. This factor was found to be constant over the total density range studied (some 150 γ). The apparent precision of a single reading was 0.1 γ, and the measurement could be repeated at different times on the same samples to 0.2 or 0.3 γ. The apparatus was submerged in a thermostat which was constant to ±0.005°. The fluctuations in the apparent density of a given sample as it stood in the bath were hardly detectable, but measurements were always made at the crests of the bath temperature fluctuations.

Each sample was evacuated to remove dissolved air, opened to the atmosphere, closed, brought to temperature in the thermostat, opened and closed once more. This procedure removed the bulk of the dissolved air, but permitted small amounts to redissolve. No effect on the density from this source could be detected. Preliminary measurements showed that increases of barometric pressure produced an apparent density increase of 0.1 γ per cm. Since control measurements on the standard water were always made within a few hours of the measurements of an unknown sample, corrections from this source were always within the precision of the measurements themselves and were not applied.

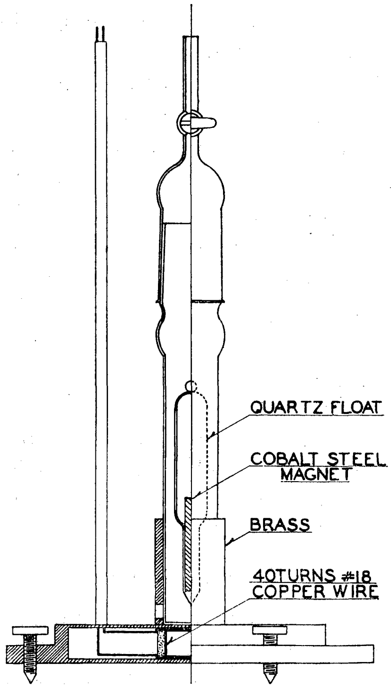

Fig. 2.—Density apparatus.

3. Carbon Dioxide Equilibration.—Saturating towers of a type described by Kraus[11] were used and filled with glass pearls. The gas current acting as an air lift circulated the water over the pearls and gave very efficient scrubbing. The gas was first scrubbed with a large quantity of the standard water which was frequently renewed. It was next thoroughly dried and then saturated by long and repeated contact with the unknown sample. As it left the sample the gas passed through reflux condensers and freezing traps to recover any water carried out, and this was united with the main sample. The density of the standard water was not affected by carbon dioxide treatment in this way.

4. Index of Refraction Measurements.—We fortunately were able to secure the loan for a time from the U. S. Forest Products Laboratory of a Rayleigh gas interferometer, through the courtesy of Dr. Alfred J. Stamm whose assistance is gratefully acknowledged. For this instrument a liquid cell-pair was constructed of Pyrex consisting of a 90-cm. long tube 3 cm. wide within which a 1-cm. tube was sealed by means of side inner seals (Fig. 3). Plate glass windows were cemented on the parallel ground ends. The standard water was placed in the larger tube and the sample in the smaller one. The whole cell was immersed in a water thermostat. Readings could be repeated to three or four scale divisions, so that the instrument was sensitive to refractive index differences of about 2×10^{-8}.

[a] In runs Ia, Id the amount of water available was too small for a determination of Δn.

Results

The columns of Table I show (1) the run (Roman numeral) and stage of electrolysis (small letter) referred to; (2) the difference in d^{25}_{25} between the purified electrolyzed sample and the purified standard water; (3) the same difference after the sample had been equilibrated with carbon dioxide and repurified; (4) the difference in index of refraction between the purified sample and the purified standard water (in run II these measurements were made on the samples which had been treated with carbon dioxide); (5) the specific gravity difference calculated from the measurement of n. In columns 2, 3 and 4 of Table I, each figure represents an individual determination. In calculating the values in column 5, the mean of the corresponding experimental values was used in each case. These results are also exhibited in Fig. 4, in which, however, only the mean values appear. The two upper curves represent the density differences obtained in runs III and IV by separation recovery. The lower two curves are the results of runs I and II by mixed recovery. The small circles and crosses on the middle curve show the values for all samples treated with carbon dioxide. The large circles give the values calculated from the index of refraction measurements.

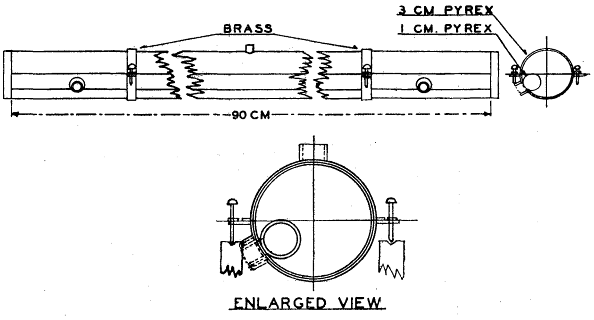

Fig. 3.—Interferometer cell.

For comparison with the water of Lake Mendota, we also made some density determinations on water from Lake Michigan, on the artesian well water of the Madison City supply, and on two samples of sea water taken from the Atlantic near the S. E. corner of Martha's Vineyard island.

TABLE II

Sample	$\Delta\gamma$		
Lake Michigan	+0.3	+0.4	+0.2
Madison City Water	−0.2	−0.3	
Atlantic Ocean I	+1.4	+1.8	
Atlantic Ocean II	+1.4	+1.6	

Table II gives the density differences of these samples from Lake Mendota water.

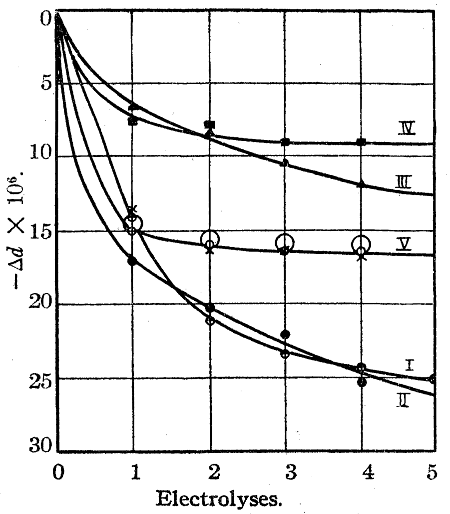

Fig. 4.—Removal of deuterium from water: ●, II knallgas water; ◓, I knallgas water; ○, V knallgas water; after carbon dioxide treatment; O, calcd. from interferometer; ▲, III hydrogen burned in air; ■, IV hydrogen burned in air; ×, air water after carbon dioxide treatment.

Discussion of Results

(a) **Mixed Recovery.**—Runs I and II are in substantial agreement with the results of Johnston[3] in that they seem to show composite density decrements due to (1) the progressive removal of all the deuterium, (2) a more or less steady but incomplete removal of O^{18}. Our results differ from his in that the decrement due to O^{18} removal does not seem to be constant and reproducible from stage to stage and run to run. Since the electrode surface and other conditions may be expected to vary with time, a completely constant fractionation factor for oxygen seems hardly to be expected. If our results are treated by Johnston's method of extrapolation to stage zero to correct for O^{18} removal, the residual density difference depends on the method of extrapolation. For these and other reasons, we have preferred to rely on the carbon dioxide method of restoring the original O^{18}/O^{16} ratio, rather than on correcting for its displacement by the electrolysis. Our average density decrease per stage due to oxygen in run II is 2.0 γ compared to the value 1.6 γ given by Johnston. (There is, of course, no reason why the gross separation factor in the two cases should be identical.)

(b) **Carbon Dioxide Equilibration.**—When samples from the mixed recovery electrolysis (run II) were treated with equilibrated carbon dioxide for several days, they showed in every case an *increase* in density (*i. e.*, an approach to the density of the original water). After removal from the apparatus, purification and density determination, the samples were returned to the apparatus and treated with carbon dioxide for several days more. The treatment was continued in every case until there was no further measurable change in density. The final values obtained (run II, column 3, Table I) point clearly to 16.5 ± 0.5 γ as the best value for the density decrement of deuterium-free water.

(c) **Separation Recovery.**—In two runs by this method density decreases of only about 12 and 9 γ, respectively, were obtained in four stages of electrolysis and burning. Since nearly all the deuterium (accounting for a density decrease of 10–15 γ) must have been removed in the first stage, the only way of accounting for this large excess density is to assume either that the nearly pure protium becomes reënriched in deuterium at each stage, or else that the oxygen isotope ratio has been significantly altered. To test the latter hypothesis, the samples from run IV were equilibrated with carbon dioxide against the standard water, and all showed further *decreases* in density (*cf.* columns 2 and 3, Table I). These decreases, which average 7.4 γ for the four stages, are in the direction, are of the order of magnitude to be expected from the work of Dole and others, since the oxygen of the original water had been replaced by (heavier) air oxygen in the burned water. The value found (7.4 γ) lies between those given by Dole and by Morita and Titani.[9] The indicated value for the density decrease of deuterium-free water is here again 16.5 $\pm$ 0.5 γ in complete agreement with the "mixed recovery" value.

(d) **Interferometry.**—Index of refraction measurements furnish independent evidence of the removal of deuterium from water, since unlike the density the value of n is relatively independent of changes in the amount of O^{18}.

It may be inferred from earlier work[3,12] that if $-\Delta d$ is the difference in density at 25° between two samples of water low in deuterium and normal as to oxygen isotope ratio, then $-10^6\Delta d$

---

(12) D. B. Luten, Jr., *Phys. Rev.*, **45**, 161 (1934); L. W. Tilton and J. K. Taylor, *Bur. Standards J. Research*, **13**, 207 (1934).

should equal about (1062/453) × $10^7 \Delta n$ where Δn is measured with white light at the same temperature. Applying this factor 2.34 to the measured index of refraction differences in run II, column 4, we obtain the calculated density differences in column 5, which are somewhat lower than the measured values (col. 3). This suggests that the factor 2.34 may be a little low. Best agreement would be secured by using the value 2.39. The extra handling and purification of the samples with the attendant dangers of fractionation or contamination may be responsible for the slight lack of agreement found, or the error may reside in the density and index of refraction work of others on which the calculation is based. In any event, the total discrepancy is less than 1 part per million in the density, and is probably within the error of the refractive index determinations.

Run I was made before we had begun to use the equilibration method, and therefore the index of refraction measurements were made on samples of which the O^{18} content had been lowered by electrolysis. This should have caused a decrease in the observed Δn, so that a positive correction should be applied to the Δn figures in Table I, run I, column 4. Subtracting from the observed value of $-\Delta d$ for stage Ib the hypothetical value 16.0 γ and correspondingly subtracting 16.5 from the observed value in stages Ic and Ie, we get the values 5.3, 7.0, and 8.6 as the decreases due to O^{18} removal. Multiplying these by the factor 0.073 to convert $10^6\ \Delta d$ into $10^7\ \Delta n$, we have as O^{18} corrections +0.4, +0.5 and +0.6. Adding these to the observed $10^7\ \Delta n$ values and multiplying by the conversion factor 2.39 we arrive at the values 15.8, 15.5 (and 16.3) which may be compared with the directly measured values 16.0 and 16.6 in run II and 16.3 and 16.4 in run IV. We thus have two fully independent and two partly independent series of values, obtained in two different ways, all of which are consistent with the value 16.5 ± 0.5 γ for the decrease in specific gravity of water due to complete removal of deuterium without disturbance of the oxygen isotope ratio. If this result is accepted, and the value 1.1074 is correct for the specific gravity of pure deuterium oxide (oxygen normalized) at 25°, the protium–deuterium ratio in Lake Mendota water becomes 6400 ± 200. (This computation takes account of the non-additivity of volumes found by Luten[12] as does the calculation of Δn just given.)

Since the measurements reported in Table II indicate in connection with many published results of others that Lake Mendota water has about the same density as surface fresh water everywhere, the value 6400 may perhaps be taken as the correct value for such water in general.

Using this ratio, Aston's recent redetermination of the physical atomic weights of the hydrogens and the Mecke–Childs conversion factor, the physical atomic weight of ordinary hydrogen becomes 1.0083 and the chemical value 1.0081.

This work was furthered by grants from the Research Committee of the University, whose aid is gratefully acknowledged.

Summary

1. Surface water from Lake Mendota (Madison, Wis.) was freed from deuterium by repeated electrolysis with recombination of the electrolytic gases. When the *deficiency* in O^{18} thus caused had been restored by carbon dioxide equilibration against the original water, the density loss due to deuterium alone was 16.5 γ.
2. The same water was electrolyzed in stages and the electrolytic hydrogen burned in air. The *excess* of O^{18} thus introduced was removed in the same way, and the density loss was again 16.5 γ.
3. Index of refraction measurements on the equilibrated water indicated that the entire decrease was due to deuterium.
4. Index of refraction measurements on electrolyzed but not equilibrated water gave values consistent with the postulated displacement of the oxygen isotope ratio.
5. The protium–deuterium ratio in surface fresh water inferred from these results is 6400 ± 200, confirming Lewis' early estimate.
6. Both the lower and the higher values of this ratio reported in the literature may possibly be due to actual differences in the water studied, but it is believed that many of them rest upon inadequate correction for alteration in the oxygen isotope ratio.

Influence of Combustion Conditions on the Density of Water Formed from Commercial Hydrogen and Oxygen

BY W. HEINLEN HALL AND HERRICK L. JOHNSTON

It was suggested in an earlier paper[1] that conditions at the time of combination of hydrogen and oxygen might influence the density of the water formed, particularly if the two gases were not present in the stoichiometric proportions. A further check on this point appeared of interest because of the possible significance of such an effect in the determination of isotope ratios.

To accomplish this a number of experiments have been carried out, with oxygen and hydrogen from commercial tanks. The gases were either combined by ignition in a small blowtorch of glass, to produce a flame, or the mixed gases reacted on a catalyst surface of platinized asbestos. The water vapor was condensed, the water purified[2] and its density determined to roughly 1 p. p. m. by the submerged float method. Precautions[3] were taken to avoid possible errors due to barometric variations or to changes in weight or volume of the glass float. Combustions were made out of contact with air.

The results of these experiments are given in Table I, where they are classified with respect to the conditions of combustion. As shown, the catalyst was employed under three sets of conditions. III represents conditions similar to those in our earlier work,[4] in which the catalyst chamber was heated to 300° and the mixed gas passed slowly through a loose plug of the platinized fiber. Reaction took place over a large area of catalyst[5] surface, without incandescence, and there was relatively long contact between the mixture of steam and the gas introduced in excess. The conditions in IV were similar, except that the catalyst chamber was not heated. An approximate temperature of 100° was maintained by the heat of reaction. In the experiments listed under II the mixed gases were directed onto a small area of the catalyst by a capillary which almost touched the asbestos. This resulted in a much more localized reaction with the result that incandescence was produced in a small zone adjacent to the capillary. In reality combustion probably occurred as a homogeneous gas phase reaction in a thin flame adjacent to the catalyst surface. In this series of experiments the walls of the catalyst chamber were cooled with water, which condensed the steam and thus removed it from the active zone.

TABLE I

Condition of combustion	Volume of O_2 per unit volume of H_2	Sample	Densities relative to normal water ΔT	Δd (p. p. m.)
I Flame at tip of glass blowtorch				
(a) Stoichiometric proportions	0.5	A3	+0.010	+2.6
(b) Oxygen in excess	4	A1	+ .010	+2.6
	0.7	B2	+ .012	+3.1
(c) Hydrogen in excess	.06	A2	+ .006	+1.6
II Glowing catalyst in water-cooled copper tube				
(a) Oxygen in excess	0.75	A5	+0.013	+3.4
(b) Hydrogen in excess	.2	A4	+ .013	+3.4
III Catalyst at 300° in heated Pyrex tube				
(a) Oxygen in excess	1.0	A8	−0.002	−0.5
	1.0	B3	− .020	−5.2
(b) Hydrogen in excess	0.1	A6	+ .018	+4.7
	.16	A7	+ .021	+5.5
	.25	B5	+ .021	+5.5
IV Catalyst at 100° in uncooled Pyrex tube				
(a) Oxygen in excess	1	B4	−0.014	−3.7
(b) Hydrogen in excess	0.125	B1	+ .025	+6.5

The columns in the table refer to: proportions in which the gases were supplied from the tanks, measured by flowmeters; identifying sample numbers, with the letters A and B used to distinguish two different pairs of oxygen and hydrogen tanks used in the investigations; and the temperatures of floating equilibrium and corresponding density increments, relative to purified samples of Columbus city water.

Interpretation and Discussion of Results

The low density of sample A2 may indicate a slight effect, due to excess hydrogen, in the flame experiments. However, the effect, if present, is no greater than the limits of error of the determination. Nor is the density of the water pro-

[3] Johnston, THIS JOURNAL, **57**, 484 (1935).

[4] The same lot of platinized asbestos was used in all of the catalyzed experiments of the present work as was used in the early investigation.

[5] Analysis of the gas which came from the catalyst in one experiment, with an initial mix of 27 parts oxygen to 73 of hydrogen, showed that the oxygen removal was 95% complete.

duced from the "B" pair of tanks significantly different from that of the "A" pair. We take 2.5, the average of the four samples secured in the flame combustions, as the value best representative of the hydrogen and oxygen in the tanks and use this as a reference point to measure the effect of the various conditions accompanying the catalytic experiments.

The consistently high values (2 to 4 parts per million relative to the flame experiments) obtained with excess hydrogen in series III and IV are well outside the experimental error and are opposite in sign to effects which might be anticipated on the basis of comparative reaction velocities of light and heavy hydrogen.[6] They may be accounted for by the exchange reaction

$$H_2O(g) + HD = HDO(g) + H_2 \qquad (1)$$

for which platinum is observed to be a catalyst.[7] Equilibrium constants for this reaction are 2.0 and 1.38 at 100 and 300°, respectively.[7b] Table II records the relative densities to be expected with equilibrium fully attained.[8]

TABLE II

EQUILIBRIUM DENSITIES (CALCULATED) FOR THE RUNS WITH HYDROGEN IN EXCESS

Sample	Hydrogen steam ratio	Density above normal water, p. p. m.
A6	4.0	7.6
A7	2.1	6.7
B5	1.0	5.4
B1	3.0	13.5

Failure to attain full equilibrium, particularly at the lower temperature, is to be expected since the time of contact with the catalyst was much shorter than that found by A. and L. Farkas[7b] for complete equilibrium.

With excess oxygen, under the conditions pertaining to series III and IV, densities are consistently low (3 to 8 parts per million). Although the exchange reaction

$$H_2O^{18} + O^{16}O^{16} = H_2O^{16} + O^{16}O^{18} \qquad (2)$$

would lead, qualitatively, to water of low density, the quantitative effect of this reaction could not exceed approximately 0.3 p. p. m. in the experiment at 300°, or about 1 p. p. m. at 100°.[9] The low densities must therefore be the result of higher reaction velocities of $O^{16}O^{16}$ as compared with $O^{16}O^{18}$. It is evident that platinum is a much poorer catalyst for the exchange of oxygen with water than for the exchange of hydrogen with water.

The results in Series II are probably to be accounted for on the theory that here we are dealing with a homogeneous gas phase reaction in which the isotope proportions remain unchanged, as in the flame, and that rapid removal of water vapor from the gas phase prevents a subsequent hydrogen exchange with sample A4.

The Density of Atmospheric Oxygen

These experiments confirm a reinterpretation[10] of an observation reported in our previous paper.[1] The fact that tank hydrogen burned in air (flame) produced water of higher density than that resulting from reaction of the same tank hydrogen with oxygen from normal water (catalyst) was attributed by us to the relative proportions in which the gases were brought together in the two combustions. On the basis of the present work we see that the density of samples 4(a, b) of the earlier work were probably *high* to the extent of about 2.7 parts per million due to the hydrogen exchange reaction on the catalyst. With this correction applied the discrepancy between samples (4) and (5) of that work is *increased* to give a difference of 6.6 p. p. m. The combustion in atmospheric oxygen gave the water of higher density. This is in good agreement with independent work of Dole,[10] who reports 6.0 p. p. m. greater density for water produced by combustion of hydrogen with atmospheric oxygen than for water produced by combustion of the same hydrogen with oxygen from normal water.

The conclusions in the earlier paper respecting the O^{18} and O^{17} enrichment of water from commercial electrolytic cells are not changed by the results reported here. Since the conditions of combustion were the same with samples 2 and 3 (a, b) the influence of the hydrogen exchange reaction must have canceled out in the comparisons of densities.

Summary

Density comparisons of water produced by

(7) (a) Horiuti and Polanyi, *Nature*, **132**, 819 (1933); (b) A. and L. Farkas, *Trans. Faraday Soc.*, **30**, 1071 (1934).

(8) The hydrogen was produced by electrolysis of water and should be nearly normal unless the electrolyte was newly prepared. The oxygen was produced by the fractionation of air and might be expected to contribute, in itself, a density abnormality of about 6 p. p. m. (*cf. seq.*) except for some probable isotope separation in its production. For purposes of this computation we have taken the hydrogen as normal (H/D ratio of 5800) and have credited the 2.5 p. p. m. abnormality to the oxygen alone.

(9) This calculation is based on the enrichment factors computed by Urey and Greiff [THIS JOURNAL, **57**, 321 (1935)] and on an O^{16}/O^{18} ratio of approximately 500.

(10) Malcolm Dole, *J. Chem. Phys.*, **4**, 268 (1936).

combustion of hydrogen and oxygen from commercial cylinders show: (1) that the proportions in which the gases are brought together for reaction results in no significant change in the isotopic composition of either hydrogen or oxygen if the combustion occurs in a flame.

(2) That changes of isotopic composition sufficient to affect the density of the resulting water by several parts per million may occur if the combination takes place on a platinum catalyst. With oxygen in excess the density of the resulting water may be low and appears to be accounted for by lower reaction velocities of oxygen molecules containing the heavier isotopes. With hydrogen in excess the resulting water was found, under certain conditions, to be high in density. This appears to be the consequence of an incomplete exchange reaction between steam and the excess hydrogen.

An exchange reaction between steam and molecular oxygen does not appear to be significantly catalyzed by platinum at 300°.

Previous data[1] corrected for the hydrogen exchange are in quantitative agreement with Dole's discovery[10] that water produced from hydrogen and atmospheric oxygen is denser by about 6 parts per million than water produced by combination of the same hydrogen with oxygen obtained from normal water.

Kinetics of the Vapor Phase Reaction of Mercury and Halogens

BY RICHARD A. OGG, JR., HENRY C. MARTIN AND PHILIP A. LEIGHTON

There appears to have been but little study of the familiar combination of mercury with halogens. In particular, no evidence has as yet been adduced to show that such a reaction can take place other than at the surface of liquid mercury. It is desired to report the preliminary results demonstrating the occurrence of a rapid vapor phase combination of mercury and bromine and to discuss the kinetics of this process.

The method previously described[1] for demonstrating visually the evaporation of mercury was extended to observe qualitatively the reaction of mercury vapor with halogens. A dish of warm liquid mercury was interposed between a mercury "resonance" lamp and a fluorescent screen. The ascending vapor was manifested as a dark shadow on the screen. Introduction of a small dish containing liquid bromine or warm iodine crystals into the space above the liquid mercury caused the shadows to vanish, only to reappear after removal of the halogen.

Estimates of the rate of the mercury–bromine reaction were made by an adaptation of the "diffusion flame" method employed by Frommer and Polanyi[2] in their studies of sodium vapor reactions. Mercury vapor (at a known partial pressure of some 0.01 to 0.1 mm.) carried in dry air at atmospheric pressure was allowed to flow through a nozzle into a reaction cell filled with air at atmospheric pressure and bromine vapor at a partial pressure of some 10 to 40 mm. The reaction zone was maintained at approximately 110°.

Quartz windows allowed a beam of light from a mercury "resonance" lamp to traverse the reaction zone and by means of quartz lenses an image of the nozzle and surrounding region was cast upon a fluorescent screen. With suitable rates of flow (a linear nozzle velocity of about 1 cc./sec.) the reaction "flame" was observed as a circular shadow projecting from the nozzle image. Visual estimation was made of the light absorption in various parts of the "flame," and compared with that in blank experiments in which air containing mercury vapor at various known concentrations was allowed to flow into the bromine-free cell. In this manner a rough estimate could be made of the total number of mercury atoms present in the mercury–bromine "flame." The reciprocal of the mean life of the mercury atoms in the "flame" divided by the bromine concentration yields the bimolecular velocity constant.

The mercury–bromine reaction appeared to be one of the first order with respect to each reactant. Upper and lower limits for the velocity constant under the above conditions were estimated as

---

(1) P. A. Leighton and W. G. Leighton, *J. Chem. Education*, **12**, 139 (1935).

(2) L. Frommer and M. Polanyi, *Trans. Faraday Soc.*, **30**, 519 (1934).

10^7(mole/cc.)$^{-1}$ sec.$^{-1}$ and 10^5 (mole/cc.)$^{-1}$sec.$^{-1}$, respectively. Experiments were also made on the temperature coefficient. The temperature of the reaction cell was rapidly lowered from 120 to 50°, other conditions (rate of flow, concentrations of reactants) being maintained constant. No appreciable change could be observed in the size of the "flame" shadow. This result allows a conservative estimate of some 5 kcal. as the upper limit of the activation energy, and it may well be zero. A few experiments with mercury–iodine "flames" indicated the rate to be essentially the same as that of the mercury–bromine reaction. The reaction products were mercuric bromide and iodide, respectively.

These preliminary results allow decision between the only two plausible mechanisms for the mercury–bromine reaction. The first mechanism embodies two consecutive metatheses, of which the first would be rate determining.

$$\mathrm{Hg} + \mathrm{Br_2} \longrightarrow \mathrm{HgBr} + \mathrm{Br} \qquad (1)$$

$$\mathrm{HgBr} + \mathrm{Br_2} \longrightarrow \mathrm{HgBr_2} + \mathrm{Br} \qquad (2)$$

The second mechanism involves only an association.

$$\mathrm{Hg} + \mathrm{Br_2} \longrightarrow \mathrm{HgBr_2} \qquad (3)$$

The heat of dissociation of HgBr is given by Sponer[3] as 25.4 kcal. per mole. Using the accepted value of 45.2 kcal. per mole for the heat of dissociation of bromine, reaction (1) is seen to be endothermic by 19.8 kcal. Hence the corresponding activation energy would be at least this great. Experimentally the observed activation energy is nearly zero. Further, a bimolecular reaction having a normal collision rate [10^{14} (mole/cc.)$^{-1}$sec.$^{-1}$] and an activation energy of 19.8 kcal. would have at 110° a rate constant of only some 10^3(mole/cc.)$^{-1}$sec.$^{-1}$—a value much smaller than the lower limit estimated for the experimental value. Hence it may be concluded that the mechanism involving reactions (1) and (2) plays no appreciable role, and that the observed mercury–bromine reaction is due to the association reaction (3). Exactly similar considerations obtain for the mercury–iodine reaction.

An association reaction such as (3) may be slower than the collision rate for three reasons: (a) activation energy may be required; (b) there may be "steric hindrance"; (c) triple collision with a third body (in this case an oxygen or nitrogen molecule) may be necessary. Were the slowness of the observed mercury–bromine reaction due only to factor (a), the activation energy would be from 12 to 15 kcal., corresponding, respectively, to the upper and lower limits of the velocity constants. The extreme smallness of the observed activation energy leads to the conclusion that the second and third factors are more important.

As an approximate estimate of the rate of triple collision the rate constant for the recombination of bromine atoms in the presence of a third body may be chosen. For a considerable number of different molecules this constant has a value[4] of approximately 10^{15}(mole/cc.)$^{-2}$sec.$^{-1}$. At 110° and atmospheric pressure the concentration of air molecules is some 4×10^{-5}(mole/cc.). Hence if reaction (3) occurred at every triple collision the apparent bimolecular velocity constant would be some 4×10^{10}(mole/cc.)$^{-1}$sec.$^{-1}$. Since this value is over a thousand-fold greater than the estimated upper limit of the velocity constant for the mercury–bromine reaction, it is entirely consistent to assume that the association reaction (3) occurs only on collision with a third body. Theoretical considerations[5] indicate that association reactions which form a triatomic molecule should require triple collisions. The design of the apparatus was not such as to allow experimental test of the above conclusion by studying the dependence of the mercury–bromine reaction upon the concentration of inert gas. In future study of the reaction it is planned to make this test.

Assuming the mercury–bromine reaction to be a three-body process, it is seen that the efficiency of triple collisions is relatively small. The experimental results do not allow decision as to whether this is due to activation energy or "steric hindrance." Were the activation energy 5 kcal., the calculated rate at 110° would be reduced by a factor of some seven hundred.

It is interesting to compare the above results on the mercury–bromine and mercury–iodine association reactions with the studies of Polanyi[6] on the initiation of hydrogen–chlorine reaction chains by atoms of zinc, cadmium and mercury. At 300° zinc and cadmium atoms were found to initiate chains, presumably by processes analogous to reaction (1) above. The respective velocity constants were estimated as some 10^{10} and

(6) M. Polanyi, *Trans. Faraday Soc.*, **24**, 606 (1928).

10^9(mole/cc.)$^{-1}$sec.$^{-1}$, respectively. This is not inconsistent with the assumption that zinc and cadmium atoms can combine with chlorine by association processes analogous to reaction (3). Presumably these reactions would also require triple collisions and have rate constants of the same order as those found for mercury–bromine and mercury–iodine association. Hence under the experimental conditions employed by Polanyi (total gas pressures of a few mm.), the bimolecular velocity constants for the zinc–chlorine and cadmium–chlorine association reactions may be estimated as at most some $10^5 - 10^6$(mole/cc.)$^{-1}$sec.$^{-1}$. This is very much smaller than the experimentally observed velocity constants for the metathetic reactions, and hence the association plays a negligible role. With mercury atoms and chlorine it appears that the reverse situation obtains, since it can be shown that the process analogous to reaction (1) is about equally endothermic for all halogens. This conclusion is in agreement with the observation of Polanyi that mercury atoms do not initiate chains in hydrogen–chlorine mixtures.

Summary

1. It has been shown that mercury atoms enter into a rapid vapor phase reaction with halogens.

2. At 110° and in the presence of air at atmospheric pressure the mercury–bromine reaction appears to be of the first order with respect to each reactant, and the velocity constant lies between 10^7 and 10^5(mole/cc.)$^{-1}$sec.$^{-1}$.

3. The temperature coefficient is very small, an upper limit of 5 kcal. being estimated for the activation energy.

4. It appears that the mercury–bromine reaction must take place as an association process, most probably in triple collisions with molecules of inert gas. The efficiency of triple collisions appears to be relatively small.

Photography of Minima in the Magneto-Optic Apparatus

BY GORDON HUGHES

The work of Allison[1] and others on the magneto-optic apparatus has been called into criticism by several investigators[2–4] due to their inability to operate the magneto-optic apparatus successfully. In the face of the many admitted complexities and difficulties encountered in its use the failure of some might be readily expected. The purpose of this investigation has been to develop a completely objective method for the study of the minima of light intensity in the apparatus and thus demonstrate, beyond doubt if possible, the reality of the minima and the validity of the visual results previously obtained with the apparatus. During the course of this study several photographic methods have been employed with only partial success. Their failure has been due entirely to mechanical difficulties. The method described here is free of these inherent defects and with it consistent positive results have been obtained. This method has been made as completely automatic as possible in an effort to reduce the personal factor to a minimum. Since the results obtained by this photographic method may be interpreted into fairly accurate quantitative measurements, this work has had the added purpose of determining the quality of the minima under varying conditions in an effort to improve them for visual work.

Experimental Technique

Methods have been devised[2–4] for testing the presence of minima by comparing the light through the apparatus with a sample of light brought to one side of the coils and then joined with the main beam. In these methods one is never sure that both beams suffer the same optical conditions at all times. The Wollaston prism was employed in this study since with it there is no doubt that the treatment of both beams is optically identical. That is to say, the intensity ratio of the two beams is independent of variations in the intensity of the incident light. It has the further advantage that its use doubles the absolute intensity change for the effect, on the hypothesis that the effect is a rotation of the plane of polarization of the incident light.

The apparatus was essentially identical with the conventional one used for visual work except for the substitu-

tion of the Wollaston prism, W in Fig. 1, for the analyzing Nicol prism. Before photographic work was started sufficient work had been done visually with the Wollaston to show that minima could be observed with this type of prism as well as with the Nicol prism. The lens L_2 focused the two images of the single vertical slit S sharply on the photographic plate P_2. The Nicol prism N was set with its plane of polarization at an angle of 45° to the horizontal. The Wollaston prism mounted in a revolving head was turned to an angle midway between the angles of extinction of each of its two beams. This procedure gave two ribbon-like beams in a horizontal plane of nearly equal intensity falling on the photographic plate.

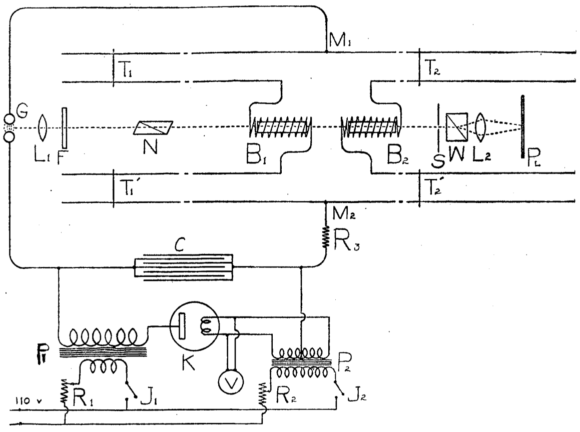

Fig. 1.—Magneto-optic apparatus.

The camera consisted of a simple frame to hold the plate which could be racked along the horizontal track by steps of 4 mm. With this horizontal motion it was possible to take 16 to 20 pictures in a row and a vertical motion of the plate in the frame permitted several rows on a plate. The time of exposure for each picture was made uniform by a synchronous motor timing device which gave to each exposure two and two-thirds seconds or some multiple of that time. At the same time the interval between exposures was kept at a constant one and one-third seconds. Eastman Hyperpress plates were used in this study since only a small amount of blue light was available for an exposure. The Hyperpress plates served admirably when developed with the contrast developer recommended for their use.

The magnesium 4481 Å. line was used. Short exposures were desirable in order that the electrodes of the spark gap should not overheat nor burn away appreciably from one exposure to the next. Exposures which gave a rather dense blackening were found to give more consistent results than those which were less dense. Plates which were not properly exposed were not included in the summary of results below.

The microphotometer employed in determining the densities of the exposures was of the conventional design with vacuum thermocouple and short-period high-sensitivity galvanometer. It was equipped with recording drum and glass scale so that the densities could simultaneously be recorded and measured directly from the galvanometer deflection on the glass scale. Most of the determinations were read directly from the scale as this was less time consuming than recording and then measuring the microphotometer traces.

The electrical system as shown in Fig. 1 is the same as that used for visual work except for the introduction of R_3, an electrolytic resistance of 130 ohms which effectively damped out oscillations in the electrical circuit and made the spark breakdown at G much steadier as well.

The breakdown at G was analyzed by means of a high-speed rotating mirror mounted on a Beams pneumatic top. The light, first focused on a narrow slit, was reflected from the mirror onto a photographic plate. Microphotometer traces of these exposures are shown in Figs. 2 and 3. The time scale is approximate only since no accurate measure of the speed of the top was made. Figure 2 is the type of breakdown obtained when R_3 was not present and shows the highly oscillatory nature of the current in the trolley system and coils. Figure 3 is the breakdown with R_3 inserted. Its damping value is apparent. Photographs of minima were attempted with both types of spark and it was found that only the damped spark gave positive results.

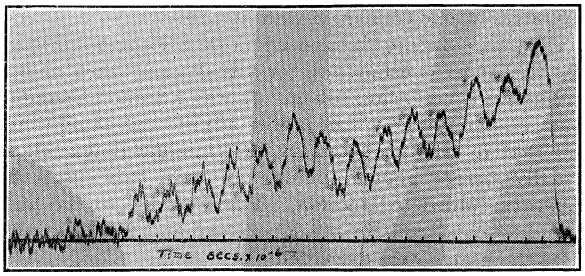

Fig. 2.—Normal spark discharge used for visual work.

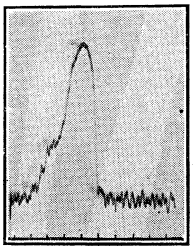

Fig. 3.—Spark discharge with damping resistance.

Since the results of visual work preclude any possible large change in light intensity to be photographed, it was apparent that a true picture of any real effect could be obtained only from the average effect in a large number of pictures. Under optimum conditions, the variable factors, intensity of light, current in the coils, and the optical condition of the liquids, would remain constant from one exposure to the next. It was with these variations in view that exposures were made in rapid succession first with the trolley contacts T_2 and T_2' at the proper position for a minimum and then off this position, alternating for possibly 16 to 20 pictures in a row. The number of rows of pictures starting with an "off" about equalled the number starting with an "on." The "on" position for any given compound had been determined previously from repeated visual observation. In determining a desirable "off" position, a position was taken which was known to be free of minima as shown from a chart of all known minima or a solution of the material to be examined was placed in the apparatus and the regions of the scale on either side of the minimum position were scanned visually to find one location free of minima. In the cases of the compounds used: for lithium chloride the "off" position was 2.1 cm. ahead of the "on" position, for cupric chloride the "off" was 0.9 cm. back of the "on" position, for phosphoric acid "off" was 1.05 cm. ahead of "on." The concentration of compound for all but a few pictures was 1 to 2 parts in 10^5 parts of water. This relatively high concentration was necessary since the Wollaston prism was set so that its two beams were at 45° angles to the plane of the polarizing nicol. Bishop, Dollins and Otto[5] report a reduced sensitivity of the apparatus at this point.

In every case water blanks were photographed prior to compounds. The compound to be studied was added to the same tube which had contained the water blank in order that the optical system should remain intact for all exposures of one compound and its blank.

The particular apparatus used for the photographic work was in almost constant use for visual work when photographs were not being taken. It was assumed therefore that the apparatus was in proper adjustment at all times and that it was not necessary that minima be examined visually before photographing. In only two cases the apparatus failed to function. This was due to the high humidity conditions in the laboratory and for these two cases the plates were discarded.

Discussion of Results

Figure 4 is an enlarged reproduction of some of the exposures on a typical plate. In the top row every other pair of lines represents an "on" exposure. Alternate pairs of lines were made when the trolley was on the position of a minimum and the other pairs when the trolley was off this position as described above. Since the two beams making lines A and B were of nearly equal intensities and were polarized at 45° angles to the light from the polarizing nicol, any rotation of the plane of the light before it reached the Wollaston would have caused a dimming of one of the beams and a brightening of the other. On the assumption that there was a change in the plane of polarization on passing through a minimum, there should have been a momentary difference in the density ratio of the lines A and B as this position was crossed.

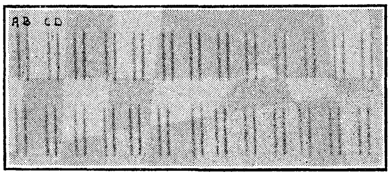

Fig. 4.—Enlarged reproduction of typical plate.

Figure 5 is a typical microphotometer trace showing only the peaks or maximum density points for a picture similar to Fig. 4.

30.25	28.20	2.05	30.10	27.95	2.15

Mean "on" 1.66 cm. Mean "off" 1.92 cm.

Difference "off" – "on" = 1.92 – 1.66 = 0.26 cm. = G

Table I presents a set of measurements made on the microphotometer trace of Fig. 5 and the reading on the glass scale for the same plate. The base line in Fig. 5 from which the peaks were measured is arbitrary and is on the opposite side of the peaks from the zero of the glass scale.

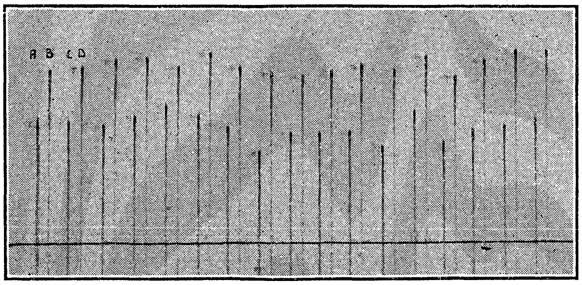

Fig. 5.—Microphotometer trace of maximum density points of typical plate.

The readings on the glass scale are presented to demonstrate the reliability of density measurements made in this manner when compared to the generally accepted method of measuring microphotometer traces. That nearly exact duplication is shown is sufficient justification for the direct measurement of the galvanometer deflection.

The value of G in the above table represents a difference in density which should be obtained if the minima have been photographed. The value

---

(5) Bishop, Dollins and Otto, THIS JOURNAL, **55**, 4365 (1933).

in centimeters as recorded has no absolute significance since the measurements were made only to show a difference in density "on" and "off" minima and are not a measure of this difference in absolute terms. Table II presents the results of water blanks photographed just prior to the photographs recorded in Table I. The photographs of the acid solution were made with the acid in the identical tube which had contained the blank placed in the apparatus in the same position as the blank. Several series of pictures were made in which different cells were used for the solution and the blank. These blank pictures were not comparable with solution pictures since the collimation of the light was different for different cells.

Mean "on" 1.24 cm.			Mean "off" 1.26 cm.		

Difference "off" – "on" = 1.26 – 1.24 = 0.02 cm. = G

If the minima are characteristic of the compound in the cell, it is necessary that the value of G for the blank be lower than this value for a compound. Such is the case in Tables I and II. The data in Tables I and II are the results of two lines of eight pictures each. Since some 90 lines each containing as many and more pictures to the line were recorded, a more complete view of the average result is seen in Table III wherein are the averages of a few typical lines under various conditions.

The value G for a compound and the corresponding value for the water blank may be compared directly since the two sets of pictures were made and microphotometered at the same time. The value of G for one blank may not be compared with that for a different compound since the various pictures of compounds were taken at different times, on different plates, and were examined with the microphotometer at different sensitivities. A fair comparison may be made between the percentage by which the value of G differs from the value of the "off" reading for any water picture and this percentage for any compound. The sign of this percentage is purely conventional. It is taken as positive when the value of "on" is greater than the value of "off." This difference in percentage between water and compound was employed in a previous publication on this work[6] as the criterion of the minima having been photographed. Although it is an unsatisfactory measure and has no quantitative meaning, nevertheless it does indicate a density difference between "on" and "off" pictures of compounds and blanks which is sufficient proof of the reality of the minima.

The seeming discrepancy in the sign of the percentage between lines number 1 and 2 of the first group of Table III and the other lines of the group and a similar discrepancy in line number 6 of the second group is explained in Fig. 2. Considering the case of lines 1 and 2 let the rectangular figures represent the density curves of a pair of lines of a picture "off" a minimum. As represented A is somewhat brighter than B. These curves from the data of Table III will look as A′, B′ for the picture "on" a minimum. For such a case the percentage would have a positive value since A−B is smaller than A′−B′. Examples of this condition are lines numbered 3, 4 and 5. For lines 1 and 2 the direction of the intensity change in each beam is the same as that of lines 3, 4 and 5 but the initial intensity ratio of the two beams is reversed. For these two lines the density curves would be as in Fig. 6. The percentage in this case is negative. Many pictures were made at each of the two settings and the sign of the percentage was consistent for all pictures at each setting. The value of the percentage for water was found to be nearly zero and to vary with no regularity in sign as may be seen in Table III.

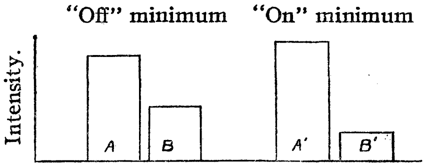

Fig. 6.—Percentage positive.

Duplicate exposures were made with the current in the coils B_1 and B_2 in Fig. 1 reversed to its original direction in order that any characteristic of the electrical circuit or optical system that might be giving these results should be detected.

The two groups in Table III show the effect of reversing the direction of the current. Minima were photographed when the two magnetic fields were in the same direction, that is, when the two adjacent ends of B_1 and B_2 were N and S, respectively, and when the fields were in opposite directions. The results listed in Table III are for fields in the same direction. Pictures were made with the current in either direction when the fields were in opposite directions. No appreciable difference was noted in the quality of the minima for the different directions of the fields or current.

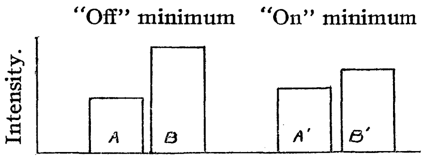

Fig. 7.—Percentage negative.

Since the purpose of this work was to show by a photographic test that minima are real it is necessary to consider the results of all the pictures which have been taken for this purpose, excluding only those which for valid reasons would not be expected to give positive results. The following reasons were considered valid for discarding pictures and the results of pictures taken under such conditions were not included in the means, percentages or totals given below.

1. Pictures taken with an unsteady spark were discarded. If the spark was unsteady for an entire plate the entire plate was discarded. If in a plate the spark was noticeably unsteady for a single line on the plate and with the proper adjustment became steady for the later pictures on the plate only the bad line was excluded. If for one picture in a line the spark was unsteady and that unsteadiness for the particular picture was recorded in the notes, the one picture affected was not included in the average for the line.

2. Plates were discarded which did not have the proper development or which showed slight scratches due to handling.

3. Plates which had an improper exposure as described above were discarded.

4. Plates were discarded which had an improper spacing between the lines. The lines on these plates were too close together due to an improper distance between camera and lens.

5. When it was found that positive results were never obtained when the resistance R_3 was omitted from the circuit those pictures taken without it were discarded.

6. This report does not carry the results of 200 pictures obtained before an automatic timing device was used. These results are positive but since the timing was uncertain they are not included.

7. A few lines of pictures taken when the concentration of material present was too low to give minima are not included.

8. Those pictures are not included for which visual observation showed the minima of an impurity present in the solution to be close to the "off" position of the minimum under consideration.

9. The pictures which were taken under conditions of high humidity are not included. Visual work has shown minima under such conditions to be very poor and with extreme humidity to disappear completely.

Table IV presents the average percentage difference for all pictures of compounds and water except those specified above with each of the four possible electrical connections. In determining the mean percentage for compounds the sign of the individual percentages is not considered since it must necessarily change with the electrical connection. In the case of water, however, an algebraic mean is given since the percentages appeared positive and negative in all connections.

Table V is reproduced from a previous publication on this work.[6] The results presented have been incorporated in Table IV. It is of interest to note that the percentage for compounds varied only 0.5% with the addition of 1158 new pictures while the water, which shifted on either side of zero for the different connections, changed the sign of its earlier mean value with the addition of only 325 new pictures.

The water blanks tabulated above were made with samples of very pure water. The difference in conductivity between this water and a solution of an acid of a concentration of 1 part in 10^5 parts of water is large, and it has been suggested that the minima might be due to this change in conductivity. To investigate this point pictures were taken with the trolley on and off the position of the phosphoric acid minimum when only 1 part of cupric chloride in 10^5 parts of water was present in the tube. The percentage for 56 of these pictures was 0.91, showing conclusively that minima can be obtained for a particular substance only when the trolley is at the proper position regardless of the other materials present in the tube.

Since the differences in density to be measured in this procedure are small, it was found that the utmost care had to be exercised in the handling and development of plates and in their examination with the microphotometer. The plates were carefully inspected before placing in the microphotometer and any dirt or lint in the exposed area was gently brushed aside. In those cases where lint was found on the plate after the lines had been measured the line or lines in question were remeasured along with neighboring lines so that a proper comparison could be made. For example, in a particular strip of picture the "on" pictures were all larger than the "off" pictures except one pair. A bit of lint was found on one of the four lines of this pair of pictures and whereas the density differences read

	A	B	Diff.
on	14.43	14.10	0.33
off	14.50	14.10	.40

before cleaning, they read

on	13.70	13.39	0.31
off	13.58	13.34	.24

after cleaning, in accord with the other pictures in the strip.

The difference in actual galvanometer deflection recorded as A and B above for the two readings of the same lines may be due to a motion of the

plate in its holder on the microphotometer causing a slightly different length of the line to have been measured. Many strips of pictures were examined along different sections on the length of the lines and although the lines varied in density along their length the density difference between the lines of a pair varied but little. Table VI presents the results of one strip measured four times.

Only the differences between the lines are recorded since it is these values that determine whether the minima have been photographed or not. Trials 1 and 3 were made on the top edge of the strip while 2 and 4 were made on the lower edge. To determine the constancy of the microphotometer Trials 3 and 4 were made several days after 1 and 2. Due to the removal of the plate from the microphotometer after each trial, a variation in the individual values recorded is to be expected. The percentages recorded in the table indicate in a measure the quality of the minima and from their values it will be observed that the minima vary but little along the length of the lines in a series of pictures. These percentages also indicate with what error a series of lines may be read over a period of time.

The means recorded in Tables I and II are simple arithmetic means. Such averages used in the course of this study gave results confirming visual work. It has been pointed out, however, by critics interested in this investigation that the simple averages used were obtained from data many of whose individual members deviated widely from the mean, and that this large deviation might be the major factor in giving the desired result. The author appreciated from the first of this study that the effect obtained was a small one and close to the experimental error. For this reason a very large number of photographs were taken with as many variations as possible. The fact that these many pictures gave the desired result was not considered sufficient evidence for the proof of this effect because all of the groups of pictures contained pictures which deviated widely from the mean. A recalculation of all the results was therefore made in which the extreme cases in the data were discarded in an effort to obtain a result free from such cases.

Using the average deviation of the individual pictures from their simple average it was found that 0.1% of all the pictures deviated from the average by more than three times the average deviation, 11.0% deviated by twice the average deviation and 34.0% by more than the average deviation. There was no appreciable difference in the number nor magnitude of the deviations for any group of pictures as compared to any other group.

The data presented in Table IV, recalculated, using only those pictures which are within twice the average deviation are presented in Table VII.

TABLE VII

SELECTED DATA FROM TABLE IV

Total 1320				Total 506	

On the basis of this calculation the minima appear better than before. The general effect on the individual strips was to raise the percentage. For some strips the percentage was lowered but in no case was there a change of sign of the percentage for compounds. In the strips for water there were many changes of sign and the direction of the change in percentage followed no general trend. This statistical treatment of results shows that the effect of the minima is superimposed on a changing background and that without this background the effect would appear larger and more pronounced than these results seem to indicate. A second recalculation using only those pictures within the average deviation gave results only slightly different from those in Table VII. Since one of the purposes of this investigation was to picture photographically that which the eye sees visually, one is hardly justified in discarding any data except the very extremes. It is the opinion of the writer that the truest picture of this effect is obtained when the result is calculated from data which come within twice the average deviation.

The Absolute Intensity Change for a Minimum

A study was made to determine the absolute value of the intensity change occurring when the trolley was moved to the position of a minimum from off this position. The measurement of the absolute value of this change was accomplished by imposing a 1% change on the intensity of each of the beams from the Wollaston prism by rotating the prism through an angle of 17′ which in accord with the cosine squared law gives the desired change. The mounting of the Wollaston was equipped with a divided circle with a vernier. Stops were placed on the vernier so that the Wollaston could be rotated readily through 17′ and a series of pictures was taken with the prism alternately at 45° and 45°17′. The 1% changes could be compared directly with pictures "on" and "off" minima. In setting up a plate in the microphotometer there is always some doubt as to the section along the length of the line that is being measured. For this reason it was thought that a proper comparison might not be made between the 1% changes and the minima pictures and a second series of pictures was made therefore in which the 1% changes were made in the same strip as the minima pictures. The sequence "on," "off" and 1% was repeated throughout the strip. The absolute value of the change thus determined was 0.7%. This value is the average of 168 pictures of compounds compared with 150 pictures of the 1% change. The maximum value of this change photographed for a series of two or more pictures was 1.0%. The value of the change when the data are treated as above using only those values which come within twice the average deviation is 0.8%. This is the average of 155 pictures compared with 145 pictures of the 1% change.

A small number of pictures were made on more dilute solutions to determine the manner in which the absolute change varied with concentration. To the average eye the apparatus as adjusted for photographing is sensitive to about 1 part of salt in 10^5 parts of water. When a dilution of 1 part in 10^7 parts of water was used a small positive effect of 0.3% was observed. A dilution of 1 part in 10^9 parts of water gave erratic results similar to a blank run.

Criticism has been made on the magnitude of this change in light intensity on the basis that such a small change could not be detected in visual work. The author appreciates that the small 0.7% change in light intensity is below the limit of a simple intensity change the normal eye can detect. A critical examination of this photographic measurement of the change in light intensity for a minimum shows however that such a measurement may be in error in itself and further that it may be in error when compared with the same effect measured by other means.

The several known facts about the minima themselves make it appear that the individual changes which over a long period of time cause the minima, must be in themselves very short lived. The very high resolving power of this apparatus is an indication of this short-timed effect. Minima which are separated by as little as 3 cm. on the trolley or 1×10^{-10} second are seen as separate minima. The photographs of the spark, plates 1 and 2, indicate that the light used in making the photographs comes in flashes of the order of 10^{-6} to 10^{-5} second duration. The composition of the light making up the minimum then must be a change in the intensity of the flash from the spark for a very small fraction of the total life of the flash.

The photographic effect of such a change is unknown but from the complicated effect of the flashes themselves it is probable that the change is not a simple one. Now in the above measurement the complex change of the minimum has been compared with the effect of flashes whose intensity has been changed by 1%. If the change for a minimum had been a simple change in the intensity of a continuous light then the procedure used would be valid but in view of the complex nature of the changes in the light in this experiment it is doubtful that a measurement in this manner gives the correct value.

The appearance of minima from the descriptions of many different observers indicates that any static measurement for the intensity change for a minimum over any appreciable period of time probably would not be an accurate measure of what the eye sees as a minimum. To one class of observers the minima appear as a gradually darkening field for a length of a few millimeters on the trolley. Minima appear best when observed with the trolley moving over them so that the change is seen by contrast. With the trolley moving in this manner the minima appear to shift slightly with the trolley. Now if a photograph is made with the trolley stationary at one point and the minima really do move slightly in their positions then the change for a minimum measured by such a photograph would show a change only for the time the minimum appeared at that setting of the trolley. This might be but a small fraction of the sudden change the eye would detect as the trolley passes over the proper position for a minimum.

A second class of observers sees the minimum as a shadow or dark band moving in the field of view as the trolley passes the position of a minimum. This change might be considered as a redistribution of the light in the field with little net change over the entire field. A photographic plate would record such a change as a very small one if the light from the entire field were focused to one point on the plate. Such a change would be easily discernible to the eye since vision would permit one to detect a darkening throughout different portions of the field.

There can be little doubt that the only valid way to measure the change the eye sees as a minimum is to use the eye to compare the minimum with a similar known change. Since the exact mechanism of the production of this effect is unknown at this time, it is impossible to produce a proper synthetic light change for comparison. Investigations are now under way to determine the mechanism of this effect.

Conclusion

The success of this photographic technique in detecting the small changes in light intensity due to minima over the other techniques which have been employed is due to the ability of the Wollaston prism to discriminate between the small changes in intensity due to minima and the changes in the incident light.

The observed photographic effect showed the following characteristics when tests were applied to prove the effects obtained were not due to changes in the electrical circuit or optical system:

1. No appreciable effect was obtained when blank solutions were used and the effect was only obtained for compounds when the trolley was placed at the proper position for one of the minima of a compound.
2. Minima were obtained when the setting of the trolley off the position of the minimum was taken on either side of the minimum position.
3. A decreasing absolute change in light intensity was found for decreasing concentrations of the compound.
4. The direction of the change in light intensity was found to change with the reversal of the direction of the current in the coils.
5. The direction of the light intensity change was found to reverse with the setting of the Wollaston prism on either side of the critical 45° position.

These five characteristics of the 2300-odd pictures taken in this investigation indicate that there is a small photographic effect in the magneto-optic apparatus which is characteristic of the compound present in the apparatus. This photographic effect was found to occur only at the positions of minima previously determined from repeated visual observation. The absence of minima in blank solutions; the absence of minima except at the proper trolley positions for a particular compound; and the reversal of the effect with the reversal of the direction of the current in the coils, have been observed in visual work. It is concluded therefore that the effect photographed is identical with the visual effect and that this effect is valid and characteristic of the compound present in the apparatus.

The author wishes to express his deep appreciation to Mr. Roy Goslin and Professor Fred Allison for their ready coöperation and many helpful suggestions in the course of this study. He wishes also to thank Mr. G. V. Waldo and Mr. H. Deer for their aid in the work and Dr. J. W. Beams for the use of his pneumatic top.

Summary

A photographic method has been developed to demonstrate the reality of minima in the magneto-optic apparatus. Microphotometer measurements of the difference in density of exposures taken on and off the positions of minima are attributed to variations in light intensity due to minima. The slight excess of the photographed effect over the experimental error necessitated a statistical study of the 2300 pictures taken in this investigation. This study showed only that the photographed effect was obscured by a background of changing light intensity. The measured change in intensity for a minimum was 0.7%. Water blanks showed approximately zero percentage change. The presence of foreign materials did not change the magnitude of the intensity change for a minimum. The direction of the effect was found to be dependent on the direction of the magnetic field in the coils.

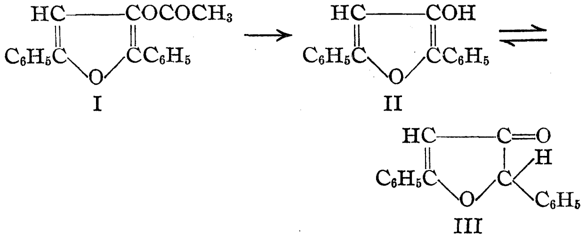
Hydroxy Furans. II. Beta Hydroxy Diphenylfuran

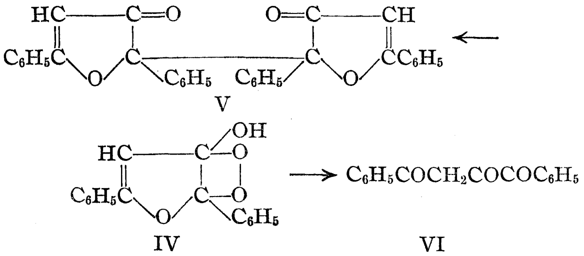
BY E. P. KOHLER AND D. W. WOODWARD

In accordance with the plan set forth in the first paper of this series[1] we have studied the properties of a β-hydroxy furan which has one phenyl group less than the one employed in the earlier work. Solutions of the new hydroxy compound were obtained by hydrolyzing the corresponding acetate[2] in the manner that was found to be best in the case of the triphenyl compound. The hydroxyl compound itself could not be isolated because it ketonizes rapidly and the less soluble ketonic modification crystallizes from the solutions.



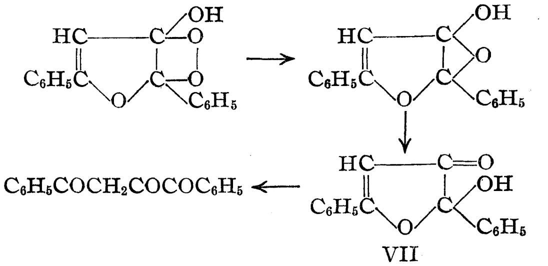
I II III

Solutions containing the enolic form, like those containing the corresponding triphenyl derivative, develop a color reaction with ferric chloride and absorb oxygen. The oxidation product is a crystalline peroxide which is unstable at the ordinary temperature and which explodes at about 100°. Like other peroxides that are formed from enols it readily gives up one atom of oxygen to mild reducing agents. Depending largely upon the medium in which it is reduced, the stable reduction product is either a dimolecular furan derivative or an open-chained triketone.



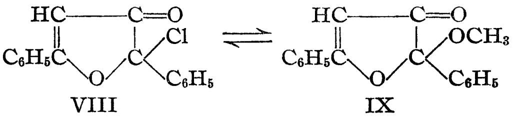
V IV VI

In accordance with the mechanism which has been established in more favorable cases in which all the intermediates were isolated, the triketone, doubtless, is the final product in a series of transformations which can be represented as follows



VII

The hydroxy furanone VII could not be isolated in this series but its ethers and esters were obtained without difficulty. Thus, when the acetate is treated either with chlorine or with phosphorus pentachloride, it is converted into a chloro furanone which passes into the ethers when it is dissolved in alcohols



VIII IX

For reasons which were enumerated in the discussion of the corresponding triphenyl derivatives, we had no doubt about the structure of these compounds, but inasmuch as others had previously obtained them by alkylating the triketone and had regarded them as open-chained compounds we decided to establish their formulas with certainty.

To this end we first prepared the two isomeric triketones, represented by formulas X and XI, and established their structure with alkaline hydrogen peroxide—the substance represented by X being oxidized to *p*-bromobenzoic acid and acetophenone while the isomer was oxidized to benzoic acid and *p*-bromoacetophenone.

$C_6H_5COCH_2COCOC_6H_4Br$ X

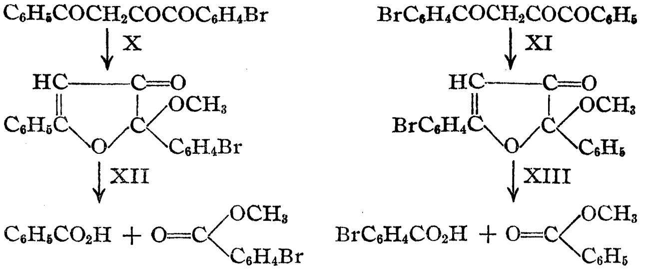
$BrC_6H_4COCH_2COCOC_6H_5$ XI

Each of these triketones was then methylated by means of methyl alcohol and hydrochloric acid and the structure of the resulting ethers was established by ozonization. The ozonization products of the ether derived from X were benzoic acid and methyl *p*-bromobenzoate, and those from XI were *p*-bromobenzoic acid and methyl benzoate. These are the degradation products to be expected from the cyclic ethers; they could not be formed from any open-chained ethers.

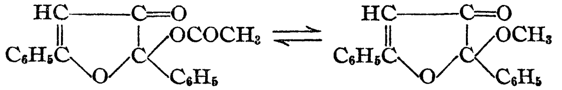
---

(1) Kohler, Westheimer and Tishler, THIS JOURNAL, **58**, 264 (1936).

(2) Lutz, *ibid.*, **48**, 2918 (1926).



With the cyclic character of the ethers established in this manner, the cyclic structure of substances related in origin and similar in properties can be accepted with confidence. Thus the acetate which is formed by the action of acetic anhydride on the triketone must be a furanone derivative because it passes into the ethers when it is dissolved in boiling alcohols.



XIV

This acetate was first obtained by Lutz and his collaborators who, misled by a faulty analysis, described it as the diacetate—"2,5-diphenyl-3,4-diacetoxy furan."[3] Both our analyses and our acetyl determination show that it is a monoacetate.

The chloro compound VIII which is related to the ethers in the same manner as the acetate must likewise have the cyclic structure with which we represent it. This chloro compound was first described by Lutz, Parrish and Wilder who obtained it by heating their supposed diacetate with acetyl chloride and sulfuric acid and therefore regarded it as a chloro acetate. It was later described again by Lutz and Wilder who obtained it from the triketone and the methyl ether and who, failing to recognize its identity with the previous preparation, now regarded it as the open-chained compound—$C_6H_5C(Cl){=}CHCOCOC_6H_5$. We repeated these reactions and found that the product in all cases is the cyclic chloro compound VIII. The simple and direct relations between the chloro compound, the ethers and the triketone nullify the elaborate mechanisms devised by Lutz and his collaborators.

A comparison of the reactions of β-hydroxy diphenylfuran with those of the triphenyl compound described in the earlier paper shows that the elimination of the phenyl group in the 4 position has virtually no effect on the chemical properties. Like the more highly phenylated analog, the new β-hydroxy furan behaves like an exceedingly reactive enolic form of a ketone.

Experimental

The acetate of β-hydroxy diphenylfuran[2] I was hydrolyzed by the same two methods that were employed with the triphenyl compound, namely, digestion with sulfuric acid in aqueous acetic acid and treatment with methylmagnesium iodide followed by acidification. The first method was employed for the purpose of isolating the keto furan and the second for preparing the peroxide.

Hydrolysis and Preparation of the Keto Furan.—A suspension of 10 g. of the acetate in a solution composed of 250 cc. of acetic acid, 250 cc. of water and 4 cc. of sulfuric acid was boiled in an atmosphere of nitrogen until all of the acetate had dissolved—about half an hour. The solution was made slightly alkaline with sodium carbonate and extracted with ether. The ethereal solution, washed and dried in the usual manner, was evaporated in a current of nitrogen. It deposited a solid product which after recrystallization from ether melted at 93°. The yield was 40–60%.

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.3; H, 5.1. Found: C, 80.9; H, 5.3.

2,5-Diphenyl Furanone-3, III.—The furanone is unstable in the air both as solid and in solution. It is not extracted from its ethereal solutions by sodium carbonate but its solutions give a feeble color reaction with alcoholic ferric chloride.

Hydrolysis and Preparation of the Peroxide.—To a solution of methylmagnesium iodide containing three equivalents of the reagent was added 10 g. of the finely powdered acetate. The mixture was boiled for fifteen minutes and then decomposed with ice and acid in the usual manner. The ethereal layer, which gave a strong reaction with ferric chloride, was washed thoroughly with ice water and shaken with air. It soon deposited the peroxide in crystalline form. The yield was about 50%.

3-Hydroxy-2,5-diphenylfuran Peroxide, IV.—The peroxide crystallizes from ether with a molecule of ether. It can be obtained free from solvent by adding hexane to its ethereal solution and boiling off the ether. Both forms decompose in the air and explode at about 100°.

Anal. Calcd. for $C_{16}H_{12}O_4$: C, 71.6; H, 4.5. Found: C, 71.2; H, 4.7. Calcd. for $C_6H_{12}O_4\cdot(C_2H_5)_2O$: C, 70.2; H, 6.4. Found: C, 70.5; H, 6.3.

Reduction: The Dimolecular Product, V.—When the peroxide was reduced with potassium iodide and acetic acid it was in part converted into a dimolecular product which was also formed in variable quantities when the acetate was treated with halogens. It crystallized in minute needles and melted at 255°.

Anal. Calcd. for $C_{32}H_{22}O_4$: C, 81.7; H, 4.7. Found: C, 81.5; H, 4.9.

Reduction: β-Benzoyl Methylphenyl Diketone, VI.—Solutions of the peroxide in ethyl acetate or methyl alcohol rapidly absorbed one mole of hydrogen. The colorless solutions left after the removal of the catalyst, doubtless, contained the hydroxy furanone VII but they gradually

---

[3] Lutz, Wilder and Parrish, THIS JOURNAL, **56**, 1986 (1934).

developed a yellow color and when they were concentrated they deposited oils. When the ethereal solutions were shaken with aqueous copper acetate they deposited a copper derivative from which acids liberated the triketone. Our examination of the two forms of the triketone which were reported by Lutz, Wilder and Parrish[3] (p. 1984) indicates that the yellow form is the triketone and the colorless form one of its enols. In the very pale yellow alcoholic solutions, equilibrated at the ordinary temperature, Kurt Meyer titrations showed 96.4% enol. In the distinctly yellow ethereal solutions the percentage of enol dropped to 71 and in bright yellow solutions in chloroform it is only 24. From these yellow solutions hexane precipitated the yellow form which has the characteristic color of α diketones.

2-Chloro-2,5-diphenyl Furanone-3, VIII.—A stream of chlorine was passed into a solution of 10 g. of the acetate of the hydroxy furan until the gain in weight was 3.2 g. The solution was washed with sodium bicarbonate, dried and evaporated. It deposited the chloro compound in colorless needles melting at 133°. The yield was 92%. The same chloro compound was formed when the acetate was treated with phosphorus pentachloride and also when the magnesium halide derivative of the hydroxy furan was treated with chlorine.

Anal. Calcd. for $C_{16}H_{11}O_2Cl$: C, 71.0; H, 4.1; Cl, 13.1. Found: C, 70.9; H, 4.3; Cl, 13.6.

2-Bromo-2,5-diphenyl Furanone-3.—The bromo compound was obtained in the same manner as the chloro compound. It crystallized in nearly colorless needles and melted at 135°.

Anal. Calcd. for $C_{16}H_{11}O_2Br$: C, 61.0; H, 3.5; Br, 25.4. Found: C, 61.0; H, 3.7; Br, 25.7.

These halogen compounds are active substances; in boiling alcohols they are transformed into ethers, methyl magnesium chloride reduces them to the magnesium derivative of the hydroxy furan, and when they are boiled with dioxane and water they are hydrolyzed to the triketone.

2-Methoxy-2,5-diphenyl furanone-3, IX, and the corresponding ethoxy compound are obtained when the halogen compounds are dissolved in boiling alcohols. They have been adequately described by Lutz, Wilder and Parrish who formulated them as open-chained compounds.

p-Bromobenzoyl Acrylic Acid, $BrC_6H_4COCH{=}CHCOOH$.—The acid, which was needed for the preparation of the bromo triketones, was made by dissolving one mole of bromobenzene in a liter of purified tetrabromoethane, adding 2.1 moles of aluminum bromide and then, with constant stirring and as rapidly as possible without raising the temperature above 50°, one mole of maleic anhydride. The mixture was stirred for three hours and then decomposed in the usual manner. A part of the acid separated from the acidified mixture, the remainder was recovered after distillation with steam. By recrystallization from acetone or benzene it was obtained in small, pale yellow prisms melting at 161°. The yield was 185 g.

Anal. Calcd. for $C_{10}H_7O_3Br$: C, 47.1; H, 2.8; Br, 31.4. Found: C, 47.1; H, 3.0; Br, 31.4.

The acid was converted into its chloride by heating it to 45° with an equivalent quantity of phosphorus pentachloride, removing the phosphorus oxychloride under diminished pressure and crystallizing the residue from benzene. The product crystallized in yellow needles which turned bright red on exposure to light and which melted at 103°.

p-Bromodibenzoyl Ethylene, $BrC_6H_4COCH{=}CHCOC_6H_5$.—To a solution of one mole of the acid chloride in 2 l. of benzene 1.2 moles of aluminum chloride was added while the solution was stirred and kept as free from hydrogen chloride as possible by sweeping it with a rapid current of nitrogen. The mixture was stirred and heated on a steam-bath for three hours, then decomposed in the usual manner. The product crystallized from benzene and chloroform in light yellow needles and melted at 127°. The yield was 62%. The same product was obtained in a yield of 50–60% by heating equivalent quantities of phenyl glyoxal and *p*-bromoacetophenone with two equivalents of acetic anhydride for an hour on a steam-bath.

Anal. Calcd. for $C_{16}H_{11}O_2Br$: C, 61.0; H, 3.5; Br, 25.4. Found: C, 60.9; H, 3.7; Br, 25.8.

Dibromides, $BrC_6H_4COCHBrCHBrCOC_6H_5$.—Addition of bromine to the unsaturated diketone in chloroform resulted, as usual, in the formation of two stereoisomeric dibromides. One of these dibromides separated from the chloroform in needles melting, with decomposition, at 170–175°; the other was obtained by evaporating the solution and recrystallizing the residue from ether. It melted at 116–119°.

Anal. Calcd. for $C_{16}H_{11}O_2Br_3$: Br, 50.6. Found: (I) Br, 50.5; (II) Br, 50.5.

2-Methoxy-2-phenyl-5-bromophenyl Furanone-3.—In order to convert the dibromide into the triketone a solution of 11 g. of potassium hydroxide in 100 cc. of methyl alcohol was gradually stirred into a solution of 27 g. of the dibromides in the same solvent. The solution was boiled for ten minutes, then acidified and boiled for fifteen minutes longer. The result was a mixture of triketones which were readily isolated by means of their copper derivatives but which were extremely difficult to separate by fractional crystallization. The mixture was therefore converted into ethers.

For this purpose a solution of 10 g. of the mixture in 30 cc. of methyl alcohol was saturated with gaseous hydrogen chloride. As the solution cooled it deposited 4.6 g. of an ether which separated in nearly colorless prisms and which melted at 158° after recrystallization from methyl alcohol.

Anal. Calcd. for $C_{17}H_{13}O_3Br$: C, 59.1; H, 3.8. Found: C, 59.1; H, 3.8.

Ozonization of the Ether.—A solution obtained by ozonizing 3 g. of the ether in carbon tetrachloride was evaporated under reduced pressure in a current of air. The residue was dissolved in ether and the solution was extracted with sodium bicarbonate. It removed *p*-bromo benzoic acid in 80% of the calculated quantity. The ethereal layer was evaporated and the residue was distilled under diminished pressure. The result was 0.8 g. of methyl benzoate boiling at 91° (15 mm.)—identified by the odor and hydrolysis to benzoic acid.

p-Bromobenzoyl Methylphenyl Diketone, XI.—The methyl ether melting at 158° was hydrolyzed in the usual way with methyl alcoholic potassium hydroxide and the product was isolated by means of the copper derivative. It crystallized from ether–petroleum ether in long yellow needles and it melted at 100–101°.

Anal. Calcd. for $C_{16}H_{11}O_3Br$: C, 58.0; H, 3.3. Found: C, 58.0; H, 3.7.

Proof of Structure.—A methyl alcoholic solution containing 4 g. of the triketone and 1.5 g. of 30% hydrogen peroxide was cooled to 0° and treated gradually with 1 g. of potassium hydroxide in the same solvent. The resulting red solution was left to itself until most of the color had disappeared, then acidified and extracted with ether. The oily residue left after the ether had been evaporated was digested for a short time on a steam-bath with sulfuric acid in order to decompose intermediate products, then subjected to the usual treatment for the separation of the acid and the neutral products. The neutral fraction contained only *p*-bromoacetophenone—identified as benzal *p*-bromoacetophenone. The acid fraction contained *p*-bromobenzoic acid and benzoic acid—separated by crystallization and identified by melting points. The yields were: 30% of the possible quantity of bromoacetophenone, 60% of bromobenzoic acid and 92% of benzoic acid.

2-Methoxy-2-*p*-bromophenyl-5-phenyl Furanone-3.—The second ether that was formed when the mixture of the triketones was alkylated, was obtained by concentrating the solution under diminished pressure. It crystallized from methyl alcohol in fine needles melting at 102°.

Anal. Calcd. for $C_{17}H_{13}O_3Br$: C, 59.1; H, 3.8. Found: C, 59.0; H, 4.0.

Ozonization.—The same procedure that was employed in the case of the isomeric ether resulted in methyl *p*-bromobenzoate melting at 80° and identified by comparison with a sample on hand—and benzoic acid. The yields were, respectively, 60 and 75%.

Benzoyl Methyl-*p*-bromophenyl Diketone, X.—The triketone was obtained without difficulty by hydrolyzing the ether and isolating the product by means of the copper derivative. It crystallized in yellow plates melting at 88–90°.

Anal. Calcd. for $C_{16}H_{11}O_3Br$: C, 58.0; H, 3.5. Found: C, 57.8; H, 3.5.

Proof of Structure.—Oxidation with alkaline hydrogen peroxide in the manner described under the isomeric triketone gave *p*-bromobenzoic acid—85% of the possible quantity—benzoic acid and acetophenone (50%) which was identified as *m*-nitrobenzal acetophenone.

2-Acetoxy-2,5-diphenyl Furanone-3.—All methods of preparation—from the chloro compound, the ether or the triketone—gave the same product melting at 140°.

Anal. Calcd. for $C_{16}H_{10}O_3(COCH_3)$: C, 73.5; H, 4.9; $COCH_3$, 14.6. Found: C, 73.4; H, 4.8; $COCH_3$, 14.3.

Summary

The properties of β-hydroxyl derivative of 2,5-diphenylfuran are compared with those of the hydroxyl derivative of 2,4,5-triphenylfuran. The removal of the phenyl group in the 4-position does not affect the properties of the hydroxyl compound but it diminishes the stability of the furanone into which the hydroxyl compound passes by spontaneous ketonization.

Researches on Pyrimidines. CLIV. Pyrimidine Side Chain Reactions Useful for the Synthesis of 1,3-Diazines Related Structurally to Vitamin B_1[1]

BY ANNE LITZINGER[2] AND TREAT B. JOHNSON

In two previous publications from this Laboratory,[3] the authors have emphasized the importance of increasing our present knowledge of aliphatic chemistry as applied to the pyrimidine cycle, and the bearing of such research developments on the determination of the correct constitution of vitamin B_1. In our preliminary paper entitled "Synthesis of Uracil-5-methylamine," we wrote as follows: "We believe that constructions of this type will prove to be of immediate interest in connection with the development of the newer chemistry of vitamin B_1."

The object of this paper is to present and describe a series of new reactions which have been applied successfully in our pyrimidine investigations, and which have opened up a practical method for synthesizing this interesting pyrimidine amine.[4] The chemistry of this amine will be discussed in the next paper of this series.[5]

The starting point of our new program of synthesis was the ethyl ester of 2-ethylmercapto-6-oxypyrimidine-5-acetic acid I which was first described by Johnson and Speh.[6] Applying suc-

cessfully the different basic reactions of the Curtius technique[7] for conversion of a carboxyl into an amino group with this pyrimidine I, we have succeeded in isolating in crystalline form all the intermediate products characteristic of the series of reactions involved in the introduction of an amino group. These intermediates are recorded in Table I. A description of several other derivatives separated and identified in the course of the work is also given in the Experimental Part of this paper. We are extending this research to include the acetate derivatives of other types of pyrimidines, and characterized structurally by side chain substitutions in positions 2, 4 and 5 of the pyrimidine cycle.

Uracil-5-acetylazide, XII
Uracil-5-methyl isocyanate or thyminyl isocyanate, XIII
Ethyl thyminyl-urethan, XV

Experimental Part

$\overline{\mathrm{NHC(SC_2H_5){=}NHC{=}C(CH_2COOC_2H_5)C}}\mathrm{O}$. **Ethyl 2-ethylmercapto-6-oxypyrimidine-5-acetate, I.**—The starting material of the series of reactions leading up to the final synthesis of thyminylamine was this ethyl ester of 2-ethylmercapto-6-oxypyrimidine-5-acetic acid. This pyrimidine was obtained in the form of its sodium salt by condensing diethyl formylsuccinate with ethyl pseudothiourea, in alkaline solution, according to the procedure previously described in a paper from this Laboratory by Johnson and Speh.[6] This pyrimidine is formed in excellent yield, is easily purified by crystallization from 50% ethyl alcohol, and crystallizes from hot solutions as a beautiful fibrous mass of colorless needles.

$\overline{\mathrm{NHC(SC_2H_5){=}NCH{=}C(CH_2CONHNH_2)C}}\mathrm{O}$. **2-Ethylmercapto-6-oxypyrimidine-5-acetylhydrazide. II.**—Thirty grams of the mercapto-pyrimidine acetate I (m. p. 146–147°) is dissolved in 300 ml. of absolute alcohol and to the hot solution is added 1.5 equivalents of 42% hydrazine hydrate (18 g.). The clear solution is then refluxed for two hours or until solid material begins to separate from the hot reaction mixture. Although the hydrazide is only moderately soluble in cold absolute alcohol, complete separation from solution is slow and, therefore, the reaction mixture is allowed to stand at room temperature for twenty-four hours before filtering off the crystalline hydrazide. This yields about 27 g. of the crude hydrazide melting at 198–200° with decomposition. On concentrating the alcohol filtrate more of the hydrazide is obtained contaminated with the unreacted pyrimidine acetate I. Such mixtures can be separated easily, however, by careful crystallization from absolute alcohol. Purification of the hydrazide is accomplished easily by recrystallization from 90% alcohol, and it crystallizes as sheaves of glistening plates which melt at 207–208° with decomposition. *Anal.* Calcd. for $C_8H_{12}O_2N_4S$: N, 24.54. Found: N, 24.46, 24.66.

This hydrazide is soluble in water (1 g. in 3 ml. hot and 10 ml. cold). Water is not recommended, however, as a solvent for purification as slight decomposition takes place in boiling solutions with evolution of ethyl mercaptan. Aqueous solutions of the hydrazide reduce Fehling's solution easily. The hydrazide is less soluble in absolute alcohol than in water (1 g. in 250 ml. hot and 450 ml. cold).

$\overline{\mathrm{NHC(SC_2H_5){=}NCH{=}C(CH_2CON_3)C}}\mathrm{O}$. **2-Ethylmercapto-6-oxypyrimidine-5-acetylazide. III.**—The mercapto-pyrimidine hydrazide II reacts smoothly with nitrous acid to form this azide, III. Twenty grams of the purified hydrazide is dissolved in 200 ml. of normal hydrochloric acid. To this clear solution, cooled in an ice-bath, is then added slowly, while stirring, an aqueous solution containing the required amount of sodium or potassium nitrite. An immediate precipitate of a fluffy solid is obtained which, after washing with water and drying, weighed 12 g. At ordinary temperatures this azide is stable, but on heating to 75–80° it evolves nitrogen vigorously, and then melts with decomposition at 175–180°. The compound responded to the characteristic reactions of an azide, and underwent quantitative transformations giving the corresponding ethyl and benzyl urethans and also the pyrimidine isocyanate derivative when treated with the proper reagents or solvents.

$\overline{\mathrm{NHC(SC_2H_5){=}NCH{=}C(CH_2NCO)C}}\mathrm{O}$. **2-Ethylmercapto-6-oxypyrimidine-6-methyl Isocyanate. IV.**—This interesting compound is easily prepared as follows: 2.4 g. of 2-ethylmercapto-6-oxypyrimidine-5-acetylazide is suspended in 20 ml. of dry toluene and the temperature of the heating bath slowly raised to about 80° when a vigorous evolution of nitrogen begins to take place. Too rapid heating leads to considerable decomposition and charring of the reaction product. When the violent evolution of nitrogen gas has ceased (twenty minutes) the toluene is then heated to its boiling point and the liquid finally refluxed for thirty minutes. At the end of this time, the toluene is cooled, and the insoluble isocyanate separated by filtration and washed with ether. The yield of crude material was 2.2 g. melting at 187–190° with decomposition. The isocyanate is purified by recrystallization from anhydrous dioxane, from which solvent it separates, on cooling, in the form of plates, which melt at 189–191° with decomposition. *Anal.* Calcd. for $C_8H_9O_2N_3S$: N, 19.90. Found: N, 19.74, 19.73.

This isocyanate is not appreciably soluble in the ordinary inert organic solvents and is unusually stable for an isocyanate compound. It underwent no detectable

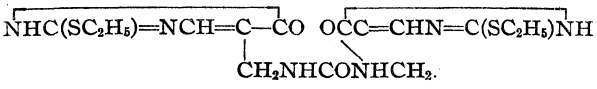
[7] Th. Curtius, *J. prakt. Chem.*, [2] **50**, 275 (1894); **58**, 190 (1898); **64**, 297, 401, 419 (1901); **91**, 1, 19 (1915); **94**, 85, 273 (1917); *Ber.*, **27**, 778 (1894).

change after preservation for five months in a tightly stoppered specimen tube. The compound responds to all the characteristic reactions of an isocyanate structure, and is a pyrimidine derivative which should prove very useful for future experimentation. It is the first mercapto-pyrimidine isocyanate derivative to be described.



$$\underset{CH_2NHCONHCH_2.}{NHC(SC_2H_5)=NCH=C\text{—}CO\quad OCC=CHN=C(SC_2H_5)NH}$$

V

Behavior toward Water: Formation of *sym.*-Di-(ethylmercapto-6-oxypyrimidine-5-methyl)-urea. V.—The rate of decomposition of the above isocyanate IV in cold water is very slow. When, however, the compound is warmed with water there is a rapid evolution of carbon dioxide, and during the time of heating there is a brief period of almost complete solution followed immediately by the precipitation of the symmetrical disubstituted urea V. While this urea constitutes the main reaction product, small quantities of the normal amine VI are also obtained when the mother liquor is concentrated to a small volume. For example: 1 g. of the isocyanate is boiled with 40 ml. of water until the evolution of carbon dioxide ceases and the solution is then cooled. We obtained 0.63 g. of the above urea crystallizing in the form of prisms and melting at 270–272° with decomposition. The compound is practically insoluble in water, and all the common organic solvents. *Anal.* Calcd. for $C_{15}H_{20}O_3N_6S_2$: N, 21.20. Found: N, 21.21, 21.16.

$NHC(SC_2H_5)=NCH=C(CH_2NH_2)CO$. **Isolation of 2-Ethylmercapto-6-oxypyrimidine-5-methylamine. VI.**—The combined filtrates and washings from the preceding experiment were concentrated to a volume of 10 ml. and the solution cooled, when 0.07 g. of this amine separated. It melted at 220–222° with decomposition. This pyrimidine is easily purified by crystallization from boiling water, and separates, on cooling, in the form of colorless needles, melting at 221–222° with decomposition. Aqueous solutions of the amine are strongly basic to the mixed indicator (methyl red and methylene blue). *Anal.* Calcd. for $C_7H_{11}ON_3S$: N, 22.70. Found: N, 23.00, 23.10.

Hydrolysis of the above pyrimidine isocyanate VI by boiling with strong hydrochloric acid leads to the formation of the hydrochloride of thyminylamine with evolution of ethyl mercaptan and carbon dioxide.

$NHC(SC_2H_5)=HCN=C(CH_2NHCONH_2)CO$. **2-Ethylmercapto-6-oxypyrimidine-5-methyl Urea. VII.**—This is formed quantitatively by action of aqueous ammonia on the pyrimidine isocyanate IV. The pyrimidine is very soluble in cold water and alcohol. It was purified by dissolving in 95% alcohol and allowing the solution to evaporate in a vacuum desiccator. In this way the urea was obtained in the form of colorless plates melting at 190–192° with decomposition. A mixture of this urea with the original isocyanate melted at 175–176°. *Anal.* Calcd. for $C_8H_{12}O_2N_4S$: N, 24.55. Found: N, 24.41, 24.64.

$NHC(SC_2H_5)=NCH=C(CH_2NHCONHC_6H_5)CO$. **2-Ethylmercapto - 6 - oxypyrimidine - 5 - methyl - phenylurea. VIII.**—This is formed by the action of aniline on the pyrimidine isocyanate IV in hot dioxane solution. The urea is easily purified by crystallization from 95% alcohol and crystallizes in plates melting at 223–224° with decomposition. The urea can be crystallized from both dioxane and water. *Anal.* Calcd. for $C_{14}H_{16}O_2N_4S$: N, 18.41. Found: N, 18.21, 18.31.

$NHC(SC_2H_5)=NCH=C(CH_2NHCOOC_2H_5)CO$. **Ethyl-2 - ethylmercapto - 6 - oxypyrimidine - 5 - methyl - urethan. IX.**—This urethan is formed by interaction of the pyrimidine isocyanate IV or the azide III with ethyl alcohol. Ten grams of the pyrimidine azide (described above) is suspended in 50 ml. of absolute alcohol and the temperature of the alcohol gradually raised by heating on a water-bath. Nitrogen is evolved vigorously and after heating one hour the azide is completely decomposed and a clear solution is obtained. The alcohol solution is now concentrated to a volume in 10 ml. and cooled when the desired urethan will separate. The yield was about 9.0 g. and the compound melted at 145–148°, to a clear liquid. The pyrimidine is purified by crystallization from 95% alcohol and separates, on cooling, in the form of plates melting at 148.5–149.5° to a clear liquid. *Anal.* Calcd. for $C_{10}H_{15}O_3N_3S$: N, 16.34. Found: N, 16.37, 16.39.

When warmed in an alcohol solution of hydrochloric acid the corresponding 2-oxypyrimidine-urethan XV is formed with evolution of ethyl mercaptan. On heating with strong sulfuric or hydrochloric acid (100–110°) the urethan is decomposed with formation of the corresponding salts of thyminylamine.

$NHC(SC_2H_5)=NCH=C(CH_2NHCOOC_7H_7)CO$. **Benzyl-2-ethyl-6-oxypyrimidine-5-methyl Urethan. X.**—The pyrimidine-azide III is decomposed smoothly, when warmed in benzyl alcohol, with evolution of nitrogen and formation of the above urethan. After thirty minutes of heating in a hot water-bath the volume of the benzyl alcohol solution is reduced to about 10 ml. and then diluted with cold water. The urethan is precipitated as an oil which finally solidifies. The yield is excellent. By recrystallization from 95% alcohol the urethan is obtained in the form of needles melting at 159–160° to a clear oil. *Anal.* Calcd. for $C_{15}H_{17}O_3N_3S$: N, 13.17. Found: N, 13.33, 13.27.

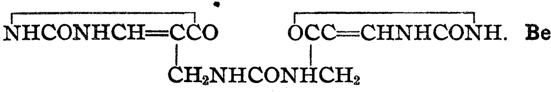
This pyrimidine is very soluble in cold benzyl alcohol (1 g. in 4 ml.), moderately soluble in 95% alcohol and insoluble in water.

Part Two

$NHCONHCH=C(CH_2CONHNH_2)CO$. **Uracil-5-acetyl Hydrazide. XI.**—The ethyl uracil-5-acetate which was used for the synthesis of this hydrazide was prepared by dissolving the ethyl ester of 2-ethylmercapto-6-oxypyrimidine-5-acetic acid I in absolute alcohol, saturating with hydrogen chloride gas and then refluxing the solution for two hours. The ester separated, on cooling, and agreed in all its properties with the pyrimidine ester previously described by Johnson and Speh.[6] To prepare the above hydrazide 2 g. of this ester, m. p. 202–204°, is dissolved in 30 ml. of 95% alcohol, and to the hot solution 1.5 g. of hydrazine hydrate is added. After refluxing for one hour and cooling for twelve hours 1.8 g. of the hydrazide separated. It is easily purified by recrystallization from boiling water and crystallizes in the form of plates which decompose without melting at about 326°, turning brown at 285°. The compound is insoluble in alcohol and the common organic solvents. Aqueous solutions of the hydrazide reduce Fehling's solution immediately. *Anal.* Calcd. for $C_6H_8O_3N_4$: C, 39.13; H, 4.40. Found: C, 39.15, 39.25; H, 4.41, 4.32.

$NHCONHCH{=}C(CH_2CON_3)CO$. **Uracil-5-acetylazide. XII.**—Four grams of the above hydrazide XI is dissolved in 100 ml. of *N* hydrochloric acid and 1.5 equivalents of sodium nitrite dissolved in the solution. There is an immediate reaction and the azide separates at once as a colorless powder. This is stable at room temperatures, but loses nitrogen when heated at 75–80° and then melts at 275–276° with decomposition. Although this pyrimidine was not analyzed, its structure was proved by its characteristic chemical behavior, yielding both urethan derivatives and the corresponding isocyanate, XIII.

$NHCONHCH{=}C(CH_2NCO)CO$. **Uracil-5-methyl Isocyanate (Thyminyl Isocyanate). XIII.**—This isocyanate was prepared according to the same technique as was used for the preparation of 2-ethylmercapto-6-oxypyrimidine-5-methyl isocyanate IV: 1.8 g. of uracil-5-acetyl azide XII yielded, when heated in toluene, 1.4 g. of the isocyanate as a colorless powder which melts at 273–275° with decomposition. *Anal.* Calcd. for $C_6H_5O_3N_3$: N, 25.15. Found: N, 25.15, 24.90.



$$\begin{array}{c} NHCONHCH{=}CCO \qquad OCC{=}CHNHCONH \\ CH_2NHCONHCH_2 \end{array}$$

XIV

Behavior toward Water: Formation of *sym.*-Di-thyminylurea. XIV.—Boiling water immediately decomposes thyminyl isocyanate XIII with vigorous evolution of carbon dioxide; 0.3 g. of this pyrimidine of m. p. 273–275°, after boiling for twenty minutes in 20 ml. of water, yielded 0.25 g. of this urea derivative. This is very insoluble in water and decomposes without further purification at 315°. *Anal.* Calcd. for $C_{11}H_{12}O_5N_6$: N, 27.26. Found: N, 27.09, 27.14.

$NHCONHCH{=}C(CH_2NHCOOC_2H_5)CO$. **Ethyl Thyminyl-urethan. XV.**—Five grams of ethyl 2-ethylmercapto-6-oxypyrimidine-5-methylurethan is dissolved in 50 ml. of 95% alcohol acidified with 5 ml. of concentrated hydrochloric acid. As soon as this solution is warmed, ethyl mercaptan is evolved, and within twenty-five minutes the urethan begins to crystallize from the hot solution, and the hydrolysis is practically complete. We obtained 3.4 g. of the above urethan melting at 254–258°. It is easily purified by crystallization from 95% alcohol and melts at 256–257° to a clear oil. The compound is more soluble in water than in alcohol. *Anal.* Calcd. for $C_8H_{11}O_4N_3$: N, 19.72. Found: N, 19.74.

This same urethan is also obtained in excellent yield by digesting uracil-5-acetylazide in absolute alcohol. When digested with either hydrochloric or sulfuric acid it is converted into the corresponding salts of thyminylamine.

$NHCONHCH{=}C(CH_2NHCOOC_7H_7)CO$. **Benzyl Thyminyl-urethan. XVI.**—When 0.8 g. of benzyl 2-ethylmercapto-6-oxypyrimidine-5-methylurethan was digested in alcohol acidified with hydrochloric acid for two hours, 0.5 g. of this urethan was formed. This is less soluble in alcohol than the corresponding mercapto compound X, and separates from this solvent in the form of microscopic plates which melt at 261–263° with decomposition. *Anal.* Calcd. for $C_{13}H_{13}O_4N_3$: N, 15.27. Found: N, 15.35, 15.55.

Summary

1. Starting with the known pyrimidine, ethyl-2-ethylmercapto-6-oxypyrimidine-5-acetate, several new derivatives have been synthesized by application of the Curtius reaction for replacement of the carbethoxy group by an amino radical.

2. Important new aliphatic derivatives of uracil have been described which will find use in developing new synthetic processes of biochemical interest.

3. A practical method is revealed for preparing uracil-5-methyl isocyanate or thyminyl isocyanate, the first isocyanate derivative to be described in the pyrimidine series.

4. Further applications of the Curtius reaction in the pyrimidine series will be made, and further synthetic work of biological interest is now in progress in this Laboratory.

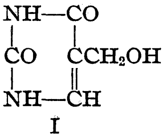
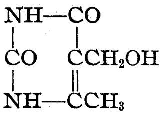
Researches on Pyrimidines. CLV. The Synthesis of Thyminylamine and its Conversion into Uracil[1]

BY TREAT B. JOHNSON AND ANNE LITZINGER[2]

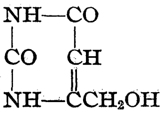
It has previously been shown that the substitution of a carbinol radical $-CH_2OH$ in the 5-position of a 2,6-dioxypyrimidine is productive of an alcohol which easily undergoes a carbon–carbon cleavage, when subjected to hydrolysis, with formation of formaldehyde and the original pyrimidine. Such an instability was observed, for example, by Kircher[3] in 1911, who showed that the 5-carbinol derivative of 4-methyluracil II is quantitatively decomposed by digesting in boiling water with regeneration of 4-methyluracil and the liberation of formaldehyde.



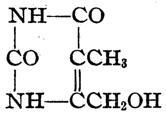
I



II



III

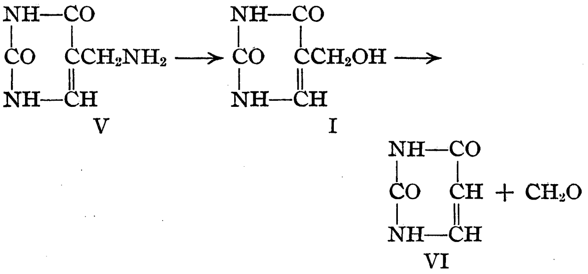


IV

A corresponding instability of a pyrimidine–carbinol linkage of this type was later found not to be the case when the carbinol radical is substituted in the 4-position of the pyrimidine cycle. Johnson and Chernoff,[4] in an investigation of synthetic pyrimidine nucleosides, prepared the thymine derivative IV which is isomeric with Kircher's pyrimidine II, and found that this compound can be heated with 10% sulfuric acid at 125° without alteration. There was no evidence of the formation of formaldehyde. Later these same investigators synthesized the corresponding carbinol derivative of uracil represented by formula III, and again made the discovery that the carbinol group could not be split off by hydrolysis,[5] with formation of uracil and formaldehyde.

These results revealed for the first time a fundamental difference in the stability of 4- and 5-carbinol substitutions in pyrimidines of the uracil type. It was, therefore, important to determine whether the fourth representative of the above series, thyminyl alcohol I, would conform to our prediction, and show the same behavior on hydrolysis as its higher homolog II.

As all attempts to produce thyminyl alcohol I by the action of formaldehyde on uracil have thus far proved unsuccessful, the authors decided to synthesize the corresponding and unknown primary base, *thyminyl-amine* V, and then convert this into the desired thyminyl alcohol I by the action of nitrous acid. A description of the preliminary reactions which have made possible the final synthesis of this interesting amine has already been given in the preceding paper of this series.[6] A complete description of the different procedures that the authors have finally applied successfully for the preparation of this interesting amine V is given in detail in the Experimental Part of this paper.



We now find that thyminylamine V, as well as thyminyl alcohol I, are both characterized by their instability when subjected to hydrolytic conditions. Both pyrimidines are decomposed by boiling with water with cleavage between two carbon atoms and regeneration of uracil VI. The primary aliphatic amine radical $-CH_2NH_2$ in the pyrimidine V is destroyed by hydrolysis with formation of uracil, ammonia and formaldehyde. The chemical evidence favors first the formation of thyminyl alcohol I as an inter-

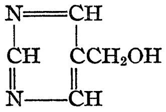
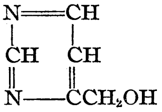
mediate, which being unstable then undergoes a normal hydrolysis like Kircher's pyrimidine-carbinol II, yielding uracil VI and formaldehyde. In fact, both transformations are practically quantitative. Because of the instability of thyminyl alcohol I in warm aqueous solutions, it has, thus far, been impossible for us to separate this pyrimidine from water solution after diazotization of the thyminylamine V without partial decomposition. Heretofore, we have discovered no pyrimidine constructions which reveal such characteristic differences in behavior between two carbon linkages attached to adjacent carbons in the pyrimidine ring.

It is the belief of the authors that these striking variations in chemical behavior will need to be considered carefully before corresponding constructions can be assigned to any pyrimidine compounds possessing the chemical properties of vitamin B_1.[7] Our next problem will be to determine whether the corresponding isomeric carbinol derivatives of a reduced pyrimidine substituted in positions 4 and 5, VII and VIII will show a corresponding difference in chemical stability. This study is now in progress in this Laboratory.



VII



VIII

Experimental Part

Thyminylamine or (Uracil-5-methylamine), V, $\overline{\text{NHCONHCH}{=}\text{C(CH}_2\text{NH}_2\text{)CO}}$.—This amino derivative of thymine can be prepared according to the following procedures:[1] (1) by hydrolysis of ethyl 2-ethylmercapto-6-oxypyrimidine-5-methylurethan with either hydrochloric or sulfuric acid leading to the formation of the corresponding salts of thyminylamine; (2) by hydrolysis of ethyl thyminyl-urethan with hydrochloric or sulfuric acid; (3) by hydrolysis of ethyl-2-ethylmercapto-6-oxypyrimidine-5-methyl isocyanate by action of hydrochloric or sulfuric acid; (4) by hydrolysis of thyminyl isocyanate with acids.[6]

Thyminylamine Sulfate, $(C_5H_7O_2N_3)_2{\cdot}H_2SO_4{\cdot}H_2O$.—This salt is formed by the action of concentrated sulfuric acid[8] on ethyl 2-ethylmercapto-6-oxypyrimidine-5-methylurethan according to procedure (1), but care must be taken in applying the reaction. It was found by experimentation that the best results are obtained by applying the hydrolysis reaction for two hours at a temperature of 110°. By lowering this temperature (90–100°) or reducing the time of heating, the desired change was incomplete. On the other hand, if the temperature of the sulfuric acid solution reached 120° and the heating was more prolonged, considerable charring and decomposition occurred. Five grams of the mercapto pyrimidine is stirred into 10 ml. of concentrated sulfuric acid. On heating this mixture, evolution of carbon dioxide begins at about 80°, and within a few minutes the pyrimidine-urethan dissolves completely and with no apparent evolution of ethyl mercaptan. A pale yellow solution is obtained. This is then cooled and poured into 200 ml. of water and the solution heated on a steam-bath until the evolution of mercaptan ceases. The solution is exactly neutralized with barium hydroxide to remove all sulfuric acid, and then a quantity of 0.2 *M* sulfuric acid is added, or the amount necessary to form the sulfate of the dissolved amine. The barium sulfate is then separated by filtration and the combined filtrates and washings are concentrated *in vacuo* to a volume of 15 ml. The addition of alcohol (25 ml.) leads to an immediate precipitation of the sulfate of the desired amine (3 g.) melting at 240–245°. This salt is finally purified by dissolving it in the least quantity of hot water and diluting with alcohol until the hot solution becomes turbid. On cooling, the sulfate separates in the form of glistening plates melting at 245–246° with decomposition. While the salt is insoluble in alcohol, 1 g. dissolves in 1.5 ml. of hot and 4 ml. of cold water. Ethyl thyminyl urethan is converted directly into thyminylamine by the action of concentrated sulfuric acid at 110°. The purified salt did not give Wheeler and Johnson's test for uracil.[9] *Anal.* Calcd. for $(C_5H_7O_2N_3)_2{\cdot}H_2SO_4{\cdot}H_2O$: N, 21.11; H_2O, 4.50. Found: N, 21.17, 21.10; H_2O, 3.90.

Thyminylamine Hydrochloride (Uracil-5-methylamine), $C_5H_7O_2N_3{\cdot}HCl{\cdot}0.5H_2O$.—This salt is formed by hydrolysis of ethyl 2-ethylmercapto-6-oxypyrimidine-5-methylurethan, or ethyl uracil-5-methylurethan with concentrated hydrochloric acid in a bomb tube. The degradation is complete after heating for two hours at 103–107°. The acid solution is then concentrated to a small volume and the hydrochloride precipitated by dilution with alcohol. On recrystallizing from dilute alcohol the salt separated in the form of glistening plates melting at 242–243° with decomposition. This salt is more soluble in water and alcohol than the sulfate. When 2-ethylmercapto-6-oxypyrimidine-5-methyl isocyanate or thyminyl isocyanate is digested on a steam-bath with concentrated hydrochloric acid, thyminylamine hydrochloride is formed.[10] *Anal.* Calcd. for $C_5H_7O_2N_3{\cdot}HCl{\cdot}0.5H_2O$: H_2O, 4.88; N, 23.66 (anhyd. salt). Found: H_2O, 4.82; N, 23.86.

Thyminylamine, V, $C_5H_7O_2N_3$.—An absolutely pure specimen of this amine has not been prepared. The purest product so far obtained was prepared as follows. One gram of the purified sulfate is dissolved in 10 ml. of water and the sulfuric acid removed by precipitation as barium sulfate in a hot solution. After filtering and cooling, the free thyminylamine (0.5 g.) deposits as a colorless amorphous powder melting at 260–270° with decomposition. The amine is insoluble in the ordinary organic solvents and moderately soluble in water. Warm aqueous solutions of the base were invariably characterized by a

distinct odor of ammonia resulting from a slow hydrolysis of the pyrimidine. The amine was purified for analysis by recrystallization from hot water, and separated on cooling as a colorless semi-crystalline powder melting at 265°. *Anal.* Calcd. for $C_5H_7O_2N_3$: N, 29.79. Found: N, 27.99, 27.93.

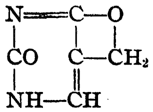
Behavior of Thyminylamine in Boiling Aqueous Solution.—An aqueous solution of 0.6 g. of thyminylamine in 40 ml. of water was boiled vigorously for twenty-five minutes, and the vapor condensed and conducted into 10 ml. of 4.5% boric acid solution. At the end of this time the borate solution was titrated with 0.02 *N* hydrochloric acid; 17.13 ml. of this standard acid was neutralized, being equivalent to 0.005824 g. of ammonia. Therefore, under these conditions, approximately 8.0% of the thyminylamine was decomposed. The acid distillate gave a positive aldehyde test with Schiff's reagent, indicating the presence of formaldehyde, and also a strong Wheeler and Johnson test for uracil.[9] It was our observation, as stated above, that thyminylamine could not be purified by crystallization from hot water without undergoing partial decomposition. The aqueous filtrates in every case responded to the characteristic color test for uracil and ammonia could be detected easily.

Behavior when Digested with Hydrochloric Acid.—0.35 g. of thyminylamine was refluxed with 15 ml. of strong hydrochloric acid for five hours, and the solution was then heated on a steam-bath for one and one-half hours longer or to complete dryness. We obtained a colorless solid residue of 0.25 g. which was recrystallized from hot water. It separated, on cooling, in the form of round, corpuscular crystals characteristic of the pyrimidine uracil and decomposed without melting at 308–312°. This solid gave a voluminous purple precipitate when it was tested according to the Wheeler and Johnson technique. It was apparent from the intensity of the color test that uracil represented the major proportion of the solid residue left after evaporation. However, the melting point is low for uracil (335°) and a nitrogen determination indicated some form of contamination. The question whether this is due to traces of thymine as a second product of hydrolysis has not been decided. In an equimolecular mixture of uracil and thymine the theoretical percentage of nitrogen would be 23.6. *Anal.* Calcd. for $C_4H_4O_2N_2$: N, 25.00. Found: N, 23.17, 23.16.

Action of Nitrous Acid on Thyminylamine

The Formation of Uracil-5-carbinol or Thyminyl Alcohol, $\mathrm{NHCONHCH{=}C(CH_2OH)CO}$.—Thyminylamine sulfate was dissolved in water and the sulfate ion removed by adding the required quantity of barium hydroxide to form barium sulfate. In the boiling solution were then dissolved two equivalents of barium nitrite, followed by the gradual addition of the required amount of 0.2 *M* sulfuric acid. The solution was then freed from barium sulfate by filtration and finally concentrated *in vacuo* to a volume of 1 cc. On adding absolute alcohol, a mixture of products was precipitated which melted from 240 to 300°. This gave a strong color test for uracil. By fractional crystallization from alcohol and ether we finally succeeded in separating a substance which melted from 190–200°, and which was probably an impure sample of the unknown thyminyl alcohol. All attempts to synthesize this alcohol by the action of formaldehyde on uracil have thus far proved unsuccessful. The carbinol radical is apparently not firmly bound at the 5-position of the uracil molecule. *Anal.* Calcd. for thyminylcarbinol, $C_5H_6O_3N_2$: N, 19.72. Found: N, 18.87, 19.01.

In a second experiment the oxides of nitrogen were conducted into an aqueous solution of thyminylamine for fifteen minutes. After concentrating the resulting solution by heating on a steam-bath, we obtained a product which decomposed at 270–295° and which also gave a good color test for uracil. Further purification finally led to a colorless substance melting at 195–200°. This material was very soluble in both cold and hot water, and was insoluble in alcohol. It was purified by crystallization from dilute alcohol. The structure of this substance was not established, but it is an interesting fact that a nitrogen determination agreed with the calculated for an inner anhydride derivative of thyminyl alcohol. *Anal.* Calcd. for $C_5H_4O_2N_2$: N, 22.57. Found: N, 22.69.



X

$\mathrm{NHCO{\cdot}NHCH{=}C(CH_2NHCSNH_2)CO}$, **Thyminyl-thiourea,** was prepared by the action of ammonium thiocyanate on thyminylamine sulfate in hot aqueous solution. It was purified by crystallization from dilute alcohol and separated in the form of glistening plates melting at 204–205° to an oil. The yield was quantitative. *Anal.* Calcd. for $C_6H_8O_2N_4S$: N, 28.00. Found: N, 27.96.

Summary

1. Methods of synthesizing the pyrimidine—*thyminylamine*—have been described in this paper.

2. A study of this amine has revealed the fact that it is very susceptible to hydrolysis and is easily converted into uracil, formaldehyde and ammonia.

3. By diazotization of thyminylamine, the corresponding thyminyl alcohol is formed. This carbinol is likewise unstable and undergoes hydrolysis with formation of uracil and formaldehyde.

4. This discovery that the substitution of hydrogen in the methyl group of thymine by an hydroxyl or amino radical weakens the carbon linkage of this side chain, is a result of biochemical significance.

The Reaction of Sodium with Triphenylchloromethane and with Triphenylmethyl in Organic Solvents

BY W. E. BACHMANN AND F. Y. WISELOGLE

From the results that have been reported by a number of investigators,[1] it has been concluded that sodium does not react with triphenylchloromethane or triphenylbromomethane in ether or in benzene solution. This result is strange in view of the ease with which the halogen atom of triphenylchloromethane can be removed by other metals as silver, mercury and copper and especially by sodium amalgam. In order to account for the formation of triphenylmethyl from sodium and triphenylchloromethane in the presence of bromobenzene, Morton and Stevens[1d] postulated the intermediate formation of an active "metal halyl" from sodium and bromobenzene, followed by interaction of this "sodium carrier" and the triphenylchloromethane.

During the past four years a number of us in this Laboratory, including Professor M. Gomberg, have utilized the reaction between sodium and triphenylchloromethane in ether to prepare triphenylmethyl, for we found that the reaction proceeds *rapidly* provided that fresh surfaces of the metal are exposed throughout the reaction. Indeed, the reaction is so rapid under certain conditions that it is necessary to cool the mixture. Thus, 5 g. of triphenylchloromethane can be converted completely to triphenylmethyl in ten minutes. In our opinion the reaction is ordinarily prevented or retarded by the formation of an insoluble coating of sodium chloride on the surface of the metallic sodium. If the coating is continually scraped off or if fresh surfaces of the metal are exposed in some other manner as by pressing the metal with a glass rod, then the reaction is able to proceed at a rapid rate. It is easy to understand why liquid sodium amalgam (1 or 40%) is capable of reacting rapidly with triphenylchloromethane.

It is not unlikely that as soon as some triphenylmethyl is formed part of the reaction leading to the further formation of triphenylmethyl takes place through the intermediate formation of triphenylmethyl-sodium, which then reacts with the triphenylchloromethane.

$$(C_6H_5)_3C + Na \longrightarrow (C_6H_5)_3CNa$$
$$(C_6H_5)_3CNa + ClC(C_6H_5)_3 \longrightarrow (2C_6H_5)_3C + NaCl$$

In this way a direct reaction between the sodium and the triphenylchloromethane is not involved. Whatever the mechanism, the reaction between sodium and triphenylchloromethane in ether can be made to proceed rapidly.

According to Schlenk and Marcus[1c] sodium does not add to triphenylmethyl in ether except in the form of sodium amalgam; instead, the radical is polymerized to *p*-benzohydryltetraphenylmethane under the influence of the sodium metal. Under the conditions employed by us triphenylmethyl and sodium powder reacted rapidly in ether to give triphenylmethyl-sodium in practically quantitative yield, only traces of the dimer being formed. The same authors reported that triphenylmethyl-sodium reacts with air to form triphenylmethyl, which oxidizes further to triphenylmethyl peroxide, but they give no experimental details. Inasmuch as interaction of triphenylmethyl-magnesium bromide and air gives triphenylcarbinol (in the form of its bromomagnesium salt) as the chief product,[2] we have investigated the behavior of the corresponding sodium derivative. Here, too, by passing air through a solution of triphenylmethyl-sodium we obtained triphenylcarbinol as the principal product and only a small amount of triphenylmethyl peroxide.

Although Morton and Stevens observed no reaction between sodium and triphenylchloromethane in benzene in sixty days, the reaction can be made to take place in this solvent also. The rate of the reaction in benzene is very much slower than the rate in ether and for this reason the reagents must be extremely pure if by-products are to be avoided. Thus, in two hours, by pressing the sodium with a glass rod, a 10% yield of triphenylmethyl was obtained. Triphenylmethyl-sodium can also be prepared in benzene from triphenylchloromethane and sodium provided the mixture is shaken with glass beads.

---

[2] Bachmann and Cockerill, *ibid.*, **55**, 2932 (1933).

Experimental

Formation of Triphenylmethyl.—To a mixture of 2 g. of sodium powder in 80 cc. of anhydrous ether (or 40 cc. of ether and 40 cc. of benzene) in an Erlenmeyer flask was added 5 g. of triphenylchloromethane. Frequently the sodium immediately became colored with red triphenylmethyl-sodium and the solution became yellow. The flask was fitted with a stopper bearing a movable glass rod flattened at one end. By pressing the sodium against the bottom of the flask a rapid reaction was initiated and the solution became orange-yellow as the radical was formed. After ten minutes the color began to change to the red color of triphenylmethyl-sodium, an indication that all of the triphenylchloromethane had reacted. Oxidation of the triphenylmethyl gave an 80% yield of triphenylmethyl peroxide, m. p. 185–186°. A similar result was obtained by vigorously shaking a mixture of the metal and triphenylchloromethane in ether with sharp particles of glass for twenty minutes.

p-Benzohydryltetraphenylmethane is formed to a slight extent when the complete reaction between the sodium and triphenylchloromethane is slow. This is the case when only the theoretical amount of sodium (1 atom) is employed and the mixture is shaken for a day or two in order to allow time for the last traces of sodium to react. When the reaction proceeds rapidly as is the case when the sodium is pressed with a glass rod, the formation of the dimer is practically entirely suppressed.

Preparation of Triphenylmethyl-sodium.—After pressing the sodium (2 g.) contained in a solution of 5 g. of triphenylchloromethane in 40 cc. of anhydrous ether and 40 cc. of benzene with a glass rod for ten minutes, the rod was removed and the mixture was shaken for two hours. Hydrolysis of the deep-red triphenylmethyl-sodium solution gave a 96% yield of triphenylmethane and only a trace of *p*-benzohydryltetraphenylmethane. The excellent yield of triphenylmethane is an indication of the completeness of the two reactions: the reaction of sodium with triphenylchloromethane and the addition of sodium to triphenylmethyl. Even after one-half hour of shaking the solution contained only 2% of triphenylmethyl that had not been converted to triphenylmethyl-sodium. Similar results were obtained by simply shaking a mixture of triphenylchloromethane and sodium powder in ether–benzene with sharp particles of glass for several hours. In addition to hydrolysis the triphenylmethyl-sodium was also treated with benzyl chloride to give *unsym*-tetraphenylethane and with carbon dioxide to form triphenylacetic acid in excellent yields.

By shaking a mixture of 2.78 g. of triphenylchloromethane, 2 g. of sodium powder and two dozen glass beads in 40 cc. of benzene for one month, triphenylmethyl-sodium was formed as a red precipitate. Hydrolysis gave a 70% yield of triphenylmethane.

Oxidation of Triphenylmethyl-sodium.—Dry air was passed through a solution of triphenylmethyl-sodium that had been prepared from 5 g. of triphenylchloromethane for one hour. From the products of hydrolysis there were isolated 3.15 g. (67%) of triphenylcarbinol and 0.2 g. (4%) of triphenylmethyl peroxide. Although the oily residue liberated iodine from hydrogen iodide, a search for triphenylmethyl hydrogen peroxide was unsuccessful.

Summary

Sodium reacts rapidly with triphenylchloromethane in ether provided fresh surfaces of the metal are exposed throughout the reaction.

Sodium adds to triphenylmethyl in ether and in benzene to form triphenylmethyl-sodium.

Triphenylcarbinol is the principal product of the oxidation of triphenylmethyl-sodium.

The Action of Aluminum Halides on *n*-Pentane

BY A. L. GLASEBROOK, N. E. PHILLIPS AND W. G. LOVELL

Recently, Nenitzescu[1] investigated the reactions of *n*-hexane and *n*-heptane in the presence of aluminum chloride and found isomerization to the 2- or 3-methyl isomer to be the main reaction. Dehydrogenation, condensation to higher paraffins, cyclization to mono and bicyclic cycloparaffins, hydrogenation and splitting of the chain to lower paraffins also occurred. Calingaert[2] repeated the work of Nenitzescu and found that only about 6% of the reacting *n*-heptane was isomerized.

We attempted to study the reported isomerization of *n*-heptane; however, preliminary experiments gave reaction products which were very difficult to analyze and we decided to use *n*-pentane as the starting material. The use of this hydrocarbon was expected substantially to reduce the number and complexity of reaction products, and, since Nenitzescu[3] had shown the reaction between *n*-pentane, acetyl chloride and aluminum chloride to lead to the formation of *unsym*-methyl isopropyl acetone, a result which can best be explained by the preliminary isomerization of *n*-

---

[1] Nenitzescu and Dragan, *Ber.*, **66**, 1892 (1933).

[2] Calingaert and Beatty, THIS JOURNAL, **58**, 51 (1936).

[3] Nenitzescu and Chicos, *Ber.*, **68**, 1584 (1935).

pentane to isopentane, we did not expect the isomerization reaction to be affected by the change in starting materials.

Using freshly sublimed aluminum chloride and dry pentane no reaction occurred even after refluxing for several days. When small amounts of water, alkyl chlorides (but not aromatic chlorides), or hydrated aluminum chloride were added to the reaction mixture, the pentane commenced to undergo decomposition almost immediately. The products did not appear to vary, regardless of the method used to start the reaction, and only the butanes and isopentane could be identified, the latter being the chief product. During the reaction, the aluminum chloride surface became coated with a layer of brown tar, which, after hydrolysis of the aluminum chloride residue, was found to consist of a mixture of highly unsaturated, halogen-containing compounds. Substances boiling higher than *n*-pentane and soluble in the reaction mixture were also formed, but, owing to the small amounts present, could not be identified.

Since water and hydrated aluminum chloride react with aluminum chloride to give aluminum oxide and hydrochloric acid, these substances were investigated for their ability to induce the decomposition of pentane in the presence of aluminum chloride. Anhydrous aluminum oxide had no effect, but when dry hydrogen chloride was bubbled through the reaction mixture, the usual reaction commenced, and, apparently, this is the substance which is responsible for the increased activity of the aluminum chloride. This fact was also observed by Ipatieff and Grosse.[4] The same explanation can also be used in the case of the alkyl chlorides, since these substances react with aluminum chloride to give hydrogen chloride.[5] In addition, we found anhydrous hydrogen bromide to be exceptionally effective in activating aluminum chloride.

Aluminum bromide was next investigated. This compound is quite soluble in *n*-pentane. The bromide proved much more effective in causing the decomposition of pentane, and it was unnecessary knowingly to add other substances to the reaction mixture to induce reaction. In one day a reaction mixture containing only 1.52 mole % aluminum bromide undergoes as much change as a reaction mixture containing 17.4 mole % aluminum chloride, and, promoted by 0.2 mole of water per mole of aluminum chloride, undergoes in two days' reaction time. Qualitatively the products obtained using the bromide catalyst were the same as those obtained using the chloride. The amount of pentane reacting increased with the reaction time and the aluminum bromide concentration. Table I gives the results obtained in a study of these variables. The amount of butanes formed is shown to increase practically linearly with the extent of the reaction, whereas the amount of isopentane formed reaches a maximum from which it slowly declines as the extent of the reaction is further increased.

The addition of such substances as anhydrous hydrobromic acid or water increases the reaction velocity. The effects caused by the addition of these substances to the reaction mixture are shown in Table II.

When gaseous *n*-pentane carried by a stream of dry nitrogen was passed over aluminum chloride at temperatures from 40 to 133°, no reaction could be detected outside of a slight discoloration of the aluminum chloride. The addition of promoter substances to the gas stream readily caused the decomposition of *n*-pentane, and it was unnecessary to use temperatures higher than 40°. Anhydrous hydrobromic acid was the most effective substance investigated for activating the aluminum chloride. Using gaseous *n*-pentane the amount of butanes formed was greatly increased and only insignificant amounts of isopentane formed. Traces of hydrogen were also formed in these experiments. Most of the higher boiling substances remained behind on the aluminum chloride and caused the latter to slowly liquefy with continued use.

The aluminum chloride became decreasingly active when the addition of hydrogen halides or halogen halide forming substances was discontinued. Aluminum chloride which had been activated by mixing anhydrous hydrobromic acid to the gas stream lost its activity more slowly than the other substances investigated, and it was also possible to activate the aluminum chloride by treatment with anhydrous hydrobromic acid prior to the introduction of the *n*-pentane vapor. This procedure was ineffective with water vapor and anhydrous hydrochloric acid. Using aluminum chloride which had been activated by treatment with anhydrous hydrobromic acid before use, we were able to test the gases leaving the

aluminum chloride for bromine content, and found that the amount of decomposition decreased as the bromine content of the exit gases dropped.

Experimental

Reagents.—The *n*-pentane used was a commercial product derived from petroleum. Before use the material was shaken with concentrated sulfuric acid until the acid remained colorless on further treatment, then washed, dried and distilled from sodium. The distilled material had a practically constant boiling point and the constants: n^{20}_{D} 1.3579; d^{20}_{4} 0.6264. The anhydrous aluminum chloride was a c. p. grade and was resublimed in a current of dry nitrogen at 200 to 230° before use. The aluminum bromide was prepared by the action of bromine on the hot metal and purified by distillation. Before use the aluminum bromide was redistilled over aluminum.

Aluminum Bromide Dissolved in *n*-Pentane.—*n*-Pentane (usually between 100 to 200 g.) was placed in a round-bottomed flask and aluminum bromide added. The flask was fitted with a reflux condenser cooled with refrigerated water at 5 to 10°. The top of the condenser was attached to a drying tube filled with dehydrite. The drying tube in turn, connected to a gas receiver. At all times the system was kept under a slight vacuum. The aluminum bromide did not dissolve immediately, and, after the closed system had been established, the flask was shaken and heated to hasten the process of solution.[6] After solution of the aluminum bromide had occurred, the heat was removed and the flask allowed to stand undisturbed at room temperature.

Before stopping the experiment, the flask containing the reaction mixture was cooled with ice water. In practically every case, this cooling sufficed to condense all the gas (usually 200–400 cc.) which had formed during the experiment. The flask was then disconnected and the flask contents slowly poured into a cooled separatory funnel containing crushed ice which hydrolyzed the dissolved aluminum bromide. The aluminum bromide–tar compounds which formed were separately hydrolyzed and extracted with ether because after hydrolysis they were slightly soluble in *n*-pentane and readily so in higher hydrocarbons.

Identification of the Reaction Products.—The analyses were obtained by distillation of 100 cc. of the reaction product. The column used for isobutane was a 91-cm., 5 mm. inside diameter Podbielniak-type column with a partial condensation head, which was cooled with a dry-ice–acetone bath. The isopentane was separated from *n*-pentane in a 28-plate vacuum jacketted column with a partial condensation head. The holdup of this column was 6 cc. A number of known mixtures were analyzed in these columns and excellent results obtained. The total distillation loss from the two distillations was usually between 0.5 and 1.5 cc. Figure 1 shows a typical distillation curve obtained.

Although the distillation curve shows only the presence of isobutane, a small amount of *n*-butane could probably

---

(6) If the pentane contains even traces of olefins the process of solution will be characterized by the formation of a yellow cloudiness in the solution. This gradually clears, and, after an hour or so, the solution becomes entirely clear and colorless. The clearing of the solution is accompanied by the precipitation of small droplets of brown polymer on the sides of the flask. These coalesce on further standing and sink to the bottom of the flask. When pure pentane is used, usually two days elapse before any tar precipitates. Outside of this, however, no differences could be detected.

be found by a redistillation of the break material between isobutane and isopentane. The isopentane fractions were always checked by their critical solution temperatures[7] and frequently the refractive index and density were measured. The average values for the refractive index and density of the isopentane fractions reported in Table I were n^{20}_D 1.3548 and d^{20}_4 0.6203.

The substances boiling higher than *n*-pentane were not present in sufficient quantities to allow purification and identification.[8] By distilling the residues from several experiments a single plateau occurred in the distillation curve at 58 to 60°, but insufficient material was obtained to allow its identification. The fractions were all saturated and measurement of the refractive index suggested the material to be largely paraffinic. Usually the analysis for the higher boiling material was obtained by measurement of the critical solution temperature of the residue from the isopentane distillation.

Likewise, the insoluble tars which formed were not present in sufficient quantities to be identified. The tars from a series of experiments were saved and distilled. The material distilled over the range 100 to 240° without the appearance of a constant boiling substance. All of the fractions were strongly unsaturated and gave tests for halogens. The tars gave an intense purple color when bromine and *m*-cresol were added to their dilute solutions in *n*-heptane or other higher paraffins. The same color reaction is also given by the tars obtained from the reactions of other hydrocarbons with aluminum halides.

Aluminum Chloride and Liquid *n*-Pentane.—In general, the same experimental procedure was used as with aluminum bromide. However, the aluminum chloride reaction mixtures were always kept at the boiling point instead of room temperature. Usually 30 to 40 g. of aluminum chloride was used for each 100 g. of pentane and 0.2 mole of water (or its equivalent when other substances were used) added per mole of aluminum chloride used. With aluminum chloride the reaction velocities were slower, and even after five to ten days' reaction only 30 to 40% of the pentane could be decomposed. In several experiments a large butane fraction was obtained by starting with quantities of *n*-pentane as much as 1000 g. In these cases up to 10% *n*-butane was found in the butane fraction.

Experiments with Gaseous *n*-Pentane.—In the usual experiment a charge of 250 to 300 g. of aluminum chloride was placed in the middle of a 91-cm. long Pyrex tube of 3.8-cm. inside diameter. The reaction tube was heated in a horizontal electric furnace. The mixture of *n*-pentane vapor and nitrogen was produced by bubbling a stream of dry nitrogen through a wash bottle containing the hydrocarbon. The amount of pentane introduced was controlled by regulation of the temperature of the liquid pentane. In experiments in which water was added to the vapor entering the reaction tube, an additional wash bottle containing water was placed in the line just previous to entrance into the reaction tube. In certain experiments anhydrous hydrogen bromide or chloride replaced nitrogen as the carrier gas. A carrier gas flow of 50 cc. per min. was used to introduce 0.2 g. per minute of *n*-pentane into the reaction tube. When water vapor was used, it was added to the gas stream at the rate of 0.005 g. per minute. Varying the rate of flow of the pentane changed only the amount of decomposition. The gases leaving the reaction tube passed through a trap cooled to −60 to −70°. The gas which did not condense in this trap was collected in a gas receiver.

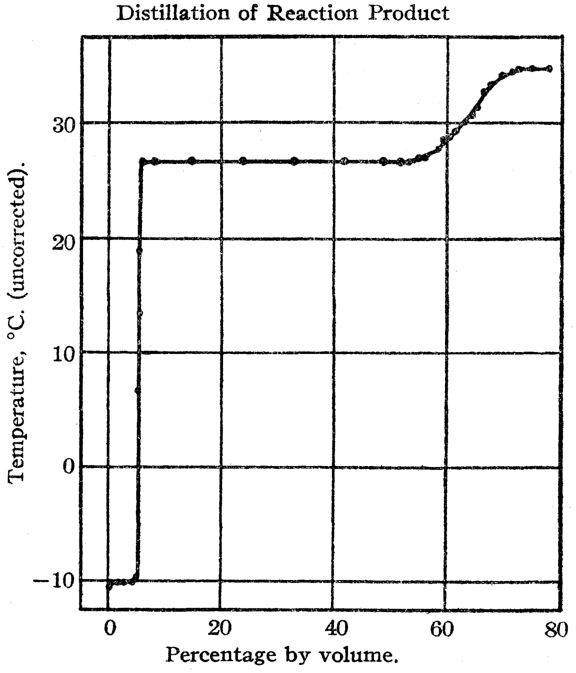

Fig. 1.—Sample used, 100.0 cc.; isobutane distillation loss, 0.4 cc.; isopentane distillation loss, 1.0 cc.

When nitrogen was used as the carrier, 85 to 95% of the pentane sent through was recovered as liquid, the tarry deposit on the aluminum chloride and the gas accounting for the balance. When the gas collected in the gas receiver was slowly passed through a trap at −30 to −40° practically the entire hydrocarbon content was condensed. Traces of hydrogen were found in the gas remaining, and its hydrocarbon content had carbon numbers between 3.9 and 4.6. When the halogen acids were used as carriers, they were removed, after leaving the reaction tube, by treatment with dilute caustic solution, and in these cases the gas loss was negligible.

In a typical experiment a product was obtained containing 33.7% butanes and 13.4% isopentane. Reducing the amount of decomposition did not materially change the relative amounts of products formed. Redistillation of the butane fractions in a Podbielniak low temperature column showed these fractions to contain from 4 to 11% *n*-butane, the balance being isobutane.

---

[7] In order to avoid the use of sealed tubes, Eastman Kodak practical *m*-cresol was used instead of aniline for the critical solution temperature measurements. This material lowered the critical solution temperature of isopentane to about 12° depending upon the water content of the cresol. The solution temperature of *n*-pentane was 10° lower. The cresol was kept protected from the atmosphere and was measured out with a mercury sealed buret. The solution temperatures so determined remained constant as long as a given sample of cresol was in use.

[8] Insoluble tars and substances boiling higher than the starting material are produced in greater abundance with *n*-heptane and are being more thoroughly investigated in the study of this substance.

Summary

1. Dry *n*-pentane, either in the form of vapor or liquid, undergoes little, if any, decomposition in the presence of freshly sublimed aluminum chloride. If, however, anhydrous hydrogen bromide or chloride, water, hydrated aluminum chloride, or alkyl chlorides are added, reaction immediately commences. In the liquid phase reaction, the butanes and isopentane have been identified as reaction products. The latter is the chief product. Undefined saturated higher boiling products and an insoluble unsaturated polymer are also produced. In the vapor phase reaction the amount of isobutane formed is greatly increased and with extensive reaction becomes the chief product. For the vapor phase reaction aluminum chloride and anhydrous hydrobromic acid provide the most active catalyst.

2. In moderate concentration, aluminum bromide is soluble in *n*-pentane. It is a much more active substance than aluminum chloride and does not require the addition of other substances to cause the decomposition of *n*-pentane. The extent of reaction has been found to depend on the aluminum bromide concentration as well as the reaction time. The reaction products were the same, qualitatively, as those obtained with the chloride catalyst. As the extent of reaction was increased, the amount of butanes formed increased linearly, whereas the amount of isopentane formed reached a maximum value and then slowly declined. As much as 55.9% isopentane was obtained from *n*-pentane. When water is added to the reaction mixture, or anhydrous hydrogen bromide bubbled through it, the reaction velocity is increased.

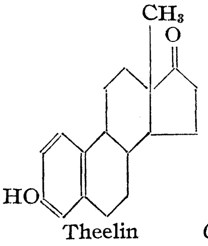
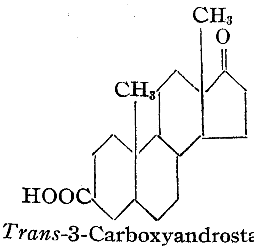
Sterols. VII. *Cis* and *Trans* 3-Carboxyandrostanone, An Oestrus-Producing Male Hormone Derivative, and *epi*-Cholesterol

By Russell E. Marker, Oliver Kamm, Thomas S. Oakwood and Joseph F. Laucius

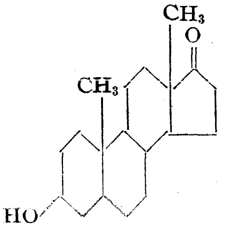
Because of the acidic nature of theelin, we prepared an androsterone derivative having a carboxyl group in the 3-position to see whether this compound would have female hormone properties in addition to male activity. The product was the mixture of *cis*- and *trans*-3-carboxyandrostanone. We made no attempt to separate the two stereoisomers. We found that the ethyl ester of this compound gave an oestrus response in rats when given in quantities of from 5–10 γ. The ethyl ester is much more active than the free acid. These compounds, however, were inactive when tested for male hormone properties by the cock's comb test in doses of 2 mg. Thus it is not necessary to have unsaturation in the molecule to have an oestrus-producing compound.



Theelin



Cis and Trans-3-Carboxyandrostanone



Androsterone

Because of the importance of obtaining *epi*-cholesterol in large quantities for research purposes avoiding the expensive digitonin process for the separation of the *cis* and *trans* isomers, we have looked for other means of separating these isomers, and found that by crystallizing the acetates from ethyl alcohol, a partial separation can be accomplished giving a product containing 80–90% of *epi*-cholesterol. The remaining cholesterol can then be removed completely by recrystallizing the benzoates from ethyl alcohol. We previously separated the two isomers by digitonin.[1]

We found that *epi*-cholesterol behaves very similarly in instability to *epi*-allocholesterol pre-

---

[1] Marker, Oakwood and Crooks, This Journal, **58**, 481 (1936).

pared by Evans and Schoenheimer.[2] In an attempt to convert *epi*-cholesterol into *epi*-allocholesterol through its hydrochloride, we obtained cholesterylene almost quantitatively by dehydration and no *epi*-cholesterol hydrochloride. The same is true when *epi*-cholesterol is warmed with a small amount of hydrogen chloride in alcohol, dehydrating to cholesterylene. Evans and Schoenheimer found the same thing to happen when *epi*-allocholesterol was warmed with alcoholic hydrogen chloride. On attempting to prepare dibromo-*epi*-cholesteryl acetate by the addition of bromine in acetic acid to *epi*-cholesteryl acetate, there was a similar splitting giving a tetrabromocholestane. This product is a different isomer from that obtained by the addition of bromine to cholesterylene.

epi-Cholesterol does not irradiate with ultraviolet light to give products of antirachitic value.

Experimental

***Cis* and *Trans*-3-Carboxyandrostanone.**—The methyl ester of *cis*- and *trans*-3-carboxycholestane was prepared according to the method of Marker, Oakwood and Crooks.[1]

A solution of 100 g. of the methyl ester in 3700 cc. of glacial acetic acid was placed in a 5-liter flask equipped with a stirrer and dropping funnel. The temperature of the flask was kept at 45–50° during the addition of a solution of 115 g. of chromic anhydride in 350 cc. of 90% acetic acid. After addition was complete (three hours) stirring and warming was continued for seven hours. At the end of this time 200 cc. of methyl alcohol was added to destroy any excess chromic acid. The acetic acid was distilled from the reaction mixture under reduced pressure, keeping the temperature of the bath below 50°. After most of the acetic acid was distilled, 500 cc. of water was added and the distillation continued for an additional two hours. The residue was extracted with five 500-cc. portions of ether and the ether extract was successively washed once with 200 cc. of 10% hydrochloric acid, once with 100 cc. of a saturated solution of sodium bicarbonate, and then twice with 100-cc. portions of a 5% sodium hydroxide solution. The extract was dried with sodium sulfate and the ether distilled. The oil was dissolved in 1500 cc. of 95% alcohol to which was added 5 g. of semicarbazide hydrochloride and 5 g. of sodium acetate. The alcohol was distilled and the residue digested with 1500 cc. of dry ether for three hours. The insoluble crystalline residue was filtered, washed with dry ether, then boiled two hours with 50 cc. of distilled water. The semicarbazone was filtered, washed with ether, then extracted with acetone in a Soxhlet extractor; yield 2.5 g.; m. p. 250–260° (dec.).

A mixture of 1.0 g. of the semicarbazone, 115 cc. of alcohol, 15 cc. of concd. sulfuric acid and 24 cc. of water was boiled for one hour. The solution was poured into 1500 cc. of distilled water and extracted with three 300-cc. portions of dry ether. The ether extract was washed twice with water and then the ether was distilled. The residue was treated overnight with a solution of 5 g. of potassium hydroxide in 50 cc. of methyl alcohol. The alcoholic solution was poured into a liter of distilled water. This was concentrated *in vacuo* until 300 cc. was distilled to remove the alcohol. The solution was extracted with alcohol-free ether to remove neutral organic material. The aqueous portion was acidified with 5 *N* sulfuric acid, and then was extracted three times with 300-cc. portions of ether. On evaporation of the ether a solid remained. This was crystallized from acetone; yield 300 mg.; m. p. 253°.

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.5; H, 9.5. Found: C, 75.7; H, 9.5.

The ether solution which was obtained from the filtration of the semicarbazone was evaporated to dryness. On recrystallization from methyl alcohol–ether, 35 g. of unoxidized methyl ester of *cis*- and *trans*-3-carboxycholestane, m. p. 69°, was obtained.

Ethyl Ester of *cis*- and *trans*-3-Carboxyandrostanone.—These acids esterify very readily in a small amount of alcohol. When ordinary ether containing ethyl alcohol was used to extract the *cis*- and *trans*-3-carboxyandrostanone from the hydrolysis in the above experiment, the resulting product was the ethyl ester of *cis*- and *trans*-3-carboxyandrostanone. It was crystallized from dilute alcohol; m. p. 108–110°.

Anal. Calcd. for $C_{22}H_{34}O_3$: C, 76.2; H, 9.9. Found: C, 75.8; H, 10.2.

Separation of *epi*-Cholesterol from the mixture of *epi*-Cholesterol and Cholesterol.—A mixture of *epi*-cholesterol and cholesterol was obtained by passing oxygen into cholesterylmagnesium chloride. 10.2 g. of magnesium turnings was covered with 50 cc. of dry ether. To this was added 1 cc. of ethyl bromide. After the Grignard had started a solution of 170 g. of well purified cholesteryl chloride dissolved in 1 liter of dry ether was added dropwise with vigorous stirring over a period of six hours. The ether solution was kept at a reflux temperature during the addition. It was then stirred vigorously for twelve hours. At the end of this time practically all of the magnesium was in solution. The product was cooled to 0° and oxygen passed into the reaction mixture for four hours. The oxygen was under a slight pressure during addition. The mixture was poured into dilute sulfuric acid and the mixture of cholesterols was extracted with ether. After washing with water, the ether layer was filtered from a small amount of insoluble white solid. The ether was then distilled leaving a white product. From 1360 g. of cholesteryl chloride was obtained 950 g. of the crude mixture of cholesterols.

A mixture of 50 g. of the above cholesterols, 20 g. of succinic anhydride and 40 cc. of dry pyridine was heated over steam for two hours. After cooling to room temperature, the product was dissolved in 300 cc. of ether, and 200 cc. of water containing 60 cc. of concd. hydrochloric acid was added. After extraction of the pyridine 300 cc. more ether was added and the half-succinic ester extracted with a solution of 25 g. of sodium carbonate in one liter of water at 33°. The alkaline extract was extracted twice with ether, then acidified with hydrochloric acid. The succinate was extracted with ether. After distilling the ether, the residue was refluxed with 25 g. of sodium hydroxide in one liter of water with stirring. The purified

---

(2) Evans and Schoenheimer, This Journal, **58**, 182 (1936).

cholesterols were extracted with ether; 820 g. was obtained from 1150 g. of crude material. This was converted into the acetate by boiling for one hour with three times excess of acetic anhydride. The excess acetic anhydride was removed by vacuum distillation. The acetates were boiled with 6 liters of 95% ethyl alcohol and the solution cooled to 5°. The precipitate was filtered and recrystallized, m. p. 101–104°. One more crystallization of the product gave pure cholesteryl acetate, m. p. 114°, which gave no depression in melting point when mixed with cholesteryl acetate prepared from pure cholesterol. The alcoholic mother liquors from the above crystallization were evaporated to dryness and hydrolyzed by means of alcoholic sodium hydroxide, giving a product consisting of approximately 90% of *epi*-cholesterol and 10% cholesterol. This mixture was then converted into the benzoate, and freed of cholesterol benzoate by crystallization from alcohol. The benzoate was then hydrolyzed and the *epi*-cholesterol crystallized from alcohol, m. p. 141.5°. Mixed with pure *epi*-cholesterol, m. p. 141.5°, it gave no depression in melting point, whereas when mixed with cholesterol, m. p. 147°, a depression of 19° was observed; $[\alpha]^{30}\text{D}$ $-35.0°$ in 1% alcohol.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.9; H, 12.0. Found: C, 83.9; H, 12.1.

Action of Bromine on *epi*-Cholesteryl Acetate.—To a solution of 100 mg. of *epi*-cholesteryl acetate in 3 cc. of ether was added a solution of 40 mg. of bromine in 5 cc. of acetic acid. A solid crystallized out. This was filtered and recrystallized from acetic acid, m. p. 110°. It gave a tetrabromocholestane.

Anal. Calcd. for $C_{27}H_{43}Br_4$: C, 47.2; H, 6.3. Found: C, 47.4; H, 6.7.

This bromide is different from the tetrabromide formed from cholesterylene and bromine, giving a depression in melting point when mixed.

Action of Hydrochloric Acid on *epi*-Cholesterol.—A solution of 1 g. of *epi*-cholesterol in 30 cc. of alcohol containing 1 g. of hydrochloric acid was refluxed for sixteen hours. The insoluble oil was sublimed under high vacuum, then crystallized from alcohol, m. p. 76–77°, uncorr. Mixed with cholesterylene, m. p. 74–76°, prepared by the action of quinoline on cholesteryl chloride it gave no depression in melting point; $[\alpha]^{30}\text{D}$ $-78.3°$ compared to $[\alpha]^{30}\text{D}$ $-80.0°$ for authentic cholesterylene, concentration 1% in benzene.

When an attempt was made to prepare *epi*-allocholesterol by the addition of hydrochloric acid in the cold to an alcoholic solution of *epi*-cholesterol the same dehydration occurred, giving cholesterylene.

Summary

A mixture of *cis*- and *trans*-3-carboxyandrostanone and its ethyl ester was prepared and found to produce oestrogenic activity in rats, but lacked male activity in the cock's comb test.

epi-Cholesterol and cholesterol can be separated into their components by crystallization of their acetates followed by crystallization of their benzoates. *epi*-Cholesterol on treatment with alcoholic hydrogen chloride forms cholesterylene. *epi*-Cholesterol acetate on treatment with bromine gives a tetrabromocholestane which is a different isomer from the product obtained by the action of bromine on cholesterylene.

The Mechanism of Carbohydrate Oxidation. XXII.[1] The Preparation and Reactions of Glyceraldehyde Diethyl Mercaptal

BY HAROLD W. ARNOLD AND WILLIAM LLOYD EVANS

During the course of our work on the synthesis of *β-d*-glucosidoglyceraldehyde derivatives[2] it seemed desirable to have available a monomeric glyceraldehyde derivative containing an unblocked hydroxyl group only on the third carbon atom. The following scheme was used in attempting to prepare such a derivative:

Glyceraldehyde diethyl mercaptal was prepared as a distillable oil by the usual procedure employed in preparing sugar mercaptals. It readily reacted with triphenylmethyl (trityl) chloride to form a crystalline trityl ether. From the work of Helferich and his students[3] it appears probable that the compound prepared was 3-trityl glyceraldehyde diethyl mercaptal. A few exceptions to Helferich's rule concerning the preferential reaction of trityl chloride with primary alcohol groups have been found[4] but they do not invalidate the rule because of the vigorous reaction conditions employed in discovering them.

The 3-trityl glyceraldehyde diethyl mercaptal could be easily acetylated or benzoylated to give

crystalline products. All attempts to detritylate these compounds failed to give derivatives containing the free hydroxyl group on the third carbon atom. Various detritylation procedures were used. In each case the trityl ether was quantitatively cleaved, but the reaction product was a dark, gummy mass from which no definite compound could be isolated. Detritylation by catalytic hydrogenation[5] was not attempted since work by Dr. M. L. Wolfrom in this Laboratory had shown that this procedure fails when applied to diethyl mercaptal derivatives, presumably because the catalyst becomes poisoned.

To show the analogy between the reactions of glyceraldehyde diethyl mercaptal and *d*-glucose diethyl mercaptal,[6] the glyceraldehyde diethyl mercaptal was acetylated. The product was subjected without purification to the hydrolytic action of mercuric chloride and cadmium carbonate in moist acetone to give a distillable oil whose properties corresponded to those reported by Fischer and Baer[7] for a monomeric glyceraldehyde diacetate which they prepared by a different procedure. Deacetylation of the oil gave a sirup which reacted with 2,4-dinitrophenylhydrazine in acid solution to yield the known 2,4-dinitrophenylhydrazone of glyceraldehyde. The oil likewise reacted with an acid solution of *p*-nitrophenylhydrazine under more drastic conditions to give a crystalline product which was apparently glyceraldehyde *p*-nitrophenylosazone acetate.

Experimental Part

Glyceraldehyde Diethyl Mercaptal.—Fifteen grams of glyceraldehyde was placed in a glass-stoppered bottle; 13 cc. of ice-cold concentrated hydrochloric acid and 30 cc. of ice-cold diethyl mercaptan were added in rapid succession, and the stopper tightly closed. The mixture was shaken vigorously, the stopper being lifted occasionally to release pressure. A light yellow solution resulted after twenty-five minutes. The mixture was again cooled in an ice–salt bath and 100 cc. of ice water added. A heavy oil settled to the bottom of the bottle. This showed no tendency to crystallize after standing in ice for two hours. It was then separated from the remainder of the liquid, the aqueous layer being extracted twice with small volumes of chloroform. The oil and the combined extracts were dried over anhydrous sodium sulfate. Removal of the chloroform under reduced pressure left 22.5 g. of the oil. This was distilled *in vacuo*. After a small forerun, the bulk of the liquid distilled smoothly at 155–160° (bath, 185°) under a pressure of 3 mm. The fraction distilling at this temperature weighed 15.0 g. The residue in the flask was a dark brown oil. Redistillation of the main fraction under 3 mm. pressure gave 13.2 g. of a light yellow oil boiling at 156–158° (bath, 180–185°). This corresponded to a yield of 40%. The oil is immiscible with water, but miscible with all common organic solvents.

Anal. Calcd. for $C_7H_{16}O_2S_2$: S, 32.66; mol. wt., 196. Found: S, 32.38; mol. wt. (ebullioscopic in benzene), 188.

The dark brown oil which remained from distillation deposited a small quantity of crystals (0.2 g.) after standing in the ice chest for several days. Recrystallization from ethyl alcohol gave small needles melting at 126–127.5° (corr.). The molecular weight as determined by the Rast method was 295. The analysis indicated a sulfur content of 10.6%. It seems probable that this compound is formed by the condensation of several molecules of the diethyl mercaptal.

3-Trityl Glyceraldehyde Diethyl Mercaptal.—A mixture of 5 g. of glyceraldehyde diethyl mercaptal, 8 g. of trityl chloride, and 50 cc. of anhydrous pyridine was allowed to stand in a stoppered flask at room temperature for forty-eight hours. At the end of this time it was filtered to remove a small quantity of trityl carbinol that had precipitated. The filtrate was then slowly dropped into one liter of rapidly stirred ice water. The product first separated as a thick sirup which crystallized entirely within an hour. The solid was filtered off and dried on porous porcelain. The weight of the crude product was 9.0 g. and the melting point was 96.5–98°. After three crystallizations from 80% alcohol, the melting point was constant at 100–101° (corr.). The weight was 5.2 g. corresponding to a yield of 55%. The compound is insoluble in water and petroleum ether, soluble in ethyl and methyl alcohol at the boiling point, and soluble in the common organic solvents at ordinary temperatures. If it is allowed to crystallize slowly from alcoholic solution, it forms large prismatic needles.

Anal. Calcd. for $C_{26}H_{30}O_2S_2$: S, 14.69. Found: S, 14.54.

3-Trityl 2-Acetyl Glyceraldehyde Diethyl Mercaptal.—A mixture of 1.72 g. of the trityl ether, 10 cc. of anhydrous pyridine and 10 cc. of purified acetic anhydride was allowed to stand in a stoppered flask at room temperature for twenty-four hours. The solution was then slowly dropped into 500 cc. of rapidly stirred ice water. After an hour, the product had become almost entirely crystalline. It was filtered off, washed with water, and dried on porcelain. After three recrystallizations from 95% ethyl alcohol, the melting point was constant at 93–94° (corr.). The weight of pure product was 1.50 g., corresponding to a yield of 80%. When the hot alcoholic solution was rapidly cooled, the compound crystallized in tiny needles.

Anal. Calcd. for $C_{26}H_{29}O_2S_2(COCH_3)$: acetyl, 2.08 cc. of 0.1 *N* NaOH per 100 mg.; S, 13.34. Found: acetyl, 2.03 cc., 2.05 cc.; S, 13.40. *Mol. wt.* Calcd. for $C_{28}H_{32}O_3S_2$: 480, Found: (cryoscopic in benzene), 458.

3-Trityl 2-Benzoyl Glyceraldehyde Diethyl Mercaptal.—1.42 g. of the trityl ether was dissolved in 10 cc. of anhydrous pyridine. The solution was cooled in ice and 4 cc. of ice-cold benzoyl chloride added. The mixture was allowed to stand in a stoppered flask at room temperature

for twenty-four hours. It was then slowly dropped into 400 cc. of rapidly stirred ice water. After the mixture had stirred for one hour it was extracted with three successive 50-cc. volumes of chloroform. The chloroform solution was washed successively with water, dilute sulfuric acid, sodium bicarbonate solution and water. After drying over calcium chloride the solvent was removed by a warm air stream. The residue was recrystallized five times from absolute alcohol. The melting point had then become constant at 90–91° (corr.). The weight of the crystalline product was 1.70 g., corresponding to a yield of 97%. The solubility relationships are approximately the same as those of the corresponding acetyl compound. If allowed to crystallize slowly from alcohol, it forms long (1–2 cm.) prismatic needles.

Anal. Calcd. for $C_{33}H_{34}O_3S_2$: S, 11.82. Found: S, 12.01.

Monomeric Glyceraldehyde Diacetate.—8.94 g. of glyceraldehyde diethyl mercaptal and a mixture of 25 cc. of purified acetic anhydride and 25 cc. of anhydrous pyridine were allowed to stand in a stoppered flask for twenty-four hours at room temperature. The mixture was then poured into 500 cc. of ice water. After standing for several hours, this was extracted with five 50-cc. portions of chloroform. The chloroform solution was washed successively with water, dilute sulfuric acid, sodium bicarbonate solution and water. It was dried over calcium chloride. Removal of the solvent left a viscous yellow oil which could not be distilled under the conditions used (2 mm. pressure and bath temp. of 230°). No apparent decomposition took place at this temperature. The weight of the oil was 11.6 g., approaching the weight required if the theoretical quantity of mercaptal diacetate (12.7 g.) were formed. No analytical data were obtained for this compound. It was used directly in the attempt to prepare aldehydoglyceraldehyde diacetate.

After the manner of Wolfrom[6] the above oil and a mixture of 40.4 g. of mercuric chloride in 70 cc. of acetone, 45 g. of cadmium carbonate and 40 cc. of water were vigorously stirred, under mercury seal, for seventy-two hours at room temperature, small amounts of fresh cadmium carbonate being added at intervals. The solution was filtered over cadmium carbonate into a flask containing the same reagent. The solution was evaporated to complete dryness without removing the cadmium carbonate. The residue was repeatedly extracted with chloroform. Concentration of the chloroform solution *in vacuo* left a viscous yellow oil. This was vacuum distilled at a pressure of 3 mm. With a bath temperature of 180–190° a fraction weighing 4 g. distilled at 154–156°. The properties of this oil corresponded to those recorded by Fischer and Baer[7] for monomeric glyceraldehyde diacetate. It rapidly reduced Fehling's solution in the cold. A molecular weight determination (cryoscopic in benzene) gave a value of 168 (calcd., 174).

The following experiments were carried out to establish the identity of the compound. (1) One and one-half grams of the oil was allowed to stand overnight at 0° with 15 cc. of a saturated solution of ammonia in methyl alcohol. The alcohol was removed *in vacuo* and the remaining sirup dissolved in 50 cc. of water. The solution was cooled in ice and a cooled solution of 1.5 g. of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid was added. Precipitation of a yellow crystalline solid began almost immediately, being complete within an hour. The precipitate was washed with water and dried. Recrystallization from 50% alcohol gave 1.0 g. of yellow needles melting at 155° (corr.). This corresponds to the melting point of glyceraldehyde-2,4-dinitrophenylhydrazone as recorded by Fischer and Baer.[8] The mixed melting point with an authentic sample prepared from glyceraldehyde according to the procedure of Fischer and Baer was likewise 155°.

(2) One and seven-tenths grams of *p*-nitrophenylhydrazine and 1.2 g. of the supposed aldehydo-glyceraldehyde diacetate in a mixture of 20 cc. of alcohol and 30 cc. of 3 *N* hydrochloric acid were heated on the water-bath for an hour and a half. Within a few minutes after beginning the heating a dark red precipitate began to form. Precipitation was complete within an hour. The precipitate was washed repeatedly with water and dried on porcelain. It weighed 1.2 g. Recrystallization from ethyl alcohol containing about 10% by volume of pyridine gave blood red needles which melted at 282–286° (block) with previous darkening at 235–240°. This compound is thought to be monoacetyl glyceraldehyde *p*-nitrophenylosazone.

Anal. Calcd. for $C_{17}H_{16}O_6N_6$: N, 21.0. Found: N, 20.8. Calcd. for $C_{15}H_{13}O_5N_6(COCH_3)$: acetyl, 2.50 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 2.60 cc.

Summary

1. The diethyl mercaptal of glyceraldehyde has been prepared. It forms a crystalline trityl ether on reaction with trityl chloride. The trityl ether yields crystalline acetyl and benzoyl derivatives. Attempts to remove the trityl group from these compounds have been unsuccessful.

2. Acetylation of the glyceraldehyde diethyl mercaptal yields an oil which is apparently the diacetate. Treatment of this oil with mercuric chloride and cadmium carbonate in the presence of aqueous acetone yields a compound whose properties correspond to those of a monomeric glyceraldehyde diacetate. The compound reacts with *p*-nitrophenylhydrazine in acid solution to yield what is apparently monoacetyl glyceraldehyde *p*-nitrophenylosazone. This view is supported by our analytical data. Deacetylation of the diacetate yields a sirup which reacts with 2,4-dinitrophenylhydrazine to form glyceraldehyde 2,4-dinitrophenylhydrazone.

Raman Spectra. I. Benzoyl Chloride and Certain of its Substitution Products

BY DOROTHY D. THOMPSON[1] AND JAMES F. NORRIS

For a number of years the relative reactivities of certain bonds in organic compounds have been studied in this Laboratory. The determination of the rates at which a type substance and certain of its substitution products react with a definite compound under fixed conditions led to results that showed the effect of the nature of the substituent and its position on the reactivity of the bond under investigation. In certain cases the relative reactivities determined by rate measurements were compared, with striking results, with the temperatures at which the members of a series containing the same radicals first gave indication of the breaking of the bonds studied.

Among the series of reaction rate measurements was that of benzoyl chloride and its derivatives with methyl alcohol,[2] with ethyl alcohol[3] and with water in the presence of acetone.[4] Although interesting conclusions and comparisons were drawn from these data, no satisfactory interpretation of the results was reached since the mechanism of the reaction was not clearly understood. The differences in rate can be traced to the carbon–chlorine bond if the reaction is either one of simple substitution or one in which an unstable addition compound of the oxonium type is involved. If, however, an unstable compound is formed by the addition of alcohol across the carbonyl, the change in the carbon–oxygen bond is being measured. Or, if the intermediate compound of any type is formed rapidly and decomposed very slowly, the rates would be a measure of the relative reactivities of a bond in the intermediate.[3] Substitution of an atom in benzoyl chloride would alter both the carbon–chlorine and carbonyl bonds. It appeared, therefore, that an examination of the lines in the Raman spectra produced by these groups would add valuable information to this problem because of the following facts.

(1) Harkins and Haun[5] determined the Raman spectra of certain alkyl chlorides. When the positions of the intense lines which give the frequency of longitudinal vibration of the halogen atom with the adjacent $-CH_2-$ group are compared with the rates of hydrolysis of the corresponding halides, a striking relationship appears. In methyl chloride, which is hydrolyzed with difficulty, this line has a displacement of 712 $cm.^{-1}$; the other primary chlorides which hydrolyze more easily have a smaller displacement (around 650 $cm.^{-1}$), which corresponds to a smaller force of binding. The more easily hydrolyzed secondary chlorides have Raman frequencies around 610 $cm.^{-1}$, and the tertiary chlorides which hydrolyze still more readily have a still smaller displacement (560 $cm.^{-1}$). It seemed probable that a similar relationship would be found for the acyl chlorides.

(2) Bourguel[6] compared the effect of different groups in olefins on the strength of the double bonds by a comparison of the displacements of the lines characteristic of the carbon–carbon double bond. This bond is similar to the carbonyl in acyl chloride.

For these reasons measurements of the Raman spectra of a series of acyl chlorides were made and examined. In attempts to determine which lines were associated with the carbon–chlorine bond, the spectra were compared with each other and, in certain cases, with the corresponding ester and aldehyde. On account of the complexity of the problem we are not able, at this time, to identify with any certainty the lines sought.

It was possible to identify the lines produced by the carbonyl linking on account of their isolated position (around 1750 $cm.^{-1}$). There appeared to be no relation between the relative reactivities of the acyl chlorides and the position of these lines.

In order to find out more about any intermediate compound formed, the spectrum of a mixture of benzoyl chloride and ethyl alcohol was photographed as soon as possible after mixing and, later, after the reaction was complete. The first spectrum contained the lines due to the substances present—ethyl alcohol, benzoyl chloride and

ethyl benzoate; the second, the lines of ethyl benzoate and ethyl alcohol. If an intermediate compound had been formed in appreciable quantities as the result of an addition to the carbonyl group, the intensities of the lines corresponding to this group would have changed. This was found not to be the case. An experiment with a mixture of chloral and alcohol gave a spectrum in which lines due to the carbonyl in the aldehyde were not present—a fact which is optical evidence of the absence of a carbonyl linking in chloral alcoholate.

After the work described in this paper was completed, a paper was published by Kohlrausch, Pongratz and Stockmair[7] in which are reported the Raman spectra of a number of derivatives of benzoyl chloride. We had determined some of these and others not reported. In certain cases we found lines not observed by Kohlrausch and in other cases lines are missing in our spectra. It seems advisable to publish all our results so that the data will be available for future interpretation when Raman spectra are better understood.

Experimental

Apparatus.—A Hilger E-439 glass spectrograph was used for these determinations. Although the dispersion is small, the resolution is good and preliminary experiments with a Hilger "Constant Deviation" spectrograph of much higher dispersion showed that the use of fine-grained plates made possible by the large aperture of the former spectrograph gave greater precision than the coarse grained plates made necessary by the slower instrument. The time of exposure varied from one to four hours. Usually both long and short exposures were taken to give the best conditions for reading both the strong and weak lines.

In order to make certain the correct assignment of exciting line to a given Raman line, an efficient system of filters was worked out. Since benzoyl chloride and some of its derivatives are decomposed by ultraviolet light, the compound being investigated was always protected by either Corning "Greenish Nultra" glass (4 mm.) or by a saturated solution of sodium nitrite (2 mm.). These filters also, of course, prevented any Raman lines from being excited by the mercury lines in the ultraviolet. For every compound at least one plate was taken with radiation by both blue and violet mercury light, another with blue light only—the violet light being removed by a solution of quinine sulfate in dilute sulfuric acid. Although this filter was protected from ultraviolet light, there was some yellowing, so the solution was changed every hour. A third plate was taken with light filtered by Corning "Red Purple Ultra" glass (2 mm.) to weaken the blue light.[8] It was found much more efficient for this purpose than iodine in carbon tetrachloride usually recommended.

The photographs were made with Eastman Spectrographic plates—"III-O" for excitation by both blue and violet light, "III-G" for blue radiation alone, "I-O" (because of the density of the filter) for excitation by violet light, and "I-G" for photographs of the nitro compounds.

A Wood's type Raman tube was used with a cooling jacket and an extra jacket for liquid filters. The light source consisted of three Pyrex mercury arcs constructed according to High and Pool running vertically on 110 d. c. at a steady current of 3.5 to 4 amperes, and cooled by an electric fan.

Accuracy.—The accuracy of measuring the plates depends on the intensity and on the sharpness of the lines. The sharp, relatively strong lines were measured with an error of less than ± 1 cm.$^{-1}$, while the error in reading the weak, diffuse lines was sometimes as great as ± 3 cm.$^{-1}$. The values in the tables are weighted averages of at least three values (usually five or six) with the following exceptions: (1) the very weak lines which are not strong enough to appear on the plate when excited by the 4047 Å. line; (2) those in the region 1650–1800 cm.$^{-1}$, which when excited by the 4047 Å. line fall on the plate on top of the very much over-exposed mercury line (4358 Å. group); and (3) those of high frequency, above 2000 cm.$^{-1}$, which when excited by 4358 Å. fall below 4916 Å. where the dispersion is very poor.

The lines on the plate were measured to 0.001 mm. by a Hilger comparator. The wave lengths were determined by reference to three dispersion curves made from the spectrum of an iron arc and the wave numbers were determined (corrected to vacuum) by reference to Kayser's "Tabelle der Schwingungszahlen."[9]

Purification of Compounds.—With the exception of benzoyl chloride, *m*-chloro, *m*-nitro and *p*-nitrobenzoyl chloride which were purchased from Eastman Kodak Company and then highly purified, all of the compounds were prepared by the action of thionyl chloride on the purified acid according to the method previously described.[2] They were distilled under reduced pressure at least three times using a still-head provided with ground-glass joints, and large quantities were prepared, so that only constant boiling middle fractions need be used, thus avoiding the possibility of contamination by thionyl chloride or polymerization compounds.

Explanation of Tables.—The values of the Raman spectra have been summarized in the usual way. The value of the Raman shift in cm.$^{-1}$ is followed by a number in parentheses indicating the relative intensity (estimated)—the large numbers indicating greater intensity and the letter "b" for broad. This is followed by letters indicating the exciting lines as follows: a = 4047 Å., b = 4078 Å., c = 4339 Å., d = 4348 Å. and e = 4358 Å., the symbols ± before a letter indicate that the line appeared both as Stokes and anti-Stokes line.

Preceding the summary of Raman values is a summary of experimental detail. The first

column gives the number of the plate which was measured. Roman numerals refer to earlier work. The second column gives the type of filter used: (G. N., Corning "Greenish Nultra" glass; Q. S., a saturated solution of quinine sulfate in dilute sulfuric acid; R. P. U., Corning "Red Purple Ultra" glass). The type of plate listed in the third column refers to those of Eastman Kodak Company. The fourth column gives the exposure time in hours. The strength of the continuous background was greatest between 4358 and 4916 Å. Column 5 refers to this region. "Very weak" indicates practically no background, and "very strong" that the plate had to be illuminated by a very strong light to see the Raman lines. The spectrograph used was, unless otherwise stated, the Hilger E-439 described above. Some of the earlier investigations, however, were carried out on a Zeiss of low dispersion and on a Hilger Constant Deviation all glass spectrograph having a dispersion two to three times that of the Hilger E-439. The employment of these instruments is indicated in the last column.

Summary

The Raman spectra of the monomethoxy and mononitro (incomplete) substitution products of benzoyl chloride have been determined for the first time. The spectra of benzoyl chloride, its monomethyl and monochloro derivatives have been determined and compared with the data of Kohlrausch, Pongratz and Stockmair.

Alkyl Phenols. I. The 4-*n*-Alkylpyrogallols[1]

BY MERRILL C. HART AND E. H. WOODRUFF

Since Johnson and Lane[2] demonstrated that the introduction of an alkyl group into resorcinol increased its germicidal activity, a vast amount of work has been done on the alkyl mono- and dihydroxy phenols and their derivatives. The literature of the past fifteen years is so voluminous in this respect that no attempt will be made to list it here.

However, during this time the alkylated trihydroxyphenols have received only a haphazard attention. Hurd and Parrish[3] recently reported the phenol coefficients of dihexenyl (2 forms), heptenyl and diheptenylpyrogallol, using *S. Aureus* as the test organism, to be 20 and 250, 120 and 20, respectively. Niederl, Natelson and Beekman[4] prepared diisobutylpyrogallol but have not reported its phenol coefficient. Klarmann[5] gives the phenol coefficients of *n*-hexyl, phenylmethyl, phenethyl and phenylpropyl phloroglucinol as 8 by the Hygienic Laboratory test.

In view of the wide divergence of the phenol coefficients as well as the lack of definite information concerning the variation of activity with structure in the trihydroxy phenols, it was thought to be of interest to prepare a homologous series of alkylpyrogallols and determine their activity as germicides. As is readily seen from Fig. 1, the phenol coefficients vary regularly with increasing length of the alkyl group attached in a manner quite similar to those series already investigated.

Since the maximum germicidal activity against

(5) Klarmann, *ibid.*, **48**, 2359 (1926).

gram negative organisms reaches a maximum with a side chain of five carbon atoms in the monohydroxy phenols and with six carbon atoms in the dihydroxy phenols, it might be expected that the maximum would not occur until a side chain of seven carbons in the trihydroxy phenols. This is not the case, the maximum occurring with a six carbon side chain as in the dihydroxy phenols. In the case of gram positive organisms as indicated by the tests with *S. Aureus* the phenol coefficient continues to rise with the length of the side chain as in the case of other alkylated phenols. The reversal of effectiveness against gram positive and gram negative bacteria occurs with the *n*-hexyl derivative. Thus the "quasi specific" effect as noted by Klarmann[6] in other series is evidenced by the alkylpyrogallols.

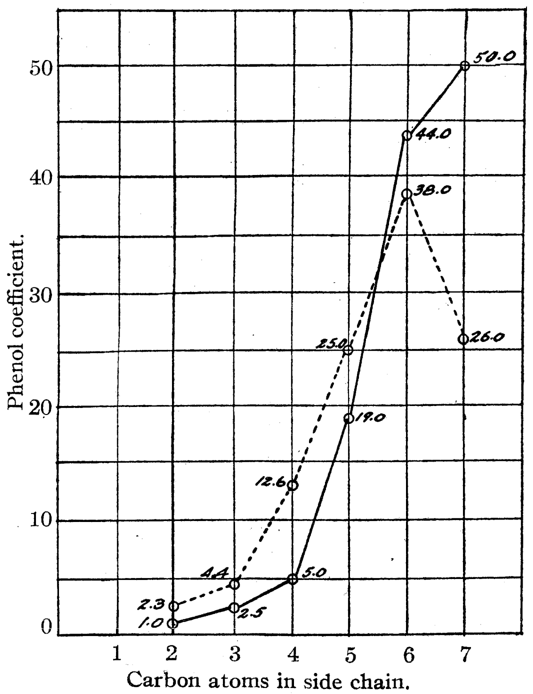

Fig. 1.– – – – –, *B. Coli;* ———, *S. Aureus.*

While the alkylpyrogallols are effective germicides they are not as effective as the alkyl mono- or dihydroxy phenols. The comparison is easily seen in Fig. 2,[7] the comparison being against gram negative organisms. Just why the phenol coefficient should diminish with the increase in number of phenolic hydroxyls, the group presumably responsible for the germicidal property of the molecule, is not clear, and in view of the conflicting theories as to the mode of action of the phenolic germicides, no attempt will be made to elucidate this point.

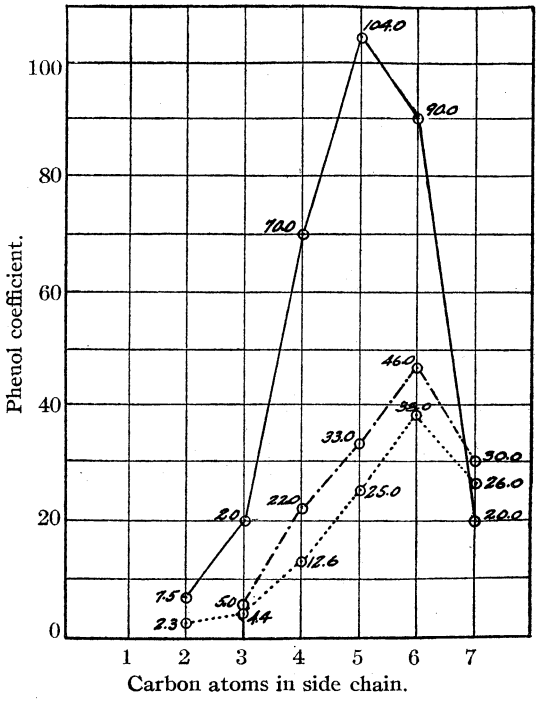

Fig. 2.———, Alkyl phenols, Coulthard, Marshall and Pyman, *J. Chem. Soc.*, 280, (1930); —·—·, alkyl resorcinols [Ref. 8]; ······, alkyl pyrogallols.

None of the alkylpyrogallols are stable in alkaline solution although the rate of oxidation is diminished as the length of the alkyl group attached is increased.

The 4-*n*-alkylpyrogallols were prepared by the reduction of the corresponding ketone by the method of Clemmensen.[8] The ketones were prepared by the method of Nencki, as given by Johnson and Lane[2] and Dohme, Cox and Miller.[9] Difficulty was encountered in the preparation of the C_5 and C_7 ketones and alkylpyrogallols, the yields being appreciably lower than the other members of the series. A similar lowering of the yield was noted by Stoughton, Baltzly and Bass[10] in the case of *n*-amylhydroquinone. Whether the lower yield was due to experimental conditions or a peculiarity of the odd numbered side chain was not investigated.

(7) The bacteriological data from the literature, as recorded in Fig. 2, were obtained by the Hygienic Laboratory method. This is a somewhat different test than the F.D.A. method used here for the alkylpyrogallols. It is not believed that this difference would change the relative order of effectiveness of the alkylpyrogallols with respect to the other two series.

[a] Chloroform. [b] Benzene. [c] Petroleum ether (b. p. 30–60°).

Experimental

2,3,4-Trihydroxyphenyl *n*-Amyl Ketone (Gallcaprophenone).—One hundred and thirty-six grams (1.0 mole) of anhydrous zinc chloride was dissolved in 250 g. (2.1 moles) of caproic acid with the aid of heat, whereupon 126 g. (1.0 mole) of pyrogallol was added. The mixture was heated at 130–140° for one and one-half hours. The unreacted caproic acid was removed by vacuum distillation. The heavy oil was washed several times with water and recrystallized from a mixture of toluene and petroleum ether; yield 68 g. or 32.1%, m. p. 83–85°. Further recrystallizations from the same mixed solvents gave white needles, m. p. 86.5–87°.

4-*n*-Hexylpyrogallol.—Fifty grams of gallcaprophenone was reduced by the method of Clemmensen[8] using 200 g. of amalgamated zinc and 500 cc. of dilute hydrochloric acid (1:1 concd. hydrochloric acid and water). After reduction the cooled solution was extracted with ether, the ether solution dried with anhydrous magnesium sulfate, filtered and the ether removed by distillation. The residual oil was poured into 1 liter of petroleum ether (b. p. 30–60°). The solid obtained melted at 102–103° and weighed 25 g. or 53.4% of the theoretical. After several recrystallizations from a mixture of benzene and petroleum ether (b. p. 30–60°) white needles, m. p. 104–105°, were obtained.

The phenol coefficients were determined by the F. D. A. technique at 37.5° using *S. Aureus* and *B. Coli* as test organisms. The authors wish to thank Dr. John F. Norton and Mr. E. A. Gibson of the Bacteriological Laboratory of The Upjohn Company for the determination of the phenol coefficients, and Mr. C. H. Emerson for the micro analyses given.

Summary

1. The 4-*n*-alkylpyrogallols from C_2H_5 through C_7H_{15} have been prepared and their phenol coefficients determined.

2. The phenol coefficients varied with increasing size of the attached alkyl group in a similar manner to the alkyl mono and dihydroxyphenols.

3. The "quasi specific" effect was found to exist in the alkyl pyrogallols.

4. The phenol coefficient of compounds having the same alkyl group tends to diminish as the number of phenolic hydroxyl groups in the molecule increases.

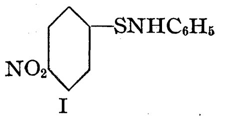
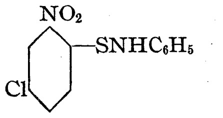
The Molecular Rearrangement of Sulfenanilides in Alkaline Solution. IV

BY MAURICE L. MOORE[1] AND TREAT B. JOHNSON

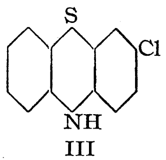
In extending our study of the molecular rearrangement of sulfenanilides in alcoholic alkaline solution, it was interesting to find that the *p*-nitro substituted derivatives of these compounds, I, do not undergo rearrangement to give mercapto-diphenylamine compounds when heated in alcoholic sodium hydroxide solution. This is all the more interesting in view of the fact that Smiles[2] has not, thus far, reported the molecular rearrangement of similar derivatives in the *o*-amino sulfide series, whereas he has done so in the *o*-hydroxysulfones.[3] Thus, 4-nitrophenylsulfen-*o*-chloroanilide, 4-nitrophenylsulfen-*o*-toluidide and 4-nitrophenylsulfenanilide did not undergo structural changes when digested in alcoholic sodium hydroxide solution for three hours. A small amount of the corresponding disulfide was isolated from the reaction mixture, but by far the chief proportion of the recovered product was the unaltered sulfenanilide used as the starting material. Thus, it appears from our results that the substitution of a nitro group in the *p*-position does not give enough activity to the carbon atom at the sulfur linkage to produce a rearrangement as is the case when the nitro group occupies an *o*-position. The latter type of compounds undergo rearrangement upon heating to give the corresponding amino sulfides.



I



II



III

A rearrangement of the 2,4-nitrochlorophenyl derivatives II was observed to occur in the usual manner to give the respective mercaptodiphenylamines. Thus, 2,4-nitrochlorophenylsulfenanilide gave the sodium salt of 2-mercaptophenyl-2′,4′-nitrochlorophenylamine when refluxed in alcoholic sodium hydroxide solution for three hours. This compound was isolated and identified by conversion into its thiomethyl ether. 2-Nitrophenylsulfen-*o*-chloroanilide, 2,4-nitrochlorophenylsulfen-*o*-toluidide and 2,4-nitrochlorophenylsulfen-*o*-chloroanilide underwent a corresponding rearrangement when treated in like manner. In each case the sodium salt of the mercapto compound was isolated as a brilliant red crystalline solid, which was converted into the corresponding thiomethyl ether for characterization by the action of methyl iodide.

This isolation of the sodium salt and the thiomethyl ether by the rearrangement of the 2,4-nitrochlorophenyl derivatives is somewhat in contradiction to the results of Smiles[2c] with the 2,4-nitrochlorophenyl derivatives of the *o*-aminosulfides, as he was unable to isolate the free mercapto-diphenylamine or the thiomethyl ether because of the rapid formation of a thiazine compound III. The latter formation involves the splitting out of nitrous acid.

Experimental Part

2,4 - Nitrochlorophenylsulfen - *o* - chloroanilide.—2,4-Nitrochlorophenylsulfur chloride (25 g.) gave 20 g. of an orange-red glistening crystalline material when treated with *o*-chloroaniline (28 g.) under the usual conditions. It was easily crystallized from boiling alcohol, m. p. 112°.

Anal. Calcd. for $C_{12}H_1O_2N_2SCl_2$: N, 8.89; S, 10.16; Cl, 22.54. Found: N, 8.89, 8.76; S, 10.41, 10.18; Cl, 22.21, 22.40.

Procedure for Rearrangement.—The necessary sulfenanilide (5 g.) was placed in alcohol (25 ml.) containing 20% sodium hydroxide (5 ml.) according to the procedure previously reported[4] and refluxed for three hours. The reaction product was isolated and purified as the sodium salt.

Methylation of the Mercaptan.—The sodium salt from the above operation (5 g.) was dissolved in alcohol (15–25 ml.), refluxed for a short time (fifteen to sixty minutes) with an excess of methyl iodide (3 ml.) and worked up in the usual manner. In certain instances it was found that the thiomethyl ether would separate out of the hot alcohol after refluxing for varying lengths of time (fifteen to sixty minutes).

In Table I are recorded the results of the rearrangement of different sulfenanilides under the influence of alkali.

Summary

Digestion of *p*-nitrophenyl derivatives of sulfenanilides in alcoholic sodium hydroxide solution

failed to bring about a rearrangement to their corresponding *o*-mercaptodiphenyl amines. The 2,4-nitrochlorophenyl derivatives, however, undergo a rearrangement to *o*-mercaptodiphenylamines when so treated, and it was possible to isolate the sodium salt as well as the thiomethyl ether without cyclization to thiazine compounds. The study of sulfenanilides will be continued in this Laboratory.

Natural and Synthetic Rubber. XVI. The Structure of Polystyrene

BY THOMAS MIDGLEY, JR., ALBERT L. HENNE AND HENRY M. LEICESTER

Polystyrene[1] is a friable solid which exhibits rubber-like properties at temperatures above 65°; it is obtained by heat polymerization of styrene.

Staudinger and his co-workers[2] have stated that polystyrene can be decomposed by heat into a mono-, di- and tristyrene; that the latter two compounds can be decomposed to monostyrene; and that 2,4-diphenyl-1-butene and 1,3-diphenylpropane can be detected among the heat decomposition products. They have therefore reached the conclusion that polystyrene is a long chain of styrene units bound together by ordinary valences, with a phenyl group linked to every second carbon. They have advocated formula I and rejected formula II.

$$\text{—CH}_2\text{CHPhCH}_2\text{CHPhCH}_2\text{CHPh—} \qquad \text{(I)}$$

$$\text{—CH}_2\text{CHPhCHPhCH}_2\text{CH}_2\text{CHPhCHPhCH}_2\text{—} \qquad \text{(II)}$$

Staudinger's experiments were repeated and found to be correct but the following additional facts were noted: (1) heat decomposition of polystyrene does not yield monostyrene exclusively; (2) rapid decomposition yields large amounts of monostyrene, while slow decomposition yields "di-styrene," "tri-styrene" and other intermediate products; (3) the partially decomposed products are complicated mixtures, and their further decomposition gives a poor yield of monostyrene; (4) diphenylbutene and diphenylpropane are present in very small quantities, and only in products obtained from incomplete decomposition; (5) all efforts to analyze the dimeric fraction by oxidation, reduction, nitration, bromination, etc., gave indifferent results. These additional experimental data cast strong doubts on the significance of the decomposition products in establishing the formula of polystyrene.

An explanation of dependence of the elasticity of natural and synthetic rubbers on their structural formula has been offered by Mack.[3] The application of his ideas to the case of polystyrene leads directly to the conclusion that the elastic properties of this substance are consistent with formula II, and not at all with the heretofore accepted formula I, for the following reasons.

In the case of formula I, the 1,3-placement of the phenyl groups results in optimum packing of the phenyl groups, optimum contacting of the hydrogen atoms, and good satisfaction of the van der Waals forces *when the chain molecule is extended;* consequently there is no tendency to fold

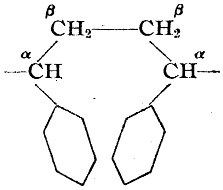
(3) Mack, THIS JOURNAL, **56**, 2757 (1934).

or shorten the chain. But in the case of formula II, the 1,4-placement throws the phenyl groups together into pairs on adjacent carbon atoms, with two chain carbon atoms separating these pairs. Not only do the two phenyl groups within a pair turn into one another to establish better contacting, but van der Waals forces draw together into contact the various separate pairs, thus folding the extended chain and giving automatic retraction, hence elastic, rubber-like behavior. The motion of the bulky phenyl groups is sluggish at room temperature, but becomes more free and more swift with increasing thermal agitation, *i. e.*, at higher temperature.

Since Staudinger's reasons for discriminating against the formula required by Mack's theory were not found convincing, it was decided to apply to styrene the experimental procedure previously used with isoprene and dimethylbutadiene to establish the course of their transformation into synthetic rubber and methyl rubber, respectively.[4] This procedure consists in stopping the polymerization at the dimeric stage by addition of nascent hydrogen generated by the interaction of sodium and ethanol. Sodium chips are added to styrene and alcohol is fed at a rate sufficient to produce a lively evolution of hydrogen; the reaction liberates a considerable amount of heat, but the boiling of the alcohol automatically regulates the temperature. The reaction products consist of about 75% of ethylbenzene and 25% of 1,4-diphenylbutane. Significant is the fact that the reaction products are pure and entirely free from isomers or by-products.

The course of the polymerization is interpreted as follows. If the thermal agitation of the liquid styrene molecules consisted only of Dulong and Petit motions, back and forth, polymerization could take place by the random linking of two carbon atoms in α-position (with regard to the phenyl group), two carbon atoms in β-position, or one α- and one β-atom, and consequently the two phenyl groups of the dimeric compounds would be located in 1,4-, 2,4- or 2,3-position. The molecules are, however, in a liquid, and therefore crowded; they are thus compelled to rotate about the center of their own volume, that is, close to the center of the phenyl group. Then, no matter how the rotation occurs, the β-carbon atoms, at the end of the side-chain, are the only ones which can eventually come close enough to link. The chances of an α-carbon coming close enough to a β-carbon of another molecule to link are very remote, and its chances of coming close enough to another α-carbon are nil, because in addition to being shielded by the bulky phenyl group, it is most effectively buried within the sphere of revolution established by the outlying CH_2 group. As soon as two molecules have linked together the dimeric compound assumes a shape such as:[5]



where the free bonds of the α-carbon atoms are now at the surface and ready to join with the bonds of another dimer. From this stage the process of polymerization takes place by mere repetition.

It is therefore concluded that formula II is the correct representation of polystyrene and that Mack's explanation of its elasticity is consistent with the facts. This conclusion has been obtained in private discussion with Dr. Mack, whom we wish to thank.

Experimental

Preparation of Diphenylbutane with Sodium and EtOH.—Alcohol was added dropwise to 17 g. (20 cc.) of freshly distilled styrene and 5.3 g. of sodium chips at such a rate that hydrogen was steadily evolved. During the first part of the reaction, it was necessary to cool the mixture occasionally. As the reaction proceeded the solution became brown and sodium alcoholate separated, so that when all the sodium had been used up, the reaction mixture was almost solid. Ether was then added and the solution washed three times with water and dried over calcium chloride. The combined ether extracts from three runs (totaling 62 g. of styrene) were fractionated. Two fractions were obtained, one boiling at 135–150°, the other at 304–308°. The latter solidified in the receiver. The first fraction weighed 46 g. (74%) and consisted of ethylbenzene containing almost no styrene, as shown by the facts that no polymerization occurred when sulfuric acid was added to the liquid, or when it was heated for a prolonged period of time. The solid material, which weighed 11.5 g. (18.5%) after crystallization from alcohol, melted sharply at 52–52.5°, and the melting point showed no depression when the crystals were mixed with 1,4-diphenylbutane prepared by the catalytic reduction of 1,4-diphenylbutadiene.[6] The mother liquors from the crystallization were di-

luted with water and extracted with ether. From the extract was obtained 2 g. (4.3%) of a semi-solid yellow oil from which more 1,4-diphenylbutane separated.

Summary

Styrene treated with sodium and alcohol gives 75% of ethylbenzene and 25% of 1,4-diphenylbutane. This shows that polystyrene should be represented by formula II, in opposition to the heretofore accepted formula I. Only formula II is consistent with Mack's explanation of the rubber-like elastic properties of polystyrene.

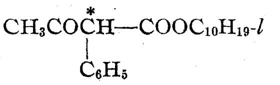
A Comparison of the Rate of Racemization with the Rate of Enolization

BY R. H. KIMBALL

It has long been assumed that optically active ketones, esters and acids can undergo racemization through formation of the inactive enol, which reverts to the racemic mixture. General acceptance of this mechanism has followed recognition of the fact that such substances can only be racemized when they are capable of enolization. This has been confirmed recently by Conant and Carlson,[1] who conclude that the rate of racemization can be considered as the rate of enolization, and point out the significant fact that whatever mechanism is assumed the rate of enolization cannot be faster than that of racemization, since the enol is necessarily inactive.

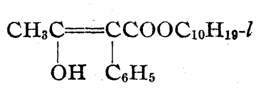
Whether enolization can be *slower* than racemization can only be determined by measuring the loss of optical activity and the development of enol simultaneously by independent methods. The familiar Kurt Meyer method of bromine titration has been applied in the past to measurement of the rate of enolization of acetoacetic ester and related substances.[2] An unsuccessful attempt to combine this method with polarimetric measurements has been described by Wren,[3] who tried to follow the development of enol during the racemization of methyl phenyl succinate by bromine titration, but failed because no detectable amount of enol was present. The difficulty has been that substances appreciably enolized racemize so easily that they cannot be obtained optically active; while substances which can be obtained optically active are not perceptibly enolized.

The substance employed in the present attack on the problem is the menthyl ester of α-phenylacetoacetic acid[4] I.



$CH_3CO\underset{C_6H_5}{\overset{*}{C}H}{-}COOC_{10}H_{19}\text{-}l$

I



$CH_3\underset{OH}{C}{=}\underset{C_6H_5}{C}COOC_{10}H_{19}\text{-}l$

II

The form of this substance obtained by crystallization from methyl alcohol is the ketonic modification, as demonstrated by the fact that the fresh solution gives no color with ferric chloride and does not absorb bromine.

Freshly dissolved in benzene or alcohol the substance is dextrorotatory. The rotation at once starts to decrease, passing through zero and finally reaching a constant strongly levo value. This takes weeks without a catalyst, but addition of a small amount of piperidine or barium hydroxide brings it to equilibrium in a few minutes.

Rupe[4] interpreted this to mean that the active menthol has brought about resolution of the α-phenylacetoacetic acid, the form crystallizing from methyl alcohol being the dextro-keto modification I because of its dextro rotation—a long series of similar menthyl esters in which resolution is not possible being strongly levorotatory like menthol itself. He ascribed the mutarotation to formation of the enol II in which the optical activity of the alpha carbon atom is lost. Since only one of the three asymmetric carbon atoms is affected, this is not a true but a partial racemization, and at equilibrium the solution will contain the enol mixed with the diameric dextro-keto and levo-keto modifications.

In the usual true or partial racemization the proportion of enol is always negligible. Here on the contrary the enol steadily increases during the mutarotation until it constitutes the major part of the equilibrium mixture. The most significant comparison between the rate of this development of enol and the rate of racemization of the carbon atom involved will be made during

the early stages of the reaction, when the reverse processes are not yet apparent and the change of *d*-keto to enol is the only thing taking place.

With this in view the solvent chosen was cyclohexane, in which enolization is 71% complete at equilibrium. About 10 g. of pure crystalline *d*-keto form was weighed into a volumetric flask and made up to 100 cc. with pure cyclohexane containing a few parts per million of piperidine as the catalyst. The solution was quickly transferred to an all-glass polarimeter tube with an attached chamber, water-jacketed to maintain constant temperature and designed to permit frequent and thorough mixing of the solution (Fig. 1). Polarimeter readings were taken at intervals through the first half of the racemization.

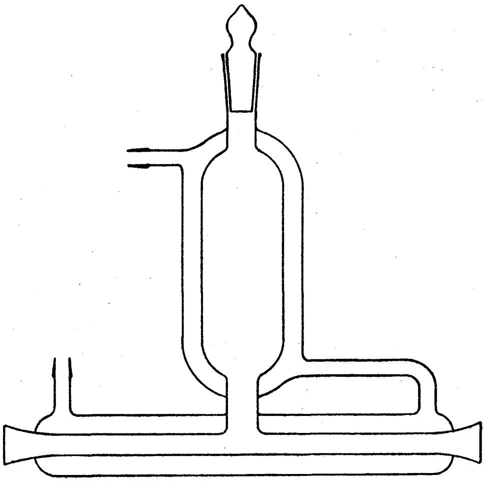

Fig. 1.—Polarimeter tube.

The development of enol was followed by pipetting out samples of the solution and titrating them with dilute alcoholic bromine to the first bromine color, the "direct" method of Kurt Meyer. Here it proved very satisfactory since the bromine was absorbed rapidly in the cold, and the sharp end-point persisted for five minutes. Finally more catalyst was added and the reaction was allowed to run to equilibrium, to obtain the values for the rotation and for the concentration of enol.

The pseudo-unimolecular velocity constant $k_1 + k_2$ for the racemization was obtained in the ordinary way by plotting the values of log $(\alpha_t - \alpha_{eq.})$ against t, where α_t and $\alpha_{eq.}$ represent the polarimeter readings at time t and at equilibrium. For the enolization the volume of thiosulfate used by each sample is proportional to the concentration of enol, so that log $(V_{eq.} - V_t)$ was plotted against t. The best straight lines were run through these points and $k_1 + k_2$ calculated from the slope in the usual manner. For both the racemization and the enolization the points fell closely along straight lines (Fig. 2, A and B) and the reactions therefore follow the unimolecular law. Measurements normally extended over a period covering the first half of the racemization and the first quarter of the enolization, in one case the racemization being followed to 80% completion and the enolization to 50% completion without the appearance of a trend.

The data for three runs with varying amounts of catalyst are summarized in Table I.

TABLE I

VELOCITY CONSTANTS × 10^4 TIME IN MINUTES FOR THE RACEMIZATION AND ENOLIZATION OF MENTHYL α-PHENYLACETOACETATE I

Run no.	I	II	III
Approx. concn. piperidine in parts per million	8	10	12
$k_1 + k_2$ for racemization	12.8	17.8	24.8
$k_1 + k_2$ for enolization	3.72	6.64	8.02
k_1 for enol. (graphically)	2.51	4.48	6.17
k_1 for enol. (calculated)	2.59	4.71	6.34
k_1 polarimetrically using α_{enol}	14.5	20.1	28.5
k_r (total racemization)	8.22	16.3	21.6
k_{dl} (racem. through ion)	5.47	10.5	14.3
k_e (racem. through enol)	2.75	5.80	7.32
Ratio k_{dl}/k_e	1.99	1.82	1.95

It is evident that racemization as measured by $k_1 + k_2$ proceeds several times as fast as enolization. However, a much more significant comparison can be made. If the *d*-keto form loses its activity through changing directly to the enol, the rate of this change k_1 can be obtained from data taken in the early stages of the reaction, and it should have the same value by both methods of measurement.

For the enolization k_1 is easily determined by plotting the log of the concentration of keto against t in the usual way. The points still fall on a straight line through the measured range (Fig. 2, D) and the slope of this line gives the values of k_1 for enolization shown in Table I.

It is also possible to calculate k_1 from the two equations for $k_1 + k_2$ and for the equilibrium constant in the usual way, and the values are in satisfactory agreement.

To measure the rate of change of *d*-keto to enol polarimetrically, it is necessary to know the rotatory power of the pure enol. Attempts to isolate the enol by chemical methods failed, shift to the equilibrium mixture taking place too easily.

Distillation under a high vacuum from a Hickman molecular still was finally successfully employed. The crystalline keto form was catalyzed with a little barium hydroxide and distilled slowly, yielding a uniform distillate containing 64% of enol, which probably represents the equilibrium in the vapor phase.[5] This mixture was repeatedly fractionated in the absence of catalyst, the distillate becoming progressively richer in enol until the concentration reached 93.8%, which apparently represents a constant boiling mixture. This is a colorless viscous oil, hardening to a glass at low temperatures without crystallization; it has the same composition as the ketonic form, gives an immediate deep purple color with ferric chloride, and absorbs bromine rapidly in the cold. Alone or in solution it is very stable in the absence of catalyst, but with a trace of piperidine it undergoes mutarotation to the same equilibrium mixture reached by the *d*-keto form.

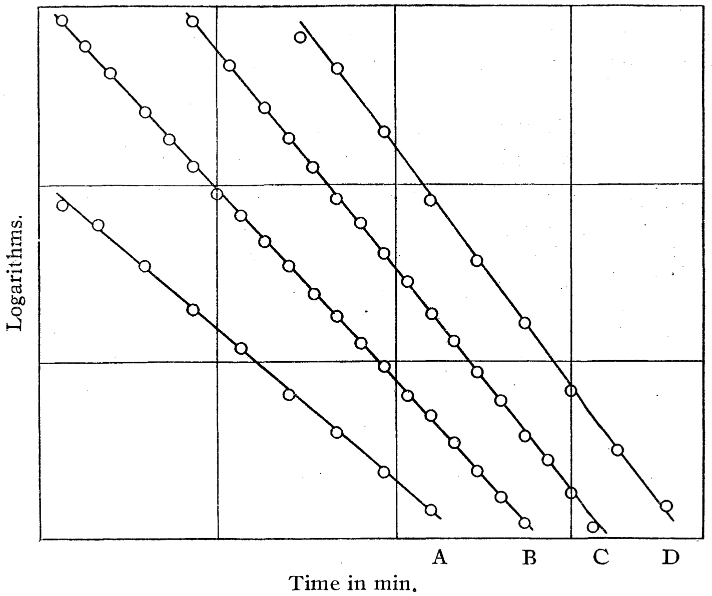

Fig. 2.—Graph of run III: A, $k_1 + k_2$ for enolization ($\times 10^4$) = 8.02; B, $k_1 + k_2$ for racemization = 24.8; C, k_1 polarimetrically using α_{enol} = 28.5; D, k_1 for enolization (titrimetrically) = 6.17. Range of measurement: A and D 3–18% enol; B and C 7–65% racemization. Time scale: unit square = 150 min. Logarithm scale: unit square for A = 0.0600; for B and C = 0.1500; for D = 0.0300.

The value for the rotation of pure enol was obtained by following this mutarotation in cyclohexane by the polarimeter and by titration in the usual way. On plotting this series of values for decreasing enol content against the rotation, a nearly straight line was obtained and extrapolated to the rotation of pure enol as shown in Fig. 3. The accuracy of this extrapolation is favored by the small change in rotation, and the value obtained $[\alpha]^{25}\text{D}$ −56.5° should be close to the true rotation of the enol.

The rate of change of *d*-keto to enol can now be determined polarimetrically by substituting α_{enol} for $\alpha_{eq.}$ and plotting log ($\alpha_t - \alpha_{enol}$) against t (Fig. 2, C). The points still fall along a straight line through the first half of the racemization, and the slope of this line gives values for k_1 (Table I) which are four or five times as large as the values of k_1 for the same change of *d*-keto to enol obtained by titration.

There seems to be no doubt therefore that in this substance the alpha carbon atom loses its optical activity much faster than the enol is produced. This can hardly be explained by some means of racemization operating independently of the enolization, in view of the almost inseparable connection between the two processes.[6] As the only alternative it is evident that *enolization cannot consist of a simple reversible change of keto to enol, but must proceed through some intermediate step.* In this intermediate step the configuration of the alpha carbon atom is destroyed, and since only part of the active substance changing to the intermediate in a given time goes on to form enol, and part reverts to *inactive* keto, the rate of racemization will be faster than the rate of enolization.

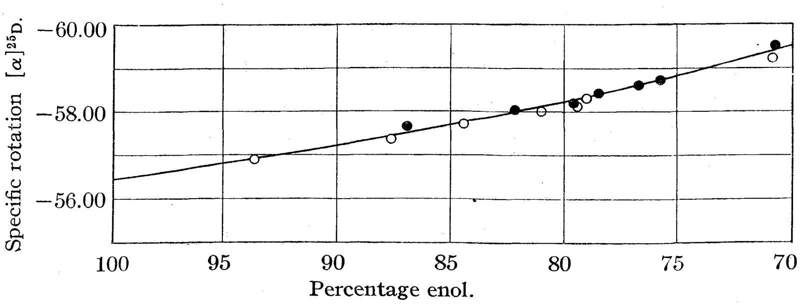

Fig. 3.—Mutarotation of constant boiling mixture extrapolated to 100% enol to obtain $[\alpha]^{25}\text{D}$ − 56.5°: ○, run I; ●, run II.

(5) Conant and Thompson, THIS JOURNAL, **54**, 4039 (1932).

(6) Conant and Carlson, THIS JOURNAL, **54**, 4048 (1932); discussion by Wagner-Jauregg in "Stereochemie," ed. Freudenberg, Franz Deuticke, Vienna, 1933, p. 858.

The relationship between racemization and enolization from the standpoint of the ionic theory of prototropic change has been discussed recently by Ingold and collaborators[7] in several papers which appeared during the course of this work. They formulate the mechanism of keto-enol tautomerism under the influence of a basic catalyst in the usual way[8]

$$B + H{-}C{-}C{=}O \rightleftarrows BH + [C{-}C{=}O]^- \rightleftarrows B + C{=}C{-}OH$$

and point out that if the configuration of the alpha carbon atom is retained in the common ion, the rate of enolization and of racemization should be equal; on the other hand, if the asymmetry is lost in the common ion, the rate of racemization must exceed that of enolization.

They tested the question in the methyleneazomethine system

$$C(H){-}N{=}C \rightleftarrows C{=}N{-}C(H)$$

by comparing the rate of racemization of an active tautomeride under the influence of sodium ethoxide with the rate of its isomerization as determined by chemical analysis. In three cases the rates were identical within the experimental error, and the authors conclude that in this system the intermediate anion does not attain kinetic freedom and therefore retains its optical activity up to the instant of transformation into the inactive isomer.

In the base-catalyzed keto–enol system now under consideration the racemization takes place much faster than the formation of enol; and some intermediate stage in the process unavoidably must be recognized. If the ionic mechanism is adopted it follows that contrary to the situation in the methyleneazomethine system the intermediate anion does not retain its asymmetry, so that recombination with the proton gives both enol and *racemized* keto forms and accounts for the higher rate of racemization.

The existence of some supplementary means of racemization apart from conversion to the enol makes it obvious that the values of k_1 so far obtained do not express the true rate of racemization nor its relationship to the rate of enolization. Both can be calculated, however, from the data at hand as follows.

Adopting some form of intermediate as necessary to acount for the results, the racemization of the menthyl ester is represented by scheme (1), where D, L, E and B represent, respectively, the *d*-keto form, the *l*-keto form, the enol and the intermediate, presumably the common anion. In the ordinary partial racemization such as the inversion of menthone where the amount of E is always imperceptible, the measured "rate of racemization" is simply the rate at which the original rotation of D changes to the rotation of the equilibrium mixture DL. As each molecule of D reacts it becomes part of the equilibrium mixture, so we can consider the *original* active substance D* as changing *irreversibly* to DL at a rate k_r equal to the measured rate of racemization.

$$\begin{tikzcd} D \arrow[r, shift left, "k_1"] & B \arrow[l, shift left, "k_3"] \arrow[r, shift right, "k_4"'] \arrow[d, shift right, "k_5"'] & L \arrow[l, shift right, "k_2"'] \\ & E \arrow[u, shift right, "k_6"'] & \end{tikzcd} \qquad (1)$$

$$\begin{tikzcd} D^* \arrow[r, "k_r"] & B \arrow[r, "k_3 + k_4"] \arrow[d, "k_5"'] & DL \\ & E & \end{tikzcd} \qquad (2)$$

$$\begin{tikzcd} & DL \\ D^* \arrow[ur, "k_{dl}"] \arrow[dr, "k_e"'] & \\ & E \end{tikzcd} \qquad (3)$$

$$k_{dl} + k_e = \frac{2.3}{t} \log \frac{C_{0D^*}}{C_{D^*}} \qquad (4)$$

$$\frac{k_{dl}}{k_e} = \frac{C_{DL}}{C_E} \qquad (5)$$

Representing the case at hand in the same way reduces (1) to (2), for early stages of the reaction where k_6 can be neglected. And since B changes immediately to DL and to E as fast as it is produced from D*, the effect is that of a direct change of D* simultaneously to DL and to E as shown in (3), where $k_{dl} + k_e = k_r$ the total rate of racemization, and $k_{dl}/k_e = (k_3 + k_4)/k_5$. The individual rates can now be obtained from equations (4) and (5), where C_{0D^*}, is the concentration of D* at t_0 and C_{D^*}, C_{DL} and C_E are the concentrations of D*, DL and E at any given time t.

In order to calculate these concentrations it is necessary to know the specific rotation of each substance. $[\alpha]_{D^*}$ and $[\alpha]$E are already known and $[\alpha]$DL can be obtained from the composition and rotation of the equilibrium mixture of DL and E resulting from complete racemization. From first principles it is apparent that in system (1) the *relative* proportions of D and L at equilibrium are independent of the presence or amount

---

[7] Ingold and Wilson, *J. Chem. Soc.*, **93**, 773 (1934); Hsü, Ingold and Wilson, *ibid.*, 1778 (1935); Hsü and Wilson, *ibid.*, 623 (1936).

[8] *Cf.* Bartlett, THIS JOURNAL, **56**, 969 (1934); Watson, Nathan and Laurie, *J. Chem. Phys.*, **3**, 170 (1935); Watson and Yates, *J. Chem. Soc.*, 1208 (1932); Pedersen, *J. Phys. Chem.*, **38**, 619 (1934).

of E or of the mechanism involved. The same mixture of D and L would result if E were negligibly small as in the ordinary partial racemization; therefore it corresponds exactly to the DL of schemes (2) and (3). Making the usual assumption that the rotations are additive in these dilute solutions, and knowing $[\alpha]E$ and the concentrations of E and DL in the equilibrium mixture, $[\alpha]DL$ can be obtained by difference. In the three runs $[\alpha]DL = -67.4, -67.8$ and $-68.5°$, respectively, the individual values being used in each case. For the others the values $[\alpha]E = -56.5°$ and $[\alpha]D^* = -15.8°$ (average) were employed.

The next step toward applying equations (4) and (5) is the calculation of C_{D^*}, C_{DL} and C_E at time t, which will be illustrated for run III. Here $C_{0D^*} = 10.584$ (g. in 100 cc. of solution), t_0 = time when *d*-keto was put into solution, and t was chosen as three hundred and fifty minutes, close to the half time of racemization. From the straight lines plotted for $k_1 + k_2$ of racemization and of enolization (B and A, Fig. 2) were read off the correct values for the rotation ($\alpha D^* + \alpha DL + \alpha E = -10.30°$) and for the concentration of enol ($C_E = 1.903$ g.) at time t. Subtracting C_E from the total concentration 10.584 g. gives equation (6).

$$C_{D^*} + C_{DL} = 8.681 \text{ g.} \qquad (6)$$
$$0.3707\ C_{D^*} + 1.603\ C_{DL} = 7.79° \qquad (7)$$

Subtracting the rotation of 1.903 g. of enol (αE) from $-10.30°$ gives $\alpha D^* + \alpha DL = -7.79°$, which by the use of $[\alpha]D^*$ and $[\alpha]DL$ can be expressed as equation (7). Solving these two equations we now have $C_{0D^*} = 10.584$, $C_{D^*} = 4.972$, $C_{DL} = 3.709$, $C_E = 1.903$, and $t = 350$. Substituting these values in equations (4) and (5) and solving, $k_r = k_{dl} + k_e = 21.6$, $k_{dl} = 14.3$, and $k_e = 7.3(\times 10^{-4})$. The values obtained in the same way for runs I and II are shown in Table I, together with the ratios of k_{dl} to k_e which are close to 2 : 1 and check satisfactorily. From the previous discussion it is evident that k_r is comparable to the rate measured in the ordinary partial racemization; k_{dl} represents the fraction of this racemization (around two-thirds) taking place through the common ion without involving the enol; and k_e the fraction (around one-third) involving actual transformation to the enol.

It seems quite probable that racemization may take place in a similar way in ordinary ketones where no detectable enol ever appears. The fact that only part of the racemization can be ascribed to "enolization" in the usual sense of the word calls into question the validity of the familiar principle that the rate of racemization can be considered as the rate of enolization. The ability of a substance to ionize and the stability of the configuration of the common ion may be the important factors governing its racemization, rather than the actual formation of molecular enol.

The other reaction of ketones commonly regarded as a measure of enolization is halogenation in the α-position to the carbonyl group.[7-9] Recent comparisons have shown that the rate of halogenation and the rate of racemization of optically active ketones are substantially equal both in the presence of acids and of bases,[10] and the suggestion has been made that the halogen actually adds to the intermediate ion, at a rate equivalent to the rate of ionization. Since it now appears that under basic catalysis ionization alone can result in racemization, the rate of halogen absorption may be a measure of racemization (k_r) but not of enolization (k_e) in the sense of actual formation of molecular enol. The more "saturated" character of the intermediate ions or salt-like complexes generally postulated in acid catalysis[7,8,10] would seem to favor a more stable configuration. Rate measurements now being made of the racemization and enolization of the menthyl ester in the presence of acids may serve as a test of this question.

In another respect, however, the present results are difficult to interpret by the ionic theory of prototropic change. On general grounds Ingold and his collaborators[7] have concluded that in basic catalysis the reversible change from anion to enol must be very much faster than that from keto to anion, so that the observed rate of racemization should be substantially equal to the rate of enolization. The same opinion has been expressed by Pedersen[8] from the fact that rapid addition of a hydrochloric acid–bromine water mixture to an alkaline solution of acetoacetic ester indicated complete transformation of the anion to the enol.

In the case at hand, however, the anion apparently reverts to the keto form twice as fast as

it goes on to the enol. In scheme (1) k_5 is less than $k_3 + k_4$, but the amount of enol at equilibrium is greater than the amount of keto; it follows that $k_1 + k_2$ is greater than k_6, or the *keto form ionizes more rapidly than the enol.* This surprising result may perhaps be explained by the fact that enols of this type probably have a chelated structure, in which the mobility of the hydrogen may be reduced even below that in the ketonic form.

These considerations point to an alternative explanation of the observed difference between the rate of racemization and the rate of enolization of the menthyl ester. We may be dealing with a rapid and highly reversible shift to a small amount of open-chain enol which governs the racemization, followed by a slower accumulation of chelated enol which determines the rate measured by titration. It is hoped that further studies now in progress may aid in answering this and related questions.

Experimental

Acetobenzyl Cyanide, $CH_3COCH(C_6H_5)CN$.—Reagents must be pure and free from water and acids. Ethyl alcohol was dried twice over quicklime. Ethyl acetate was washed and fractionated from phosphorus pentoxide collecting over 0.5° range. Benzyl cyanide was freshly distilled at ordinary pressure and collected over 1.5° range.

Sixty-nine grams (3 moles) of sodium is dissolved in 870 cc. of dry alcohol, and a mixture of 351 g. (3 moles) of benzyl cyanide and 264 g. (3 moles) of ethyl acetate added, the mixture refluxed for an hour and allowed to stand overnight. The solid sodium derivative is quickly dissolved by adding 1.5–2 liters of water at 25°, and cracked ice added to keep the solution ice cold. It is washed with ether and air drawn through the solution under a partial vacuum till free from ether. A cold mixture of 195 cc. of acetic acid and 600 cc. of water is added slowly with shaking and the precipitated acetobenzyl cyanide filtered off and washed. It is purified by dissolving in 800 cc. of hot methyl alcohol, boiling with Norit if necessary, diluting with warm water and cooling; yield 300–310 g. (63–65%) of colorless material m. p. 88.5–89.5°.

Alpha-Phenylacetoacetic Ester, $CH_3COCH(C_6H_5)COOC_2H_5$.—The low yields of the previous methods[4,11] are avoided by hydrolyzing the imido ester in aqueous acid where the insolubility of the product protects it from decomposition.

A solution of 159 g. (1 mole) of acetobenzyl cyanide in 403 cc. of dry alcohol is saturated in the cold with carefully dried hydrogen chloride. After five to eight hours saturation is complete and the flask is allowed to stand overnight at room temperature with occasional shaking for the first hour.

Excess hydrogen chloride is removed by adding boiling chips and evacuating the flask in a water-bath at 40°. Two hundred grams of sodium carbonate is dissolved in 1200 cc. of water and ice added. Into this the reaction mixture is poured with vigorous shaking, the liberated imido ester extracted at once with generous portions of ether, and the ether washed well to remove alcohol.

The imido ester is extracted from the ether and hydrolyzed as follows: 100 g. of 98% C. P. sulfuric acid is poured into 700 cc. of water, and excess ice stirred in. The ether is shaken with cracked ice till cold, and the water separated. About one-half of the ice-cold acid is added, shaken vigorously for exactly fifteen seconds[12] and drawn off at once. The operation is repeated with the remaining acid in two portions. The ether is washed with sodium bicarbonate and dried over sodium sulfate, and yields 20–30 g. of crude α-phenylacetoacetic ester on distillation.

The solution of imido ester sulfate quickly turns cloudy from hydrolysis to the product. This is completed by heating on the steam-bath to 50° for one-half hour, separating the ester and reheating the aqueous layer vigorously for forty-five minutes. Extraction with ether and fractional distillation *in vacuo* yields 103–167 g. (50–81%), b. p. 139–143° (12 mm.).

Menthyl α-Phenylacetoacetate, I.—A mixture of 100 g. of α-phenylacetoacetic ester (freshly distilled) and 94 g. of *l*-menthol (E. K. Co., C. P.) in a 250-cc. modified Claisen flask with a wide side-arm is heated to 150–160° (thermometer in the mixture) for three hours.[4] The excess menthol is removed on the water pump and the menthyl ester distilled on the oil pump between 140–155° (0.5 mm.). From this mixture rich in enol the *d*-keto form is obtained by the asymmetric isomerization which takes place on slow evaporation of a methyl alcohol solution of the oil from an open dish at room temperature, adding alcohol at intervals to maintain a crystalline mush which favors the separation of the less soluble *d*-keto form. After a week or more the accumulated solid is purified by rapid recrystallization five or six times from pure methyl alcohol. The filtrates evaporated slowly in the same way yield a larger crop of pure product, and the process can be continued till most of the material is obtained as the pure *d*-keto form.

Menthyl α-phenylacetoacetate I crystallizes in long colorless prisms melting not quite sharply at 77–78.3° in Pyrex capillary tubes (67–76° in soft glass—Rupe[4] gives 69°). A fresh solution does not absorb bromine and gives no color with ferric chloride, slowly turning deep purple as enolization sets in. It is not completely stable and was always recrystallized shortly before use.

Contrary to Rupe[4] the substance is dextrorotatory in alcohol. Since his alcoholic solution gave an immediate color with ferric chloride it was doubtless partially racemized. This or the use of soft glass melting point tubes may also explain the lower melting point (69°) reported by him. Other constants check satisfactorily.

Enol, %	64.7	71.0	72.8	73.2	73.9

Enolic Form of Menthyl α-Phenylacetoacetate, II.—The pure *d*-keto form racemized quickly at 100° but only slowly at 80°. Since it could not be distilled below 135° by ordinary methods, high vacuum distillation was employed, using a butyl phthalate condensation pump[13] and Hickman high vacuum still (Fisher model) heated by a small metal bath with a tall closed can between dish and flame for even temperature control. In general about 50–60 g. of pure *d*-keto form was catalyzed with a pinch of barium hydroxide and distilled slowly at 85–95°, coming over as a colorless oil with a uniform enol content of 64%. This was redistilled in two portions without catalyst and the first half or two-thirds collected and redistilled in the same way. The temperatures varied from 75–85° (bath temp.) at 2–6 × 10^{-4} mm. pressure. As the fractions became too small they were combined with others of the same grade from additional runs. Four or five fractionations increased the enol content to 92–94%, the highest which could be reached by distillation. Repeated attempts failed to increase this by fractionation under the most favorable conditions; for example, 12 g. containing 93.4% enol was distilled and the first 3.5 g. collected contained 93.8% enol. That this was not the result of ketonization during distillation but shows the presence of a constant boiling mixture of keto and enol was confirmed by distilling 23 g. containing 92% enol and separating it into six fractions which contained, respectively, 93, 90, 94, 93, 89 and 75% of enol. The proportion of enol in the distillate was therefore constant until two-thirds of the material had distilled over, and the effect of ketonization only became apparent in the last two fractions.

This constant boiling mixture contains 93.8% enol as the average of fourteen preparations. It is a colorless viscous oil, hardening to a glass at low temperatures, and is isomeric with the ketonic form.

Anal. Calcd. for $C_{20}H_{28}O_3$: C, 75.9; H, 8.9. Found: C, 75.7; H, 8.8.

Fresh solutions give an immediate deep purple color with ferric chloride and absorb bromine rapidly in the cold. It is quite stable in the absence of catalyst, showing little or no decrease in enol content after two weeks in the refrigerator. A 10% solution in cyclohexane showed a constant rotation $[\alpha]^{25}\text{D}$ −56.9° for an hour but on the addition of a trace of piperidine it mutarotated to the same equilibrium mixture reached by the keto form: from enol $[\alpha]^{25}\text{D}$ −59.2°, −59.5°; 70.9, 70.7% enol; from keto $[\alpha]^{25}\text{D}$ −59.8°; 71.0% enol.

The specific rotation of pure enol was obtained by following the mutarotation in cyclohexane polarimetrically and by titration exactly as described below for the ketonic form. In run I the catalyst was added after the first point (Fig. 3) had been obtained. In run II the catalyst was mixed with the solvent as customary with the keto form and mutarotation had proceeded somewhat before the first reading.

Purification of Materials. Methyl Alcohol.—C. P. absolute acetone-free methanol was distilled three times through an all-glass Pyrex apparatus with a 6-ball Snyder column rejecting about one-third. This was used in the titrations and all apparatus was rinsed with it just before use and dried in a current of air or by evacuation.

Cyclohexane.—E. K. Co. Pract. was treated to remove benzene,[14] washed with potassium hydroxide solution, dried and distilled through the all-glass fractionating apparatus, then a second time over potassium hydroxide and twice alone and obtained constant boiling. In this solvent mutarotation was so slow as to be insignificant compared to the catalytically induced rates.

Piperidine.—The unsaturates present in commercial C. P. piperidine were removed by differential oxidation of nitrosopiperidine[15] and fractionation from potassium hydroxide, yielding material boiling at 105.4–105.7° and stable toward permanganate. The amount used was regulated by adding small drops of a 1:100 solution in cyclohexane.

Rate Measurements.—From 10.0–10.6 g. of freshly recrystallized menthyl ester was weighed into a 100-cc. Pyrex volumetric flask and made up to volume with cyclohexane containing the piperidine catalyst. The solution was quickly transferred to the polarimeter tube (Fig. 1) and reading started, using a Franz Schmidt & Haensch half shade polarimeter read to 0.01° and a G. E. Sodium Lab-Arc. The temperature was held at 25 ± 0.1° by circulating water from the thermostat through the polarimeter tube jacket. The total change of rotation in the 2.340-dm. tube was 10.5° and some 20–30 readings were taken in the range between 7–15 and 50–65% racemization.

The enolization was followed over the same period. At intervals the solution was shaken and 5 cc. removed with a Pyrex pipet, run into 13 cc. of ice-cold methyl alcohol, and titrated with fresh methyl alcoholic bromine of such strength that 10–20 cc. was required. Bromine was absorbed instantly and was added to the first bromine color. The end-point was sharp and persisted for five minutes, and could be restored for an equal time by an additional drop or two of bromine. A correction was applied for the excess of bromine by subtracting the amount needed to bring an equal volume of methyl alcohol to the same color. This corrected volume was run into double the equivalent amount of 0.2 *N* potassium iodide and titrated with standard 0.05 *N* thiosulfate. From seven to nine titrations were made covering the increase from about 3 to 17% of enol.

The equilibrium values for rotation and enol content were obtained by adding more piperidine and allowing the mixture to stand at constant temperature. A series of concordant readings twelve hours apart were accepted as the equilibrium rotation and four of five titrations checking to about 1 part in 100 gave the average per cent. of enol.

Summary

1. Simultaneous measurements have been made of the rate of racemization and of enoli-

zation of menthyl α-phenylacetoacetate.

2. The results show that enolization takes place through some intermediate step. In this step nearly two-thirds of the racemization occurs, only one-third involving actual transformation to the enol.

3. Alternative explanations are offered, one involving loss of configuration in an intermediate anion, the other reversible formation of a small amount of open-chain enol followed by a slower accumulation of chelated enol.

The Determination of Activity Coefficients from the Potentials of Concentration Cells with Transference. II. Hydrochloric Acid at 25°

BY THEODORE SHEDLOVSKY AND DUNCAN A. MACINNES

In the first article of this series[1] it was shown that the activity coefficients, f, of chlorides in aqueous solution could be obtained from the potentials, E_t, of galvanic cells of the type

$$\text{Ag; AgCl, MCl } (C_1)\text{: MCl } (C_2)\text{, AgCl; Ag} \qquad \text{(A)}$$

with aid of the relation

$$E_t = \frac{2RT}{F}\int_{C_1}^{C_2} t \, \mathrm{d} \log Cf \qquad (1)$$

in which t is the transference number of the positive ion constituent, M, C is the concentration, and the other terms have their customary significance.[2]

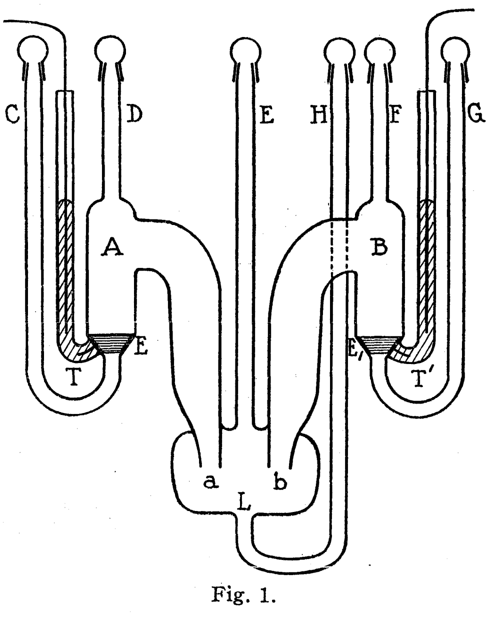

Fig. 1.

However, cells of type A contain a liquid junction and, until the present researches, have not been used to obtain activity coefficients. It was therefore decided to include hydrochloric acid in the series of measurements since the activity coefficients of that substance have been determined, with considerable accuracy, by various workers, using concentration cells without liquid junction of the form

$$\text{Ag; AgCl, HCl } (C_1)\text{; } H_2 \text{ (Pt)} - \text{(Pt) } H_2\text{; HCl } (C_2)\text{, AgCl; Ag} \qquad \text{(B)}$$

Since cells of type B do not involve amalgam electrodes, with their attendant experimental difficulties, this case affords the most favorable comparison of the methods involving cells with and without liquid junction.

This paper will therefore deal with the determination of the potentials of the cell

$$\text{Ag; AgCl, HCl } (C_1)\text{: HCl } (C_2)\text{, AgCl; Ag} \qquad \text{(C)}$$

in which C_2 varied from about 0.003 to 0.08 N, and C_1 was 0.1 N. The results have afforded a test of the Debye-Hückel relations connecting the activity coefficients of aqueous solutions of hydrochloric acid with the concentration.

Apparatus and Experimental Procedure

Although the principle involved is the same as that utilized in the work of Brown and MacInnes[1] decided changes have been made in the apparatus used. The new cell is shown diagrammatically in Fig. 1. Instead of forming the silver–silver chloride electrodes on wire, as in the previous work, hollow truncated cones of platinum foil, indicated at E and E', are used. The outer surfaces of these cones are sealed into the glass, contact being made with the mercury in tubes T and T'. The chief advantage of electrodes of this design is that they are completely protected from mechanical disturbance of their active surfaces. This we have found to be essential if the reproducibility is to reach 0.01 mv. or better. The electrodes are plated with silver and chloridized electrolytically, using the precautions suggested by Brown.[3] It is also found desirable to wash the plated silver with

(3) Brown, THIS JOURNAL, **56**, 646 (1934).

strong ammonia, followed by water, before chloridizing. This assures the removal of the last possible traces of silver cyanide. In filling the cell it is first turned upside down. Solution is run into half-cell A, for instance, through either tube C or D (from a flask of the type shown in Fig. 3 of the article by Brown and MacInnes[1]), and out of the other tube or tube E. Several thorough rinsings are given, after which the half-cell is filled to the point a. The half-cell B is then filled in a similar manner with the second solution. The apparatus is then turned from its inverted to its normal position. A liquid junction is next made at a or b by flowing the heavier of the two solutions through tube H and filling the connecting vessel L. Unless pendent drops are present at a and b air bubbles form that rise through the connecting tubes and mix the solutions. Such pendent drops may be readily formed if necessary by a momentary lifting of an appropriate ground glass cap. The apparatus is next placed in an oil thermostat regulating to ±0.002° and readings of the potential are available as soon as the cell has reached its final temperature. These readings remain constant, within a few microvolts, for many hours. This constancy is due to the fact that the only important source of variation of potential is a change of composition of the solution in immediate contact with the electrodes, such as could be brought about by diffusion or convection. An advantage of this apparatus and procedure over that of Brown and MacInnes is that by avoiding the sliding contact in making the liquid junctions a source of contamination from the grease is avoided.

There is usually a slight difference of potential (of the order of 0.01 mv.) between the electrodes E and E′ which may be corrected for in two ways. In the first place, this potential is measured directly by placing the same chloride solution in both halves of the apparatus. In addition measurements with each pair of solutions are made which are duplicates but with the positions of the solutions reversed. Since the design of the apparatus is symmetrical this is possible. The difference between the potentials of these duplicate determinations should be twice the directly measured difference of potential of the electrodes. This was true within a few microvolts for all the measurements described in this paper.

The potential measurements were made with a calibrated type K potentiometer. The potential standard consisted of five Eppley saturated Weston standard cells kept at 25° in the thermostat. The standard cells were calibrated by the Bureau of Standards.

Results and Discussion

The results of all the measurements are given in columns 1 and 2 of Table I. The solutions of the concentrations given in moles per liter at 25° were prepared by weight from constant boiling acid[4] and their compositions were checked by conductance measurements.[5] As indicated, one of two solutions in the cell was always 0.1 N hydrochloric acid. The water used had a conductance of $2 \pm 1 \times 10^{-7}\ \Omega^{-1}$. Since the greater part of this conductance was due to traces of carbon dioxide the effective conductance of the solvent in the acid solutions was less than this value, and the correction (discussed in the previous paper) for solvent impurities is therefore negligible even at the lowest concentrations.

The method for obtaining the change Δf of the activity coefficient with the concentration from the e. m. f. data, using equation (1), is given in the previous paper.[1] The necessary transference numbers, given in column 3 of the table, are interpolated from the work of Longsworth.[6] The resulting values of $-\Delta \log f$ relative to 0.1 N are given in the fourth column. To obtain activity coefficients f from these data use may be made, as in the earlier paper, of a plot, Fig. 2, of $(\Delta \log f - \alpha \sqrt{C})$ against $(A - \Delta \log f)\sqrt{C}$ in which α is the constant (0.5056 at 25°) of the Debye–Hückel equation

$$-\log f = \alpha \sqrt{C}/(1 + \beta \sqrt{C}) \qquad (2)$$

The constant (A), which is the logarithm of the activity coefficient of the reference 0.1 N hydrochloric acid solution, must be obtained by a short series of approximations in which the value of A chosen finally agrees with the intercept of the plot. The slope of the straight portion of the curve for the lower concentrations yields the constant β of equation (2). The plot yields a value of $A = -0.0973$ from which the activity coefficients f (observed) in column 5 of Table I were obtained from the relation

$$\log f = A - \Delta \log f \qquad (3)$$

The constant β has a value of 1.847, corresponding to a distance of closest approach of 5.62 Å. for the ions. With this value of β equation (2) represents the data up to about 0.04 normal, as is shown in column 6 of the table. Agreement throughout the whole concentration range measured can be obtained, however, with the aid of the Hückel equation

$$-\log f = \alpha \sqrt{C}/(1 + \beta \sqrt{C}) - DC \qquad (4)$$

As is also the case with sodium chloride[1] it is necessary to shift the value of β in order to fit this equation to the results. The computed values of f, using equation (4) and the constants $\beta = 1.527_4$ and $D = 0.105$, are given in the last column of the table. These computed values agree with the "observed" values in column 5 throughout the range of the measurements.

The most extensive study of cells without liquid junction involving hydrochloric acid has been made by Harned and Ehlers.[7] From their critical summary of their work they have obtained potentials at round molalities from which e. m. f. values of cells of type B may be computed, making allowance for the difference in the concentration scales used in our work and theirs. These results are also plotted in Fig. 2, using the A value given above. It will be seen that there is substantial agreement in the results from the cells with and without liquid junction. Less complete agreement, though probably within the limits of error of the available data, is found with the earlier critical summary of results from cells without liquid junction by Scatchard.[8] Carmody[9] gives his results on cells without liquid junctions only to 0.1 mv. and a plot of his figures indicates errors greater than that amount. However, if allowance is made for this rather large experimental error there is substantial agreement between his results and ours. The deviation produced by an error of 0.1 mv. is shown in the figure.

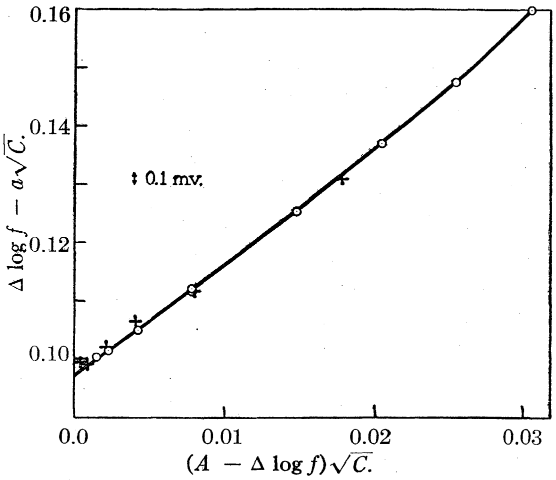

Fig. 2.— O, Shedlovsky and MacInnes; +, Harned and Ehlers.

Summary

Accurate measurements of hydrochloric acid concentration cells, with liquid junction, have been obtained, from which activity coefficients of the ions of the acid have been computed. The results are shown to be in close agreement with those obtained using cells without liquid junctions. The activity coefficients have been found to follow the Debye–Hückel theory with a "distance of closest approach" of 5.62 Å., up to about 0.04 N. Accurate agreement with the Hückel equation is observed throughout the concentration range of 0.003 to 0.1 N.

Partial Vapor Pressures of Aqueous Methylamine Solutions

BY W. A. FELSING AND B. A. PHILLIPS

Object of the Investigation

The purpose of this investigation was the determination of the partial vapor pressures of aqueous solutions of mono-, di- and trimethylamines. This investigation was one of a series[1] dealing with the thermodynamic properties of these amines in relation to their use as refrigerating fluids in the absorption type of refrigerating units. The completeness of the absorption of the gaseous refrigerant by the aqueous absorber can be ascertained from the data of this investigation.

In calculating the free energy decrease attending the reaction Amine (liquid) = Amine (1 *M*), it was found that vapor pressure data for trimethylamine were lacking, except for a few scattered boiling point determinations. Accordingly, the vapor pressures and the densities of liquid trimethylamine were determined.

Incidentally, since no free energy content data for these amines are available in the literature, the data of this investigation yield information leading to a partial determination of such values. A high temperature dissociation investigation, of exploratory nature, has yielded some preliminary data for the calculation at 25° of the free energy content of these gaseous amines; the results of this investigation will be reported in a later paper.

Previous Investigations

No data have been found for the partial vapor pressures of aqueous amine solutions.

Vapor pressure data for monomethylamine have been reported by Felsing and Thomas;[1] for dimethylamine, there are the data of Berthoud;[2] and for trimethylamine, there were found no data.

Density data for liquid trimethylamine also are very meager. Landolt–Börnstein, "Tabellen," list 0.675 g./cc. at $-4°$, Lange[3] gives 0.662 at $-5°$, and Elsey[4] gives a value of 0.702 g./cc. at $-33.5°$.

Methods of the Investigation

(a) The method of determining partial vapor pressures of the aqueous amine solutions was the dynamic or air-saturation method originally developed by Berkeley and Hartley.[5] The method embodied the modifications of Washburn and Heuse[6] and of Bates and Kirschman;[7] additional modifications were made during the investigation, but they were concerned more with minor details of size and design than with departures from the principles of the later modifications listed.

The process consisted of passing, at an optimum rate, an unmeasured volume of dry air through a series of saturators containing pure water and the solutions whose vapor pressures were to be measured. The weights of water vapor carried out by the gas from the pure water saturator, w_1, the weight of the amine absorbed by the acid absorber and the weight of the water carried out from the solutions, w_2, and the barometric pressure, p_B, were the measurements actually made.

A rocking device ensured the continual presentation of a fresh liquid film to the air passing through three sets of saturators in series. The air passed over but not through the liquids. Water vapor was removed by dehydrite-filled absorbers and the amines were absorbed by double, acid-containing absorbers. The rate of air flow varied from 1 to 5 liters per hour for periods of approximately four to five hours, depending upon the particular amine and its concentration. The whole apparatus was immersed in a thermostat maintained at 25 ± 0.05°.

The amine solutions were prepared by dissolving in cold distilled water the gaseous amines generated from C. P. Eastman hydrochlorides by concentrated potassium hydroxide solution. Standard acid and base solutions used in absorption and in titration were prepared from tested C. P. reagents and standardized against each other and against C. P. sodium carbonate. Weight burets were used throughout. The indicator was

methyl red, as recommended by Treadwell and Hall[8] and by Thompson.[9]

(b) The vapor pressures and the densities of pure liquid trimethylamine were determined by the method of Felsing and Thomas.[1]

The Results Attained

(a) **The partial pressures** of the amines were determined at four concentrations; four to six acceptable determinations were made at each concentration, the mean of which is reported in the table. The partial pressures were calculated by the relation

$$P \text{ (amine from solution)} = \frac{p_w \dfrac{N_2}{N_1}\left[1 - \dfrac{(1 - F)p_w}{p_B - p_w}\right]}{1 + p_w \dfrac{N_2}{N_1}\left[\dfrac{1}{p_B - p_w}\right]}$$

in which F is the ratio p_s/p_w, where p_w is the vapor pressure of pure water at 25° and p_s the partial water vapor pressure of the amine solution and N_2/N_1 is the ratio of the number of moles of amine to water. It was assumed that the vapors of the amines consisted of simple, non-associated molecules and that they obeyed the ideal gas law.

The following table presents the partial vapor pressures of the amines from their solution as calculated by means of the relation above.

Concn. (molar)	p, mm.	p/c, obsd.	"Best" K
	Monomethylamine		
0.250	1.88	7.52	
.525	4.01	7.64	
1.030	8.03	7.79	
2.205	17.08	7.75	7.75
	Dimethylamine		
0.261	2.81	10.76	
.500	5.59	11.18	
.952	10.62	11.15	
2.379	25.58	10.75	11.15
	Trimethylamine		
0.248	16.93	68.26	
.538	38.30	71.18	
1.071	72.67	67.85	
1.961	133.10	67.86	67.87

The value of "best" K was obtained by plotting the data and determining the equation for the "best" straight line that could be drawn through the data; a straight line represents best the data over the range investigated.

(b) **The vapor pressures** of liquid trimethylamine were measured over a temperature range of −20 to +45°. The following equation represents the data obtained, approaching equilibrium at each temperature from above and below: $\log_{10} p(\text{mm.}) = -1410.5/T + 8.57435 - 0.0021158T$. The over-all accuracy of these data is believed to be better than 1 part in 2500. The normal boiling point calculated by this relation is 2.90°.

The densities of liquid trimethylamine were determined over the same temperature range as were the vapor pressures. The relation which reproduced the observed data is density (g./cc.) $= 0.87406 - 4.433 \times 10^{-4}\,T - 1.29236 \times 10^{-6}\,T^2$. This relation presents true values of the density, it is believed, to within 1 part in 5000.

Derived Quantities

(a) **The Free Energy of Solution.**—The partial vapor pressures of the amine solutions at exactly 1 molar were determined, by interpolation, to be 7.60 mm. for the mono-, 11.64 mm. for the di- and 67.64 mm. for the trimethylamine. With the aid of these data, the following free energy values were calculated for the reaction: Amine (760 mm.) = Amine (1 M) + $(-\Delta F)$. The values of $-\Delta F$ were found to be 2727 cal./mole for the mono-, 2502 cal/mole for the di-, and 1434 cal./mole for the trimethylamine.

From the sources cited and from the data of this investigation, the vapor pressures of the three liquid amines at 25° were found to be 2681 mm. for the mono-, 1763 mm. for the di- and 2299 mm. for the trimethylamine. From these values, the free energy decrease attending the change Amine (p, mm.) = Amine (760 mm.) was calculated and then combined with the preceding free energy value to yield the free energy decrease attending the change: Amine (liquid) = Amine (1 M) + $(-\Delta F)$. The results attained for $-\Delta F$ were 3474 cal./mole for the mono-, 2991 cal./mole for the di-, and 2090 cal./mole for the trimethylamine.

(b) **Heat of Vaporization of Trimethylamine.**—

$$\Delta H_v = T(v_2 - v_1)\,\mathrm{d}p/\mathrm{d}T$$

The exact Clapeyron equation was applied at the normal boiling point, 2.90°. The molal volume of the vapor, v_2, was calculated by means of the ideal gas law, since data for another equation of state were lacking, and the molal volume of the liquid, v_1, was calculated from the experimental density relation. The heat of vaporization was thus found to be 95.6 cal./g. or 5706 cal./mole.

Summary

1. The partial vapor pressures of aqueous solutions of mono-, di- and trimethylamine have been determined over a range of concentration from approximately 0.2 to 2.5 *M*.

2. The vapor pressures and the densities of liquid trimethylamine have been determined over a temperature range from −20 to +45°.

3. Certain free energy values and other derived quantities have been calculated from the data of the investigation.

[CONTRIBUTION FROM FERTILIZER INVESTIGATIONS, BUREAU OF CHEMISTRY AND SOILS, U. S. DEPARTMENT OF AGRICULTURE]

The System Magnesium Sulfate–Urea–Water at 30°

BY COLIN W. WHITTAKER, FRANK O. LUNDSTROM AND JAMES H. SHIMP

Urea and magnesium sulfate are now common constituents of mixed fertilizers. The urea is introduced as a source of nitrogen either in the form of crystal urea or as a solution of urea in ammonia. Magnesium sulfate is an impurity in much of the crude potash imported for fertilizer use and is, therefore, often included in mixtures incidentally. The recent emphasis on the importance of the lesser elements in fertilizer practice has, however, resulted in the occasional use of magnesium intentionally as calcined kieserite or as crude potassium magnesium sulfate or in other forms. Dolomite has been found superior to calcite in some types of mixed fertilizers, and magnesium is now being introduced into mixtures quite extensively in that form. It is possible also for magnesium sulfate to be formed *in situ* by chemical reactions occurring in the mixture. It has recently been found that magnesium phosphate is formed from dolomite under certain conditions[1] and it is not unlikely that this compound would react with the calcium sulfate present in most mixed fertilizers to form magnesium sulfate and one of the calcium phosphates. In view of these considerations, a knowledge of the equilibria in the system magnesium sulfate–urea–water is an aid in understanding the chemistry of mixed fertilizers. The present paper presents data establishing the 30° isotherm in this system.

Experimental

Materials.—Urea was recrystallized from water. In order to avoid any possibility of hydrolysis the temperature of the solution was always kept below 60°. The magnesium sulfate was also recrystallized from water under such conditions that the heptahydrate was obtained. Both compounds were dried *in vacuo* over sulfuric acid, the urea completely and the heptahydrate sufficiently to permit approximation of the amounts taken.

Methods of Analysis.—Urea was determined by the modified urease procedure recently described by Yee and Davis[2] except that 0.025 *N* sodium hydroxide was used to improve the accuracy of titration. Carefully calibrated burets were used. All pipets and other volumetric glassware used bore the official Bureau of Standards stamp. The urease enzyme has been reported to be sensitive to various salts and the effect of added magnesium sulfate was, therefore, determined. It was found, using about 0.15 g. of urease and digesting for twenty-five to thirty minutes, that amounts of magnesium sulfate several times greater than the urea present did not interfere. Tests of the method on the recrystallized urea described gave results ranging from 99.6 to 99.8% urea. These slightly low values are in agreement with those obtained by Yee and Davis and by Dalman,[3] who used the Fox and Geldard[4] modification of the urease procedure. Yee and Davis attribute the slightly low results to impurities in the urea rather than inaccuracy of the method, an opinion in which the writers concur.

Magnesium was weighed as magnesium hydroxyquinolate. If the solution contained urea, the aliquot was evaporated to dryness, the urea destroyed by digestion to dryness with aqua regia and the magnesium sulfate taken up with water. This preliminary destruction of urea was decided upon after experiments had shown that urea interfered slightly when determining high concentrations of magnesium sulfate. All precipitations of magnesium as the quinolate were made in the presence of ammonium acetate by adding sufficient ammonium hydroxide to give a *p*H of at least 9.5 to the solution containing 8-hydroxyquinoline and previously heated to 60–70°. The solution was filtered on a tared fritted glass filter (10G3), the precipitate washed with 1:40 ammonium hydroxide and dried to constant weight at 135°. The procedure was tested by analyzing a pure magnesium sulfate solution by the procedure just described and by evaporating an aliquot to dryness, adding a little sulfuric acid and heating to constant weight at 450°. Satisfactory agreement was obtained.

Perhaps the best check on both analytical methods is the good agreement obtained for the solubilities of urea and of magnesium sulfate with those reported in the literature as described below.

Preparation of Equilibrium Solutions.—The systems to be studied were prepared by mixing amounts of the three components sufficient to give convenient quantities of solution and of solid phase after establishing equilibrium conditions. The components were taken in such proportions that the composition of the resulting saturated solutions fell in the desired portion of the curve. Usually each solution was used for determining two to four points on the isotherm, additional magnesium sulfate heptahydrate or urea being added after each determination in order to adjust the composition in the desired direction. It was, of course, necessary to consider the water of crystallization when adding $MgSO_4 \cdot 7H_2O$.

All mixtures were stirred in glass containers in a thermostat, the temperature of which was constant to ±0.01° and was exactly 30°, as closely as it could be read on a Bureau of Standards calibrated thermometer graduated to 0.1°. The stirrers were motor driven and operated through mercury seals to keep out dust and laboratory fumes. In most cases the mixtures were stirred for three to five hours, allowed to stand overnight, stirred another two to three hours and sampled after being allowed to settle. That equilibrium was obtained is indicated by the following. Two solutions analyzed after stirring for three to five hours and standing overnight showed no significant change in composition on an additional three to five hours of stirring and again standing overnight. Some of these solutions were so viscous that settling was extremely slow. Over part of the urea branch of the curve the solid phase floated on top. Suitable precautions were taken to prevent contamination of the liquid samples with the solid phase.

Solubility of Magnesium Sulfate and of Urea

As a check on the entire procedure the solubilities of magnesium sulfate and of urea at 30° were determined. The solubility of magnesium sulfate was found to be 28.42% by weight (average of four determinations). This is higher than the value of 28.05 obtained by interpolation between the values for 29.89 and 34.72° obtained by Ting and McCabe[5] but agrees well with the value of 28.43% (3.30 moles per 1000 g. water) given by the "International Critical Tables."[6]

The solubility of urea at 30° was found to be 57.0% (average of three determinations). The best value to take from the literature is somewhat of a problem. By plotting log N (mole fraction of urea) against $1000/T$, using what Shnidman and Sunier[7] term their best data, the value of 57.08 was obtained. Similar plotting of the data of Dalman[8] gave the value of 57.15%. Pinck and Kelly[9] report a higher value of 57.63%, while graphical interpolation of the data of Speyers[10] and of the "International Critical Tables"[11] yields the lower figure of 56.59%.

These results for magnesium sulfate and urea having indicated that the technique in general was satisfactory, the 30° isotherm of the system was studied. The identification of solid phases was accomplished in the usual way by analysis of the wet solid phase and the use of extrapolated tie lines.

Discussion

The results are shown in Table I and are plotted in Fig. 1. The curve shows three branches, corresponding to the stable solid phases $MgSO_4 \cdot 7H_2O$, $MgSO_4 \cdot CO(NH_2)_2 \cdot 3H_2O$, and $CO(NH_2)_2$.

TABLE I

(11) "International Critical Tables," Vol. IV, McGraw-Hill Book Co., Inc., New York, New York, 1928, p. 251.

The tie lines do not all pass exactly through the points corresponding to the composition of the three solid phases mentioned, but it must be considered that the analytical errors become greatly magnified as the tie lines are extended. No evidence of the existence of solid phases other than the three mentioned was obtained. So far as the writers are aware, the compound $MgSO_4 \cdot CO(NH_2)_2 \cdot 3H_2O$ has not been reported previously.

A curious feature of this isotherm is the practically unchanged solubility of magnesium sulfate over a wide range of urea concentration (0–21%). Mixtures of solid urea and $MgSO_4 \cdot 7H_2O$, of such composition that the resulting equilibrium solution falls in the range represented by the middle branch of the isotherm, at first go completely or almost completely into solution, but on continued stirring the reaction

$$MgSO_4 \cdot 7H_2O + CO(NH_2)_2 = MgSO_4 \cdot CO(NH_2)_2 \cdot 3H_2O + 4H_2O$$

takes place quite rapidly and is probably complete in an hour or so after it starts. The crystals of the complex so obtained are very small. Attempts to prepare large crystals for detailed examination have, so far, been unsuccessful.

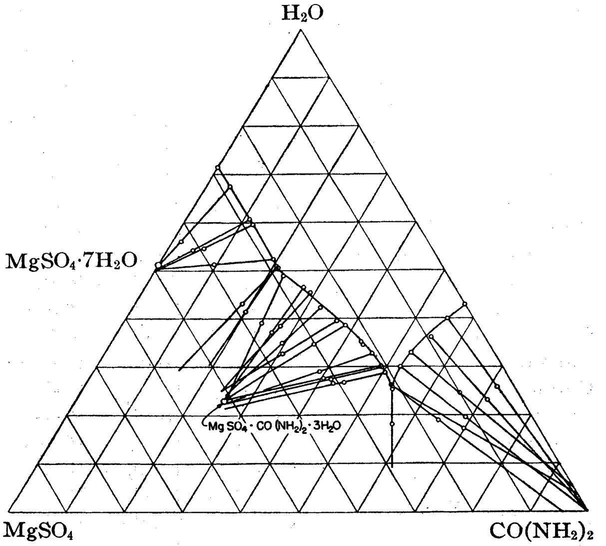

Fig. 1.—The system magnesium sulfate–urea–H_2O at 30°.

Summary

Data were obtained establishing the 30° isotherm of the system magnesium sulfate–urea–water. It was found to consist of three branches corresponding to the solid phases $MgSO_4 \cdot 7H_2O$, $MgSO_4 \cdot CO(NH_2)_2 \cdot 3H_2O$ and $CO(NH_2)_2$.

Optical Crystallographic Data for Some Salts of the Cinchona Alkaloids

BY MARY LOUISE SHANER AND M. L. WILLARD

Introduction

Very few data on the optical properties of the salts of quinine, quinidine, cinchonidine and cinchonine can be found in the literature. Groth,[1] Poe and Swisher,[2] Wright,[3] and Wherry and Yanovsky[4] have listed some optical properties of these four alkaloids. However, the information is very scant.

Many salts of quinine were available, while just a few of quinidine, cinchonidine and cinchonine could be obtained. All salts were of commercial origin.

Optical Crystallographic Data

The optical properties, given in the table, were determined by methods given by Chamot and Mason.[5] Refractive indices were determined by the Becke line method. In several cases it was impossible to determine the indices because the crystals dissolved in the immersion oils. The quartz wedge and selenite plate were used in various determinations.

The fluorescence of the salt and its aqueous solution were determined by means of an ultraviolet lamp.

All crystals were found to be biaxial and to give parallel extinction, except in the case of quinine bihydrochloride carbamate and quinine tetrasulfate where oblique extinction was obtained. The sign of elongation was positive in all cases except quinine nitrate and picrate.

Summary

The crystallographic data for four cinchona alkaloids—quinine, quinidine, cinchonine and cinchonidine—have been worked out. The fluorescent properties in ultraviolet light also have been determined.

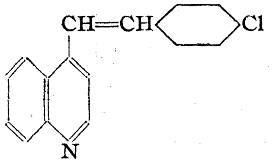
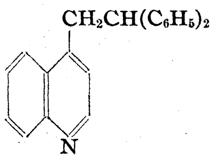
The Addition of Benzene to Benzalquinaldines and Benzallepidines

BY REYNOLD C. FUSON, L. L. ALEXANDER, ELLSWORTH ELLINGBOE AND ARNOLD HOFFMAN

The conversion of benzalquinaldines[1] and similarly constituted compounds[2] into the corresponding α-benzohydryl derivatives appears to involve a reversible 1,4-addition of aromatic compounds to conjugated systems. The principle of vinylogy[3] suggests that a similar result might be obtained with benzallepidines in which the reaction would depend on a reversible 1,6-addition. To test this, benzallepidine and *p*-chlorobenzallepidine (I) were prepared and subjected to the treatment with benzene in the presence of aluminum chloride and hydrogen chloride. A compound corresponding to the expected α-benzohydryllepidine (II) was produced. The action of phenylmagnesium bromide likewise converted benzallepidine into a compound with the same composition as II. The two products proved, however, to be isomeric rather than identical.



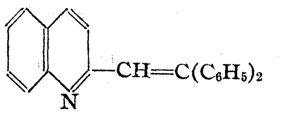
I



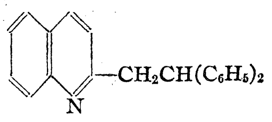
II

In view of this result, it became necessary to determine the structures of these isomers as well as that of α-benzohydrylquinaldine whose structure had been assigned upon the results of these two types of addition reactions which have now been called in question.

The structure of α-benzohydrylquinaldine (IV) was established by synthesis. β-Phenylbenzalquinaldine (III) was made from benzophenone and lithiumquinaldine according to the method of Ziegler and Zeiser[4] and reduced catalytically. The hydrogenation was also effected by the use of benzene, aluminum chloride and hydrogen chloride. Efforts to synthesize the corresponding chloro compound from 1-*p*-chlorophenyl-1-phenyl-2-(2-quinolyl)-ethanol were unsuccessful.

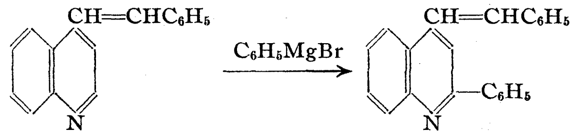


III



IV

The product obtained by the action of phenylmagnesium bromide on benzallepidine was shown to be 2-phenyl-4-styrylquinoline (VI). This compound was prepared by condensing α-phenyllepidine with benzaldehyde according to the method of John and Fischel.[5] From this result it became evident that the addition of phenylmagnesium bromide involved the 1,2- rather than the 1,6-positions



V VI

The isomer produced by the addition of benzene to benzallepidine is evidently α-benzohydryllepidine (II). This is indicated by the close analogy with α-benzohydrylquinaldine, the structure of which is now certain. The synthesis from the *p*-chlorobenzallepidine by the action of benzene, aluminum chloride and hydrogen chloride shows that the phenyl group takes the position adjacent to the *p*-chlorophenyl radical rather than that adjacent to the quinoline ring. Otherwise, the quinolyl rather than the *p*-chlorophenyl radical would have been replaced.

Experimental

***p*-Chlorobenzallepidine.**—Equivalent amounts of lepidine and *p*-chlorobenzaldehyde were heated for six hours at 125° in the presence of a small amount of anhydrous zinc chloride. The product was triturated with ammonium hydroxide, removed by filtration and washed with cold alcohol. It crystallized from alcohol in yellow fibrous needles melting at 127–128°; yield 70%. The benzal compound decolorized a solution of bromine in carbon tetrachloride and discharged the color of permanganate solutions in acetone.

Anal. Calcd. for $C_{17}H_{12}NCl$: C, 76.83; H, 4.56; Cl, 13.4. Found: C, 76.95; H, 4.61; Cl, 13.2.

α-Benzohydryllepidine

A. From Benzallepidine.—Following the general procedure of Fuson, Farlow and Hoffman,[1a] dry hydrogen chloride was passed into a mixture of 2 g. of benzallepidine, 4 g. of anhydrous aluminum chloride and 40 cc. of

[5] John and Fischel, *Ber.*, **59**, 722 (1926).

dry benzene until the gas was no longer absorbed. The mixture was stirred for three hours and then poured into an ice–hydrochloric acid mixture. The semi-solid product was heated with ammonium hydroxide for a short time, cooled and extracted with ether. The crystalline product remaining after the evaporation of the ether was recrystallized from alcohol; m. p. 130–131°.

Anal. Calcd. for $C_{23}H_{19}N$: C, 89.28; H, 6.19; N, 4.53. Found: C, 89.18; H, 6.21; N, 4.60.

B. From *p*-Chlorobenzallepidine.—α-Benzohydryllepidine was obtained from *p*-chlorobenzallepidine by a procedure similar to the preceding one.

β-Phenylbenzalquinaldine (III).—This compound was prepared by the method of Ziegler and Zeiser.[4] Its structure was confirmed by oxidation. With chromic acid it gave benzophenone.

α-Benzohydrylquinaldine (IV).—This compound was prepared by the reduction of β-phenylbenzalquinaldine. The reduction was carried out in two ways.

(a) By the Friedel–Crafts Method.—A mixture of 5.5 g. of β-phenylbenzalquinaldine, 50 cc. of dry benzene and 15 g. of anhydrous aluminum chloride was saturated at room temperature with dry hydrogen chloride gas. The mixture was shaken in a closed container for twenty hours. The color changed from bright red to brown. The reaction mixture was decomposed in an ice–hydrochloric acid mixture. The semi-solid hydrochloride was separated on a filter, washed with benzene and with water and finally heated with ammonium hydroxide for one hour to regenerate the free amine. The solid was recrystallized from alcohol; m. p. 119–121°. The yield was 92%. A mixed melting point determination with α-benzohydrylquinaldine showed no depression.

(b) By Catalytic Reduction.—Hydrogenation in the presence of a platinum–platinum oxide catalyst converted the β-phenylbenzalquinaldine into α-benzohydrylquinaldine. The samples prepared by methods (a) and (b) and that of Hoffman, Fuson and Farlow proved to be identical.

1-*p*-Chlorophenyl-1-phenyl-2-(2-quinolyl)-ethanol.—The method of Ziegler and Zeiser for the halogen-free carbinol was used. From 30 g. of *p*-chlorobenzophenone was obtained 43 g. of carbinol melting at 127–130°. The pure compound (from alcohol) melted at 140.5–141°.

Anal. Calcd. for $C_{23}H_{18}ONCl$: C, 76.75; H, 5.02. Found: C, 76.60; H, 5.18.

Attempts to dehydrate this carbinol by treatment with sulfuric acid, iodine, potassium bisulfate or acetic anhydride were unsuccessful. The only solid product which was isolated was *p*-chlorobenzophenone.

2-Phenyl-4-styrylquinoline (VI).—To an ether solution of benzallepidine an excess of phenylmagnesium bromide was added. The mixture was heated, with stirring, for five hours. Decomposition with ice and hydrochloric acid gave a gummy mass which, when treated with ammonium hydroxide, gave the free base. The pure compound (from alcohol) melted at 102.5–103.5°.

Anal. Calcd. for $C_{23}H_{17}N_3$: N, 4.56. Found: N, 4.74.

A mixture of this compound with a specimen of 2-phenyl-4-styrylquinoline, prepared by the method of John and Fischel,[5] melted at 102–103°.

Summary

1. Benzallepidine and *p*-chlorobenzallepidine react with benzene in the presence of aluminum chloride and hydrogen chloride to give α-benzohydryllepidine.
2. Benzallepidine reacts with phenylmagnesium bromide to give 2-phenyl-4-styrylquinoline.
3. The structure of α-benzohydrylquinaldine has been confirmed by synthesis.

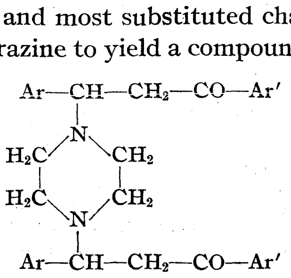
Derivatives of Piperazine. IX. Addition to Conjugate Systems. I

BY VINCENT E. STEWART AND C. B. POLLARD

Additive compounds of benzalacetophenone (chalcone) with ammonia and primary aromatic amines were prepared by Tambor and Wildi.[1] The reaction goes readily in the cold, generally with or without alkali. They were not successful in adding secondary aromatic or mixed secondary bases. An addition compound of benzalacetophenone with piperidine was prepared by Georgi and Schwyzer;[2] upon heating with water it splits into the original substances. Bain[3] reported that he obtained an addition compound of benzalacetophenone with piperazine. We have verified his results, and have endeavored to determine the generality of this addition.

Chalcone and most substituted chalcones readily add piperazine to yield a compound of the type



The addition is effected readily by refluxing the

chalcone with anhydrous piperazine in toluene solution for a few hours; alkali does not facilitate the reaction. The addition compounds separate in minute crystals upon cooling. They can be recrystallized readily from toluene, and in most cases are pure white. The compounds are insoluble in water, alcohol and ether, moderately soluble in hot benzene and toluene and readily soluble in chloroform and other halogenated solvents. In most cases the yield of crude product is almost the theoretical; however, subsequent recrystallizations increase the melting point markedly although a substantial loss of product is incurred.

The compounds are all stable under ordinary conditions, and are not decomposed by heating with water as is the case with the piperidine additive compound. Treatment of 1,4-bischalcone piperazine with dilute hydrochloric acid, or passing dry hydrogen chloride into a chloroform or hot toluene solution of the compound, induces complete decomposition into piperazine dihydrochloride and chalcone. Similarly, refluxing the toluene solution of the compound with ethyl iodide results in complete decomposition into chalcone and a substance identical with the product obtained by refluxing piperazine with ethyl iodide. These decompositions are noteworthy, since the unsaturated ketone results; however, this is entirely analogous to the usual degradation of amines whereby the alkyl group is split off as an unsaturated hydrocarbon.

Certain α,β-unsaturated ketones, including some chalcones, apparently do not yield addition compounds with piperazine. These are being investigated further, and a classification of these compounds will form the basis of a forthcoming publication.

Experimental

Preparation of Chalcones.—These were prepared readily by the Claisen reaction. The theoretical quantities of the corresponding aldehyde and the ketone were dissolved in a suitable quantity of alcohol, and 100 g. of 10% aqueous sodium hydroxide was added per mole of reactant. Separation of the chalcone generally occurred immediately. Alcohol or commercial heptane is most suitable as a solvent for recrystallization.

Preparation of Addition Compounds.—Anhydrous piperazine (0.05 mole) was dissolved in a minimum amount of toluene under reflux, and a toluene solution of the chalcone (0.1 mole) was added. The solution was refluxed for about ten hours and then allowed to stand in the icebox for several hours. The addition compound separated upon cooling. It was filtered, washed with alcohol and water to remove unreacted piperazine, air-dried and recrystallized from toluene three times before being subjected to analysis.

Summary

1. Addition compounds of piperazine with conjugate systems have been studied. One mole of piperazine and two moles of a chalcone are involved in the addition.

2. Some α,β-unsaturated ketones apparently do not yield addition compounds with piperazine. These are being investigated further.

Helenalin. I. Helenalin, the Bitter Sternutative Substance Occurring in *Helenium Autumnale*

BY E. P. CLARK

From the plant *Helenium autumnale* Reeb[1] obtained a crystalline compound which he designated as "helenic acid (d'acide helenique)." He assigned the formula $C_8H_{10}O_2$ to the material, but the combustion data presented indicate that his results were miscalculated. In reality his figures are in good agreement with the formula $C_{15}H_{18}O_4$, which will be shown in the experimental part to be the correct composition of the substance.

Later Lamson,[2] working with some of Reeb's preparations, studied their physiological action and made some chemical observations. He designated the material "helenin," and on the basis of one combustion analysis arrived at the molecular formula $C_{20}H_{25}O_5$, a formula which inspection shows to be impossible. His analytical figures are in moderate agreement with Reeb's results, but they constitute insufficient evidence upon which to base a correct formula.

Since Reeb states that the crystalline material is a vermifuge and our experiments indicate that it is a fairly effective fish poison, its possibilities as an insecticide are being investigated. In the course of this work a method of preparing the material in a pure condition has been elaborated, and sufficient chemical data have been obtained to indicate that the compound has the molecular formula $C_{15}H_{18}O_4$, as suggested by Reeb's analysis.

The compound is a colorless, crystalline, optically active material, which melts at 167°. It has a bitter taste, and its dust causes violent sneezing. A 1–5000 aqueous solution kills *ca.* 3 g. goldfish in three hours.

From a chemical standpoint the compound is highly unsaturated. In the presence of catalysts it absorbs 4 atoms of hydrogen per molecule, indicating that it has two double bonds. It adds bromine to give a dibromide, and it forms monoacyl derivatives, indicating the presence of one hydroxyl group. The acetyl compound was prepared with ease, but as acetyl determinations on this preparation were not entirely satisfactory, a methoxyacetyl derivative was prepared, and the methoxyl value was taken as an indication of the number of acyl groups present. In this way it was proved definitely that only a monoacyl derivative was formed. The compound has no methoxyl groups and is neutral.

Tests for other functional groups have not yet been successful, but further work is in progress.

It is proposed to designate the compound "helenalin," a euphonious combination of syllables of the generic and specific names of the plant. This nomenclature is adopted because Reeb's name, "helenic acid," does not apply inasmuch as the material is not an acid, and Lamson's name, "helenin," has been applied for a long time to alantolactone.[3]

Experimental

Preparation and Properties of Helenalin.—Twenty-five hundred grams of the ground whole plant of *Helenium autumnale*[4] was moistened with 2 liters of chloroform and allowed to stand in a tight container overnight. The drug was then packed in a percolator and extracted with 10 liters of chloroform. The percolate was concentrated under reduced pressure to a thick sirup and then dissolved in 1.5 liters of hot ethanol. The alcoholic liquid was diluted with 6 liters of boiling water and acidified (litmus) with acetic acid, and a solution of 20 g. of normal lead acetate was added. After standing overnight the solution cleared and was filtered through a folded filter paper. The filtrate was evaporated under reduced pressure to 1 liter and then extracted with chloroform.

The chloroform extract was dried with sodium sulfate and evaporated *in vacuo* to a thick sirup, which was then dissolved in 50 cc. of hot benzene. The solution was allowed to crystallize at low temperature, after which the crystals were separated from the mother liquor by filtration and washed with cold benzene. The crude material melted at 167°. The yield varied considerably with different lots, but from 27.5 kg. 97.7 g. of helenalin, or a yield of 0.36%, was obtained.

The material was recrystallized from boiling benzene. Thus obtained it consisted of colorless rods and irregular fragments which melted at 167°. In parallel polarized light (crossed nicols) the extinction was straight and the elongation was positive. The refractive indices as determined by the immersion method were η_α, 1.550 (crosswise

---

[4] This material was obtained through the coöperation of H. R. Reed, Bureau of Animal Industry, U. S. Department of Agriculture, McNeill, Miss.

on rods); η_β, 1.568 (common, crosswise on rods), η_γ, 1.603 (lengthwise).[5]

Helenalin is optically active; 0.5017 g. dissolved in 10 cc. of 95% alcohol at 20° rotated the plane of polarized light in a 1-dm. tube 5.11° to the left; therefore $[\alpha]^{20}_D$ is $-101.9°$.

When 6.46 mg. of helenalin was dissolved in 49.26 mg. of camphor, the melting point of the latter was depressed 17.5°. This corresponds to a molecular weight of 300.

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92; mol. wt., 262. Found: C, 68.60; H, 6.91; mol. wt., 300.

Acetylhelenalin.—A mixture of 1 g. of helenalin, 0.25 g. of dry sodium acetate and 4 cc. of acetic anhydride was boiled for ten minutes. Approximately one-half the acetic anhydride was then removed by distillation, and the residue was treated with 5 cc. of methanol. After the reaction had subsided, water was added to the solution, and the acetyl compound was allowed to crystallize. The yield was 1 g. It was recrystallized from its solution in methanol by adding an equal volume of water. Thus obtained, it consisted of colorless crystals which melted at 184°.

Anal. Calcd. for monoacetate $C_{17}H_{20}O_5$: C, 67.09; H, 6.63; mol. wt., 304. Found: C, 67.15; H, 6.67; mol. wt. (Rast), 333.

Methoxyacetylhelenalin.—A solution of 0.5 g. of helenalin in 2 cc. of pyridine was treated with 1 cc. of methoxyacetic anhydride. The liquid was heated to its boiling point and then allowed to cool and stand for two hours. Water was then added, and the oil which separated crystallized at once. The yield of the crude product was 0.55 g., and its melting point was 131–132°. It was recrystallized by adding 5 volumes of water to its methanolic solution, which had been filtered through norit. The purified product consisted of colorless six-sided rods that melted at 135°. In parallel polarized light (crossed nicols) its extinction is straight and its elongation is positive. In convergent polarized light (crossed nicols) fragments showing sections perpendicular to the acute bisectrix are common. The optic sign is negative and the axial angle (2E) is small. The refractive indices determined by the immersion method are: η_α, 1.525 (usually shown crosswise); η_β, 1.580; η_γ, 1.590 (usually shown lengthwise), all ±0.003.

Anal. Calcd. for $C_{18}H_{22}O_6$: C, 64.66; H, 6.44; OCH_3 (1), 9.28. Found: C, 64.27; H, 6.80; OCH_3, 9.39.

Tetrahydrohelenalin.—Five grams of helenalin dissolved in 150 cc. of ethyl acetate was reduced at atmospheric pressure with hydrogen and the platinum catalyst of Voorhees and Adams.[6] Two mols of hydrogen was absorbed. After the catalyst had been removed, 50 cc. of *n*-butyl ether was added to the solution, and the ethyl acetate was removed by distillation. Practically a quantitative yield of tetrahydro compound was obtained. It melted at 174–175°, and in a high vacuum it could be sublimed or distilled.

Recrystallized from boiling *n*-butyl ether, it consisted of long, colorless needles which melted at 176°. In parallel polarized light (crossed nicols) the extinction is straight and the elongation is negative. Many of the fragments do not extinguish sharply. In convergent polarized light (crossed nicols) many fragments show sections perpendicular to the acute bisectrix and extinguish in a hazy, indefinite manner. The optic sign is positive and the axial angle (2E) is small. Its refractive indices as determined by the immersion method are η_α, 1.545 (lengthwise on rods); η_β, 1.550; η_γ 1.570 (crosswise on rods) all ±0.003.

Anal. Calcd. for $C_{15}H_{22}O_4$: C, 67.65; H, 8.33. Found: C, 67.78; H, 8.40.

Acetyltetrahydrohelenalin.—This compound was made and purified in the same manner as acetylhelenalin. Its melting point was 145°.

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.22; H, 7.85; mol. wt., 308. Found: C, 66.39; H, 8.0; mol. wt., 321.

Dibromohelenalin.—A solution of 1 g. of helenalin in 10 cc. of chloroform was treated with a chloroform solution of 0.63 g. of bromine. The liquid was soon decolorized without the evolution of hydrobromic acid. The solvent was removed in a current of air, and the residue dissolved in hot ethanol. Two volumes of hot water were then added to the alcoholic liquid, and the dibromide was allowed to crystallize. It was recrystallized to a constant melting point of 161° from 50% acetic acid.

Anal. Calcd. for $C_{15}H_{18}O_4Br_2$: Br, 37.88. Found: Br, 37.87 and 37.97.

Summary

A method for the preparation of the physiologically active material that occurs in *Helenium autumnale* has been developed. The name "helenalin" has been proposed for this compound. It has been shown by analysis of the material itself, as well as of several of its derivatives, that it has the formula $C_{15}H_{18}O_4$ and that the molecule contains a hydroxyl group and two double bonds.

Monosodium Urea and its Reactions

BY RALPH A. JACOBSON

The preparation of monopotassium urea and dipotassium urea by the reaction of potassium amide on urea in liquid ammonia solution has been described by Franklin and Stafford,[1] and more recently by Blair.[2] The corresponding sodium derivatives have been prepared by the action of sodium hydride on urea,[3] but the properties of the sodium compounds apparently have not been investigated. The present paper is concerned with the formation and properties of monosodium urea and its use for the synthesis of ureides.

Monosodium urea is obtained readily by the action of metallic sodium on urea in liquid ammonia solution, using ordinary laboratory equipment. The most convenient procedure consists in slowly adding the theoretical amount of sodium to a well-agitated solution of urea in ammonia. Evolution of hydrogen and precipitation of monosodium urea begin almost immediately and the blue color disappears as the sodium is utilized. The product is obtained either by evaporation of the liquid ammonia or by filtration of the ammonia suspension.

The monosodium urea obtained in this manner is a dusty white powder. It has no definite melting point but begins to decompose in a capillary tube at about 150–160°. It is insoluble in aliphatic and aromatic hydrocarbons, chlorinated hydrocarbons, ethers and other inert solvents. It dissolves with reaction in water, alcohols and in other compounds containing an hydroxyl group. It is rather hygroscopic but can be handled in the dry condition and can be retained indefinitely in a closed container.

Attempts to prepare disodium urea were only partly successful. While one equivalent weight of sodium reacted readily with urea in boiling liquid ammonia, sodium in excess of this amount reacted only very slowly. Presumably, the insolubility in ammonia of the monosodium derivative initially formed was an important inhibiting factor. By employing very dilute solutions of urea in liquid ammonia and permitting the reaction to continue for several days, considerably more than one equivalent weight of sodium was finally introduced. The product was an exceedingly hygroscopic white powder which formed a dibenzoyl derivative upon reaction with benzoyl chloride. The analytical data, however, indicated that the product was not pure disodium urea but a mixture of the mono- and the disodium derivatives.

Reaction of Monosodium Urea with Halogen Compounds.—Benzoyl chloride, oleyl chloride and stearyl chloride reacted with sodium urea to yield the corresponding acyl derivatives. Benzyl chloride also reacted with monosodium urea to give benzyl urea. On the other hand, several unsuccessful attempts were made to prepare alkyl ureas by the reaction of monosodium urea with alkyl halides, *e. g.*, butyl iodide, butyl chloride and dodecyl bromide. These results indicate that a fairly active halogen is required for reaction.

Reaction of Monosodium Urea with Esters.—Esters reacted at room temperature with monosodium urea to yield acyl derivatives. It was usually necessary to add acetone or some other ketone (or an alcohol) to the mixture in order to obtain reaction. In a few instances condensation was effected in the absence of acetone by treating a solution of the ester and urea in liquid ammonia with sodium, thereby forming the monosodium urea *in situ*.

The reaction has been applied to simple esters such as ethyl acetate, ethyl benzoate and ethyl oleate for the preparation of the corresponding acyl derivatives. It has also been applied to dibasic esters such as malonic ester, ethylmalonic ester, isopropylmalonic ester, butylmalonic ester and to such higher esters as ethyl glutarate and ethyl pimelate. The malonic ester derivatives yielded the corresponding cyclic barbituric acids, whereas the higher esters appeared to yield straight chain diureides, *e. g.*, glutaryl diureide.

Another interesting application of the sodium urea-ester reaction is its use for the preparation of mixed long-chain acyl ureas by the reaction of monosodium urea with vegetable oils, *i. e.*, esters of glycerol. Such naturally-occurring ester de-

rivatives as coconut oil, Chinawood oil and linseed oil react with monosodium urea in the presence of acetone to yield the corresponding mixed acyl ureas. The latter are white, crystalline, rather high-melting compounds of limited solubility in most organic solvents though crystallizable from hot acetic acid or dioxane. The acyl ureas from linseed and Chinawood oils retain the unsaturation of the oil acids and are characterized by rather high iodine numbers (around 130).

During this study the monosodium derivatives of a number of other amides and amines also were prepared, some of which have already been described by Franklin,[1,4] Titherley[5] and others.[2,6] In general, the condensation of these with esters followed the expected course, and furnished a convenient method for preparing certain acyl derivatives not readily obtained by other methods.

Experimental Part

Monosodium Urea.—Two-mole lots of monosodium urea were prepared by slowly adding 46 g. of sodium to 120 g. of urea dissolved in 1.5 liters of liquid ammonia contained in a 3-necked 2-liter flask provided with a mercury-sealed stirrer. The product was obtained as a white powder upon evaporation of the ammonia; yield 160 g.

Anal. Calcd. for CH_3ON_2Na: Na, 28.05. Found: Na, 27.85 (as sodium sulfate), 28.40 (by titration with acid).

Attempted Preparation of Disodium Urea.—Sodium in excess of one atom reacted slowly and incompletely with a very dilute solution of urea in liquid ammonia. Apparently the product was a mixture of monosodium urea and disodium urea. *Anal.* Calcd. for $CH_2ON_2Na_2$: Na, 44.23. Found: Na, 34.72. Upon treatment of the product with benzoyl chloride, dibenzoyl urea (m. p. 204–205° from benzene) was obtained. *Anal.* Calcd. for $C_{15}H_{12}O_3N_2$: N, 10.44. Found: N, 10.70.

Oleyl Urea.—To 13.5 g. of monosodium urea was added, slowly during gentle warming, 50 g. of oleyl chloride. Boiling isobutanol was added to the mixture and then sufficient water to dissolve the sodium chloride formed in the reaction. The isobutanol layer deposited crystals of oleyl urea upon cooling; m. p. 155–160° (literature 161°).[7]

Anal. Calcd. for $C_{19}H_{36}O_2N_2$: C, 70.37; H, 11.11; N, 8.64. Found: C, 69.77; H, 10.65; N, 8.24.

Stearyl urea (m. p. 175°) and benzoyl urea (m. p. 212°) were similarly prepared but satisfactory results were not obtained with some of the lower aliphatic acid chlorides.

Benzyl urea, m. p. 147–148°, was obtained from benzyl chloride and monosodium urea in liquid ammonia (literature m. p. 147°). *Anal.* Calcd. for $C_8H_{10}ON_2$: N, 18.66. Found: N, 18.24.

Reaction of Monosodium Urea and Simple Esters

Benzoyl Urea.—To 30 cc. of methyl benzoate was added 10 g. of powdered sodium urea and 15 cc. of acetone. Considerable heat was evolved and the mixture became pasty. The mixture was allowed to stand overnight, diluted with water, and acidified with hydrochloric acid. The benzoyl urea thus obtained was filtered, washed in a beaker with boiling alcohol and dried. The product melted at 213–214° (literature 215°); yield 12 g. (60%).

Acetyl urea (m. p. 213°) and oleyl urea (m. p. 160°) were similarly prepared from ethyl acetate and methyl oleate, respectively.

Reaction of Monosodium Urea and Esters of Dibasic Acids.—Monosodium urea reacted with substituted malonic esters in the presence of acetone to yield substituted barbituric acid derivatives. Thus, butylbarbituric acid (m. p. 208° from alcohol)[8] was obtained in 79% yield from butylmalonic ester.

Anal. Calcd. for $C_8H_{12}O_3N_2$: C, 52.17; H, 6.52; N, 15.21. Found: C, 52.46; H, 6.23; N, 14.79.

Ethylbarbituric acid (m. p. 185–186°, yield 79%), isopropylbarbituric acid (m. p. 212°) (*Anal.* Calcd. for $C_7H_{10}O_3N_2$: C, 49.41; H, 5.88. Found: C, 49.62; H, 5.94), and barbituric acid (m. p. 192°) were prepared from the corresponding malonic esters. The unsubstituted barbituric acid was obtained as the dihydrate.

Anal. Calcd. for $C_4H_4O_3N_2\cdot 2H_2O$: N, 17.07. Found: N, 17.48.

The melting points given in the literature are: ethylbarbituric acid, m. p. 193–194° corr.; isopropylbarbituric acid 214–214.5°.[8]

The reaction of monosodium urea with esters of dibasic acids higher in the series than malonic yielded high melting insoluble products which appeared to be diureides. From ethyl glutarate a white compound melting at 247–248° was obtained. (*Anal.* Calcd. for $C_7H_{12}O_4N_4$: C, 38.88; H, 5.55; N, 25.92. Found: C, 38.75; H, 5.81; N, 24.62.)

A product of similar properties (m. p. 240–245°) was obtained from ethyl pimelate. A small amount of a compound melting at 205–206° (crystallized from acetic acid) was also obtained. This appeared to be the monoureide of pimelic acid ($NH_2CONHCO(CH_2)_5COOH$).

Anal. Calcd. for $C_8H_{14}O_4N_2$: N, 13.86. Found: N, 13.48.

Reaction of Monosodium Urea with Natural Oils.—The mixed acyl ureas from coconut oil were prepared from 300 g. of coconut oil, 200 cc. of acetone and 100 g. of sodium urea. The white solid after an alcohol wash melted at 165–170°. Upon crystallization from acetic acid or dioxane, it melted at 172°; yield 150 g. The product contained 9.95% nitrogen.

[7] Stendal, *Compt. rend.*, **196**, 1810 (1933). Oleyl urea (m. p. 161°) and stearyl urea (m. p. 176–178°) were obtained by heating urea with the corresponding esters in the presence of sodium ethylate and pyridine.

[8] Volwiler, THIS JOURNAL, **47**, 2239 (1925), reported 208–209°.

The mixed acyl ureas from linseed oil and from Chinawood oil were obtained in low yield. The former melted at 154–158° (from alcohol) and the latter at 155–162° (from alcohol). The iodine numbers were, respectively, 128 and 108.8, and the nitrogen contents 7.71 and 8.13%.

Summary

1. Monosodium urea has been prepared by the reaction of urea in liquid ammonia with one equivalent of sodium. It is a white powder insoluble in inert solvents. A mixture of disodium urea and monosodium urea was obtained from urea and two equivalents of sodium.

2. Several acyl ureas including stearyl, oleyl and benzoyl have been prepared by the reaction of monosodium urea with acid chlorides. Alkyl halides such as butyl iodide and dodecyl bromide did not react with monosodium urea.

3. Simple esters such as ethyl acetate and methyl benzoate reacted with monosodium urea in the presence of acetone to yield acyl ureas. Natural oils such as coconut, linseed and Chinawood also reacted to yield high-melting mixed acyl ureas.

4. Malonic ester and its substituted derivatives reacted with monosodium urea to give barbituric acid derivatives. Barbituric acid, ethylbarbituric acid, isopropylbarbituric acid and butylbarbituric acid have been prepared in this manner.

5. Esters of higher dibasic acids, such as ethyl glutarate and ethyl pimelate, apparently yielded diureides.

The Interconversion of Mixed Benzoins

BY H. H. WEINSTOCK, JR., AND REYNOLD C. FUSON

The reduction of 2,4,6-trimethylbenzoin (II) and 2′,4′,6′-trimethylbenzoin (III) to the same desoxybenzoin, phenyl 2,4,6-trimethylbenzyl ketone,[1] can be explained on the basis of an initial transformation of one of the benzoins into its isomer. If this explanation is correct, the benzoins should be interconvertible under mild conditions. This has proved to be the case, for when either 2,4,6- or 2′,4′,6′-trimethylbenzoin was warmed in alcoholic sodium acetate solution, the corresponding isomer was formed. Isolation of starting material in each case indicated the existence of an equilibrium.

Because of this ease of interconversion, an investigation was made of the reaction of the two benzoins toward reagents commonly employed in testing for the hydroxyl group. The benzoins, when treated with benzoyl chloride, yielded a single benzoate instead of the expected isomeric benzoates. Presumably in one case benzoylation had been preceded by conversion of the benzoin into its isomer.

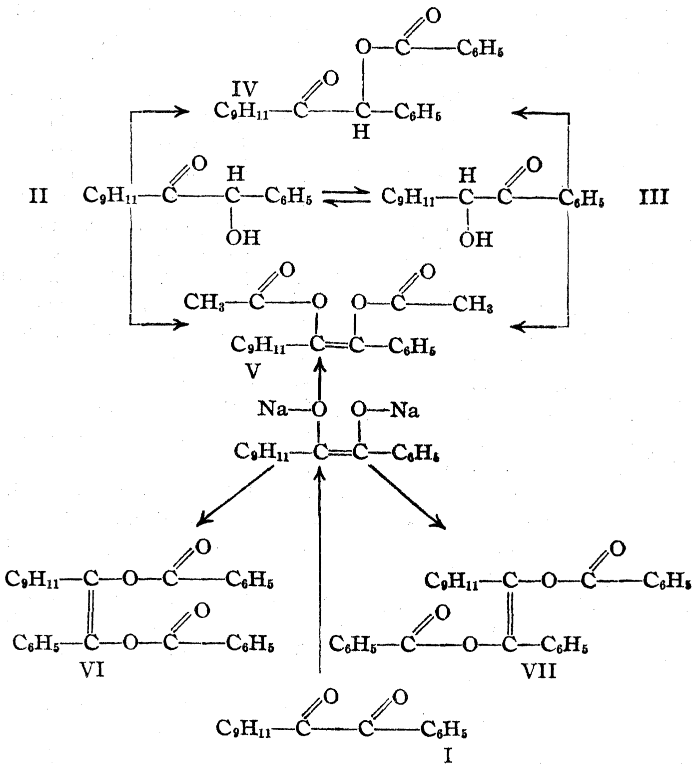
Such a conversion suggests the intermediate formation of the ene-diol. Longer treatment was, accordingly, attempted in the hope of obtaining the dibenzoate of the ene-diol. The monobenzoate was, however, the only product which could be isolated. The dibenzoate was made for reference by the action of benzoyl chloride on the sodium derivative of the diketone (I). Two forms (VI and VII) of the dibenzoate were isolated. The lower-melting form (139°) was converted into its isomer (170°) by heating above the melting point.

It was found possible, however, to obtain the diacetate of the ene-diol (V) by a method similar to that which was unsuccessful in the case of the corresponding dibenzoate. Subjection of either of the isomeric benzoins to the action of acetic anhydride resulted in the formation of the diacetate. This structure was proved by preparing the compound by the action of acetyl chloride on the disodium salt of mesityl phenyl diketone (I). Compound III formed the diacetate more readily than did its isomer (II); when II was treated with acetic anhydride for five hours a monoacetate was formed while, under the same conditions, III formed the diacetate.

This implies that in the benzoylation III rather than II isomerizes. It is for this reason that the monobenzoate (IV), the structure of which is conjectural, is represented as a derivative of II rather than of III.

---

[1] Weinstock and Fuson, THIS JOURNAL, **58**, 1233 (1936).



That both II and III readily rearrange to the ene-diol form was confirmed by treatment of the two benzoins with methylmagnesium iodide, according to the method of Kohler, Stone and Fuson.[2] Considerably more than one mole of gas was formed by each of the isomers and, as would be expected, II, which contains the sterically hindered carbonyl group, and thus would have a longer period of time to enolize before addition took place, gives the greater amount of methane.

The action of iodine upon the isomeric benzoins produced an unexpected result In the presence of small amounts of iodine, both II and III were found to undergo disproportionation to yield mesityl phenyl diketone (I), and phenyl 2,4,6-trimethylbenzyl ketone.[3]

The reaction took place in hot, glacial acetic acid or at high temperatures in the absence of solvent. Disproportionation could not be made to take place in the absence of a trace of iodine. One explanation would be that the iodine oxidized one molecule of the benzoin to I with the formation of hydrogen iodide, which then reduced another molecule of the benzoin to phenyl 2,4,6-trimethylbenzyl ketone, regenerating the iodine.

Experimental

Because of the ease of oxidation of 2,4,6- and 2′,4′,6′-trimethylbenzoin in solution, all reactions were carried out in an atmosphere of nitrogen.

Interconversion of the Benzoins.—Two grams of 2,4,6-trimethylbenzoin (II),[4] 0.75 g. of sodium acetate, 30 cc. of ethyl alcohol and 1 cc. of water were heated under reflux for twenty hours. The solution was diluted with water and cooled. From 1.2 g. of colorless material which separated, there was obtained on fractional crystallization, 0.1 g. of substance which melted at 93–94°. A mixed melting point with a known sample of 2′,4′,6′-trimethylbenzoin (III) showed no depression.

From 1 g. of III[5] 0.1 g. of II was obtained by the same method. In both cases the equilibrium mixture was difficult to separate, and the yield of converted isomer was probably higher than given above.

A simple *monobenzoate* (IV) was obtained from both II and III by the following procedure. One gram of the benzoin was added to 1 cc. of benzoyl chloride in 5 cc. of pyridine. The reaction was maintained at a temperature of 80° for thirty minutes, and poured into 10 cc. of sodium carbonate solution. The emulsion was extracted with ether, the ether layer dried over calcium chloride, and the ether removed by evaporation. The residual oil was taken up in alcohol. When allowed to stand, the solution deposited a colorless, granular substance, melting at 127–127.5°, which was only slightly soluble in alcohol. The benzoates obtained from II and III were shown to be identical by the method of mixed melting points.

Anal. Calcd. for $C_{24}H_{22}O_3$: C, 80.44; H, 6.14. Found: C, 80.55; H, 6.29.

Allowing the reaction to proceed for a longer period of time did not yield the dibenzoate. Two grams of II, 15 cc. of pyridine and 2.5 cc. of benzoyl chloride were boiled under reflux for ten hours. There was obtained 1.5 g. of substance, melting at 115°, which, on purification, proved to be the monobenzoate. Hydrolysis of the monobenzoate with alcoholic potassium hydroxide solution gave I, m. p. 134–135°. A mixed melting point with mesityl phenyl diketone showed no depression. It seems probable that the monobenzoate has the structure represented by formula IV.

The isomeric dibenzoates of 2,4,6-trimethyl-α,α′-stilbenediol (VI and VII) were prepared by the action of benzoyl chloride on the disodium derivative of mesityl phenyl diketone. In a typical experiment, 3.5 g. of one dibenzoate was obtained from 8 g. of I. No method was evolved by which one could predict the isomer which would be

---

(3) Matsumura [*ibid.*, **57**, 955 (1935)] by treating β-*p*-dimethylaminobenzoin with alcoholic hydrochloric acid, obtained *p*-dimethylaminobenzil, and α-*p*-dimethylaminodesoxybenzoin. Compound II would not undergo disproportionation under the same conditions. It is interesting to note that the desoxybenzoin formed by disproportionation of both benzoins is the same one which is formed exclusively in the reduction of I, II and III.[1]

(4) Fuson, Weinstock and Ullyot, *ibid.*, **57**, 1803 (1935).

(5) Arnold and Fuson, *ibid.*, **58**, 1295 (1936).

formed. The isomers were both colorless compounds and melted at 138.5–139° and 169.5–170°. They were recrystallized from ethyl alcohol, in which they were difficultly soluble.

Anal. Calcd. for $C_{31}H_{26}O_4$: C, 80.52; H, 5.63. Found: (139°) C, 80.58; H, 5.79; (170°) C, 80.35; H, 5.68.

The substance melting at 139° was quantitatively converted into its isomer by heating above the melting point for five minutes. The high-melting isomer was hydrolyzed with alcoholic potassium hydroxide to give a mixture from which I (m. p. 133–135°) and II (m. p. 100–101°) were isolated. These substances were identified by mixed melting point determinations. The spatial configuration of the dibenzoates was not determined.

The monoacetate of 2,4,6-trimethylbenzoin was obtained by heating a solution of 2 g. of II and 1 g. of sodium acetate in 20 cc. of acetic anhydride under reflux for five hours. The solution was cautiously treated with water and extracted with ether. The ether layer was dried over calcium chloride, and the ether removed by evaporation. The residual yellow oil was taken up in alcohol and allowed to stand at room temperature; 1.5 g. of a colorless, granular substance separated. On recrystallization from dilute ethyl alcohol, the compound melted at 73–73.5°.

Anal. Calcd. for $C_{19}H_{20}O_3$: C, 77.03; H, 6.76. Found: C, 77.10; H, 6.75.

Diacetate of 2,4,6-Trimethyl-α,α′-stilbenediol (V).—A. Treatment of II by the above procedure, except that heating was carried out for twenty-four hours, gave 0.8 g. of a colorless product; m. p. 92–98°. The pure compound melted (from alcohol) at 104–104.5°.

Anal. Calcd. for $C_{21}H_{22}O_4$: C, 74.56; H, 6.51. Found: C, 74.61; H, 6.49.

B. Treatment of III by the same procedure, except that the reaction mixture was heated for five hours, resulted in the formation of the diacetate; m. p. 104–104.5°. A mixed melting point with the product prepared from II showed no depression.

C. The diacetate was prepared by the action of acetyl chloride on the sodium derivative of mesityl phenyl diketone, according to the usual procedure. From 2 g. of I, 0.4 g. of sodium and 6 cc. of acetyl chloride was obtained 0.6 g. of product, m. p. 95–100°. The melting point was 103–104° after recrystallization. A mixed melting point with the diacetate prepared from II and III showed no depression.

Reaction with the Grignard Reagent.[6]—The benzoins (II and III) were treated with methylmagnesium iodide, in an apparatus of the type described by Kohler and Richtmyer.[7] Approximately 0.0005 mole of substance was used in each run. The solution of the benzoin in the excess Grignard reagent was held at a temperature of 90° for thirty minutes before decomposition to allow the reaction to go to completion. The results showed that II gave 1.78 moles of gas, and 0.29 mole of the reagent was added. Compound III likewise used two moles of reagent, but in this case 1.30 moles of gas was evolved and 0.75 mole of reagent was added.

Reaction with Iodine.—A. A solution of 1 g. of II and 0.1 g. of iodine in 50 cc. of glacial acetic acid was heated under reflux for three hours. The solution was poured, while hot, into 25 cc. of 2% sodium bisulfite solution. The hot solution was filtered and allowed to cool. A solid formed which, by a process of slow crystallization and decantation from alcohol, was separated into two sets of crystals: (a) 0.40 g. of large, yellow needles which melted at 135–136°—a mixed melting point with mesityl phenyl diketone showed no depression; (b) 0.37 g. of colorless fibrous clusters; m. p. 161–162°. After recrystallization from alcohol, the crystals melted at 164–165°. This substance was shown to be identical with phenyl 2,4,6-trimethylbenzyl ketone by means of a mixed melting point determination.

In another experiment, 2 g. of II and a small crystal of iodine were placed in a small Pyrex flask and held at a temperature of 200° for five minutes. The water which was formed in the reaction collected as a vapor on the upper surface of the flask. The product was taken up in alcohol after cooling. There was obtained 0.60 g. of mesityl phenyl diketone (m. p. 135.5–136.5°) and 0.55 g. of phenyl 2,4,6-trimethylbenzyl ketone (m. p. 162–163°).

Only starting material was recovered when II was heated to 220° or boiled under reflux in glacial acetic acid for three hours, no iodine being used in either case. Treatment of II with alcoholic hydrochloric acid and copper sulfate caused no disproportionation.

B. One and four-tenths grams of III was heated at 220° in the presence of a crystal of iodine. There was obtained 0.60 g. of phenyl 2,4,6-trimethylbenzyl ketone (m. p. 158–161°) and 0.55 g. of mesityl phenyl diketone (m. p. 133.5–135°). Mixed melting points of the purified substances with authentic samples showed no depression.

Summary

2,4,6-Trimethylbenzoin (II) and its isomer, 2′,4′,6′-trimethylbenzoin (III), underwent interconversion when heated in the presence of sodium acetate. It is postulated that the ene-diol is an intermediate in these transformations. Evidence in support of this is that with benzoyl chloride the two benzoins yield the same monobenzoate, and with acetic anhydride they give the same diacetate.

With methylmagnesium bromide, II and III react in the ene-diol form to the extent of 78 and 30%, respectively.

When heated in the presence of a crystal of iodine, II and III underwent disproportionation to the diketone and phenyl 2,4,6-trimethylbenzyl ketone.

[Contribution from Mellon Institute of Industrial Research, and E. R. Squibb and Sons]

Local Anesthetics Containing the *ac*-Tetrahydro-beta-naphthylamine Pressor Group[1]

By Harold W. Coles[2] and William A. Lott[3]

Attempts are being made continually to prepare local anesthetics with vasoconstricting properties in order to eliminate the use of pressor drugs (usually epinephrin) to localize and synergize the local anesthetic action.[4] Until recently,[5] however, the compounds synthesized to this end have shown little or no pressor action on pharmacological assay.

Although the powerful pressor activity of *ac*-tetrahydro-β-naphthylamine is well known,[6] no attempt has been made previously to employ this amine as the nitrogen-containing portion of a local anesthetic molecule. It is known[7] that the introduction of an acid group, such as the acetyl or formyl, on the nitrogen atom, completely reverses the vasoconstricting and pyretic properties of *ac*-tetrahydro-β-naphthylamine, whereas the replacement of a hydrogen atom by an alkyl group changes them only in degree. There is a double action if an acid and alkyl group are both introduced. However, it was believed possible that the reversal effect of the acyl groups might not take place if the acyl groups were separated from the pressor amine portion by means of an alkylene group. As shown later, this hope was not realized in the large number of local anesthetics prepared.

Experimental Part

The *ac*-tetrahydro-β-naphthylamine was prepared according to the directions given in "Organic Syntheses."[8]

Preparation of the (*ac*-Tetrahydro-β-naphthylamino)-alkanol Hydrochlorides.—The general literature methods were changed in some respects. Two molecular equivalents of freshly distilled *ac*-tetrahydro-β-naphthylamine, one molecular equivalent of ethylene chlorohydrin (or trimethylene chlorohydrin) and some xylene (as diluent) were placed in a round-bottomed 3-necked flask equipped with a thermometer, reflux condenser and glass tubing reaching to the bottom of the flask through which a steady stream of dry nitrogen was passed during the entire reaction. The nitrogen prevents almost completely the formation of the usual red color. The flask and contents were immersed in an oil-bath, the temperature of the flask contents was raised to 110° and the reaction was allowed to continue for three hours at a temperature of 110–115°. The mixture was cooled, a large excess of ether added and the precipitated *ac*-tetrahydro-β-naphthylamine hydrochloride was filtered off and washed repeatedly with ether.

The ether–xylene filtrate was chilled, and both nitrogen and dry hydrogen chloride were passed slowly through the solution, until precipitation of the amino alcohol hydrochloride was complete. The precipitate was filtered off and washed well with ether, then recrystallized from isopropyl alcohol to a constant melting point with a yield of 80–85%. The compounds are white crystalline solids, soluble in water, acetone and the different alcohols, but insoluble in ether and benzene.

Beta-(*ac*-tetrahydro-β-naphthylamino)-ethanol Hydrochloride (m. p. 183.8–184.8°).[9]—*Anal.* (Volhard). Calcd. for $C_{12}H_{18}NOCl$: Cl, 15.58. Found: Cl, 15.59, 15.64.[10]

Gamma-(*ac*-tetrahydro-β-naphthylamino)-propanol Hydrochloride (m. p. 161°).—*Anal.* Calcd. for $C_{13}H_{20}NOCl$: Cl, 14.67. Found: Cl, 14.75, 14.89.

Preparation of the Esters.—These were prepared essentially by general methods reported in the literature[11] in which one molecular equivalent of the (*ac*-tetrahydro-β-naphthylamino)-alkanol hydrochloride was allowed to react with 1.5 molecular equivalents of the acyl chloride until no further hydrogen chloride was evolved. No attempt was made to work out the conditions for optimum yields, but these were satisfactory in most cases. The reaction product was washed repeatedly with ether to remove the excess acid chloride, and was then recrystallized from mixtures of methyl and isopropyl alcohols.

In most cases, little trouble was experienced in securing nicely crystalline hydrochlorides. Certain aliphatic derivatives, however, as the caproyl, propionyl and furylacryloyl, produced gums and were not secured in pure form. The *p*-toluene sulfonyl chloride seemed to react normally[12] with formation of a compound containing chlorine but the halogen was not precipitated by silver nitrate in nitric acid solution. The compound produced appreciable anesthesia when applied to the tongue, but it has not yet been separated completely from about 25% of inert material.

The nitro esters were reduced with iron and hydrochloric acid.[13] The aminobenzoates were isolated and tested as

Pharmacologically,[14] the compounds showed no mydriatic action on the rabbit's cornea, and produced no blanching of tissues when injected intradermally or subcutaneously in guinea pigs. The onset of anesthesia was usually delayed, although the duration and depth of anesthesia was satisfactory in most cases. However, the steep slope of the dose-effect curves and the marked difference between the duration of anesthesia following endermic and subcutaneous injections of the same concentration in the guinea pig were undesirable characteristics. The compounds were not irritating. Kymograph tracings of their action on the blood pressure of the rabbit revealed a sudden drop in the pressure, with considerable disturbance of the rhythm as the blood pressure rose gradually again to normal.

It should be recorded, too, that *ac*-tetrahydro-β-naphthylamine hydrochloride, in practical concentrations (up to 1%), does not exhibit sufficient peripheral vasoconstriction to synergize or localize the effect of a local anesthetic such as procaine (up to 2%). Injections were made subcutaneously in guinea pigs. These results are similar to those obtained with ephedrine.[15]

The authors wish to record their appreciation of the helpful advice of Dr. George D. Beal, Assistant Director of Mellon Institute.

Summary

Two new alkanol derivatives of *ac*-tetrahydro-β-naphthylamine have been prepared and described.

From these two derivatives, a series of seventeen new local anesthetics has been prepared. Although possessing, in most cases, satisfactory local anesthetic properties, they lack vasopressor characteristics.

Hydrogen Bond Formation between Hydroxyl Groups and Nitrogen Atoms in Some Organic Compounds

BY S. B. HENDRICKS, O. R. WULF, G. E. HILBERT AND U. LIDDEL

Many molecules containing hydrogen bonds between oxygen atoms have no measurable absorption in the infra-red region where characteristic OH absorption occurs in other hydroxylic compounds.[1] Such absence of absorption was used as an analytical method in our previous work. In extending that study, the question naturally arises as to what groups can take part in the formation of hydrogen bonds. The following work deals with some molecules in which a hydrogen bond if formed would be between an hydroxylic oxygen and a nitrogen atom of the type =N—.

Moore and Winmill's[2] explanation of the difference in the basicity of the tertiary and quaternary ammonium bases was that a hydrogen bond could be formed between oxygen and nitrogen atoms in the former case but not in the latter. Hydrogen bond formation was also suggested by Latimer and Rodebush[3] as an explanation for the weak basicity of ammonium hydroxide. Sidgwick[4] has reviewed this evidence and further has pointed out that nitrogen can act as a "donor," that is, form coördination compounds with appropriate groups or elements including OH. Pfeiffer and his co-workers[5] postulated hydrogen bond (partial valence) formation to explain the unusual properties of the phenylazo-1-naphthol-2.

The experimental technique and the spectroscopic procedure was the same as that described in previous work from this Laboratory.[6] However, some comment should again be made about the region 7100–7400 cm.$^{-1}$. Atmospheric water absorption lies here and makes observation difficult, so that weak absorption could be missed. The curves of Fig. 2 have been brought down to the axis of abscissa, but since the accuracy attained permits a considerable variation from zero they *must not be construed as indicating no absorption in this region* (7100–7400 cm.$^{-1}$). Very weak absorption due to presence of CH is known to lie here and there have been frequent indications of its presence in variations that were too small, at the concentrations used in this work, to be established definitely.

Compounds used were either prepared by known methods with analysis as a criterion of purity or were purified commercial products. We are indebted to Dr. T. W. J. Taylor, of Oxford University, for generous samples of 1-benzoylnaphthol-2-hydrazone and 1-benzoylnaphthol-2-acetonylhydrazone and to Dr. A. H. Blatt, of Howard University, for 2-hydroxy-5-methylbenzophenoneoxime acetate, 2-hydroxyacetophenoneoximeacetate, *cis*- and *trans*-2-hydroxybenzophenoneoximeacetates and 2,2′-dihydroxybenzophenoneoximeacetate. Drs. H. L. Haller and D. L. Vivian of the Bureau of Entomology kindly supplied us with samples of α-(β-naphthol)-2,5-dichloroazobenzene, 2,5-dichloro-2′-hydroxy-4′-methyl-5′-chloroazobenzene and 4-hydroxyazobenzene.

Results and Discussion

Absorption in the region 6200–7500 cm.$^{-1}$ characteristic of the presence of OH groups was found to be absent for a number of compounds having configurations that would favor formation of a hydrogen bond between hydroxyl oxygen and a nitrogen atom. It was found to be present in related compounds the configurations of which excluded possible formation of such bonds. Absence of a measurable amount of such absorption thus can probably be used as a positive analytical device in detecting the presence of a hydrogen bond in this type of molecule.

Factors similar to those previously discussed as possibly affecting hydrogen bond formation between oxygen atoms are also to be considered here. One of the important requirements is that the nitrogen and oxygen atoms sharing the hydrogen bond be correctly placed, the interatomic distance, N to O, being about 2.6 Å. The ring formed should contain a minimum number of single bonds about which there could be free

rotation and the entire system should be one relatively free of strain produced by deformation of valence angles. These conditions were best met in the case of oxygen compounds by formation of six-membered rings including hydrogen, there being possibly a single example of a seven-membered ring but none of five. Other important factors are electron affinities of groups sharing hydrogen bonds and resonance phenomena, particularly those associated with a conjugate system of double bonds. Absence of discussion of resonance phenomena arises from the authors' lack of familiarity with the subject.

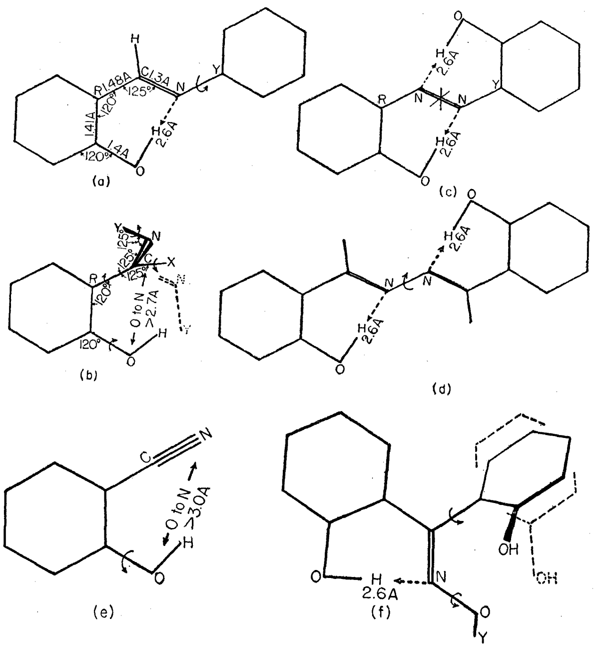

Fig. 1.—Structural formulas showing probable interatomic distances. A converging line indicates that the line departs from the plane of the figure.

Nitrogen compounds are of particular interest in that additional steric factors, arising from three rather than two directed valences, are introduced. Thus compounds R—CX=N—Y where R is unsymmetrical, can theoretically exist in two isomeric forms. Difficulty of determining their configurations by chemical methods is well recognized. The nitrogen atom of the —CX=N—Y group would be expected to have an additional coördination valence, associated with its single pair of non-binding electrons,[7] and hydrogen bond formation under otherwise favorable conditions would be possible for one isomer but not for the other. A method is thus available for absolute assignment of configuration.

The influence of the various factors mentioned above can be best studied on the ortho substituted phenols and a number of these having —CX=N—Y substituents were examined, X and Y being varied widely. Among these was salicylaldehydeanil ($2\text{-HOC}_6\text{H}_4\text{CH}{=}\text{NC}_6\text{H}_5$), which did not give characteristic OH absorption. The probable geometrical configuration of this compound, which serves to illustrate the type, is shown as (a) in Fig. 1, the rotation of the second benzene ring (Y) about the NY bond being unknown. Formation of a hydrogen bond between the oxygen and nitrogen atoms restricts the rotation about the bond RC, the only single bond involved, and requires RCNO to be approximately coplanar with the neighboring benzene ring. Moreover the bond NY is required to have a *trans* (*anti*) configuration with respect to RC.

Presence or absence of hydroxyl absorption is used below as a criterion for determining the structures of some oximes. The methods that have been used in the past usually involved chemical transformations and thus alteration of the molecule investigated. Prominent among these are the Beckmann rearrangement and condensations presumably involving adjacent groups, such as that leading to formation of isoxazole rings, both of which are open to criticism.[8]

Absorption characteristic of the presence of OH was not observed for 2-hydroxy-5-methylbenzophenoneoxime acetate ($2\text{-HO-5-CH}_3\text{C}_6\text{H}_3\text{C}({=}\text{NO-COCH}_3)\text{C}_6\text{H}_5$, m. p. 114°) which thus must contain a hydrogen bond and have an *anti* configuration of the (—OCOCH_3) group with respect to the C—ROH group. Acetyl groups were introduced into this compound and most of those discussed below in order to prevent confusion arising from absorption due to the NOH group.

Since the energy of binding enhances the stability of the isomeric form having a hydrogen bond, it is not surprising to find that most such compounds have been obtained in only one form. However, Kohler and Bruce have prepared geometrical isomers of 2-hydroxybenzophenoneoxime and have shown that no evidence independent of the Beckmann rearrangement, with its corollary assumption of a *trans* shift, exists as to their

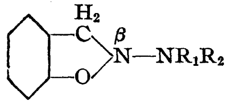
configurations.[9] Their "n" form of the oxime (m. p. 141–142°) was considered to have a *syn* configuration with respect to the RC bond (Fig. 1a) and was less stable thermally with respect to the isomeric "h" or *anti* oxime[7] (m. p. 142–143°). Acetates of these two compounds, namely, the *syn* acetate (m. p. 156°) and the *anti* acetate (m. p. 95°) ($2\text{-}HOC_6H_4C({=}NOCOCH_3)C_6H_5$), were placed at our disposal by Dr. Blatt. The former compound gave the absorption shown in Fig. 2[10] while no measurable value was obtained for the latter. Thus a hydrogen bond is present in the *anti* acetate and this is in agreement with the configuration assigned on the basis of Meisenheimer's interpretation of the Beckmann rearrangement. A probable geometrical configuration for the *syn* acetate, which does not contain a hydrogen bond and is thus the unstable form, is shown in Fig. 1b. Spatial proximity of H and Y as in the dotted position would necessitate rotation of the CNY group about the RC bond.

Considerably less is known about the structures of the aldoximes than of the ketoximes. As might be expected the common forms, and thus probably the stable forms, that we have studied, all contain hydrogen bonds. Thus neither salicylaldoxime acetate ($2\text{-}HOC_6H_4CH({=}NOCOCH_3)$) nor the 2-hydroxy-5-methylbenzophenoneoxime acetate ($5\text{-}CH_3\text{-}2\text{-}HOC_6H_3C({=}NOCOCH_3)C_6H_7$) gave measurable OH absorption. Both of these compounds therefore have configurations similar to that of salicylaldehydeanil, that is, NY of $R{-}\overset{H}{C}{=}N{-}Y$ *anti* with respect to R—C. Salicylaldoxime ($2HOC_6H_4CH{=}NOH$) (absorption measured at 0.00333 and 0.0100 molal) was also examined and found to have the absorption shown in Fig. 2.[11] Similarity of this absorption to that of other oximes indicates that it is entirely to be accounted for by the presence of oxime OH. Chemical methods applied to studying the configuration of the aldoximes have been handicapped by lack of evidence as to whether the Beckmann rearrangement involved a *syn* or an *anti* shift, the former being assumed in the older literature. The results given above for the aldoximes, however, support the chemical findings of Brady and Bishop[12] in favor of the *anti* shift in the Beckmann rearrangement.

Salicylaldehyde α-methyl-α-phenylhydrazone ($2\text{-}HOC_6H_4CH{=}NN(CH_3)C_6H_5$) and salicylaldehydedimethylhydrazone ($2\text{-}HOC_6H_4CH{=}NN(CH_3)_2$) failed to give characteristic OH absorption. Hydrogen bond formation in these compounds probably takes place between the OH group and the β nitrogen atom, the NR_2 group being a variant of Y as defined above. Where the hydrogen bond is present the Y substituent must necessarily be *trans* with respect to the aromatic grouping. It is possible, however, that these results, namely, absence of measurable OH absorption in the region studied could be explained by the presence of five membered rings such as



The ordinary hydroxylic reactions of these compounds is strong evidence against this explanation.

In order further to vary the basicity of the Y group several hydrazones were studied in which NH groups were present. Salicylaldehydehydrazone ($2\text{-}HOC_6H_4CH{=}NNH_2$) and salicylaldehydephenylhydrazone ($2\text{-}HOC_6H_4CH{=}NNHC_6H_5$) gave the absorptions shown in Fig. 2. Comparisons of these absorptions with those of analogous compounds that do not contain hydroxy groups shows that the absorptions are entirely to be accounted for by the presence of NH_2 or NH groups. Both compounds are thus thought to contain hydrogen bonds. In varying the substituent Y group of the hydrazone from $—N(CH_3)C_6H_5$ to NH_2 the limits of basicity were approximately encompassed and thus shown not to be determinative at least in this series of compounds for hydrogen bond formation.

Two substituted naphthols, 1-benzoylnaphthol-2-hydrazone ($2\text{-}HOC_{10}H_6\text{-}1\text{-}CH({=}NNH_2)C_6H_5$) and 1-benzoylnaphthol-2-acetonylhydrazone ($2\text{-}HOC_{10}H_6\text{-}1\text{-}C({=}NN{=}C(CH_3)_2)C_6H_5$) were examined. The former of these compounds[13] gave the absorption shown in Fig. 2, which should be compared with that of salicylaldehydehydrazone, the complexity of which is to be accounted for by

[9] Kohler and Bruce, THIS JOURNAL, **53**, 1569 (1931).

[10] This absorption showed a change with temperature (60 to 20°) which is indicative of association as might be expected for this compound. Decomposition, which was not tested for, could give rise to a similar effect.

[11] The absorption of this compound showed a slight change with concentration. This is indicative of association which is well known for oximes (N. V. Sidgwick, *Ann. Reports Chem. Soc.*, **31**, 41 (1934)).

[12] Brady and Bishop, *J. Chem. Soc.*, **127**, 1357 (1925).

[13] Neither of these compounds is described in the literature. The first as supplied to us by Dr. Taylor, was recrystallized from benzene and found to have the following constants: m. p. 157°. *Anal.* (M. S. Sherman) C, 78.44; H, 5.65; N, 10.51. Calcd. C, 77.84; H, 5.39; N, 10.68.

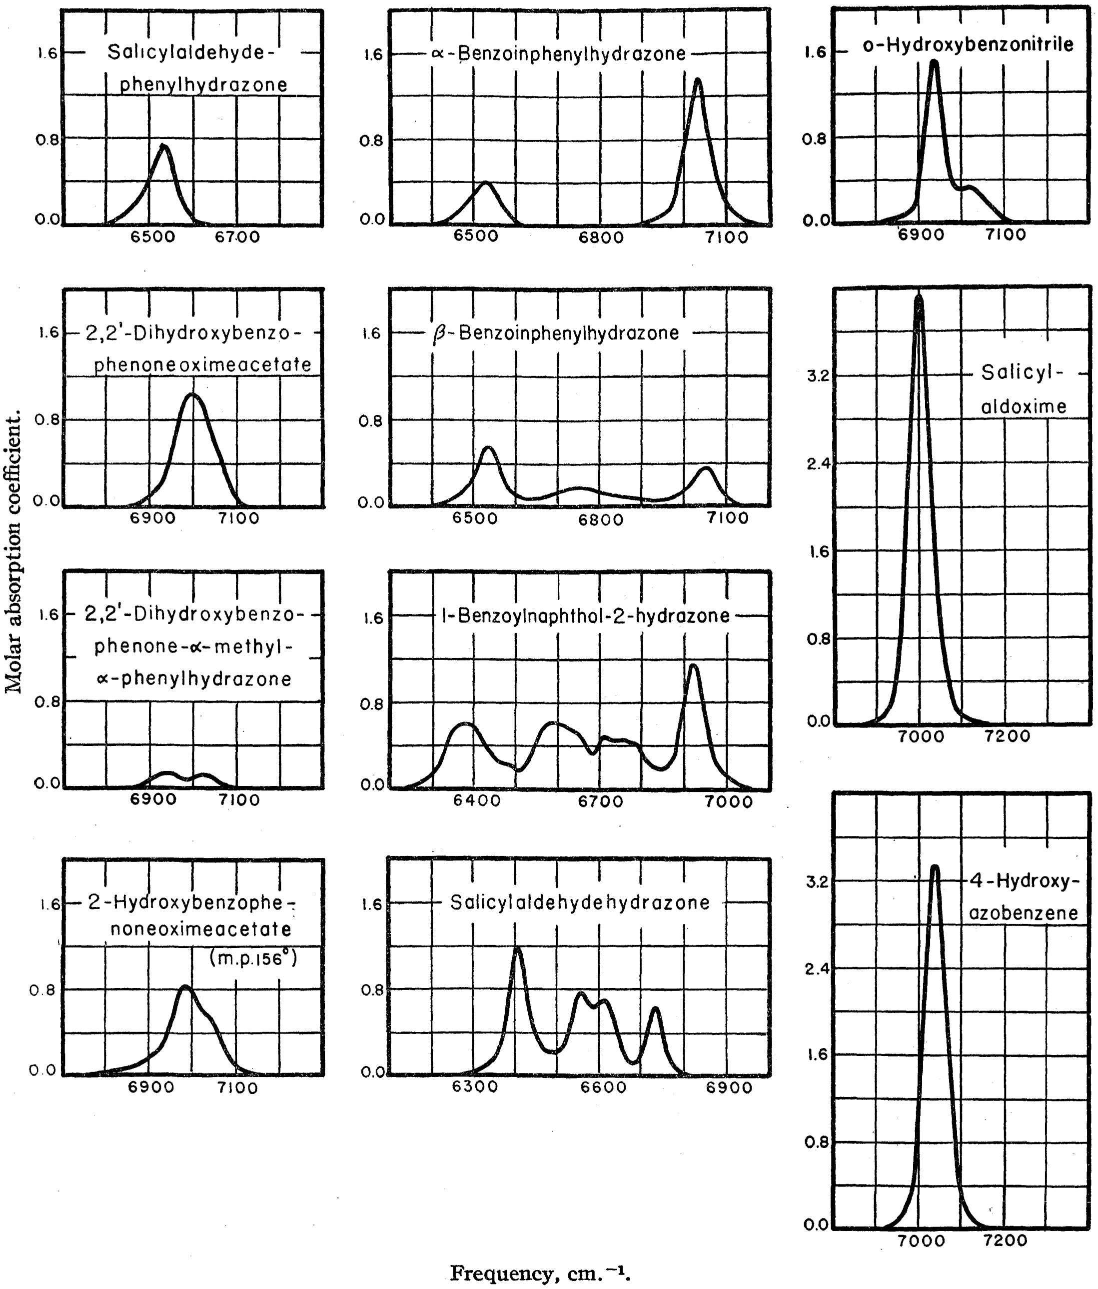

Fig. 2.—Molar absorption coefficients for some compounds of interest in the question of hydrogen-bond formation.

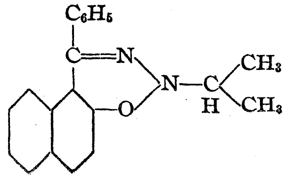
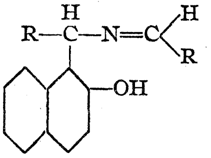
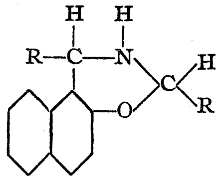
the presence of the hydrazine —NH_2 group. However, the absorption in the region of 7000 cm.$^{-1}$ is similar in shape and area to that found in many other phenolic compounds. It thus would seem that this substance does not contain a hydrogen bond and the possibility of ring formation through nitrogen is also eliminated. The latter compound on the other hand gave no absorption in the region studied which is of particular interest since it is derived from the hydrazone. Several explanations can be suggested for this behavior, one of which is that a six-membered ring through nitrogen



is present in the acetonyl derivative which, of course, is impossible in the case of the hydrazone. This situation is analogous to that existing in Schiff bases of the type



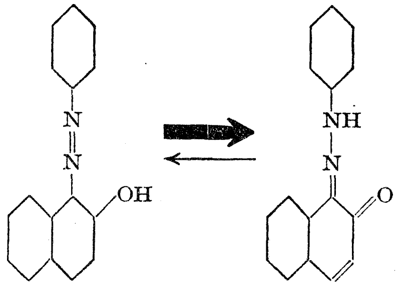
that in certain cases[14] are considered to be cyclicized as



Another possibility is that a hydrogen bond really is present in the one compound but not in the other. If this is the case it might arise from a combination of steric factors associated with an added *ortho* substituent, namely, the eight position of the naphthalene ring. Such a substituent is effective in preventing hydrogen bond formation in 2,5-dihydroxy-3,6-dibromodiethylterephthalate[1] but does not prevent it in 1-acetylnaphthol-2, a result in accord with the greater size of the bromine atom. If this explanation is correct the difference in behavior of the two naphthol derivatives probably arises from alteration of the electron affinity of the β-nitrogen atom, induced by variation of the Y group.

Characteristic OH absorption was absent for several *ortho* hydroxyazo compounds which are of the general type $R_1—N=N—R_2$. Among these were 2,5-dichlorobenzeneazo-1-naphthol-2 ($2,5\text{-}Cl_2C_6H_3N=N\text{-}1\text{-}C_{10}H_6OH\text{-}2$), 2,5-dichloro-2′-hydroxy-4-methyl-5′-chloroazobenzene ($2,5\text{-}Cl_2C_6H_3N=NC_6H_2OH(2)CH_3(4)Cl(5)$) and phenylazo-1-naphthol-2 ($1\text{-}C_{10}H_6OH(2)N=NC_6H_5$). In these compounds formation of five- or six-membered rings through nitrogen would require the presence of NH absorption which was not observed. Absorption due to the presence of OH in 4-hydroxyazobenzene is shown in Fig. 2 for comparison in order further to emphasize the striking departure of the hydrogen bonded compounds from normal behavior. The geometrical configurations of these compounds are probably similar to that of salicylaldehyde anil (Fig. 1) with hydrogen bonds between the hydroxylic oxygen and the β-nitrogen atom leading to six-membered rings including hydrogen. It also follows that the R_2 group is *trans* with respect to R_1 which is of particular value since chemical evidence on this point is lacking.

Presence of hydrogen bonds in the above azo compounds is further of interest in that the question of their configuration has been the subject of much discussion in the recent literature. The argument has chiefly centered upon phenylazo-1-naphthol-2 about which three discordant points of view have been held. Chemical evidence led Pfeiffer and his co-workers[5] to suggest that a hydrogen bond (partial valence) is present. Kuhn,[15] however, challenged this interpretation and suggested rather that the compound exists as a "Zwitter ion." The character of the ultraviolet absorption spectrum, however, later led Kuhn and Bär[16] to retract the earlier speculations and to interpret their results on the basis of an equilibrium between a quinoid and azo form of the molecule



the equilibrium being predominantly on the quinoid side. Burawoy,[17] who had earlier suggested, with Markowitsch,[18] a quinoid formula challenged the evidence indicative of such an equilibrium. Absence of absorption in the region studied characteristic of the presence of OH or NH definitely eliminates this third possibility. Since resonance is probably an important factor in the formation of hydrogen bonds in compounds of this type, both of the above forms possibly contribute to the stable state of the molecule.

Presence of two hydrogen bonds between oxygen and nitrogen atoms within a single molecule is indicated by the absence of OH absorption in 2,2′-dihydroxyazobenzene ($2\text{-}HOC_6H_4N=N\text{-}C_6H_4OH\text{-}2$) and salicylaldehydeazine ($2\text{-}HOC_6H_4\text{-}$

CH=NN=CHC$_6$H$_4$OH-2). The geometrical requirements are interesting in both these cases but particularly so in the former which probably has the configuration shown in Fig. 1c, the atoms of the entire molecule being co-planar with a center of symmetry (x). In both compounds the R groups of R—X=N—R must have a *trans* configuration which gives a *trans trans* arrangement for salicylaldehydeazine as shown in Fig. 1d.

Factors limiting the number of hydrogen bonds to a particular atom are obscured by our general lack of understanding of the entire phenomenon. Experimental work, however, showed that at least two such bonds could form to oxygen;[1] either within a single molecule, 2,2′-dihydroxybenzophenone, or by association of two molecules, salicylic acid (2-HOC$_6$H$_4$COOH)$_2$. The steric factors introduced by the three directed valences of nitrogen unfortunately make it difficult to devise a suitable molecule for testing possible formation of two hydrogen bonds to a single nitrogen atom within a molecule. Examination of 2,2′-dihydroxybenzophenoneoxime acetate (2-HOC$_6$H$_4$C(=NOCOCH$_3$)C$_6$H$_4$OH-2) and 2,2′-dihydroxybenzophenone - α - methyl - α - phenylhydrazone (2-HOC$_6$H$_4$C(=NNCH(C$_6$H$_5$))C$_6$H$_4$-OH-2) showed that both compounds gave absorptions that probably are to be associated with the presence of OH groups (Fig. 2). For neither substance, however, does the molal absorption exceed that given by normal phenolic compounds containing single OH groups and that of the latter compound is extremely low. If a hydrogen bond is formed in 2,2′-dihydroxybenzophenoneoxime acetate, then the geometry of the molecule is probably that shown in Fig. 1f, the ring R$_2$ being forced out of the plane of the figure by the proximity of the —OCOCH$_3$ group. Thus the molecule has a configuration similar to both the *syn* and *anti* forms of 2-hydroxybenzophenoneoxime acetate and would be expected to give an absorption similar to that of the non-hydrogen bonded form of this latter substance as was observed. The absorption of the α-methyl-α-phenylhydrazone derivative on the other hand is much less than that of the oxime acetate. This is possibly to be associated with the fact that while one of the —C$_6$H$_3$OH(R) groups must be *syn* with respect to the R$_2$(—NCH$_3$C$_6$H$_5$) substituent of R$_1$—C=N—R$_2$ the other can tend to form a hydrogen bond with the α nitrogen atom. The weak absorption naturally brings up the question of the limit dividing hydrogen bonded from non-hydrogen bonded compounds or possible gradations from one extreme to the other. The body of experimental evidence is not yet sufficient to permit of reasonable discussion of this point.

Measurements were made on a number of compounds in which hydrogen bond formation was not particularly expected. Among these was 2-hydroxybenzonitrile (2-HOC$_6$H$_4$CN) and this gave OH absorption as shown in Fig. 2. In this compound the nitrogen atom of the —C≡N group, note Fig. 1e, is so far from the OH group as to make impossible hydrogen bond formation within the molecule. Absorptions given by α- (m. p. 155°) and β- (m. p. 106°) benzoinphenylhydrazones are shown in Fig. 2. These compounds give absorptions near 6600 cm.$^{-1}$ which is to be expected from the presence of NH groups. However, additional absorption between 6600 and 7100 cm.$^{-1}$ is probably due to the presence of OH groups. Results obtained from α- and β-benzoinoxime acetates[1] and from 8-hydroxyquinoline[6] have been published previously. While all these compounds show complex absorption which is worthy of further analysis, it is sufficient for the present purpose to point out that they give considerable absorption in the OH region. A hydrogen bond to a nitrogen atom forming a five-membered ring including hydrogen is possible for all these compounds but apparently is not present in any of them.

Summary

Presence of hydrogen bonds in a number of *ortho* hydroxy aromatic compounds of the general type 2-HOC$_6$H$_4$X=NY, where X is nitrogen or carbon, and Y is carbon, nitrogen or oxygen was indicated by absence of infrared absorption associated with presence of hydroxyl groups. Formation of hydrogen bonds requires the HOC$_6$H$_4$ group to have a *trans* configuration with respect to Y and this is true for the oximes, hydrazones, substituted imides and azo compounds that were studied.

WASHINGTON, D. C. RECEIVED JULY 20, 1936

[CONTRIBUTION FROM THE BUREAU OF CHEMISTRY AND SOILS, UNITED STATES DEPARTMENT OF AGRICULTURE]

Concerning "β"-2,3,4,6-Tetraacetyl-*d*-glucose

BY S. B. HENDRICKS, O. R. WULF AND U. LIDDEL

During a general study of the absorption of organic compounds in the infra-red region of the spectrum in progress in this Laboratory, an attempt was made to obtain information about the structures of the sugar hydrazones and oximes. In the course of this work, which now does not hold much of promise, various acetylated hexoses and pentoses were prepared. Results of some observations, that started in a rather accidental manner, on β-2,3,4,6-tetraacetyl-*d*-glucose are described below.

Two different 2,3,4,6-tetraacetyl-*d*-glucoses are described in the literature and, in harmony with sugar nomenclature, are designated as α and β. The β-form, as prepared by Fischer and Delbrück,[1] melted at 117°, but later investigators, particularly Georg[2,3] using Fischer and Delbrück's method of preparation, obtained materials melting near 135° with somewhat more negative optical activities. Georg[2] concerned himself about these differences, accounting for the depressed melting points by presence of alkaline impurities from the melting point tubes. Actually more abstruse factors are present and further study shows that the differences in properties of the various preparations arise from admixture of two different molecular forms to which peculiar interest attaches because of the nature of their mutarotations.

Samples of "β"-2,3,4,6-tetraacetyl-*d*-glucose prepared after the method of Fischer and Delbrück gave, when crude, melting points between 118 and 128° and specific optical activities from +28 to +7° in ethyl alcohol. Melting points and optical activities were brought into agreement with the values found by Georg, m. p. 138°, $[\alpha]^{25}_{\mathrm{D}}$ −3.0°, by recrystallization from ether. Several samples of this recrystallized material (later referred to as Ia) after standing for two years had melting points near 120° and positive optical rotations. Recrystallization of the altered materials from ether changed them back into Ia. Change of Ia to this second form (later referred to as Ib) could also be effected by several days' heating in carbon tetrachloride or benzene solutions.

That the explanation for these observations is not simply the presence of impurities is best shown by the absorptions of the various materials in the infra-red region, 6000–7500 cm.$^{-1}$. Absorption due to the presence of OH groups is found near 7000 cm.$^{-1}$ [4] and since tetraacetylglucose contains only one OH group measurements in this region are particularly valuable for characterizing its possible molecular forms. According to the present technique measurements are made on carbon tetrachloride solutions, preferably about 0.02 molal, since it is undesirable to have RH groupings present in the solvent. Samples of the two forms of "β"-2,3,4,6-tetraacetyl-*d*-glucose gave the molal absorptions shown in Fig. 1, Ia showing two maxima and Ib a single maximum. Absorption curves for α-2,3,4-triacetyl-*d*-xylose and β-2,3,4,6-tetraacetyl-*d*-galactose are also shown in Fig. 1 in order that one unfamiliar with this type of measurement might have a more general basis for evaluating the work.

The specific optical activity of Ib in ethyl alcohol indicates that it might be a compound[5] containing three parts of Ia and one part of α-2,3,4,6-tetraacetyl-*d*-glucose. This possibility is not supported by the optical activity in chloroform and is definitely eliminated by the absorption data. It would not be possible to derive the absorption curve for Ib from any mixture, xIa + yI (hypothetical), with $x = y$ since then I (hypothetical) would have negative absorption values.

That Ia and Ib are strictly isomorphous is shown by the microscopic examination, the identity of their x-ray powder diffraction patterns, and by the fact that the transition in the solid state takes place without destruction of single crystals. This isomorphism suggests that the geometrical shapes of Ia and Ib are similar.

Thirteen or more reasonable forms can be suggested for the configurations of Ia and Ib; α and β on the 1 carbon atom, ortho acetate formation between the OH in the 1-position and the 2- or 3-acetyl group either of which might exist in *d*

or *l* forms, aldehydo and *cis* and *trans* isomers. Neither Ia nor Ib is probably the *α* form since it would have a considerably more positive optical activity.[6] Neither form gave the usual aldehyde tests nor did they react with diazomethane which was tried at the suggestion of Dr. G. E. Hilbert of this Laboratory. It was thought that an ortho acetate would be a sufficiently strong acid to be methylated by diazomethane. The presumptive conclusion then is that the materials are *cis* and *trans* ring isomers, the danger being that the chemical tests are not trustworthy.

"*β*"-2,3,4,6-Tetraacetyl-*d*-glucose as prepared after the method of Weizmann and Haskelberg[7] showed a rather peculiar behavior. The crude material was similar in optical activity and melting point to that prepared according to the method of Fischer and Delbrück but many recrystallizations from ether did not change it into Ia. Large crystals with intermediate melting points (125–131°) could be grown from ether solutions and various fractions from these solutions had the same characteristics. It would seem either that some minor impurity difficult to separate is present or that an obscure catalyst is needed.

Experimental

"*β*"-2,3,4,6-Tetraacetyl-*d*-glucose was prepared from acetobromoglucose and moist silver carbonate after the method of Fischer and Delbrück save that the acetone was evaporated after reaction for a few minutes at 0°. The crude residue was immediately washed with ether and recrystallized from dry ether; yield 40–60%. Crude crystalline materials (m. p.'s 105–120°) upon standing gave odors of acetic acid and could not then be recrystallized from ether.

A number of methods of purification were tried and some of these are indicated schematically below, starting materials, solvent, number of recrystallizations, and final melting points, optical activities, etc., being given: (a) crude, twice ethyl acetate, m. p. 122–125°, $[\alpha]^{20}_D$ +15° (1.3% in C_2H_5OH) calcd. for $C_{14}H_{20}O_{10}$: C, 48.25; H, 5.79. Found: C, 48.33; H, 5.94. (b) crude, twice amyl acetate, m. p. 125–128°, twice dry ether, m. p. 136–138°, $[\alpha]^{20}_D$ −3° (1.0% in C_2H_5OH); (c) crude, four times from dry ether, m. p. 136–138°, twice benzene, m. p. 138–140°, $[\alpha]^{20}_D$ $-4.2 \longrightarrow +75°$ after ten days (1.9% in C_2H_5OH) $+18.8° \longrightarrow +78°$ after ten days (1.7% in $CHCl_3$). Five grams of (c) was dissolved in 10 cc. of freshly distilled nitromethane and set aside in the ice box.

---

(6) Schlubach and Wolf, *Ber.*, **62**, 1507 (1929), have prepared a form of 2,3,4,6-tetraacetyl-*d*-glucose having $[\alpha]_D$ +139.4° (in ethyl alcohol) and have designated it as *α*.

(7) Weizmann and Haskelberg, *J. Chem. Soc.*, 1023 (1935).

A single crystal weighing *ca.* 3 mg. separated during two days, m. p. 138°, the mother liquor was concentrated and the material was thrown out with ether. The final fraction had a melting point of 138°. Acetylation of (b) yielded pentaacetyl-*d*-glucose melting at 130°, unchanged upon mixing with an authentic sample.

Transformation of Material Melting at 138 to 120° Form.—Four separate samples of (b) above were set aside for two years at the end of which time they had the following melting points: (d) 114–118°, (e) 119–120°, (f) 118–124°, (f′) strong odor of acetic acid, material quite spongy. Sample (d) was recrystallized twice from ether and gave (g) with a melting point of 136–139°. Five grams of (d) kept at 60° in carbon tetrachloride solution for two days gave 1.0 g. of material melting at 120–120.5°, $[\alpha]^{20}_D$ +30° + ⟶ (1% in C_2H_5OH). Five grams of (c) heated, near the boiling point, for three days with 800 cc. of carbon tetrachloride upon concentration to 200 cc. gave 1.5 g. of crystals, m. p. 120–122° (h) $[\alpha]^{20}_D$ +32.6 ⟶ +79° after ten days (1.9% in C_2H_5OH) +40° ⟶ (1.6% in $CHCl_3$). Five grams of (c) refluxed with 50 cc. of benzene gave (j) about 1.0 g. of crystals, m. p. 114–117° $[\alpha]^{20}_D$ +36° (1.6% in C_2H_5OH) +46° (1.4% in $CHCl_3$). Sirups from (h) and (j) were not brought to crystallization upon long standing and repeated addition of (c) in 0.5-g. amounts.

Microscopic and X-Ray Examination.—Samples (b) and (c) gave well-formed crystals about 2.0 × 0.5 × 0.5 mm. from ether, with parallel extinction; α_D = 1.483, γ_D = 1.495, biaxial positive with large optic axial angle. Crystals from (g) and (h) had the same constants but differed in habit. Samples (d), (e) and (f) contained only crystals similar to (b) and (c) and showed uniform extinction. X-ray powder diffraction patterns of (j) and (c) were identical in all details (Cu K radiation).

Attempted Methylation of 138 and 120° Materials.—One gram ($^{1}/_{340}$ mole) of (c) was treated in 75 cc. of ether solution with $^{1}/_{25}$ mole of fresh diazomethane. No reaction was apparent and the yellow color remained after five days of standing. The ether was removed and after recrystallization 0.7 g. of material melting at 133–136° was obtained. One-half gram of (h) ($^{1}/_{680}$ mole) was treated in a similar manner in carbon tetrachloride solution without evident evolution of nitrogen. After five days the solution was evaporated but the residues could not be brought to crystallize.

"β"-2,3,4,6-Tetraacetylglucose after Weizmann and Haskelberg.[7]—Acetobromoglucose (115 g.) was treated as directed with sodium nitrite solution. After five days the acetone-rich phase was evaporated and a sirup was obtained which did not crystallize overnight but from which 10 g. of a material melting between 118–123° separated after two days' standing with ether. During a month in the presence of ether and ligroin 15 g. more of this material was obtained. These combined samples designated as (m) had $[\alpha]^{20}_D$ +14° (1.6% in C_2H_5OH) and +27° (2.4% in $CHCl_3$). The following results were obtained when purification was attempted, the number of crystallizations and melting points being indicated: one carbon tetrachloride (121–124°), two ether (125–128°), two hours of boiling ether (125–128°), residues from mother liquors (125–128°), twenty-four hours of boiling in absolute ether (fraction 1 (125–128°) fraction 2 (125–128°)), three hours of boiling in absolute ether with 0.1% acetic acid (125–128°), four hours of boiling with charcoal in ether (125–131°), absolute ether (128–131°). The final material was divided into two parts one of which was refluxed for two hours in ether solution with the silver carbonate–silver bromide residues from preparation (c) (124–131°) and the other was recrystallized from the mother liquors of (c) which contained about 10% as much of Ia (133–137°).

Infra-red Absorption.—Molal absorptions were measured for carbon tetrachloride solutions, usually about 0.018 molal, that were maintained near 60°. Preparation (c) gave the results shown in Fig. 1, the absorption being measured about one and one-half hours after preparation of the solution, and this slowly changed (at 60°) over a three-day period to that having a single maximum. Qualitative absorption data obtained from various samples are described below. Crude materials from the preparation after the method of Weizmann and Haskelberg gave absorptions corresponding to about equimolal mixtures of Ia and Ib, after many recrystallizations from ether the results were nearer those obtained for Ia but still indicated the presence of Ib. Samples prepared after the method of Fischer and Delbrück were examined after a single recrystallization from ether and were found to be quite pure Ia. A sample of Ia after standing for two years gave the absorption of Ib and after recrystallization from ether that of Ia.

We are indebted to Dr. R. T. Milner and Mrs. M. S. Sherman for the various microanalyses.

Summary

"β"-2,3,4,6-Tetraacetyl-*d*-glucose can be separated into two different molecular forms having different optical activities, spectral absorptions and melting points. The form having the higher melting point usually can be obtained by recrystallization from ether. Upon standing for a long time in the solid state it changes to the second form through a complete series of solid solutions.

Single Bond Energies. IV. The Vapor Pressure of Hexaphenylethane

BY G. R. CUTHBERTSON AND H. E. BENT

The first three papers of this series[1] present data on the heat of oxidation and hydrogenation of certain organic free radicals. From these data conclusions are drawn regarding the strength of the C–C bond in the substituted ethane which gives rise to a free radical on dissociating.[2] If one makes certain assumptions regarding the strength of single bonds, one can calculate the effect of steric hindrance in the substituted ethane, which shows up as an increased heat of oxidation or hydrogenation. Without making any assumptions regarding the absolute values for single bond energies, one can compare various substituted ethanes and determine the relative significance of steric hindrance in passing from one to another. Finally one can estimate the significance of resonance energy in each case in promoting dissociation.

The above study led to the conclusion that both steric hindrance and resonance are very important factors in describing the behavior of free radicals. Furthermore these two factors may vary in passing from one free radical to another in such a way as largely to cancel each other and therefore give no evidence of their importance in a determination of the degree of dissociation alone.

The results heretofore reported have been obtained by a study of reactions involving solutions only. In order to draw conclusions free from uncertainty introduced by the presence of solvent, we determined to carry out experiments which would enable us to calculate the heat of oxidation and hydrogenation in the vapor state. Presumably these experiments would also give an answer to the time-honored question of the importance of the solvent in the whole phenomenon of the existence of free radicals. The experiments of Ziegler and Ewald[3] make it seem very probable that the solvent is not of prime importance since the free energy and the heat of dissociation are not greatly affected by a change in solvent. Nevertheless, a direct determination of the importance of the solvent is greatly to be desired.

The problem of determining the vapor pressure of a free radical is not easy. The instability of the compound precludes the possibility of working at elevated temperatures and the extremely low vapor pressure of even the simplest free radical at ordinary temperatures eliminates most methods of study. We have chosen a quartz fiber gage. Coolidge has greatly improved the design of this gage and has suggested its use in such problems as the one in hand.[4] From the vapor pressure curve can be calculated the heat of sublimation of hexaphenylethane. Similar measurements on triphenylmethane and on the peroxide formed in the oxidation of hexaphenylethane then give data which can be combined with the values obtained for the heat of hydrogenation and oxidation of hexaphenylethane in solution. We have already reported data on the heats of solution and therefore have a method for calculating the heat of hydrogenation and of oxidation in the vapor phase. From these data we may discover the effect of the solvent on the heat of the reaction and can estimate the effect on the free energy of dissociation.

As Coolidge has pointed out, it is not possible to determine with the quartz fiber gage the molecular weight of a vapor, some independent means of measuring the pressure being necessary for this purpose. It seemed barely possible, however, that a temperature and concentration might be available at which dissociation of the ethane was incomplete and the temperature dependence of the pressure would then give the second desired relation necessary for a determination of the molecular weight. This did not prove to be the case and we were therefore forced to devise additional experiments in order to solve this part of the problem. The most convenient determination seemed to be that of the vapor density. Unfortunately this part of the work is incomplete at the present time. Since the work has been temporarily interrupted it seems best to report progress to date.

Materials

The hexaphenylethane was part of the material used in the work reported in the first two papers of this series. The determination of the purity of the material by means

of oxygen absorption indicated that any impurity was probably not more than 1%. The sample of triphenylmethyl peroxide was also prepared in connection with the oxidation of hexaphenylethane and was purified by recrystallization. The sample of triphenylmethane, after crystallization, melted at 92.1 ± 0.1°.

Experimental Procedure

The quartz fiber gage is of the type described and developed by Coolidge.[4] In order to simplify the calculations the fibers were made rather long (about 15 cm.) and small in diameter. The loss of energy in the fiber thus becomes so small as to be entirely negligible. When the gage is highly evacuated, many hours are required for the amplitude to die down to one-half while in the course of ordinary measurements the time required is from twenty to one hundred seconds. This justifies the neglect of the energy dissipated in the fiber.

The gage was calibrated by measuring the pressure of nitrogen with the quartz fiber gage and a McLeod gage. As a second method it was calibrated by measuring the pressure of mercury at various temperatures. The latter method agrees quite well with the former and has been used to calculate the constant "b" in the equation

$$\log p = \log \ln A_1/A_2 - \log b + {}^1/_2 \log T - {}^1/_2 \log M - \log t$$

in which p is the pressure expressed in millimeters of mercury, A_1 and A_2 are the amplitudes of the fiber, usually being about 10 and 5 mm., respectively. b is a constant characteristic of the fiber, M is the molecular weight, T is the absolute temperature and t is the time required for the fiber to die down from A_1 to A_2. The following table will indicate the reliability of the gage, the value of log b being 0.665. The values for the vapor pressure of mercury are calculated by the formula[5]

$$\log p = 8.99393 - 3250/T - 0.30 \log T - 0.00018\,T$$

in which p is expressed in millimeters.

TABLE I

THE VAPOR PRESSURE OF MERCURY

Temp., °C.	Pressure, mm.	
	Found	Calcd.
16.8	0.00097	0.00099
29.8	.00291	.00294
40.8	.00781	.00789
49.0	.0127	.0124
52.2	.0158	.0156
52.4	.0160	.0158

At the beginning of a run the gage and tube in which the sample is to be placed are baked at 400° for several hours while evacuating the apparatus to a pressure of 10^{-5} mm. The apparatus is then allowed to cool and the capsule containing the triphenylmethane broken and allowed to drop down into the apparatus. The tube containing the capsule and magnetic hammer is sealed off and the triphenylmethane twice sublimed to different parts of the tube with intermittent pumping to remove gases which might be liberated. In making a measurement the system is pumped, using a liquid air trap, to remove any foreign gas and then the system shut off from the pump and trap by means of a magnetically controlled ground-glass stopper. The fiber is set oscillating by means of a slight impulse given to the furnace in time with the natural frequency of the fiber. A micrometer eyepiece on a telescope serves to give any convenient change in amplitude, the time required for this change being noted with a stop watch. After taking a reading the system is again pumped at the same temperature and the pressure again determined.

The thermostat is an electrically heated air-bath with windows of thin mica and a blower within the thermostat to circulate the air. The reasons for choosing an air thermostat (which of course cannot be regulated easily with high precision) are to allow high temperatures for baking the apparatus, to avoid parallax in reading the gage, and to be able to change the temperature rapidly in the case of hexaphenylethane in order to avoid decomposition as much as possible.

In the case of hexaphenylethane and the peroxide it was not possible to sublime the material without undue decomposition. Probably some of the earlier determinations are in error on account of foreign gas. However, the final runs which are here reported indicate that the method of pumping just before each determination gave reproducible results which could be repeated with either a rising or falling temperature.

As was to be expected, decomposition took place with both the ethane and the peroxide. We therefore made careful measurements of the pressure over a period of time sufficiently long to enable us to extrapolate back to zero time for the true pressure. Fortunately the rate of decomposition is less than the rate of evaporation or this procedure would not have been possible. The pressure turns out to vary nearly as a linear function of the time so that it is possible to take the time required for the fiber to decrease in amplitude by a given amount as an accurate measure of the pressure at the mid-point of this time interval. This may readily be justified as follows. If we assume that the pressure is a linear function of the time and is represented by the expression

$$p = \alpha + \beta t$$

we can substitute this in the expression given for the gage[4] to give

$$\mathrm{d}A/A\mathrm{d}t = a + b\sqrt{M}\,(\alpha + \beta t)$$

Neglecting the constant "a" which we have shown to be justified for this gage we have on integration

$$1/t \ln A/A_0 = b\sqrt{M}\,(\alpha + \beta t/2)$$

which enables one to solve for the quantity in parentheses, namely, the pressure at a time half-way between the initial and the final time for the gage reading. These values for the pressure, when plotted against the total time, since the apparatus was closed from the pump, give a smooth curve which can be extrapolated back to zero time to give the pressure which would be obtained if no decomposition had taken place. The error introduced by this extrapolation is probably of the order of 10% in the pressure.

Discussion of Experimental Results

The experimental values for the pressure are given with the values calculated from the following equations. For triphenylmethane the pres-

---

(5) *C. A.*, **28**, 4935 (1934).

sures can be expressed by the equation $\log p = -5260/T + 12.72$, which gives a value for ΔH of 24.1 ± 1.0 kcal. For hexaphenylethane the equation is $\log p = -5987/T + 12.85$, giving a value for ΔH of sublimation of 27.4 ± 1.5 kcal. For triphenylmethyl peroxide the equation is $\log p = -8259/T + 16.98$ and the value for ΔH is 37.8 ± 1.5 kcal.

[a] The experimental values at low pressures may be brought into agreement with those calculated from the equation by assuming the presence of foreign gas to the extent of about 10^{-5} mm.

We may now combine these values with those previously reported for the heat of oxidation and hydrogenation of solid hexaphenylethane to give solid product. We thus obtain a value for the heat of hydrogenation of gaseous hexaphenylethane of −19.7 kcal. and of oxidation of gaseous hexaphenylethane of −35.1 kcal. We may compare these values with the values to be predicted from single bond energies and thermal data of −8 and −4 kcal. The fact that the energy change for the reaction in the gaseous phase is so much more negative than that predicted, we take to be an indication of the steric hindrance in the molecule. The weakening of the C–C bond is therefore inferred to be equivalent to 12 kcal. if we consider the reaction of hydrogenation and 31 kcal. if we consider the oxidation. The agreement between these two figures is not satisfactory but at present we have no explanation.

The measurements on the rate of decomposition shed some light on the nature of this reaction. The reaction appears to be a unimolecular reaction with zero heat of activation, one of the products of the reaction being triphenylmethane. The rate of decomposition, as measured by the increase in pressure while the gage was open to the sample but closed from the pump, varied from $1\text{–}5 \times 10^{-3}$. However, as the concentration was varied by a factor of 200 and the temperature by 45° the variation in rate probably is not significant. Furthermore, the variation in rate was little more than the variation obtained in successive runs at a given temperature and when plotted gave no indication of a variation dependent upon the temperature. The product of the reaction was identified by a mixed melting point as triphenylmethane. Other products are also formed of high molecular weight and having a yellow color.

The rate of decomposition of the peroxide appeared to be much more reproducible and in fact a plot of the log of the rate constants against the reciprocal of the absolute temperature permits one to draw a smooth curve through the points. However, the curve has a maximum at about 140° and therefore we attach little significance to these data. The activation energy for the decomposition as determined from the lower part of the curve is roughly 30 kcal.

The data on the heat of vaporization of triphenylmethane and hexaphenylethane give a pretty conclusive answer to the question of dissociation in the vapor phase. The value for triphenylmethane is 24.1 and for hexaphenylethane is 27.4. We would expect the latter compound to have a greater heat of vaporization on account of its greater molecular weight. The most probable explanation of these figures is that hexaphenylethane is not dissociated in the vapor state and that the value 27.4 represents the true heat of vaporization of hexaphenylethane. The possibility of dissociation being negligible at the lower temperatures but becoming important at higher temperatures is ruled out on account of the straight line obtained by plotting log p against $1/T$. Dissociation would increase the pressure, the partial pressure of the undissociated material being that given by the sublimation pressure of the ethane at that temperature. Hence the curve would be convex toward the temperature axis. Almost complete dissociation of the ethane at all temperatures reported in this work would give a straight line plot but seems very improbable for two reasons. In the first place the total pressure would have to be the sublimation pressure of the ethane plus the pressure of the free radical. If the ethane were practically completely dissociated, this would lead to a total pressure of perhaps 100–1000 times that of the ethane, since the solid ethane would have to be in equilibrium with its vapor. This is not compatible with the observed pressure which is only 1/100 of that of triphenylmethane at about 90°. Furthermore, the slope of the curve would give in this case half the heat of dissociation plus half the heat of sublimation of the ethane. If we were to assume 10 kcal. for dissociation, this would lead to 50 kcal. for sublimation, which seems unreasonably large when compared with the value of 24.1 for triphenylmethane. The fact that hexaphenylethane has twice the molecular weight of triphenylmethane would not lead to doubling the heat of sublimation, as an increase of only 50% is observed in going from triphenylmethane to the peroxide.

If we assume that the dissociation is less than 10% at the lowest temperature, we can calculate that ΔF must be at least + 15 kcal., expressing concentrations in atmospheres. If there is an increase in entropy on dissociation, as seems very probable, the value for ΔH of dissociation in the vapor state may be considerably more than 15 kcal.

Summary

1. The vapor pressures of triphenylmethane, hexaphenylethane and triphenylmethyl peroxide have been measured by means of a quartz fiber gage.

2. The values calculated for the heat of vaporization of these compounds indicate that the C–C bond in hexaphenylethane in the vapor state is weaker than a normal C–C bond. The heat of dissociation, however, is probably greater than that found for hexaphenylethane in solution.

Equilibria in the Saturated Solutions of Salts Occurring in Sea Water. II. The Quaternary System $MgCl_2$–$CaCl_2$–KCl–H_2O at 0°

BY IVER IGELSRUD WITH THOMAS G. THOMPSON

No data on the quaternary system $MgCl_2$–$CaCl_2$–KCl–H_2O occur in the literature. This system is of importance in the study and utilization of the secondary salts in natural deposits originating from sea water. Data at lower temperatures are important to an adequate understanding of the geological processes to which the natural salts and their solutions are subject during cold winter periods.

A survey of the literature on the bounding ternary systems, together with data for their 0° isotherms, has been given in a previous paper.[1] The experimental procedure, the methods of purification of the salts, and the methods of chemical analysis used in the study of the quaternary isotherm were the same as for the ternary systems. Samples of the saturated solutions and solid phases in equilibrium were taken for chemical analysis as described. The time found sufficient for the attainment of equilibrium in the quaternary system was from twelve to fifteen hours as compared with eight to ten hours for the ternary solutions.

The results of the chemical analyses for solutions and residues are given in Table I. The data for the saturated solutions are depicted graphically in Figs. 1, 2 and 3. Figures 4 and 5 illustrate the methods used for the identification of the solid phases.

The Quaternary Isotherm.—The quaternary isotherm requires a three-dimensional coördinate system for a complete representation of the compositions of the saturated solutions. It is schematically so represented in the conventional regular tetrahedron in Fig. 1. The usefulness of this figure is impaired because it is impossible to represent a three-dimensional figure on a flat sheet of paper in a manner so that quantitative measurements may be made upon it. It is necessary, therefore, to resort to projections. The most simple method of projection of the tetrahedral figure is that suggested by Schreinemakers.[2] One of the vertices, the H_2O vertex, is made the origin of a coördinate system. The three edges radiating from this vertex and making angles of 60° with one another, are the magnesium, calcium and potassium chloride axes. The three planes determined by the three pairs of axes are the coördinate planes of the system. In the coördinate planes are represented the ternary equilibria in the usual manner. Projections of the quaternary equilibria upon the coördinate planes are made parallel to the axes. For example, a quaternary point representing 30% $MgCl_2$, 15% $CaCl_2$, 2% KCl, and (100 − 30 − 15 − 2)% H_2O projected parallel to the $CaCl_2$-axis appears on the $MgCl_2$–H_2O–KCl plane at 30% $MgCl_2$ and 2% KCl; projected parallel to the $MgCl_2$-axis, it appears on the $CaCl_2$–H_2O–KCl plane at 15% $CaCl_2$ and 2% KCl. Two of the three possible projections are sufficient to determine the point completely.

Figures 2 and 3 present, in this way, the complete data for the saturated solutions of the quaternary isotherm. The space figure has been projected upon the two planes $MgCl_2$–H_2O–KCl and $CaCl_2$–H_2O–KCl. Because some of the saturation surfaces, notably that of $MgCl_2 \cdot 6H_2O$, are small it was necessary for the sake of clearness to make the scale on the KCl-axis three times as great as on the other two axes.

The most striking feature of this system is the smallness of the area representing solutions satu-

---

(2) F. A. H. Schreinemakers, *Z. physik. Chem.*, **59**, 641 (1907).

rated for $MgCl_2 \cdot 6H_2O$. The same characteristic of magnesium chloride solutions is noted in the quaternary system that was found in the ternary system, namely, that carnallite is almost wholly insoluble in solutions saturated for $MgCl_2 \cdot 6H_2O$. Calcium chloride solutions dissolve, relatively, more carnallite.

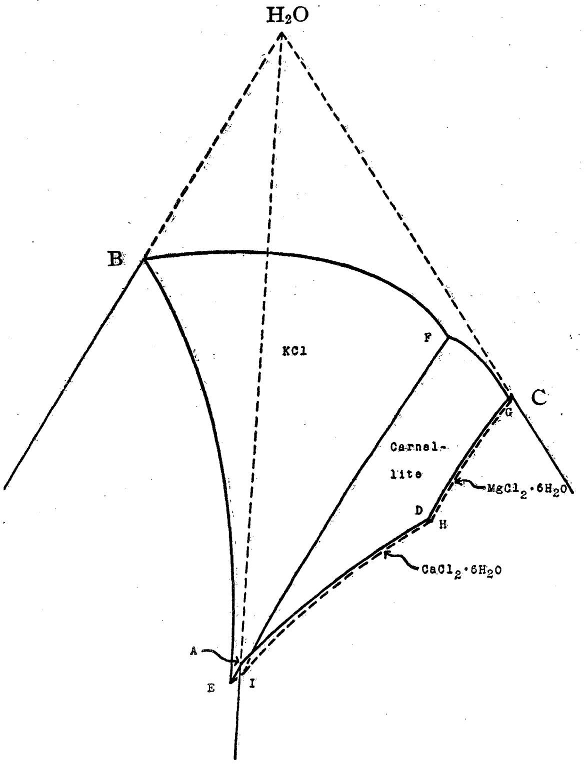

Fig. 1.—The system $MgCl_2$–$CaCl_2$–KCl–H_2O at 0°. Only the upper portion of the tetrahedron is shown.

The saturation surface for $CaCl_2 \cdot 6H_2O$ is also small but not so small as that for $MgCl_2 \cdot 6H_2O$. The chief reason for the larger area is undoubtedly the fact that calcium and potassium chlorides, at this temperature, form no hydrated double salt similar to carnallite. Menge,[3] working with the fused salts, obtained an anhydrous calcium carnallite, $CaCl_2$–KCl, which melted at 754° and formed eutectics at 641 and 597°.

The solubility of potassium chloride in solutions saturated for $CaCl_2 \cdot 6H_2O$ is but slightly less than in solutions saturated for carnallite. In going from F to I along the KCl–carnallite curve, the solubility drops only about 0.3%. The effect of the addition of calcium chloride to carnallite solutions on this curve is, however, quite marked. In proceeding along FI the magnesium chloride in solution is exchanged for calcium chloride and precipitates as carnallite. As shown by the data in Table I, the magnesium chloride content is decreased from 26.7% at F to 3.3% at I by successive additions of calcium chloride. When the magnesium chloride content of the solution falls below 3.3% or the calcium chloride content rises above 33.4%, carnallite cannot exist as a solid phase and KCl and $CaCl_2 \cdot 6H_2O$ become the only two possible solid phases.

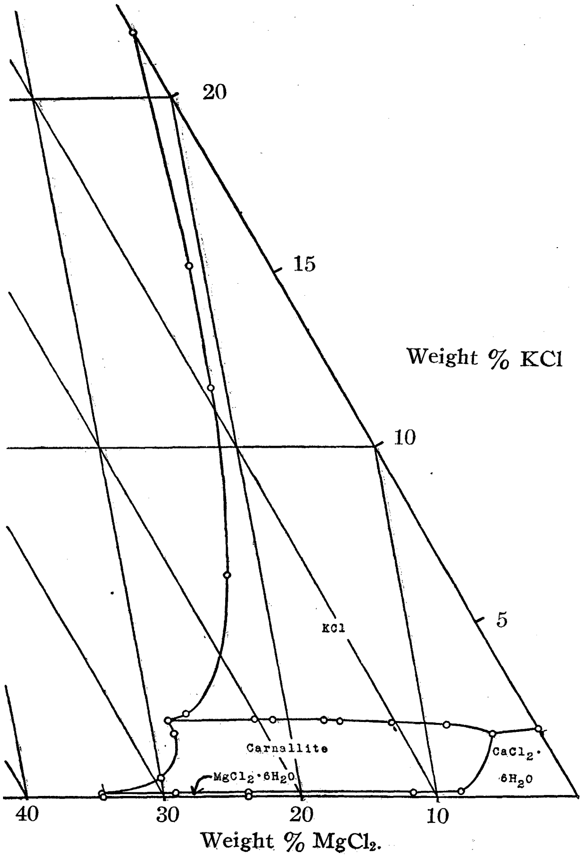

Fig. 2.—The quaternary isotherm projected upon the plane $MgCl_2$–H_2O–KCl.

In discussing the system $MgCl_2$–KCl–H_2O,[1] it was remarked that all solutions saturated for carnallite were incongruently saturated. The same may be said of all saturated carnallite solutions in the quaternary system. The ratio of potassium chloride to magnesium chloride, by weight, in carnallite is the ratio of their molecular weights, 74.56/95.23 = 0.783. All points on the curve FI which borders on the carnallite saturation surface, have lower ratios than this. The point I thus represents an incongruently saturated solution in equilibrium, in the presence of an ex-

(3) O. Menge, *Z. anorg. Chem.*, **72**, 162 (1911).

cess of solid potassium chloride, with the three solid phases $CaCl_2 \cdot 6H_2O$, KCl and carnallite. The point H, on the other hand, represents a congruently saturated solution in equilibrium with $CaCl_2 \cdot 6H_2O$, carnallite and $MgCl_2 \cdot 6H_2O$. The composition of the solution at I is 3.30% $MgCl_2$, 33.39% $CaCl_2$ and 1.87% KCl; the composition of that at H is 23.97% $MgCl_2$, 14.04% $CaCl_2$ and 0.035% KCl.

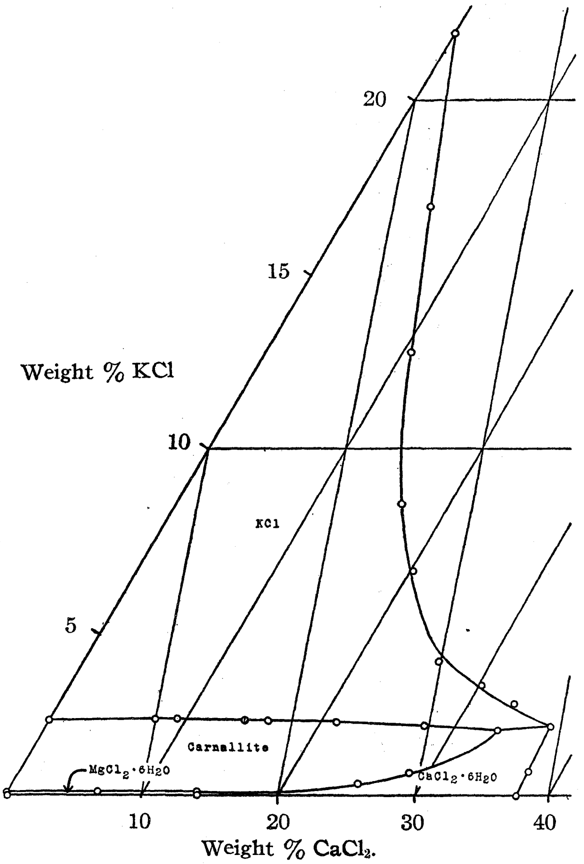

Fig. 3.—The quaternary isotherm projected upon the plane $CaCl_2$–H_2O–KCl.

A point of interest in connection with this isotherm is the water content of some of the solutions. At the monovariant point of the 0° isotherm of the system $CaCl_2$–KCl–H_2O, the percentage of water was 60.77.[1] At I, it is 61.44 and at H, 61.95. From the motion observed along the curves, on successive additions of the fourth component, during the experimental work, the point H appeared to be the isothermal drying-up point of the solutions. This anomaly disappears when the percentages are computed on a molecular basis. The molecular percentages of water are 90.63, 90.74 and 90.09, respectively. The difference between the values for the first two points, 0.11%, is of no significance since it lies within the experimental error of the analytical determinations.

The Quaternary Solid Phases.—The Schreinemakers residue method, since originally published in 1893, has been widely used for the identification of unknown phases in ternary systems. This method was later extended by the discoverer[2] to quaternary systems, but this extension has received no notice in the more common treatises on phase rule methods. It was used in the present investigation and, since it is a valuable tool, its application is described somewhat in detail.

In applying it to a quaternary system, it need only be remembered that where the single solid phase occurs along a saturation curve in the ternary system, it occurs on a saturation surface in the quaternary system. If the compositions of two or more saturated solutions of this surface and the compositions of the corresponding residue samples are determined, conjugation lines are obtained which intersect at the point representing the composition of the unknown phase. The method may be used also to show the simultaneous presence of two or more solid phases in contact with a saturated solution. This is of great convenience in experimental work because it furnishes an absolute check on the phases present and eliminates much uncertainty when working with complicated systems.

In the three component system $CaCl_2$–KCl–H_2O, Fig. 4, for example, a series of conjugation lines, EE′, EE″ and EE‴, determined by the residue method, radiate from the point E which represents saturation for the two salts $CaCl_2 \cdot 6H_2O$ and KCl. The points on any one of these lines represent mixtures of the saturated solution with various amounts of the two coexisting solid phases. Each of these lines, since it lies in the same plane, intersects the line joining the points corresponding to the compositions of the two salts $CaCl_2 \cdot 6H_2O$ and KCl and thus shows the presence of both of these solid phases. Now consider this system and its relation to the four-component system. If a small amount of magnesium chloride be added to the solution, the resultant solution has a composition represented by a point on the quaternary line EI. But the solid phases are still KCl and $CaCl_2 \cdot 6H_2O$. If the composition of the residue sample is represented by the point a′, the conjugation line aa′ must intersect the line KCl–$CaCl_2 \cdot 6H_2O$ in the point a″.

If enough magnesium chloride is added so that the composition of the solution becomes that at the point I, a third solid phase, carnallite, separates. Because carnallite contains magnesium chloride, the composition of the mixture of solid phases can now no longer have a value lying on the line KCl–$CaCl_2·6H_2O$. While the composition of a mixture of three substances cannot be represented on a straight line, it can be represented in a triangle each of whose vertices corresponds to 100% of one of the substances. In the present case, the triangle KCl–carnallite–$CaCl_2·6H_2O$ is the one required. The appearance of carnallite shifts the foot of the conjugation line to I′′ for a residue sample whose composition corresponds to I′ and to K′ for one whose composition corresponds to K.

In order to show the simultaneous presence of two or more solid phases in a four-component system, it is thus only necessary to find the point of intersection of a given conjugate line with the plane determined by the three phases concerned. If the intersection falls in the interior of the triangle determined by the three solid phases, it shows that all three are present; if it falls on the edge of the triangle, that is, on a line joining the points representing the compositions of two solid phases, it shows that the two phases determining this line are present and that the third phase is absent.

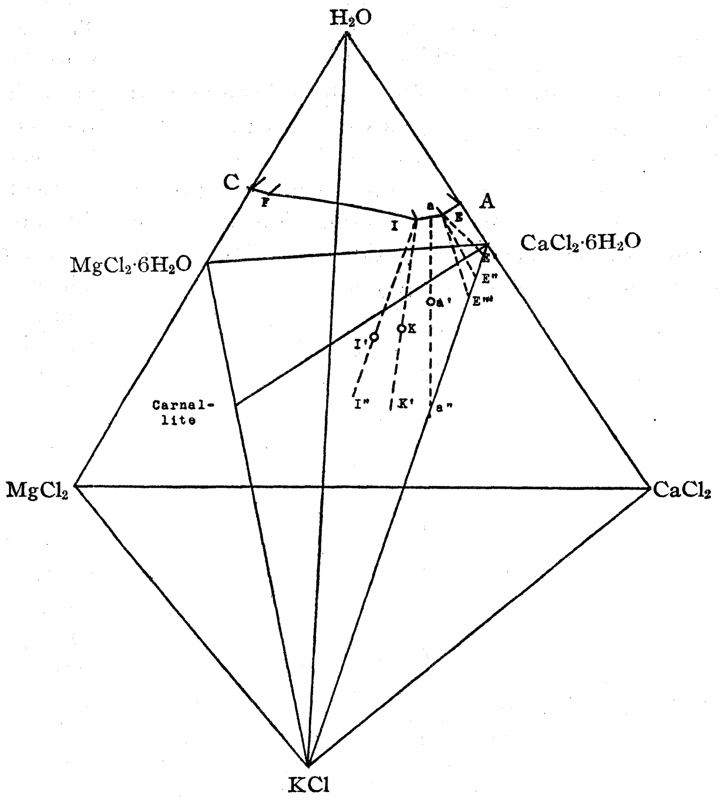

Fig. 4.—Diagram illustrating the method for determining the simultaneous presence of two and of three solid phases.

The intersection of a conjugation line with a plane may be found either analytically or graphically. The analytical problem is equivalent to finding the point of intersection of three planes, two of which pass through the conjugation line. This is done by solving the equations of the three planes simultaneously for the coördinates, or percentages of the three salts, at the point of intersection. The analytical method has, as far as is known to the authors, never been described in the chemical literature.

The analytical process will be illustrated by finding the point of intersection of the plane KCl–carnallite–$CaCl_2·6H_2O$ with the conjugation line from the point I in Fig. 4. The necessary data are taken from Table I. The saturated solution contains 1.92% KCl, 33.40% $CaCl_2$ and 3.30% $MgCl_2$ and the residue sample 16.15% KCl, 25.55% $CaCl_2$ and 8.96% $MgCl_2$. These values furnish two points. Since three points determine a plane, two more are needed, one for each of the two planes through the conjugation line. The points representing pure KCl and pure $CaCl_2·6H_2O$ are convenient. The amounts of the three salts in KCl are 100% KCl, 0% $CaCl_2$ and 0% $MgCl_2$ and in $CaCl_2·6H_2O$ are 0% KCl, 50.64% $CaCl_2$ and 0% $MgCl_2$. The equation of the plane through the conjugation line and the KCl corner of the tetrahedron, in determinant form, is then

$$\begin{vmatrix} x & y & z & 1 \\ 100 & 0 & 0 & 1 \\ 1.92 & 33.40 & 3.30 & 1 \\ 16.15 & 25.55 & 8.96 & 1 \end{vmatrix} = 0$$

where x = % KCl, y = % $CaCl_2$ and z = % $MgCl_2$. Upon expanding this determinant, there is obtained the equivalent equation

$$x + 2.801y + 1.371z - 100 = 0.$$

The equation of the plane through the conjugation line and the point representing $CaCl_2·6H_2O$, obtained in a similar manner, is

$$x - 0.5036y - 3.213z + 25.50 = 0.$$

That through the points representing all three solid phases is

$$x + 1.975y + 2.135z - 100 = 0.$$

Solving the three equations simultaneously there are obtained as the coördinates of the point of intersection, I″

$$x = 35.0\%\ \text{KCl}$$
$$y = 15.2\%\ \text{CaCl}_2$$
$$z = 16.4\%\ \text{MgCl}_2$$

The projections of the point I″ have been plotted in Fig. 5 as e and e′. It lies well within the triangle determined by the three solid phases.

The points of intersection, with their proper planes, of the remaining conjugation lines, for which analytical values are given in Table I, were obtained by similar procedures.

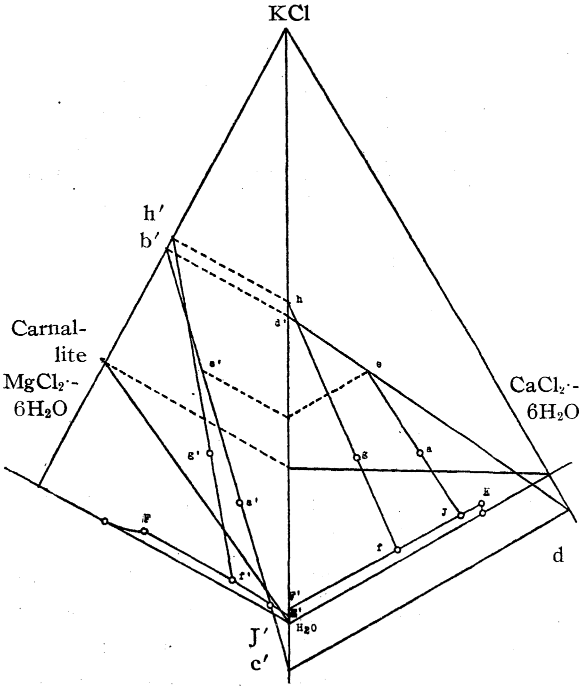

Fig. 5.—Method for determining the solid phases by projection of the conjugation lines upon the sides of the tetrahedron.

It usually involves less labor to obtain the points of intersection graphically as done by Schreinemakers. The points determined by chemical analysis are projected upon two sides of the tetrahedron taken as coördinate planes. The projections of the conjugation line for each solution and residue are drawn through the proper points and intersection with the plane determined by the three solid phases found by the methods of ordinary descriptive geometry.

The graphical method is illustrated to scale in Fig. 5 for the point I and for the line FI of Fig. 4. At I the solid phases are supposed to be KCl, carnallite and $CaCl_2 \cdot 6H_2O$ and on FI, carnallite and KCl. If the data used in illustrating the analytical method are plotted, the two projections of the point I are J and J′ and of the point corresponding to the composition of the residue, a and a′. The two projections of the conjugation line are thus Ja and J′a′. The line J′a′ is extended to meet the line KCl-carnallite in b′ and its projection in the KCl-axis in c′. From b′, the line b′d′ is drawn parallel to the $MgCl_2$-axis and from c′, the line c′d parallel to the $CaCl_2$-axis. If now d is joined to d′, the line dd′ cuts the line Ja in one projection, e, of the point of intersection sought. The other projection is found as indicated in Fig. 5 at e′. Since e and e′ lie well within the respective projections of the triangle KCl–carnallite–$CaCl_2 \cdot 6H_2O$, it is shown that all three of these phases are in contact with the solution at I. It is to be noted that the point found graphically coincides with the point previously found analytically.

The intersection for a conjugation line originating on the line FI, along which two solid phases exist, is obtained even more simply. On FI the composition of a solution was 10.37% $MgCl_2$, 21.13% $CaCl_2$ and 2.10% KCl and of the corresponding residue sample 14.56% $MgCl_2$, 12.89% $CaCl_2$ and 21.91% KCl. The projections of the point for the solution are f and f′ and for the residue g and g′. The projections of the conjugation line are the lines fg and f′g′. The line f′g′ is extended to meet the line carnallite–KCl in h′ and the line fg to meet its projection in the KCl-axis in h. But h is the projection in the KCl-axis of the point h′. This is readily seen because the line hh′ lies parallel to the $MgCl_2$-axis. The conjugation line thus meets the line KCl–carnallite and shows the presence of both of these solid phases and absence of the third phase $CaCl_2 \cdot 6H_2O$.

The application of the Schreinemakers method of residues to other systems whose phases, in addition to the vapor phase, are all liquids, all solids, or combinations of liquids and solids, differs only in the details of application. It may further be extended, although it never has been, to systems containing metathetical elements. A quaternary isotherm of this type is commonly represented in a regular pyramid with a square base. If the diagonal planes of this pyramid are made the projection planes, the foregoing methods are readily applied.

Summary

1. The isotherm for the quaternary system $MgCl_2$–$CaCl_2$–KCl–H_2O has been determined at 0°.

2. The solid phases occurring in the quaternary isotherm are KCl, $MgCl_2 \cdot 6H_2O$, $CaCl_2 \cdot 6H_2O$ and the double-salt hydrate carnallite, $MgCl_2 \cdot KCl \cdot 6H_2O$.

3. The isotherm at 0° is characterized by the extreme insolubility of potassium chloride and of carnallite in solutions saturated for magnesium chloride. This was noted previously[1] in studying the 0° isotherm of the system $MgCl_2$–KCl–H_2O. Both potassium chloride and carnallite are more soluble, within a restricted concentration range, in magnesium chloride solutions containing calcium chloride. Carnallite, however, cannot exist at 0° in contact with solutions containing less than 3.3% magnesium chloride or more than 33.4% calcium chloride.

4. All quaternary solutions saturated for carnallite are incongruently saturated.

5. Schreinemakers' method of residues was used for identification of the solid phases in this isotherm.

6. A method is suggested for extending the method of residues to quaternary systems containing metathetical components.

The Solubility of Cupric Oxide in Alkali and the Second Dissociation Constant of Cupric Acid. The Analysis of Very Small Amounts of Copper

BY LEON A. MCDOWELL AND HERRICK L. JOHNSTON

The blue solutions produced when either cupric oxide or cupric hydroxide is treated with alkali have been objects of investigation[1-3] for more than a century. They were thought by some investigators[2] to be colloidal but have been shown, more recently, to represent true cases of chemical solution.[3] The most decisive work in support of this conclusion is that of Müller,[3] who obtained reproducible values of solubility and determined solubility curves, both for the oxide and for the hydroxide, between five normal and about twenty normal sodium hydroxide concentrations. At about fifteen normal alkali maxima were obtained in the solubility curves and at concentrations above these maxima the stable solid phase consisted of dark blue crystals whose analysis corresponded to the formula Na_2CuO_2. Aldridge and Applebey[4] have identified similar copper salts of the alkaline earths.

Müller observed that the solubility of the hydroxide exceeds that of the oxide several fold, which represents a case of metastable equilibrium since the hydroxide solubility diminishes with time and, simultaneously, the solid phase is converted to what appears to be a solid solution of hydroxide with oxide. The oxide solubility does not change with time. An apparently permanent difference between the solubility of the oxide and that attained, after several days, by the hydroxide is not explained.

The present investigation, at lower alkalinities than those employed by Müller, was carried out to obtain additional information on the nature of the copper-bearing ions present in solution and to determine dissociation constants of cupric acid.

Experimental

The method employed was similar to that followed by Johnston, Cuta and Garrett[5] in a similar study with silver oxide, and the solubility apparatus and general manipulations were the same.

Cupric oxide was prepared by dropping 0.06 *N* solutions of copper sulfate and of potassium hydroxide, simultaneously, into an initial 500 cc. of boiling conductivity water in a Pyrex reaction vessel. The entire process including subsequent washings (15 to 20 in number) was carried out in an atmosphere of nitrogen. The wash water gave no test for sulfate ion (barium chloride test) after seven or eight washings and the final product gave no test for sulfate when dissolved in nitric acid and the solution diluted.

Potassium hydroxide at concentrations below 1 *N* was prepared from pure amalgams in the manner described by Johnston, Cuta and Garrett. Potassium and sodium hydroxides at concentrations above 1 *N* were prepared from solutions of the reagent quality hydroxides by the addition

of sufficient barium hydroxide to precipitate the carbonate.

Salts, except potassium ferrocyanide as noted later, were twice recrystallized from "reagent quality" products.

Conductivity water which even after several weeks' storage had a conductivity no higher than 2 × 10^{-6} mho was employed in the preparation of all solutions and in the washing and purification of materials.

Equilibrium was approached both from the cold and from the hot side. For approach from the cold side samples were agitated at 25 ± 0.01° for from fourteen to fifty days. For approach from the hot side samples were first agitated at 45° for four days, then transferred to the 25° thermostat for an additional fourteen days. The shorter period appeared adequate in every instance. Seven days were allowed for *sedimentation*. A portion of the clear solution was then siphoned from each flask and *filtered* through a No. 1 sintered Jena glass filter, preparatory to analysis for total alkali and for copper. The first portions of the solutions which passed through the filter were discarded.

Analytical Procedure

After testing various methods which have been used for the determination of small concentrations of copper, including colorimetric methods and the polarigraph, electrometric titration with potassium ferrocyanide as precipitant was employed.

There have been several previous attempts to determine copper electrometrically but none were entirely satisfactory for very small amounts. Dutoit and von Weisse[6] concluded that a copper electrode is unsuitable for cupric copper because of irregularities in the change of its potential. By using a polarized platinum electrode they were able to titrate 0.01 *N* copper solutions with potassium sulfide, potassium ferrocyanide or sodium thiosulfate to a precision of about 1% but the low sensitivity of the method and the deposit of some copper by the polarizing current render the method unsuitable for determinations in which the copper concentration falls as low as 1 × 10^{-6} *M*. Titration as cuprous thiocyanate, with a copper electrode,[7] or reduction with an excess of titanous chloride followed by back titration with either potassium dichromate or potassium bromate,[8] is not sufficiently accurate for our requirements.

After unsatisfactory trials of a copper electrode in titrations with either sodium sulfide or potassium ferrocyanide, in which our experience was similar to that of Dutoit and von Weisse, we substituted an electrode of platinum foil. With sodium sulfide results were still unsatisfactory due to the fact that the end-point depended to too great an extent on the *p*H value of the solution. With ferrocyanide as precipitant,[9] and a technique similar to that employed by Johnston, Cuta and Garrett, high sensitivity and good accuracy were obtained. Titration of 10 cc. of a standard copper solution 6 × 10^{-4} *M* in cupric ion with potassium ferrocyanide which had a copper equivalence of 1 × 10^{-6} mole of copper per cc. led to an inflection of from 10 to 16 mv. per drop (0.02 cc.) at the equivalence point and the end-point could usually be located to within one or two drops. It was found best to clean the electrode with pumice after each titration; otherwise the sensitivity was continuously reduced. The position of the end-point was independent of the dimensions of the platinum foil (absence of adsorption). Titrations were carried out in a 250-cc. beaker which was connected by a bridge of potassium nitrate set in agar-agar to a calomel half cell. The copper solution was made just acid to methyl orange indicator. Readings of electromotive force were taken at three-minute intervals and near the end-point the standard ferrocyanide solution was added one drop at a time from a microburet.

The ultimate standard for the determination of copper was an approximately 0.06 *M* solution of copper sulfate which was analyzed for copper by electrolytic deposition and then diluted one hundred fold. Potassium ferrocyanide solutions, of copper equivalences varying from 1 × 10^{-6} to 6 × 10^{-8} mole of copper per cc. were prepared from Baker and Adamson reagent quality potassium ferrocyanide without recrystallization. These were standardized by titration against the standard copper solutions under conditions closely identical with those employed in the analysis of samples (*i. e.*, acidity, salt concentrations, total volume, temperature, etc.).

Total alkalinity was determined by titration with standard sulfuric acid to the first sharp color change with methyl orange.

Our experience with the use of the ferro–ferricyanide couple for the titration of copper differs from that of Müller and Takegami,[10] who found no sharp inflection in the e. m. f. curve and concluded that the difficulty lay in some secondary reaction such as

$$3Cu_2Fe(CN)_6 + K_4Fe(CN)_6 = 2K_2Cu_3Fe_2(CN)_{12}$$

We found, in titrations which employed weighed amounts of the reagent quality potassium ferrocyanide, that the sharp break in the e. m. f. curve came at a position within 5% of the stoichiometric value for the assumed formation of $Cu_2Fe(CN)_6$. This approximate 5% deviation was reproducible. With our method of standardization described above, this reproducible deviation from the stoichiometric end-point did not introduce error into the analyses.

The Solubility Data

The results obtained are given in the following tables in which all concentrations are expressed in moles per 1000 g. of water. These are also illustrated in the accompanying figure. Samples were always run in pairs to obtain approach to equilibrium both from the side of undersaturation and from that of supersaturation. In the tables, the data obtained with individual samples are shown separately[11] while, in the figures, the circles

Data obtained by Müller[3] are included in Fig. 1, in which the curve is empirical. The solid curves in Figs. 2 and 3 are calculated from equation (4). The basis of this calculation and the significance of the broken lines will be referred to later.

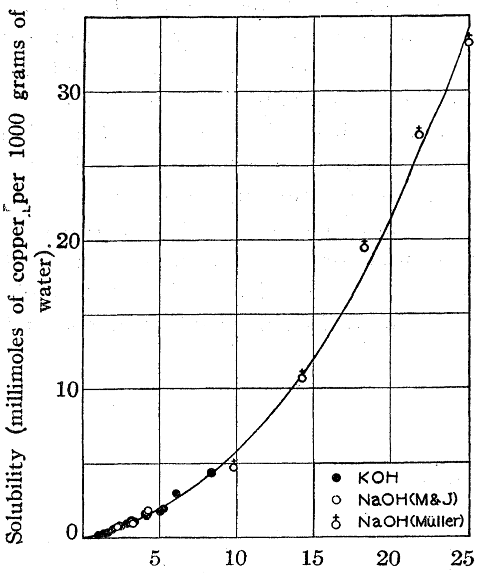

Fig. 1.—Solubility of cupric oxide in strong alkali.

We attempted to determine the solubility of the oxide in pure water and to locate accurately the position of the minimum on the solubility curve. In this we were faced with the difficulty that the solutions usually came out colloidal unless the alkalinity exceeded about 0.03 normal. It was thought best not to include data obtained for several alkalinities below 0.04 normal because of non-reproducibility. But we may conclude from the solubility product of hydroxide or oxide in pure water that the minimum on the solubility curve must lie at an alkali concentration below 0.01 normal.

We were successful in obtaining a rough value for the solubility of the oxide in pure water. This value is 2.9×10^{-5} mole/liter at 25° and is the mean of four determinations (2.5, 3.5, 3.7 and 1.7×10^{-5}, respectively) in which colloidal material was not visible. Three other samples, which were similarly handled, were definitely colloidal and were not analyzed. This result is represented by the triangle in the border of Fig. 2. While we do not regard this value as particularly accurate, we do not believe that the solubility of the oxide can be appreciably higher than this since the nature of the experimental difficulties were such as would lead to high rather than to low results. This constitutes the only value in the literature based on a direct analytical determination. Jellinek and Gordon[12] obtained 1.7 × 10^{-13} for the solubility product of the hydroxide at 20° by concentration cell measurements, in the presence of excess alkali. This result, which is not corrected for the changing activity coefficients of the ions, corresponds to a solubility about double that which we have determined. There is probably a real difference between the oxide and the hydroxide solubilities in water, as there is in alkali,[3] so that this value probably corresponds to a more soluble form than the stable oxide. Remy and Kuhlmann[13] obtained 6.7 × 10^{-5} mole/liter for the oxide at 20°, by conductimetric methods.

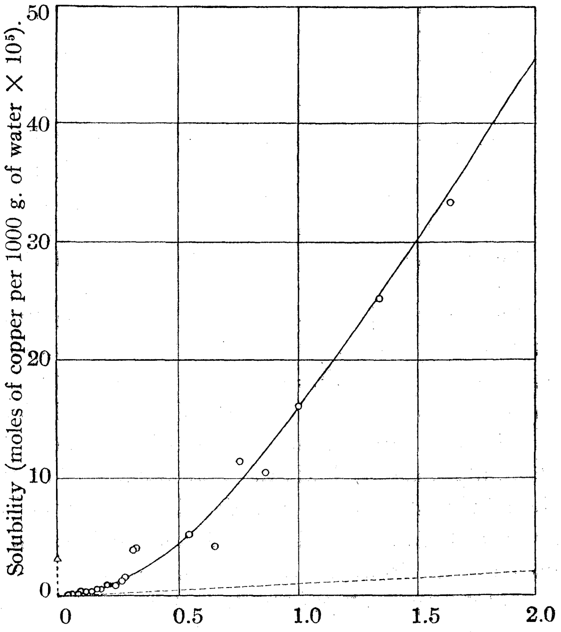

Fig. 2.—Solubility of cupric oxide in potassium hydroxide of moderate concentration: ————, total copper (calculated by Eq. 4); — — — — —, bicuprate ion concentration; Δ, water solubility.

Discussion and Interpretation of Results

Solution of copper oxide in alkali may be represented by the reactions

$$CuO + OH^- = HCuO_2^- \qquad (1)$$

$$K_1 = (m_{HCuO_2^-}/m_{OH^-})\,(\gamma_{HCuO_2^-}/\gamma_{OH^-})$$

$$CuO + 2OH^- = CuO_2^{=} + H_2O \qquad (2)$$

$$K_2 = (m_{CuO_2^{=}}/m^2_{OH^-})\,(\gamma_{CuO_2^{=}}/\gamma^2_{OH^-})a_{H_2O}$$

with their corresponding equilibrium constants. In these equations the m's represent stoichiometrical molalities of the ions; the γ's their corresponding activity coefficients and a_{H_2O} the activity of water from the solutions. For practical purposes this latter may be replaced by p/p^0, the ratio of the vapor pressure to that of pure water.[14] The total solubility of copper at concentrations of alkali too great to permit the existence of Cu^{++} ions is thus given by the relationship

$$S_{Cu} = m_{Cu(OH)_2} + K_1 m_{OH^-}(\gamma_{OH^-}/\gamma_{HCuO_2^-}) + K_2 m^2_{OH^-}(\gamma^2_{OH^-}/\gamma_{CuO_2^{=}})(p^0/p) \qquad (3)$$

in which $m_{Cu(OH)_2}$ is included to represent a probable low concentration of undissociated hydroxide in equilibrium with the solid phase. This might ordinarily be evaluated from the intercept of the solubility curve on the solubility axis but in this case, as is evident from Fig. 3, the value of this term must be quite low and the data do not permit its evaluation. For this reason we

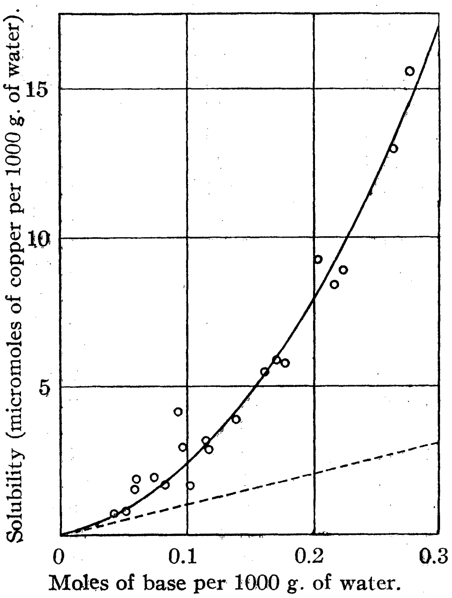

Fig. 3.—Solubility of cupric oxide in dilute potassium hydroxide: ————, total copper (calculated by Eq. 4); — — — — —, concentration of bicuprate ion.

---

(12) Jellinek and Gordon, *Z. physik. Chem.*, **112**, 207 (1924).

(13) Remy and Kuhlmann, *Z. anal. Chem.*, **65**, 161 (1925).

(14) These expressions represent cupric oxide as the solid phase in equilibrium with the saturated solutions. If, in reality, this phase is a solid solution of cupric hydroxide in cupric oxide, as the data of Müller seem to indicate, reactions (1) and (2) may be rewritten

$$(XCuO, yCu(OH(_2)\text{ solid} + OH^- = HCuO_2 + yH_2O \qquad (1a)$$

$$K_{1a} = K_1 a^y_{H_2O}$$

$$(XCuO, yCu(OH)_2)\text{ solid} + 2OH^- = CuO_2^{=} + (1 + y)\,H_2O \qquad (2a)$$

$$K_{2a} = K_2 a^y_{H_2O}$$

Since Müller's data show that the mole fraction of the hydroxide cannot exceed 0.1 at most (*i. e.*, y cannot exceed 0.1) K_{1a} and K_{2a} will not differ from K_1 and K_2 by more than 1% even in 3 N alkali. It should be noted also that the solid solution, rather than pure copper oxide, is taken as the standard state in defining K_{1a} and K_{2a}. This defines the significance of the standard free energy change computed from these constants.

have chosen to neglect it. This will introduce no appreciable error into the evaluation of the constants K_1 and K_2.

At low and moderate ionic strengths, equation (3) may be considerably simplified, since the several activity coefficients will approach the values given by the Debye–Hückel interionic attraction theory and the ratio $(\gamma_{OH^-}/\gamma_{HCuO_2^-})$ may be expected to remain near unity even in solutions for which the theory no longer correctly evaluates the separate activities. In the analogous case of silver oxide dissolved in alkali it was found[5] that the ratio $(\gamma_{OH^-}/\gamma_{AgO^-})$ did not depart appreciably from unity even in 1 N alkali. A further simplification comes in the final term. Here $(\gamma^2_{OH^-}/\gamma_{CuO_2^=})$ may be accurately replaced by $(\gamma^4_{KOH}/\gamma^3_{K_2CuO_2})$ and $\gamma^3_{K_2CuO_2}$ may be, in turn, replaced[15] by $\gamma^6_{KHCuO_2}$. Introduction of unit ratio between hydroxide and bicuprate ions now completes the simplification in this term and we have

$$S_{Cu} = K_1 m_{OH^-} + K_2 m^2_{OH^-}(p^0/p\gamma^2_{KOH}) \qquad (4)$$

The parenthetical expression in the last term of (4) is easily evaluated from reliable data.[16] On the assumption that equation (4) remains valid to an ionic strength of unity we have evaluated the two constants of this equation, by an empirical "best fit" to the data recorded in Table I. We have obtained for these constants: $K_1 = 10.3 \times 10^{-6}$, $K_2 = 81 \times 10^{-6}$. The solid lines in Figs. 2 and 3 are calculated with these constants in equation (4). The excellent agreement with the experimental results both at high and low concentrations of alkali is regarded as confirmation both of the assumptions on which (4) is based and on the reliability of the chosen constants. The constants cannot be varied more than a few per cent. without destroying this agreement.

The broken lines in the figures were computed with the final term in (4) omitted and so represent the concentration of bicuprate ion alone. It is clear from these curves that even at low concentrations of alkali a considerable portion of the dissolved copper exists as the divalent acid ion. Other authors[17] have considered the divalent ion concentration as negligible in dilute alkali, in their interpretation of other cases similar to this. It appears from this work that such interpretations will warrant further investigation.

Dissociation Constants of Cupric Acid

The first dissociation constant of cupric acid cannot be determined without more information on the concentration of undissociated hydroxide (*i. e.*, a more reliable basis for extrapolation of the solubility curve to zero alkalinity). But the present data permit the evaluation of the constant for the second step in the acid dissociation

$$HCuO_2^- = H^+ + CuO_2^=$$
$$K_5 = (a_{H^+}a_{CuO_2^=})/a_{HCuO_2^-} \qquad (5)$$

by substituting for a_{H^+} its equivalent $K_w(a_{H_2O}/a_{OH^-})$, and substituting for $a_{CuO_2^=}$ and $a_{HCuO_2^-}$ from equations (1) and (2). This gives

$$K_5 = K_w(K_2/K_1) = 7.9 \times 10^{-14} \qquad (6)$$

with K_w taken to be 1.01×10^{-14} at 25°.[18]

We may estimate the first dissociation constant of cupric acid to be of the order of magnitude of 10^{-10} from the generalization that the first and second constants of di- and tri-basic acids of this approximate strength ordinarily differ by a factor of 10^3 or 10^4. This would make the concentration of undissociated hydroxide of the order of magnitude of 10^{-9} mole per liter, which we could not hope to determine by extrapolation of solubility data even if the colloidal difficulties at low alkalinities were entirely avoided.

Summary

The solubilities of cupric oxide in aqueous potassium hydroxide have been determined for the alkaline range 0.04 normal to about 8 normal, and for a few concentrations of sodium hydroxide. The data at high concentrations are in good agreement with the results obtained, in strong alkali, by Müller.[3c] Up to 2 normal alkali the solubility is well reproduced by the relationship

$$S_{Cu} = 10.3 \times 10^{-6} m_{OH^-} + 81 \times 10^{-6} m^2_{OH^-}/(a_{H_2O}\gamma^2_{KOH})$$

which is derived by application of the interionic attraction theory. The two constants in this equation are the thermodynamic equilibrium constants for the respective reactions

$$CuO + OH^- = HCuO_2^-$$
$$CuO + 2OH^- = H_2O + CuO_2^=$$

---

(15) This follows from the fact that at low ionic strengths, where the Debye–Hückel limiting law is obeyed, the activity coefficient of a 1–2 electrolyte is the square of that of a 1–1 electrolyte at the same ionic strength and that where ions are of nearly the same size, as must be true with cuprate and bicuprate ions since they only differ by a proton, this relationship will continue to hold when the limiting law has broken down and terms for the ionic radius are included. This relationship was first called to attention by Walker, Bray and Johnston [THIS JOURNAL, **49**, 1235 (1927)] and shown by them to hold quite accurately for carbonate and bicarbonate solutions even to ionic strengths of 2.

(18) "International Critical Tables," Vol. VI, p. 152.

From these data we obtain 7.9×10^{-14} for the second acid dissociation constant of copper hydroxide

$$HCuO_2^- = H^+ CuO_2^=$$

The relative proportions of bicuprate ($HCuO_2^-$) and cuprate ($CuO_2^=$) ions in the solutions are evaluated and it is shown that the second of these predominates even below 0.1 normal alkali.

The solubility of the oxide in pure water is found to be approximately 3×10^{-5} mole per liter, which is somewhat lower than values now in the literature.

An accurate potentiometric method of determining copper in low concentrations is described.

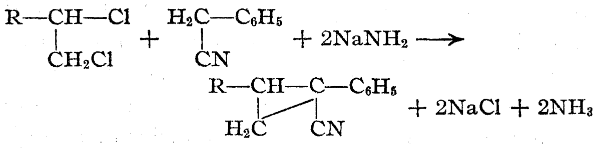
Alkylene and Alkylidene Phenylacetonitriles and Derivatives. 1-Phenyl-2-ethylcyclopropanecarbonitrile, α-Phenyl-β-ethylacrylonitrile and α-Phenyl-β-isopropylacrylonitrile[1]

BY JAMES V. MURRAY AND JOHN B. CLOKE

It has been shown that 1-phenylcyclopropanecarbonitrile and its 2-methyl homolog can be prepared by the alkylenation of phenylacetonitrile with suitable dihalide derivatives, such as ethylene chloride and propylene chloride, in the presence of sodium amide, according to the reaction[2]



Directions have also appeared for the condensation of acetaldehyde[2] and *n*-butyraldehyde[3] with phenylacetonitrile by the action of sodium ethoxide as generalized below

$$RCHO + H_2C(CN)C_6H_5 = RCH{=}C(CN)C_6H_5 + H_2O$$

This work constitutes an extension of the work of Meyer and Frost[4] on the aromatic aldehydes to the aliphatic group.

The present paper describes the preparation of one alkylene phenylacetonitrile, 1-phenyl-2-ethylcyclopropanecarbonitrile, and two alkylidene phenylacetonitriles, *viz.*, α-phenyl-β-ethylacrylonitrile and α-phenyl-β-isopropylacrylonitrile, together with some of their derivatives.

The proof of the structures of the alkylidene phenylacetonitriles follows from (1) their method of preparation, if aldehydes are used, (2) their reaction with alkaline hydrogen peroxide to give glycidamides, [3] although not all α,β-ethylenic nitriles react, and (3) their oxidation with potassium permanganate. On the other hand, the isomeric cyclopropanecarbonitriles may be recognized (1) by their reaction with hydrogen peroxide to give simple amides, if they react at all, and (2) by their stability in the presence of permanganate. In addition, molecular refractivities have been useful in the differentiation of the cyclopropane and ethylenic isomers, although they are less reliable than the chemical methods.

1 - Phenyl - 2 - ethylcyclopropanecarbonitrile.—This nitrile was obtained in yields up to 40% by the interaction of phenylacetonitrile (I), 1,2-dichlorobutane and sodium amide, as indicated in the accompanying flow sheet. In this reaction it is advantageous to deviate from the original procedure of Knowles and Cloke by preparing the sodium amide in liquid ammonia, according to the method of Vaughn, Vogt and Nieuwland,[5] and using this solution in the initial stages of the reaction.

In passing, it may be pointed out that the glycidamide and Radziszewski reactions may be employed for the removal of phenylacetonitrile and α,β-ethylenic nitrile from the 1-phenyl-2-alkylcyclopropanecarbonitriles, since the latter are quite inert to the reagent.

Following the synthesis of 1-phenyl-2-ethylcyclopropanecarbonitrile (VI), it was essential to produce evidence for the presence of the cyclo-

---

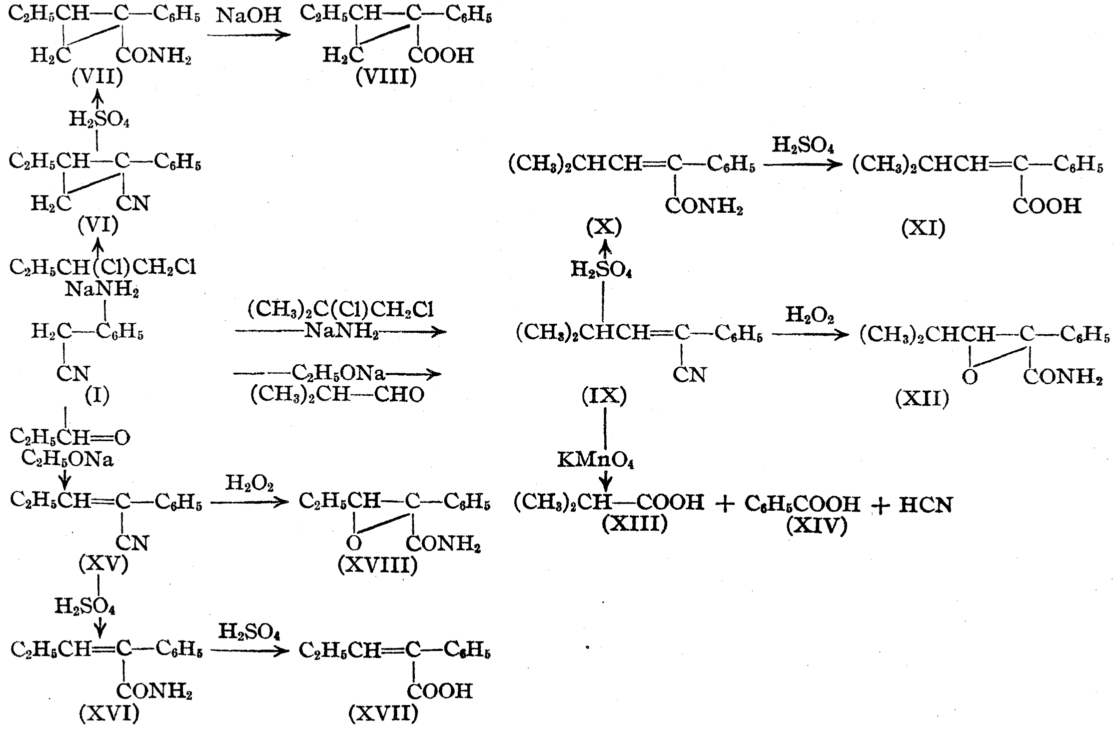
propane ring, since it appeared possible that the reaction might have given the isomeric 2-phenyl-3-hexenonitrile, which in the presence of alkali would be expected to rearrange to give an α-phenyl-β-*n*-propylacrylonitrile (V). The formation of a second series of nitriles is also possible if the secondary halogen atom of the 1,2-dichlorobutane were to react with the monosodium salt of (I).

Several lines of evidence point unquestionably to the cyclopropane structure for the nitrile (VI). In the first place, the nitrile (VI) differs widely from the isomeric ethylenic derivative (V).[3] Thus, the amide (VII) and the acid (VIII) derived from (VI) by hydrolysis are distinct from those obtained from (V). Furthermore, the molecular refractivities of the nitriles are different. In addition, the failure of (VI) to give a glycidamide with alkaline hydrogen peroxide, as well as its stability toward cleavage by alkaline potassium permanganate, definitely excludes the ethylenic structure. Moreover, its striking resistance toward hydrolysis and the ease with which it is altered by cold, concentrated sulfuric acid closely parallel the behavior of 1-phenyl-2-methylcyclopropanecarbonitrile (III), the next lower homolog. Finally, the good agreement between the observed molecular refractivity and that calculated on the basis of the cyclic structure indicates the presence of the cyclopropane nucleus in (VI).

α-Phenyl-β-isopropylacrylonitrile (IX).—With the expectation of obtaining 1-phenyl-2,2-dimethylcyclopropanecarbonitrile, phenylacetonitrile (I) was allowed to react with 1,2-dichloroisobutane and sodium amide. The resulting nitrile was obtained in yields up to 38%.

In the early stages of this work the cyclic structure for the nitrile was inferred on the basis of the method of preparation. However, consistently high values observed for the molecular refractivity cast considerable doubt on the cyclic structure, but were in harmony with the value computed for the ethylenic structure (IX). The cyclopropane structure was definitely excluded when it was found that the nitrile (IX) gave the glycidamide (XII), when it was subjected to the action of alkaline hydrogen peroxide. Still further confirmation of the ethylenic structure was obtained when it was observed that the nitrile (IX), upon oxidation with potassium permanganate in alkaline solution, absorbed three atoms of oxygen with the formation of isobutyric acid (XIII), benzoic acid (XIV), and hydrogen cyanide. This oxidation will be discussed more fully in a future communication.

Synthetic proof for the ethylenic structure (IX)



was also secured by the preparation of the nitrile in an 85% yield by the alkylidenation of phenylacetonitrile with isobutyraldehyde in the presence of dilute sodium ethoxide. The complete identity of the two nitriles was established by the fact that both yield the same amide (X), acid (XI), and glycidamide (XII) as shown by mixed melting point determinations.

It will be noted that the formation of the α-phenyl-β-isopropylacrylonitrile (IX) by the condensation of the 1,2-dichloroisobutane with phenylacetonitrile by the action of sodium amide involves a rearrangement. It is clear that the primary halogen atom of the dichloride must react with the phenylacetonitrile. This reaction is probably accompanied by the elimination of the remaining halogen atom with an adjacent hydrogen atom to give the β,γ-nitrile, $(CH_3)_2C=CH-CH(C_6H_5)CN$, which then rearranges to give the α,β-nitrile (IX), although other paths are possible.

α-Phenyl-β-ethylacrylonitrile (XV).—This nitrile, which may also be called propylidenephenylacetonitrile, was obtained in a 60% yield by the condensation of propionaldehyde with phenylacetonitrile by the use of sodium ethoxide. The structure is established by its method of preparation; the formation of the glycidamide, when it is treated with alkaline hydrogen peroxide; its instability toward alkaline potassium permanganate; and its refractivity. On hydrolysis, it yields the corresponding amide (XVI) and acid (XVII).

Experimental Part

Preparation of 1-Phenyl-2-ethylcyclopropanecarbonitrile (VI).—A two-liter, three-necked, round-bottomed flask was fitted with a dropping funnel, a reflux condenser provided with a lime tower, and an efficient mechanical stirrer which operated through a mercury seal.

One and one-half liters of liquid ammonia was placed in the reaction flask followed by 2 g. of bright sodium. The stirrer was set in motion and 1.5 g. of $Fe(NO_3)_3 \cdot 6H_2O$[5] (in later runs the hydrated chloride was used) was introduced and then 46 g. (2 atoms) of sodium in the form of small chips was added over the course of twenty minutes. The reaction mixture was then allowed to stand until the initial deep blue color had faded, denoting the completion of the reaction.

At this point, 117 g. (1 mole) of freshly distilled phenylacetonitrile[6] was cautiously added to the sodium amide solution during a period of one hour. The mixture in the flask was then stirred while 700 cc. of anhydrous ether was added at about the same rate at which the liquid ammonia evaporated. When the reaction mixture attained room temperature, it was refluxed gently for one hour.

At the end of this first stage, the sodium phenylacetonitrile mixture was cooled to −5° in an ice-salt bath and 127 g. (1 mole) of 1,2-dichloro-*n*-butane was added slowly over the course of one hour. Stirring was continued overnight while the bath came to room temperature. Following this, the reaction mixture was refluxed gently for two hours. Finally water was added to dissolve the solid precipitate and the mixture was acidified with acetic acid. The ether layer was removed and dried over anhydrous sodium sulfate. The fractionation of the dried ether extract gave 35 g. of a fraction boiling at 77–80° at less than 1 mm., which was mainly unchanged phenylacetonitrile, and a 68 g. fraction boiling at 93–94° at the same pressure. This corresponds to a 40% yield on the basis of the starting quantity of phenylacetonitrile. The nitrile possessed the following properties: d^{20}_4 0.9921; n^{20}_D 1.52457; MR_D (obsd.), 52.70; MR_D (calcd.), 52.29.[7] *Anal.* (micro.) Calcd. for $C_{12}H_{13}N$: N, 8.18. Found: N, 8.17, 8.25.

The foregoing procedure was varied in several runs by using commercial sodium amide or the specially prepared salt with ether exclusively as the reaction medium. These variations, however, markedly decreased the yield. Low yields were likewise obtained when liquid ammonia was used throughout as the reaction solvent, no provision being made for reflux periods.

1-Phenyl-2-ethylcyclopropanecarbonamide (VII).—In a 125-cc. acetylation flask were placed 10 cc. of water, 10 cc. of concentrated sulfuric acid, 10 cc. of glacial acetic acid, and 2 g. of 1-phenyl-2-ethylcyclopropanecarbonitrile. The mixture was refluxed for five hours and then poured into ice water. The aqueous solution was extracted with ether and this extract was then washed with 10% sodium carbonate solution. Evaporation of the ether solution gave the crude amide, which after decolorization and recrystallization from hot water yielded the pure amide as needles which melted at 84°.

The same amide was also obtained by hydrolysis of the nitrile with alcoholic potassium hydroxide. This method however, requires a reflux period of about sixty hours. Attempts to hydrolyze the nitrile by means of 100% phosphoric acid or by alkaline hydrogen peroxide were unsuccessful. *Anal.* Calcd. for $C_{12}H_{15}ON$: N, 7.41. Found: N, 7.35, 7.43.

1-Phenyl-2-ethylcyclopropanecarboxylic Acid (VIII).—A weight of 2 g. of the 1-phenyl-2-ethylcyclopropanecarbonamide was refluxed for fifty hours with *N* alcoholic potassium hydroxide. The crude acid was isolated in the usual manner and after recrystallization from hot water the pure acid melted at 105–105.5° (corr.).

Preparation of α-Phenyl-β-isopropylacrylonitrile (IX).—This nitrile was prepared by two different methods.

Method 1.—When phenylacetonitrile (1 mole) was allowed to react with 1,2-dichloroisobutane (1 mole) and sodium amide (2 moles) according to the procedure described for the preparation of (VI), the nitrile (IX) was obtained in yields up to 38%. After repeated fractiona-

[6] Adams and Thal, "Organic Syntheses," Coll. Vol. I, p. 101.

[7] The molecular refractivities were calculated on the basis of Eisenlohr's data. Ostling's value of 0.7 unit is added for the cyclopropane ring. Corrections for conjugation, distribution of groups, etc., have not been included.

tion of the reaction product, the nitrile boiled at 94.5–95° at less than 1 mm.

Method 2.—A solution of 58.5 g. (0.5 mole) of phenylacetonitrile and 54 g. (0.75 mole) of isobutyraldehyde in 120 cc. of absolute alcohol was cooled to −10° and a volume of 10 cc. of 20% sodium ethylate was added at such a rate that the temperature did not rise above −5°. The resulting solution, contained in a tightly stoppered flask, was allowed to stand in the refrigerator for one week. The reaction mixture was then poured into 700 cc. of ice water and was neutralized with acetic acid. The oily layer was taken up in an equal volume of ether and the resulting solution washed with water and dried over sodium sulfate. Fractionation of the dried product gave 73 g. of the nitrile boiling at 95–95.2° at less than 1 mm. which corresponds to a yield of 85%. The nitrile possessed the following properties: d^{20}_4 0.9613; n^{20}_D 1.53530; MR_D (obsd.) 55.41; MR_D (calcd.) 53.32.[8] *Anal.* Calcd. for $C_{12}H_{13}N$: N, 8.18. Found: N, 8.25, 8.19, 8.22, 8.20.

α-Phenyl-β-isopropylacrylamide (X).—A weight of 2 g. of the nitrile (IX) was hydrolyzed by the acetic acid–sulfuric acid method utilized in the case of the nitrile (VI). The ether solution, after extraction with 10% sodium carbonate, deposited the impure amide upon evaporation. Recrystallization of the crude product from boiling water gave the pure amide melting at 123–124° (corr.).

Anal. Calcd. for $C_{12}H_{15}ON$: N, 7.41. Found: N, 7.45, 7.52.

α-Phenyl-β-isopropylacrylic Acid (XI).—The sodium carbonate extract from the foregoing hydrolysis was acidified with dilute sulfuric acid and the impure α-phenyl-β-isopropylacrylic acid precipitated. Recrystallization of the crude product from hot water gave the pure acid as fine, white needles melting at 133–134° (corr.).

Hydrolysis of the α-phenyl-β-isopropylacrylonitrile prepared by either of the two methods resulted in the same products. The identity of the derivatives from the two nitriles was established by mixed melting point determinations.

α-Phenyl-β-isopropylglycidamide (XII).—Following the procedure of Murray and Cloke,[3] 2 g. of α-phenyl-β-isopropylacrylonitrile and 25 cc. of 10% hydrogen peroxide were dissolved in acetone and enough 10% sodium carbonate added to make the solution definitely alkaline. After standing for one day, the acetone was evaporated and the residue was recrystallized from boiling water. The resulting α-phenyl-β-isopropylglycidamide melted at 148–149° (corr.). *Anal.* Calcd. for $C_{12}H_{15}O_2N$: N, 6.82. Found: N, 6.72, 6.86.

The Oxidation of α-Phenyl-β-isopropylacrylonitrile.—A weight of 30 g. of α-phenyl-β-isopropylacrylonitrile was placed in a glass-stoppered Pyrex bottle containing 5 cc. of 10% sodium carbonate solution and 100 cc. of water. Solid potassium permanganate was added in small portions with shaking until the purple color persisted. This required 54.2 g. of permanganate and corresponds to the absorption of three gram atoms of oxygen per mole of nitrile.

Extraction of the alkaline solution with petroleum ether showed no unreacted nitrile. Acidification of the filtered aqueous solution gave a precipitate of benzoic acid (XIV), which was identified by a mixed melting point determination with a known sample of the acid. After the removal of the benzoic acid, the filtrate was made alkaline and evaporated to dryness. From the residue isobutyric acid was isolated and identified as the anilide. The presence of cyanide ion was demonstrated by the Prussian blue test.

Preparation of α-Phenyl-β-ethylacrylonitrile (XV).—A solution of phenylacetonitrile (0.4 mole) and propionaldehyde (0.5 mole) in 100 cc. of absolute alcohol was treated with 9 cc. of 20% sodium ethylate according to the procedure used for the preparation of the nitrile (IX) by method 2. Purification of the nitrile gave a 55% yield of the desired product boiling at 112–112.5° at 3 mm. The nitrile possessed the following properties: d^{20}_4 0.9897; n^{20}_D 1.54300; MR_D (obsd.), 50.00; MR_D (calcd.), 48.69.[8] *Anal.* Calcd. for $C_{11}H_{11}N$: N, 8.92. Found: N, 8.97, 9.00.

An earlier run of the nitrile, originally started by Rogers[9] and allowed to stand for one year, was found on purification to give a somewhat lower yield. A considerable amount of a brown, tarry material appeared during the distillation. Rogers' first run, which was allowed to stand for three days only at a temperature not far from 0°, gave a low yield, which was difficult to separate.

α-Phenyl-β-ethylacrylamide (XVI).—Hydrolysis of the α-phenyl-β-ethylacrylonitrile by the acetic acid–sulfuric acid method gave the amide, which after recrystallization from water melted at 130° (corr.). *Anal.* Calcd. for $C_{11}H_{13}ON$: N, 8.00. Found: N, 7.93, 8.06.

α-Phenyl-β-ethylacrylic Acid (XVII).—Following the usual procedure, the α-phenyl-β-ethylacrylic acid was isolated from the foregoing hydrolysis mixture. The pure acid after recrystallization from hot water melted at 67.5–68.5°.

α-Phenyl-β-ethylglycidamide (XVIII).—The glycidamide,[9] obtained in the usual manner by the action of alkaline hydrogen peroxide on the nitrile (XV), was recrystallized from boiling water and found to melt at 155° (corr.). *Anal.* Calcd. for $C_{11}H_{13}O_2N$: N, 7.33. Found: N, 7.26, 7.30.

Summary

1. 1 - Phenyl - 2 - ethylcyclopropanecarbonitrile has been prepared in yields up to 40%. Several derivatives and reactions of this nitrile have been discussed in connection with the proof of its cyclic structure.

2. α-Phenyl-β-isopropylacrylonitrile was prepared by two different methods in yields of 38 and 95%. Proof for the ethylenic structure is given and several derivatives of the nitrile are described.

3. The preparation of α-phenyl-β-ethylacrylonitrile is described together with a number of its derivatives.

---

[8] These abnormally high exaltations (not included in the calculations) have been observed in all of the alkylidene-phenylacetonitriles so far prepared. The exaltation apparently arises from a combination of conjugation of multiple linkages and distribution of groups about the ethylenic bond. Further, the anomaly appears to depend also upon the nature of the hydrocarbon residue in the β-position.

[9] D. T. Rogers, Master's Thesis, Rensselaer Polytechnic Institute, 1934.

4. Some preliminary work on the oxidation of α,β-ethylenic nitriles is described.

5. Whereas the condensation of ethylene, propylene and α-butylene dichlorides with phenylacetonitrile gives cyclopropanecarbonitriles, the use of isobutylene dichloride under the same conditions leads to the formation of an ethylenic nitrile.

The Molecular Weight of Cinobufagin

BY DOROTHY CROWFOOT AND H. JENSEN

It has been suggested[1] that cinobufagin ($C_{25}H_{32}O_6$) can be considered as the acetyl derivative of an unsaturated hydroxylactone, $C_{23}H_{30}O_5$, and apparently is closely related chemically to certain plant aglucones which are also C_{23} derivatives.[1] The x-ray crystallographic examination of this principle by Crowfoot[2] has given values, however, which do not agree with the proposed formula $C_{25}H_{32}O_6$ and which indicate that the compound probably contains twenty-six carbon atoms.

In order to check these results, x-ray measurements have now been made on two derivatives of cinobufagin, namely, acetylcinobufagin and cinobufagone. The measurements obtained on these compounds provide two independent determinations of the molecular weight of cinobufagin and both more nearly agree with the formulas derived from C_{26}. Thus the molecular weight of acetylcinobufagin was found to be 487 ± 10, the calculated values for the acetyl derivatives of $C_{26}H_{34}O_6$ and $C_{25}H_{32}O_6$ being, respectively, 484 and 470. Cinobufagone has a molecular weight of 443 ± 10 which is in agreement with the formula $C_{26}H_{32}O_6$, 440, and not $C_{25}H_{30}O_6$, 426. Details of the crystallographic measurements are given below.

The analytical values previously reported for cinobufagin and certain of its derivatives[3] agree with the formula $C_{26}H_{34}O_6$. This new formula would bring cinobufagin into very close relationship to bufotalin (present in the secretion of *Bufo vulgaris*) to which Wieland and co-workers[4] assigned the formula $C_{26}H_{36}O_6$ and which they showed can be considered as an acetyl derivative of an unsaturated hydroxylactone ($C_{24}H_{34}O_5$). It might be mentioned, in connection with this, that the results of the pharmacological studies by Chen and Chen[5] on the action of the various animal cardiac principles indicate that their physiological properties show more resemblance to the physiological action of scillaridin than of other plant aglucones. Chemical researches by Stoll and co-workers[6] have shown that scillaridin is a C_{24} derivative, while most other plant aglucones have been found to be C_{23} derivatives. The investigation of Wieland and co-workers[4] on bufotalin indicates that the lactone ring in the animal cardiac principles is a six-membered ring probably similar to that found by Stoll and co-workers[6] for scillaridin. In view of our findings on the molecular weight of cinobufagin, it appears that arenobufagin and regularobufagin are also probably C_{24} rather than C_{23} derivatives as originally suggested by Jensen.[7] Further research on the exact chemical composition of these two principles has been undertaken in order to answer this question.

It should be added that the crystallographic examination of cinobufagone and acetylcinobufagin alone would not exclude molecular weights of twice the magnitude deduced since the asymmetric unit in each case contains two C_{26} molecules. This possibility, however, is excluded by the original measurements on cinobufagin itself in which the single molecule is the asymmetric unit.

The actual crystal structures indicated by the measurements for cinobufagin, acetylcinobufagin and cinobufagone do not seem to bear very simple relation to one another or to those of any of the compounds in the cardiac aglucone series so far examined. This is not surprising since the introduction of many hydroxyl groups is known to produce considerable variation in the crystallo-

CRYSTALLOGRAPHIC DATA

Compound	Space group	*a*	*b*	*c*	No. in cell	No. asymmetric unit	Density	Mol. wt.
Cinobufagin	$P2_12_12_1$	7.61 α	15.79 γ	19.45 β	4	1	1.261	447 ± 10
Acetylcinobufagin	$C222_1$	28.74 γ	8.14 β	44.76 α	16	2	1.229	487 ± 10
Cinobufagone	$P2_12_12_1$	21.79 β	8.62 γ	24.22 α	8	2	1.280	443 ± 10

Acetylcinobufagin: fine orthorhombic needles elongated along (010), (001) dominating. Birefringence low.

Cinobufagone: small orthorhombic needles elongated along (010) and growing least on (001). The crystals appear partly redissolved and show curved surfaces instead of the *c* face. Birefringence low.

The densities of both compounds were determined by flotation in zinc sulfate solutions, the centrifuge being used to hasten equilibrium. These are correct to ±0.4%. The probable error on the x-ray dimensions is not more than ±0.5%.

graphic arrangement of the molecules as is found, for example, in the study of the sugars. Both the presence of the hydroxyl groups and the orthorhombic symmetry shown by the crystals of these cinobufagin compounds render it impossible to make deductions in regard to the molecular arrangement and molecular dimensions from the combination of the optical with the crystallographic data. One can only state that the data are not incompatible with formulas of the cardiac aglucone type and for comparison reference may be made to the complex crystal structures assumed by strophanthidin and certain of its derivatives.

Summary

The determinations of molecular weights of cinobufagin and two of its derivatives, acetylcinobufagin and cinobufagone, indicate that cinobufagin has the composition $C_{26}H_{34}O_6$. The analytical data previously reported for cinobufagin and certain of its derivatives agree with this new formula.

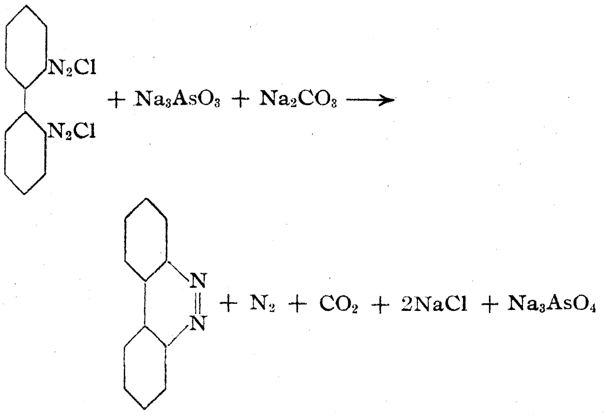
The Formation of Cyclic Azo Compounds from 2,2′-Diaminodiphenyls

BY R. B. SANDIN AND T. L. CAIRNS

The compound 4,4′-diarsonodiphenyl[1,2] has been prepared from benzidine, according to the method of Bart. In an attempt to prepare the isomeric 2,2′-diarsonodiphenyl by an analogous procedure, the authors of this paper have found that when tetrazotized 2,2′-diaminodiphenyl is treated with arsenious oxide in sodium carbonate solution, a considerable part of the tetrazotized compound is converted into *o,o′*-azodiphenyl.[3] The authors believe it to be a general reaction. It is also believed that the arsenite functions as a reducing agent instead of proceeding according to the typical Bart reaction.

The proposed equation for this reaction is



Experimental

Cyclic *o,o′*-Azodiphenyl.—In a mixture of 250 cc. of 2 *N* hydrochloric acid and 150 cc. of water, 18.4 g. of 2,2′-diaminodiphenyl was dissolved. The solution was cooled to 0°, and to it was added gradually 100 cc. of 2 *N* sodium nitrite and an excess of nitrite was maintained for thirty minutes. The clear solution of the tetrazotized compound

---

(1) Bauer and Adams, THIS JOURNAL, **46**, 1925 (1924).

(2) Hill, *ibid.*, **46**, 1855 (1924).

(3) This compound is also called phenazone and *o*-diphenyleneazone [Täuber, *Ber.*, **24**, 3081 (1891)]. Bigelow [*Chem. Rev.*, **9**, 117 (1931)] has suggested the name cyclic *o,o*-azoxydiphenyl, in place of diphenazonoxyd. For that reason it might, perhaps, be better to call phenazone or *o*-diphenyleneazone, cyclic *o,o*-azodiphenyl.

was made neutral to Congo red by the addition of 50 cc. of 2 *N* sodium carbonate which had been diluted to 100 cc. A solution of sodium arsenite was prepared by dissolving 30 g. of arsenious oxide in 300 cc. of 2 *N* sodium carbonate, and to it was added 2 g. of copper sulfate to serve as a catalyst. After this had been cooled to 0°, the tetrazotized diaminodiphenyl solution was siphoned into the arsenite solution during fifteen to twenty minutes. During this procedure there was much gas evolved and there was considerable foaming, which was very difficult to get rid of. An olive-green precipitate was produced, which was filtered by suction and washed with water. The precipitate was extracted with hot 10% hydrochloric acid and the extract was neutralized with ammonia or sodium hydroxide. This gave a precipitate of crude cyclic *o,o'*-azodiphenyl. The yield was 7.5 g. or 45% of the theoretical amount. The crude material melted at 153–154°. It was crystallized from alcohol and gave yellow crystals melting at 155°. A mixed melting point carried out with a sample of the cyclic azo compound prepared according to Täuber,[3] showed no depression of the melting point. It also gave a picrate melting at 191°.

Cyclic Azo Compound from 2,2'-Diamino-4,4'-dimethyldiphenyl.[4]—This compound was prepared in a manner similar to the above, from 2,2'-diamino-4,4'-dimethyldiphenyl. It consisted of yellow needles, soluble in dilute hydrochloric acid, and melted at 184–185°. A mixed melting point carried out with this sample and the compound produced by the sodium amalgam and methanol reduction of 2,2'-dinitro-4,4'-dimethyldiphenyl showed no depression of the melting point.

Acknowledgment.—The authors wish to thank the Carnegie Corporation Research Fund Committee for a grant which enabled the purchase of certain chemicals.

Summary

Tetrazotized diaminodiphenyls, when treated with arsenious oxide in sodium carbonate solution, are in part converted into cyclic azo compounds.

Carboxymethoxylamine

By E. Borek[1] and H. T. Clarke

In the course of experiments on the synthesis of canaline and analogous compounds, the need arose for a convenient process for preparing carboxymethoxylamine (hydroxylamineacetic acid). In view of the recent report by Anchel and Schoenheimer[2] of the use of this substance as a reagent for the isolation of ketones from natural sources, an early description of our method of preparation seems advisable.

Carboxymethoxylamine was first prepared by Werner[3,4] by the hydrolysis of ethylbenzhydroximinoacetic acid; it has also very recently been prepared by Kitagawa and Takani[5] by condensation of benzhydroxamic acid and ethyl bromoacetate, with subsequent hydrolysis by hydrochloric acid.

The method here described consists in condensing the sodium derivative of acetoxime with ethyl chloroacetate, followed by successive alkaline and acid hydrolysis of the condensation product. The intermediate acetone carboxymethoxime may also be prepared, though in somewhat smaller yields, by condensing acetoxime with sodium chloroacetate in alkaline solution by a modification of the method of Hantzsch and Wild.[6]

The carboxymethoxylamine is isolated in the form of its hydrochloride, which melts at 151°. This product in our hands has invariably proved to consist of the hemihydrochloride; that prepared by Werner was reported to melt at 147-148°[3] and at 156°[4,5] and to give analytical figures agreeing satisfactorily with the normal hydrochloride. We are unable to account for this discrepancy.

Experimental

A solution of 24.4 g. of acetoxime in 250 cc. of absolute alcohol was added to a solution of 7.7 g. of sodium in 150 cc. of absolute alcohol. The alcohol was removed by distillation under diminished pressure and the white crystalline residue was dried *in vacuo* over phosphorus pentoxide. To the dry salt 100 cc. of ethyl chloroacetate was added and the mixture refluxed for thirty minutes. When cool, the salt was filtered off and well washed with absolute alcohol. The alcohol and the unreacted ethyl chloroacetate were removed under diminished pressure, the fraction distilling up to 52° under 28 mm. being discarded.

The sirupy residue, which consisted mainly of acetone carbethoxymethoxime, together with the corresponding

---

[1] This report is from a dissertation submitted by Ernest Borek in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Faculty of Pure Science, Columbia University.

[2] Anchel and Schoenheimer, *J. Biol. Chem.*, **114**, 539 (1936).

[3] Werner, *Ber.*, **26**, 1567 (1893).

[4] Werner and Sonnenfeld, *ibid.*, **27**, 3350 (1894).

[6] Hantzsch and Wild, *Ann.*, **289**, 285 (1896).

free acid, acetoxime and other contaminants such as ethyl glycolate, was heated for one hour at 100° with 125 cc. of 11.4% sodium hydroxide. When cool, the alkaline solution was extracted five times with one-fourth its volume of ether; the ether solution, which contained slight amounts of unreacted acetoxime and unsaponified ester, was discarded. The aqueous solution was acidified to Congo red with concentrated hydrochloric acid, saturated with sodium chloride and extracted with three times its volume of ether in six portions. The ether solution was dried with sodium sulfate, and the ether removed by distillation. After the last traces of ether had been removed under diminished pressure, acetone carboxymethoxime crystallized. The weight of the crude preparation was 25 g. (58% of the theoretical).

Acetone carboxymethoxime can also be prepared in aqueous solution: a solution of sodium chloroacetate prepared by neutralizing 212 g. of chloroacetic acid with 450 g. of 20% sodium hydroxide was added to a solution of 146 g. of acetoxime in 450 cc. of water; 200 g. of 40% aqueous sodium hydroxide solution was then added and the whole refluxed for one hour. When cold, the alkaline solution was four times extracted with one-fourth of its volume of ether; the ether solution, which contained some unreacted acetoxime, was discarded. The aqueous layer was acidified with hydrochloric acid to Congo red, saturated with sodium chloride and six times extracted with one-half its volume of ether. The ether solution was dried with sodium sulfate, and the ether removed on the steam-bath, finally under diminished pressure. The crude acetone carboxymethoxime which crystallized weighed 128 g. (49%). By the original method of Hantzsch and Wild[6] the yield was 46%.

The crude acetone carboxymethoxime from either preparation can be purified by distillation; b. p. 110–118° (1 mm.). It solidifies in the receiver in long needles. There is considerable carbonization and hydrogen cyanide is formed. It can be crystallized from a hot concentrated solution of acetone by the addition of ligroin. The resulting plates, the odor of which is not unlike that of phenylacetic acid, melt at 76–76.5° (uncorr.).

Anal. Calcd. for $C_5H_9O_3N$: C, 45.80; H, 6.87; N, 10.69; neut. equiv., 131. Found: C, 46.12; H, 6.49; N, 10.92; neut. equiv., 131.5.

For the preparation of carboxymethoxylamine hemihydrochloride 10 g. of the crude acetone carboxymethoxime in 100 cc. of 6 *N* hydrochloric acid was refluxed for three hours; the solution was then treated with charcoal and concentrated to about 10 cc. under diminished pressure. To the sirup was added 200 cc. of a solution of 1:1 ether and ethyl alcohol, and the cloudy solution was placed in an ice box. Four grams of crystals deposited. The mother liquor was again concentrated to a sirup and ether and alcohol solution added. One gram more of the crystals was thus obtained. The melting point of the crystals after one recrystallization from water, ether–alcohol solution is 151°.[7]

Anal. Calcd. for $(C_2H_5O_3N)_2HCl$: C, 21.95; H, 5.03; N, 12.81; Cl, 16.23. Found: C, 22.26; H, 5.45; N, 12.54; Cl, 16.29.

Acetophenone carboxymethoxime was prepared by adding a solution of 150 mg. of carboxymethoxylamine hemihydrochloride in 4 cc. of water to a solution of 0.2 cc. of acetophenone in 4 cc. of ethyl alcohol. After the solution was made alkaline to litmus with *N* sodium hydroxide, it was warmed on the steam-bath for one hour. The cool, alkaline solution was extracted five times with ether and the ether solution discarded. The aqueous solution was acidified to Congo red and placed in the ice box. The large plates that formed were filtered and recrystallized from alcohol–water solution; colorless plates, m. p. 97–97.5°, soluble in ether and alcohol; almost insoluble in water.

Anal. Calcd. for $C_{10}H_{11}O_3N$: C, 62.15; H, 5.74; N, 7.25. Found: C, 62.07; H, 5.66; N, 7.12.

Benzaldehyde carboxymethoxime was prepared in the same way as the above; it melted at 96°. Hantzsch and Wild,[6] who prepared this compound by condensing sodium chloroacetate with benzaldoxime, report a melting point of 98°.

Pyruvic acid carboxymethoxime was prepared the same way, but since it is water-soluble the solution, after acidification, was five times extracted with one-half its volume of ether, the ether solution dried with sodium sulfate and the ether distilled. The crystals which were obtained were recrystallized from ether and chloroform; m. p. 129° (Hantzsch and Wild[6] report 130–132°).

Summary

Directions are given for the preparation of carboxymethoxylamine hemihydrochloride, a reagent of use for the isolation of ketones.

NEW YORK, N. Y. RECEIVED JULY 22, 1936

Adsorption of Vapors on Glass Spheres. I. The Adsorption of Nitrogen

BY J. L. SHERESHEFSKY AND CHARLES E. WEIR

Introduction

In a previous investigation[1] of the adsorption of oxygen by glass spheres, it was observed that the amount of adsorption at corresponding pressures increased with the number of contacts per sphere. As this effect could also be due to differences in the degree of activation of the surface resulting from unequal periods of the degassing process, it was considered essential to obtain reproducible isotherms under the same conditions of treatment and packing before any definite conclusions as to the effect of the number of contacts on the adsorption could be reached.

Inasmuch as every oxygen isotherm exhibited a peculiar pressure reversal apparently connected with a discontinuity or break in the isotherm it was considered desirable to use nitrogen in place of oxygen in order to ascertain whether the peculiarity was characteristic of oxygen or was more general in nature. Nitrogen has the added advantage of being more strongly adsorbed while very similar to oxygen in its physical properties. The experiments were carried out at the temperature of liquid air where the nitrogen, as well as the oxygen previously investigated, may be classed as a vapor.

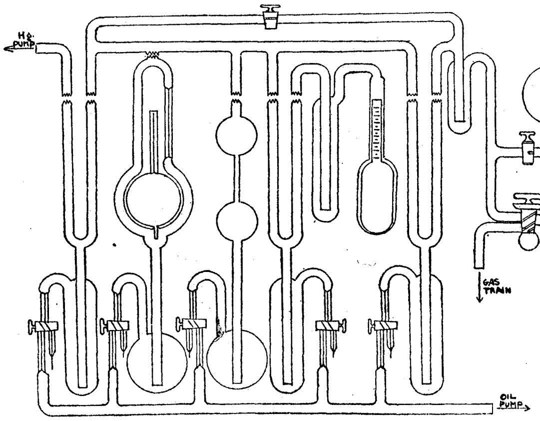

Fig. 1.—Apparatus.

Apparatus

A schematic representation of the apparatus is shown in Fig. 1. As may be seen the adsorption system proper is the conventional arrangement used when adsorption is to be calculated from pressure measurements. The McLeod gage was calibrated in three ranges, from 1×10^{-6} to 1×10^{-4}, from 1×10^{-5} to 1×10^{-3}, and from 1×10^{-4} to 5×10^{-3} cm. of mercury. F is a gas reservoir, D is a dosing stopcock, and C_1 and C_2 are auxiliary stopcocks. By varying the pressure in F, or by repetitive use of stopcock D, any desired quantity of gas could be introduced into the adsorption system by filling the bore of the dosing stopcock from the reservoir and then discharging this gas into the adsorption apparatus through mercury stop S_3.

The volumes of the various parts of the apparatus were determined with hydrogen at pressures ranging from 2 to 20 cm. of mercury. In these determinations we made use of the calibrated bulbs B_1 and B_2. All pressures were read on the mercury stop S_3 with a cathetometer reading to 0.01 mm. The pre-expansion volume extending from X_2 to X_3 was found to be 981 cc.; the total volume consisting of the pre-expansion volume and the adsorption chamber and extending from X_2 to A was 1599 cc.

Preparation of Materials

Tank hydrogen containing water and oxygen as possible impurities was purified by passage through activated charcoal at liquid air temperature.

Commercial helium containing hydrocarbons as possible impurities was likewise purified[2] by passage through activated charcoal at liquid air temperature.

Nitrogen was prepared from pure ammonium hydroxide and bromine water in a manner described by Waran.[3] The nitrogen was stored over phosphorus pentoxide for forty-eight hours before being used.

The spheres 3 mm. in diameter and of soft glass were cleaned with chromic and nitric acids and washed with distilled water. The actual surface was obtained by measuring the adsorption of methylene blue in accordance with the method of Paneth.[4] The isotherms thus obtained showed a well-defined maximum at about 1.53 mg. of the dye. Using the value given by Paneth of 1 mg. of methylene blue per square meter, the actual surface of 1000 spheres was found to be 15,380 sq. cm. as compared with the 283 sq. cm. of apparent surface calculated from the dimensions of the spheres.

Results and Discussion

Thermal Flow.—In view of the phenomenon of thermal flow observed by Knudsen[5] at low temperatures and pressures, it was necessary to establish a correction curve relating the equilibrium pressure in the apparatus at room temperature with the equilibrium pressure in the cooled portion of the system. Using a gas which is not

---

[5] Knudsen, *Ann. Physik*, **31**, 205, 633 (1910).

adsorbed, the pressure in the cooled portion can be calculated from the equation

$$P_1V_1/RT_1 = P_2V_2/RT_1 + P_3V_3/RT_3 \qquad (1)$$

where P_1 is the calculated pressure obtained from a knowledge of the total gas in the system and the total volume V_1 at temperature T_1, P_2 is the equilibrium pressure measured with the McLeod gage in the volume V_2 at temperature T_1, and P_3 is the equilibrium pressure in the volume V_3 kept at temperature T_3. In this equation all quantities except P_3 are measured.

Four runs were carried out, two using helium and two using hydrogen. One of the hydrogen runs was made with an empty vessel having the same volume as the voids in the chamber filled with spheres. The other runs were made with the spheres in the chamber. The results of these measurements are given in Tables I and II, and Fig. 2. The dotted line in Fig. 2 represents the values obtained from the relation

$$P_3 = P_2\sqrt{T_3/T_1} \qquad (2)$$

which is required by the theory[6] of thermal flow under conditions where the mean free path of the gas is large compared to the diameter of the tubing. It is to be observed that the experimental values approach the theoretical at low pressures, but in the region of 1×10^{-5} to 1×10^{-3} cm. of mercury the deviation is large.

TABLE I

THERMAL FLOW OF HELIUM

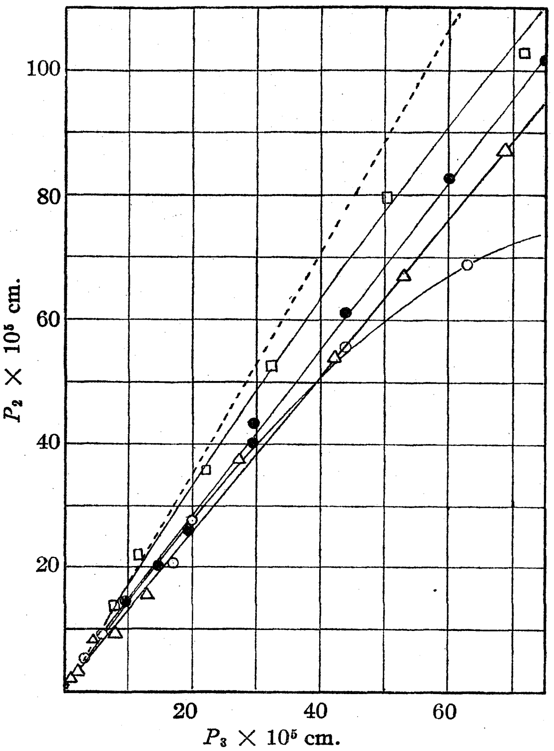

Fig. 2.—Thermal flow: □, helium Run 1; ●, helium Run 2; ○, hydrogen in blank; △, hydrogen with spheres in chamber; – – –, theoretical.

The lack of agreement between the hydrogen curves can be explained by the large adsorbing surface due to the presence of the spheres in one of the two runs. Even though the adsorption of hydrogen is negligible, the disparity in the surfaces of the two experiments is great enough to account for the difference. In the case of the helium no such explanation can be offered. However, it is in accord with observations reported by many experimenters[7] who found that repeated treatment of adsorbing surfaces with a gas enhances the adsorption of the gas.

In comparing the ratios P_3/P_2 for hydrogen in the blank chamber with corresponding ratios for the first helium run, we found them to agree with the assumption of Langmuir[8] that these ratios are

equal at pressures corresponding to equal mean free paths. Slight differences in these ratios, those of hydrogen always being higher, most likely indicate the presence of adsorption for hydrogen. This correspondence was taken into consideration in the adsorption calculations of nitrogen described below.

Nitrogen Adsorption.—The results of the experiments on nitrogen are presented in Tables III-IV and Figs. 3 and 4. Column 1 of each table gives the pressures of the gas in the system previous to adsorption. They were calculated from the known amount of gas introduced and the total volume of the system. The values given are all reduced to 0°. In column 2 are given the corresponding pressures reduced to 0° after adsorption has taken place and equilibrium was established. These pressures were measured with the McLeod gage at room temperature. From the measured values of this column and the calibration curve, we obtained the equilibrium pressures in the adsorption chamber which are given in column 3. The adsorption values given in column 4 were calculated by means of the equation

$$A = P_1V_1/RT_1 - (P_2V_2/RT_1 + P_3V_3/RT_3) \qquad (3)$$

where the terms have the same meaning as in equation (1).

To establish a procedure of treatment for the purpose of obtaining reproducible activation of the adsorbing surface, we first tried degassing at

room temperature, to eliminate the bursting of the sphere chamber on heating, until an arbitrary but fixed rate of rise of pressure in a good vacuum was obtained. This method did not prove successful as shown by the lack of agreement between the isotherms given in Table III and Fig. 3. We next studied adsorption on these spheres after they were degassed at 250° for two and one-half hours.

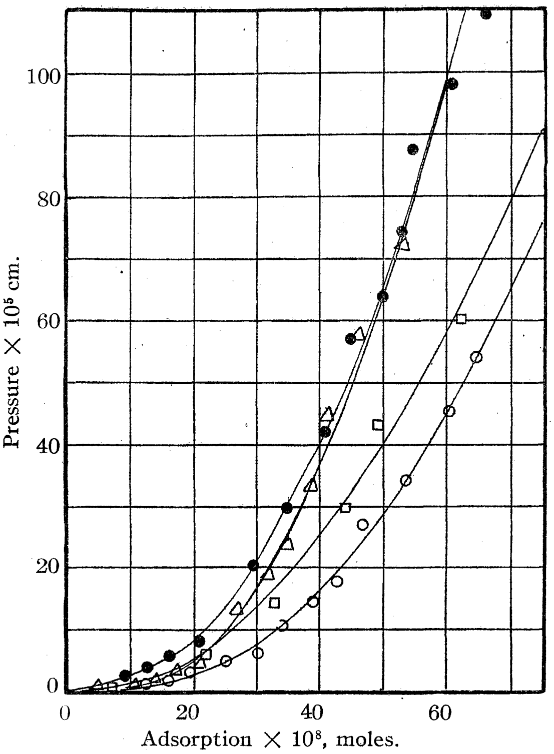

Fig. 3.—Adsorption of nitrogen on glass spheres activated at room temperature: ○, Run 1; □, Run 3; △, Run 4; ●, Run 5.

The results of these runs are given in Table IV and Fig. 4. Curves 9 and 10 are practically identical. Curve 11 shows a slight negative deviation, and is most likely due to a decrease in the adsorbing surface resulting from the greater compactness of the spheres. This higher packing was purposely brought about in order to test for the effect of capillarity. If capillarity played any role, an increase in the number of contacts per sphere should result in an increased adsorption; but since the reverse was actually observed, we must conclude that in this pressure range capillarity seems not to have influenced the adsorption of nitrogen. The observed variations in the adsorption of oxygen of a previous investigation[1] were most likely due to differences in activation of the glass spheres.

Pressure Reversal.—Similar to the results obtained with oxygen we observed pressure reversals also in the isotherms of nitrogen. As shown in Figs. 5 and 6, all isotherms show an abrupt lowering of the equilibrium pressure and a corresponding rapid rise in adsorption. The pressure at which this phenomenon sets in and the lowest pressure reached, referred to here as the reversal point, vary slightly with the isotherm.

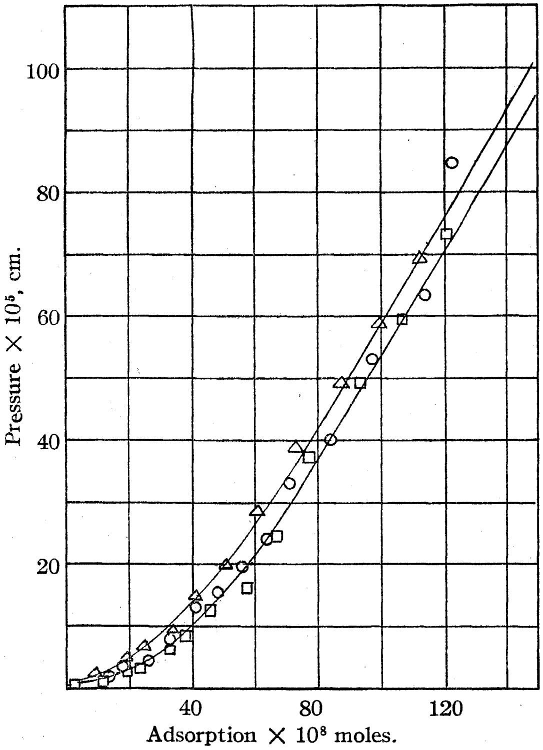

Fig. 4.—Adsorption of nitrogen on glass spheres activated at 250°: ○, Run 9; □, Run 10; △, Run 11.

It was also observed that the rates of adsorption before and after the break were at great variance. Along the linear portion of the isotherm equilibrium was established in the course of a few minutes, while in the receding portion it was established very slowly, sometimes requiring as long as forty-eight hours. It is due to this slowness of the process that curves 1, 2 and 3 show more than one equilibrium point in the receding portions of the isotherms. In all others there was observed only one equilibrium point, namely, the reversal point. Beyond this point equilibrium was attained again very rapidly, although somewhat more slowly than along the linear portion of the isotherm.

This made it evident that the rate of adsorption in the interval in which reversal took place was dependent upon some intermediate slow process which was responsible for the lowering of the equilibrium pressure.

To study the nature of this process the rates of sorption in this region of the isotherm were measured. The intervals of time over which the pressures were observed varied from ten to twenty hours, depending upon the initial pressure, *i. e.*, the quantity of gas introduced. The pressure–time curves so obtained on a number of isotherms were found to be identical in character. With the exception of the initial period of approximately five minutes where the pressure falls very rapidly and adsorption is apparently the dominating process, as shown by the typical curve in Fig. 7, each curve follows fairly closely the equation

$$\text{Ln } P/P_0 = kt \qquad (4)$$

where P is the pressure at time t, and P_0 is the initial pressure of the intermediate slow process at $t = 0$. The value of k, the specific reaction rate, was found to be the same for all isotherms studied.

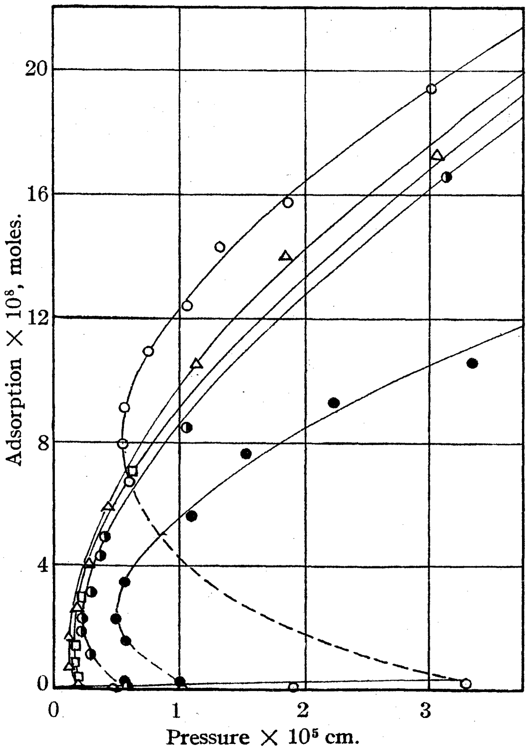

Fig. 5.—Adsorption of nitrogen at low pressures on glass spheres activated at room temperature: ○, Run 1; ◑, Run 2; □, Run 3; △, Run 4; ●, Run 5.

It might be assumed, in view of its being frequently associated with adsorption in porous bodies, that the intermediate slow process is due to absorption and the slow diffusion of the gaseous molecules through the cracks and crevices in the spheres which may have been there or have formed during the activation treatment to which the system was subjected numerous times. This seems to be supported by the consideration that theoretically absorption processes follow equation (4). However, because it was not observed after carefully testing for it at higher pressures both along the linear portion of the isotherm preceding and the portion of the isotherm following the point of reversal, absorption is most likely not the cause of the reversal phenomenon. The phenomenon is easily explained, if we assume that the adsorbed phase exists in two different states of aggregation. While there is no direct evidence to that effect, the behavior of films on liquid surfaces makes this assumption very plausible. On this basis the break in the isotherm represents the transition of the adsorbed phase from one state into the other; and the reversal in the equilibrium pressure is undoubtedly due to the tendency of the initial state toward supersaturation, as indicated by the abruptness or explosiveness of the first stage of the reversal process. The assumption is also in agreement with the measurements on the rate of the reversal process, as all transition processes follow the equation of first order reactions.

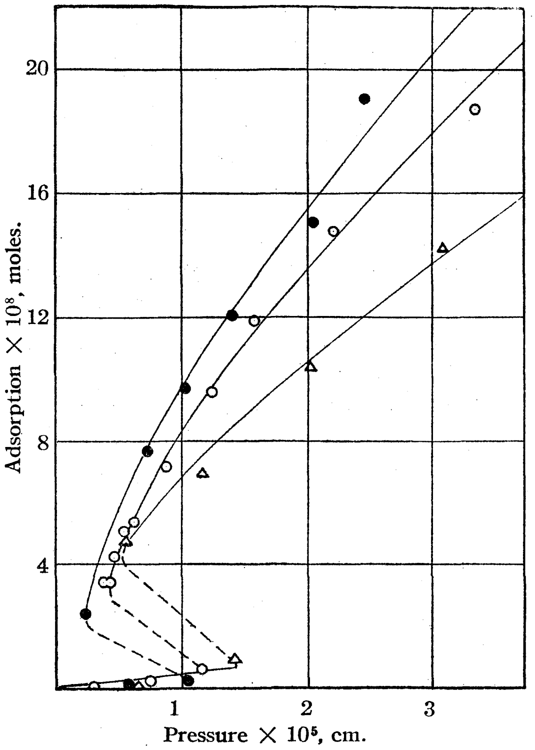

Fig. 6.—Adsorption of nitrogen at low pressures on glass spheres activated at 250°: ○, Run 9; ●, Run 10; △, Run 11.

As to the nature of the states, only the most general observations can be made. The branch of the isotherm to the left of the break seems, in view of the low pressures and the linear relationship between it and the adsorption, to represent a state in which the adsorbed gas obeys Boyle's law. In this state the van der Waals constants are either ineffective or compensating, with the result that the gas is ideal in behavior, and the adsorption isotherm follows Henry's law. In the state of the adsorbed phase described by the branch of the isotherm extending to the right of the break, the gas due to the van der Waals forces is most likely liquefied, as evidenced by the increased rise of adsorption with pressure and the abruptness of the transition. The course of adsorption in this phase seems to depend also upon the heterogeneity of the surface, as will be shown in the discussion to follow.

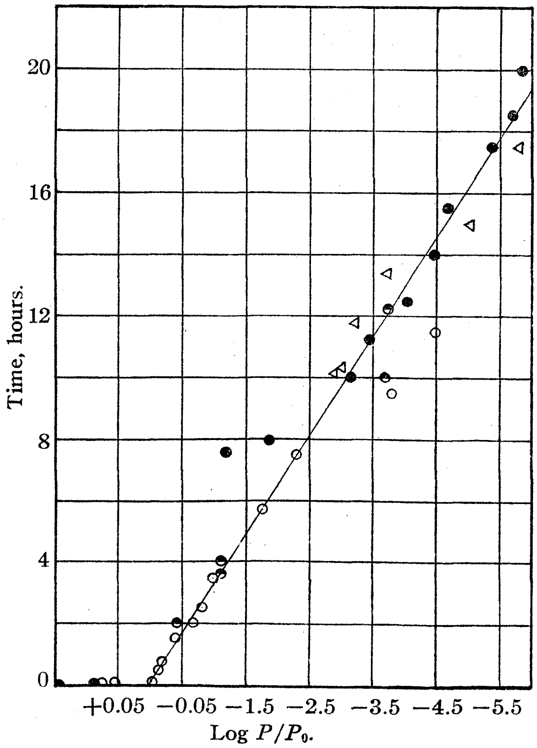

Fig. 7.—Rate of sorption at reversal point: ●, Run 1; ◑, Run 5; ○, Run 9; △, Run 10.

Adsorption Isotherm.—It is clear that no present adsorption theory will apply to the complete isotherm obtained in these experiments, and consequently in subsequent discussions reference is made only to the regular branch shown in Figs. 3 and 4.

A graphical analysis of a typical adsorption isotherm in the manner described by Cunningham[9] yielded the information that two principal types of adsorption occurred in this region. It was therefore expected that Langmuir's simple equation[10]

$$A = abP/(1 + bP) \qquad (5)$$

will not apply to these data. Such is actually the case, for graphs of P/A against P show consistently large deviations from linearity. However, an equation based on the assumption of two different elementary spaces,[10] namely

$$A = a_1b_1P/(1 + b_1P) + a_2b_2P/(1 + b_2P) \qquad (6)$$

was also found not to apply. Attempts to fit this equation to several sets of data by a few different methods, including the method of least squares, produced results which were meaningless from the point of view of Langmuir's hypotheses. Similar attempts to apply to our results the equations of Zeise[11] and of Williams–Henry[12] proved unsuccessful. On the other hand, fitting our data to the Freundlich equation[13] results in two straight lines for every isotherm, which seems to be in agreement with the two types of adsorption shown by Cunningham's method of analysis.[9]

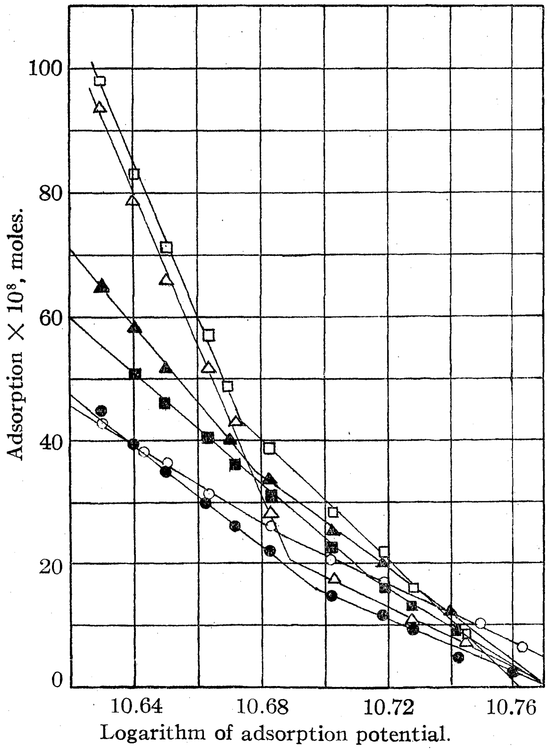

Fig. 8.—Application of equation of Palmer and Clark: ▲, Run 1; ■, Run 3; ○, Run 4; ●, Run 5; □, Runs 9 and 10; △, Run 11.

We next attempted to apply the relationship recently suggested by Palmer and Clark,[14] who assumed direct proportionality between the logarithm of the adsorption potential and the adsorption, the potential being defined in accordance with Polanyi[15] by the equation

$$\epsilon = RT \ln (P_x/P_s) \qquad (7)$$

where P_s is the saturation pressure, in this case 283 cm. of mercury,[16] and P_x is the equilibrium pressure. The plotting of our results in this manner produced two straight lines for each isotherm as shown in Fig. 8. Assuming that the two straight lines represent two different types of adsorption, we obtain by extrapolating each line to zero adsorption the maximum potential corresponding to each type. These maximum potentials correspond to the minimum pressures below which the corresponding types of adsorption cannot take place. This assumption seems to be verified by the fact that the calculated values of P_x corresponding to the maximum potentials of the upper straight line of each isotherm check fairly closely the pressures corresponding to the reversal points, which are most likely points of inflection marking the beginning of the condensed adsorption phase. This agreement is shown in Table V where the values of ϵ_m obtained by extrapolation are given in column 1; the corresponding calculated equilibrium pressures are given in column 2 and the observed pressures in column 3.

pressures corresponding to equal mean free paths.

2. The activation of glass surfaces was studied under different conditions.

3. The adsorption of nitrogen on glass spheres at liquid air temperatures was studied. Different degrees of packing of the spheres was found to have no effect on the adsorption.

4. Similar to oxygen the adsorption isotherm of nitrogen at low pressures shows the unusual phenomenon of recession of the equilibrium pressure. A possible explanation for this behavior is suggested.

5. The application of various adsorption theories to the data is discussed.

The Mutual Solubilities of Hydrocarbons. I. The Freezing Point Curves of Dotriacontane (Dicetyl) in Propane and Butane

BY W. F. SEYER AND REID FORDYCE

A considerable amount of information exists concerning the mutual solubilities of hydrocarbons. Thus over thirty years ago Holde was familiar with the fact that light hydrocarbons when added to petroleum caused the asphalt portion to be precipitated. This idea was further extended by Kling[1] in 1922 and by S. V. Pilatt and M. Godlevicz[2] in 1932. This work established the fact that mutual solubility among hydrocarbons was governed largely by the molecular weights of solute and solvent. Already extensive use has been made of this knowledge to isolate and purify certain petroleum fractions by utilizing solvents of various selective powers. So far all the information which has been forthcoming has been of a qualitative nature; consequently before much more headway can be made along this line, quantitative measurements concerning the solubility relationships existing among simple systems of hydrocarbons must be made. The following pages deal with the results obtained from a study of the systems, dotriacontane (dicetyl, $C_{32}H_{66}$) and propane and dotriacontane and butane.

Materials.—The propane and butane were purchased from The Ohio Chemical & Manufacturing Company, Cleveland. These gases were listed C. P. and the butane was claimed to be free of propane but to contain a trace of isobutane, while an analysis of the propane failed to reveal any traces of either of the two isomeric butanes. The hydrocarbon, dicetyl, was synthesized from Eastman C. P. cetyl alcohol by the method first used by Kraft.[3] The hydrocarbon was recrystallized five times from ether until no change in melting point could be detected. The final melting point was 69.9° as measured by a standardized mercury thermometer. This agrees with the findings of Hildebrand and Wachter who have pointed out that the true melting point of the hydrocarbon must be in the neighborhood of 70°.[4]

Experimental Procedure

The time honored bulb method was considered the most practical one for the determination of the freezing points. In the present case this method was susceptible of considerable accuracy because of the "cloud effect"; *i. e.*, whenever a solution of dicetyl in either propane or butane was cooled beyond the limits of solubility a white suspension immediately developed. The phenomenon is apparently due to the formation of tiny crystals of the high molecular weight hydrocarbon. The point of appearance and disappearance of these crystals was extremely sharp and did not vary more than ±0.02° in any case. The difference between the two temperatures was never greater than 0.05°.

Thick-walled uniform bulbs, 2 cm. in diameter, were blown and to these were attached glass stems 9 cm. long and 2 mm. in diameter. Varying amounts of dotriacontane were introduced by first melting the hydrocarbon and then allowing it to run down a long stemmed funnel into the bulb proper. The bulbs, after weighing, were then sealed onto the apparatus outlined in Fig. 1, evacuated and the required amounts of butane or propane condensed in each. These gases were stored in two 5-liter flasks which served as gas holders and which were placed in an insulated box whose temperature could be controlled. Before allowing either of these two gases to diffuse into the systems, it was evacuated by means of a mercury vapor pump down to a pressure of the order of 0.001 mm. as measured by a McLeod gage. Knowing the volume of the apparatus and noting the pressure changes on the manometer, it was a simple matter to calculate the amounts of gases condensed in the bulbs before they were sealed and detached from the apparatus. The amounts of the hydrocarbons in each bulb were again measured by weighing the sealed bulb after the freezing point had been obtained, then breaking off the tip, allowing the gas to escape and then weighing again.

Besides the buoyancy correction one other one was con-

sidered necessary. This was the amount of solvent present in the vapor phase. This amount of propane or butane is of course not effective in dissolving the dicetyl. Since this correction was small in any case, no great error was made in assuming the perfect gas law in the calculations. The values of the vapor pressures of butane at the various temperatures were calculated from the equation $\log_{10}p = 7.3948 - 1224.8/T$ given in the "International Critical Tables." The best values obtainable for the propane pressures over the temperature range of the investigation were those of A. W. Francis and G. W. Robbins[5] whose equation $\log_{10}p = 4.375 - 1010/T$ was used. The volume of vapor was found approximately by measuring the amount of water required to fill the vapor space in each bulb. Throughout the range of temperature covered by the investigation, the partial pressure of the dicetyl was so small it could be neglected and the total pressure was therefore sensibly equal to the vapor pressures of the low molecular weight hydrocarbons.

[a] From "International Critical Tables."

The weights of dicetyl, of butane or propane, the effective weight, the molal concentration and the freezing points of these concentrations are given in Tables I and II.

In Fig. 1 the freezing point temperatures have been plotted against concentrations in mole per cent. It will be seen that in the neighborhood of 55° there is a slight change in curvature. From this point downward solubility changes rapidly with temperature. It would thus appear that there were two forms of the hydrocarbon and that at the above-mentioned temperature transition from one form into another takes place. Further evidence for the existence of two forms has been found by measuring the refractive index of the solid dicetyl at various temperatures below its melting point with the help of an Abbé refractometer. These figures are given in Table III.

1.5632	40
1.5676	30

the figures are plotted against temperature as in Fig. 2, it is quite evident that two forms of the hydrocarbon exist and that the transition point is in the vicinity of 55°. This of course is what one should expect from the observations of Carpenter,[6] Rhodes[7] and others.

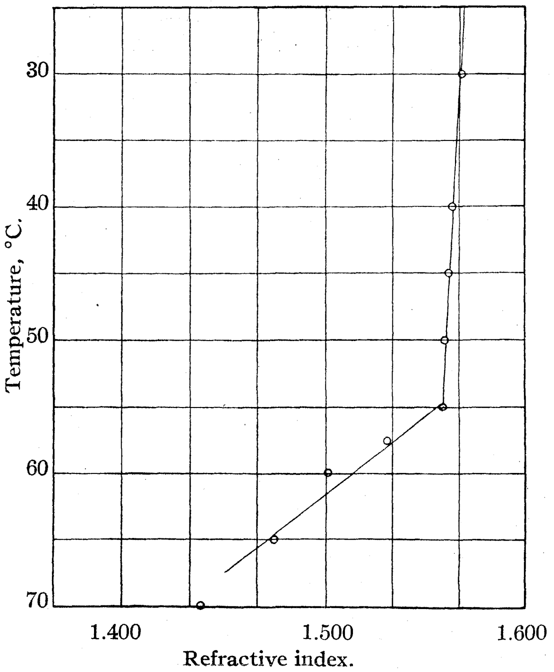

Fig. 2.

The solubility curves of the dotriacontane in propane and butane coincide until a concentration of about 50% is reached; from here on they diverge until a very low concentration is reached at temperatures below 30°. It is obvious from the shape of the curves that the solubility of the high molecular weight hydrocarbon falls off to extremely low values at low temperatures.

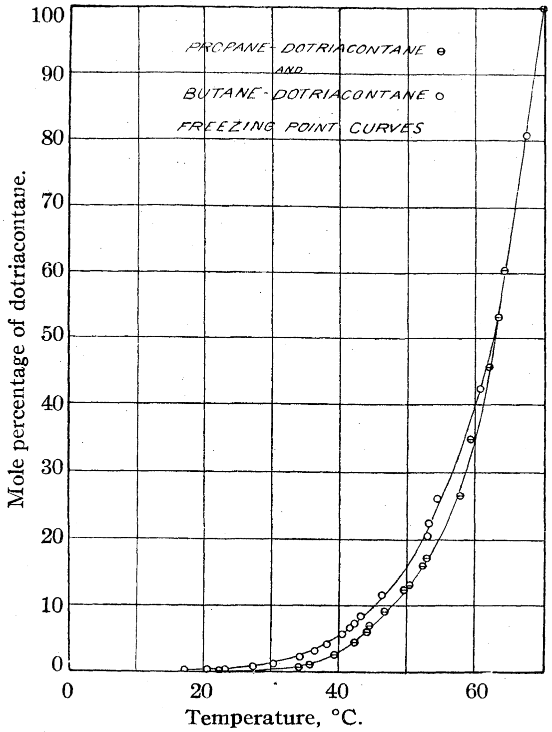

Fig. 3.—Freezing point curves: ⊖, propane–dotriacontane; ○, butane–dotriacontane.

Summary

1. The freezing points of solutions of dotriacontane (dicetyl) in propane and in butane have been found.

2. The curves constructed from the freezing point data indicate the occurrence of two forms of the high molecular weight hydrocarbon. Change of refractive index with temperature shows this to be the case and that the transition temperature is about 55°.

The Activity and Osmotic Coefficients of Aqueous Solutions of Lanthanum Chloride at 25°

BY CHARLES M. MASON AND GRACE L. ERNST

The present communication is concerned with the calculation of the activity and osmotic coefficients of lanthanum chloride in aqueous solution at 25°. These quantities have been calculated from the vapor pressures of the aqueous solutions obtained by the isotonic method of Robinson and Sinclair.[1]

Experimental Details

Apparatus.—The apparatus employed was the same as that described by Mason and Gardner[2] except for a few minor alterations. Six glass weighing bottles with ground-in stoppers were employed instead of the nickel crucibles. The metal tee tube was replaced by a brass needle valve to which was soldered the female half of a brass union. The male half of the union was connected by means of rubber tubing to the vacuum line. Another male half of the union interchangeable with the first was soldered shut and served to keep water out of the valve during immersion in the thermostat.

All measurements were carried out in a water thermostat at 25 ± 0.01°. The temperature was determined by thermometers checked against thermometers calibrated by the Bureau of Standards.

Lanthanum Chloride.—The lanthanum salt had been prepared carefully by repeated recrystallization. The chloride was prepared from the oxalate by ignition to the oxide and solution of this in redistilled, arsenic free hydrochloric acid. The chloride so prepared was then twice recrystallized by concentration of the aqueous solution and shaking out with hydrogen chloride gas at 0°. It was then carefully air-dried at 50° and placed for several weeks in a vacuum desiccator over potassium hydroxide. Examination of the solutions with the hand spectroscope and by chemical test showed the absence of other rare earths. The lanthanum chloride was dissolved in water to make a concentrated solution which was carefully analyzed gravimetrically for chloride content. This solution was then weighed out into the weighing bottles as needed.

Potassium Chloride.—The best C. P. grade of potassium chloride was twice recrystallized from conductivity water and then dried for twenty-four hours at 120°. This salt was weighed directly into the weighing bottles.

Results

Three samples of each concentration of lanthanum chloride solution were allowed to come to isopiestic equilibrium with three samples of the reference, potassium chloride solution. The data obtained are, therefore, in each case the mean of three determinations. These data are given in Table I.

TABLE I

CONCENTRATIONS OF ISOPIESTIC SOLUTIONS OF POTASSIUM CHLORIDE (m_1) AND LANTHANUM CHLORIDE (m_2)

m_1	m_2	m_1	m_2
0.2157	0.1091	2.5870	1.0272
.4298	.2281	2.8414	1.0967
.5697	.3063	3.2548	1.2071
.7399	.3895	3.4075	1.2472
1.0312	.5069	3.4381	1.2574
1.4362	.6603	3.5795	1.2908
1.7105	.7548	3.7674	1.3381
1.7321	.7618	3.8541	1.3595
2.0895	.8767	3.8814	1.3663
2.4924	.9985	4.1533	1.4317
		4.2776	1.4573

It was found that forty-eight hours were sufficient for equilibrium between the concentrated solutions. For the dilute solutions it was necessary to run them as long as four days to obtain equilibrium. Concentrations below 0.1 m would not come to equilibrium in any length of time. This is in accordance with the experience of Robinson and Jones[3] for higher valence types.

The data given in Table I were plotted, m_1 *vs.* m_2, on a large scale. Values of m_1 and m_2 were then obtained from this curve at round concentrations of lanthanum chloride. The vapor pressures of these isopiestic solutions were then obtained by calculation from the equation

$$R = (p_0 - p)/mp_0$$

The values of R for this calculation were obtained from a large scale plot of the values given by Robinson and Sinclair[1] for potassium chloride solutions.

The values of the activities of the water in the solutions were then calculated from the equation $a_1 = p/p_0$.

The osmotic coefficient φ was calculated by means of the equation $\varphi = (55.51/4m_2) \ln p_0/p$. These data are all given in Table II.

The activity coefficients of the lanthanum chloride in the solutions were calculated by the method of Randall and White[4] using the value 2.84 as the

zero intercept on the $h/m_2^{1/2}$ axis, which was calculated from the value for the dielectric constant for water obtained by Wyman.[5] The calculated values are tabulated as $\gamma_{\text{obsd.}}$ in Table II. In order to provide some means of comparison with existing data the values of the activity coefficients obtained by this means have been plotted with similar values for lanthanum nitrate obtained from Landolt–Börnstein.[6] This plot, which also contains the values of the osmotic coefficients obtained, is shown in Fig. 1.

The constants A and B have been calculated for the Hückel equation[7]

$$\log \gamma = -\frac{1.068\sqrt{12c}}{1 + A\sqrt{12c}} + B(12c) - \log(1 + 0.072m)$$

A and B were found to be 1.096 and 0.02027, respectively. These values were used in the Hückel equation to calculate the activity coefficients of the lanthanum chloride solutions for which the densities had been determined by Mason and Leland.[8] The values which were obtained from the calculation are given as $\gamma_{\text{calcd.}}$ in Table II.

The value of A obtained gives a tentative value of 4.7×10^{-8} cm. for the mean distance of approach "a."

The values obtained follow the general trend noted for all electrolytes, namely, a minimum in the curve when the activity coefficient is plotted against the ionic strength. They are, of course, open to the criticism of some uncertainty due to possible variation of the graphical integration below 0.1 molal. This is, however, unavoidable with this method which is not applicable with accuracy below this concentration.

Summary

1. The vapor pressures of aqueous solutions of lanthanum chloride have been determined by the isopiestic method, using potassium chloride for the reference substance.

2. The activity and osmotic coefficients of the lanthanum chloride solutions have been calculated from the vapor pressure data.

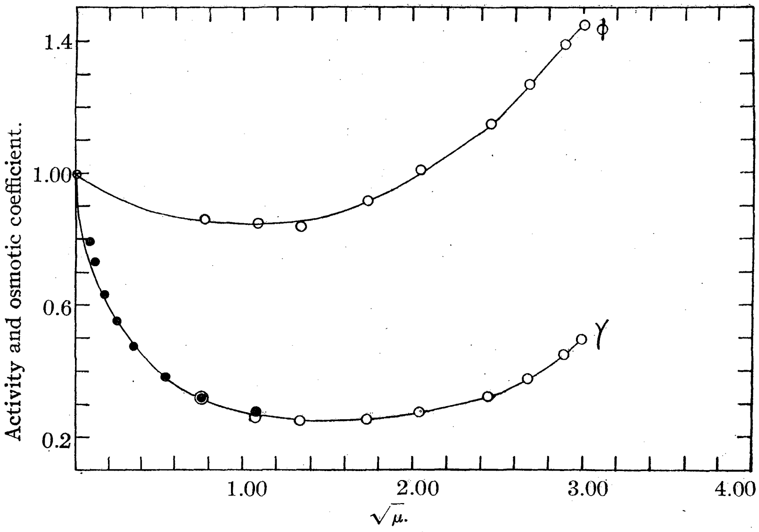

Fig. 1.—Activity and osmotic coefficients: ○, $LaCl_3$; ●, $La(NO_3)_3$.

3. The activity coefficient of lanthanum chloride in aqueous solution may be calculated by Hückel's equation, which is

$$\log \gamma = -\frac{1.068\sqrt{12c}}{1+1.096\sqrt{12c}} + 0.02027(12c) - \log(1 + 0.072m)$$

for lanthanum chloride solutions.

Deutero-acetaldehyde (Acetaldehyde-d_4)

BY J. E. ZANETTI AND D. V. SICKMAN

The synthesis of acetaldehyde-d_4 by the hydration of acetylene-d_2 appeared to the writers as a desirable method of approach to the organic chemistry of deuterium inasmuch as the reacting materials were easily obtainable and the reaction lent itself to being carried out in a closed system.

The hydration of acetylene-d_2 with deuterium oxide was first attempted in the vapor phase by passing acetylene-d_2 and deuterium oxide vapor over a tungsten oxide catalyst at 400° but the copious formation of polymerization products made this method unsuitable for working with a comparatively expensive material. The absorption of acetylene by a deuterium oxide solution of phosphoric acid in the presence of mercuric sulfate was finally adopted and found to work very satisfactorily.

Deutero-acetaldehyde and the corresponding polymerization product, deutero-paraldehyde were thus obtained in a reasonably pure state. A preliminary notice of this work has already been published.[1]

The product obtained does not appear to differ chemically from ordinary acetaldehyde although there remains the question as to whether the reactions exhibited are due to the deutero-aldehyde group—CD=O or to an ordinary aldehyde group formed by an interchange reaction either with the solvent or the reagent. Until a set of pure deuterium reagents becomes available or it can be definitely established that such an interchange does not occur, that question cannot be answered.

The physical properties are, however, definitely changed. The densities, particularly, are considerably increased. It is to be noted that the molecular volumes—as far as they can be determined by comparing densities at equal temperatures—remain constant. The melting points of both the deutero-acetaldehyde and the corresponding paraldehyde are distinctly higher but there is little difference in the boiling points.

The Raman spectrum as determined by Professor R. W. Wood of Johns Hopkins University[2] showed the expected shift in lines.

For purposes of comparison the physical constants of acetaldehyde and of deutero-acetaldehyde are given together in Table I.

Experimental Part

Materials.—As the calcium carbide of commerce contains considerable amounts of calcium hydroxide which by exchange reactions would contaminate the deutero-acetylene made from it, the calcium carbide used in these experiments was made in an induction furnace by heating to 1800–2000° precipitated calcium carbonate mixed in proper proportions with thermatomic carbon (carbon from the thermal decomposition of natural gas). The carbonate had but traces of sulfate and no phosphate that could be detected. There were no mineral impurities in the carbon used. The crucibles were made by boring out 3″ (7.6 cm.) graphite electrodes. Every precaution was taken to prevent contamination of the carbide, which was kept in glass-stoppered bottles sealed with paraffin. The carbide for this and other experiments was made in small batches of about 250 g. as needed so as to avoid keeping any of it over long periods.

The deuterium oxide was procured from Rjukan, Norway, and was redistilled and checked for purity by the interferometer method.[3] It analyzed 99.6% deuterium oxide.

Apparatus.—In order to avoid as much as possible contamination with moisture from the air the synthesis was carried out in a closed system made entirely of Pyrex glass. The apparatus, Fig. 1, consisted of a generator A into which the carbide was dropped through a side tube and the deuterium oxide dropped on it from a small separatory funnel. The deutero-acetylene was collected over mercury in the reservoirs B and B′ each holding about one liter and from there passed into the absorption vessel C which during the reaction was shaken vigorously. This was permitted by a glass spiral in the gas line. The shaking machine was operated by a small motor D provided with an eccentric.

Operation.—About 1 g. of dry mercuric sulfate was placed in the absorption vessel. A tube containing approximately the amount of phosphorus pentoxide was sealed to one of the side tubes of the absorption vessel, the entire apparatus exhausted to dry it as completely as possible and, after letting in dry air, 25 to 30 g. of phosphorus pentoxide was volatilized into the reaction vessel in a current of dry oxygen.

A tube containing 25 g. of deuterium oxide was then sealed in and the water distilled into the reaction vessel under a pressure of less than 1 mm. Every precaution was taken at all times to prevent not only contamination with moisture from the air but with moisture from the oxygen torch employed in sealing. Stopcocks were suitably arranged so that any moisture formed could be pumped out without coming in contact with the reaction materials. The absorbing solution consisted then of a 40–50% deutero-

phosphoric acid in deuterium oxide with 1 g. of mercuric sulfate as catalyzer. Acetylene-d_2 was then led in from one of the reservoirs, the other being used as storage for the acetylene that continued to be evolved after the deuterium oxide had been turned off. Vigorous shaking greatly facilitated the reaction.

The absorption was rapid at first, as much as 1 liter of acetylene-d_2 being absorbed in twenty minutes, but the rate gradually diminished to about 1 liter an hour. When acetylene ceased to be absorbed, the apparatus was connected with a cooling system and the contents of the vessel distilled under reduced pressure at room temperature, except toward the end when gentle heat was applied. Dissolved acetylene-d_2, acetaldehyde-d_4, deuterium oxide and paraldehyde-d_{12} came over and had to be fractionated. The fractionation was carried out entirely under a pressure of a fraction of a millimeter, using solid carbon dioxide–acetone and liquid air for obtaining the desired temperatures. Some 50 g. of the acetaldehyde and 6 g. of the paraldehyde were thus prepared.

The residue in the reaction vessel consisting of phosphoric acid, polymerization products and compounds of mercury was treated with anhydrous sodium carbonate and potassium permanganate to recover the deuterium as deuterium oxide. The residue of calcium deuteroxide from the acetylene generator was distilled at 700–800° and the deuterium oxide recovered.

Deutero-acetaldehyde.—After numerous fractionations deutero-acetaldehyde was obtained as a water white mobile liquid with a sharp odor and burning taste. The physical constants are given in Table I. Chemically it behaves, as far as could be determined, as ordinary acetaldehyde. It reduces ammoniacal silver oxide, restores the color to a fuchsine–sulfur dioxide solution and gives crystalline compounds with ammonia (small white cubes, m. p. 92–94°, dec.) and with sodium bisulfite. It resinifies when heated with alkalies.

About 2 g. was burned over copper oxide in a current of oxygen and the recovered water analyzed by the interferometer method showing 99.2% pure D_2O. This means that despite all precautions about 0.4% of ordinary water must have entered into the reaction and contaminated the deuterium.

The tendency of the acetaldehyde to polymerize is present in the deutero compound particularly after exposure to the air. Appreciable amounts of deutero-paraldehyde were found when sealed tubes in which the aldehyde was kept were opened after standing for some weeks.

Deutero-paraldehyde.—One of the fractions of the reaction consisted of deutero-paraldehyde and deuterium oxide. The same relation appears to exist between these two as between paraldehyde and water. The solubility of the paraldehyde decreases with increasing temperature. The paraldehyde layer which floated on top of the deuterium oxide was separated, dried with "drierite" and fractionally distilled. The paraldehyde was obtained as a water white oily liquid with a mint-like odor and a cooling taste. The physical properties are given in Table I. When solidified below 13°, the paraldehyde crystallizes in long prismatic needles.

The Molecular Structures of the Methyl Derivatives of Silicon, Germanium, Tin, Lead, Nitrogen, Sulfur and Mercury and the Covalent Radii of the Non-Metallic Elements

BY L. O. BROCKWAY AND H. O. JENKINS[1]

Introduction

The electron diffraction investigation of the fluorides and chlorides of carbon, silicon, germanium, tin, phosphorus and arsenic[2] showed the bond distances in most of these compounds to be shorter than the corresponding sums of the covalent radii.[3] Corrections applied to the accepted values for the radii would have removed some of the discrepancies but it was impossible to set up a single set of radii which gave agreement with all of the observed distances. It was suggested that the observed shortening could be explained on the basis of two effects: (1) an extra ionic character of the bonds which is not found in the compounds from which the table of radii was obtained and (2) the contribution of a partial double bond character due to the resonance of the molecule among several structures which have some double bonds. Since structures containing double bonds are not possible in the methyl derivatives of the elements concerned the study of the methyl compounds was proposed as a means of distinguishing between the two effects and also of testing the covalent radii. The tetramethyls of silicon, germanium, tin and lead, trimethyl nitrogen, and the dimethyls of sulfur and mercury have now been investigated by the electron diffraction method. The apparatus and the method of interpreting have recently been described in detail.[4] All of the compounds were photographed with electrons having a wave length of 0.0611 Å. with a camera distance of 10.43 cm.

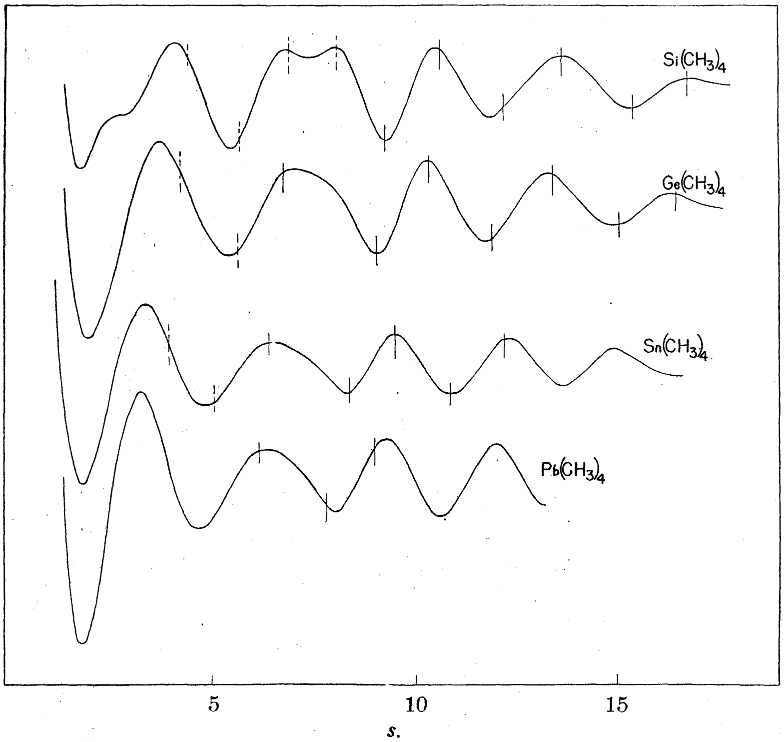

Fig. 1.—Theoretical electron diffraction curves for the tetramethyls. The observed maxima and minima are marked by the vertical lines. For $Pb(CH_3)_4$ a 3.14% shift in the s scale of the curve leads to agreement with the three observed points.

Tetramethyls.—Samples of the tetramethyls of silicon, germanium and tin were obtained from Dr. Warren C. Johnson of the University of Chicago and of lead tetramethyl from Mr. T. A. Boyd of the General Motors Research Laboratories.

Theoretical intensity curves for these compounds are reproduced in Fig. 1. For these curves the atomic scattering factors have been set equal to the respective atomic numbers. They are based on a molecular model in which the central atom is surrounded by four carbon atoms at the corners of a regular tetrahedron with three hydrogen atoms attached at tetrahedral angles to each carbon atom. In case of silicon and germanium tetramethyls an approximation to the free rotation of the methyl groups was made by averaging curves whose models differed in having successive

60° rotations in the orientation of the methyl groups. The use of a smaller interval in the methyl group rotation angle would have led to the same averaged curve since this effect was tested in the case of tetramethylmethane.

The photographs show the general features of the respective curve in Fig. 1. The positions of the maxima and minima which were measured are marked by the vertical lines. In silicon tetramethyl the second maximum was observed to be a double ring. The components of this doublet were not very well resolved and visual measurements of their diameters showed wide fluctuations. Measurements of the first maximum and second minimum showed the usual displacement toward larger diameters because of their proximity to the dense central spot on the photograph. These four points, marked by dashed vertical lines in Fig. 1, were not used in the determination of the size of the molecule as given in Table I. In this table are listed the visually observed s values (equal to $4\pi(\sin\theta/2)/\lambda$), the calculated s values based on the assumed distances Si–C = 1.94 Å. and C–H = 1.06 Å., and the experimental Si–C distances. The average value taken from the more reliable ring measurements is Si–C = 1.93 ± 0.03 Å. The radial distribution function[5] was calculated with the use of the estimated intensities given in the third column of Table I. In Fig. 2 the radial distribution functions are shown for the various compounds. In each case the principal maximum corresponds to the bond distance between the central atom and the carbon atoms, and the vertical line indicates the value found for this distance by the usual method of comparing theoretical intensity curves with the photographs. The maximum for silicon tetramethyl occurs at 1.94 Å. in good agreement with the foregoing result of the usual method of interpretation, 1.93 Å.

5		1	16.43	16.31	1.976
				Average	1.977

Radial distribution function result: 2.00 Å. Final value: Ge–C = 1.98 ± 0.03 Å.

The results for germanium tetramethyl are given in Table II. The model from which the theoretical intensity curve was calculated is the tetrahedral model described above with Ge–C = 1.99 Å. and C–H = 1.06 Å. The photographs show five maxima of which the second is distinguished by the gradual decrease of intensity on its outer edge. This characteristic is also shown by the theoretical curve in Fig. 1. The first maximum and second minimum again lead to interatomic distance values which are smaller than the average. The second maximum shows the anticipated St. John effect and the corresponding interatomic distance value is too large. The average from the remaining three minima and three maxima is 1.977 Å. with a mean deviation of only 0.007 Å. The radial distribution function shown in Fig. 2 has a maximum corresponding to the Ge–C distance at 2.00 Å. The most probable value for this distance is 1.98 ± 0.03 Å.

Radial distribution function result: 2.16 Å. Final value: Sn–C = 2.18 ± 0.03 Å.

---

(5) L. Pauling and L. O. Brockway, THIS JOURNAL, **57**, 2684 (1935).

The tin tetramethyl photographs show four maxima. The theoretical intensity curve was calculated with an assumed Sn–C distance of 2.17 Å. and a C–H distance of 1.06 Å. The comparison of observed and calculated s values for three maxima and two minima leads to an average value of Sn–C of 2.18 ± 0.03 (Table III). The value 2.16 Å. given by the radial distribution function is in satisfactory agreement.

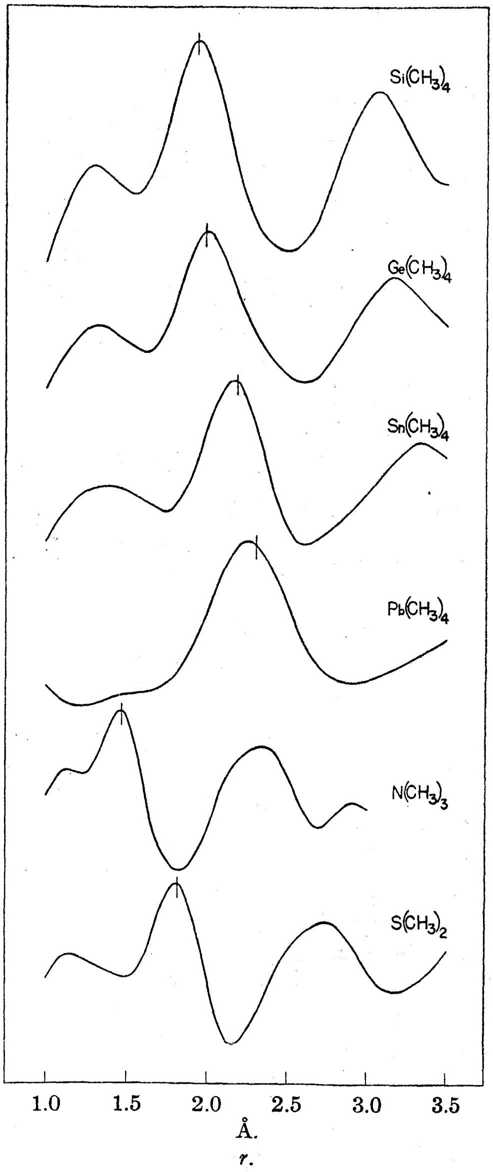

Fig. 2.—Radial distribution functions for the methyl compounds. In each case the maximum corresponding to the bond distance between the central and the carbon atoms is marked at the value for this distance as determined by the method illustrated in Fig. 1.

Good photographs of lead tetramethyl were not obtained. The heavy background on the negatives made it possible to distinguish only three rings, and of these the first was so uncertain that measurements of its diameter gave widely scattered values. Fairly consistent measurements were made on the second and third maxima and third minimum as reported in Table IV. The theoretical curve shown in Fig. 1 is based on an assumed Pb–C distance of 2.23 Å. while the experimental value is 2.30 Å. A change in the scale of the theoretical curve of 3.14% leads to excellent agreement between theory and experiment. The three term radial distribution function shows the Pb–C maximum at 2.26. Because of the relatively poor quality of the photographs, an unusually large estimate of the probable error is made; the best value for the Pb–C distance is 2.29 ± 0.05 Å.

TABLE IV

LEAD TETRAMETHYL

Max.	Min.	I	s, obsd.	s, calcd. for Pb–C = 2.23 Å.	Pb–C, Å.
1		12	(3.5)	3.26	
	2		(4.6)	4.69	
2		10	6.15	6.32	2.291
	3		7.76	8.05	2.312
3		5	8.98	9.28	2.306
				Average	2.303

Radial distribution function result: 2.26 Å. Final value: Pb–C = 2.29 ± 0.05 Å.

Comparison of the photographs of the four compounds shows the effect of the increasing size and scattering power of the central atom. The maxima occur at successively smaller angles due to the increase in the size of the molecule. This is shown in Fig. 1 by the shift toward smaller angles of the maxima on successive curves. The increase of the scattering power of the central atom is shown in the curves by the approach to a simple $(\sin x)/x$ curve; this is due to the preponderant effect of a single term in the formula for the theoretical intensity. Especially notable is the change in the appearance of the second maximum from a resolved doublet in $Si(CH_3)_4$ to an asymmetric single maximum in $Ge(CH_3)_4$ to a symmetric maximum in $Pb(CH_3)_4$.

It will be noted that the number of rings observed on the photographs of this series of compounds decreased with increasing scattering power of the central atom. This is due to the disproportionate increase of the background of atomic scattering relative to the molecular scattering

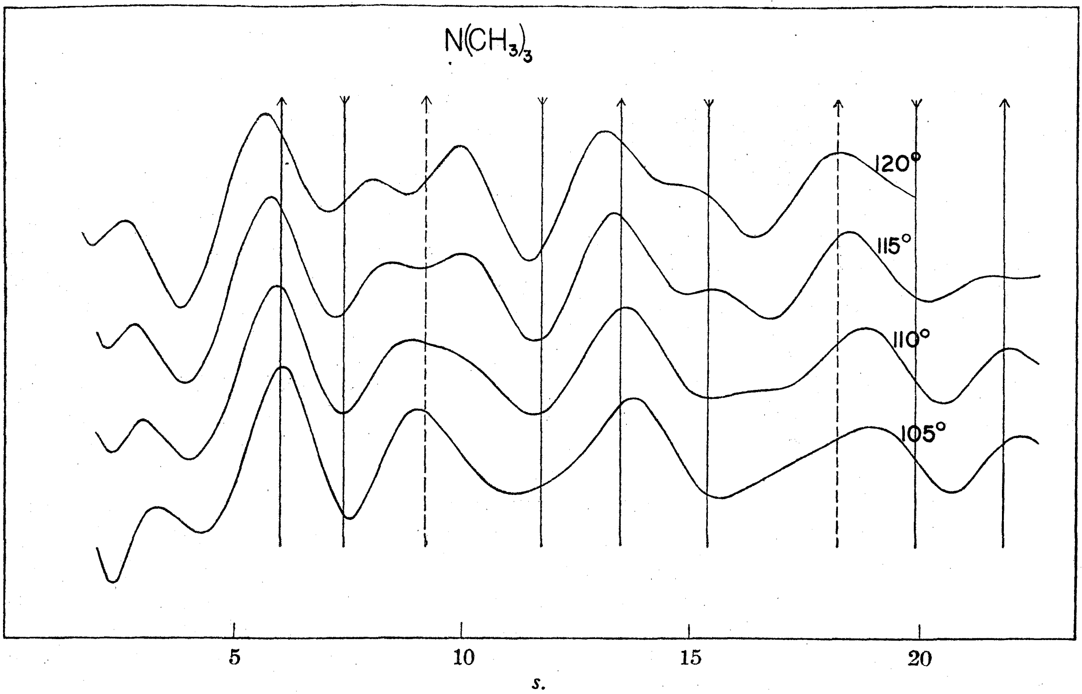

Fig. 3.—Theoretical electron diffraction curves for nitrogen trimethyl. The observed points marked by the dashed lines are not reliable for quantitative comparisons.

(*i. e.*, the part of the scattering in which the interference effects appear). Since the apparent intensity of the diffraction maxima is approximately proportional to the ratio of the molecular to the atomic scattering,[6] the relative increase of atomic scattering in a series of molecules in which one atom progressively scatters much more strongly than the others causes the maxima to become weaker and a smaller number of them to appear in the diffraction patterns of the successive molecules. On microphotometer records the fluctuations due to the interference effects become less pronounced and the intensity curve approaches that for monatomic scattering. Thus it happens that increased scattering power of a molecule results in less pronounced interference effects and poorer photographs for structure determination if the increase of scattering power occurs in only one of the atoms of the molecule.

Nitrogen Trimethyl.—The photographs of nitrogen trimethyl were obtained with the use of the Eastman product redistilled.

Theoretical intensity curves were calculated for pyramidal models having the nitrogen atom at the apex and with C–N–C bond angles of 120, 115, 110 and 105°. All terms except the H–H terms were included. Free rotation of the methyl groups was assumed and for each curve shown in Fig. 3 the scattering was averaged from a set of models which differ in having 30° intervals in the orientation of the methyl groups. The C–N distance assumed for the curves was 1.47 Å.

The measured positions of the maxima and minima are shown by the vertical lines in Fig. 3. The 120° model is eliminated since the corresponding curve shows two maxima in the region from 8 to 10 on the *s* scale where only one maximum is observed; also it shows a well-marked shelf near $s = 15$ at the position of an observed minimum. For the same reasons the 115° model is also unsatisfactory. The third ring on the photographs is broad with no well-defined maximum point and this appearance agrees better with the 110° curve than with any other. The fourth maximum is sharp whereas the fifth is indistinct on the inner edge in agreement with its appearance in the 105° curve. The general qualitative features correspond to an angle of 108 ± 4° for the C–N–C bonds.

The quantitative comparison for the 110 and 105° models is given in Table V. The wide deviations in the measurements of the third and fifth maxima make them unreliable and they are not included in the average value for the N–C distance. The five term radial distribution function

5		3	18.13	18.54	18.56	1.851	1.853
					Average	1.823	1.818
					Mean deviation	0.017	0.022

Radial distribution function result: 1.81 Å. Final value: S–C = 1.82 ± 0.03 Å.

using the estimated intensities given in the table is shown in Fig. 2 with its N–C maximum at 1.46 Å. This result combined with the average value from Table V leads to an N–C distance of 1.47 ± 0.02 Å.

X-Ray diffraction photographs of nitrogen trimethyl vapor were taken by Richter,[7] who considered three models having bond angles of 60, 110 and 120° and an assumed N–C distance of 1.5 Å. Of these three the second gave the best agreement with his photographs, a conclusion which is supported by the result of the present investigation.

The observed dipole moments, 0.60 D[8] and 0.82 D,[9] also require a pyramidal structure for nitrogen trimethyl.

Sulfur Dimethyl.—Sulfur dimethyl (redistilled Eastman product) gave photographs showing five good rings. Theoretical curves for two bond angles, 110 and 100°, were calculated (Fig. 4) but no significant differences appear since the interference terms which change with the bond angle are much smaller than the unchanging term associated with the sulfur–carbon distance. This distance was taken as 1.81 Å. and the C–H as 1.06 Å. The radial distribution function (Fig. 2) shows a sharp peak at 1.81 Å. The quantitative comparison of Table VI leads to a final value of 1.82 ± 0.03 Å.

The dipole moment of sulfur dimethyl is 1.40 D.[10] The sulfur bond angle in this compound is very probably between 100 and 110°.

Mercury Dimethyl.—Photographs of mercury dimethyl were obtained from a sample supplied by Professor D. M. Yost of this Laboratory. The maxima were not well resolved from the very heavy background of atomic scattering due to the mercury atom and the measured diameters are not very reliable. For this reason the data are not given in detail; they lead to the approximate value Hg–C = 2.20 ± 0.10 Å. A determination of the bond angle in this compound by electron diffraction experiments is not possible.

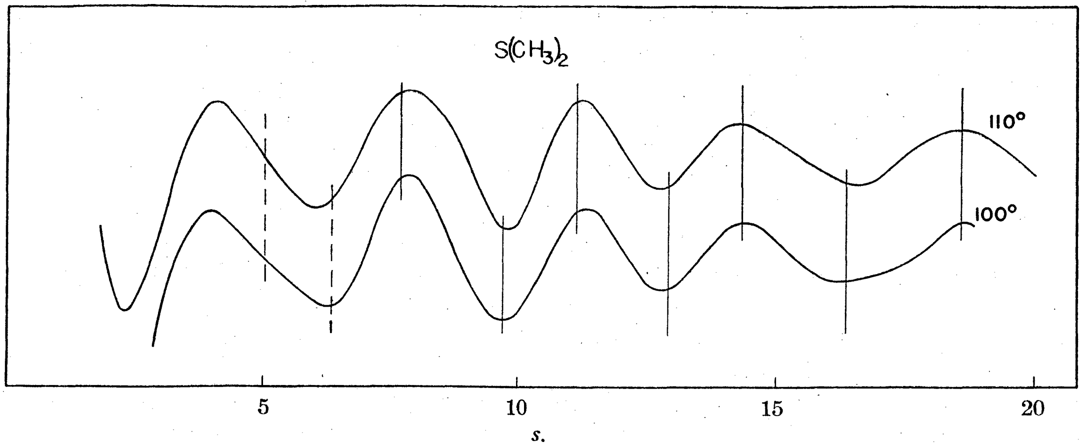

Fig. 4.—Theoretical electron diffraction curves for sulfur dimethyl.

Discussion

The data obtained from the methyl compounds are of special interest in the study of the normal covalent radii of the elements. The single bond radii proposed by Pauling and Huggins[3] for the non-metals are as follows:

C	N	O	F
0.77	0.70	0.66	0.64
Si	P	S	Cl
1.17	1.10	1.04	0.99
Ge	As	Se	Br
1.22	1.21	1.17	1.14
Sn	Sb	Te	I
1.40	1.41	1.37	1.33

These values for the carbon and halogen groups are half of the observed interatomic distances in the elements; the intermediate values were obtained by interpolation with the aid of crystal structure data. Radius sums taken from this table are intended to represent interatomic distances for single bonds when the elements have their normal valence, *i. e.*, four for the carbon group, three for the nitrogen group, two for the oxygen group and one for the halogens. Small corrections are to be applied for other valence states.

The observed bond distances in the methyl compounds may be compared with the corresponding radius sums. In Table VII this comparison is made for the elements whose methyl derivatives are reported in this paper (except lead and mercury) in addition to oxygen and chlorine, whose methyl derivatives were previously reported,[11] and for carbon, fluorine and bromine for which the details of the structure determinations will appear in forthcoming publications. The upper number in each case is the observed bond distance and the lower is the sum of the covalent radii.

TABLE VII

BOND DISTANCES AND RADIUS SUMS IN METHYL COMPOUNDS

C–C	N–C	O–C	F–C
1.55 ± 0.02	1.47 ± 0.02	1.42 ± 0.03	1.42 ± 0.02
1.54	1.47	1.43	1.41
Si-C		S–C	Cl–C
1.93 ± 0.03		1.82 ± 0.03	1.77 ± 0.02
1.94		1.81	1.76
Ge–C			Br–C
1.98 ± 0.03			1.91 ± 0.05
1.99			1.91
Sn–C			
2.18 ± 0.03			
2.17			

The agreement between the observed distances and the radius sums for all of these compounds is excellent, the differences being less than the experimental error. This shows that with respect to the factors affecting the distance the bond type in the methyl compounds is the same as in the elements where the bonds are formed between atoms of the same element. It may be pointed out that the existence of a dipole moment can have only a very small effect on the bond distance. In the methyl halides, which have appreciable moments, the distances are the averages of the carbon–carbon distance in diamond and aliphatic hydrocarbons and of the distances in the respective halogen molecules. For the other compounds, too, the bond between unlike atoms, with which there is associated an electric moment, has just the average distance of the two bonds between like

---

[11] L. E. Sutton and L. O. Brockway, THIS JOURNAL, **57**, 473 (1935).

atoms, which have zero moments. The introduction of the moment has no appreciable effect on the distance.

It is now possible to discuss the data for the halogen derivatives. In Table VIII are shown the observed bond distances and the radius sums for the fluorides and chlorides in which the carbon group elements form four bonds to halogens, the nitrogen group form three, the oxygen group two and the halogens one. The table includes the compounds on which electron diffraction measurements have been made and the data are taken from a recent survey.[4] For Cl_2 and ICl the band spectral results are reported in preference to the electron diffraction results.

TABLE VIII

BOND DISTANCES AND RADIUS SUMS IN CHLORIDES AND FLUORIDES

	As–F 1.72 ± 0.02 1.85 −0.13		

Five of the chlorides have bond distances which within the experimental error are equal to the corresponding radius sums. Among these is the chlorine molecule whose bond distance determines the chlorine radius. The chlorides of silicon, germanium, tin, phosphorus and arsenic, on the other hand, have distances which are appreciably shorter than the radius sums. It was suggested in a previous paper[2] that two effects might contribute to this shortening. The first is related to the extra ionic character of the bonds due to the differences in the electronegativities of the atoms involved. The covalent radii quoted above were obtained from bonds between atoms of the same element having the same electronegativity; and the bonds in question between atoms with different electronegativities might well be expected to show an extra ionic character which would strengthen and shorten the bonds. The results on the methyl compounds, however, show that this explanation is not valid. Although the differences in electronegativity are more extreme in some of these compounds than in the chlorides, no deviations from additivity of the covalent radii are observed.

The alternative explanation for the shortening is that the bonds may have some double bond character. If one of the structures contributing to the normal state of the molecule has two atoms joined by a single bond and one of the atoms has an unshared pair of electrons while the other has an unoccupied orbital, then another structure in which a double electron pair bond is formed between two atoms may contribute to the normal state of the molecule. If this occurs the bond distance will be shorter than the single bond distance by an amount depending on the relative contributions of the various resonating structures. The maximum shortening will be ten per cent. since the ratio of double to single bond distance is 90%.

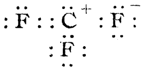
Shortening due to double bond character will not be expected when the formulation of the structure having the double bond would violate the octet rule for an atom of the first row of the periodic table. In one of these atoms the four orbitals of the L shell are filled by the four electron pairs and the higher lying levels of the M shell are not available for bond-formation. In the later rows of the periodic table, however, four electron pairs occupy the *s* and *p* orbitals with *d* orbitals of the same shell available for the formation of additional bonds.

In examining the data for the chlorine compounds we see that carbon tetrachloride could not show a double bond effect, and no shortening is observed. In chlorine monoxide the fact that no shortening occurs shows that chlorine has little or no tendency to hold five pairs. The 8% shortening observed in silicon tetrachloride indicates a considerable double bond effect. If it is the only cause of the shortening, the bonds in silicon tetrachloride have 40% double bond character according to the relation between interatomic distance and single bond–double bond resonance.[12] This requires a considerable contribution to be made by structures having two and three double bonds to silicon.

All of the shortenings observed in the chlorine compounds are compatible with the explanation on the basis of double bond character. In the methyl compounds double bonded structures are not possible because there are no unshared electrons, and no shortening is observed. Another example of shortening due to double bond character has been observed in the case of nickel carbonyl.[13]

The deviations from additivity shown in Table VIII become less in passing to the right or down through the periodic arrangement of the elements. In the second row this is inevitable since the distance in the molecule Cl_2 furnishes the standard for comparison. We have in reality measured the excess of the effect over that in Cl_2 itself. It is probable, however, that Cl_2 has very little double bond character inasmuch as the distance in carbon tetrachloride would be larger than the sum of the radii if the chlorine radius were affected by double bond character in Cl_2. The zero deviation observed for ICl also lends some significance to the apparent trend in the tendency toward double bond formation.

The bond distances of the fluorides require additional explanation. It will be noted that the C–F distance in methyl fluoride is 1.42 Å. and in carbon tetrafluoride 1.36 Å. This difference is beyond the range of experimental error. The shortening below the sum of the radii for the second compound is not due merely to ionic effects since it would also appear in some degree in the first. Professor Pauling has suggested that in addition to the single bonded structure the CF_4 molecule resonates among structures having an F^- ion bonded electrostatically to a CF_3^+ ion in which one double and two single covalent bonds are formed.



$$\begin{array}{c} :\ddot{F}: \\ :\ddot{F}::\ddot{C}^{+}\ :\ddot{F}:^{-} \\ :\underset{..}{\ddot{F}}: \end{array}$$

The quantum mechanical principle of resonance among structures having equal energies would require the four bonds to be equivalent and they would show an equal shortening. The effect could not take place in methyl fluoride and thus the difference between the two compounds is accounted for. If this explanation is correct, the effect should be observed whenever two or more fluorine atoms are attached to the same carbon or even when a fluorine and one or more chlorine atoms are bonded to carbon. It is known that the halogen derivatives of methane containing two or more halogen atoms of which fluorine is one have different chemical properties from the others. This fact is undoubtedly associated with the variations in the bond distances. A report of the electron diffraction investigation of the mixed fluorine and chlorine derivatives of methane will be published soon.

The described effect should be especially important in the fluorides on account of the pronounced electronegativity of fluorine. That the explanation is not entirely satisfactory is indicated by the magnitude of the deviations observed in silicon tetrafluoride and phosphorus trifluoride. The shortenings here are 15 and 13%, respectively, although the maximum difference observed between single and double bonds is 10%. The contribution of structures involving triple bonds is probably small in view of the slight tendency for elements of the second row to form triple bonds. If the large shortening can be explained by the combined extreme ionic-double bond character described above, then the shortening in the fluoromethanes should be greater.

As in the chlorides, the shortening for fluorides becomes less toward the right and in lower rows of the periodic system. In fluorine monoxide the bond distance is larger than the sum of the radii. No explanation of this anomaly is apparent.

Because of the agreement found for methyl compounds we believe that the covalent radii given in Pauling and Huggins' table are reliable and applicable even to bonds with considerable ionic character. The radii are also useful for predicting distances in compounds in which deviations from additivity occur due to resonance of the molecule among several electronic structures. The results for the chlorine compounds indicate the circumstances under which such deviations may be expected.

We express our indebtedness to Professor Linus Pauling for valuable discussions on the interpretation of the data on internuclear distances.

Summary

By electron diffraction investigation of the gases the structures of certain methyl compounds have been determined. Four tetramethyls with tetrahedral symmetry have the following bond distances: Si–C = 1.93 ± 0.03 Å., Ge–C = 1.98 ± 0.03 Å., Sn–C = 2.18 ± 0.03 Å., Pb–C = 2.29 ± 0.05 Å. Nitrogen trimethyl has a bond angle of 108 ± 4° with N–C = 1.47 ± 0.02 Å. In sulfur dimethyl and mercury dimethyl the interatomic distances are S–C = 1.82 ± 0.03 Å. and Hg–C = 2.20 ± 0.10 Å., respectively. These distances agree with the sums of covalent radii given by Pauling and Huggins.

In a discussion of previous data for the chlorides it is shown that relative electronegativities (or the existence of electric moments in the bonds) are not responsible for the shortening observed in some of the chlorides. This effect is instead probably due to the contribution of structures having double electron pair bonds. Further investigation is required to explain the observed deviations in the chlorides.

Diazotization of Weakly Basic and Insoluble Amines. The Use of Pyridine, Quinoline and Isoquinoline as Solvents for the Amines

BY CLARA DEMILT AND GERTRUDE VAN ZANDT[1]

A series of experiments in this Laboratory on the diazotization of 4-aminobiphenyl with the use of pyridine as a solvent for the amine[2] led the authors to an investigation of the use of pyridine as a solvent for other weakly basic and insoluble amines. The success of this work led to experimentation on the use of quinoline and isoquinoline as solvents.

The use of pyridine as a solvent for the difficultly diazotizable amines has been described by Krishna and Bhatia,[3] who reported the successful diazotization of tribromoaniline, 2,6-dichloro-4-nitroaniline, dibromo-*p*-aminobenzoic acid and dibromo-*p*-aminobenzaldehyde.

The experimental work described in this paper substantiates the conclusion so often expressed that the diazotization proceeds only with the substituted ammonium salt and never with the free amine.[4,5] As groups which decrease the basicity of the amine replace the hydrogen atoms in the benzene ring, the concentration of the ammonium salt in the aqueous solution is correspondingly decreased. In order to prevent this hydrolytic action, Schoutissen[5] found that it was necessary to use a large excess of strong mineral acid or a solvent which reduces the dissociating effect of water. With the use of pyridine, quinoline and isoquinoline as solvents for the weakly basic and insoluble amines, it is possible to introduce the amine into the diazotizing mixture, namely, sulfuric acid and sodium nitrite, so that the amine is evenly distributed throughout the mixture in a very finely divided condition. The amine solution is added slowly to the cold nitrosylsulfuric acid. The solvent seems to hold the amine in solution until the sulfate is formed, which in turn reacts with the nitrous acid that is liberated by the action of the solvent on the nitrosylsulfuric acid. It is to be noted, however, that even though all other quantities and factors are the same, complete diazotization of the amine is not obtained in a reasonable length of time unless the amine is entirely dissolved in the liquid that is being used as the solvent.

The excess of mineral acid that is necessary depends upon the solubility of the amine and the nature, number and position of the groups that are present in the benzene ring. A study of the acid concentrations used in the diazotization of the substituted amines, showed that when a relatively small volume of organic solvent was used, the more dilute acid solution is satisfactory except for 4,6-dibromo-2-nitroaniline and picramide. If, however, a much larger volume of solvent is necessary to dissolve the amine, then the stronger acid solution must be

---

[5] Schoutissen, THIS JOURNAL, **55**, 4531 (1933).

used, although the final concentration of the diluted acid is approximately the same. The effect of solubility is illustrated by the diazotization of 2,6-dibromo-4-nitroaniline. The amine is very soluble in quinoline and is easily diazotized with the use of this solvent. When pyridine is used as the solvent, a large volume is necessary to dissolve the amine and complete diazotization results only when a stronger acid concentration is used. It was not found possible to use dilute hydrochloric acid described by Krishna and Bhatia[3] as being satisfactory for the diazotization of difficultly diazotizable amines, when pyridine was used as the solvent for the amines. Pyridine reacts vigorously with concentrated hydrochloric acid, and weaker solutions of hydrochloric acid do not furnish the concentration of mineral acid that is necessary for the diazotization of the very weakly basic amines. For this reason, sulfuric acid has been used almost exclusively and has been found to furnish sufficient acid concentration even for the diazotization of the least basic amine, picramide.

Even though sulfuric acid is the best mineral acid to furnish the necessary acid concentration, Schoutissen[5] showed by experiment that the sulfuric acid, used alone, combines with all the nitrous acid. In order to release the nitrous acid from the nitrosylsulfuric acid, he used phosphoric acid. Glacial acetic acid was used for the same purpose by Misslin[6] in the diazotization of picramide. The addition of pyridine, quinoline or isoquinoline to a solution of nitrosylsulfuric acid was found to release the nitrous acid. Thus besides acting as a solvent for the difficultly soluble amines, these tertiary amines, which do not reduce the concentration of the sulfuric acid appreciably, have another function, that of releasing the nitrous acid from the nitrosylsulfuric acid.

Even though the three solvents have the same function in the diazotization process, each has its advantages. Much heat is generated when pyridine is added to nitrosylsulfuric acid, and it is sometimes difficult to keep the temperature as low as necessary, while little heat is evolved when quinoline or isoquinoline is used. On the other hand, pyridine shows almost no tendency to hold the azo compound formed in a coupling process in solution, while quinoline and isoquinoline do hold the coupled product in solution, especially when a proportionately large volume of the solvent has been used. Moreover, quinoline and isoquinoline cannot be used with those amines the diazonium salts of which couple with β-naphthol in alkaline solution, since they separate out as oils.

Further work on the diazotization of amines with the use of these solvents followed by the Sandmeyer reaction is in progress.

Experimental Part

1. Diazotization with Pyridine

2,6-Dichloro-4-nitroaniline.—Three grams of sodium nitrite was added to a solution of 30 cc. of concentrated sulfuric acid and 15 cc. of water, which had been cooled to 10°. To this was slowly added 4.14 g. of 2,6-dichloro-4-nitroaniline dissolved in 15 cc. of pyridine. During the addition, the mixture was stirred mechanically and the temperature was maintained below 10°. The diazonium salt solution was stirred for a half hour after the amine–pyridine solution had been added. Twice the volume (120 cc.) of ice water was then added. Finally 2 g. of urea was added to remove excess nitrous acid, and the solution was stirred until foaming had ceased. The diazonium salt solution was filtered to remove a slight residue that seemed to result on the addition of the urea. To the clear solution 2.88 g. of β-naphthol dissolved in 10 cc. of pyridine was added, and coupling took place at once. The mixture was allowed to stand for an hour, and was then diluted with 200 cc. of water. The coupled product was filtered, washed with water and digested with 150 cc. of 25% alcohol on a water-bath for a half hour to remove adhering pyridine. The yield was quantitative. Recrystallization of 2,6-dichloro-4-nitrobenzene-azo-β-naphthol from toluene gave deep red needles, m. p. 219°.

3-Nitro-4-aminobiphenyl.—The 3-nitro-4-aminobiphenyl, m. p. 165.5°, was prepared by the nitration of 4-aminobiphenyl, obtained from Eastman Kodak Co.; 4.04 g. of 3-nitro-4-aminobiphenyl dissolved in 20 cc. of pyridine was added slowly to a cold mixture of 3 g. of sodium nitrite in a solution of 30 cc. of concd. sulfuric acid and 15 cc. of water. The diazotization was carried out in the usual way. Coupling took place immediately on the addition of 2.88 g. of β-naphthol dissolved in 10 cc. of pyridine to the clear diazonium salt solution. The coupled product was filtered, washed and digested with 25% alcohol. The 2-nitro-4-phenylbenzene-azo-β-naphthol formed fine red-brown crystals from toluene, m. p. 228°.

Anal. Calcd. for $C_{22}H_{15}O_3N_3$: N, 11.38. Found: N, 10.22, 10.06.

Picramide, 2,4,6-Trinitroaniline.—A solution of 60 cc. of concd. sulfuric acid and 21 cc. of water was cooled to 10° and 3 g. of sodium nitrite was added. This mixture was heated on a water-bath until it became clear (70°) and was then cooled to 0°; 4.56 g. of picramide dissolved in 30 cc. of pyridine was added during an hour and a half to the nitrosylsulfuric acid solution. During the addition, the mixture was stirred mechanically and the temperature kept below 10°. The diazonium solution was allowed to stand for two hours. To the concentrated solution 2 g. of urea was added. Very little foaming resulted, and it was not necessary to filter the clear solution. A solution of

---

[6] Misslin, *Helv. Chim. Acta*, **3**, 626 (1920); *C. A.*, **15**, 61 (1921).

2.88 g. of β-naphthol in 10 cc. of pyridine was then added, and coupling took place immediately. The coupled product was allowed to stand for an hour, diluted with 300 cc. of water and filtered. It was washed and digested with 25% alcohol; yield quantitative. Recrystallization of 2,4,6-trinitrobenzene-azo-β-naphthol from toluene gave a brick-red powder, m. p. 147°.

3-Aminophenanthrene in Sulfuric Acid.—1.93 g. of 3-aminophenanthrene (a gift from Professor W. E. Bachmann of the University of Michigan), m. p. 87.5°, dissolved in 10 cc. of pyridine was added slowly to a cold solution of 15 cc. of concd. sulfuric acid and 7 cc. of water containing 1.5 g. of sodium nitrite. The diazonium salt solution was diluted with 50 cc. of ice water and treated with 1 g. of urea. To this was added 1.44 g. of β-naphthol dissolved in 5 cc. of pyridine. Coupling took place when the solution was made alkaline with sodium hydroxide. The coupled product was filtered and washed with water. The yield of the crude product was quantitative. The phenanthrene-azo-β-naphthol recrystallized from toluene gave fine, dark red crystals, m. p. 249°.

Diazotization of 3-Aminophenanthrene in Hydrobromic Acid.—A solution of 1.93 g. of 3-aminophenanthrene in 5 cc. of pyridine was added alternately with a solution of 1.5 g. of sodium nitrite in 4 cc. of water to 18 cc. of 40% hydrobromic acid, cooled below 4°. The diazotized solution was diluted with 50 cc. of ice water and treated with 1 g. of urea. It was now added to a solution of 1.44 g. of β-naphthol in sodium hydroxide. The yield of the crude product was quantitative. The recrystallized product melted at 249°.

2. Diazotization with Quinoline[7]

4,6-Dibromo-2-nitroaniline.—A solution of 5.91 g. of 4,6-dibromo-2-nitroaniline in 15 cc. of quinoline was diazotized in a reaction mixture of 3 g. of sodium nitrite in 40 cc. of concd. sulfuric acid and 15 cc. of water. Coupling took place when to the clear diazonium salt solution a solution of 2.88 g. of β-naphthol in 10 cc. of quinoline was added. The coupled product was filtered, washed and digested with 25% alcohol. The yield was quantitative. Recrystallization of the 4,6-dibromo-2-nitrobenzene-azo-β-naphthol from toluene gave red crystals, m. p. 250°.

Anal. Calcd. for $C_{16}H_9O_3N_3Br_2$: N, 9.32. Found: N, 9.46, 9.30.

3. Diazotization with Isoquinoline

Picramide.—A mixture prepared by adding 3 g. of sodium nitrite to a cold solution of 60 cc. of concd. sulfuric acid and 21 cc. of water was heated on a water-bath to 70° until clear; 4.56 g. of picramide dissolved in 50 cc. of isoquinoline on a water-bath was added as a thick suspension to the nitrosylsulfuric acid. The mixture was stirred mechanically and the reaction carried out at room temperature. The solution was diluted with a mixture of 30 cc. of concd. sulfuric acid and 35 cc. of water and allowed to stand for an hour with stirring. Two grams of urea was added. After the foaming had ceased, the solution was clear. Water was then added until a precipitate began to form. A solution of 2.88 g. of β-naphthol in 10 cc. of isoquinoline was then added. The mixture was allowed to stand, then diluted with water. The product was filtered, washed and digested with 25% alcohol. The yield was not quantitative, apparently because the isoquinoline held some of the coupled product in solution. Recrystallization from toluene gave 2,4,6-trinitrobenzene-azo-β-naphthol as a red powder, m. p. 147°.

Summary

1. A new method for the diazotization of weakly basic and insoluble amines has been devised with the use of pyridine, quinoline and isoquinoline as solvents for the amines. The diazotization of 2,6-dichloro-4-nitroaniline, 2,4-dinitroaniline, 3-nitro-4-aminobiphenyl, 2,4,6-tribromoaniline, 2,6-dibromo-4-nitroaniline, 4,6-dibromo-2-nitroaniline, 3-aminophenanthrene and 2,4,6-trinitroaniline has been carried out with the use of these solvents.

2. Complete diazotization is not obtained in a reasonable length of time unless the amine is entirely dissolved in the liquid that is being used as the solvent.

3. Two new compounds have been prepared: 2-nitro-4-phenyl-benzene-azo-β-naphthol, m. p. 228° and 4,6-dibromo-2-nitrobenzene-azo-β-naphthol, m. p. 250°.

Polysulfones from Acetylenes and Sulfur Dioxide[1]

BY L. L. RYDEN AND C. S. MARVEL

In an earlier communication,[1] we have shown that one acetylene, 1-heptyne, combines with sulfur dioxide in a one-to-one ratio to yield a polymeric product. This reaction has now been studied with a wide variety of substituted acetylenes and it appears to be a general reaction for monosubstituted acetylenic hydrocarbons.

The monoalkylacetylenes, RC≡CH, in which R is a normal alkyl group containing one to five carbon atoms, have been found to combine readily with sulfur dioxide in the presence of alcohol and paraldehyde which contains peroxides. Phenylacetylene also combines readily with sulfur dioxide under the same conditions used for alkylacetylenes. Disubstituted acetylenes apparently do not enter into the reaction as shown by failure to obtain sulfur dioxide addition products from 2-butyne, 2-hexyne and methylphenylacetylene. Ethyl acetylenedicarboxylate also failed to react with sulfur dioxide. Further experiments on monosubstituted acetylenes will have to be made before the exact limits of the reaction can be set forth.

The products of the addition of sulfur dioxide to monosubstituted acetylenes are presumably polysulfones. They still contain one double bond for each hydrocarbon residue in the polymer, since oxidation gives the acid which would be expected from this structure. That the addition of sulfur

$$(\underset{|}{RC}{=}CH{-}SO_2{-})_n \xrightarrow{\text{Oxid.}} RCOOH$$

dioxide is to the acetylene and not to an allene which might result from a rearrangement of the acetylene is established by the above observation. Moreover, phenylacetylene, which could not rearrange to an allene, adds sulfur dioxide, and allene itself fails to combine with this reagent.

The polymers are readily hydrolyzed with 10% aqueous sodium hydroxide, but all of the products of this hydrolysis are not known. The phenylacetylenepolysulfone was most extensively investigated, since it was thought that the presence of the phenyl group would give products which were more readily identifiable. The products which have been isolated are benzylmethylsulfone (8%), acetophenone (trace), benzoic acid (20%) and sodium sulfite (50%). The remainder of the sulfur was present in the tarry organic products which are produced in the hydrolysis. The fact that almost exactly half of the sulfur is isolated as sulfur dioxide and half as organic sulfur compounds indicates that there is possibly the same type of alternation in the manner of combination of phenylacetylene and sulfur dioxide to give a polymer of structure I as was previously demonstrated in the case of propylenepolysulfone.[2] However, this structure does not account for the formation of benzylmethylsulfone on hydrolysis. At least a part of the polymer must have the structure shown in formula II. It seems likely that the acetophenone is produced from one end group of the polymer. Addition of water to stop the polymeric reaction would give at one end of the chain the group $C_6H_5COCH_2SO_2$-, and this would give acetophenone on alkaline hydrolysis.

Hydrolysis of 1-pentynepolysulfone gave a trace of methyl *n*-propyl ketone which also probably came from the end group of the molecule. About 40–50% of the sulfur was removed as sulfur dioxide. No other products of hydrolysis have been identified. An attempt was made to reduce 1-pentynepolysulfone with hydrogen over a platinum catalyst to see whether the reduction product could be shown to be identical with 1-pentenepolysulfone. No reduction occurred at room temperature in dioxane. The polymer lost sulfur dioxide when heated. Almost exactly half of the sulfur was eliminated as sulfur dioxide at the boiling point of dioxane. The only product besides sulfur dioxide which could be isolated after decomposition with heat was a crystalline material which analysis and molecular weight showed to be $C_{10}H_{16}SO_2$. The structure of this compound is yet unknown.

Pyrolysis in boiling dioxane removed approxi-

[1] This is the fourth communication on polysulfones. For the third, see THIS JOURNAL, **57**, 2311 (1935).

[2] Hunt and Marvel, *ibid.*, **57**, 1691 (1935).

mately half of the sulfur from 1-heptynepolysulfone as sulfur dioxide. Phenylacetylenepolysulfone was insoluble in dioxane, but heating the polymer alone at 140° for the forty-five minutes liberated 62–73% of the sulfur as sulfur dioxide. No definite products could be isolated from the organic residue. When 1-pentynepolysulfone was heated to 200° until frothing ceased, only 50% of the sulfur was removed as sulfur dioxide. The evidence is as yet too meager to ascribe definite formulas to these acetylene–sulfur dioxide polymers but there is apparently considerable difference between the alkyl substituted and aryl substituted products.

No satisfactory molecular weight determinations have been made on any of the acetylene derivatives.

Experimental Part

Preparation of Polysulfones from Acetylenes.—Ten cubic centimeters each of liquid sulfur dioxide and the substituted acetylene were placed in a pressure bottle, and 5 cc. of ethyl alcohol was added. The bottles were sealed and allowed to stand overnight, then cooled and opened to permit the addition of 1 to 5 cc. of paraldehyde which contained peroxides. The amount of paraldehyde to be added varied roughly with various samples. Fresh paraldehyde was inert, but older samples which had been exposed to the air were very effective catalysts for the addition reaction. The flasks were sealed and allowed to come to room temperature. The contents of the flask were usually solid at this time. With 1-pentyne and 1-hexyne, the reaction was distinctly exothermic.

The reaction mixtures were poured into water and the products collected on a filter. The excess of sulfur dioxide and paraldehyde was removed by triturating with alcohol and ether several times. The polymer from 1-pentyne was further purified by dissolving in dioxane and reprecipitating by the addition of water. The products from 1-hexyne and 1-heptyne were purified similarly with acetone as the solvent.

The polysulfones from methyl-, ethyl- and propylacetylene were white, powdery, amorphous substances. The butyl- and amyl-acetylene derivatives were more flaky and were not easily ground to powder.

The products which have been prepared are listed in Table I.

Under the same experimental conditions which gave addition products when the monosubstituted acetylenes were used, no polysulfones could be obtained from dimethylacetylene, 2-hexyne, methylphenylacetylene, diethyl acetylenedicarboxylate or allene and sulfur dioxide. Acetylene itself was not investigated.

The polysulfones derived from methyl-, ethyl- and phenyl-acetylene were insoluble in water, alcohol, ether, acetone, carbon tetrachloride, chloroform, benzene and cold concentrated sulfuric acid. The polysulfones from *n*-propyl-, *n*-butyl- and *n*-amyl-acetylene were soluble in dioxane and could be precipitated from this solvent by the addition of water. Acetone could be substituted for dioxane when *n*-butyl- and *n*-amylacetylenes were used.

Table I

Polysulfones from Monosubstituted Acetylenes

[a] These decomposition temperatures were determined by heating a sample in a capillary melting point tube in an oil-bath which was heated rapidly. The temperature of decomposition varies widely, depending on the rate of heating. [b] Calcd.: C, 34.6; H, 3.85. Found: C, 34.52, 34.23; H, 3.95, 3.94. [c] Analysis reported previously; see ref. 1.

All of these new polysulfones were sensitive to alkalies. The products did not dissolve in cold, aqueous, 10% sodium hydroxide, but on warming the mixture the sulfones dissolved and were hydrolyzed rapidly.

Oxidation of the Polysulfones from Acetylenes.—Five grams of 1-pentynepolysulfone was boiled for fifteen minutes with a solution of 24 g. of potassium permanganate in 500 cc. of water. The hydrated manganese dioxide was removed by filtration, and the solution was acidified with phosphoric acid. The distillate was distinctly acid. The Duclaux constants[3] for the volatile acid were 17.7, 16.0 and 14.1, whereas the values reported for *n*-butyric acid are 17.9, 15.9 and 14.6. To confirm the identification of the volatile acid the sodium salt was prepared and converted to the *p*-bromophenacyl derivative, which melted at 63°. A mixture of this product with an authentic specimen of the *p*-bromophenacyl ester of *n*-butyric acid melted at 63°.[4]

Similarly, 2 g. of 1-butynepolysulfone was oxidized with 12 g. of potassium permanganate. The product of this reaction was identified as propionic acid by the Duclaux constants, and preparation of the *p*-bromophenacyl ester which melted at 62°. There was no depression in the melting point when this ester was mixed with an authentic sample of the *p*-bromophenacyl ester of propionic acid.

When 1 g. of phenylacetylenepolysulfone was boiled with 1 g. of potassium permanganate in 20 cc. of water in a like manner, benzoic acid was obtained, m. p. 121.5°.

Hydrolysis of the Polysulfones.—Two grams of phenylacetylenepolysulfone was added to a solution of 2 g. of sodium hydroxide in 75 cc. of water, and the mixture was distilled. A very small amount of oily material came over with the water. The distillates from several such runs were combined, extracted with ether and the extract was concentrated and treated with 2,4-dinitrophenylhydrazine. The 2,4-dinitrophenylhydrazone, after crys-

tallization from alcohol, melted at 238°, and showed no depression of melting point when mixed with an authentic specimen of the 2,4-dinitrophenylhydrazone of acetophenone.[5]

In another experiment, 4 g. of phenylacetylenepolysulfone was hydrolyzed by boiling with 60 cc. of 3% sodium hydroxide solution for thirty minutes. The volatile material was distilled with steam and the alkaline residue was extracted with ether. From this extract a solid was obtained. After recrystallization from benzene it melted at 124°, and showed no depression of melting point when mixed with an authentic specimen of benzylmethylsulfone (m. p. 124.5°).[6]

Anal. Calcd. for $C_8H_{10}SO_2$: C, 56.47; H, 5.88. Found: C, 56.38; H, 5.75.

The yield of benzylmethylsulfone was 0.28 g. (8%).

In another similar alkaline hydrolysis 2 g. of phenylacetylenepolysulfone was refluxed two hours with 50 cc. of 10% sodium hydroxide. The hydrolysate was extracted with ether to remove neutral compounds. Hydrogen peroxide was added to oxidize the sulfite, the solution was acidified with hydrochloric acid and the benzoic acid was extracted with ether. The ether was evaporated and the benzoic acid was extracted from the tarry residue with hot water and determined by titrating with 0.1 *N* sodium hydroxide. Twenty-five cubic centimers of base was used. This is equivalent to 2.5 millimoles (0.305 g.), or, roughly, 20% of the theoretical amount of benzoic acid

The amount of sulfite which had been produced in the hydrolysis was determined by oxidation with hydrogen peroxide and precipitation as the sulfate. The barium sulfate weighed 1.253 g. (5.37 millimoles). This accounts for 45% of the sulfur in the polymer.

In another experiment, analyses were run on the dried residue (after extraction with ether). This showed that 25% of the sulfur was removed by extraction with ether. An aliquot part of the dried residue was extracted with alcohol. This process removed 25% of the total sulfur, leaving a residue containing 50% of the total sulfur as sodium sulfite.

Five grams of 1-pentynepolysulfone was mixed with 100 cc. of 10% sodium hydroxide solution, and the mixture was slowly distilled. The distillate was treated with an alcohol solution of 2,4-dinitrophenylhydrazine and a small amount of the 2,4-dinitrophenylhydrazone of methyl *n*-propyl ketone, m. p. 135–137°, was obtained. This material was mixed with an authentic specimen of the methyl *n*-propyl ketone derivative (m. p. 141°),[5] and the mixture melted at 138–139°. No definite products except sodium sulfite could be identified in the alkaline residue. By making the mixture acid with phosphoric acid, and distilling the sulfur dioxide into standard alkali, it was found that between 40 and 50% of the original sulfur in the 1-pentynepolysulfone was removed as sulfite.

Pyrolysis of the Polysulfones.—A 0.2372-g. sample of 1-pentynepolysulfone was placed in a test-tube fitted with a gas delivery tube dipping into standard alkali. The test-tube was then heated to 200° until frothing in the tube ceased (thirty minutes) and the tube was swept out with air. Titration of the standard alkali showed that 50% of the sulfur of the polymer was liberated as sulfur dioxide. When the polymer was heated at 200° for one hour, 51% of the sulfur dioxide was liberated. When the polymer was heated at 205–215° for one hour, roughly 60% of the sulfur dioxide was eliminated, showing that further decomposition takes place at higher temperatures.

With phenylacetylenepolysulfone, pyrolysis at 140° for forty-five minutes liberated from 62 to 73% of the sulfur dioxide. There seemed to be no really definite stopping place in the decomposition of this derivative.

By dissolving 1-pentynepolysulfone in dioxane and heating the solution to boiling, sulfur dioxide was liberated slowly, and the amount lost approached 50% as a limiting value. 1-Heptynepolysulfone showed a similar behavior. This is shown best by the accompanying curve (Fig. 1).

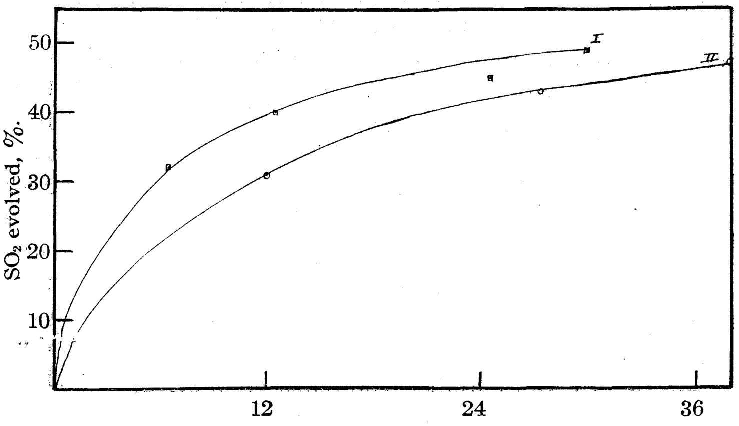

Fig. 1.—I, Pyrolyis of 1-heptynepolysulfone in dioxane; II, pyrolysis of 1-pentynepolysulfone in dioxane.

When 100 g. of 1-pentynepolysulfone was heated in 50 cc. of dioxane until approximately 50% of the sulfur dioxide was evolved and the solution evaporated and poured into ether, a small amount of the original polymer was obtained. In addition, a small amount (0.05 g.) of a crystalline compound, m. p. 88°, was obtained. This product did not add bromine, but did decolorize aqueous potassium permanganate solution.

Anal. Calcd. for $C_{10}H_{16}SO_2$: C, 60.00; H, 8.00; S, 16.00; mol. wt., 200. Found: C, 59.43; H, 7.97; S, 14.73; mol. wt. (Rast), 203.

The structure of this compound has not been determined, but its behavior toward bromine and potassium permanganate solution, together with the analysis and molecular weight, suggest that it may be a dipropylthiophenesulfone.

The polysulfones from 1-heptyne, 1-hexyne and phenylacetylene gave no product of this type.

Summary

1. A number of alkylacetylenes and phenylacetylene have been shown to combine with sul-

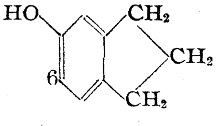
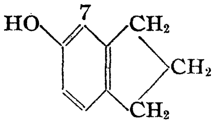
An Investigation of the Mills–Nixon Effect

BY LOUIS F. FIESER AND WARREN C. LOTHROP

In an important and much-discussed[1] paper, Mills and Nixon[2] advanced the hypothesis that hydrindene, or a given substituted hydrindene, is in a condition of less strain when it has the bond structure shown in formula I than when it exists in the alternate Kekulé form (II) in which the carbon atoms common to the two rings are connected by a double bond. As a means of testing the conclusion that I should be the more stable form of 5-hydroxyhydrindene, or the predominant isomer in the tautomeric equilibrium mixture, these investigators studied the diazo coupling of the substance and its behavior on bromination. Since these are reactions characteristic of enolic systems, substitution should occur at the ortho position joined to the hydroxylated carbon atom by a double linkage, that is, position 6 of I and position 7 of II. It was found that, although substitution does not proceed entirely in a single direction, about 90% of the reaction product is the 6-substituted isomer, indicating that I is the more stable form.

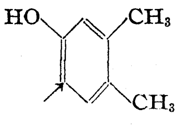


I

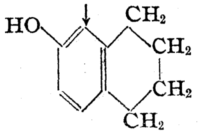


II

The observation loses some of its significance because of the fact, noted by Mills and Nixon, that *as-o*-xylenol (II) also is attacked chiefly in the 6-position (arrow), showing that in 5-hydroxyhydrindene the chemical effect of the alicyclic ring may be sufficient, without assistance from a steric factor, to control substitution largely into one of the two available ortho positions. The contrasting behavior of 6-hydroxytetralin (IV), which yields 5-substitution products, afforded the only evidence in the original work of the existence of the Mills–Nixon effect, that is, of a fixation of the bonds in one of the two Kekulé forms as the result of the stereochemical demands of an attached ring. The behavior of IV pointed to the bond structure indicated and, since the 5- and 6-membered rings must be quite similar chemically, the difference was attributed to the different spatial requirements of the two rings. From a theoretical analysis of the configuration of the tetralin molecule, Mills and Nixon concluded, albeit with less conviction than in the other case, that there should be a preference for the Kekulé structure IV.



III



IV

It seemed to us that the preferential formation of one of two possible isomers may be the result of only a moderate preponderance of one tautomeric form, or of even a very slight difference in reactivities, and that the Mills–Nixon effect may be at most a subtle one in comparison to the fixation of bonds resulting from the fusing together of two aromatic nuclei,[3] and we undertook to apply to hydrindene and to tetralin the much more severe test previously employed in investigating naphthalene,[3] anthracene,[4] and phenanthrene.[5] For this purpose phenolic derivatives in which one of the two ortho positions is blocked by an alkyl group were synthesized and tested for their ability to couple with diazotized amines. If the 5-hydroxyhydrindene derivatives V and VI exist in the stable state suggested by Mills and Nixon, coupling at the free ortho position should occur easily in the case of VI, but only following a migration of the double linkages in the case of V.

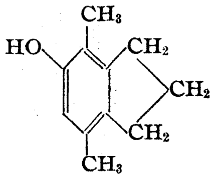
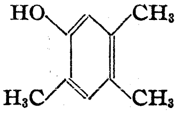
V



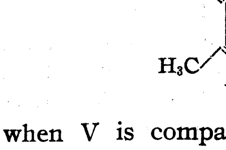
VI

Actually VI readily yielded azo derivatives whereas with V the coupling tests were entirely negative.[6] The observation is particularly striking when V is compared with pseudocumenol, VII, for the latter substance readily enters into the coupling reaction[7] and therefore is free to react in the Kekulé form shown in the formula. This evidence clearly indicates that the five-membered ring of hydrindene restricts the movement of the double linkages in the benzene nucleus exactly as supposed by Mills and Nixon and to an even greater extent than the results of these investigators would indicate.

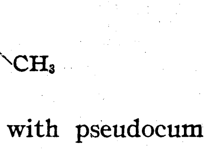


VII

In the tetralin series the situation is quite different. If the bond structure is that deduced by Mills and Nixon, and if the fixation imposed by the six-membered ring is comparable with that noted above, VIII should couple and IX should not. The first of these compounds is already known from the work of Vezelý and Štursa[8] to be capable of coupling with diazotized amines, and on examining IX we found that this substance behaves in a similar manner. Since with typical 6-hydroxytetralins both ortho positions are capable of functioning as enolic groups, it is concluded the double bonds of tetralin are at least fairly free to migrate and that if the Mills–Nixon effect is operative in this case the restriction is comparatively slight.



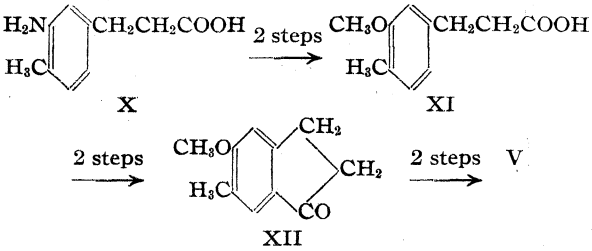
VIII



IX

Our conclusions with regard to both hydrindene and tetralin agree precisely with those recently reached by Sidgwick and Springall[9] from a study of the dipole moments of *o*-dibromo derivatives of the two hydrocarbons.

For the synthesis of 5-hydroxy-6-methylhydrindene (V), 3-amino-4-methylhydrocinnamic acid[10] (X) was prepared by known methods from 3-nitro-4-methylbenzaldehyde[11] and converted to the hydroxy compound and its ether XI.



This was cyclized through the acid chloride, and the hydrindone XII was reduced by the Clemmensen method and demethylated. That the ring closure takes the expected course is clearly indicated by the failure of V to couple with diazotized amines, for the alternate substance would have available a free para position and would surely react.

For the preparation of VI we at first investigated a synthesis from *p*-xylenol, through the aldehyde and acrylic acid derivatives, which Clemo, Haworth and Walton[12] carried as far as 6-methoxy-4,7-dimethylhydrindone-1, but as considerable difficulty was experienced in methylating the hydroxy aldehyde other methods were investigated. Since 4,7-dimethylhydrindone-1 is readily obtainable from *p*-xylene and β-chloropropionyl chloride,[13] this was reduced to 4,7-dimethylhydrindene and attempts were made to introduce a hydroxyl group through the monosulfonate or the mononitro compound. The sulfonate was obtained without difficulty, but the alkali fusion was wholly unsuccessful, and the nitration of the hydrocarbon under very moderate conditions afforded only a dinitro derivative. The hydrocarbon resembles prehnitene[14] in the latter respect. The following synthesis finally was developed. *p*-Xylyl methyl ether was condensed with β-chloropropionyl chloride in the presence of

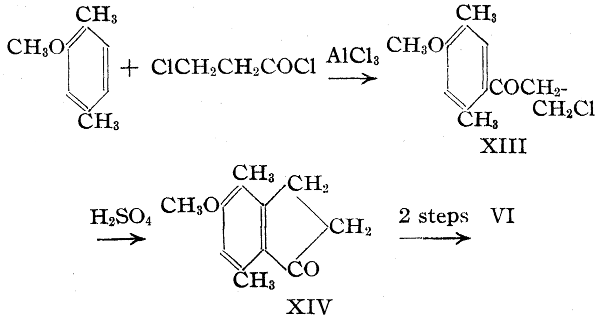
aluminum chloride, giving in good yield a crystalline chloro ketone. In analogy with other Friedel and Crafts reactions[12] and since the ring closure described below proves that the entering group is not ortho to the methoxyl group, the substance can be assigned the formula XIII. The cyclization of the chloro ketone with sulfuric acid proceeded poorly (27% yield), but gave a pure ketone, 5-methoxy-4,7-dimethylhydrindone-1 (XIV). It is interesting that this substance melts at the same temperature as the isomeric 6-methoxy compound of Clemo, Haworth and Walton,[12] for the melting points of the 5- and 6-methoxy derivatives of hydrindone-1 are within one degree of each other.[15]



The remaining compound, 6-hydroxy-5,8-dimethyltetralin (IX) was obtained from 7-methoxy-5,8-dimethyltetralone-1, synthesized according to Clemo, Haworth and Walton.[12]

Experimental Part

3-Amino-4-methylhydrocinnamic Acid.[10]—To prepare 3-nitro-4-methylbenzaldehyde[11] 120 g. of tolualdehyde was added in three to four hours to a well-stirred mixture of 600 cc. of concentrated sulfuric acid and 60 cc. of concentrated nitric acid, keeping the solution at 0-3°. After pouring the solution onto ice the pale yellow product was washed free of acid, dried in ether with calcium chloride, and vacuum distilled; yield 132 g. (80%), m. p. 43°. 3-Nitro-4-methylcinnamic acid was prepared from the aldehyde both by the Perkin reaction[11] (63% yield), and by condensation with malonic acid in the presence of pyridine and piperidine (70% yield), following the procedure given by Brand and Horn[16] for an analogous case.

The reduction of the nitro group and simultaneous saturation of the double bond was accomplished conveniently by the hydrogenation of the unsaturated acid (20.7 g.) dissolved in 95% alcohol (275 cc.) using Adams catalyst (0.2 g.). Some solid material which separated was dissolved by warming and the filtered solution was diluted with 1 liter of water and cooled well. The product separated in slightly pink crystal aggregates; yield 13.6 g. (76%), m. p. 140–141°.

3-Hydroxy-4-methylhydrocinnamic Acid.—A solution of 8.96 g. of the above amine and 2.65 g. of sodium carbonate in 100 cc. of water was cooled, treated with an aqueous solution of 3.7 g. of sodium nitrite, and poured into a mixture of 10 cc. of concentrated hydrochloric acid, 50 g. of ice and 4.7 g. of boric acid. The mixture was gradually warmed, with stirring, and finally boiled for a few minutes and clarified with Norite. After cooling, the hydroxy acid was obtained by extraction with ether as a crystalline mass, m. p. 154–156°. Recrystallization from a very small volume of water gave slightly buff colored flat needles, m. p. 156–157°; yield 5.5 g. (61%).

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.63; H, 6.72. Found: C, 66.58; H, 6.95.

3-Methoxy-4-methylhydrocinnamic acid was obtained by the action of dimethyl sulfate on the above acid in warm alkaline solution. The substance crystallized from 50% alcohol as fine, colorless needles, m. p. 82–83°.

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27. Found: C, 67.78; H, 7.35.

5-Methoxy-6-methylhydrindone-1.—The acid (9.25 g.) was warmed with thionyl chloride (4.6 cc.) and after the completion of the reaction and the removal of the excess reagent at the water pump the acid chloride was taken into 200 cc. of carbon bisulfide. Treatment with Norite gave a clear yellow solution, which was then cooled to 0° and treated with 14 g. of aluminum chloride. An oily complex separated, and after refluxing for four hours the mixture was cooled and treated with ice and hydrochloric acid. The residue remaining on removing the solvent by steam distillation was extracted with ether, which left much tarry material undissolved. On extracting the ethereal solution with sodium carbonate solution, 2.1 g. of starting material was recovered, while the residual ethereal solution yielded 2.7 g. of the hydrindone (42% conversion). The substance dissolves readily in petroleum ether and crystallizes from this solvent as lustrous, colorless needles, m. p. 114–115°.

Anal. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.87. Found: C, 75.24; H, 7.05.

An attempt to demethylate the hydrindone (2.7 g.) with 48% hydrobromic acid (3.5 cc.) and glacial acetic acid (30 cc.) led to the formation of a dimer. After boiling the solution for one hour a considerable quantity of orange-red needles had deposited and the mixture was cooled and filtered. From the mother liquor 1.7 g. of unchanged hydrindone was recovered. The orange-red needles (0.65 g., m. p. 215–217°, dec.) became yellow when boiled with dilute alkali, and this material on crystallization from acetic acid formed small yellow needles, m. p. 237–240°.

Anal. Calcd. for $C_{22}H_{24}O_4$: C, 74.97; H, 6.87; mol. wt., 396. Found: C, 75.47, 75.62; H, 6.85, 6.90; mol. wt. (Rast), 346.

5-Hydroxy-6-methylhydrindene.—A mixture of 1.7 g. of the hydrindone, 13.5 g. of amalgamated zinc, 34 cc. of concentrated hydrochloric acid, 10 cc. of water and 13 cc. of toluene was refluxed for eighteen hours. After steam distillation of the solvent the product was extracted with ether, but as the crude material (1.3 g.) appeared sensitive to oxidation and turned blue, it was demethylated without

further purification by refluxing under nitrogen with 25 cc. of glacial acetic acid, 1.8 cc. of 48% hydrobromic acid and 1 cc. of 45% hydriodic acid for three and one-half hours. After pouring the solution into 200 cc. of water and neutralizing the acids with sodium carbonate, the hydroxy compound separated as large, buff colored plates, m. p. 74–76°. Recrystallization from petroleum ether gave material melting at 83–84°, but the color was not entirely removed; yield 0.7 g. (49%). The compound has an odor reminiscent of that of β-naphthol.

Anal. Calcd. for $C_{10}H_{12}O$: C, 81.02; H, 8.17. Found: C, 80.84; H, 8.37.

Coupling tests in alkaline solution with diazotized sulfanilic acid were somewhat indecisive for there was considerable discoloration. With diazotized *p*-nitroaniline test solutions remained quite clear and were hardly distinguishable from alkaline solutions containing only the diazo component.

The benzoyl derivative crystallized from dilute alcohol as small, colorless plates, m. p. 111–112°.

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39. Found: C, 80.79; H, 6.74.

4,7 - Dimethylhydrindene.—4,7 - Dimethylhydrindone-1 (m. p. 77°) was prepared according to Mayer and Müller[13] in 71% yield. Reduction by the Clemmensen method and recovery of the product by steam distillation gave a product boiling at 223–225° at atmospheric pressure and solidifying in a freezing mixture, m. p. −1.5°, yield 73%. The substance did not form a picrate.

Anal. Calcd. for $C_{11}H_{14}$: C, 90.35; H, 9.65. Found: C, 90.00; H, 10.10.

Sodium 4,7 - Dimethylhydrindene - 5 - sulfonate.—A mixture of 6.5 g. of the hydrocarbon and 75 cc. of concentrated sulfuric acid was stirred mechanically for fifteen minutes on the steam-bath and the resulting solution was poured onto 500 cc. of ice. After neutralization with soda the solution was saturated at the boiling point with sodium chloride and on cooling the sulfonate separated as large white flakes. The yield after recrystallization was 8.7 g. (79%). For characterization and analysis the substance was converted into the *p*-toluidine salt, which formed long glistening needles from water, m. p. 248–249°, dec.

Anal. Calcd. for $C_{18}H_{23}O_3NS$: C, 64.83; H, 6.96. Found: C, 64.95; H, 7.16.

Attempted fusions of the sodium salt with potassium hydroxide gave either unchanged material or intractable tars.

5,6 - Dinitro - 4,7 - dimethylhydrindene.—To a mixture of 1.6 cc. of concentrated nitric acid and 17 cc. of concentrated sulfuric acid at 0°, 3 g. of 4,7-dimethylhydrindene was added with stirring in one-half hour. The pasty mixture was poured onto ice and the pale yellow solid obtained was crystallized twice from glacial acetic acid, giving 2.3 g. of buff colored plates, m. p. 191–192°.

Anal. Calcd. for $C_{11}H_{12}O_4N_2$: C, 55.91; H, 5.13. Found: C, 56.28; H, 5.20.

2-Methoxy-5-β-chloropropionyl-*p*-xylene (XIII).—Sodium *p*-xylene sulfonate, obtained in 85–95% yield after heating the hydrocarbon (20 g.) with concentrated sulfuric acid (100 cc.) for about fifteen minutes on the steam-bath, gave *p*-xylenol in 66% yield on fusion with potassium hydroxide at 280–290°, and the methyl ether was prepared in the usual way.[12] After several trials the following procedure was found most satisfactory for the Friedel and Crafts reaction.

To a vigorously stirred suspension of 37.2 g. of finely powdered aluminum chloride in 250 cc. of carbon bisulfide there was added over a half-hour period 35.6 g. of β-chloropropionyl chloride, a bright yellow complex separating as a solid. After cooling to 0°, 34 g. of *p*-xylyl methyl ether was added by drops with stirring in the course of forty-five minutes. On allowing the mixture to come to room temperature hydrogen chloride was evolved copiously and a dark purple complex collected as a heavy oil. After standing overnight ice and hydrochloric acid were added and the carbon bisulfide layer was separated and combined with ether extracts of the aqueous layer. After washing with dilute acid, dilute alkali and water, the solution was dried over sodium sulfate and the solvent removed by distillation. The residual yellow oil solidified on cooling and pure material was easily obtained by crystallization from petroleum ether; yield, 41.9 g. (74%). The ketone forms colorless, prismatic plates melting at 85–86°; it is volatile with steam but decomposes on attempted distillation at reduced pressure.

Anal. Calcd. for $C_{12}H_{15}O_2Cl$: C, 63.55; H, 6.66. Found: C, 63.38; H, 7.01.

A derivative, **1-phenyl-3-(2′,5′-dimethyl-3′-methoxyphenyl)-Δ²-pyrazoline,** was obtained by heating the chloro ketone (0.5 g.) in absolute alcohol (7 cc.) with phenylhydrazine (0.5 g.) on the steam-bath. The difficultly soluble product separated rapidly and was recrystallized from its faintly fluorescent solution in alcohol, giving nearly colorless small plates, m. p. 171–172°.

Anal. Calcd. for $C_{18}H_{20}ON_2$: C, 77.09; H, 7.21. Found: C, 76.69; H, 7.49.

5-Methoxy-4,7-dimethylhydrindone-1 (XIV).—In trial cyclizations of the above chloro ketone warm concentrated sulfuric acid either left the material largely unchanged or gave extensive sulfonation. Formic acid at 100° was without effect, and aluminum chloride in carbon bisulfide solution gave an alkali-soluble product. The following procedure, although far from satisfactory, was the best found. To a cold solution of 1.5 g. of the chloro ketone in 8 cc. of glacial acetic acid, 12 cc. of concentrated sulfuric acid was added and the clear red solution was warmed on the steam-bath for one hour and poured onto ice. The somewhat orange material which precipitated was collected and crystallized twice from glacial acetic acid, giving almost colorless needles, m. p. 163–165°; yield 0.35 g. (27%).

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.41. Found: C, 75.54; H, 7.25.

5-Methoxy-4,7-dimethylhydrindene.—A solution of 4 g. of the hydrindone in warm alcohol was added in small portions in one and one-half hours to a refluxing mixture of 42 g. of amalgamated zinc, 29 cc. of concentrated hydrochloric acid and 14 cc. of water, waiting after each addition until the yellow color had disappeared before adding a fresh portion. After adding 20 cc. more of the concentrated acid and refluxing for three hours, the reduction product was recovered by steam distillation as a colorless oil. Further purification was effected by steam distillation from an alkaline medium, and on cooling the distillate with ice the substance solidified to a mass of colorless needles, m. p. 25–26°; yield 3.25 g. (90%).

Anal. Calcd. for $C_{12}H_{16}O$: C, 81.79; H, 9.14. Found: C, 81.49; H, 9.32.

5-Hydroxy-4,7-dimethylhydrindene (VI).—The above ether (3.25 g.) was refluxed with 25 cc. of glacial acetic acid and 4 cc. of 48% hydrobromic acid for three hours in a nitrogen atmosphere, and on pouring the solution into water the hydroxy compound separated as a pink solid. It was taken up in dilute alkali, the solution was clarified with Norite and acidified, and the dried product was crystallized twice from petroleum ether; yield 2 g. (66%). The substance forms fine colorless needles melting at 111–112°.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.70. Found: C, 81.32; H, 8.76.

The benzoyl derivative forms colorless plates, m. p. 72–73°, from dilute alcohol.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.18; H, 6.80. Found: C, 80.82; H, 6.95.

5 - Hydroxy - 4,7 - dimethyl - 6 - *p* - nitrobenzeneazohydrindene was obtained by coupling the components in 1% alkali at 0°. A red precipitate separated at once and it was unaffected by rendering the solution acidic and boiling the mixture to coagulate the material. Recrystallized from glacial acetic acid, in which it is sparingly soluble, the azo compound formed brownish-red needles, m. p. 220–222°, dec. It is insoluble in alkali.

Anal. Calcd. for $C_{17}H_{17}O_3N_3$: C, 65.58; H, 5.50. Found: C, 65.72; H, 5.85.

6-Methoxy-5,8-dimethyltetralin.—On condensing *p*-xylyl methyl ether and succinic anhydride with aluminum chloride in benzene solution as described by Clemo, Haworth and Walton,[12] the yield was even lower than that (70%) reported by these investigators, but the general procedure described by Fieser and Hershberg[17] proved very satisfactory. Using 0.2 mole of the ether, 0.21 mole of succinic anhydride, 200 cc. of tetrachloroethane, 50 cc. of nitrobenzene and 0.42 mole of aluminum chloride, stirring at 0° until solution was complete, and allowing the mixture to stand for four days at 0°, β-4-methoxy-2,5-dimethylbenzoylpropionic acid, recovered as usual and crystallized from dilute alcohol, was obtained as colorless crystals, m. p. 130–131°, in 86% yield. The reduction to γ-4-methoxy-2,5-dimethylphenylbutyric acid (m. p. 98–99°) by the Clemmensen–Martin method has been described[18] already. Cyclization was effected according to Clemo, Haworth and Walton[12] in 64% yield.

7-Methoxy-5,8-dimethyltetralone-1 (6 g.) was reduced by the ordinary Clemmensen method, refluxing for twenty-one hours, and the material extracted with ether after distillation (b. p. 116–125° at 12–13 mm.) was obtained as a solid, m. p. 36–38°; yield 4.25 g. (76%). Crystallization from petroleum ether gave colorless needles melting at 38–39°.

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.52. Found: C, 82.36; H, 9.76.

6-Hydroxy-5,8-dimethyltetralin (IX).—For demethylation the ether (4.25 g.) was refluxed with glacial acetic acid (25 cc.) and 45% hydriodic acid (9.75 g.) for three hours. The crude product was precipitated from a clarified solution in dilute alkali and crystallized from petroleum ether, giving nearly colorless needles, m. p. 104–105°, yield 2.45 g. (62%). The substance dissolves in dilute alkali slowly on warming.

Anal. Calcd. for $C_{12}H_{16}O$: C, 81.79; H, 9.14. Found: C, 81.78; H, 9.48.

The benzoyl derivative forms very long, slender, colorless needles, m. p. 119–120°, from dilute alcohol.

Anal. Calcd. for $C_{19}H_{20}O_2$: C, 81.38; H, 7.18. Found: C, 81.44; H, 7.26.

6 - Hydroxy - 5,8 - dimethyl - 7 - *p* - nitrobenzeneazotetralin was obtained by coupling as described above and crystallized from glacial acetic acid, in which it is sparingly soluble. The substance forms bronze-red needles, m. p. 229–231°. It is insoluble in alkali and stable to acids.

Anal. Calcd. for $C_{18}H_{19}O_3N_3$: C, 66.42; H, 5.90. Found: C, 66.50; H, 6.11.

Summary

β-Hydroxy derivatives of hydrindene and of tetralin with one ortho position blocked with a methyl group and the other free have been tested in the coupling reaction to determine if both ortho positions are capable of constituting enolic groups, or if there is any fixation of the bonds in the aromatic nucleus as the result of the spatial requirements of the attached alicyclic rings (Mills–Nixon effect). This test affords a more severe criterion of fixation than that of Mills and Nixon, based upon reactivities, and the results indicate that hydrindene has a rigid bond structure comparable with that of naphthalene, but that tetralin, like all ordinary benzene derivatives, can react in both Kekulé forms.

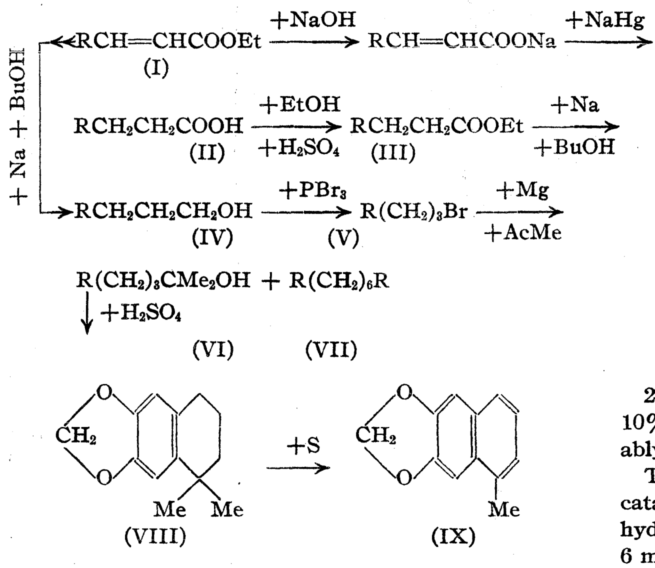
The Synthesis of 1,1-Dimethyl-6,7-methylenedioxytetralin[1]

BY RUBY MURRAY ORCUTT AND MARSTON TAYLOR BOGERT

In continuation of our investigations in the ionene field,[2] and in the cyclodehydration of aromatic alcohols,[3] we have had occasion to synthesize a methylenedioxytetralin by the following steps, in which formulas R = 



Experimental

Ethyl Piperonylacetate (III).—Ethyl piperonylideneacetate (I), prepared from piperonal and ethyl acetate, according to Hoering's directions,[4] was saponified by boiling with the calculated amount of 0.1 *N* sodium hydroxide. The solution was cooled quickly, to prevent the crystallization of the sodium salt, and a 10% excess of sodium amalgam was added slowly. When the reduction was complete, the mixture was filtered, the filtrate cooled with ice and acidified with hydrochloric acid. The precipitated piperonylacetic acid was washed, dried, and crystallized from ether, giving a colorless crystalline product, m. p. 87–90°, which did not decolorize a cooled 10% carbon tetrachloride solution of bromine; yield 75–80%.

Lorenz,[5] who prepared this acid by a similar method, differing only in certain details, gave its m. p. as 84°. Kaufmann and Radosević,[6] who obtained it by hydrolysis of its methylamide, also recorded the m. p. as 84°.

Warmed with absolute ethanol and a little sulfuric acid, the acid yielded the ethyl ester as a colorless transparent liquid, of pleasant odor, b. p. 184–185° at 14 mm., which did not decolorize a cooled 10% carbon tetrachloride solution of bromine; yield 83%.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.84; H, 6.35. Found: C, 64.94; H, 6.64.

2-Piperonylethanol (IV), prepared from the foregoing ester by reduction with sodium and *n*-butyl alcohol, formed a colorless viscous liquid, b. p. 170–172° at 8 mm., 182–183.5° at 14 mm., 184–186° at 16 mm., and 186–188° at 19 mm.; yield 87%. Cooled to −10°, it slowly congealed to a crystalline mass. When the temperature of this solid was permitted to rise slowly, it began to melt at 28° and was completely liquefied at 29°. The m. p. of 2-piperonylidene ethanol is given in the literature[7] as 78–78.8° (corr.). Hence the product cannot be the unsaturated alcohol.

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.63; H, 6.72. Found: C, 66.30; H, 6.75.

2-Piperonylethanol immediately decolorized a cooled 10% carbon tetrachloride solution of bromine, presumably being promptly oxidized thereby.

This saturated alcohol has been reported[8] as one of the catalytic reduction products of piperonylidene acetaldehyde, although the b. p. recorded (149–150°, uncorr., at 6 mm.) was lower than that given above.

Phenylurethan, m. p. 98–99°.

Anal. Calcd. for $C_{17}H_{17}O_4N$: C, 68.20; H, 5.72. Found: C, 67.97; H, 5.83.

A more direct and shorter road to the same goal (IV), was the reduction of the ethyl piperonylideneacetate (I) by sodium and *n*-butyl alcohol, as follows:

A 3-necked 2-liter flask, equipped with mercury-sealed stirrer, a reflux condenser, and a dropping funnel, protected with calcium chloride guard tubes, and containing 37.8 g. of sodium and 100 cc. of dry toluene, was heated above the m. p. of the sodium and then allowed to cool during vigorous stirring, so as to obtain the sodium in a finely divided state. To this mixture, there was added, as rapidly as possible, a solution of 36.2 g. of the ester (I) in 100 cc. of *n*-butyl alcohol. There ensued a vigorous reaction, with much foaming. When this subsided, more (150 cc.) *n*-butyl alcohol was added, to dilute the mixture, to aid in keeping the alcoholate in solution, and to react with any unattacked sodium.

The mixture was hydrolyzed by addition of water, the oily layer separated from the aqueous alkaline one, the latter extracted twice with *n*-butyl alcohol and the extracts added to the oily layer. This was distilled at ordinary pressure, to remove the toluene and butyl alcohol, and then under reduced pressure, to isolate the

piperonylethanol (IV); b. p. 184–186° at 16 mm.; yield 62%.

From the aqueous alkaline layer there was obtained a small amount of piperonylideneacetic acid, $(CH_2O_2)C_6H_3CH{=}CHCOOH$, m. p. 237–238° (from acetic acid), agreeing with that in the literature.

Repeating the above experiment, with amyl in place of butyl alcohol, the results were much the same, except that the initial reaction was more vigorous, the yield somewhat lower (60%), and the by-product piperonylacetic acid, $(CH_2O_2)C_6H_3CH_2CH_2COOH$ (large, colorless crystals, m. p. 84°; m. p. in literature,[6] 84°).

In another series of experiments, replacing the toluene by xylene, the results were less satisfactory. The same alcohol (IV) was obtained and, as by-products, there were recovered both piperonylidene and piperonylacetic acids, in the ratio of 3:1. The former was reduced to the latter, in 80% yield, by sodium amalgam.[5]

1-Bromo-2-piperonylethane (V) could not be secured from the alcohol (IV) by the action of 48% aqueous hydrogen bromide, alone or with the addition of sulfuric acid, because of the decomposition which almost immediately ensued. It was obtained, however, by the following process.

The alcohol (28 g.), contained in a flask well protected from access of any moisture, was congealed in a freezing mixture and phosphorus tribromide (10 g.) added. After a few minutes' standing, the container was removed from the freezing mixture and allowed to come slowly to room temperature. The reaction began gradually, with evolution of hydrogen bromide, and accelerated considerably as the temperature approached that of the m. p. (28–29°) of the alcohol, so that some cooling occasionally was necessary at this point. The crude yellowish-brown product was poured into a mixture of dilute sodium bicarbonate solution and cracked ice, and the bromide (V) extracted with ether. The aqueous layer, containing some of the original alcohol as sodium alcoholate, was acidified and the alcohol recovered. The bromide obtained from the ether extracts, when freshly distilled and pure, was a colorless liquid, b. p. 163–165° at 7.5 mm., $n^{25}D$ 1.5599, but darkened rapidly on exposure to air and light; yield, 50–53%; original alcohol recovered, 20–25%.

Anal. Calcd. for $C_{10}H_{11}O_2Br$: C, 49.38; H, 4.56. Found: C, 49.41; H, 4.87.

1,4-Dipiperonylbutane (VII).—The Grignard reagent was prepared by mixing 48.8 g. of the above bromide, 8 g. of magnesium, and 50 cc. of dry ether, and adding 100 cc. more of dry ether when the reaction was well started. A final warming for an hour completed the reaction. After cooling the mixture to −5°, 14 g. of acetone in an equal volume of dry ether was slowly stirred in, and the stirring continued for a further half hour. It was then poured upon ice acidulated with the calculated quantity of sulfuric acid, extracted with ether, the ether extract dried over anhydrous potassium carbonate and the ether evaporated. As the residue cooled, crystals began to separate, and this separation was greatly hastened by the addition of some 95% ethanol. These crystals were colorless and their m. p. remained constant at 77–78.5° after six crystallizations from alcohol; b. p. about 240° at 3 mm.; yield, about 28%. Their analysis, however, indicated retention of some of the solvent alcohol. They were therefore fused for an hour at 120° and a pressure of 7.2 mm. (m. p. then 78°), and analyzed again.

Anal. Calcd. for $C_{20}H_{22}O_4$: C, 73.58; H, 6.79. Found: C, 73.79; H, 6.65.

2-Methyl-4-piperonylbutanol-2 (VI).—The mother liquors from the crystallization of the dipiperonylbutane (VII) were freed of solvent and distilled at 2 mm. pressure. Two fractions were thus obtained. One boiled at 65–75° and had a safrole odor. The other, b. p. 150–160°, consisted of the nearly pure tertiary alcohol (VI); yield 32%. Purified by two rectifications, it boiled at 145–148° at 2 mm. pressure.

Anal. Calcd. for $C_{13}H_{18}O_3$: C, 70.23; H, 8.17. Found: C, 70.07; H, 8.50.

This alcohol was a very viscous pale yellowish liquid, which congealed to a glass, but did not crystallize, when cooled to −17°. No phenylurethan could be obtained from it, because phenyl isocyanate immediately withdrew the elements of water, with formation of carbanilide.

Attempts to isolate the olefin formed by this dehydration were not very successful, because the repeated rectifications to which it was subjected rearranged it to the tetralin, a change which takes place very easily, as shown by tests with potassium permanganate in acetone solution.

From the residue of the above distillation, more of the dipiperonylbutane was recovered.

1,1-Dimethyl-6,7-methylenedioxytetralin (VIII).—Into 5 g. of vigorously stirred 85% sulfuric acid, there was dropped slowly 4 g. of the above alcohol (VI), maintaining the temperature at 10° or below. After all the alcohol had been added, the stirring was continued for thirty minutes. The mixture was poured upon ice, extracted with ether, to free it from insoluble tarry contaminants, the ether extract washed with dilute sodium bicarbonate solution, dried over anhydrous sodium sulfate, the ether removed, and the residual liquid distilled twice over sodium. The tetralin was thus obtained as a colorless transparent liquid, of camphoraceous odor, b. p. 148–149° at 10 mm.; yield 70%.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.43; H, 7.89. Found: C, 76.38; H, 7.76.

1-Methyl-6,7-methylenedioxynaphthalene (IX).—Fusion of the tetralin (VIII) with sulfur gave such small yields of the expected naphthalene derivative (IX) that it could be satisfactorily characterized only by its *picrate*, which melted at 134–136°.

Anal. Calcd. for $C_{18}H_{13}O_9N_3$: N, 10.12. Found: N, 9.91.

Summary

Starting with ethyl piperonylideneacetate, the 1,1-dimethyl-6,7-methylenedioxytetralin has been synthesized by a series of steps analogous to those used by Bogert, Davidson and Apfelbaum[2c] for the preparation of ionene.

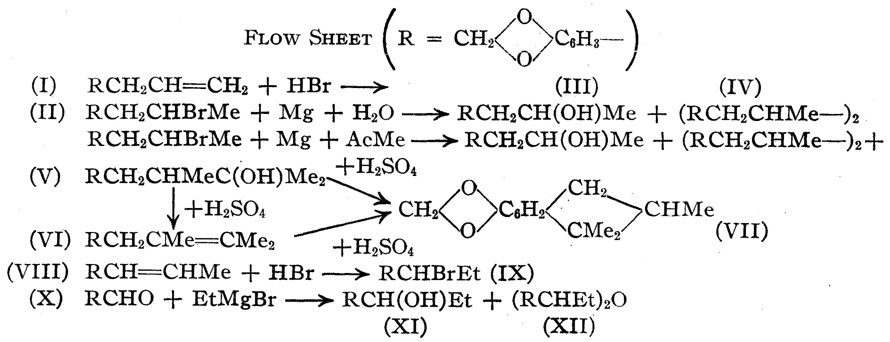
The Synthesis of 1,1,2-Trimethyl-5,6-methylenedioxyindane from Safrole

BY RUBY MURRAY ORCUTT AND MARSTON TAYLOR BOGERT

Supplementing our previous work in the indane group,[1] some experiments have been carried out with safrole (I) and isosafrole (VIII), which have led to a simple synthesis of 1,1,2-trimethyl-5,6-methylenedioxyindane by the following steps.



Many of these compounds contain asymmetric carbon atoms and should therefore exist in optical isomers, but these stereochemical problems have not been attacked as yet.

Experimental

1-Piperonyl-1-bromoethane (II).—When a current of dry hydrogen bromide was led into carefully dried safrole, cooled to −5°, in a flask protected from access of moisture, there was a slow gain in weight up to 25% of that calculated for the addition of an equimolar quantity of hydrogen bromide. No further increase in weight occurred although the gas was passed in for several hours longer.

On working up the crude product, the yield of pure bromide (II), b. p. 145° at 9 mm., was 22%.

In another set of experiments, the safrole (25 g.) cooled to 0°, was mixed with an aqueous solution of hydrobromic acid (100 g.), saturated at 0° (or about 69% hydrogen bromide), and the mixture kept in a closed bottle at low temperature, with occasional shaking, for two or three days. The crude product was diluted with an ice-cold salt solution, the heavy bromide removed by extraction with ether, washed several times with the cold salt solution, dried over anhydrous potassium carbonate, the ether distilled off and the remainder fractionated under diminished pressure; b. p. 154–157° at 13 mm., 145° at 9 mm.; n^{25}_D 1.5614; yield 75%.

Anal. Calcd. for $C_{10}H_{11}O_2Br$: Br, 32.88. Found: Br, 32.82.

This process gave a very satisfactory product, with the by-products in the form of a decomposed residue easily eliminated. This secondary bromide was much more stable than the isomeric primary bromide, 2-piperonyl-1-bromoethane, described in a recent paper.[2]

In 1914, E. Merck took out a patent[3] for the manufacture of aromatic amines, in which this bromide, from safrole and aqueous hydrobromic acid, was an intermediate product, but was separated only in a crude state as a slightly colored heavy unstable oil, which decomposed when distilled *in vacuo* and was not analyzed.

1-Piperonylethanol-1 (III).—The bromide (II) was converted into the Grignard compound in the customary way, after activating the magnesium by a small crystal of iodine. The reaction, after starting rather slowly, proceeded satisfactorily, and the initial cloudiness disappeared as the reaction advanced. Due apparently to its sensitivity to oxygen, this Grignard compound tended to pass into the secondary alcohol (III) with surprising ease, even in a closed system from which all moisture had been carefully excluded, and this introduced complications in using it for the synthesis of other compounds as explained in the next section. No such difficulty was encountered[2] in the preparation of the isomeric $RCH_2CH_2CH_2MgBr$. At the close of the reaction, the mixture was warmed for thirty minutes, then cooled to 0°, stirred for two hours, hydrolyzed by acidulated ice water and worked up as usual. The crude product (8.5 g.) was distilled under reduced pressure, and yielded 4 g. of the alcohol (III) sought, b. p. 127–129° at 3 mm., 2.5 g. of a by-product of safrole-like odor and 0.5 g. of the butane derivative (IV).

In contradistinction to its primary isomer, 2-piperonylethanol-1, this alcohol showed no tendency whatever to crystallize.

Phenylurethan.—Colorless needles (from alcohol), m. p. 93–94° (uncorr.).

Anal. Calcd. for $C_{17}H_{17}O_4N$: C, 68.20; H, 5.72. Found: C, 67.87; H, 5.75.

2-Methyl-3-piperonylbutanol-2 (V) was prepared by the Grignard reaction from the bromide (II) and acetone. Due to the sensitivity of the $RCH_2CH(MgBr)Me$, mentioned above, the preparation proved more troublesome than expected.

When the experiments were conducted in the air, there were obtained from 46 g. of the bromide (II), 16 g. of safrole, 10.4 g. of the secondary alcohol (III), 3 g. of the tertiary alcohol (V), and 1 g. of the 2,3-dipiperonylbutane (IV). The figures for the two alcohols are only approxi-

mate, because of the difficulty of separating these alcohols quantitatively.

The secondary alcohol (III) isolated, b. p. 127–129° at 3 mm., was analyzed with the following results.

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.63; H, 6.72. Found: C, 66.09; H, 6.69.

Its phenylurethan crystallized from alcohol in colorless needles, m. p. 93–94°. Mixed with the phenylurethan described in the foregoing section, the m. p. was unchanged.

Anal. Calcd. for $C_{17}H_{17}O_4N$: C, 68.20; H, 5.72. Found: C, 68.10; H, 5.77.

The tertiary alcohol (V), on account of the relatively small amount present, could not be isolated in satisfactory purity.

But when the experiments were carried out in an atmosphere of nitrogen, the same amount (46 g.) of initial bromide (II) gave 17 g. of safrole, none of the secondary alcohol (III), 11 g. of the tertiary alcohol (V), and 1.5 g. of the butane derivative (IV). From this mixture, the *tertiary alcohol* was easily isolated by fractional distillation as a colorless, very viscous liquid, b. p. 142–144° at 3 mm., which congealed in thick colorless needles, m. p. 49°, with some softening as low as 43°. The isomeric 2-methyl-4-piperonylbutanol-2 differs from it in persistently remaining liquid and refusing to crystallize.

Anal. Calcd. for $C_{13}H_{18}O_3$: C, 70.23; H, 8.17. Found: C, 69.86; H, 8.37.

It did not form a phenylurethan. Phenyl isocyanate abstracted water from it, with separation of carbanilide.

2,3-Dipiperonylbutane (IV).—In the residues from the distillation of the crude products obtained in the preparation of both the secondary (III) and tertiary (V) alcohols, this by-product was found. It was purified by repeated crystallization, first from methyl and finally from ethyl alcohol, and then formed thick colorless needles or plates, m. p. 74°.

Anal. Calcd. for $C_{20}H_{22}O_4$: C, 73.58; H, 6.79. Found: C, 73.26; H, 6.53.

1,1,2-Trimethyl-5,6-methylenedioxyindane (VII).—To 20 g. of well-cooled (7°) 85% sulfuric acid, there was stirred in gradually 7 g. of the tertiary alcohol (V). The resultant reddish mixture was diluted with ice water, extracted with ether, the ether extracts dried over fused potassium carbonate, the ether removed and the residue fractionated thrice over sodium. The indane so obtained was a colorless oil, b. p. 137° at 11 mm., of penetrating camphoraceous odor; yield about 65%. It did not decolorize an acetone solution of potassium permanganate.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.43; H, 7.89. Found: C, 76.15; H, 8.20.

Fused with selenium for six hours at 266–270°, a strong odor of methyl mercaptan was noted, and from the tarry product there was isolated a small quantity of a clear yellow liquid, b. p. about 140° at 7 mm., which darkened rapidly and on re-distillation exhaled an odor resembling that of the original indane. It was not obtained in sufficient amount or purity for analysis or identification, nor could a picrate be prepared from it. These results are in accordance with our previous experience with indanes.[1b]

2-Methyl-3-piperonylbutene-2 (VI).—Occasionally this olefin was isolated from the crude product of the above indane synthesis, by fractional distillation of a cyclization product which was unsaturated to an acetone solution of potassium permanganate. It formed an oil, b. p. 120° at 7 mm., colorless when freshly distilled, which rapidly turned yellow, even in a tightly sealed bottle, possessed a citrous or alliaceous type of odor, quickly decolorized an acetone solution of potassium permanganate, and did not form a picrate. For analysis, it was freshly distilled.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.43; H, 7.89. Found: C, 76.21; H, 8.06.

Subjected to the further action of sulfuric acid, it was rearranged to the isomeric indane (VII).

***alpha*-Ethylpiperonyl Bromide (IX).**—This bromide appeared to be formed in good yield by the action of aqueous hydrobromic acid (69%) upon isosafrole at 0°, as described for the preparation of its isomer (II) from safrole, but it was so unstable that it decomposed when distilled at a pressure of 2 mm.

The Merck patent,[3] already mentioned, refers also to the preparation of this bromide, in an impure state, from isosafrole and hydrobromic acid, and describes it as a slightly colored heavy unstable oil, which decomposed when distilled *in vacuo*, and was not analyzed.

This patent also claims the formation of the corresponding amine when the crude bromide is treated with ammonia. When we treated our product with alcoholic ammonia, even at low temperature, a vigorous reaction ensued, with immediate separation of ammonium bromide in an amount which indicated the presence of approximately 50% of the desired bromide (IX) in the original crude.

***alpha*-Ethylpiperonyl alcohol (XI)** was prepared from piperonal (X) and ethylmagnesium bromide, as recorded by Mameli.[4] Inasmuch as the compound obtained by us (yield 50%) showed a b. p. of 126–127° at 3 mm., whereas that reported by him was 172–175° at atmospheric pressure, our product was analyzed.

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.63; H, 6.72. Found: C, 66.77; H, 6.42.

No phenylurethan could be secured from this alcohol, because the phenyl isocyanate immediately withdrew from it the elements of water. In this respect it differed strikingly from the isomeric 1-piperonylethanol-1 (III). Nor could we prepare a benzoate from it, or convert it into the corresponding bromide by the action of phosphorus tribromide.

The pure alcohol, after standing for three months at laboratory temperature, turned cloudy and began to crystallize. Dried in an evacuated desiccator and analyzed, it proved to be the ether (XII); yield, equal to that calculated. Apparently this alcohol tends to split out a molecule of water on standing even at ordinary temperature. When warmed or distilled under reduced pressure, however, it loses water quite easily with formation of isosafrole, as found also by Mameli.[4]

Di-*alpha*-ethylpiperonyl Ether (XII).—The distillation residues from the preparation of the foregoing alcohol (XI), when crystallized from methyl alcohol, gave a 5% yield of this ether in colorless leaflets, m. p. 85°.

---

(4) Mameli, *Rend. Accad. Lincei*, [5] 13, II, 315 (1904).

Anal. Calcd. for $C_{20}H_{22}O_5$: C, 70.14; H, 6.48; mol. wt. (Rast), 342.2. Found: C, 70.04, 69.85; H, 6.21, 6.42; mol. wt. (Rast), 336.3.

Mameli,[5] who was the first to describe this ether, found that it was formed when an ether solution of the alcohol was left for many weeks in contact with traces of inorganic salts, and gave its m. p. as 88°.

Summary

1. By the addition of hydrobromic acid to safrole, 1-piperonyl-1-bromoethane has been prepared and from this the corresponding alcohol.

2. The Grignard reaction applied to the bromide, in the presence of acetone, yielded a mixture of 1-piperonylethanol-1, 2-methyl-3-piperonylbutanol-2 and 2,3-dipiperonylbutane.

3. This butanol has been converted by the action of sulfuric acid into the corresponding butene and 1,1,2-trimethyl-5,6-methylenedioxyindane.

4. From isosafrole and hydrobromic acid, *alpha*-ethylpiperonyl bromide has been obtained. The corresponding alcohol, from piperonal and ethylmagnesium bromide, has been shown to lose water on standing, with formation of the ether.

Some N-Aryl Barbituric Acids. II

BY JOHANNES S. BUCK

The present work is a continuation of that described in an earlier paper.[1] Two further series of 1-aryl-5,5-dialkyl barbituric acids have been prepared, the aryl groups being, as before, phenyl, *o*-, *m*- and *p*-tolyl, *o*-, *m*- and *p*-anisyl, *o*-, *m*- and *p*-phenetyl, and α- and β-naphthyl, while the alkyl groups are now 5,5-ethyl-isobutyl and 5,5-ethyl-isoamyl. The alkyl groups were selected to allow comparison, pharmacologically, with a series of isoalkylaryl ureas at present under examination.

Since the sodium salts of the N-aryl barbituric acids show a tendency to hydrolyze in aqueous solution, a number of barbituric acids having a dialkylamino group on the phenyl ring was prepared. These compounds are soluble both in alkaline and in acid solution. The presence of the dialkylamino group should also facilitate the resolution of those barbituric acids which carry, in addition to this group, an asymmetric carbon atom.

The two phenyl compounds have been previously described by Hjort and Dox;[2] the others are new. The pharmacological data will be given later in another place.

Experimental

Ethyl isobutylethylmalonate[3] and ethyl isoamylethylmalonate[3] were prepared by the action of the isoalkyl iodide on ethyl ethylmalonate, in the presence of sodium ethylate. It was found advantageous to carry out the reaction as rapidly as possible and to shake the crude ester several times with 5% sodium hydroxide solution.[4] After fractionation under reduced pressure the isobutyl compound boiled at 128.5–130° (15 mm.) (yield 71%) and the isoamyl compound at 126–127° (7.5 mm.) (yield 64%).

The condensation of the ester with the aryl urea and the subsequent purification were carried out substantially as previously described.[1] The procedure was modified in the case of the dialkylamino compounds, the cold reaction mixture being diluted, extracted with ether when possible, and saturated with carbon dioxide to precipitate the product, which was purified by recrystallization from aqueous alcohol, and usually also from ethyl acetate–hexane. No particular trouble was encountered except with 1-*m*-phenetyl-5,5-ethyl-isoamyl barbituric acid which was very difficult to obtain crystalline.

The barbituric acids are tabulated below. They are all white, crystalline, tasteless compounds, soluble in cold 5% sodium hydroxide solution, practically insoluble in water, slightly soluble to insoluble in petroleum ether, soluble in ether, soluble in alcohol, moderately to readily soluble in benzene, and readily soluble in ethyl acetate. In addition, the dialkylamino compounds dissolve readily in 5% hydrochloric acid. The solvents used for purification are given in the order used. Three or more crystallizations were generally necessary. In the tables the appearance described is that of the bulk specimen, crystallized from the last solvent given. The appearance varies greatly with solvent, etc.

The ureas are the same as those previously used.[1] Dimethylaminophenyl urea and diethylaminophenyl urea were prepared by the action of potassium cyanate on the amine hydrochloride in aqueous solution.

Summary

1. To complete previous work, a series of 1-aryl-5,5-ethyl-isobutyl barbituric acids and a series of 1-aryl-5,5-ethyl-isoamyl barbituric acids have been prepared, the N-aryl groups in both series being phenyl, *o*-, *m*- and *p*-tolyl, *o*-, *m*- and *p*-anisyl, *o*-, *m*- and *p*-phenetyl and α- and β-naphthyl.

2. A series of acid-soluble barbituric acids was prepared in which the N-aryl groups were *p*-dimethylaminophenyl and *p*-diethylaminophenyl. The 5,5-dialkyl groups were diethyl, ethyl-*n*-butyl, ethyl-isobutyl and ethyl-isoamyl.

Oxalato Complex Compounds of Tervalent Manganese

BY G. H. CARTLEDGE AND W. P. ERICKS

Complex compounds containing manganese in the tervalent or quadrivalent state have been prepared in a few instances, but there has never been a thoroughgoing study of the field, such as has been made in the compounds of chromium and cobalt. From a consideration of the structure of the manganese atom there is every reason to expect it to form complexes readily, since the manganic ion has the combination of available *d*, *s* and *p* eigenfunctions which is required for the formation of covalent bonds, according to the theory of Pauling.[1] That so few of such possible compounds have been prepared is readily ascribed to the complicated oxidation–reduction relations of manganese. The simple manganic ion is like the cobaltic ion in its large oxidation potential, but is even more difficult to manipulate because of the readiness with which it dismutates into the manganous ion and manganese dioxide.

The oxalato complexes are of particular interest in connection with the kinetics of the reaction between potassium permanganate and oxalates.[2] Potassium trioxalatomanganiate, $K_3[Mn(C_2O_4)_3]\cdot 3H_2O$, seems to have been prepared first by Souchay and Lenson.[3] Kehrmann[4] rediscovered the compound and isolated it in crystalline form. Meyer and Schramm[5] in 1922 attempted to prepare dioxalatodiaquomanganiates, but without success. Instead, they were able to obtain the corresponding dimalonatodiaquamanganiate, which is a fairly stable compound and readily prepared. In 1926 the same authors[6] reported that by treating cold sodium tetroxalate (in excess) with manganese dioxide they obtained an impure green material. This product was very unstable, turned yellowish-brown, and decomposed before it could be isolated for analysis. Meyer and Schramm concluded from analogy with the green sodium dimalonatodiaquomanganiate that the unstable product was the corresponding oxalato complex.

We have been able to prepare a number of pure compounds containing the trioxalatomanganiate and dioxalatodiaquomanganiate ions, as well as a difluodioxalato compound and, unexpectedly, a dioxalatodihydroxo complex of quadrivalent manganese. The oxalatomanganiates have turned out to be extremely interesting in that in aqueous solution they are easily converted one into the other, according to the reversible reaction

$$[Mn(C_2O_4)_3]^{\equiv} + 2H_2O \rightleftarrows [Mn(C_2O_4)_2(H_2O)_2]^- + C_2O_4^=$$

Using a spectrophotometric procedure we have been able to measure the equilibrium constant for this reaction, as will be shown in the following paper. The complexes are far more reactive than the corresponding chromium or cobalt compounds, but when properly isolated in pure form may be analyzed accurately and, in some instances, may be preserved indefinitely in a refrigerator.

Potassium Trioxalatomanganiate.—Our interest in the oxalato complexes arose from a need for some potassium trioxalatomanganiate of extreme purity, with particular reference to its freedom from iron. Trioxalato complexes are formed by tervalent chromium, iron and cobalt; the salts are all probably isomorphous with the manganic complex, and all of them have moderately high solubilities. Because of the instability of the manganic complex the principal purification is necessarily applied to the reagents rather than to the final product. We have accordingly devised a procedure which involves as few reagents as possible. The chief difficulty in obtaining a homogeneous product is due to the sparing solu-

bility of the acid oxalates, and numerous procedures were investigated before a dependable one was obtained.

The method which has been developed consists in reducing potassium permanganate with oxalic acid in proper excess, followed by oxidation of the resulting manganous oxalate by a second portion of permanganate which is added along with sufficient potassium carbonate to furnish the necessary potassium and the most favorable hydrogen-ion concentration. The over-all reaction and the stoichiometric proportions actually used are expressed by the equation

$$5H_2C_2O_4 + KMnO_4 + K_2CO_3 \longrightarrow K_3[Mn(C_2O_4)_3] + 5H_2O + 5CO_2 \quad (1)$$

Preparation of Reagents.—Water was prepared by redistilling the laboratory distilled water with alkaline permanganate, using a spray trap and condenser of block tin. The middle portion of this distillate was again redistilled in an all-quartz still for conductivity water.

Oxalic acid was prepared by the hydrolysis of ethyl oxalate, Eastman ester being used in part, along with a sample prepared in this Laboratory.[7] The hydrolysis of the redistilled ester (boiling range 1°), evaporation of the alcohol and recrystallization of the resulting oxalic acid were conducted entirely in quartz.

Potassium permanganate (Baker C. P.) was dissolved in warm purified water and after digestion filtered through acid-washed asbestos. The crystals obtained by evaporation and cooling were recrystallized in quartz four times.

Potassium carbonate was prepared from potassium acid tartrate obtained from pure tartaric acid and potassium carbonate. After four recrystallizations the acid salt was decomposed at as low a temperature as possible and the carbonate formed was evaporated to crystallization in a silver dish.

Alcohol and ether were purified and dehydrated in the usual manner. Before distillation the ether was agitated with potassium hydroxide and potassium permanganate. The quartz still was used for the distillations.

Preparation of Potassium Trioxalatomanganiate.—The stoichiometric proportions represented in equation (1) were used in the reaction, which, however, was conducted in two stages. To the entire quantity of oxalic acid to be used, four-fifths of the indicated amount of potassium permanganate was added and completely reduced. After the solution had cooled to about 0° the potassium carbonate and remaining potassium permanganate were added. All operations were carried out in quartz apparatus and in a darkened room. The details were as follows.

A quarter of a mole (31.5 g.) of oxalic acid dihydrate was dissolved in 200 cc. of pure distilled water in a 500-cc. beaker. The solution was heated to 70–75° and 0.04 mole (6.32 g.) of powdered potassium permanganate was added in small portions, while agitating the solution. When the solution had become colorless, 0.05 mole (6.9 g.) of solid potassium carbonate was added in small portions, with agitation. Occasional agitation was maintained to prevent the precipitate from sticking in a solid mass. When the temperature of the mixture was about 4–5°, 150 cc. of pure water at 0–1° was added.

One one-hundredth of a mole (1.58 g.) of powdered potassium permanganate was then added in small portions; after addition of the last portion the agitation was continued for about ten minutes, and the temperature maintained at 0–2°. The formation of an intense, cherry-red color was observed. Previously, into the freezing mixture was placed a flask mounted with a Gooch crucible fitted into a rubber ring which was placed on top of the neck of the flask. The cold solution was then filtered with suction through acid-washed asbestos.

The filtrate was transferred to a cooled beaker and ice-cold alcohol, in quantity corresponding to one-half of the potassium trioxalatomanganiate solution, was added. The solution was placed in an efficient cooling mixture (ice and salt) and kept in the dark for about two hours.

The precipitated potassium trioxalatomanganiate was then filtered with suction on a cooled Büchner funnel. The precipitate was washed with ice-cold 50% (by volume) pure alcohol four times, using about 25 cc. for each wash, then with 95% alcohol, absolute alcohol and, finally, three portions of purified ether. The temperature of all solvents used for washing was in the neighborhood of 0°.

The crystals so obtained were sucked dry on a silica crucible, then removed to an evaporating dish and dried at room temperature and atmospheric pressure for twelve hours, and preserved in a colored glass bottle to prevent decomposition by light. It is important that the organic solvents evaporate completely before the bottle is stoppered.

The filtration and washing of the crystals were carried out in the shortest time possible. Based on the data of four experiments, the yield was approximately 50%.

Analysis.—Microscopic examination of the product revealed no inhomogeneity, whereas samples prepared by the other procedures investigated almost invariably contained white crystals of potassium acid oxalate. A complete analysis of the crystals was made by the following methods: (a) total manganese, by gravimetric determination as $Mn_2P_2O_7$; (b) manganese, oxidation equivalent, by liberation of iodine and titration with thiosulfate; (c) oxalate, by titration with permanganate, making allowance for the oxalate oxidized by the manganic ions, as determined in (b); (d) potassium, by decomposition of a sample with sulfuric acid and ignition to constant weight at 500°, subtracting the weight of manganous sulfate calculated from (a); (e) water, by decomposition in a combustion furnace and absorption of the water liberated. The results were as follows, the theoretical values calculated from the formula $K_3[Mn(C_2O_4)_3]\cdot 3H_2O$ being in parentheses: potassium, 24.12 (23.92); manganese 11.19 (11.21); oxalate, 53.90 (53.85); water, 10.9 (11.02).

A sample was examined for iron spectrographically.[8] No iron lines could be detected, the test being sensitive to 0.0001%.

The density of potassium trioxalatomanganiate was determined in a pycnometer, toluene, xylene and ethyl oxalate being used as liquids in different experiments. Three determinations were made with the usual precautions to

(8) We are indebted to Dr. E. Weiner for conducting this test.

displace adhering air, the results being d^{20}_4 2.148, 2.152, 2.148; mean, 2.149.

Potassium trioxalatomanganiate in the solid state has a deep reddish-purple color. Impure samples often decompose overnight at room temperature, especially if imperfectly dried. We have found that very pure samples keep well even at 20° if protected from the light, and in a refrigerator at −6° no decomposition is apparent after storage for a year or more. The salt is insoluble in alcohol, ether, acetone, toluene and xylene, but is very soluble in water, and very slightly soluble in methyl alcohol. The color of aqueous solutions varies markedly with the concentration. A 0.001 *M* solution is yellowish-brown; with increasing concentration the solution becomes cherry-red, and concentrated solutions in an oxalate–oxalic acid buffer at *p*H 5 are deep red with a purplish shade. These color changes are due to the partial replacement of an oxalate ion by water molecules, as shown by spectrophotometric studies which will be reported in the succeeding paper. When a solution is made moderately acid the color changes to a golden-yellow, but rapidly fades, owing to reduction of the manganese. A brown precipitate forms in an acetate buffer if the acidity is decreased appreciably below a *p*H of 5.

Potassium Dioxalatodiaquomanganiate.—Whereas the trioxalto complexes of cobalt and chromium are very stable with respect to dissociation of the anion, or the replacement of an oxalate group by water molecules, a number of facts made it apparent that the trioxalatomanganiate ion is decidedly less stable in this respect. Addition of silver ions or calcium ions to a solution of the pure salt produces an immediate precipitation of an oxalate, with decomposition of the red salt. Furthermore, the yellow color produced by acidifying the solution is restored to red by addition of an excess of potassium oxalate. Before we discovered the work of Meyer and Schramm we had been successful in isolating the green dioxalatodiaquomanganiate, though considerable work was required before a dependable procedure was developed. Four methods were studied, all of which gave the desired compound in varying degrees of purity.

(a) A concentrated solution of the trioxalato complex at 0° was treated with dilute sulfuric acid until the color changed to a clear golden-yellow; the green dioxalato salt crystallized out upon addition of alcohol. The salt was contaminated with colorless crystals, presumably of potassium acid oxalate.

(b) and (c) Manganous oxalate was oxidized by potassium permanganate in the presence of oxalic acid and potassium oxalate in varying proportions.

(d) The best results were obtained by a simple modification of the procedure developed for making the trioxalato complex. The total reaction is

$$4H_2C_2O_4 + KMnO_4 \longrightarrow K[Mn(H_2O)_2(C_2O_4)_2] + 4CO_2 + 2H_2O \quad (2)$$

The reaction is carried out in one step, and because of the strongly acid character of the solution during the initial stages it is necessary to control the temperature very accurately and to work rapidly according to the following procedure.

Preparation of Potassium Dioxalatodiaquomanganiate.—Eight hundredths of a mole (10.08 g.) of oxalic acid ($H_2C_2O_4 \cdot 2H_2O$) was dissolved in 200 cc. of water in a 750-cc. Erlenmeyer flask. The solution was cooled to 1° and 0.02 mole (3.16 g.) of powdered potassium permanganate was added. The mixture was thoroughly agitated for about twenty minutes and the temperature was allowed to rise to 7°, at which temperature the reaction started, as judged by the evolution of carbon dioxide. The flask was immersed quickly in an efficient cooling mixture of ice and salt. The agitation was continued and the temperature was lowered gradually to 0°. When the evolution of gas began to diminish, 25 cc. of ice-cold ethyl alcohol (95%) was added and the temperature was allowed to drop to −3°. At this stage the solution was greenish-brown in color, without any red shade. The solution was filtered very quickly through a Gooch crucible with an asbestos mat, which was previously washed and cooled. The filtrate was collected in an externally-cooled flask.

The filtrate was cooled below 0° and 200 cc. of 95% alcohol was added in portions, keeping the temperature below 0°. The solution was allowed to stand in an efficient cooling mixture for about half an hour. If no crystallization had begun at this time the inner wall of the flask was scratched slightly with a stirring rod and the solution allowed to stand at a temperature of −5 to −10° for one hour. Green, lustrous crystals were observed at this time on the bottom of the flask. They were filtered with suction and washed with ice-cold ethyl alcohol (50, 95% and absolute), followed by three washes with ice-cold dry ether. The yield was about 45% of the theoretical.

Anal. The compound was analyzed by the methods described in connection with the trioxalato complex. The results on two samples were as follows, the percentages calculated from the formula $K[Mn(C_2O_4)_2(H_2O)_2] \cdot 3H_2O$ being in parentheses: potassium, 10.76, 10.75 (10.85); manganese, 15.16, 15.22 (15.25); oxalate, 48.70, 48.92 (48.90); water, 25.1 (25.0).

Under the microscope the green crystals appear as well-formed, thin, diamond-shaped plates. The salt dissolves readily in water, giving a golden-yellow solution which rapidly decomposes at room temperature. As the decomposition liberates oxalate ions some trioxalato salt forms in the reaction. The solution does not immediately give a precipitate of calcium oxalate when treated with calcium chloride. Addition of potassium oxalate immediately gives the trioxalato complex. Pink compounds are also formed by addition of chloride ion or fluoride ion. At room temperature the crystals decompose rapidly, as a rule, but in a refrigerator may be preserved.

In one experiment the preparation was conducted by a slight variation of the procedure described. Instead of the theoretical quantity of oxalic acid a 1% excess was used, and only 50 cc. of alcohol was used to precipitate the salt. The product consisted of golden crystals which appeared homogeneous under the microscope. Analysis gave: manganese, 15.1; oxalate, 49.0, 48.7. It is evident that the composition of the two products is identical. The dioxalatodiaquo complex may exist in isomeric *cis* and *trans* forms, and we are of the opinion that the differences observed may be accounted for in this way. The two solids give solutions of the same color, which may indicate that the solution contains both forms in equilibrium. Further work is in progress in this connection.

In a further preparation the reaction mixture was made as nearly anhydrous as would permit the reactions to occur. Eight hundredths of a mole (10.08 g.) of powdered oxalic acid ($H_2C_2O_4 \cdot 2H_2O$) was dissolved in 200 cc. of absolute alcohol and cooled to 0°. Two hundredths of a mole (3.16 g.) of powdered potassium permanganate was added. The solution was shaken and a few pieces of ice were added until the solution turned brown and the larger portion of the permanganate went into solution. Then the solution was filtered. The precipitate consisted mainly of unreacted materials. The filtrate was brown in color; 1.12 g. of potassium hydroxide was dissolved in 50 cc. of 95% alcohol. The potassium hydroxide solution was cooled and portions of it were added until a precipitate appeared. The yellowish-green precipitate was filtered off. It was washed in the usual way and analyzed for oxalate and manganic ions. The results follow, the percentages calculated for $K[Mn(C_2O_4)_2(H_2O)_2]$ being in parentheses: manganese, 17.8 (17.91); oxalate, 56.8 (57.5).

The product was apparently the anhydrous form of potassium dioxalatodiaquomanganiate. It was more stable than the trihydrate and remained undecomposed at room temperature for several days. Other characteristics were identical with those of the hydrated form of the salt.

It is claimed by Brintzinger and Eckardt[9] that dioxalato complexes of bivalent central ions often polymerize to double ions in dilute solution. Freezing point measurements accordingly were made on 0.05 *M* solutions of yellow potassium dioxalatodiaquomanganiate by the Beckmann method.[10] The results showed an apparent degree of dissociation of the same magnitude as is commonly found for solutions of uni-univalent salts of the same concentration. The solution is weakly acidic, probably as a result of a slight dissociation according to the reaction $[Mn(C_2O_4)_2(H_2O)_2]^- \rightleftharpoons [Mn(C_2O_4)_2(OH)(H_2O)]^= + H^+$.

Complexes Containing Complex Cations

On account of the high solubility of the potassium salts obtained an effort was made to find some other cation which might give complexes of lower solubility. The alkaline earths and heavy metals are necessarily eliminated because their oxalates also are insoluble. The oxalato anions are relatively large in size, and since it is often true that the solubility of salts with large anions decreases as the cation becomes larger, it was thought likely that compounds containing a complex cation as well as the complex anion might be favorable forms in which to isolate the unstable manganese complexes.

Hexamminecobalti Trioxalatomanganiate, $[(CoNH_3)_6][Mn(C_2O_4)_3] \cdot xH_2O$.—One hundredth of a mole (2.67 g.) of hexamminecobalti chloride $[Co(NH_3)_6]Cl_3$, (yellow) was dissolved in 100 cc. of water at a temperature of 2° and 0.01 mole (4.90 g.) of potassium trioxalatomanganiate dissolved in 50 cc. of water at a temperature of 2° was added. The mixture was shaken, after which a purplish-pink precipitate was observed. The precipitate was filtered off and washed in the usual way; yield 4.8 g. The theoretical yield of anhydrous hexamminecobalti-trioxalatomanganiate is 4.80 g. Upon addition of alcohol to the filtrate, a precipitate formed in small quantity. The mixture was allowed to stand overnight in the refrigerator and the lustrous pink crystals which formed were filtered off and washed with alcohol.

A partial analysis of the first crop of crystals gave manganese 10.6 (10.29), cobalt 10.9 (11.03); oxalate 50.2 (49.44), the values in parentheses being calculated for the trihydrate. The atomic ratio found corresponds to $Co:Mn:C_2O_4 = 0.96:1.00:2.96$, the percentage values lying between those for the dihydrate and the trihydrate.

The dioxalatodiaquomanganiate anion also unites with complex cations to form sparingly soluble double complexes. With *cis*-dinitrotetrammine cobalti ion an olive-yellow precipitate was obtained. The product was heterogeneous under the microscope, however, and was not subjected to analysis.

Note on Potassium Dimalonatodiaquomanganiate

Meyer and Schramm[5] prepared their complex manganiates by using manganic hydroxide or manganese dioxide as the source of manganese. Their procedures gave impure products in many instances, and they report that they were not able to obtain potassium dimalonatodiaquomanganiate in a form suitable for analysis. We have conducted several experiments in which it was hoped that the greater stability of malonic acid toward oxidation would permit isolation of a type of hydroxo complex that we have not been able so far to obtain in pure form in the oxalate series. It was found that suitable modification of our procedure, in which potassium permanganate is used, easily produces pure crystals of the potassium salt, $K[Mn(C_3H_2O_4)_2(H_2O)_2] \cdot 2H_2O$.

Four procedures were investigated in which malonic acid, potassium permanganate and, in two cases, potassium carbonate were mixed in various proportions in aqueous solution at 0°. In all cases the same product was obtained, the yield being highest (80%) when stoichiometric proportions were used according to the equation

$$5CH_2(COOH)_2 + 2KMnO_4 \longrightarrow 2K[Mn(C_3H_2O_4)_2(H_2O)_2] + 3CO_2 + 2H_2O$$

The reactions were carried out at about 0° in solutions containing 0.01 mole of permanganate with the other reagents in 100 cc. of water. To precipitate the crystals 50 cc. of alcohol was also present. The average of four closely concordant analyses for manganese was as follows, the value calculated for the dihydrate being in parentheses: Mn, 14.85% (14.83). Potassium and water were determined on one sample: K, 10.4 (10.57); H_2O, 2.63 (2.7). The dark-green crystals dissolve readily in water to give an unstable yellow solution, as reported for the other salts by Meyer and Schramm. The salt may be recrystallized from cold 0.05 *M* malonic acid by addition of alcohol.

---

(9) Brintzinger and Eckardt, *Z. anorg. allgem. Chem.*, **224**, 93 (1935).

(10) We are indebted to Mr. J. T. Grey, Jr., for making the measurements.

Summary

1. A procedure has been developed whereby potassium trioxalatomanganiate may be prepared spectroscopically free from iron.

2. Potassium dioxalatodiaquomanganiate has been prepared in the pure crystalline state. Two forms of the trihydrate have been obtained, as well as the anhydrous salt.

3. It has been shown that these manganiate ions form sparingly soluble salts with complex cations.

4. Pure potassium dimalonatodiaquomanganiate has been prepared and certain of its properties have been determined.

Equilibrium between the Trioxalatomanganiate and Dioxalatodiaquomanganiate Ions

BY G. H. CARTLEDGE AND W. P. ERICKS

In spite of the enormous number of transformations among complex compounds that have been developed in the course of the classic researches of Werner and his successors, very few of such reactions have been investigated quantitatively from the standpoint of chemical equilibrium. The complexes of the metals that have been most fully studied are, as a rule, so stable with respect to dissociation that readily measurable equilibria are comparatively rare. Such measurements as have been made concern principally the dissociation of solid ammine complexes or the instability constants of such relatively stable complexes as the silver–ammonia or silver–cyanide ions in solution. In a few cases the acidic dissociation of aquo complex ions has also been studied.[1] Investigations of affinity in the complex compounds are desirable on account of the renewed interest in the question as to the type and strength of the chemical bonds in such substances.

Meyer and Schramm[2] observed that the trioxalatomanganiate ion and the dioxalatodiaquomanganiate ion are convertible one into the other according to the equation

$$[Mn(C_2O_4)_3]^{\equiv} + 2H_2O \rightleftarrows [Mn(C_2O_4)_2(H_2O)_2]^- + C_2O_4^=$$

That a measurable equilibrium is established rapidly is evident from the color changes observed in aqueous solutions of the trioxalatomanganiates. A concentrated aqueous solution is ordinarily described as cherry-red. We have found that the color is perceptibly changed to a more purplish-red upon addition of an oxalate oxalic acid buffer at *p*H 4.5. As an aqueous solution is diluted its color changes steadily; in 0.001 *M* solution the color is brown, but may be restored to red by addition of an excess of the oxalate buffer. The dioxalatodiaquomanganiate ion reacts immediately with the oxalate ion to produce the trioxalato complex. In this respect the dioxalato ion contrasts with the dimalonato ion, which is very incompletely converted to the trimalonato ion. The dioxalatodiaquomanganiate ion itself has a golden-yellow color in cold aqueous solution, but the solution is acid and soon becomes turbid. This effect is no doubt due to an acidic ionization of the water molecules in the complex, whereby a sparingly soluble hydroxo complex is formed. We have found that the solution in 0.01 *M* nitric acid remains clear and is stable enough for our purposes. The nitric acid evidently suppresses the ionization, giving the pure color of the aquo complex ion.

The method of determining the equilibrium concentrations consisted in a spectrophotometric analysis of solutions of the trioxalatomanganiate in water at various concentrations and also in various oxalate–oxalic acid buffer mixtures. Equilibrium was also approached from the dioxalatodiaquomanganiate side of the reaction. As has been found by Uspensky and his collaborators[3] in a number of cobaltic and chromic complexes, when water molecules replace an acido group within a complex ion the maximum absorption in the visible region is displaced in the direction of shorter wave lengths. In the oxalatomanganiates

the same shift is observed, and is so great as to permit convenient determination of the ions in a mixture. The calculation of the concentrations depends upon a knowledge of the extinction coefficients of the pure components. In the case of the dioxalatodiaquomanganiate the extinction coefficient is relatively small in the region of most importance for our measurements. Furthermore, the values differ only slightly whether the salt is dissolved in pure water, in dilute oxalic acid or in dilute (0.01 *N*) nitric acid. We have therefore taken the measurements on this salt in 0.01 *N* nitric acid, since this concentration was found ample to prevent dissociation to a hydroxo complex; at 0° the solution does not decompose rapidly enough to interfere with the analysis.

In the case of the trioxalatomanganiate it was found that there is an appreciable replacement of an oxalate ion by water molecules even in the most favorable oxalate buffer. It is therefore impossible to determine the extinction coefficients for the pure component in these solutions. We have avoided this difficulty by making measurements at a low concentration of the complex in a pair of buffered solutions of known oxalate-ion concentration. By treating both the extinction coefficient of the trioxalato ion and the equilibrium constant as unknowns we arrive at pairs of equilibrium equations from which both quantities may be calculated. The extinction coefficients thus found at three wave lengths were then used for other solutions in which the oxalate-ion concentration was not necessarily known.

For the calculation of the concentration of the components in the equilibrium mixture the Lambert–Beer law was used in the form

$$\log (I_0/I) = lc(x_1E_1 + x_3E_3) \qquad (1)$$

in which c is the formality as to manganese, l the cell length in cm., x_1 and x_3 the fractions of the complex in the form, respectively, of the univalent dioxalato ion and the tervalent trioxalato ion, and E_1 and E_3 the molecular extinction coefficients of the corresponding ions. If the apparent extinction coefficient calculated from the measured transmittance of any mixture is E, we obtain

$$E = x_1E_1 + x_3E_3 \qquad (2)$$

The fractions of the complex in the two forms are then given by

$$x_1 = (E_3 - E)/(E_3 - E_1) \text{ and } x_3 = (E - E_1)/(E_3 - E_1) \qquad (3)$$

The extinction coefficients were measured from 440 mμ to 600 mμ in certain cases, but the three wave lengths 550, 540 and 520 mμ were selected for the equilibrium calculations. The extinction coefficients at these points were then repeatedly determined on freshly prepared solutions. A Bausch and Lomb visual spectrophotometer was used, the cells being jacketed in ice during the measurements. A jet of dry air prevented the condensation of moisture on the cells. The least stable solutions showed no alteration during the few minutes they were in use. Distilled water boiled in quartz was used for preparing the unbuffered solutions. All salts used were pure, as determined from careful analyses.

For the equilibrium equation we have

$$\frac{\gamma_1[\mathrm{Mn(C_2O_4)_2(H_2O)_2}^-]\gamma_2\mathrm{C_2O_4}^=]}{\gamma_3[\mathrm{Mn(C_2O_4)_3}]^\equiv} = K \qquad (4)$$

the γ's being the activity coefficients of the respective ions. Expressed in terms of the fractions of the two colored ions this becomes

$$\frac{\gamma_1\gamma_2}{\gamma_3} \times \frac{x_1}{1 - x_1} \times [\mathrm{C_2O_4}^=] = K \qquad (5)$$

The values of the activity coefficients were obtained from graphs of the coefficients of the chlorate, sulfate and ferricyanide ions. For the univalent ion the activity coefficient was plotted against the cube root of the ionic strength. In the case of the bivalent and tervalent ions the reciprocal of the activity coefficient was plotted against the square root of the ionic strength. Taking the numerical values from Lewis and Randall,[4] essentially linear graphs were obtained from which the required activity coefficients could be read with only moderate extrapolation to the more concentrated mixtures. In calculating the oxalate-ion concentration in the buffered solutions due regard was paid to the secondary ionization of oxalic acid in all cases where required. In terms of the individual extinction coefficients the equilibrium equation takes the form

$$\frac{\gamma_1\gamma_2}{\gamma_3}\left(\frac{E_3 - E}{E - E_1}\right)\left[c_0 + \left(\frac{E_3 - E}{E_3 - E_1}\right)c\right] = K \qquad (6)$$

when equilibrium is approached from the trioxalato side; c_0 is the concentration of oxalate ions in the buffer solution itself.

In making the calculations different values were employed for the extinction coefficient E_1 of the dioxalatodiaquomanganiate ion depending upon the acidity of the solution. In the acidic, buffered solutions the values were taken from measurements on the pure component in 0.01 *N* nitric acid as the solvent. In the more nearly neutral,

unbuffered solutions the values obtained from a simple aqueous solution of the dioxalato salt were used, as these undoubtedly represent more closely the actual state of the substance in the equilibrium mixtures. Owing to the unavoidable uncertainty in these extinction coefficients, however, we have selected wave lengths at which the values are still relatively small in comparison with those of the trioxalato ion.

The values of the extinction coefficients of the trioxalato ion were first determined approximately from measurements on a 0.001 *M* solution of the complex in buffers consisting of 0.08 *M* potassium oxalate and 0.02 *M* potassium hydrogen oxalate, KHC_2O_4, in one case, and the same buffer diluted with an equal volume of water in the second case. In these buffers the oxalate ion contributed by the reaction of the complex ion with water is negligibly small. From the approximate results so obtained final values for the extinction coefficients of the trioxalato ion were then obtained from three series of measurements in buffers containing 0.02 *M* potassium oxalate and 0.08 *M* potassium hydrogen oxalate, or the same diluted with an equal volume of water. The approximate values of the extinction coefficients E_3 previously obtained made it possible to calculate with sufficient accuracy the amount of oxalate ion formed in the reaction. The replacement reaction proceeds further in these more acidic buffers, and the calculated extinction coefficients are consequently less sensitive to errors in the measurements.

For the determination of the extinction coefficients of the trioxalatomanganiate ion experiments 3, 4, 12, 13, 16 and 17 (Table II) were used. The results are summarized in Table I.

The general results and calculated equilibrium constants in buffered and aqueous solutions are shown in Table II. Certain of the measured extinction coefficients are shown in Fig. 1.

Discussion of Results

From Table II it will be seen that in different experiments we have carried the replacement reaction from 10–70% toward completion in the solutions containing added oxalate ions. In simple aqueous solution the range was from 31–85%. Equilibrium has been approached from both sides, and it is evident that the reaction proceeds to equilibrium almost instantaneously, since the absorption measurements were started

as quickly as possible after the preparation of the solution. The range of concentrations as to the complex salt is necessarily restricted by the intensity of the absorption, but we have covered as wide a range as could be measured with any degree of precision with the visual spectrophotometer, namely, from 0.001 to 0.025 *M*. Considering the instability of the system, the necessity of approximating the activity coefficients, and the inherent difficulties in the precise determination of the extinction coefficients, the concordance of the equilibrium constants is all that could be expected.

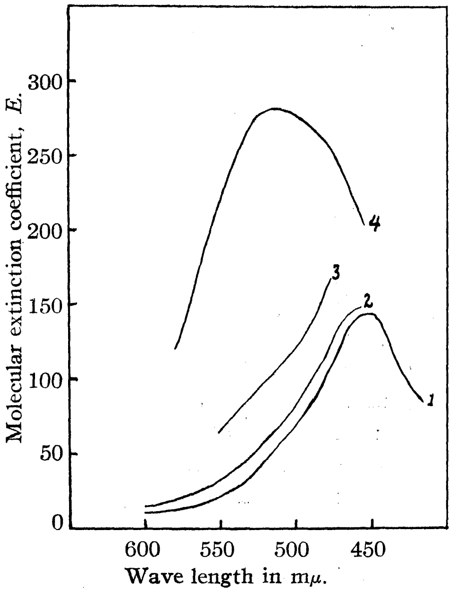

Fig. 1.—Absorption spectra: curve 1, $K[Mn(C_2O_4)_2(H_2O)_2]$, 0.01 *M* in 0.01 *M* HNO_3; curve 2, $K[Mn(C_2O_4)_2(H_2O)_2]$, 0.01 *M* in water; curve 3, $K_3[Mn(C_2O_4)_3]$, 0.001 *M* in water; curve 4, $K_3[Mn(C_2O_4)_3]$, 0.01 *M* in buffer 0.08 *M* in $K_2C_2O_4$ and 0.02 *M* in KHC_2O_4.

The absence of any trend in the calculated constants as the replacement reaction becomes extensive shows that under the prevailing conditions the dioxalato ion does not lose a second oxalate ion to an appreciable extent. The dioxalato ion may be decomposed by addition of ions that form very insoluble oxalates, but it is evident that such a reaction proceeds only at decidedly lower concentrations of oxalate ions than were present even in our most dilute solutions. The ready loss of one oxalate ion from the trioxalatomanganiate ion contrasts strongly with the behavior of the trioxalato chromiates and cobaltiates, which are not decomposed even by addition of cations which form very insoluble oxalates.

Figure 1 shows the extinction coefficients of certain of the systems measured. In the case of the dioxalatodiaquomanganiate the same absorption was observed whether the green or the yellow form of the salt was used.[5] Either form of the salt is converted immediately to the trioxalato complex by addition of potassium oxalate. When preparing the dioxalato complex we have sometimes isolated both kinds of crystals from the same solution. These results appear to indicate that in aqueous solution there is an equilibrium between the yellow and green forms, which we assume to be *cis* and *trans* isomers.

The maximum absorption of the dioxalato complex lies at about 450 mμ, whereas that of the trioxalato salt is at about 520 mμ. This shift of 70 mμ is in the same direction as observed by Uspensky and collaborators,[3] but is considerably greater in magnitude. The Russian authors have also observed that in the case of *cis-trans* isomers the *trans* isomer often has an absorption minimum at approximately the same wave length at which the *cis* isomer has a maximum. This rule was found to hold for a number of chromium and cobalt complexes, and if it applies to the manganese compounds it would indicate that our yellow dioxalato salt is the *cis* isomer. That this form predominates to such a large extent in aqueous solution is in accordance with the statistical probability, which, for the *cis* isomer, is 0.8 in such a case.

The magnetic susceptibility of potassium trioxalatomanganiate has been determined by Johnson and Mead[6] and found to correspond to four unpaired electrons. These authors therefore concluded that the complex must be held together by ionic bonds, since if there were six covalent bonds there would be only two unpaired electrons. Another possibility has to be considered, however. According to Pauling's rules for the covalent bonds in complex ions[7] tervalent manganese in its normal state should have four unpaired electrons and just the combination of available *d*, *s* and *p* eigenfunctions required for the formation of four covalent bonds directed toward the corners of a square. The readiness with which the trioxalatomanganiate ion loses its first oxalate ion, and the abnormally large shift in the absorption

maximum when this occurs, suggest the hypothesis that two of the oxalate ions are covalently bound, while the third is held by the weaker ionic forces. Such a structure would agree with the observed magnetic susceptibility. Further work is in progress in an attempt to gain more insight into the structure of these complexes.

Summary

1. The extinction coefficients of aqueous and buffered solutions of potassium trioxalatomanganiate and potassium dioxalatodiaquomanganiate at various concentrations have been measured in the visible region of the spectrum. The trioxalato salt has a maximum absorption at about 520 mμ and the dioxalato salt at about 450 mμ.

2. The two salts are convertible into each other according to the reaction

$$[Mn(C_2O_4)_3]^{\equiv} + 2H_2O \rightleftarrows [Mn(C_2O_4)_2(H_2O)_2]^- + C_2O_4^{=}$$

Equilibrium is established almost instantaneously. The equilibrium constant of the reaction has been determined by spectrophotometric analysis and found to be 3.8×10^{-3} at 0°.

3. The green and yellow dioxalato salts both give a golden-yellow solution with the same absorption curve, and the solution presumably consists of an equilibrium mixture of the two isomers. The optical evidence makes it likely that the yellow form is the statistically more probable *cis* isomer.

4. It is suggested that the complex manganiates may be derived from a covalent *dsp*^{2} structure fundamentally, the fifth and sixth valence bonds being ionic or ion-dipole in character.

BUFFALO, N. Y. RECEIVED JUNE 19, 1936

An Oxalato Complex of Quadrivalent Manganese

BY G. H. CARTLEDGE AND W. P. ERICKS

In the course of the investigation described in a previous paper[1] an attempt was made to prepare a hydroxo-oxalato complex compound containing tervalent manganese. In the previous experiments on the trioxalatomanganiate potassium permanganate was first reduced all the way to the manganous state by an excess of oxalic acid; the manganous ion was then oxidized by addition of a second portion of permanganate, the exact product being determined by the proportions of the reactants used. In view of the weakly acidic character of the water molecules in the dioxalatodiaquomanganiate ion, it was thought that the corresponding hydroxo ion might be obtained by suitable decrease of the hydrogen-ion concentration. Accordingly, a preparation was carried out in which part of the oxalic acid was replaced by potassium oxalate, using the proportions:

$$3.5H_2C_2O_4 : 0.5\ K_2C_2O_4 : KMnO_4$$

The materials were allowed to react at a little above 0° and the result was a mixture of two kinds of crystals. Microscopic examination showed the presence of some potassium trioxalatomanganiate along with a considerably larger proportion of dark, olive-green crystals. The experiment was repeated with further alteration in the reacting proportions until a method was finally developed which gave the green material in pure form. Although the substance is very unstable we were able to isolate it and prove that it contains quadrivalent manganese, its composition being represented accurately by the formula $K_2[Mn^{IV}(C_2O_4)_2(OH)_2]\cdot 2H_2O$. It is therefore to be called potassium dioxalatodihydroxomanganeate. So far as we have been able to discover it is the only known complex of quadrivalent manganese with the exception of the hexahalogenato complexes $[MnX_6]^{2-}$ and a diglycerol complex reported by Schottländer.[2]

Preparation.—The preparation is conducted according to the reaction

$$3.5H_2C_2O_4 + 0.65K_2C_2O_4 + KMnO_4 \longrightarrow K_2[Mn(C_2O_4)_2(OH)_2] + 0.5H_2C_2O_4 + 0.15K_2C_2O_4 + 3CO_2 + 2H_2O$$

The operations are conducted rapidly, in a cool and darkened room. Fourteen hundredths of a mole of oxalic acid (17.64 g. $H_2C_2O_4\cdot 2H_2O$) is dissolved in 250 cc. of distilled water. The solution is cooled to 0° and 0.04 mole (6.32 g.) of powdered potassium permanganate is added, followed by 0.026 mole of potassium oxalate (4.78 g. $K_2C_2O_4\cdot H_2O$). The mixture is agitated vigorously for about twenty minutes and the temperature is allowed to rise to 7°. At this point carbon dioxide begins to be

---

(1) Cartledge and Ericks, THIS JOURNAL, **58**, 2061 (1936).

(2) Schottländer, *Ann.*, **155**, 230 (1870).

evolved rapidly, and the flask containing the mixture is submerged in an efficient cooling mixture to reduce the temperature quickly to 0°, the agitation being maintained meanwhile.

When the reaction is complete the solution has a dark green color. It is filtered rapidly through paper on a cold Büchner funnel, the filtrate being collected in a flask standing in a freezing mixture. Alcohol is added to the filtrate in small portions, keeping the temperature at about 0°, until 100 cc. has been added. The precipitation of the crystals begins almost at once.

The crystals are filtered rapidly and washed successively with ice-cold 50% alcohol, 95% alcohol, absolute alcohol and anhydrous ether. The filtrate from the crystals is red and upon standing often deposits the trioxalatomanganiate. The green crystals decompose rapidly at room temperature, especially in the light, but keep for some weeks if preserved in the dark at −6°.

Analysis.—The analytical procedures used were similar to those described in a preceding paper.[1] Volumetric and gravimetric determinations of manganese showed that two equivalents of iodine are liberated for each atomic weight of manganese, indicating the presence of quadrivalent manganese. In the determination of oxalate by titration with permanganate the proper allowance was made for the oxidation of a portion of the oxalate by the quadrivalent manganese. Before the final procedure had been developed as described above, five preparations were obtained which were somewhat impure but gave analyses with sufficient concordance to establish the composition. A sample prepared by the final procedure appeared to be homogeneous under the microscope and gave the following analysis:

Constituents	Found	Calculated for $K_2[Mn(C_2O_4)_2(OH)_2]\cdot 2H_2O$
K^+	20.3	20.62
Mn (gravimetric)	14.5	14.49
Mn^{4+} (volumetric)	14.3	
$C_2O_4^=$	46.2	46.42
H_2O (total)	14.2	14.26

Attempts to prepare the compound during the summer were at first unsuccessful, but the product was obtained without difficulty by the following method. The Büchner funnel was jacketed in an ice-bath, and closed at the top with a large one-holed rubber stopper. A glass tube passed from the funnel to the bottom of the reaction flask, which stood in a freezing mixture. The washing liquids were added through this flask by means of a separatory funnel; the air entering the flask and subsequently drawn through the crystals was first dried with calcium chloride and then chilled in a cooling coil. By this means the crystals were protected from the warm, humid air until completely washed and dried. Thorough and rapid drying is essential.

Although potassium dioxalatodihydroxomanganeate decomposes rapidly at room temperature, we have kept pure specimens for several weeks in a refrigerator at −6° before decomposition became apparent. The salt dissolves in water to give a clear, deep green, neutral solution which quickly becomes brown and turbid, and later changes into the red trioxalatomanganiate. The green color of a cold aqueous solution is unaffected by addition of small amounts of acids or alkalies. At 0° a solution containing a little oxalic acid remains clear and is stable enough to permit a determination of the absorption spectrum.

As obtained by the procedure described above, the product is an impalpable powder in which no distinct crystals can be seen under the microscope. The salt may be recrystallized as follows. The powder is dissolved in twenty-five times its weight of cold 0.1 *M* oxalic acid. After rapid filtration the solution, at 0°, is treated with one-sixth its volume of ice-cold 95% alcohol and placed in a freezing mixture until crystallization occurs. If the precipitation is sufficiently gradual well-defined crystalline rods are formed. A photomicrograph of one of our products is shown in Fig. 1; for this we are indebted to Professor E. Raymond Riegel. The crystals photographed were clearly seen to be of two colors, green and orange. Careful analysis showed the material to be pure, however, and it is probable that the two kinds of crystals were the *cis* and *trans* isomers theoretically possible. So far we have been unable to separate the two forms, owing to their instability.

Barium Dioxalatodihydroxomanganeate.—From the fact that our analysis indicated that we had a complex bivalent anion of rather large size, it was expected that its barium and lead salts should be sparingly soluble. Preliminary qualitative tests showed the correctness of this surmise, and the barium salt was obtained without difficulty. To 20 cc. of 5% barium chloride solution 1 cc. of concentrated hydrochloric acid was added. This mixture gives no precipitate of barium oxalate if a small quantity of oxalate ion is added. To 0.8 g. of potassium dioxalatodihydroxomanganeate dissolved in 40 cc. of ice-cold water, 13 cc. of the acidified barium chloride was added (a 25% excess). A silky precipitate appeared almost at once. The brown mixture was filtered, leaving a pale, apple-green precipitate which was washed and dried in the usual manner. The salt is sparingly soluble in water, giving a pale green color. Addition of sulfuric acid causes the color to disappear with the precipitation of barium sulfate. Analysis of the salt gave the following results:

Constituents	Found	Calculated for $Ba[Mn(C_2O_4)_2(OH)_2]\cdot 3H_2O$
Ba^{++}	29.8	30.09
Mn (gravimetric)	12.1	12.03
$C_2O_4^=$	38.6	38.56

Chloropentamminecobalti - dioxalatodihydroxomanganeate.—In qualitative tests it was found possible also to isolate the new complex ion as a sparingly soluble double complex with cobalt cations. Stoichiometrically equivalent amounts of chloropentamminecobalti chloride and potassium dioxalatodihydroxomanganeate were mixed, using 0.001 mole of each dissolved separately in the least possible quantity of water at 0°. Soon after mixing the solutions fine crystals formed, of fawn color with a greenish cast. The crystals were filtered rapidly and washed with cold alcohol and ether in the usual manner. The yield was 85%.

Microscopic examination showed that the product was homogeneous and had a needle-like structure. The crystals are sparingly soluble in water, forming a silky suspension. Upon addition of potassium oxalate the crystals gradually dissolve, giving a yellowish-green color. Sulfuric acid gives a brown solution which quickly changes to the pink of the chloropentamminecobalti ion. Qualitative tests showed the presence of cobalt and manganese. The double complex appears to be decidedly more stable than the potassium salt.

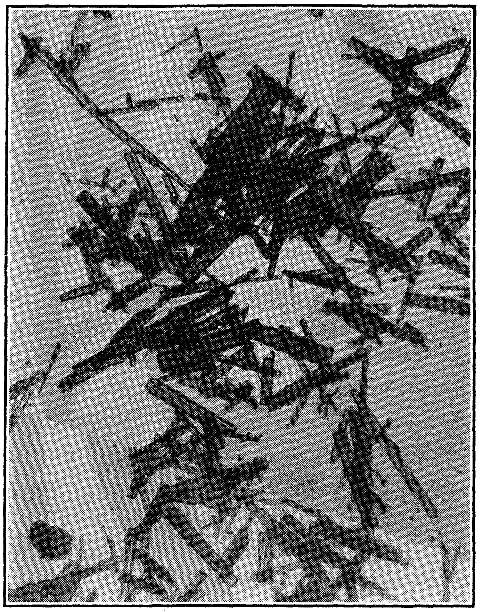

Fig. 1.—Potassium dioxalatodihydroxomanganeate, × 354.

The Absorption Spectrum of Potassium Dioxalatodihydroxomanganeate.—The absorption spectrum cannot be measured accurately in simple aqueous solution owing to the rapid appearance of a turbidity. In the presence of dilute oxalic acid, however, the solution remains clear and spectrophotometric measurements can be made with a considerable degree of accuracy, provided the solution is kept at 0° and the observations do not extend over three or four minutes on any one solution. Three series of determinations were made in 0.1 M oxalic acid, the concentration of the complex compound being 0.005, 0.01 and 0.025 M, respectively. The measurements were made with a Bausch and Lomb spectrophotometer, the precautions described in the preceding paper[3] being observed. The solutions were in all cases prepared immediately before use, and the cell was jacketed in ice during the measurements. The extinction coefficients obtained indicate that Beer's law is followed within the accuracy of the procedure over the concentration range employed. The solution has a minimum absorption at 566 mμ, with a pronounced maximum at 643 mμ, as shown in Fig. 2.

According to Pauling's theory of the bonds in complex compounds[4] quadrivalent manganese should be expected to form six equivalent octahedral bonds, since in its lowest state six d^2sp^3 eigenfunctions are available for bond formation. Magnetic susceptibility measurements cannot distinguish such a covalent structure from one involving purely ionic bonds in the present case, since both structures should give a susceptibility corresponding to three unpaired electrons. Considering the high valence of the manganese, however, it is more than likely that the covalent structure is favored.

It is noteworthy that in the case of tervalent manganese a diaquo complex forms readily and functions only very weakly as an acid, whereas with quadrivalent manganese the hypothetical aquo-ion dissociates into its corresponding hydroxo ion even in moderately acid solutions. This behavior is in accordance with the relation between the acidic strength of aquo ions and ionic potentials as developed by one of the authors.[5] From the ionic potential of quadrivalent manganese we should expect manganese dioxide to be somewhat more acidic than titanium dioxide. Although a sufficiently high hydrogen-ion concentration should theoretically convert the hydroxo ion into the aquo ion, there is no evidence from color changes that such an effect occurs in the presence of dilute acids. Higher hydrogen-ion concentrations cannot be used because of the rapid reduction of the manganese in strongly acid solutions. It is significant that Tschugajeff[6] has prepared a hydroxo complex of quad-

rivalent platinum which is not converted into an aquo compound even by concentrated hydrochloric acid.

Summary

1. A new complex compound of quadrivalent manganese has been prepared which has the composition $K_2[Mn(C_2O_4)_2(OH)_2]\cdot 2H_2O$. The barium and chloropentamminecobalti salts were also isolated.

2. The absorption spectrum was measured in the visible region.

BUFFALO, NEW YORK RECEIVED JUNE 19, 1936

NOTES

Sodium Fluorenone as a Dehydrating Agent[1]

BY H. E. BENT AND H. M. IRWIN, JR.

The most rapid method of drying an organic liquid is to dissolve in it some compound which reacts rapidly with water. For this purpose sodium benzophenone has been widely used although this involves using an alkali metal, sodium–potassium alloy or some other material which introduces considerable hazard into such work. Fluorenone has the advantage over benzophenone that it will react readily with dilute sodium amalgam to form an addition compound which has a deep green color and therefore like benzophenone gives a definite indication by its color of the absence of water. Dry solvent is then obtained by distilling from this solution.

The object of this investigation is to compare the efficiency of sodium fluorenone with the customary drying agents, magnesium perchlorate and activated alumina. Since the compound formed by the addition of sodium to fluorenone is more stable than that formed with benzophenone, it is important to be sure that the ketyl is still sufficiently reactive to be an effective drying agent.

A dilute solution of sodium fluorenone was prepared for this work by introducing 0.025 g. of fluorenone and evacuating with a mercury pump for one hour. Three to five cubic centimeters of a saturated amalgam (about 1%) was then added *in vacuo* and 50 cc. of dry ether. Shaking produced a solution which was sufficiently concentrated to react with at least one hundred times as much water as is retained by the glass on its surface.[2] A tube, connected to the reaction flask by a capillary capable of being broken and thereby opened by a magnetic hammer, carried four side-tubes. The first two were empty and used as a check on the method. The third and fourth contained activated alumina and magnesium perchlorate, respectively. The samples of alumina and magnesium perchlorate were prepared by exposing them in a thermostat to one liter of air saturated with water vapor at 25°. The quantity of water absorbed by the sample was at least one hundred times as much as was necessary to destroy the sodium fluorenone with which it came in contact, while still being small enough to give the very low vapor pressure characteristic of the dehydrating agent. The tubes containing the solid dehydrating agents were evacuated for a short time before sealing the apparatus, and immediately the capillary was broken in order to prevent diffusion from one solid to the other. The fluorenone was decolorized in the first empty tube on account of moisture on the glass and in the vapor state. In the second tube the solution retained its color. In the third and fourth tubes the solution was immediately decolorized by the alumina and by the magnesium perchlorate, indicating that the vapor pressure of water was sufficiently high to be removed by the ether solution of sodium fluorenone. A duplicate run verified the conclusion from this experiment.

The vapor pressure of water is given as 0.003 mm. for alumina and the water is given as unweighable in 210 liters for magnesium perchlorate.[3] If unweighable means less than 1 mg. this would give a vapor pressure of less than 0.005 mm. If we assume that in the presence of a small amount of water the ketyl is converted to fluorenone and fluorenole,[4] then we can estimate a mini-

mum value for the equilibrium constant for the reaction

$$NaR + H_2O = NaOH + {}^1/_2R + {}^1/_2RH_2$$

Since the sodium hydroxide is present as a solid we may express the equilibrium constant by the equation

$$K = (R)^{1/2}(RH_2)^{1/2}/(NaR)(H_2O)$$

If we assume, as a consequence of the complete destruction of the green color of the solution, that the reaction goes at least 99.9% to completion, then we obtain

$$K = 0.5 \times 999 \times 23/0.003 = 3.8 \times 10^6$$

referring the vapor pressure of water to that of pure liquid water as the standard state. This gives a value for ΔF of -9.0 kcal. These figures represent the minimum efficiency of sodium fluorenone as a drying agent. In any normal procedure a large excess of the drying agent would be used which would result in the removal of water until the pressure is at least as low as 10^{-7} mm.

The Vapor Density of Hexaphenylethane

BY H. E. BENT AND E. S. EBERS

In a recent publication the statement is made that hexaphenylethane probably does not dissociate in the vapor state.[1] In order to verify this statement an attempt was made to measure directly the vapor density of hexaphenylethane. This measurement combined with the previous data on the vapor pressure would give the molecular weight in the vapor state.

Since the vapor pressure of hexaphenylethane at 120° is only 0.004 mm. a very large volume would be necessary in order to produce a weighable amount of compound. For this purpose a ten-liter flask was attached to the fiber gage used in the previous research and to a capsule of hexaphenylethane. Ground joints controlled by electromagnets were so arranged as first to saturate the ten-liter flask with the ethane and then, closing the ethane capsule, condense the vapor in a small ampoule. The flask could then be saturated again and the vapor a second time condensed and in this way any desired amount of material obtained.

The method was checked by determining the vapor density and the molecular weight of triphenylmethane. The result was high by about 20% which we assume to be due to adsorption. As it was expected that difficulty would be encountered with hexaphenylethane on account of decomposition a procedure was adopted with triphenylmethane which would avoid this difficulty as far as possible. The ground joint to the pump was opened just enough to reduce the pressure to about three-fourths of the saturation pressure. After the pressure had become constant the valves to the pump and to the capsule of sample were closed simultaneously and the valve to the receiver opened for a time sufficiently long to condense about half of the total amount of material in the ten-liter flask. The valve to the receiver was then closed and the pressure again measured, the difference between the initial and the final pressure giving a measure of the amount of material condensed. This process was repeated about ten times and the flask then cooled and the receiver cracked off. The amount of material was determined by weight, both by difference and by evaporation of the solution of the compound to dryness in a crucible. This method of operating between three-fourths and three-eighths saturation would also be effective in avoiding condensation in the ten-liter flask or in removing adsorbed material from the surface of the glass during condensation.

When the method was applied to hexaphenylethane it was found that decomposition was too rapid to permit even an approximate determination of the vapor density. In a flask of such a large size decomposition was so great that even with the pump operating the pressure remained several times that of hexaphenylethane for a space of three hours at 120° (the valve to the solid remaining open). By this time apparently all of the ethane had decomposed for the pressure gradually decreased. However, the material in the flask was no longer hexaphenylethane but a decomposition product for on closing off the flask the pressure remained perfectly constant. Under these conditions hexaphenylethane decomposes rapidly enough to be measured easily. We concluded, therefore, that it is not possible to meas-

Relative Reactivities of Organometallic Compounds. XIV. Orientation in Metalation

BY HENRY GILMAN AND ROBERT H. KIRBY

Schlenk and Meyer[1] have shown that Abeljanz[2] did not obtain phenylpotassium from benzene and potassium. However, Schorigin[3a] very probably had phenylpotassium in hand, despite the confusion due to the paucity of experimental data.[4] We have found that carbonation of the products resulting from interaction of benzene, diethylmercury and potassium gives benzoic acid (45% yield) as well as phthalic and terephthalic acids. The same products, in different quantities, are obtained when sodium is used in place of potassium.

The organo-alkali compounds appear to arise largely as a consequence of metalation by ethylalkali compounds

$$C_6H_6 + C_2H_5K \longrightarrow C_6H_5K + C_2H_6$$

and not by the action of the alkali metals or their amalgams on benzene, for the evolved gas consists predominantly of ethane and contains only small quantities of ethylene and hydrogen.[5] The isolation of phthalic and terephthalic acids establishes the intermediate formation of *o*- and *p*-dialkalibenzenes, and indicates that phenylsodium (or potassium) orients subsequent metalation to the *ortho* and *para* positions. Mercuration may not follow such orientation.[6] It is noteworthy that isophthalic as well as terephthalic acid has been obtained from successive interaction of benzene, diamylmercury, sodium and carbon dioxide in the interesting studies by Morton and Hechenbleikner.[7]

The results are consistent with some of the earlier generalizations on relative reactivities of organometallic compounds,[8] particularly the increase in reactivity of RM compounds with increase in atomic weight of the alkali metal. For example, Mr. R. V. Young, in a study of organoalkali compounds, has shown that ethyl-lithium does not metalate benzene during a two-month period at room temperature;[3b] the over-all metalation of benzene by ethylsodium is less than that by ethylpotassium; and ethylpotassium gives much more of the dimetalated compounds than does ethylsodium.[9]

The metalations reported are merely special cases of general metalation which may be a direct metathesis, and, when RM compounds are used, a metathesis resulting in the formation of the salt of the stronger acid. Metalation of aromatic nuclei by RM compounds may involve preliminary addition, with subsequent elimination of RH.[10] Metalation by RM compounds is, of course, possible with all compounds, saturated as well as unsaturated, for all hydrogens are acidic to varying degrees from the viewpoint of metalation. A pertinent illustration is the metalation of saturated aliphatic hydrocarbons of the R_3CH type by ethylpotassium. In such cases, it is unlikely that unsaturated compounds are intermediates, even though it has been shown that RM compounds can act as dehydrogenating agents.[11]

Experimental Part

Metalation with Ethylpotassium.—To a suspension of 3.13 g. (0.08 g. atom) of potassium shavings in 35 cc. of benzene was added 5.17 g. (0.02 mole) of diethylmercury. Reaction set in at once as was evident by amalgamation of the potassium, evolution of gas and warming of the benzene. The mixture was stirred without heating for forty-eight hours, cooled to 7° and carbonated with carbon dioxide gas. The yields of products, based on diethylmercury, were 33% benzoic acid and 14% terephthalic acid (mixed melting point of dimethyl ester). The odor of propionic acid was noticeable, and a strong fluorescein test established the presence of phthalic acid. Isophthalic acid was not isolated, but may have been present in small quantities. The gas evolved contained 8 cc. of ethylene,

(7) Morton and Hechenbleikner, THIS JOURNAL, **58**, 1024 (1936). Dr. Morton and co-workers have shown, in some unpublished studies, that phthalic acids are obtained in this reaction when diamylmercury is replaced by amyl chloride.

Possibly the amylidene disodium of Morton may orient differently from ethylsodium. A pertinent illustration is the different orientation effects of the very closely related phenyl-calcium and phenyl-lithium compounds in metalations.

(8) Gilman and Nelson, *Rec. trav. chim.*, **55**, 518 (1936).

(9) The extent of metalation varies with the R group. A 77% yield of benzoic acid was obtained from benzene and *n*-butylsodium followed by carbonation.[6]

(11) An illustration is the study by C. W. Bradley on the conversion of 1,4-dihydrodibenzofuran by phenyl-lithium to 4-dibenzofuryl-lithium and dibenzofuran.

2.5 cc. of hydrogen and 535 cc. of ethane, all volumes being corrected.

In a second experiment, using 75 cc. of benzene, reaction started slowly and four hours elapsed before an appreciable quantity of mercury separated. The yields were: 45% of benzoic acid and 17% of terephthalic acid.

From a third experiment, which differed from the second only in limiting the time of reaction to twenty hours, the yield of benzoic acid was 33% and the yield of terephthalic acid was 11%. Positive fluorescein tests were also obtained in the second and third experiments.

Metalation with Ethylsodium.—The procedure was identical with the first experiment with ethylpotassium, 1.84 g. (0.08 g. atom) of sodium being used. Reaction set in immediately. The products identified were: 41% of benzoic acid; a small quantity of terephthalic acid (mixed melting point with dimethyl ester); and phthalic acid (as indicated by a positive fluorescein test). The gas evolved contained 12 cc. of ethylene, 10 cc. of hydrogen and 420 cc. of ethane. Incidentally, the limited evolution of ethylene and hydrogen belies any considerable metalation by alkali hydride which arises from the thermal decomposition of ethylalkali compound.[12]

Comparison of the Total Nitrogen in Wheat Seeds by the Gunning (Modified Kjeldahl) and the Dumas Combustion Methods

BY W. Z. HASSID

Smyth and Wilson[1] analyzed peas for total nitrogen before and after germination in distilled water, in salt solution media and in alkaloids. The peas showed an increase of 0.2 to 0.3% nitrogen in the dry residue after germination.

In the opinion of these authors, the increase in nitrogen was not the result of atmospheric nitrogen assimilation, but was due to the inadequacy of the Kjeldahl method to measure the total nitrogen in the ungerminated peas. By the official Kjeldahl procedure only 90% of the total nitrogen as compared with the Dumas combustion method could be obtained, and this varied with different modifications of the official procedure. On the basis of these results, Smyth and Wilson concluded that in the process of germination the nitrogen of the seeds was converted into compounds which were more easily determinable by the Kjeldahl method than those in the dry seeds.

Since Smyth and Wilson's results cast doubt on the validity of the conclusions drawn by Lipman and Taylor[2] and others who obtained similar results relative to the power of green plants to fix atmospheric nitrogen, it seemed desirable to make a study of the modified Gunning method and the Dumas combustion method as a means of determining the nitrogen in seeds and seedlings. To this end, wheat seeds of the "little club" variety were subjected to analysis for total nitrogen by both the modified Gunning and Dumas combustion methods.

TABLE I

N ANALYSIS OF 12 SAMPLES OF WHEAT SEEDS BY THE MODIFIED GUNNING METHOD

Sample no.	Sample wt.	% N	
1	1.0000	2.27	Average 2.25%
2	1.0000	2.20	
3	1.0920	2.18	
4	1.4060	2.25	
5	1.4060	2.25	
6	1.4040	2.27	
7	1.4000	2.25	
8	1.4000	2.25	
9	1.4026	2.25	
10	1.4000	2.20	
11	1.4010	2.30	
12	1.4020	2.31	

N ANALYSIS OF 6 SAMPLES OF WHEAT SEEDS BY THE DUMAS METHOD (COMBUSTION)

Sample no.	Sample wt.	% N	
1	1.0205	2.25	Average 2.28%
2	1.1100	2.27	
3	1.0000	2.28	
4	1.0344	2.31	
5	1.0000	2.30	
6	1.0000	2.29	

A study of the table makes it clear that the modified Gunning method as used in this experiment yields as much nitrogen as the Dumas method for the wheat seeds analyzed. It appears, therefore, that such results as were obtained by Lipman and Taylor and by others who claimed to have shown nitrogen fixation by wheat plants cannot be invalidated on the basis of the results and conclusions of Smyth and Wilson, cited above.

COMMUNICATION TO THE EDITOR

THE STRUCTURES OF THE ACETONE DERIVATIVES OF GALACTOSE-, GLUCOSE- AND MANNOSEDIBENZYLMERCAPTALS

Sir:

In 1929 Brigl and Schinle [*Ber.*, **62,** 1716 (1929)] found that their 2-methylglucose was capable of osazone formation with the loss of the methyl group. This striking discovery cast doubt on the structure of those partially methylated sugars whose formulas had previously been assigned on the assumption, till then unquestioned, that a 2-methyl sugar could not possibly form an osazone. Among those partially methylated sugars affected by this discovery were 4-methylglucose [Pacsu, *ibid.*, **58,** 1455 (1925)], 4-methylmannose [Pacsu and v. Kary, *ibid.*, **62,** 2811 (1929)], and 4-methylgalactose [Pacsu and Löb, *ibid.*, **62,** 3104 (1929)]. Levene and co-workers [Levene, Meyer and Raymund, *Science*, **73,** 291 (1931); *J. Biol. Chem.*, **91,** 497 (1931)] were the first to notice that the supposed 4-methylglucose was identical with 2-methylglucose. In a later publication [Pacsu, *Ber.*, **65,** 51 (1932)] this fact has been confirmed. In the same place it has also been stated that in the light of Brigl's discovery it appears certain that the supposed 4-methylmannose is likewise a 2-methyl derivative, whereas nothing definite could be said as to the structure of the supposed 4-methylgalactose until the necessary revision of the entire problem has been concluded. For the past year this reinvestigation has been in progress in this Laboratory. In a recent publication, Munro and Percival [*J. Chem. Soc.*, 640 (1936)] apparently undertook "A Revision of the Constitutions of the Supposed 4-Methyl Galactose and 4-Methyl Mannose of Pacsu. . ." and stated "The structures of the acetone compounds of the dibenzylmercaptals of glucose, galactose, and mannose, assigned by Pacsu, require revision in the light of the facts now known and this problem is under investigation." This was precisely the conclusion arrived at in my publication (*loc. cit.*), which Munro and Percival doubtless overlooked. Therefore, it is deemed advisable briefly to communicate the results so far obtained with John W. Green during the course of our reinvestigation. We have found that the formerly described crystalline "2,3-monoacetone galactosedibenzylmercaptal" with m. p. 102–103° and $[\alpha]^{18}D$ 8.8° ($C_2H_2Cl_4$), in spite of its apparent uniformity, is not a chemical individual. By repeated fractional crystallization from different solvents we have succeeded in separating this mixture into two monoacetone mercaptals, one with m. p. 112.5° and $[\alpha]^{20}D$ 17.4° ($CHCl_3$), and the other with m. p. 101.5° and $[\alpha]^{20}D$ 30.5° ($CHCl_3$). Neither compound reacts with triphenylmethyl chloride in pyridine solution. Therefore, the OH-group at carbon atom 6 must be occupied in each substance. We have tentatively assigned to them the structure of 5,6- and 4,6-monoacetone galactosedibenzylmercaptal, respectively. By removing the mercaptan residues from one of these compounds in methyl alcoholic solution according to our method which yields glycofuranosides [Pacsu and Green, THIS JOURNAL, **58,** 1723 (1936)], a crystalline, non-reducing substance has been obtained which still contains the acetone residue. The structure of this key compound is being investigated. If the formation of the diacetone mercaptal in the presence of concd. sulfuric acid will prove to have passed through the monoacetone stage, then neither the sirupy diacetone mercaptal, always used as a starting material, nor any of its sirupy derivatives could represent uniform substances. A detailed account of the revisionary work on these derivatives of galactose as well as glucose and mannose will be published as soon as it has been completed.

NEW BOOKS

Differential Equations in Applied Chemistry. By FRANK LAUREN HITCHCOCK, Ph.D., Professor of Mathematics, and CLARK SHOVE ROBINSON, S.M., Associate Professor of Chemical Engineering, Massachusetts Institute of Technology. Second edition, revised and enlarged. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, New York, 1936. viii + 120 pp. 12.5 × 19 cm. Price, $1.50.

A review of the first edition was given in THIS JOURNAL, 46, 1066 (1924). As stated there "The present volume, although frankly limited in its scope, is a splendid introduction to the application of differential equations to chemistry and chemical engineering." The book has been revised, many new examples have been added, and Chapter VI, dealing with "Numerical Solution of Differential Equations," is entirely new. The examples illustrate excellently the value of higher mathematics in the solution of the technical problems, and the reviewer is convinced that even those who have had only an elementary training in calculus will derive considerable stimulation from a study of these examples.

SAUL DUSHMAN

Annual Review of Biochemistry. Vol. V. Edited by JAMES MURRAY LUCK, Stanford University. Annual Review of Biochemistry, Ltd., Stanford University P. O., California, 1936. ix + 640 pp. Illustrated. 16 × 23 cm. Price, $5.00.

This volume contains four new sections as follows: X-ray studies on the structure of compounds of biochemical interest, by O. L. Sponsler and W. H. Dore; Clinical applications of biochemistry, by J. P. Peters, C. L. Robbins and P. H. Lavietes; The role of special elements (boron, copper, zinc, manganese, etc.) in plant nutrition, by P. Maze; and Soil microbiology, by S. A. Waksman.

A considerable number of new authors also appear, and in particular a group of eminent English biochemists, including D. E. Green and D. Keilin on oxidations and reductions; J. H. Quastel who wrote the section on enzymes; W. N. Haworth and E. L. Hirst on carbohydrates and glucosides; T. P. Hilditch on acyclic constituents of natural fats and oils; R. Robison on chemistry and metabolism of compounds of carbon; H. A. Krebs on metabolism of amino acids. In addition, other new contributors include C. Rimington on chemistry of proteins and amino acids; V. du Vigneaud and H. M. Dyer on chemistry and metabolism of compounds of sulfur; I. L. Chaikoff on carbohydrate metabolism; E. F. Terroine on fat metabolism; E. A. Doisy and D. W. MacCorquodale on the hormones; H. von Euler on the water-soluble vitamins; E. V. McCollum on the fat-soluble vitamins; A. J. Kluyver on bacterial metabolism; Hart and Elvehjem on mineral metabolism; A. C. Ivy and L. A. Crandall, Jr., on liver and bile; J. Roche on animal pigments; G. T. Nightingale on the biochemistry of the nitrogenous constituents of the green plants.

Several of the former contributors again prepared four sections. As heretofore, certain phases covered in earlier volumes are not included in volume V. On pages vii and viii appear the errata for volume I to IV, inclusive, the small number of which are a tribute to the careful work of the editorial staff.

The new sections are very appropriate and come from responsible sources. All the contributors have been carefully selected, in fact, and each is qualified to discuss the subject to which he is assigned. While the resulting reviews inevitably, and doubtless properly, reflect the individual interests of the reviewer somewhat, the changes in the staff of authors that are made from year to year militate against any overemphasis on particular aspects of the several subjects.

C. H. BAILEY

Handbuch der biologischen Arbeitsmethoden. (Handbook of Biological Procedures.) Edited by Prof. Dr. EMIL ABDERHALDEN. Abt. IV, Angewandte chemische und physikalische Methoden, Teil $^1/_2$, Heft 10 (Schluss). Fermentforschung. Urban & Schwarzenberg, Friedrichstrasse 105B, Berlin, N 24, Germany, 1936. 205 pp. 17.5 × 25.5 cm. Price, RM. 13.

This volume includes a comprehensive review on pectinases, the isolation of crystalline trypsinogen and its change to crystalline trypsin, demonstration of protective enzymes, and amylases. The treatment of pectinases by Felix Ehrlich is very thorough and complete. The author gives a good discussion of the nature, occurrence, and properties of protopectinase, pectase, pectolase, and arabanase. Methods of preparing the various enzyme infusions and the qualitative and quantitative analyses of these infusions are presented.

M. Kunitz and J. H. Northrop describe an improved method for the preparation of crystalline trypsin from crystalline trypsinogen. Complete details of the methods used are given.

The literature on amylases has been reviewed by T. Sabalitschka. This review consisting of 85 pages covers the degradation of starch by amylase, the influence of various factors such as temperature, *p*H and enzyme activity.

The various methods of determining amylase activity are discussed and methods of obtaining and purifying amylases and the properties of the various amylases are described. While the review is thorough and comprehensive in most respects, one is surprised to find that there is no reference to the literature or any discussion on the phenomenon of the action of diastase on raw starch. This is a subject of increasing importance in the malting, baking and brewing industries. Many of the analytical methods described in the review are open to serious criticism. The reviewers believe that this work would be of greater value if presented in a more critical manner.

Emil Abderhalden discusses the simplification of the methodology of demonstrating protective protease activity. The role of these enzymes in connection with the problems of immunity is discussed. He also discusses the demonstration of protective proteases without employing dialysis or using the usual ninhydrine technique. Several other improvements in methods are also given.

The volume has a complete index and table of contents.

C. N. FREY
W. R. JOHNSTON

Die Photoelemente und ihre Anwendung. 2 Teil. **Technische Anwendung.** (Photo-Cells and their Uses Part 2. Industrial Application.) By Dr. BRUNO LANGE, Berlin. Preface by Dr. Hans Thirring. Verlag Johann Ambrosius Barth, Salomonstrasse 18 B, Leipzig C 1, Germany, 1936. viii + 94 pp. 67 figs. 16 × 23.5 cm. Price, RM. 6.75.

In this second part of Dr. Lange's treatise, numerous practical applications of photo-cells are recorded. Most of the apparatus described and illustrated was designed by the author himself.

Dr. Lange is primarily interested in the cuprous oxide cell, and those of similar type. Very little space is devoted to the cesium cell. Accordingly, applications of the photo-cell to television, the talking moving pictures, etc., are not specifically included in the "technische Anwendungen."

After general discussion of cell construction, sensitivity, effect of temperature, etc., the applications are discussed under the following headings: "Determination of Light Intensity," "Photography," "The Photoelectric Cell in Photometry," "The Photoelectric Cell in Signal Devices," "Applications—in Astronomy, in Meteorology, in Medicine," and, finally, a few lines on the conversion of sun energy into electrical energy. The author closes with the statement, "Perhaps in years to come, when we know more about the inter-relation between light and electricity, this application of the photo-cell will be the most important of all."

The text is very readable and the illustrations very clear and instructive.

Dr. Bruno Lange is visiting the United States this fall.

COLIN G. FINK

A Comprehensive Treatise on Inorganic and Theoretical Chemistry. Vol. XV. **Ni, Ru, Rh, Pd, Os, Ir.** By J. W. MELLOR, D.Sc., F.R.S. Longmans, Green and Company, 114 Fifth Avenue, New York, N. Y., 1936. viii + 816 pp. 423 figs. 15.5 × 25 cm. Price, $20.00.

The first 497 pages of this volume are given over to the chemistry of nickel; the remaining 319 pages to the chemistry of the elements of the platinum group, exclusive of platinum itself, and to an Index. The treatment follows that of the preceding volumes of the series and affords a very complete presentation of all the available information in these fields. It is enriched with an unusually large number of excellent diagrams.

This volume is the next to the last of the series. The final volume will be devoted to the chemistry of platinum and to the General Index of the Treatise. The publishers announce that it is already in the press.

ARTHUR B. LAMB

Die Interferenzen von Röntgen- und Elektronenstrahlen. (The Interference of X-Rays and Cathode Rays.) Five lectures by M. v. LAUE, Professor at the University of Berlin. Verlag von Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1935. 46 pp. 15 figs. 14.5 × 22 cm. Price, RM 3.60.

The book presents a brief outline of the dynamical theory of x-ray diffraction using the author's method of derivation, and making connection with the wave mechanical method of treatment. Kossel's interference of x-rays generated within a single crystal is explained in terms of the theory, and the connection with the Kikuchi lines is discussed. The mathematical development is omitted.

The System Cadmium Oxalate, Potassium Oxalate and Water at 20 to 30°

BY W. C. VOSBURGH, IRA G. NEWLIN, LUCILLE A. PUETTE, ROBERT L. PECK AND ROBERT DICK

The purpose of this research was to determine what compounds can exist in equilibrium with solutions containing cadmium and potassium oxalates at 20 to 30°. Souchay and Lenssen[1] prepared the compound $K_2Cd(C_2O_4)_2 \cdot 2H_2O$, and the corresponding sodium and ammonium compounds. Schaefer[2] reported the formation of three complex salts from cadmium and ammonium oxalates in the proportions of 1:4, 1:6 and 1:8, respectively. Scholder, Gadenne and Niemann[3] prepared the salt $(NH_4)_2Cd_3(C_2O_4)_4 \cdot xH_2O$. In this investigation two complex salts were found to exist in equilibrium with saturated solutions containing an excess of potassium oxalate, namely, the compounds $K_2Cd(C_2O_4)_2 \cdot 3H_2O$ (or $K_2Cd(C_2O_4)_2 \cdot 4H_2O$) and $K_2Cd_3(C_2O_4)_4 \cdot xH_2O$ where x is uncertain.

Cadmium oxalate was prepared by slow precipitation from C. P. cadmium chloride and potassium oxalate. A complex salt was prepared by dissolving some cadmium oxalate in a hot 15 to 25% solution of potassium oxalate and allowing it to cool, when the complex salt crystallized out. The quantity of cadmium oxalate was adjusted so that the solution would contain more than 7% potassium oxalate at the end. This complex salt proved to be the compound $K_2Cd(C_2O_4)_2 \cdot 3H_2O$. Solubility experiments with this compound and with cadmium oxalate indicated the existence of a second complex salt capable of existing in equilibrium with solutions containing between 2.3 and 7.1% of potassium oxalate. By slow addition of cadmium chloride solution to a 7% potassium oxalate solution the second complex salt was precipitated. The precipitation was discontinued when the potassium oxalate content of the solution had been reduced to about 3%.

Mixtures consisting of a potassium oxalate solution and either cadmium oxalate or the appropriate complex salt were sealed in Pyrex tubes and rotated for two days or more. The solution was then separated from the wet solid phase in a manner previously described[4] and both were analyzed. Cadmium was determined electrolytically and oxalate by titration with permanganate. Many of the mixtures were made in duplicate and the analyses performed after different times of rotation. It was important that the proper solid phase be introduced at the start because otherwise the approach to equilibrium was very slow.

In most of the experiments the solutions were saturated at 25°. However, the solubilities of cadmium oxalate and the complex salts in potassium oxalate solutions is small, and the variation with temperature between 20 and 30° (and with concentration) was less than the experimental error; therefore, some of the solutions were saturated at 30° and some at temperatures between 20 and 25°.

The results are given in Table I and Fig. 1. The small values for the concentration of cadmium

oxalate in the saturated solutions are omitted from the table. They were of the order of 0.15% and subject to a large relative error. In the last column of Table I the letter A stands for cadmium oxalate, $CdC_2O_4 \cdot 3H_2O$, B for the compound $K_2Cd_3(C_2O_4)_4 \cdot xH_2O$, C for the compound $K_2Cd(C_2O_4)_2 \cdot yH_2O$ and D for hydrated potassium oxalate. The percentage of water in the dry solid in the fourth column of Table I was found by algebraic extrapolation with the assumption of the formulas $K_2Cd_3(C_2O_4)_4 \cdot xH_2O$ and $K_2Cd(C_2O_4)_2 \cdot yH_2O$.

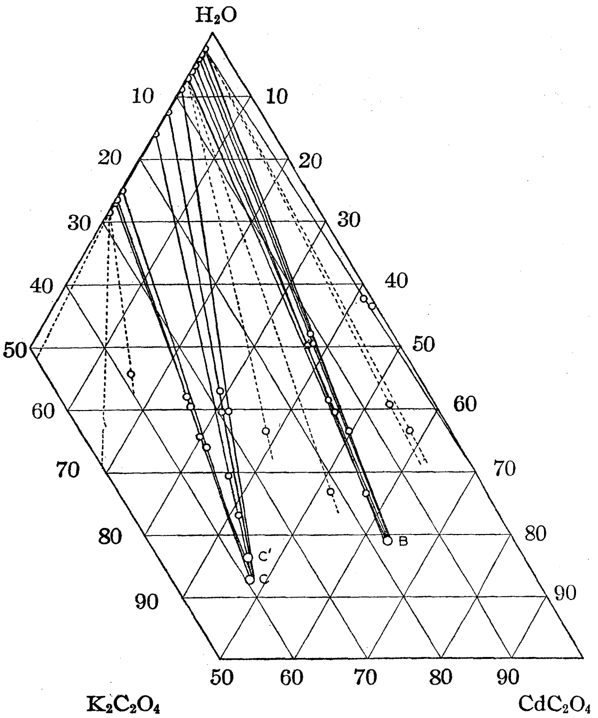

Fig. 1.—The system cadmium oxalate, potassium oxalate and water at 20 to 30°. Point B represents the composition calculated from the formula $K_2Cd_3(C_2O_4)_4 \cdot 10H_2O$ and points C and C′ the compositions calculated from the formulas $K_2Cd(C_2O_4)_2 \cdot 3H_2O$ and $K_2Cd(C_2O_4)_2 \cdot 4H_2O$.

TABLE I

COMPOSITION OF SATURATED SOLUTIONS AND SOLID PHASES

Solution	Wet solid		Dry solid	
$K_2C_2O_4$ wt. %	$K_2C_2O_4$ wt. %	CdC_2O_4 wt. %	H_2O wt. %	Solid
2.28	0.46	43.16	..	A
2.25	1.05	41.35	..	A
2.31	5.54	57.90	..	A + B
2.24	6.20	53.06	..	A + B
2.35	13.82	49.64	34	B
3.10	11.17	36.78	31	B
3.87	11.60	37.80	31	B
3.80	15.96	53.57	2	B
4.67	12.24	37.19	18	B
4.89	12.51	37.34	13	B
4.89	14.11	44.40	9	B
5.77	11.64	33.83	27	B
5.86	14.13	46.32	13	B
6.87	16.60	56.82	17	B
7.11	25.18	38.26	..	B + C
7.06	21.35	51.75	..	B + C
8.59	28.50	31.77	22.2	C
12.29	27.95	29.00	22.1	C
12.39	29.46	30.91	17.9	C
15.73	33.73	36.77	15.2	C
15.87	35.67	41.19	16.7	C
24.75	34.51	31.52	12.7	C
26.25	34.48	29.79	13.1	C
26.66	33.05	24.81	14.6	C
26.79	33.44	26.09	14.6	C
28.20	50.30	18.98	..	C + D
28.37	38.68	15.57	..	C + D
28.73	77.66	3.53	..	C + D

The percentage of water found by algebraic extrapolation for both compounds is uncertain. For compound C the first three values are subject to the largest extrapolation error, and if these three are neglected the average lies between 12.85%, which is the theoretical value for $y = 3$ and 16.43% for $y = 4$. Of the two, the value $y = 3$ is more probable because positive errors in the determination of cadmium would lead to a high value for y, and a check of the method of determining cadmium on known samples gave somewhat high results.

Summary

The compound $K_2Cd_3(C_2O_4)_4 \cdot xH_2O$ in which x is uncertain but may be as high as 10 can exist in equilibrium with solutions containing between 2.3 and 7.1% of potassium oxalate. The compound $K_2Cd(C_2O_4)_2 \cdot yH_2O$, in which y is probably 3, can exist in equilibrium with solutions from 7.1% of potassium oxalate to saturation. At temperatures of 20 to 30° the solubility of both compounds is small.

Thermodynamic Properties of the Tellurides of Zinc, Cadmium, Tin and Lead

BY J. H. MCATEER[1] AND HARRY SELTZ

Introduction

The application of reversible galvanic cells to the study of the thermodynamic properties of compounds at higher temperatures has been made recently by Ölander,[2] who has studied a number of intermetallic compounds in the neighborhood of 250° using a mixture of fused acetates for an electrolyte. Seltz and DeHaven[3] have studied extensively the thermodynamic properties of cadmium antimonide (CdSb) over a rather large temperature range. The use as an electrolyte of a eutectic mixture of potassium and lithium chlorides to which was added a small amount of cadmium chloride enabled them to make observations from 390 to 440°.

Their results have shown that measurements of the electromotive force at various temperatures of cells of the type

$$\mathrm{A(s\ or\ l)}\ |\ \mathrm{A}^{\nu+}\ |\ \mathrm{A}_x\mathrm{B}_y\mathrm{(s)} + \mathrm{B(s)}$$

permit the calculation of the thermodynamic properties of the reaction.

$$x\mathrm{A(s\ or\ l)} + y\mathrm{B(s)} = A_xB_y\mathrm{(s)}$$

It is necessary, of course, that the metal electrode A have a higher electrode potential in the fused electrolyte than that of the element B. It will be noticed also that no measurements can be taken above the eutectic temperature of the compound and pure B constituent. For any system which involves an equilibrium between the solid compound and a solid solution of A in B it would be necessary to know the activity of B in the solid solution in order to determine the free energy change for the above reaction. It is obvious that a change in concentration of the metal ions in the electrolyte or the amount of the second pure constituent in equilibrium with the solid compound will have no effect upon the electromotive force of the cell.

The results of a study of the tellurides of zinc, cadmium, tin and lead by these methods are presented in this paper. Each of the four metals was substituted for the A constituent and tellurium formed the B constituent. The eutectic temperatures of the various tellurides and pure tellurium were obtained from the phase diagrams[4] of these metals with tellurium.

Experimental

Purification of Materials.—Silver-free lead was purified by electrodeposition from a fluosilicic acid bath. Baker "C. P. analyzed" cadmium, tin and lead were used without further purification. Each metal was cast into sticks under a molten mixture of lithium chloride and potassium chloride. This effectively removed any oxide from the metal.

C. P. tellurium was further purified by dissolving it in concentrated nitric acid, evaporating to dryness and then adding concentrated hydrochloric acid. After diluting this solution the insoluble material was removed and the tellurium was precipitated by the addition of sodium bisulfite. The tellurium was converted into telluric acid which, after three or four crystallizations from concentrated nitric acid, was reduced to free tellurium. The purified substance was then melted in an atmosphere of hydrogen.

Baker "C. P. analyzed" zinc chloride, cadmium chloride and lead chloride were used without further purification. These salts were fused, cast into sticks and kept in an oven at 100° until used. Stannous chloride was prepared by passing dry hydrogen chloride over molten tin and then subliming the product in a stream of carbon dioxide. The sublimed stannous chloride was kept in a desiccator. C. P. lithium chloride and potassium chloride were kept dry in an oven until used. In making the electrolyte the correct quantities of lithium chloride and potassium chloride were weighed and melted. Varying amounts of zinc, cadmium, tin or lead chloride were added to this molten mixture which was then cast into sticks and kept in an oven.

Preparation of Electrodes.—The electrodes containing the telluride were formed by melting weighed amounts of the metal and tellurium in a 6-mm. Pyrex tube under a hydrogen atmosphere. Varying amounts of tellurium in excess of that required to react with the metal were used. After the compound had dissolved completely in the molten excess tellurium, a tungsten lead, which will be described below, was inserted and the material permitted to solidify. When the electrode had cooled, the glass tubing was carefully chipped away and the electrode, now firmly attached to the tungsten tip, was removed.

Cadmium, tin and lead are liquids at the temperatures employed. The pure metal electrodes were made by melting the metals in the cells under the molten electrolyte. The tungsten leads were then immersed in the liquid

metals. The pure solid zinc electrodes were made in the same manner as the telluride electrodes.

All leads consisted of tungsten wire which was welded to the copper potentiometer leads some distance from the furnace in which the measurements were made. The union at this point prevented the occurrence of thermal electromotive forces at the copper–tungsten junctions. The tungsten leads were sealed in 3-mm. Pyrex tubing in such a manner that only 2 or 3 mm. projected. This prevented contact of the leads with the electrolyte. During the process of sealing the leads in the glass a coating of oxide invariably formed on the small projecting tips. This was removed by treating with molten potassium pyrosulfate and then, after cooling, with a concentrated caustic solution. The tungsten tips were wound into the form of a small helix to ensure a tight connection with the solid electrodes.

Procedure.—The apparatus used was similar to that of Seltz and DeHaven[3] with the exception that the furnace was fitted with an iron cylinder containing a low melting mixture of lead, tin and bismuth. In this were placed the cells and thermocouple. It was impossible to detect with this arrangement any temperature gradients. The thermocouple was incased in Pyrex tubing to which a small Kipp hydrogen generator was attached. This precaution prevented oxidation and subsequent deterioration of the hot junction. The temperature lag of the thermocouple was negligible.

The necessary amount of electrolyte was melted in an H-cell by means of a Meker burner. About 2 g. of pure metal was placed in one leg. After the metal had melted, the tungsten lead was inserted and adjusted to the proper position. The gas flame was then removed, the solid telluride electrode introduced in the other leg and the cell placed in the furnace. The cell was evacuated slowly for an hour to a final pressure of 0.05 mm. of mercury. This slow evacuation prevented violent bumping caused by gas bubbles escaping from the molten electrode and electrolyte. Usually after three hours all gassing had ceased and the cell was found to have reached equilibrium. In some series of measurements pumping was continued throughout the run while in others, after complete evacuation, carbon dioxide was admitted. The results obtained with the carbon dioxide atmosphere were concordant with those obtained under vacuum except in the cells which were used for the study of tin telluride.

In the study of tin telluride the vacuum technique had to be modified since a loss of the stannous chloride occurred owing to its volatility under reduced pressures at these temperatures. For this reason an atmosphere of carbon dioxide was used exclusively. The stannous chloride was not added to the electrolyte until the initial three-hour period of pumping had been completed. Measurements were made also with cells containing pure stannous chloride as an electrolyte. These cells functioned satisfactorily even in the presence of air.

Simultaneous readings of the electromotive force and the temperature were taken from the melting point of the electrolyte to the limiting eutectic temperature except in the case of zinc telluride where readings were carried only to the melting point of zinc. The cells responded rapidly to variations in temperature, but to ensure equilibrium the temperature was never permitted to change by more than fifteen degrees an hour.

Results and Calculations

The observed values of the electromotive force are contained in Table I. The weight per cent. of the total amount of tellurium in the telluride electrode is given together with the type of atmosphere within the cell. The results appear to be correct within ±0.2 mv. at each temperature except for the measurements on zinc telluride where the limit of error is more nearly ±0.3 mv. The temperature readings can be considered accurate to within ±0.5°. These data are plotted in Fig. 1. From large scale reproductions of the

figures the values of the electromotive force at a given temperature and dE/dT have been obtained. It will be noticed that in all cases the electromotive force–temperature curves are straight lines within the limits of experimental error.

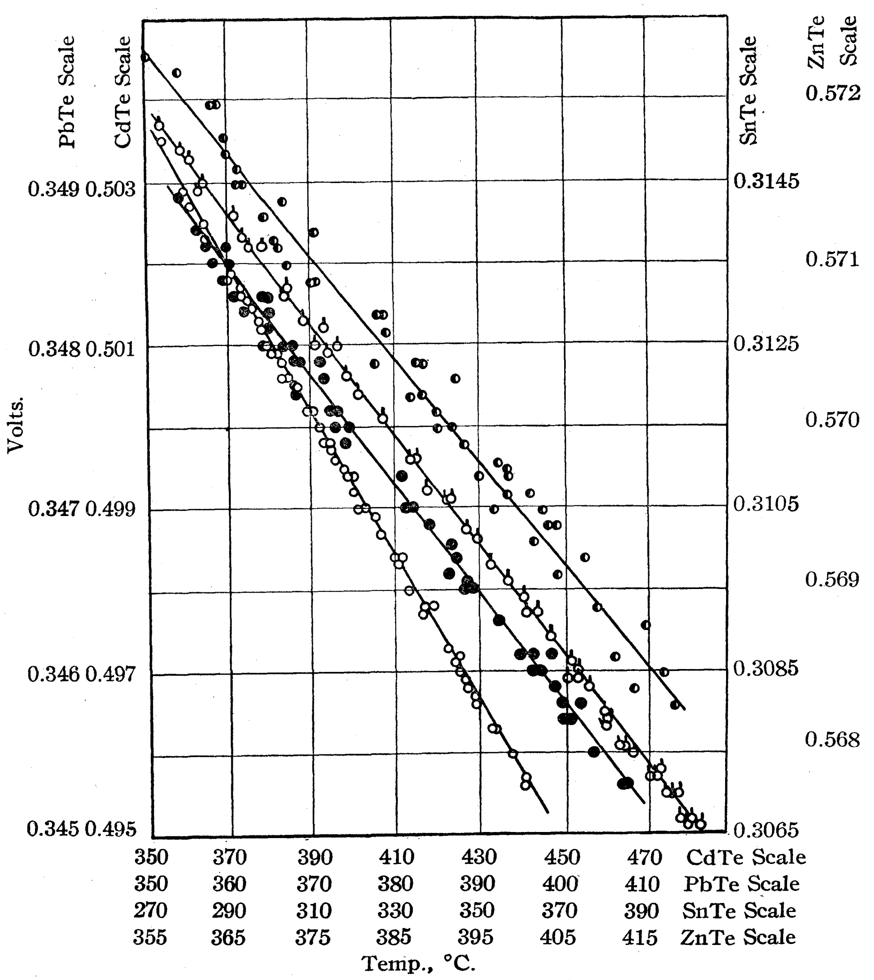

Fig. 1.—E. m. f. curves: ○, CdTe Cells; ●, PbTe Cells; ọ́, SnTe Cells; ◐, ZnTe Cells.

The free energy change, ΔF, of a cell reaction at any given temperature is related to the reversible electromotive force, E, of the cell by the equation $\Delta F = -nFE$ where n is the number of equivalents involved and F is the value of the faraday (23,074 cal. per volt equivalent). In this study all substances involved in the reactions are at their standard states (activity equal to unity) and the free energy change becomes the standard free energy change $\Delta F°$. The value of $\Delta F°$ may be expressed as a function of the temperature if the heat of reaction, ΔH, is known. This quantity may be evaluated with the aid of the Gibbs–Helmholtz equation, $\Delta H = nF \times (T\,(\mathrm{d}E/\mathrm{d}T) - E)$. If the change in heat capacity, ΔC_p, is small the value of ΔH will be nearly independent of the temperature and $\Delta F°$ at any temperature will be given by the equation $\Delta F° = \Delta H + IT$ where I is a constant of integration. The entropy change for the reaction may be calculated from the fundamental relation $\Delta F° = \Delta H - T\Delta S$.

The results of the calculations for the various tellurides are summarized in Table II. The heats of fusion used for cadmium, tin and lead were 1254, 1594 and 1228[5] cal. per gram atom, respectively.

Discussion

The cells studied in this investigation functioned reversibly and the electromotive forces were quite reproducible. Changes in composition of the electrolyte and in the amounts of tellurium in equilibrium with the solid tellurides had no effect upon the electromotive forces of the cells. The consistent data of Table I for cells in which the zinc electrode was replaced by a zinc–zinc telluride electrode also indicate the reversibility of the cell reaction.

TABLE II

THERMODYNAMIC PROPERTIES OF THE TELLURIDES AT 25°

Reaction	$\Delta F°$, cal.	ΔS, cal./°C.	ΔH, cal.	ΔH, cal. (Fabre)
$Zn(s) + Te(s) = ZnTe(s)$	−27,360	−2.9	−28,210	−33,200
$Cd(s) + Te(s) = CdTe(s)$	−23,950	−2.0	−24,530	−15,800
$Sn(\gamma) + Te(s) = SnTe(s)$	−14,660	0.0	−14,650	.....
$Pb(s) + Te(s) = PbTe(s)$	−16,590	−1.0	−16,810	− 5500

The limits of error for the values tabulated in Table II depend somewhat on the calorimetric data which have been employed. The deviations in the values of the electromotive force of the cells and of dE/dT lead to an uncertainty of

---

(5) "I. C. T.," Vol. II, p. 458.

about ±50 cal. The probable errors in the heats of fusion amount to about ±40 cal. and the assumption that Kopp's law can be applied to these tellurides might introduce an error of not more than ±30 cal.

The calculations at 25° for tin telluride have been made using the γ form of the metal. Apparently this form is stable above 161° and consequently is not stable at 25°. Unfortunately no data on the heat of transition exist so that it is impossible to make calculations for the compound using the allotropic modification which is stable at 25°. The question of the existence of tellurium in two allotropic forms has been raised by S. Umino,[6] who in measuring the specific heat of tellurium up to 550° reported a transition at 348° accompanied by the absorption of 630 cal. per gram atom. However, no other investigator has mentioned this behavior and Simek and Stehlek[7] were unable to confirm his results. For this reason it has been assumed that no transition occurs. No data are available for the entropy of tellurium. Consequently the entropies of the tellurides have not been calculated.

No other measurements of the thermodynamic properties of the tellurides have been reported except those of Fabre[8] on the heats of formation. His results which were obtained by a calorimetric method are tabulated in Table VII. They are not, as will be seen, in agreement with the present values. A review of his work, however, indicates that his results may be unreliable owing to the uncertainty of some of the thermal values he used to calculate the heats of formation. Lack of data prevents recalculation of these values.

Summary

1. A potentiometric study of the tellurides of zinc, cadmium, tin and lead has been made at higher temperatures using fused salt electrolytes.

2. The method has been shown to give results which are reliable and accurate when applied to the proper substances.

3. The data thus obtained have been employed in calculating the free energies of formation, heats of formation and entropies of formation at 25°.

A Thermodynamic Study of the Lead–Bismuth System

BY H. S. STRICKLER[1] AND HARRY SELTZ

Although the properties of the alloys of lead and bismuth have been investigated extensively, the phase diagram of the system is not well established. In the "International Critical Tables"[2] diagram, two series (α and β) of solid solutions forming a eutectic at 58 weight per cent. bismuth are shown. The limits of solubility are 18 and 99% bismuth at 0° and 37 and 97.3% bismuth at 125°, the eutectic temperature. References cited for this are Guertler[3] and Herold,[4] from whose critical reviews it is evident that the limits of solubility and the solidus curves are not too well defined. Furthermore, Solomon and Jones,[5] studying alloys of this system by means of x-rays, have found recently a new solid solution phase existing from 25 to 33% bismuth.

In the present work, thermodynamic data obtained from measurements of galvanic cells of the general form Pb/Pb^{++}/Pb (in Pb–Bi solution) have been used to calculate a considerable portion of the phase diagram, making use of the methods previously proposed by Seltz.[6]

Experimental

The cells used were of the three types:

I. Pb(l)/$PbCl_2$ in LiCl–KCl(l)/Pb(in Pb–Bi liquid solution)

IIa. Pb(s)/$Pb(OAc)_2$–NaOAc(l)/Pb(in Pb–Bi liquid solution)

IIb. Pb(s)/$Pb(OAc)_2$–NaOAc(l)/Pb(in Pb–Bi equilib. liquid and solid solutions)

III. Pb(s)/$Pb(OAc)_2$–NaOAc(l)/Pb(in Pb–Bi solid solution)

---

[6] Seltz, THIS JOURNAL, **56**, 307 (1934); **57**, 391 (1935).

The liquid alloys of this system have been studied by Wagner and Engelhardt,[7] who determined the electromotive forces of cells Pb(l)/KCl–$PbCl_2$(l)/Pb(in Pb–Bi liquid solution) at two temperatures, 475 and 665°. Since no reliable values of the relative partial molal heat contents could be obtained from their data, it was necessary to study cells of Type I in the present investigation.

The metals used were purified electrolytically, the lead being plated from a Betts[8] bath and the bismuth by a method described by Swift.[9] Before use, the metals were cast under oil and then *in vacuo*. The electrolytes were prepared from commercial "chemically pure" materials without further purification.

The cells of Type I were studied over the temperature range 380–470°, with variation of the composition from $N_{Bi} = 0.15$ to 0.89. The technique employed was, with modifications, that used by Seltz and DeHaven[10] in their study of the intermetallic compound CdSb. The pure metal was placed in one leg of a Pyrex H-cell containing the electrolyte and the weighed alloy constituents in the other. The electrolyte was the molten eutectic mixture of lithium and potassium chlorides, to which a small amount of lead chloride was added. Contact with the metals was made by tips of tungsten wire sealed into Pyrex tubing, the connections to the potentiometer being made by copper wire welded to the tungsten where it extended from the cell. The system was evacuated by means of a Cenco Hyvac pump. The cell was placed in an electrically heated furnace, manually controlled. Temperatures were determined by means of an iron–constantan thermocouple. A Leeds and Northrup type K potentiometer in conjunction with a Fritz Koehler galvanometer was used. The attainment of equilibrium was quite rapid and the cells were exceedingly steady and reproducible. The experimental results are given in Table I and are plotted in Fig. 1. The reaction occurring in these cells was the transfer of lead from the pure liquid state to a solution of a definite composition, Pb(l) = Pb(in Pb–Bi liquid solution). The free energy change of this reaction is given by the relation $\Delta F = -nFE$, and the activity (a_1) of lead in the alloy referred to the pure liquid as a standard state is then obtained from $-nFE = \Delta F = RT \ln a_1$. The change of heat content in the process is calculated from the Gibbs–Helmholtz equation $T\,dE/dT = E + (\Delta H/nF)$ and the electromotive force E of the cell at a given temperature T. ΔH is here the difference between the partial molal heat content of lead in the alloy and the molal heat content of liquid lead, and is designated as the relative partial molal heat content,[11] $\bar{L}$. The

The corresponding quantities for the second component, bismuth, were obtained by graphical integration of the Duhem equation

$$\int_0^{\bar{L}_2} \mathrm{d}\bar{L}_2 = -\int_0^{N_1/N_2} N_1/N_2 \, \mathrm{d}\bar{L}_1$$

and

$$\int_0^{\log a_2/N_2} \mathrm{d} \log a_2/N_2 = \int_0^{N_1/N_2} N_1/N_2 \, \mathrm{d} \log a_1/N_1$$

The calculated terms, with those for lead at rounded mole fractions, are given in Table III.

Study of the Eutectic.—In order to determine the limits of solubility and the eutectic composition, cells of types IIa and IIb were studied from 200 to 120°, the maximum temperature range over which the mixture of lead and sodium acetates could be used safely. The composition was varied from $N_{\mathrm{Bi}} = 0.337$ to 0.995. The experimental technique differed considerably from that previously described. The lead electrode was generally lead plated on tungsten, using a bath described by Getman,[12] though in some cases bulk electrodes, cast in the same manner as the solid alloys, were used. The alloy constituents were first melted together under mineral oil or *in vacuo*, after which the alloy button was placed under the electrolyte in the cell, which was a 25-cm. test-tube blown out at the bottom to form a depression in which the molten alloy could rest. In preparing the electrolyte, the trihydrates of lead and sodium acetates were melted together in the proportions $3\mathrm{Pb(OAc)_2 \cdot NaOAc}$, the mixture then being dehydrated. Contact with the alloy was made by means of a tungsten lead as used for the higher temperature work. In these runs, the system was not evacuated, because of the increased deterioration of the electrolyte under such conditions. The type K potentiometer was used as before, with a sensitive type R Leeds and Northrup galvanometer. The cells were placed in an electrically heated oil-bath which, when desired, was thermostated by a mercury regulator and an Aminco supersensitive relay. Temperatures were measured by means of a copper–constantan thermocouple.

In the course of a run, the temperature was raised above the liquidus of the alloy, when the tungsten lead was fixed in position. Equilibrium was usually attained rapidly, after which the temperature was lowered. In only a few cases was the range of temperature above the liquidus sufficient to permit accurate measurement of the temperature coefficient for the determination of the heat content change. The first separation of solid was marked by a change in slope of the electromotive force–temperature curve, and then the temperature was decreased more slowly, at a rate of 2–4° per hour. However, the temperature was usually maintained constant for twelve hours or more at the eutectic temperature and frequently at higher temperatures. The electromotive forces then observed are designated by an asterisk. In Table IV data are given only at intervals of 5 to 10°.

In the interpretation of these data, it must be remembered that within the heterogeneous region of the system the α and β phases are in thermodynamic equilibrium, whence at a given temperature $a_{\mathrm{Pb}(\alpha)} = a_{\mathrm{Pb}(\beta)}$ and $a_{\mathrm{Bi}(\alpha)} = a_{\mathrm{Bi}(\beta)}$. Therefore, the electromotive forces of two cells $\mathrm{Pb(s)/Pb^{++}/Pb(\alpha)}$ and $\mathrm{Pb(s)/Pb^{++}/Pb(\beta)}$ should be identical if the α and β compositions correspond to the limits of the heterogeneous range. Thus every cell in which the alloy electrode contains the solid eutectic must show the same electromotive force (E_e) at the eutectic temperature, and E_e should also be the electromotive force of the cell $\mathrm{Pb(s)/Pb^{++}/Pb}$(liquid eutectic) at that temperature. A summary of the electromotive forces

---

(12) Getman, THIS JOURNAL, **38**, 792 (1916).

observed for the various compositions at the eutectic temperature is given in Table V. From these data it is evident that the solubility of lead in bismuth is very small at this temperature, certainly $N_{Pb} < 0.005$. This value agrees well with that obtained by Herold[4] in his metallographical work, but is less than the values obtained by other investigators. On the lead side, the limit of solubility is seen to be very close to N_{Bi} = 0.360, and from the shape of the activity curve at this temperature, the limit is determined as N_{Bi} = 0.365, which is in fair agreement with the "Critical Tables" diagram.

.564	125.3	13.48*
.638	124.0	13.30
.995	124.8	13.38*

From the chosen value for E_e, 13.40 mv., the activity of lead in the eutectic is calculated to be 0.457, referred to solid lead as the standard state. In order to find the activity referred to pure liquid lead, it is necessary to calculate the activity at this temperature of liquid lead relative to the solid. At 600°K. (327°C.), the melting point of lead, the activity is unity, for there the fugacities are identical. Therefore, the equation

$$R \ln a = \bar{L}/T + \text{const.}$$

becomes at that temperature

$$0 = L/600 + \text{const.}$$

it being assumed that the heat of fusion of lead does not change with temperature, accurate thermal data for any other treatment being lacking. Using the value 1161 cal. for the heat of fusion from the "International Critical Tables," and calculating at the eutectic temperature, one obtains the value 1.641 for the activity of liquid lead relative to the solid. On dividing 0.457 by this figure, one obtains 0.279 for the activity of lead in the eutectic (a_e) with reference to liquid lead.

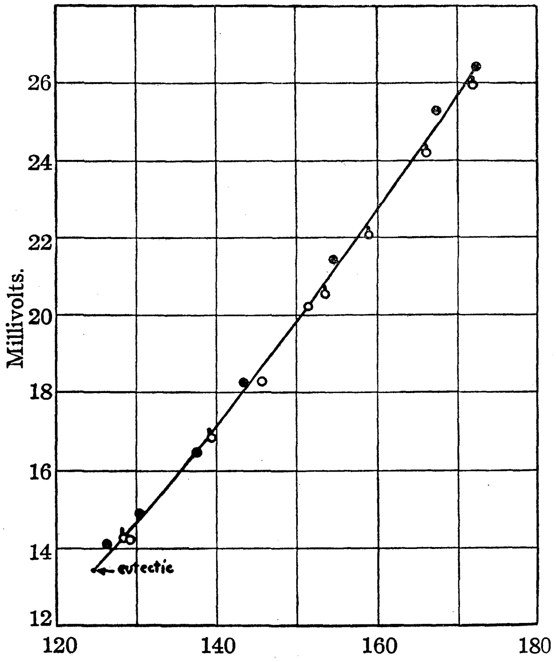

Fig. 2.—E. m. f. curve for type II-b cells: ○, N_{Bi} = 0.636; ●, N_{Bi} = 0.987; ȯ, N_{Bi} = 0.995.

The eutectic composition is now fixed within the limits of error of the computation, by comparing this a_e with values extrapolated, for different compositions, from the activity data for the liquid alloys. The necessary data are

$$N_2 = 0.510,\ a_1 = 0.320$$
$$N_2 = 0.540,\ a_1 = 0.283$$
$$N_2 = 0.563,\ a_1 = 0.257$$

Plotting activity *versus* mole fraction, one finds graphically the composition corresponding to a_e to be N_2 = 0.544. The accuracy of this calculation was checked experimentally by determining the behavior of alloys whose compositions were close to the above value. The data for these confirmatory runs are given in Table VI.

The eutectic composition is thus determined at N_{Bi} = 0.547 (54.9 wt.%), in excellent agreement with the calculated value, considering the lengthy extrapolation of the liquid data. From the intersection of the electromotive force–temperature curves for the eutectic composition in the liquid and solid states, the eutectic temperature is found to be 125°, confirming the previously accepted value. The values of the eutectic composition as determined by other investigators vary, but in general are somewhat higher, the "Critical Tables" diagram giving the value 58%, while Guertler[3] lists 55.8% (Kapp[13]) and 56.5% is the value accepted by Herold[4] from Barlow's[14] data.

region were evidently for cells of Type IIb. If the two solutions, solid and liquid, composing the alloys under these conditions were in equilibrium, then the same electromotive force should be observed in different runs (on the same side of the eutectic) at the same temperature. As the data and Figs. 2 and 3 show, this has been realized approximately. If the liquidus data obtained by thermal analysis are correct, the activity at a given temperature can be calculated from the data of the study of the liquid alloys, and some further idea as to the attainment of equilibrium in the cooling process can be obtained. A few of these calculations are tabulated in Table VII. The liquidus data of Barlow were employed, and the usual extrapolations and conversions to the same reference state (here solid) were made. The agreement is fair with the exception of the value at 63.5%. However, it is probable that Barlow's determination of the liquidus was here at fault, as will be indicated later.

Study of the Solid Phases.—In the investigation of the cells of Type III, the chief difficulty encountered was in obtaining homogeneous electrodes. Further, the probable existence of solid phases other than α complicated the interpretation of some of the data. The range of composition covered was from $N_{\text{Bi}} = 0.05$ to 0.33. The experimental arrangement was that used in the investigation of the eutectic. The electrolyte was also the same. The cells were merely Pyrex test-tubes of various sizes, depending on the number and dimensions of the electrodes placed at one time in the cell. The preparation of the alloys was, however, entirely different. It was found most convenient to cast and anneal the alloys *in vacuo* in Pyrex glass containers. These containers or electrode forms were of two types, constructed as follows. For the simpler variety, a 30-cm. piece of 5-mm. Pyrex tubing was partially constricted in the oxy-gas flame about 7 cm. from one end. Into this was slipped a length of tungsten wire, one end of which was wound into a spiral. The spiral was placed about 3 mm. from the constriction and the wire was then sealed into the glass. The short end of the tube was then bent at right angles. The other type of form was of more complex construction. A piece of Pyrex capillary was sealed at both ends to sections of 5 mm. tubing, one being about 7 cm. long and the other 20 cm. The tungsten wire was sealed into the capillary close to one end. Then the short piece of tubing was bent at right angles, and the capillary through 180°. The simpler variety was designed for use where the alloy was to be cast and annealed below the solidus, while the other was used when the alloy was to be slow-cooled. In casting the electrodes, the weighed materials were placed directly in the glass container. The open end of the electrode form was then attached to the Cenco Hyvac pump, and the metals were melted, degassed and finally sealed *in vacuo*. When the electrode was to be used, the glass was broken away cleanly from the alloy about 2 mm. below its tip. The electrode was placed immediately in the cell.

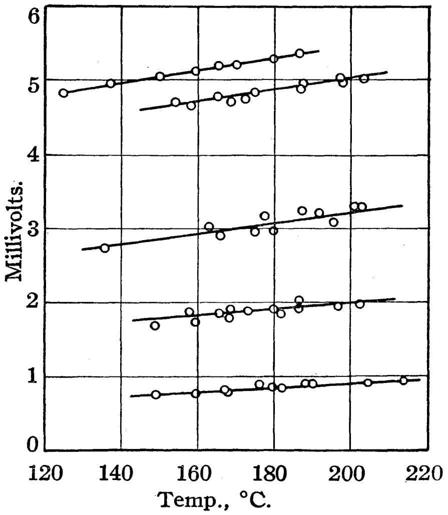

Fig. 4.—E. m. f. curves for type III cells: Starting from the bottom: $N_{\text{Bi}} = 0.050$; 0.096; 0.147; 0.200; 0.225.

For annealing, a small oil-bath and an electric furnace were used. When an alloy was to be slow-cooled, the electric furnace was connected in series with a variable electrolytic resistance, alternating current being used. The construction of the electrolytic resistance is briefly described. Two copper or brass rod electrodes were placed in a large bottle, containing a predetermined amount of calcium chloride solution. The solution was cooled by circulating water through glass tubing placed in the jar. Water was dropped in at a steady rate from a capillary connected with a constant-head device, thus lowering the conductivity of the solution and slowly decreasing the current passing through the furnace.

The data for the solid alloys are given in Table VIII and plotted in Fig. 4. The length of annealing or conditions of slow-cooling are always specified. Reproducibility of electromotive forces with different alloys of the same composition was the sole criterion of sufficient heat treatment. The data for compositions $N_{Bi} = 0.050$ to 0.200 may be considered satisfactory, but those for the region $N_{Bi} = 0.225 - 0.330$ are not accurate. The discrepancies may be attributed to non-attainment of homogeneity in the alloys or to the presence of phase changes. The difficulties in the first case might arise from the decreased velocity of diffusion in the solid state at these lower temperatures, and to the greater spread between liquidus and solidus curves. However, evidence for the existence of another solid phase has been offered by Solomon and Jones,[5] and behavior pointing to some abnormality in this region of the system has been definitely noted here. The first

effect is a marked increase in electromotive force–temperature slope observed with alloys of composition $N_{Bi} = 0.225$ in passing through the narrow temperature range 185–190°. The fact that the activities for $N_{Bi} = 0.250$ and 0.300 are considerably above the values read from a smooth curve drawn from the limit of solubility to $N_{Bi} = 0.200$ constitutes the second definite indication. Other less marked irregularities also have been observed.

In Table IX, the activity and $\bar{L}_1$ data for the compositions $N_{Bi} = 0.050$ to 0.200 at 124.5° are given, together with data representative of the region $N_{Bi} = 0.225 - 0.330$. The activities are plotted *versus* mole fraction of bismuth in Fig. 5, where the dotted line indicates the possible appearance if the unusual results noted are due to the presence of two solid phases. It should be noted that in the first range practically perfect solution behavior prevails.

Determination of the Phase Diagram of the System.—In the previous section, the limits of solubility have been found to be $N_{Bi} = 0.365$ and $N_{Bi} = 0.995$, and the eutectic composition has been determined as $N_{Bi} = 0.547$. It is possible to check the liquidus curve on the bismuth side of the eutectic since, from the above, the solid phase there is practically pure bismuth. On the lead side, accepting the liquidus data of Barlow,[14] the solidus may be calculated up to about 20% bismuth. The methods of calculation are briefly as follows. The activity of solid relative to liquid bismuth is calculated at several temperatures between the eutectic and the melting point. In the equation for the dependence of this activity on temperature, the heat of fusion is assumed independent of the temperature, since no reliable heat capacity data for bismuth are available. The value of the heat of fusion used here is 2518 calories, the mean of the results of several investigators listed by Awbery and Griffiths.[15] The activity curves of bismuth in the liquid alloys are now extrapolated to these temperatures. The intersection of one of these curves with a calculated activity of solid bismuth fixes the liquidus composition for that particular temperature. The results, tabulated in Table X, are in fair agreement with Barlow's data, but those of Kapp are found to be far too low. In a similar manner, the solidus on the lead side of the eutectic is calculated. From the smoothed curve through Barlow's liquidus data, the temperatures corresponding to various concentrations are read. The activities of lead in the liquid alloys are now extrapolated to those temperatures by the usual procedure. The standard state is changed by multiplying these values by the activity of liquid lead relative to solid lead, whence the activities are referred to solid lead. Since at a given temperature the activity in the equilibrium solidus and liquidus must be the same, the activity curves for the solid solutions may be extrapolated to the chosen temperatures, where by interpolation the solidus composition is fixed. These results also are listed in Table X. A survey of the literature on the sys-

tem has failed to reveal any other accurate solidus data.

The results of the above determinations and calculations are summarized graphically in Fig. 6 where data from other studies of the system are plotted also. The possible change of the solubility of bismuth in lead with temperature is indicated by the dotted line drawn from Solomon and Jones' limit of 33% at room temperature to our value at 125°. In drawing a smooth curve through all of Barlow's liquidus data on the lead side, the shape of the curve indicates the possibility of a peritectic. This, with the behavior of the solid alloys previously mentioned, and the report of Solomon and Jones, led us to postulate such a transition at about 180°. This was subsequently verified by thermal analysis, the temperature being fixed at 184°. In the thermal work, large amounts of the metals, 150 to 300 g., were taken and a differential copper–constantan thermocouple was used. The effect was observed with a 26 and a 30% alloy, but not with a 37% alloy, whose liquidus was about two degrees under the peritectic temperature. It should be noted that Hansen[16] has postulated the existence of the peritectic change for this system in his recent treatise, based entirely on the x-ray study of Solomon and Jones and on superconductivity measurements of Meisner.[17]

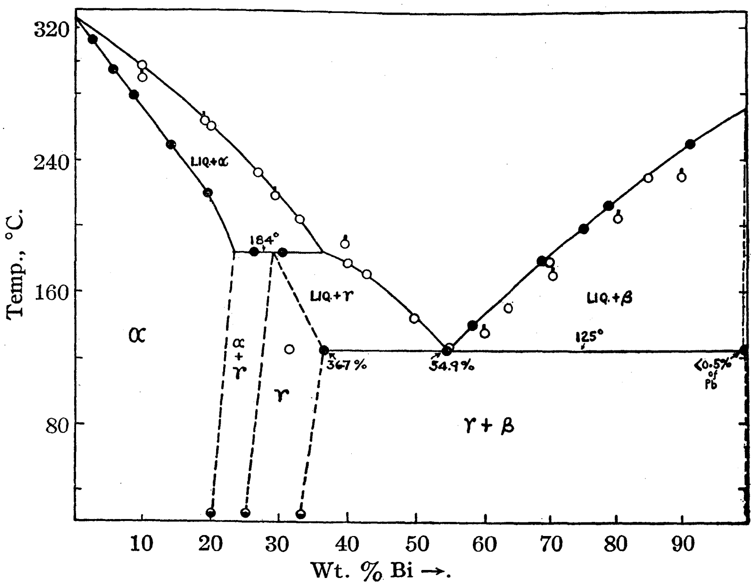

Fig. 6.—Phase diagram for the Pb–Bi system: ●, this study; ○, Barlow; ȯ, Kapp; ◒, Solomon and Jones.

Regular Solution Behavior of the Liquid Alloys

Hildebrand,[18] in the study of deviations from perfect solution behavior, introduced the term "regular solutions" to apply to those in which, due to the absence of particular orientations, the partial molal entropies of the constituents may be assumed the same as in an ideal solution of the same composition. Where the atomic volumes are the same, which is true for lead and bismuth, his most recent treatment yields the result

$$\overline{U}_1 - U_1^0 = [(\Delta U_1^0)^{1/2} - (\Delta U_2^0)^{1/2}]^2 N_2^2$$

where $\overline{U}_1$ and U_1^0 are the partial molal and molal total energies, respectively, of the first constituent and where the ΔU terms represent the energies of vaporization. As may easily be shown, the equation may be converted by a simple assumption into the form

$$RT \ln a_1/N_1 = bN_2^2$$

where a_1/N_1 is the activity coefficient of the first component and "b" represents the square of the quantity in brackets above. In this case, because of the extreme variation of reported values for the heat

of vaporization of bismuth, it was impossible to evaluate the term $[(\Delta U_1^0)^{1/2} - (\Delta U_2^0)^{1/2}]^2$. However, as a test for regular solution behavior, the quantity "b" was calculated from the experimental data and its approximate constancy with variation of composition demonstrated. The results of these calculations are given in Table XI and plotted in Fig. 7. Also, it may be shown that from the above $dE_1/dT = -R/nF \ln N_1$ for regular solutions; that is, the slope of the electromotive force–temperature curve should be a function of composition only. This is true for the lead–bismuth liquid alloys, as shown by the values in Table XII.

Summary

1. Methods of calculation have been presented whereby thermodynamic data can be used to establish accurately the conditions of phase equilibria in binary systems.

2. The activities and relative partial molal heat contents of lead and bismuth in their liquid alloys have been determined, and it is shown that the alloys may be classified as regular solutions.

3. The activities and relative partial molal heat contents of lead in solid solutions of lead and bismuth have been determined accurately up to 20% bismuth, and the approximate activities have been established from 22.5 to 33% bismuth.

4. The eutectic composition and temperature are fixed at 54.7 atomic per cent. bismuth and 125°. The compositions of the two solid phases comprising the eutectic solid have been found to be 36.5 atomic per cent. bismuth and practically pure bismuth.

5. The liquidus curve on the bismuth side of the eutectic and the solidus on the lead side up to 20% bismuth have been calculated.

6. The indicated existence of a peritectic at 184° on the lead side of the system has been verified by thermal analysis.

7. A revised phase diagram of the system is presented.

Zinc and Zinc Amalgam Electrodes

BY WILLIAM J. CLAYTON AND WARREN C. VOSBURGH

The difference of potential between zinc and saturated zinc amalgam electrodes in a solution containing zinc ion was considered by Cohen in 1900 to be practically zero.[1] This conclusion was based partly on the results of earlier workers and partly on some measurements of his own. The results of the latter measurements, given in a footnote in the same article[1] (pp. 618–619), are 0.570 mv. at 25° and 0.488 mv. at 0° for the cell

$$\text{Zn(s)/Zn}^{++}\text{/Zn (satd. amalgam)} \qquad (1)$$

On the basis of these results Scatchard and Tefft[2] and Shrawder, Cowperthwaite and La Mer[3] used the value 0.6 mv. at 25° in the calculation of the normal electrode potential of zinc. Puschin[4] found a value of about −2 mv. for cell 1. Garner, Green and Yost[5] have assumed that the electromotive force of cell 1 is zero.

In this investigation the electromotive force of cell 1 has been found to be zero. A similar cell in which a superficially amalgamated zinc electrode was substituted for the pure zinc electrode was found to have zero electromotive force also. The

latter would be expected because Clark cells made with superficially amalgamated zinc electrodes agree in electromotive force with those made with saturated amalgam electrodes, as pointed out by Cohen[1] (p. 613).

Materials and Apparatus.—Mercury was purified by washing with a solution of nitric acid and mercurous nitrate and distilling in a current of air. Zinc sulfate was recrystallized. The zinc chloride used was of the best commercial grade. Most of the zinc used was the best grade of commercial stick zinc, but a few measurements were made with some spectroscopically pure zinc which the Research Division of the New Jersey Zinc Company kindly furnished, and a few with strips of sheet zinc intended for standardizing. The treatment of the stick zinc in making the electrodes was found to be of considerable importance, and is described below. Zinc amalgam containing 5% of zinc was prepared electrolytically with stick zinc as the anode and zinc chloride as the electrolyte.

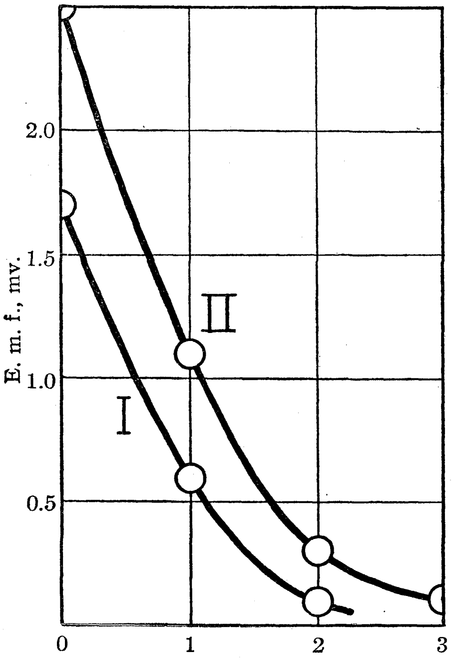

Fig. 1.—Electromotive force of the cell Zn(stick)/Zn^{++}/Zn (Hg) when the stick zinc electrode has been immersed in acidified zinc chloride solution from one to three days.

Zinc sulfate solution for use in the cells was made by dividing a solution containing 20 g. per liter of hydrated zinc sulfate in two equal parts, digesting one part with precipitated zinc hydroxide, filtering off the excess and reuniting the two parts. Zinc chloride solution for use in the cells was prepared by dissolving 20 g. of anhydrous zinc chloride per liter with the addition of enough hydrochloric acid to prevent precipitation of basic material and digesting with zinc oxide. Zinc acetate solution was prepared in the same manner as the zinc chloride solution, using 20 g. of hydrated zinc acetate per liter.

Nitrogen was prepared by passing air through four bottles of ammoniacal cuprous chloride solution.[6] The solution in the last bottle remained colorless.

Preparation of Zinc Stick Electrodes.—Most of the zinc sticks used as pure zinc electrodes were annealed, and all were treated as described below with an acidified solution of zinc chloride. Annealing was accomplished by sealing the zinc inside a glass tube and heating it in a muffle furnace to a temperature near or in some cases above the melting point, and cooling very slowly. The treatment with an acidified zinc chloride solution was best carried out in the following manner. The zinc sticks were immersed in a concentrated zinc chloride solution (200 g. of anhydrous zinc chloride to 100 ml. of water) and concentrated hydrochloric acid was added until hydrogen was generated uniformly over the surface of the zinc. Additional small portions of acid were added from time to time (about six or seven times a day) to keep the reaction going slowly.

To show the changes taking place during the treatment with acidified zinc chloride solution, the treatment of eight zinc sticks was interrupted at one-day intervals and the difference of potential between the sticks and zinc amalgam electrodes was determined by the procedure described below. The results are shown in Fig. 1. Curve I shows the change in the average electromotive force as the treatment progressed for four annealed electrodes and curve II for four unannealed electrodes. In two days for the annealed electrodes and three days for the unannealed the electromotive force had fallen to about 0.1 mv. Experience with other electrodes showed that a further slow decrease goes on for two to three weeks, after which no further change takes place, and the electrodes are in very good agreement with each other.

It is shown in Fig. 1 that for commercial stick zinc the annealing process is of less importance than the treatment with the acidified zinc chloride solution. Occasionally unannealed electrodes had to be rejected for disagreement with the others, but annealed electrodes could always be brought to excellent agreement. The annealing was essential for electrodes cast in the laboratory in Pyrex tubes.

Some of the spectroscopically pure zinc was treated with acidified zinc chloride solution, and some was not treated, but used for electrodes as received. No attempt was made to anneal it.

Superficially amalgamated zinc electrodes were prepared by immersing zinc sticks about 0.5 cm. in diameter to a depth of 4 cm. in 0.1 *M* hydrochloric acid solution at 40° and touching them to three or four small droplets of mercury about 1 mm. in diameter. By rubbing two sticks together the spreading of the mercury over the surface was hastened. No annealing or other treatment was necessary.

Preparation of the Cells.—Figure 2 is a diagram of the cell vessel used, with the electrodes in place. Stick electrodes, either of pure or superficially amalgamated zinc, were soldered to brass rods of small diameter which were passed through one-holed rubber stoppers. The strips of sheet zinc were treated similarly. A clean, dry cell vessel was connected by means of the tube projecting downward from the cross-arm to the three-way stopcock of the

---

[6] Van Brunt, This Journal, **36**, 1448 (1914).

apparatus shown in Fig. 3, using a rubber tube for a connector. The cell vessel was stoppered and evacuated and filled with nitrogen. Some amalgam was washed with dilute acid and water, then dried and heated to a temperature near its boiling point. It was then passed through a small hole in a filter paper into the two legs of the cell vessel, with a stream of nitrogen flowing to protect from oxidation. The stick electrodes which had been treated as described above were next washed with dilute hydrochloric acid, water and alcohol and then quickly placed in an empty cell vessel, the rubber stoppers fitting tightly in the tops of the vertical tubes. The vessel was immediately evacuated and the alcohol all evaporated. The electrodes were then transferred to the cell vessel containing the amalgam electrodes. The cell vessel was evacuated for at least forty-five minutes by means of an efficient vacuum pump.[7] Then some zinc sulfate solution was allowed to flow into the flask of the apparatus of Fig. 3. The low pressure caused it to boil, expelling dissolved gases. By allowing air to enter the flask, part of the solution was forced into the cell vessel. The vessel was filled to the lower part of the stick electrodes, then the three-way stopcock was turned to allow the entrance of nitrogen. Care was taken that no nitrogen bubbles stuck to the electrodes, as these seemed to cause disagreement. The cell was removed from the apparatus of Fig. 3 by closing the rubber tube connection by means of a screw clamp and disconnecting from tube A. Some of the cells were placed in a constant-temperature air-bath for measurement, and some were measured at room temperature.

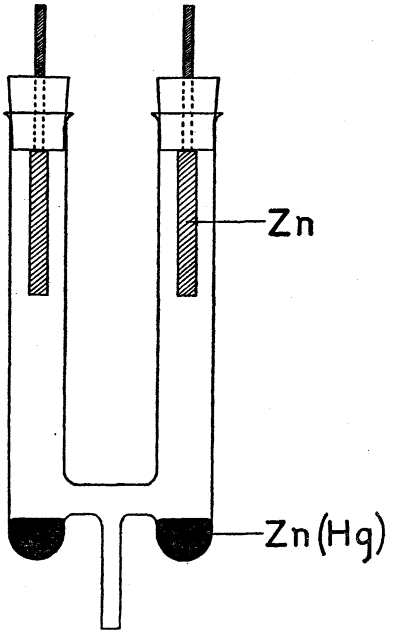

Fig. 2.—Diagram of cell vessel with electrodes in place.

The spectroscopically pure zinc was used in the form of irregular chunks as received. Chunks of the proper size were soldered to platinum wires which at the opposite ends were sealed into glass tubes. The level of the electrolyte was adjusted so that only part of the zinc electrode was immersed and the platinum wire did not touch the electrolyte.

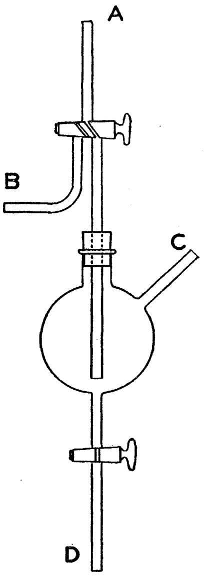

Fig. 3.—Apparatus used in evacuating the cell vessels and introducing the electrolyte without contact with air. The cell vessel was connected at A. Tube B was connected with a source of nitrogen, and tube C with either a vacuum pump or the atmosphere by means of a three-way stopcock. The electrolyte was introduced through D.

Electromotive Force Measurements.—In the best cells, as soon as temperature equilibrium was attained, the electromotive force became constant at a value very near zero for all combinations of the electrodes and remained so indefinitely. As an example of the agreement obtainable between similar electrodes, the potential difference between pure zinc stick electrodes averaged 0.01 mv. for eight pairs, between amalgamated stick electrodes 0.006 mv. for five pairs, and between amalgam electrodes 0.006 mv. for eight pairs. Average potential differences between zinc and amalgam electrodes in cells in which the electrolyte was zinc sulfate are given in Table I. A positive value indicates that the zinc electrode was negative. In giving the number of cells, each cell as described above is counted as two, since it contained two of each kind of electrode. For cells with pure zinc electrodes the average deviation from the mean value in the table was 0.01 mv. and for the amalgamated stick electrodes the average deviation was 0.003 mv.

It was found that a zinc chloride solution or a zinc acetate solution if prepared as described above could be used in the cells in place of the zinc sulfate solution. The results so obtained were practically the same as those shown in Table I, and need not be given in detail.

The strips of sheet zinc as purchased were covered with grease. Washing with alcohol (without further treatment) gave electrodes that were positive toward amalgam to the extent of 3.5 to 4.5 mv. Washing the same strips with ether left a surface that still seemed to be greasy but

TABLE I

ELECTROMOTIVE FORCE OF THE CELL $Zn(s)/Zn^{++}/Zn$ (SATD. AMALGAM)

Spectroscopic (untreated)	4	...	− .002	− .005

---

(7) The evacuation is an important part of the process. When properly carried out equilibrium was reached in the cells as soon as the temperature became uniform. When a water pump was used for the evacuation more time was required for equilibrium, but about 80% of the cells came to excellent agreement within three or four days.

lowered the potential difference to about 0.5 mv. Immersion of the ether-washed electrodes in very dilute hydrochloric acid solution resulted in potential differences within 0.1 mv. of zero against amalgam electrodes. On greasing these electrodes with petrolatum the performance could be repeated.

The zinc strip electrodes could not be treated successfully with an acidified zinc chloride solution because the dissolution of some of the zinc left the strip so fragile that it was difficult to avoid bending it in subsequent operations. Bending caused an electrode potential considerably more negative than that of the amalgam, as might be expected.

The Normal Electrode Potential of Zinc.—The electromotive force of cell 1 is shown to be zero within the rather narrow limits of experimental error. A correction of −0.6 mv. is therefore necessary to the values for the electrode potential of zinc given by Scatchard and Tefft and Shrawder, Cowperthwaite and La Mer. Application of this correction makes better agreement between these two values and the value of Getman[8] which was obtained from cells with pure zinc electrodes. The three values are as follows:

Scatchard and Tefft (corr.)	0.7610 v.
Getman	.7613
Shrawder, Cowperthwaite and La Mer (corr.)	.7614

Additional Observations.—Of the three kinds of zinc electrode, namely, pure zinc, amalgamated zinc stick and zinc amalgam, the first is the most troublesome to prepare in a highly reproducible condition. The amalgamated stick electrode is easy to prepare and handle, and gives the same potential difference against a zinc salt solution as a pure zinc electrode when measured as described above. For some purposes this electrode might be preferable to amalgam electrodes. Amalgamated electrodes rubbed with filter paper for the purpose of spreading the mercury over the zinc surface were found to be about 0.2 more negative than zinc amalgam when first put in contact with an electrolyte in the presence of air. This value persisted for some time when the electrolyte contained a small amount of free acid, but when the electrolyte had been treated with zinc oxide or hydroxide the electromotive force soon dropped to zero.

Sticks of pure zinc prepared as described above when partially immersed in a 60% slightly acidified zinc chloride solution in contact with air agreed within 0.02 mv. However, when such a solution was used as a cell electrolyte, with exclusion of oxygen, the agreement of the zinc electrodes was poor.

Zinc salt solutions containing added acid, or even the quantity of acid resulting from hydrolysis, gave erratic results in the cells. The treatment of the solutions with zinc oxide as described above was necessary for the best results. The disturbing effect of acid was less in the presence of air than in its absence.

Twelve cells with amalgamated stick electrodes prepared with slightly acid electrolytes and with fairly good protection from air differed rather widely for some time, but after four months the electromotive forces were between −0.01 and +0.05 mv.

The introduction of hydrogen into a cell in place of nitrogen caused the pure zinc electrodes to be more positive than the amalgams by 0.2 to 0.3 mv. When bubbles stuck to the electrode the values were a little higher. Air when introduced caused a large temporary effect and a more or less permanent effect of the same order of magnitude as that of hydrogen. A few cells were allowed to come to thermal equilibrium and measured before the introduction of the nitrogen. These gave the same values as after the introduction of nitrogen, showing that nitrogen has no effect on the electrodes. This seems to disagree somewhat with Getman's[9] conclusion on the effect of nitrogen.

Finely divided zinc samples prepared both by electrolysis and by reduction by magnesium and also zinc deposited by electrolysis on platinum wires were tried. A few samples of the finely divided zinc came to good agreement with the stick electrodes. Most of the difficulty was probably in washing this zinc properly. The zinc deposited on platinum wires was always positive with relation to the other electrodes.

Summary

The electromotive force of the cell Zn(s)/Zn^{++}/Zn (satd. amalgam) is zero. The symbol Zn(s) may be understood to stand for either a pure zinc electrode or a superficially amalgamated zinc electrode, these two having the same electrode potential.

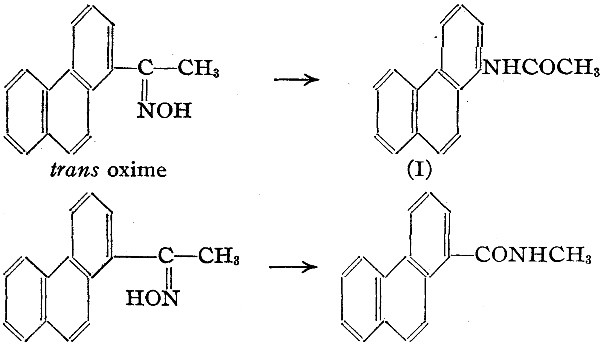
Phenanthrene Derivatives. V. The Beckmann Rearrangement of the Oximes of Acetylphenanthrenes and Benzoylphenanthrenes

BY W. E. BACHMANN AND CHARLOTTE H. BOATNER[1]

We have investigated the Beckmann rearrangement of the oximes of acetylphenanthrenes and benzoylphenanthrenes for two reasons. First, we wished to know how various phenanthryl groups were oriented with respect to the hydroxyl group in the two series of oximes. Secondly, the rearrangement appeared to offer a method for the practical preparation of certain phenanthrene derivatives. Accordingly we have prepared the oximes of 1-, 2-, 3- and 9-acetylphenanthrene and of 1-, 2-, 3- and 9-benzoylphenanthrene, and have submitted them to rearrangement by the action of phosphorus pentachloride. A preliminary communication was reported a year ago and one more recently.[2]

All eight ketones containing the phenanthryl group give mixtures of stereoisomeric oximes, *cis* and *trans*.[3] Although it would be difficult or even impossible to separate these mixtures quantitatively into the two components in order to determine the relative proportions of the two forms, this is not the case with the products obtained on rearrangement of the oximes. Thus, an acetylphenanthrene oxime would rearrange to give either an acetylaminophenanthrene (as I) or a N-methyl-phenanthroic acid amide (as II). Hydrolysis of these products would yield an aminophenanthrene and a phenanthroic acid, respectively, and these can be separated easily and quantitatively through their water-soluble salts. If we assume that each oxime gives rise to a single rearrangement product—and the work of most investigators indicates that this is the case—then the proportions of aminophenanthrene and phenanthroic acid would be a measure of the relative amounts of the *cis* and *trans* oximes in the original mixture. We have therefore rearranged the *mixture* of stereoisomeric oximes which was obtained in each case, and have determined the relative proportions of the two isomers by this procedure. The results obtained from the oximes of 1-, 2-, 3- and 9-acetylphenanthrene are presented in Table I.



trans oxime (I)

cis oxime (II)

The yields of the products do not total 100% because a certain amount of decomposition occurred during the rearrangement. On the basis of Meisenheimer's proof of the interchange of the hydroxyl group and the *trans* group[4] our results show that in the acetylphenanthrene oximes the 1-, 2-, 3- and 9-phenanthryl groups orient themselves for the most part *trans* with respect to the hydroxyl group.

TABLE I

REARRANGEMENT OF ACETYLPHENANTHRENE OXIMES

	Rearrangement products	
Isomer	$C_{14}H_9NHCOCH_3$, %	$C_{14}H_9CONHCH_3$, %
1-	71	1
2-	81	1
3-	87	2
9-	50	6

Inasmuch as the 1-, 2-, 3- and 9-aminophenanthrenes can be obtained in yields of 50–87% from the ketones, the Beckmann rearrangement constitutes the most practical method of preparing these aminophenanthrenes, and by this procedure we have prepared several hundred grams of the amines. Although the 1-acetylphenanthrene is not obtained as easily as its isomers, nevertheless this method is the only one available for preparing the new 1-aminophenanthrene. Of interest in this connection is the work of Adelson and Bogert[5] who recently obtained 6-aminoretene by hydrolysis of the rearrangement product from 6-acetylretene oxime.

The mixtures of the stereoisomeric oximes ob-

tained from 1-, 2-, 3- and 9-benzoylphenanthrene are rearranged quantitatively without decomposition to mixtures of benzoylaminophenanthrene $C_{14}H_9NHCOC_6H_5$ and phenanthroic acid anilide $C_{14}H_9CONHC_6H_5$. The proportions of these products obtained from the various isomeric ketones are shown in Table II. From these results it is apparent that in the benzoylphenanthrene oximes the phenanthryl group is oriented chiefly *cis* with respect to the hydroxyl group. Apparently the size of the groups has little effect on the orientation of the groups in the oximes. From the results obtained with the two classes of oximes the various groups may be arranged in the following order of decreasing tendency toward *trans* orientation with respect to the hydroxyl group: phenyl, 2-phenanthryl, 3-phenanthryl, 1-phenanthryl, 9-phenanthryl, methyl.

Table II

Rearrangement of Benzoylphenanthrene Oximes

	Rearrangement products	
	$C_{14}H_9NHCOC_6H_5$, %	$C_{14}H_9CONHC_6H_5$, %
1-	18	82
2-	44	56
3-	37	63
9-	4	96

The products obtained by rearrangement of the stereoisomeric oximes of 1-benzoylphenanthrene proved particularly valuable, for on hydrolysis there are produced 1-phenanthroic acid (hitherto rare) and the new 1-aminophenanthrene. Moreover, by reduction of the 1-phenanthroic acid anilide the new 1-phenanthraldehyde can be prepared in excellent yield. As a result the way is now open for the preparation of 1-phenanthrene derivatives.

Experimental Part

1-Acetylphenanthrene was prepared in two ways: (A) by oxidation of 1-phenanthrylmethylcarbinol and (B) by interaction of 1-cyanophenanthrene and methylmagnesium iodide.

(A) **1-Phenanthrylmethylcarbinol.**—To the Grignard reagent which had been prepared from 1.5 cc. of methyl iodide in 10 cc. of ether was added 10 cc. of benzene, followed by 2.6 g. of 1-phenanthraldehyde (preparation described later). After being refluxed for fifteen minutes the solution was hydrolyzed by ice-cold ammonium chloride solution; evaporation of the solvents gave the carbinol in crystalline form. By recrystallization from benzene 1-phenanthrylmethylcarbinol was obtained in the form of colorless plates: yield 2.5 g. (90%); m. p. 108–110°.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.5; H, 6.3. Found: C, 86.3; H, 6.6.

1-Acetylphenanthrene.—A solution of 1.5 g. of 1-phenanthrylmethylcarbinol in 25 cc. of glacial acetic acid was treated with a solution of 0.5 g. of chromic acid anhydride in 0.5 cc. of water and 10 cc. of acetic acid; throughout the reaction the temperature was kept at 20°. After standing for twelve hours the solution was poured into water and the ketone was extracted with benzene. The benzene solution, after being heated with charcoal and filtered, was evaporated and the residue was recrystallized from alcohol, yielding 1-acetylphenanthrene as large colorless diamond-shaped plates; weight 0.80 g. (53%); m. p. 112–113°.

Anal. Calcd. for $C_{16}H_{12}O$: C, 87.2; H, 5.5. Found: C, 87.0; H, 5.7.

(B) 1-Cyanophenanthrene was prepared from 1-phenanthroic acid amide which was obtained from the acid through the acid chloride.[6] A mixture of 5 g. of 1-phenanthroic acid amide and 5 g. of phosphorus pentoxide was heated at 140° for fifteen minutes; throughout the reaction the mixture was stirred and pressed with a glass rod. Most of the nitrile was obtained by decantation; the remainder was secured after extracting the phosphoric acid by water. The 1-cyanophenanthrene was then recrystallized from benzene–methyl alcohol; yield 4.3 g. (96%).

To the Grignard reagent prepared from 3 cc. of methyl iodide in 15 cc. of ether was added 25 cc. of benzene and then 4.3 g. of 1-cyanophenanthrene. After being refluxed for five hours the clear solution was cooled, whereupon the addition product crystallized; this solid was filtered off, washed with benzene and hydrolyzed to 1-acetylphenanthrene by refluxing it with dilute hydrochloric acid for four hours. The ketone which crystallized on cooling was obtained pure by distillation under reduced pressure, followed by recrystallization from alcohol; yield 4.0 g. (85%). The product was identical with the ketone prepared by method (A).

9-Acetylphenanthrene.—We prepared this ketone by the Grignard reaction from 9-cyanophenanthrene. The latter compound was made by heating 9-bromo-phenanthrene and cuprous cyanide[7] in a Claisen flask; when the reaction was at an end the nitrile was distilled from the flask under reduced pressure, b. p. 190–200° (3 mm.). This procedure avoids the long extraction otherwise required to separate the nitrile and cuprous salts.

To the Grignard reagent prepared from 7 cc. of methyl iodide in 30 cc. of ether was added 25 cc. of benzene and then 15 g. of 9-cyanophenanthrene. After being refluxed for three hours, the mixture was cooled and hydrolyzed with ice-cold ammonium chloride solution. The ether–benzene layer was shaken with ice-cold dilute hydrochloric acid and the aqueous solution which now contained the ketone-imine hydrochloride was heated for an hour in order to hydrolyze the product to the ketone. The latter, which precipitated as an insoluble oil, was purified by distillation under reduced pressure, followed by recrystallization from alcohol; yield 9.5 g. (57%); m. p. 73–74°. Mosettig and van de Kamp,[8] who prepared the ketone by a different method, reported a melting point of 74.5°.

2- and 3-acetylphenanthrene were prepared according to the procedure of Mosettig and van de Kamp[9] with the modification that the mixture of crude ketones was distilled under reduced pressure, b. p. 180–214° (4 mm.). By digestion of the distillate with ether most of the 3-isomer was dissolved; the residue of the 2-isomer was obtained pure by two recrystallizations from benzene, the 3-isomer by recrystallization from methyl alcohol.

Oximation of Acetylphenanthrenes.—The preparation of oximes of ketones with large hydrocarbon radicals has often been found difficult and sometimes impossible. The use of pyridine by Bryant and Smith[10] in the hydroxylamine method for the titration of ketones and aldehydes suggested its use for the preparation of the oximes whose rearrangement we wished to study. With the modification of leaving out the water entirely we found that quantitative oximation of 1-, 2-, 3- and 9-acetylphenanthrene could be accomplished by heating a mixture of the ketone and hydroxylamine hydrochloride in a solution of absolute alcohol and pyridine for three hours on a steam-bath. The advantages of this procedure have been pointed out by one of us;[11] by this method it is possible to prepare oximes which do not form readily under the usual conditions.[12]

A mixture of 20 g. of 3-acetylphenanthrene (similarly for the 1- or 9-isomer) and 16 g. of hydroxylamine hydrochloride in 75 cc. of absolute alcohol and 28 cc. of pyridine was refluxed for three hours. A practically quantitative yield of the oxime was obtained by removing most of the solvent and pouring the residue into water. For the preparation of the 2-acetylphenanthrene oxime we refluxed a mixture of 2 g. of the ketone with 1.6 g. of hydroxylamine hydrochloride in 4 cc. of absolute alcohol and 12 cc. of pyridine on a steam-bath for three hours; a 97% yield of oximes (m. p. 187–190°) was obtained. By recrystallization from methyl alcohol the pure *trans*-2-acetylphenanthrene oxime was obtained as colorless needles; m. p. 196–197°.

Anal. Calcd. for $C_{16}H_{13}ON$: N, 6.0. Found: N, 6.2.

The properties of the 3- and 9-acetylphenanthrene oximes were similar to those prepared by the usual method.[9] Mosettig and Krueger[2] reported a melting point of 196–198° for the 2-acetylphenanthrene oxime which they prepared recently by the pyridine method.

1-Acetylphenanthrene Oxime.—The *trans* form of this oxime crystallizes from methyl alcohol in colorless plates; m. p. 174–176°.

Anal. Calcd. for $C_{16}H_{13}ON$: N, 6.0. Found: N, 6.0.

Rearrangement of the Acetylphenanthrene Oximes.—Anhydrous ether is generally employed as the solvent in the Beckmann rearrangement and at first we employed this solvent. We found, however, that the cheaper solvent benzene could be substituted and, indeed, in several cases we obtained better results; moreover, smaller volumes of this solvent suffice. The mixture of *cis* and *trans* oximes prepared from 5 g. of 3-acetylphenanthrene (or 1- or 9-isomer) was suspended in 80 cc. of dry benzene and treated with 5 g. of powdered phosphorus pentachloride. After the mixture had been refluxed for fifteen minutes, the mixture was cooled and hydrolyzed. In the rearrangement of the 2-acetylphenanthrene oximes 20 cc. of benzene was used for each gram of oxime and the solution was refluxed for a period of three hours. Using these procedures we have rearranged quantities of 50–100 g. of oxime at one time.

The mixture of acetylaminophenanthrene and N-methylphenanthroic acid amide obtained on rearrangement of the oximes from 5 g. of ketone was refluxed with 200 cc. of alcohol and 7 cc. of concentrated hydrochloric acid for twenty-four hours. After the alcohol had been removed by distillation the residue was digested with 300 cc. of boiling water and filtered. Addition of ammonium hydroxide to the aqueous filtrate precipitated the free aminophenanthrene (3.12 g. of 1-, 3.58 g. of 2-, 3.83 g. of 3- and 2.21 g. of 9-amine). The residue was then heated with a solution of 7 cc. of hydrochloric acid in 200 cc. of alcohol in order to hydrolyze the acid amide, and the phenanthroic acid was isolated through its water-soluble sodium salt (after hydrolysis by potassium hydroxide of any ester formed in the previous reaction). The acid amide was also hydrolyzed by a mixture of acetic acid and hydrochloric acid in a sealed tube at 200° for six hours.

The amines as obtained were usually practically colorless and pure. Further purification can be best accomplished by distillation under reduced pressure. The melting points of the 2- and 3-amines and their acetyl derivatives were in agreement with the values reported by Werner[13] for the products obtained from the corresponding phenanthrene sulfonic acids. Although Werner obtained 2-aminophenanthrene as yellow crystals we were able to isolate it in a colorless state.

1-Aminophenanthrene.—This amine, obtained in 72% yield (based on the ketone) in the manner described, crystallizes from a mixture of benzene and petroleum ether in broad, colorless glistening needles; m. p. 145–146°. The amine is insoluble in water, slightly soluble in cold petroleum ether and benzene and soluble in hot benzene.

Anal. Calcd. for $C_{14}H_{11}N$: N, 7.2. Found: N, 7.0.

The hydrochloride of this amine crystallizes from alcohol in the form of fine colorless needles; m. p. 253–255° with previous decomposition. The salt is soluble in water but not very soluble in cold alcohol.

1-Acetylaminophenanthrene.—This substance is the principal product of the rearrangement of 1-acetylphenanthrene oxime. A 90% yield of this compound was obtained by refluxing a mixture of 0.1 g. of 1-aminophenanthrene and 2 cc. of acetic anhydride for ten minutes, adding 3 cc. of water and cooling the solution. 1-Acetylaminophenanthrene crystallizes from acetic acid in broad colorless needles or plates; m. p. 219–220.5°.

Anal. Calcd. for $C_{16}H_{13}ON$: N, 6.0. Found: N, 6.2.

1-Benzoylaminophenanthrene.—A 99% yield of this derivative was obtained by treating a solution of 0.1 g. of 1-aminophenanthrene in 1 cc. of pyridine with 0.2 cc. of

benzoyl chloride and heating the mixture for five minutes. 1-Benzoylaminophenanthrene crystallizes from acetic acid in broad colorless needles; m. p. 224–226°.

Anal. Calcd. for $C_{21}H_{15}ON$: N, 4.7. Found: N, 4.9.

1-Aminophenanthrene Picrate.—The picrate, prepared by mixing hot benzene solutions of the amine and picric acid, crystallizes from *n*-propyl alcohol in fine pale-yellow needles; m. p. 203–204° with decomposition. The picrate is nearly insoluble in cold benzene, chloroform and alcohol.

Anal. Calcd. for $C_{14}H_{11}N \cdot C_6H_3O_7N_3$: N, 13.3. Found: N, 13.7.

1-Phenanthrylurethan.—A solution of 0.1 g. of 1-aminophenanthrene in 5 cc. of benzene was treated with 0.1 cc. of ethyl chlorocarbonate and 0.1 cc. of pyridine. After being warmed for a few minutes the mixture was allowed to stand at room temperature for three hours. 1-Phenanthrylurethan crystallizes from alcohol in colorless transparent plates; yield, quantitative; m. p. 153.5–154°.

Anal. Calcd. for $C_{17}H_{15}O_2N$: N, 5.3. Found: N, 5.3.

N-Phenyl-N′-(1-phenanthryl)-urea.—A solution of 0.2 g. of 1-aminophenanthrene and 0.15 g. of phenyl isocyanate in 5 cc. of benzene was warmed on a steam-bath for fifteen minutes and then allowed to stand at room temperature twelve hours. N-Phenyl-N′-(1-phenanthryl)-urea crystallizes from a mixture of chloroform and alcohol in fine colorless needles; m. p. 323–325° with decomposition; yield, quantitative. The compound is nearly insoluble in alcohol and in benzene but is soluble in hot chloroform.

Anal. Calcd. for $C_{21}H_{16}ON_2$: N, 9.0. Found: N, 8.8.

Synthesis of N-Methylphenanthroic Acid Amides.—These compounds, formed to a slight extent in the rearrangement of the acetylphenanthrene oximes, were synthesized from the acids. The acid chloride[6] from 1 g. of phenanthroic acid (1-, 2-, 3- or 9-isomer) was dissolved in 10 cc. of acetone and the resulting solution was poured into an ice-cold 33% aqueous solution of methylamine. The amide which precipitated immediately was filtered off, washed with water, dried and recrystallized from a mixture of benzene and methyl alcohol; yields 90–95%.

The properties of the N-methylphenanthroic acid amide (calcd. for $C_{16}H_{13}ON$: N, 6.0) are: 1-isomer, plates, m. p. 204–205.5° (N, 5.7); 2-isomer, needles, m. p. 201–202° (N, 6.2); 3-isomer, needles, m. p. 207–207.5° (N, 5.9); 9-isomer, needles, m. p. 191–192° (N, 6.3).

Benzoylphenanthrene Oximes.—1-Benzoylphenanthrene was prepared by the Perrier modification of the Friedel and Crafts reaction and the other ketones were prepared from the corresponding cyanophenanthrenes by means of the Grignard reaction.[6] Oximation was carried out according to the procedure described for the acetylphenanthrenes though usually twelve to twenty-four hours were allowed for heating. The yields of oximes were nearly quantitative. Thus, by heating a mixture of 70 g. of 1-benzoylphenanthrene and 68 g. of hydroxylamine hydrochloride in 500 cc. of absolute alcohol and 100 cc. of pyridine for twelve hours 67 g. of the oximes was obtained.

All of the oximes crystallized from methyl alcohol as colorless needles. The properties of the benzoylphenanthrene oximes (Calcd. for $C_{21}H_{15}ON$: N, 4.7) are: 1-isomer, m. p. 185–186° (N, 4.4); 2-isomer, m. p. 182–183° (N, 4.5); 3-isomer, m. p. 201–203° (N, 4.9); 9-isomer, m. p. 218–220 (N, 4.9).

The benzoylphenanthrene oximes were rearranged in the same manner as the acetylphenanthrene oximes. Thus, a mixture of 20 g. of the oximes in 100 cc. of ether (or benzene) was treated with 15 g. of phosphorus pentachloride. After being warmed for fifteen minutes the solution was carefully hydrolyzed; 19 g. of rearrangement products was obtained. When the mixture was heated with alcoholic hydrochloric acid for three weeks on a steam-bath, the benzoylaminophenanthrene was hydrolyzed to aminophenanthrene while the phenanthroic acid anilide was only slightly affected. The weight of aminophenanthrene (2.45 g. 1-aminophenanthrene from 20 g. of 1-benzoylphenanthrene, for example) indicated the proportion of *trans*-benzoylphenanthrene oxime in the original mixture.

1-Phenanthroic Acid Anilide.—This compound was obtained in a pure state by recrystallization of the rearrangement products obtained from the 1-benzoylphenanthrene oximes. For identification it was synthesized from 1-phenanthroic acid. The acid chloride, prepared from 0.15 g. of 1-phenanthroic acid by means of phosphorus pentachloride, was dissolved in warm acetone and treated with 1 cc. of aniline. After five minutes the mixture was digested with dilute hydrochloric acid and the precipitate of the anilide was filtered off. 1-Phenanthroic acid anilide crystallizes from acetone in colorless plates; m. p. 248–249°; yield, quantitative.

Anal. Calcd. for $C_{21}H_{15}ON$: N, 4.7. Found: N, 4.4.

1-Phenanthraldehyde.—This new aldehyde was prepared from the rearrangement product of 1-benzoylphenanthrene oximes which contained 82% of 1-phenanthroic acid anilide. An intimate mixture of 36 g. of the rearrangement product and 25 g. of phosphorus pentachloride in 40 cc. of anhydrous ether was heated on a steam-bath for fifteen minutes. The ether and phosphorus oxychloride were removed under reduced pressure at 140° (temperature of oil-bath), the imide chloride was dissolved in 50 cc. of ethylene dibromide and added to a solution of 94 g. of anhydrous stannous chloride in 340 cc. of anhydrous ether saturated with dry hydrogen chloride. After the mixture had stood at 0° for twenty hours, the precipitate was filtered off, washed with benzene and hydrolyzed by hot dilute hydrochloric acid. The crude aldehyde was digested with carbon tetrachloride and the filtered solution was evaporated to dryness. The residue was dissolved in a mixture of chloroform and ether and the solution was shaken with a saturated aqueous solution of sodium bisulfite for thirty-six hours; the addition product was filtered off and the filtrate was shaken with a fresh solution of sodium bisulfite for four days. The aldehyde obtained by hydrolysis of the addition compound with dilute hydrochloric acid was purified by distillation under reduced pressure and recrystallization; yield 16 g. (75%). 1-Phenanthraldehyde crystallizes from benzene and petroleum ether in colorless needles; m. p. 110.5–111.5°.

Anal. Calcd. for $C_{15}H_{10}O$: C, 87.3; H, 4.9. Found: C, 87.2; H, 5.1.

1-Phenanthraldehyde oxime crystallizes from benzene in colorless needles; m. p. 187–189°.

Anal. Calcd. for $C_{15}H_{11}ON$: N, 6.3. Found: N, 6.0.

1-Phenanthroic Acid.—1-Phenanthroic-acid-anilide hydrolyzes with difficulty; it is practically unaffected by a boiling alcoholic solution of hydrochloric acid or potassium hydroxide. Small amounts can be hydrolyzed readily in a sealed tube. A mixture of 2.0 g. of the product which was obtained by rearrangement of the oximes (containing 82% of 1-phenanthroic-acid-anilide), 10 cc. of concentrated hydrochloric acid and 50 cc. of glacial acetic acid was heated in a sealed tube at 200° for eight hours. The liquids were evaporated and the residue was digested with hot water in order to remove the 1-aminophenanthrene (0.17 g.). The 1-phenanthroic acid which remained was purified through its ammonium salt; yield 0.95 g. (77%).

For making larger amounts of 1-phenanthroic acid it was found more practical to carry out the following reactions: $C_{14}H_9CONHC_6H_5 \longrightarrow C_{14}H_9C(Cl){=}NC_6H_5 \longrightarrow C_{14}H_9COOH$. The imide chloride prepared from 20 g. of the rearrangement products as described above was added to a solution of sodium methylate which had been prepared from 5 g. of metallic sodium, 20 cc. of methyl alcohol and 20 cc. of ether. After the mixture had been refluxed for an hour, the solvents were distilled off, and the inorganic material was removed by extraction with water. The methoxyl derivatives of the imides were then hydrolyzed by heating them with a mixture of 50 cc. of concentrated hydrochloric acid and 200 cc. of methyl alcohol for two days. After removal of the solvents, the residue was heated with 100 cc. of a 25% solution of potassium hydroxide in methyl alcohol for twelve hours in order to hydrolyze the methyl ester of 1-phenanthroic acid which had formed in the preceding treatment. The solvent was removed, and the potassium salt of 1-phenanthroic acid was extracted from the residue by 1 liter of boiling water; yield of 1-phenanthroic acid, 7.2 g. From the undissolved residue 2.45 g. of 1-aminophenanthrene was extracted by hot dilute hydrochloric acid. The remainder of the product was unchanged 1-phenanthroic-acid-anilide which could be used over again.

Summary

The orientation of the 1-, 2-, 3- and 9-phenanthryl groups with respect to the methyl and the phenyl group in the oximes of the acetylphenanthrenes and benzoylphenanthrenes has been determined.

The Beckmann rearrangement has been developed as a practical method for the preparation of 1-, 2-, 3- and 9-aminophenanthrene.

A number of new 1-phenanthrene derivatives have been synthesized.

The Effect of Various Catalysts on the Phenanthrene–Bromine Reaction

BY CHARLES C. PRICE

The reasons for undertaking an investigation of the influence of catalysts on the reaction of phenanthrene with bromine have been presented in a previous paper.[1]

Since dioxane, one of the few available non-polar solvents unattacked by bromine at room temperature, has been found useless as a solvent for the rate determinations due to its phenanthrene-induced bromination,[1] carbon tetrachloride was used, although it was by no means ideal for the purpose. The slight solubility of hydrogen bromide in this solvent makes it difficult to determine accurately the rate of formation of this product, even when ground-glass-stoppered reaction flasks are used. In a blank test at the maximum concentration of hydrogen bromide of the experiments, the sodium hydroxide titer decreased about 25% in ten hours. The bromine, carbon tetrachloride and phenanthrene were purified as described in the previous paper. The iodine was resublimed.

All the rate measurements were made at 25°. Samples of the reaction mixture were pipetted into dilute potassium iodide, the liberated iodine then being titrated with sodium thiosulfate and the acid with carbonate-free sodium hydroxide. The disappearance of the iodine color was taken as the end-point of the first titration while phenolphthalein was the indicator in the second. The thiosulfate titer is a measure of the course of both addition and substitution, while the acid is produced by substitution alone.

The bromination catalysts investigated included aluminum chloride, antimony pentachloride, iodine, phosphorus trichloride, phosphorus pentachloride and stannic chloride. When one-tenth equivalent of catalyst was added to an equimolecular solution of bromine and phenanthrene, all of these compounds, especially iodine, catalyzed the formation of hydrogen bromide in appreciable quantities within an hour or two, although without the catalyst there was none formed after several days. Since iodine gave the

---

(1) Price, THIS JOURNAL, **58**, 1834 (1936).

best catalysis, as well as more conveniently and accurately measurable rates, it was employed in a majority of the experiments.

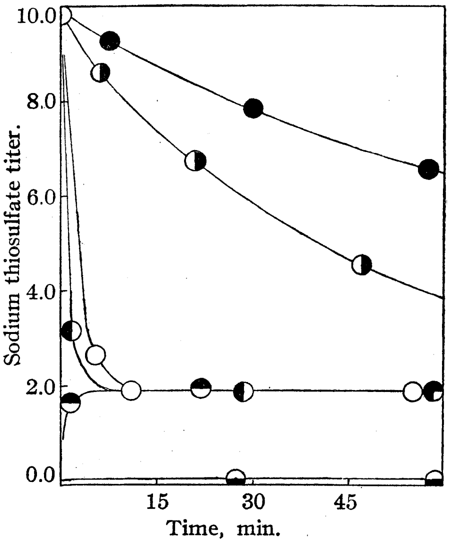

Fig. 1.—Rate of phenanthrene–bromine addition reaction: ○, phenanthrene and pure bromine; ◑, phenanthrene and commercial bromine; ◐, phenanthrene, commercial bromine and antimony pentachloride (10:10:1); ●, phenanthrene, pure bromine and iodine (20:20:1); ◒, phenanthrene dibromide; ◓, phenanthrene dibromide and antimony pentachloride (10:1).

In addition to their effect on the substitution reaction, two of the catalysts had a pronounced effect on the addition, iodine retarding the rate while antimony pentachloride greatly accelerated it. As little as one-twentieth equivalent of iodine in 0.05 *M* phenanthrene and bromine increased the time required to reach the equilibrium of the addition reaction from less than ten minutes to at least three or four hours. With twice as much iodine the rate was practically identical, while with five times as much, or one-fourth the equivalent amount, the rate was slightly greater. The reason for this retardation of the bromination being so little dependent on the iodine concentration may be because, although the rate of the addition reaction is diminished in some fashion proportional to the iodine concentration, the rate of bromine substitution increases so as to become appreciable.

This inhibitory effect of iodine is most probably due to interruption of the chain mechanism for the reaction suggested in the previous paper.[1]

$$C_{14}H_{10} + Br \rightleftharpoons C_{14}H_{10}Br \overset{Br_2}{\rightleftharpoons} C_{14}H_{10}Br_2 + Br$$

The iodine probably reacts with the chain-propagating bromine atoms.

The results of the experiments showing the catalytic effect of antimony pentachloride on the addition reaction are given graphically in **Fig. 1.** Since the rate of addition of pure bromine to phenanthrene was so rapid as to make it difficult to detect a catalytic effect, commercial "pure" bromine was employed. That the effect of the antimony pentachloride is true catalysis of the addition reaction and not neutralization of the effect of some negative catalyst present was clearly demonstrated by its catalytic effect on the reverse reaction, the attainment of equilibrium by the dissociation of the dibromide. Since antimony pentachloride has frequently been employed as a chlorinating agent, it appears capable of donating a molecule of halogen, perhaps stepwise as atoms, which would initiate the chain reaction for the bromine addition or its reversal.

The results of three measurements of iodine-catalyzed substitution are shown in Fig. 2. In one experiment one-fifteenth equivalent of iodine was added to equimolecular quantities of phenanthrene and bromine (*ca.* 0.10 *M*), while in a second the same amount of iodine was added to 0.10 *M* phenanthrene dibromide. A third experiment was identical with the second with the exception of the addition of bromine equivalent to the iodine.

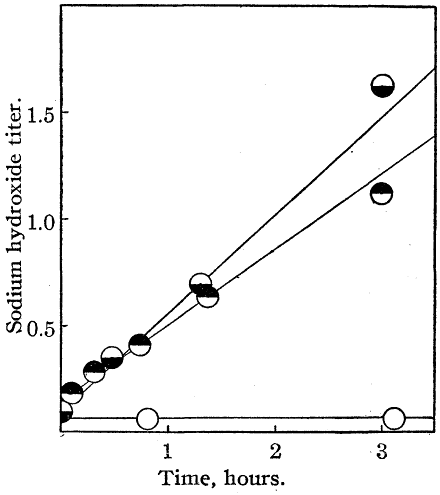

Fig. 2.—Rate of formation of 9-bromophenanthrene: ◓, phenanthrene, bromine and iodine (15:15:1); ○, phenanthrene dibromide and iodine (15:1); ◒, phenanthrene dibromide, bromine and iodine (15:1:1).

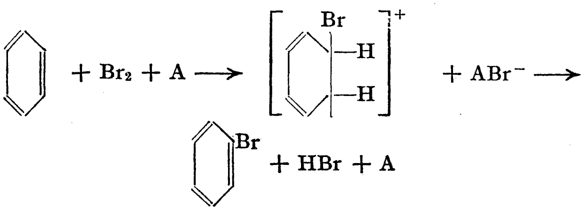
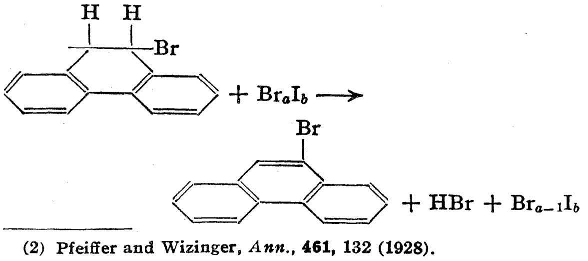
The only way to reconcile the experimental data with the addition–elimination theory is to suppose that iodine strongly catalyzes the elimination reaction, thus counteracting its inhibitory effect on the addition reaction. The fact that no hydrogen bromide was formed in the second experiment above might then be explained by supposing that the presence of bromine is essential. The identity of the rates in the first and third experiments, however, eliminates the possibility of direct action on phenanthrene dibromide (or phenanthrene) as the mechanism of the production of the hydrogen bromide since in either case the initial rate in one of the two experiments would have been zero. Thus an addition–elimination definitely does not seem to be involved.

Since solutions of phenanthrene dibromide are quite stable and only proceed to equilibrium on the addition of a small amount of bromine, and from the results of the second and third experiments above, it appears that the progress of the addition reaction is necessary to the catalytic effect. These facts, as well as the identity of the rate of hydrogen bromide formation starting with phenanthrene or the dibromide, seem to point to an intermediate radical, perhaps that of the addition reaction, as the molecular species influenced by the catalyst, since this would be present in approximately equal amounts in both experiments. The course of the reaction would then be quite similar to that proposed by Pfeiffer and Wizinger[2] for aromatic substitution. Taking the bromination of benzene as an example, they propose the mechanism



A being a catalyst for the reaction, perhaps a molecule of bromine itself. It seems more likely, at least in the case under investigation, that the intermediate is not a carbonium ion type but a free radical.



Due to lack of completely quantitative accuracy in the experimental method the exact values of the quantities *a* and *b* could not be determined. An indication of their probable value, however, can be obtained by a recalculation of experimental work of Bruner,[3] who has presented a detailed account of extensive kinetic measurements of the bromination of benzene with iodine as catalyst. Since excess benzene was used as the solvent, the rates were dependent only on the bromine and iodine concentrations. Bruner calculated rate constants of the second order with respect to bromine but was unable to derive any relation for their dependence on the iodine concentration. However, rate constants of the three-halves order with respect to bromine have been calculated from Bruner's data and found to be equally as good as his second order constants with the additional argument in their favor that the dependence on the iodine concentration now can be determined readily by assuming proportionality to the five-halves power, giving the following expression for the rate of bromination of benzene in benzene as solvent with iodine as catalyst

$$dx/dt = k[Br_2]^{3/2}[I_2]^{5/2}$$

Table I summarizes the results of these calculations with Bruner's second order constants included for comparison. If the substitution is considered to take place in two steps, it would then appear that, either according to the mechanism proposed by Pfeiffer and Wizinger with charged intermediates or with radicals as intermediates, the catalyst molecule is BrI_5. Further experimental work is contemplated to determine the exact kinetics of the reaction with phenanthrene in order to verify the identity of the kinetics for the bromination of benzene and phenanthrene.

TABLE I

RATE CONSTANTS FOR THE IODINE-CATALYZED BROMINATION OF BENZENE FROM BRUNER'S DATA

Table[a]	k_2	$[I_2]$, (M)	$k_{3/2}$, exptl.	$k_{3/2}$, calcd.[b]
1A	9.35	0.214	6.70	(6.70)
1B	2.70	.143	2.41	2.43
1C	1.15	.107	1.19	1.19
1D	0.54	.0856	0.65	0.67
2A	3.10	.144	2.54	2.50
2B	0.67	.0898	0.78	0.77
3A	.25	.0717	.38	.42
4D	1.35	.1002	.97	1.00

[a] Numbered as in Bruner's paper.[3] [b] Calculated from the relation $k_{3/2} = 6.70(0.214/[I_2])^{5/2}$.

Grateful acknowledgment is due Professor Louis F. Fieser for proposing the problem and for advice and criticism.

Summary

The effects of iodine on the phenanthrene-bromine reaction have been determined, and from an analysis of the results it is shown that the observations cannot be reconciled with the addition-elimination theory for aromatic substitutions.

High Vacuum Distillation of N-Acyl Amino Acid and Polypeptide Esters

BY SAMUEL GURIN[1]

An observation that certain N-benzenesulfonyl polypeptide esters suffer no apparent decomposition at temperatures appreciably above their melting points, suggested that such substances might be distilled satisfactorily under suitable conditions. Since Fischer's work upon the vacuum distillation of amino acid esters, very little further extension of this technique to N-acyl amino acid esters has been made; apparently no successful distillation of polypeptide derivatives of this type has been reported.

Acetylglycine ethyl ester,[2] as well as carbethoxyglycine and alanine ethyl esters[3] may be distilled easily. Muhlemann[4] attempted to apply this technique to several benzoylated amino acid esters, but observed considerable decomposition at a pressure of 2 mm. Cherbuliez[5] prepared a number of N-acetyl amino acid esters, and successfully distilled them, although considerable racemization accompanied the distillation of optically active compounds of this type.

It was found that butyl esters of benzenesulfonylated amino acids could be distilled without decomposition or racemization at pressures of 10^{-6}–10^{-7} mm. with the aid of a mercury vapor pump of the type described by Copley, Simpson, Tenney and Phipps.[6] In Table I are described the results obtained with a number of such compounds which were prepared in most cases by the method previously described by Gurin and Clarke.[7] Although butyl esters were first prepared in order to obtain greater stability (in contrast to methyl and ethyl esters),[8] this precaution was later found to be unnecessary since corresponding ethyl esters could be equally well distilled. Under these conditions distillation begins, in most cases, at temperatures ranging from 10 to 35° above the melting point. No racemization was observed to take place when optically active derivatives of this type were distilled. Thus, benzenesulfonyl-*l*-leucine butyl ester as well as di-benzenesulfonyl-*l*-tyrosine butyl ester showed no change in rotation after distillation. In Table I are listed the approximate distillation temperature ranges, as well as mixed melting points which were made with original and distilled material. Di-benzenesulfonyl-*d*-lysine butyl ester[9] distils extremely slowly, and at a temperature consid-

TABLE I

Substance	M. p., °C.[a]	Dist. temp.	Mixed m. p., °C.
$PhSO_2$-Glycine butyl ester[b]	26	50–55	25–26

erably higher than its melting point, while dibenzenesulfonyl-*l*-cystine diethyl ester does not distil but slowly decomposes at 185–200° yielding a colorless oily distillate.

In Table II are shown the results obtained with similar peptide derivatives. Again, ready distillation took place, although very little decomposition was observed. Successful distillation of N-benzenesulfonyl peptide ethyl esters indicates that it is unnecessary to prepare butyl esters for this purpose. Furthermore, carbethoxy peptide esters were found to be still more readily and rapidly distilled than their N-benzenesulfonyl analogs. For example, 0.2–0.3 g. of carbethoxyglycylglycine ethyl ester was distilled in approximately fifteen minutes at 95–100°.

[a] Prepared by method previously described.[7]

Several artificial mixtures were fractionated by this method. Benzenesulfonyl-methionine ethyl ester was almost quantitatively separated from dibenzenesulfonyl-cystine diethyl ester by distillation at 75–95°, while the cystine component was left behind unchanged and undecomposed. Similarly, benzenesulfonyl-glycine butyl ester and benzenesulfonylalanine butyl ester were separated in pure form from a mixture of the two. From a mixture of carbethoxyglycylglycine ethyl ester and carbethoxydiglycylglycine ethyl ester, both components were separated easily in pure form as were the N-benzenesulfonyl butyl ester derivatives of glycylalanine and alanylglycine from a mixture of the two. Finally, benzenesulfonylleucylglycylglycine ethyl ester and benzenesulfonylglycylalanine ethyl ester were similarly separated. Recoveries of 90% or better were obtained in every case.

The application of this method to problems of protein structure is at present in progress.

Experimental

Benzenesulfonyl - *d,l* - alanylalanine Butyl Ester.—*d,l*-Alanylalanine was prepared according to Fischer and Kautzsch[10] (amino-N, 8.60; calcd. amino-N, 8.75). To 0.6 g. of the dipeptide dissolved in 10 cc. of water plus 1 cc. of 5 *N* sodium hydroxide were added with good stirring 1.4 g. of benzenesulfonyl chloride and 2 cc. of 5 *N* sodium hydroxide. The reaction mixture was kept just alkaline to thymolphthalein, and, after stirring for four hours, was acidified to Congo red with concentrated hydrochloric acid. The solution was extracted repeatedly with butyl alcohol and esterification carried out as previously described.[7] The ester crystallized as needles from ether and petroleum ether and weighed 0.569 g. (40%); m. p. 102°.

Anal. Calcd. for $C_{16}H_{24}O_5N_2S$: N, 7.86. Found: N, 8.02.

Benzenesulfonyl - glycyl - *d,l* - alanine Ethyl Ester.—Glycyl-*d,l*-alanine, prepared according to Fischer and Schulze,[11] was benzenesulfonylated as previously described.[7] The precipitate which separated out of the aqueous acid reaction mixture was filtered, dried and esterified by boiling for a few minutes with absolute ethyl alcohol previously saturated with dry hydrogen chloride gas. On evaporation of the alcoholic solution, followed by recrystallization from chloroform and petroleum ether, needles were obtained melting at 74°.

Anal. Calcd. for $C_{13}H_{18}O_5N_2S$: N, 8.90. Found: N, 8.93.

Benzenesulfonyl - *d,l* - leucylglycylglycine Ethyl Ester.—Two and forty-five hundredths grams of *d,l*-leucylglycylglycine prepared according to Fischer[12] (N, 17.30; calcd. 17.12) was dissolved in 10 cc. of *N* sodium hydroxide and treated with 3.5 g. of benzenesulfonyl chloride and 20 cc. of *N* sodium hydroxide; the reaction mixture was kept just alkaline to thymolphthalein. After stirring for three hours, a small amount of insoluble material was removed by filtration, and the filtrate acidified to Congo red with 5 *N* hydrochloric acid. The solution was concentrated *in vacuo* to dryness, and the residue extracted with 3–15 cc. portions of the hot methyl alcohol. After evaporating the methyl alcohol solution to dryness, the residue was suspended in 75 cc. of cold absolute ethyl alcohol previously saturated with dry hydrogen chloride gas, and boiled for a few minutes until a clear solution was obtained. The solution was concentrated *in vacuo* to approximately 10 cc. and, after chilling, the ester was obtained in the form of small bars. A further crop was obtained by addition of petroleum ether to the mother liquor. After recrystallization from hot absolute alcohol, the product weighed 2.51 g. (61% yield); m. p. 171°. *Anal.* Calcd. for $C_{18}H_{27}O_6N_3S$: N, 10.16. Found: N, 10.27.

Carbethoxyglycylglycine Ethyl Ester.—Prepared according to Fischer and Fourneau;[13] m. p. 86°; N, 12.20; calcd. for $C_9H_{16}O_5N_2$: N, 12.07.

(12) E. Fischer, *ibid.*, **38**, 605 (1905).

(13) E. Fischer and E. Fourneau, *ibid.*, **34**, 2868 (1901).

Carbethoxydiglycylglycine Ethyl Ester.—Carbethoxydiglycylglycine was prepared according to the method described by Fischer;[14] m. p. 208–209°; N, 16.02; calcd. for $C_9H_{15}O_6N_3$: N, 16.08. The ester was obtained by treatment with absolute ethyl alcohol and dry hydrogen chloride; the solution obtained after boiling for a few minutes, was concentrated *in vacuo* to a small volume and the ester precipitated by addition of ether. On recrystallization from hot absolute alcohol, needles were obtained melting at 159°: N, 14.44; calcd. for $C_{11}H_{19}O_6N_3$, N, 14.53. This ester was prepared by Fischer[15] using a different method of synthesis.

Dibenzenesulfonylcystine Diethyl Ester.—Dibenzenesulfonylcystine was prepared according to the method described by Fruton and Clarke;[16] m. p. 208°. The diethyl ester was obtained by suspending in absolute ethyl alcohol and saturating with dry hydrogen chloride. After refluxing for ten minutes, the clear solution was concentrated *in vacuo* to dryness, and the residue recrystallized from hot ethyl acetate. The ester (tufts of needles) melted at 121°: N, 4.96; S, 22.40; calcd. for $C_{22}H_{28}O_8N_2S_4$, N, 4.86; S, 22.22.

Benzenesulfonyl-*d,l*-phenylalanine Butyl Ester.—This was prepared from benzenesulfonyl-*d,l*-phenylalanine by vacuum distillation in the presence of excess butyl alcohol by the general method described by Gurin and Clarke.[7] The product is obtained in the form of needles after recrystallization from ether and petroleum ether: m. p. 107°; N, 3.95; calcd. for $C_{19}H_{23}O_4NS$, N, 3.88.

***N*-Benzenesulfonyl-*d,l*-serine Butyl Ester.**—After esterifying in the same manner with butyl alcohol, needles are obtained from ether and petroleum ether, m. p. 55°; N, 4.78; calcd. for $C_{13}H_{19}O_5NS$, N, 4.65.

Dibenzenesulfonyl-*l*-tyrosine Butyl Ester.—Obtained as needles from ethyl acetate and petroleum ether or from amyl ether; m. p. 98°; N, 2.74; calcd. for $C_{25}H_{27}O_7NS_2$, N, 2.72. $[\alpha]^{26}_D$ +20.1° (1% in ethyl alcohol). After distillation $[\alpha]^{26}_D$ +20.2°.

Benzenesulfonyl-*d,l*-methionine Ethyl Ester.—Prepared from benzene-sulfonyl-*d,l*-methionine by treatment with absolute ethyl alcohol and dry hydrogen chloride gas. The product crystallizes from ether and petroleum ether as tufts of fine needles; m. p. 45°; N, 4.60; calcd. for $C_{13}H_{19}O_4NS_2$, N, 4.41.

Separation of Dibenzenesulfonylcystine Diethyl Ester and Benzenesulfonyl-*d,l*-methionine Ethyl Ester.—From a mixture containing 50 mg. of dibenzenesulfonylcystine diethyl ester and 50 mg. of benzenesulfonyl-*d,l*-methionine ethyl ester, 49 mg. of the methionine derivative was recovered by high vacuum distillation at a temperature range of 75–95°. The benzenesulfonyl-*d,l*-methionine ethyl ester so recovered, melted at 45°; N, 4.50; calcd. for $C_{13}H_{19}O_4NS_2$, N, 4.41. The dibenzenesulfonylcystine diethyl ester remained in the distillation bulb unchanged; m. p. 120–121°.

Benzenesulfonylglycine Butyl Ester and Benzenesulfonyl-*d,l*-alanine Butyl Ester.—A mixture containing 100 mg. of benzenesulfonylglycine butyl ester and 85 mg. of benzenesulfonyl-*d,l*-alanine butyl ester was similarly subjected to high vacuum distillation. On heating to 50–75°, 98 mg. of a colorless oil was recovered, which crystallized on chilling and proved to be benzenesulfonylglycine butyl ester; m. p. 26°; N, 5.01; calcd. for $C_{12}H_{17}O_4NS$, N, 5.16. Upon raising the temperature to 125–135°, 81 mg. of benzenesulfonyl-*d,l*-alanine butyl ester was recovered; m. p. 113.5–114°; N, 4.78; calcd. for $C_{13}H_{19}O_4NS$, N, 4.91.

Carbethoxydiglycylglycine Ethyl Ester and Carbethoxyglycylglycine Ethyl Ester.—A mixture was made up consisting of 35.0 mg. of carbethoxyglycylglycine ethyl ester and 27.0 mg. of carbethoxydiglycylglycine ethyl ester. After distilling at 95–115° for one hour, a first fraction was recovered weighing 34.8 mg. and melting at 86°; N, 12.02; calcd. for $C_9H_{16}O_5N_2$, N, 12.07. The product obviously was pure carbethoxyglycylglycine ethyl ester.

A second fraction weighing 24.1 mg. was obtained at 175–185°, and appeared to be pure carbethoxydiglycylglycine ethyl ester; m. p. 158–159°; N, 14.35; calcd. for $C_{11}H_{19}O_6N_3$, N, 14.53. The remaining few mg. was accounted for by a small amount of decomposed material in the distilling bulb.

Benzenesulfonyl-*d,l*-leucylglycylglycine Ethyl Ester and Benzenesulfonyl-glycyl-*d,l*-alanine Ethyl Ester.—In a similar manner, a mixture consisting of 75.4 mg. of benzenesulfonyl-glycyl-*d,l*-alanine ethyl ester and 54.1 mg. of benzenesulfonyl-*d,l*-leucylglycylglycine ethyl ester was fractionated. At 90–110° a colorless oil was obtained weighing 70.3 mg.; after chilling, crystals were obtained melting at 74°, thereby indicating the product to be benzenesulfonyl-glycylalanine ethyl ester; N, 9.08; calcd. for $C_{13}H_{18}O_5N_2S$, N, 8.90.

The second fraction, obtained at 190–200°, weighed 48.5 mg. and appeared to consist of pure benzenesulfonylleucylglycylglycine ethyl ester; m. p. 171°; N, 10.25; calcd. for $C_{18}H_{27}O_6N_3S$; N, 10.16.

Summary

N-Benzenesulfonyl amino acid esters have been distilled at pressures of 10^{-6}–10^{-7} mm. No racemization and very little decomposition were observed under the conditions described.

A number of N-benzenesulfonyl di- and tripeptide esters were prepared and similarly distilled without decomposition. Carbethoxy peptide esters may likewise be distilled.

Several artificial mixtures containing N-acyl amino acid, dipeptide and tripeptide esters were fractionated by this method. In every case reported, the individual components were isolated in pure form, and in yields corresponding to 90% or more.

Helianthates of Amino Acid and Polypeptide Esters

BY SAMUEL GURIN[1] AND C. F. SEGAL

Sulfonic acid salts of amino acid and polypeptide esters have been infrequently described, or prepared for the characterization of such substances. Colombano[2] reported the preparation of the *d*-camphor-10-sulfonates and *d*-bromocamphorsulfonates of glycine and alanine ethyl esters. In addition to their mineral acid salts, the tartrates and picrates of amino acid esters have been described.[3] The preparation of helianthates of a number of bases by Dehn,[4] as well as the use of helianthin by Williams[5] for the removal of bases from aqueous solution, suggested the possible application of this method to the characterization of amino acid and polypeptide esters.

It was found that such salts could be prepared by the addition of methyl orange to amino acid ester hydrochlorides in aqueous solution (Table I). Orange colored crystalline precipitates of low solubility in water were obtained in yields ranging from 65–95%. These substances were generally recrystallized from hot water, alcohol or aqueous acetone; they are sparingly soluble in ether, chloroform and other organic solvents.

$$\mathrm{RCH(NH_2)COOR{\cdot}HCl + (CH_3)_2NC_6H_4N_2C_6H_4SO_3Na \longrightarrow RCH(NH_2)COOR{\cdot}(CH_3)_2NC_6H_4N_2C_6H_4SO_3H + NaCl}$$

Similar salts likewise may be prepared by the addition of helianthin to the free esters in appropriate solvents. This method has been employed only with butyl esters since they show considerably less tendency to form piperazines than do their corresponding methyl and ethyl esters.[6] For this purpose, several amino acids and peptides were esterified successfully at temperatures below 55° by prolonged vacuum distillation in the presence of a continuous excess of butyl alcohol containing just enough mineral acid for neutralization of the amino groups. The free esters were liberated with sodium hydroxide and sodium carbonate, followed by extraction with ether; after drying, and evaporating *in vacuo*, the residual sirup was usually dissolved in aqueous acetone and converted to the helianthate by the addition of an equivalent amount of helianthin.

Similar well crystallized salts are obtained with peptide esters (Table II). In these cases, hot aqueous solutions of methyl orange were added in equivalent proportion to cold and well-stirred aqueous solutions of peptide ester hydrochlorides.

In general, all of the helianthates are orange in color, and decompose over a narrow temperature range upon heating; in most cases darkening and gas formation were observed before the salts melted.

Colorimetric helianthin estimations were carried out in 50% aqueous acetic acid against helianthin standards dissolved in the same solvent. Concentrations of approximately 10^{-5} molar were used, since readings can be taken quite easily at this strength. The analytical figures given in the tables were obtained with a "Step" photometer equipped with an appropriate light filter, or with a K. and E. color analyzer using monochromatic light at 5100 Å.

In Table III are listed helianthates prepared from esters having one or more functional basic groups. It will be observed that lysine, histidine, arginine and cystine esters, as well as α-glycyllysine methyl ester,[7] form di-helianthates whereas ϵ-carbobenzoxylysine ester[7] yields a mono-helianthate. Within limits, therefore, colorimetric estimation of helianthin in such compounds affords another method for the titration of combining basic groups.

Guanidine salts are rapidly and almost completely precipitated from aqueous solution by methyl orange. It is interesting to note that free amino acids and polypeptides as well as their N-acyl derivatives do not yield similar products; cystine hydantoic acid and 5-methylhydantoin likewise failed to react.

Although helianthates of volatile bases have been decomposed by heating at temperatures sufficiently high to produce appreciable dissociation,[8] this method of recovering the base appar-

ently cannot be applied to the more heat stable amino acid ester helianthates; alanine butyl ester could not be recovered by dry distillation of the helianthate. A satisfactory method of recovery involves acidification of an alcoholic solution of the salt with dry hydrogen chloride. A very small amount of acid is generally sufficient to precipitate the greater part of the helianthin, leaving the ester hydrochloride in solution. Glycine ethyl ester hydrochloride was recovered in this manner from its helianthate in a yield of 79%. Attempts to decompose helianthates with alkali, followed by extraction with ether, have in several cases resulted in poor recovery of the amino acid esters.

Preliminary experiments indicate that salts of similar sparing solubility in water are apparently formed by Congo red, although this reagent appears to offer no advantage over methyl orange. Furthermore, ethane sulfonic, *n*-butane-sulfonic, benzyl-sulfonic, *m*-nitrobenzenesulfonic and *d*-camphor-10-sulfonic acids were found to yield hygroscopic and extremely water soluble sulfonates of amino acid and polypeptide esters. These substances were not investigated further.

Experimental

Glycine Ethyl Ester Helianthate.—To 10 cc. of a chilled aqueous solution of 1.39 g. of glycine ethyl ester hydrochloride was added with good stirring and cooling, 75 cc. of a hot water solution containing 3.27 g. of methyl orange. After stirring for twenty minutes, a heavy orange precipitate was filtered and washed several times with cold water. The product after recrystallization from hot methyl alcohol weighed 3.2 g. (78%). It may also be recrystallized from hot water.

Dibutyl-*d*-glutamate Helianthate.—To a solution of 5 g. of *d*-glutamic acid in 20 cc. of water containing 2 cc. of concentrated sulfuric acid, 100 cc. of butyl alcohol was added, and the material subjected to prolonged vacuum distillation at a temperature not higher than 55°. Butyl alcohol was added from time to time as required, and distillation continued for eight to ten hours, although esterification is practically complete in four to five hours. After removal of excess butyl alcohol by vacuum distillation, the residual yellow oil was dissolved in 20 cc. of cold water, made alkaline, and the butyl ester extracted into ether by the usual Fischer method. From the ether solution, 7.445 g. (84%) of the ester was obtained as a yellow oil. It was then dissolved in 50 cc. of 50% aqueous acetone, and a solution of 8.7 g. of helianthin in 100 cc. of the same solvent added. On evaporation to approximately 75 cc., a heavy precipitate of orange needles was filtered, and washed with 50 cc. of cold water. After recrystallization from hot methyl alcohol (1 g. requires 40 cc. boiling alcohol), 11.83 g. of helianthate was obtained (75% from ester). The product is sparingly soluble in cold water, ether or petroleum ether, but somewhat more so in acetone, aqueous acetone, and hot methyl alcohol, dioxane or water.

***d,l*-Alanine Butyl Ester Helianthate.**—Alanine (5 g. in 50 cc. of water containing 3.5 cc. concentrated sulfuric acid) was converted to its butyl ester sulfate by vacuum distillation in the presence of excess butyl alcohol as described above. From this material, 4.37 g. of free ester was obtained and converted to the helianthate by the addition of 9.2 g. of helianthin in aqueous acetone solution. After recrystallization from hot alcohol, the salt weighed 10.45 g. (77% from ester).

Methionine Ethyl Ester Helianthate.—Methionine ethyl ester hydrochloride was prepared from synthetic methionine with absolute ethyl alcohol and dry hydrogen chloride gas; it was recrystallized from alcohol and ether; m. p. 212° dec., N, 6.61; calcd. for $C_7H_{16}O_2NSCl$, N, 6.55. To a solution of 1 g. of methionine ethyl ester hydrochloride in 10 cc. of cold water, was added 1.5 g. of methyl orange in 25 cc. of hot water. After stirring and cooling for thirty minutes, the precipitate was filtered, washed with cold water and recrystallized from boiling methyl alcohol (1 g. requires 150 cc. of methyl alcohol). The product weighed 1.8 g. (81%).

Glycylglycine Ethyl Ester Helianthate.—Ninety-eight hundredths gram of glycylglycine ethyl ester hydrochloride prepared according to Fischer and Fourneau[9] (m. p. 181–182°), was dissolved in 5 cc. of cold water, and a solution of 1.63 g. of methyl orange in 25 cc. of hot water added with good stirring and chilling. The precipitate was filtered, washed with cold water and, after recrystallization from boiling alcohol, weighed 1.97 g. (85%).

Glycyl-*l*-leucine Ethyl Ester Helianthate.—Glycyl-*l*-leucine ethyl ester hydrochloride was prepared in the usual way from glycyl-*l*-leucine.[10] The product is appreciably soluble in alcohol from which it may be precipitated by 2–3 volumes of ether in the form of glistening plates; m. p. 163–164°; N, 11.20; calcd. for $C_{10}H_{21}O_3N_2Cl$, N, 11.09. The helianthate was obtained as described above in 92% yield after recrystallization from hot ethyl alcohol.

Guanidine Helianthate.—To a solution of 2 g. of guanidine sulfate in 50 cc. of water was added with stirring a hot solution of 6.1 g. of methyl orange in 150 cc. of water. After filtering and washing with water, the precipitate was recrystallized from 800 cc. of boiling water. The product weighed 6.35 g. (95%).

Glycine Ethyl Ester Hydrochloride from Glycine Ethyl Ester Helianthate.—Two-tenths gram of glycine ethyl ester helianthate was dissolved in 100 cc. of hot absolute ethyl alcohol and acidified with a small amount of dry hydrogen chloride gas producing an almost immediate precipitate of helianthin. After cooling, the helianthin was removed by filtration, and the alcoholic solution concentrated *in vacuo* to a volume of 10 cc. On chilling, glycine ethyl ester hydrochloride was obtained, and, after recrystallization from 10–15 cc. of hot absolute alcohol, weighed 0.0539 g. (78.9%); m. p. 142°. A mixed m. p. with synthetic glycine ethyl ester hydrochloride showed no depression.

Summary

By the addition of methyl orange to amino acid and polypeptide ester hydrochlorides, crystalline helianthates have been prepared. These salts are non-hygroscopic and sufficiently insoluble in water to serve as a convenient means for isolating or characterizing amino acid and polypeptide esters. Similar salts may likewise be prepared by the addition of helianthin to the free esters.

Butyl esters of amino acids and polypeptides may be prepared conveniently by vacuum distillation with excess butyl alcohol containing small amounts of mineral acid.

Amino acids and polypeptides do not yield similar products; guanidine forms a characteristic helianthate having a low solubility in water.

Colorimetric estimations of helianthin in these salts have been carried out in 50% aqueous acetic acid, thereby furnishing a simple method for the titration of combining basic groups as well as analysis of the substances. Lysine, histidine, arginine and cystine esters have been found to form di-helianthates.

A method is described for the recovery of ester hydrochlorides from their helianthates.

The Action of Alkalies on Mixtures of Aromatic Aldehydes

BY JOHN C. BAILAR, JR., ALLAN J. BARNEY AND R. F. MILLER

It has been shown[1] that a crossed Cannizzaro reaction may take place between two aliphatic aldehydes or an aromatic and an aliphatic aldehyde. This paper reports some experiments which demonstrate that a crossed Cannizzaro reaction may also take place between two aromatic aldehydes.

The first experiments undertaken were directed toward carrying out such a reaction between benzaldehyde (which undergoes the Cannizzaro reaction readily) and *p*-dimethylaminobenzaldehyde (which does not react under the conditions of our experiments). That the reaction might take place seemed logical in view of Staudinger's discovery[2] that both benzaldehyde and *p*-chlorobenzaldehyde form mixed benzoins with *p*-dimethylaminobenzaldehyde although *p*-dimethylaminobenzaldehyde alone does not undergo the benzoin condensation. It was found, however, that the *p*-dimethylaminobenzaldehyde could be recovered unchanged, the benzaldehyde reacting in the normal manner. Likewise, when a mixture of benzaldehyde and *m*-nitrobenzaldehyde was stirred with 14% potassium hydroxide, only the *m*-nitrobenzaldehyde seemed to react. Benzaldehyde undergoes the Cannizzaro reaction readily with concentrated alkali but will not react in a solution of this concentration.

When a mixture of *p*-chlorobenzaldehyde and anisaldehyde was allowed to react with alkali, a definite disproportionation took place. This discovery led to a study of several mixtures containing halogen substituted benzaldehydes, the results of which are summarized in Table I. In every case a crossed Cannizzaro reaction took place. In two cases (numbers 7 and 14) the individual acids were separated from their mixtures, but in most cases the mixtures were simply analyzed for halogen and the composition of the mixture calculated. Experiments 1, 2 and 8 were carried out under different conditions than the rest.

The analysis of the alcohol mixtures containing benzyl alcohol did not give consistent results. This evidently is due to the volatility of benzyl alcohol, which makes it difficult to free the alcohol mixture from ether and water without losing benzyl alcohol, and so altering the composition of the mixture. On this account, the analyses for the alcohol mixtures obtained from meta- and para-bromobenzaldehyde with benzaldehyde are not reported, and the results in these cases must be considered as tentative.

While the data are insufficient to allow any theoretical deductions, they indicate plainly that crossed Cannizzaro reactions can take place with mixtures of aromatic aldehydes. It is interesting to note that in every case the halogen substituted aldehyde is preferentially oxidized at the expense of the other aldehyde.

Experimental

Benzaldehyde and *p*-Dimethylaminobenzaldehyde.—A mixture of five grams of each of the aldehydes was shaken vigorously with 20 g. of a 50% solution of potassium hydroxide for two hours and allowed to stand for twenty-four hours. The mixture was diluted with 300 cc. of water, and extracted with three 40-cc. portions of ether. The ether extract was shaken with a saturated solution of sodium bisulfite (which precipitated part of the dimethylaminobenzaldehyde as the bisulfite addition product) and was then distilled. The fraction boiling between 200–206° was taken as benzyl alcohol. The yield was 2.2 g. (88% of the theoretical). The residue from the distillation solidified on cooling. After recrystallization, this solid melted at 73°. *p*-Dimethylaminobenzaldehyde melts at 74°. The recovery of the substituted aldehyde from the bisulfite compound and from the distillation was almost quantitative.

The aqueous residue from the ether extraction was acidified, and the precipitated benzoic acid was filtered off. It melted at 121° and weighed 2.1 g. (84% yield). The filtrate was neutralized carefully, but no *p*-dimethylaminobenzoic acid could be obtained.

Benzaldehyde and *m*-Nitrobenzaldehyde.—A mixture of 18.1 g. of *m*-nitrobenzaldehyde and 13.7 g. benzaldehyde was allowed to drip into 280 g. of a 14% solution of potassium hydroxide with vigorous stirring. After standing for twenty-four hours, the solution was diluted and extracted with ether as before. Treatment with sodium bisulfite resulted in the recovery of 11.9 g. of unchanged aldehydes, practically all of which was benzaldehyde. The aqueous residue from the ether extractions was acidified, and the copious precipitate of acid steam distilled. No benzoic acid was present in the distillate, as was shown by extracting it with ether and evaporating the extract.

TABLE I

Substituted benzaldehydes	Expt.	Ratios: Halo acid to other acid				Ratios: Halo alcohol to other alcohol			
p-Chloro- and *p*-methoxy-	1, 2, 3, 4	2.3:1	2.3:1	1.6:1	1.6:1	1:2.7	1:2.5	1:2.0	....
p-Chloro- and benz-	5, 6, 7, 8	1.45:1	1.3:1	1.7:1	2.5:1	1:1.3	1:1.3	....	1:2.8
p-Chloro- and (*m*,*p*-methylenedioxy)-	9			1.8:1					1:1.95
p-Bromo- and *p*-methoxy-	10, 11			2.3:1	2.8:1			1:1.8	1:2.1
p-Bromo- and benz-	12, 13, 14		1.4:1	1.3:1	1.2:1				
m-Bromo- and *p*-methoxy-	15, 16			1.9:1	1.7:1			1:1.8	1:2.0
m-Bromo- and benz-	17, 18, 19		2.4:1	2.1:1	2.2:1				

Procedure for Experiments Recorded in Table I (Except Numbers 1, 2 and 8).—A mixture of the two aldehydes (0.05 mole of each) was allowed to drop slowly into a solution of 27.5 g. of potassium hydroxide in 25 cc. of water with vigorous stirring. When the addition was complete, the temperature was raised slowly to 100° and held at that point for two hours. The solution was diluted to 400 cc. and extracted with four portions of ether. The ether extracts were combined, treated with bisulfite (which in no case gave more than 0.1 g. of precipitate), washed with water, dried over anhydrous sodium sulfate, and evaporated. The residue was analyzed for halogen by decomposition in the Parr bomb and titration by the Volhard method. The aqueous residue from the ether extractions was acidified with hydrochloric acid, and extracted with four portions of ether. The ether solutions were dried and evaporated and the residue analyzed as described for the alcohols.

Procedure for Experiments 1, 2 and 8 of Table I.—A mixture of five grams of each aldehyde, 10 g. of potassium hydroxide, and 10 cc. of water was shaken vigorously for two hours and allowed to stand a day. The remainder of the procedure was the same as that described above.

In Experiments 7 and 14 the acids were separated by steam distillation. This does not give a sharp separation of *p*-chlorobenzoic acid and benzoic acid, so the ratio given in Experiment 7 is only approximate. The separation of *p*-bromobenzoic acid and benzoic acid is very good, however, the recovered acids melting at 249 and 120° (reported, 251–253 and 122°).

Summary

It has been shown that 50% potassium hydroxide solution, acting on a mixture of benzaldehyde and *p*-dimethylaminobenzaldehyde induces the Cannizzaro reaction for the benzaldehyde only. The other aldehyde is not affected. A mixture of *m*-nitrobenzaldehyde and benzaldehyde, under the action of 14% potassium hydroxide, gives nitrobenzoic acid and nitrobenzyl alcohol, without attacking the benzaldehyde.

Seven reactions have been studied in which a crossed Cannizzaro reaction takes place between aromatic aldehydes. One member of the aldehyde pair in each of these was halogen substituted, and in every case, the halogen substituted molecule showed a tendency to be oxidized to the acid at the expense of the other aldehyde.

URBANA, ILL. RECEIVED AUGUST 19, 1936

Dipole Moment and Structure of Organic Compounds. XVI.[1] The Electric Moments of Some Chlorinated Diphenyls

BY G. C. HAMPSON AND A. WEISSBERGER

It has been suggested[2] that the electric moments of mono- and dichloronaphthalenes indicate a polarization of the naphthalene system by the polar C–Cl link, this polarization causing the observed moments to deviate considerably from those calculated when this effect is neglected, and a similar behavior has been found with the chlorodiphenyls. In the case of the dichlorodiphenyls with substituents in *both* rings, in either the ortho or meta position, a further complication is introduced, for there the moment will depend primarily on the configuration of the two rings about the diphenyl link. In view of the forces which govern the probability of the various configurations, special attention has been drawn to the case of *o*,*o*′-dichlorodiphenyl. The moment of this compound is larger than that of the *m*,*m*′-isomeride, and this is even more surprising in view of the fact that in the *o*,*o*′-compound the *cis*-configuration and a wide range of positions in the neighborhood of the *cis*-position which would contribute to a large moment are precluded for steric reasons. To account for the facts we suggested that *London forces* play an important role in determining the inner configuration of the molecule.

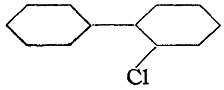
(1) Hampson and Weissberger, Paper XV, *J. Chem. Soc.*, 393 (1935).

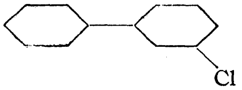
(2) Weissberger, Sängewald and Hampson, *Trans. Faraday Soc.*, **30**, 884 (1934).

In the preceding paper[1] the polarization effect in the case of the chloronaphthalenes has been treated quantitatively. The present paper deals in a similar way with the three monochlorodiphenyls, and also attempts to give a quantitative treatment of the factors governing rotation about the diphenyl link in the case of the *o,o'*- and *m,m'*-dichlorodiphenyls.

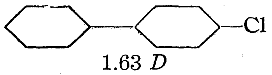
The moments of the compounds under consideration have been redetermined to obtain consistent data of sufficient accuracy. They are



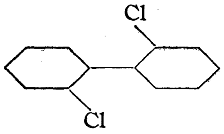
1.45 *D*



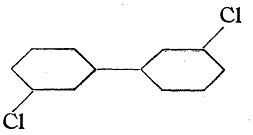
1.64 *D*



1.63 *D*



1.91 *D*



1.80 *D*

In calculating the polarizing influence of the C–Cl bond, each of the monochlorodiphenyls has been regarded as a chlorobenzene molecule to which a polarizable benzene ring has been attached, the method of calculation following precisely as in the case of the monochloronaphthalenes.[1] Each of the rings has been assumed to be a regular hexagon of side 1.4 Å.,[3] the length of the internuclear C–C bond being taken as 1.48 Å.[4] The substituted chlorine atom has been assumed to be directed as from the center of the ring and μ_{C-Cl} has been taken as 1.55 *D*.[5] Since a benzene molecule is more polarizable in the plane of the ring than perpendicular to the ring, the magnitude of the polarization in the case of the chlorodiphenyls will vary with the relative configurations of the two rings.

Table I gives the calculated moments for *o*-, *m*- and *p*-monochlorodiphenyl (a) when the rings are co-planar, (b) when they are mutually perpendicular, (c) when there is free rotation, the polarizability of a benzene ring in the plane of the ring being taken as 12.5×10^{-24} and perpendicular to the ring 6.2×10^{-24}.[6]

TABLE I

	Rings co-planar	Rings perpendicular	Free rotation
o-Chlorodiphenyl	1.31	1.40	1.355
m-Chlorodiphenyl	1.601	1.604	1.603
p-Chlorodiphenyl	1.64	1.64	1.64

The results are in quite good agreement with the experimentally determined values, especially as one would expect that in *o*-chlorodiphenyl there would be a tendency for the rings to be perpendicular for steric reasons. An obvious cause of the small discrepancies is the fact that the moment 1.55 of chlorobenzene has been assumed to be located solely in the C–Cl bond, whereas part of it is certainly spread over the rest of the molecule.

In dealing with the *o,o'*- and *m,m'*-dichlorodiphenyls the most important factor in deciding the resultant moment of the molecules is the disposition of the two rings about the diphenyl link. The forces which regulate the probabilities of the various configurations are (a) electrostatic repulsions and attractions, (b) quantum mechanical attractions (London forces), (c) quantum mechanical repulsions (impenetrability of colliding atoms).

In the calculation of these forces the authors have enjoyed the help of Dr. F. London and they acknowledge with sincere thanks his valuable assistance.

Suppose that in any molecule the two rings are oriented about the diphenyl link so that the angle between their planes is ϕ; if now the component moment of each of the two C–Cl bonds perpendicular to the axis of rotation is μ'

$$\text{the resulting moment of the molecule} = 2\mu' \cos \phi/2 \quad (1)$$

In calculating the electric moment of an assemblage of such molecules the problem is to determine the mean angle ϕ. Now the measured polarization is a function of the square of the dipole moment, which in turn is a function of $\cos \phi/2$, hence the measured polarization is made up of a series of terms characteristic of the various orientations, each term being a function of $\cos^2 \phi/2$. Having performed the summation and deduced the mean square of $\cos \phi/2$, the dipole moment is calculated from the root mean square according to equation (1).

The potential as a function of the disposition of the rotating groups has been calculated and discussed for ethane by Eyring[7] and by Teller and

[7] Eyring, THIS JOURNAL, **54**, 3191 (1932).

Weigert.[8] A general quantum mechanical treatment which involves all forces between the hydrogen atoms results in showing minima for the positions in which the hydrogen atoms of one CH_3 group are not eclipsing those of the other CH_3 group when viewed along the C–C axis. The potential differences however are so small in comparison with kT, that at ordinary temperatures free rotation is developed; *i. e.*, all positions from 0 to 2 π have practically the same probability. Calculations for 1,2-dichloroethane have been made by Meyer[9] and by Smyth, Dornte and Wilson.[10] Meyer treats the problem classically and considers only the electrostatic effect of the C–Cl moments on each other. These are assumed to be located on the C–Cl axis in a point one-eighth of the C–Cl distance from the center of the chlorine atom.

The calculation gives a minimum of the potential for the *trans*-position, and the potential difference between the *cis*- and *trans*-positions is sufficiently large in comparison with kT to establish a distinct preference for the *trans*-position at ordinary temperatures. This result has been confirmed by Smyth, Dornte and Wilson[10] with a different location of the C–Cl moment and also taking into consideration the effect of the C–H dipoles. These authors further undertake a wave-mechanical treatment and show that the classical treatment of the problem is adequate.

More recently a complete mathematical treatment of the interaction between rotating polar groups in a molecule has been given by Lennard-Jones and Pike[11] and by Altar.[12] Altar introduces a factor neglected hitherto by considering the effect of the variation of the moment of inertia of the molecule with rotation of the polar groups. In a molecule such as 1,2-dichloroethane, for example, where the polar groups are heavy in comparison with the rest of the molecule and unsymmetrically distributed about the molecular axis, the three moments of inertia of the molecule do not remain constant, but vary with the internal configuration of the molecule. Also since the probability of a molecule existing in a given configuration depends on the moment of inertia of the molecule in that configuration, the probability being greater the greater the moment of inertia, one cannot apply simply a Boltzmann formula in order to deduce the mean angle ϕ, but one has to consider the statistics of all degrees of freedom involved, *i. e.*, one must weigh each individual configuration according to its moment of inertia, by multiplying by an appropriate weight factor. The weight factors calculated[12] in the case of 1,2-dichloroethane for several configurations are as follows:

	ϕ	W
cis config.	0°	0.68
	45°	.96
	90°	1.20
	135°	1.02
trans config.	180°	0.96

the effect of the moment of inertia being to favor the 90° configuration.

In the case which we are considering, namely, *o,o'*-dichlorodiphenyl, the variation of the moment of inertia with rotation will be smaller since the molecule is a comparatively large and heavy one and the only dissymmetry is caused by the two chlorine atoms. Also since configurations with small values of ϕ are precluded for steric reasons, the variations in the weight factor will certainly not be more than 10%, which, in view of the other uncertainties involved in these calculations, justifies the neglect of this effect.

Stuart,[13] in discussing the equilibrium between *cis* and *trans* dichloroethylene, also considers the London forces and the induction effect which in this case is high, due to the great polarizability of the double bond. These calculations, owing to the rigidity of the double bond, deal only with the two "plane" configurations of the geometrical isomers. They show, in agreement with the experimental facts, that the potential for the *cis*-position is lower than that for the *trans*-position.

With dichlorodiphenyl, as with dichloroethane, rotation about a single bond is involved, and one needs to know the potential over the whole range of a revolution.

The general method of procedure was to calculate the sum of the potentials Σv due to the electrostatic and quantum mechanical forces for various values of ϕ and construct Boltzmann terms $e^{-\Sigma v/kT}$ giving the probabilities of the molecules existing in the different configurations. The dipole moment μ was then calculated from the formula

[13] Stuart, *Physik. Z.*, **32**, 793 (1931).

$$\mu = 2\,\mu' \sqrt{\frac{\int_0^\pi e^{-\Sigma v/kT} \cos^2 \frac{\phi}{2}\, d\phi}{\int_0^\pi e^{-\Sigma v/kT}\, d\phi}} \qquad (2)$$

In computing the *electrostatic* potentials we have adopted a method which is different from that of either Meyer or of Smyth, Dornte and Wilson. We consider the dipole as being formed by positive and negative charges of magnitude ϵ at the centers of the constituting atoms, ϵ being equal to μ/d where μ is the moment and d the distance between the atomic centers. The electrostatic potential is then given by $\Sigma(\epsilon_i\epsilon_j/r_{ij})$; r is the distance between the point charges ϵ_i and ϵ_j and varies with the angle of rotation ϕ.

The variable distances are calculated from the formulas

$$\begin{aligned} r &= \sqrt{b^2 + 4a^2 \sin^2 \phi/2} \\ r' &= \sqrt{b'^2 + (a - a')^2 + 4aa' \sin^2 \phi/2} \qquad (3) \\ r'' &= \sqrt{b''^2 + 4a'^2 \sin^2 \phi/2} \end{aligned}$$

where r, r' and r'' are the distances Cl_1 to Cl_2, Cl_1 to C_2, and C_1 to C_2, respectively; the significance of the symbols is evident from Fig. 1.

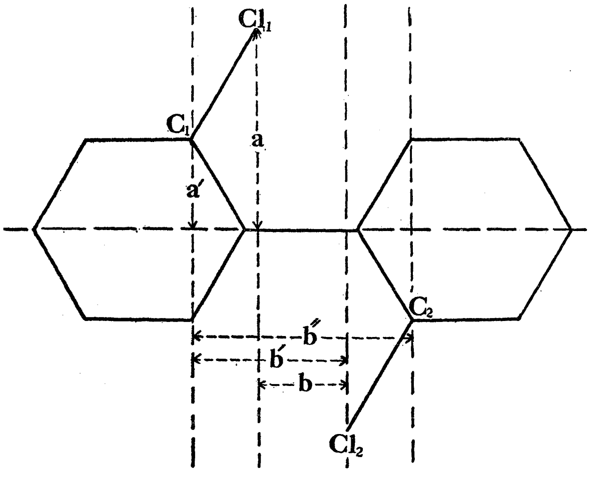

Fig 1.

The numerical data used are those given on page 2112; the distance C–Cl has been taken as 1.69 Å.;[14] $\phi = 0$ indicates the co-planar *cis* configuration. The total electrostatic potential for each angle is $\epsilon^2(1/r + 1/r'' - 2/r')$.

As was shown by Smyth, Dornte and Wilson,[10] the nature of the potential energy curve varies somewhat with the arbitrary location of the dipoles. We have no reason to believe that our convention, just described, is any more exact than that of other authors, and so for the purpose of comparison we have also calculated the electrostatic potential energies by Smyth's method. The results obtained by the two methods are shown in Fig. 2, U_1 being the electrostatic potential energy curve calculated by the charge-separation method, and U_2 the electrostatic potential energy curve calculated by Smyth's method. They have the same general shape and give approximately the same potential energy difference between the *cis*- and *trans*-positions. The most important factor, however, in governing the orientation of the molecule is the *London dispersion force.*

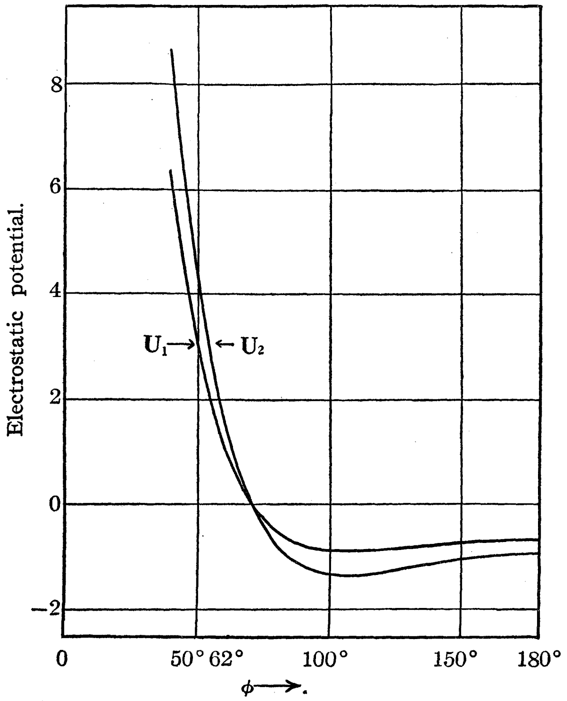

Fig. 2.

The *London forces* are of interest only for the chlorine atoms in *o,o′*-dichlorodiphenyl since for the other atoms they are negligible in their absolute magnitudes and furthermore do not vary much with ϕ. This applies also to the chlorine atoms in *m,m′*-dichlorodiphenyl but in this case they have been evaluated for comparison with the *o,o′*-compound. The London potential for the chlorine atoms has been taken as $115 \times 10^{-60}/r^6$, terms involving higher powers of r, which become important only when the atoms approach very close to each other, being neglected.

The numerical results for *o,o′*- and *m,m′*-dichlorodiphenyl are given in Tables II and III under the appropriate symbols.

The case of *m,m'*-dichlorodiphenyl, where the centers of the chlorine atoms even in the *cis*-position do not come nearer to each other than to a distance of 7.37 Å., is not of any special interest except for comparison with the *o,o'*-compound. Figure 3 shows the probability $e^{-(U+L)/kT}$ for the *m,m'*-isomeride. It indicates a slight preference for the *trans*-position, but the potential energy $(U + L)$ difference between the *cis*- and *trans*-positions (*ca.* 0.3×10^{-14} ergs) is so small in comparison with kT (*ca.* 4×10^{-14} ergs) that free rotation is virtually established. The moment for free rotation ($\sqrt{2} \times 1.55 \cos 30°$) would be 1.90 *D*, that calculated from eq. (2) is 1.89 *D*,[15] the measured moment is 1.80 D. The difference is probably due to induced effects by the two dipoles, similar to those calculated in the case of the monochlorodiphenyls on page 2112.

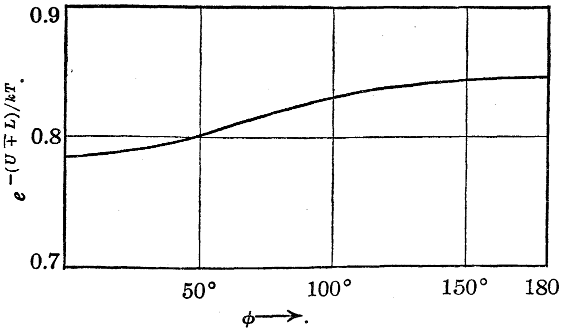

Fig. 3.—Probability distribution curve for *m,m'*-dichlorodiphenyl.

---

[15] The integrals were evaluated graphically.

For *o,o'*-dichlorodiphenyl the data reveal the striking fact that the electrostatic potentials (U_1 or U_2 according to the mode of calculation), which favor the *trans*-position, are largely overcompensated by the London potentials, and that the internal configuration of the molecule depends almost entirely on the latter. As these decrease with the sixth power of r, they produce a considerable preference for positions with small angles ϕ. The probability of the various configurations as a function of ϕ is given by the numerical values of $e^{-(U_1 + L)/kT}$ and by the full line in Fig. 4.[16] This proves our suggestion of the influence of the London forces as previously stated.[2] The curve indicates that the smaller the angle ϕ the greater is the probability. A limit, of course, must be set by a steric factor. In agreement with the resolvability of *o*-substituted diphenyl compounds, the table of values of r shows that no chance of a co-planar *cis*-configuration exists. Already at an angle $\phi = 35°$, the Cl–Cl distance is that of two chlorine atoms in a chlorine molecule. At a value $\phi = 60°$ they are at the distance 2.93 Å. which has been measured for the two chlorine atoms in methylene chloride,[17] where there still seems to be a slight repulsion between the chlorine atoms as is indicated by a deflection (2–3°) of the carbon valences. Configurations with a smaller angle ϕ can have only a small probability, and so the probability function must be characterized by a maximum where the repulsion forces (electrostatic and steric) are in equilibrium with the London attraction forces.

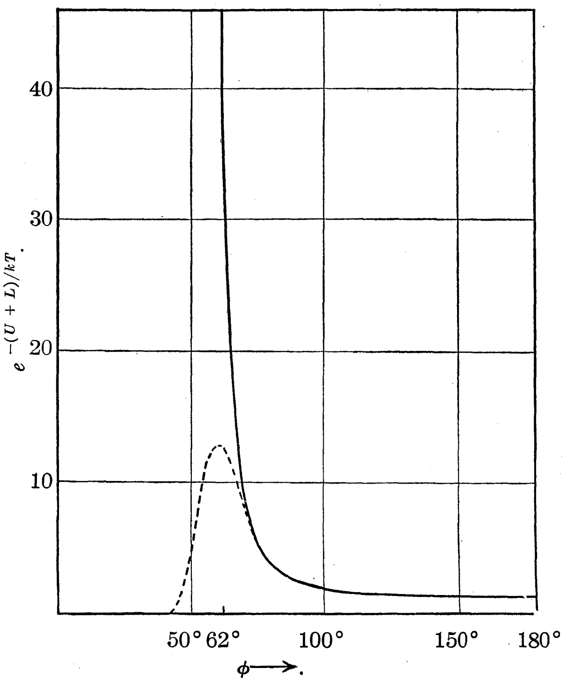

Fig. 4.—Probability distribution curve for *o,o'*-dichlorodiphenyl.

Little is known about the law of steric repulsion in question. For ions Born and Mayer[18] use a repulsion law of the form $be^{-r/\rho}$ (4) where b is a constant characteristic of the ions in question and they found that for the alkali halides ρ has a mean value of 0.345×10^{-8} cm. It seems reasonable to assume that such a law holds also in the case of covalently bound atoms but there is, of course, no reason for assuming that ρ especially equals 0.345.

In order to get an idea of the equilibrium distance the value for 60°, whose significance has been pointed out above, will be taken as a lower limit. The close packing distance between two chlorine atoms not belonging to the same molecule, and found to be 3.74 Å. for hexachlorobenzene,[19] gives the upper limit. The distance of equilibrium for *o,o'*-dichlorodiphenyl should be smaller than that owing to the smaller freedom of motion. Sidgwick's suggestion to add 0.5 Å. to the radius of the bound atom[20] gives a value of about 2.98 Å. for the distance of equilibrium. No other data appear to be available. In these circumstances the least hypothetical treatment will be to consider the repulsion potential as a rigid barrier, and to try at what angle we must cut the probability curve by a straight line parallel to the ordinate to obtain the experimental value for the moment from equation (2). This angle is 62° and it corresponds to a distance of 3.0 Å. between the chlorine atoms. If instead of this vertical barrier we multiply the probability function by an exponentially increasing repulsion term of the form $e^{-be^{-r/\rho}/kT}$ we get a probability curve shown by the dotted line in Fig. 4. Owing to the uncertainty in the law of repulsion, however, a calculation of the moment from this probability curve hardly seems justified.

Another effect which should be considered is the induction effect of the two C–Cl dipoles. This will tend to make the resultant moment of the compound low, especially in the case of the

---

[16] $e^{-(U_2+L)/kT}$ gives essentially the same type of curve.

o,o'-compound where the two dipoles come close to one another. On the other hand, this induction will contribute to the forces which favor molecules with smaller angles ϕ, and since both effects will be small and of inverse influence on the measured moment, their evaluation *in extenso* has not been undertaken.

The main results of our investigation may be summarized thus. The moments of the monochlorodiphenyls are explained if one takes into account the inducing effects of the polar group on the unsubstituted nucleus, as in the case of the chloronaphthalenes. The configuration of *o,o'*-dichlorodiphenyl is governed predominantly by the London forces.

Experimental

Polarization Results.—The measurements were carried out in benzene solution at 25.0°. The symbols have their usual significance.

The substances were either identical with, or prepared by, the same methods as those described by Weissberger and Sängewald.[21] A slight alteration has been made in the preparation of *o,o'*-dichlorodiphenyl. The Ullmann reaction was carried out for twelve hours at 260° with an *o*-chloroiodobenzene obtained from *o*-chloroaniline (purified according to Orton and King),[22] and worked up by vacuum distillation; b. p. (16 mm.) 145–165°; m. p. 52–55°; yield 40%; m. p. after repeated recrystallization from alcohol and finally from hexane 60.7–62°.

We wish to thank Professor R. Robinson, F.R.S. for his hospitality to A. W., and Imperial Chemical Industries Ltd. for a grant.

Summary

The electric moments of the monochlorodiphenyls and the dichlorodiphenyls with the substituents in identical position in both rings have been determined.

The moments of the monochlorodiphenyls are explained by taking into account the inducing effects of the polar group on the unsubstituted nucleus, as in the case of the chloronaphthalenes.

The forces which determine the configuration of *m,m'*- and *o,o'*-dichlorodiphenyl have been evaluated. Since the electrostatic attraction and repulsion forces largely compensate each other, the configuration of the latter substance is predominantly determined by the London dispersion forces between the chlorine atoms. This explains the high moment of *o,o'*-dichlorodiphenyl.

A Differential Method Employing Variable Heaters for the Determination of the Specific Heats of Solutions, with Results for Ammonium Nitrate at 25°

BY FRANK T. GUCKER, JR., FRED D. AYRES AND T. RICHARD RUBIN

Introduction

The adiabatic twin-calorimeter method is admirably suited to the precise measurement of the specific heats of solutions. A "thermal balance" employing this method has been in use for some time in this Laboratory.[1] In preparation for a new series of experiments, several modifications and improvements were introduced and a method was worked out whereby the electrical energy input in the calorimeters could be changed by means of variable resistance heating coils. This made the new apparatus much more flexible and convenient; and also increased its accuracy somewhat, as the new experimental results indicate. After a brief summary of the experimental method the significant new features of the present apparatus will be considered in more detail. For experimental details which were not appreciably changed, the reader is referred to the earlier articles mentioned above.

The apparatus consists of two similar calorimeters, one containing a solution, the other a fixed tare weight of water, enclosed side by side in a submarine jacket contained in an adiabatic water-bath. Starting at the same initial temperature, the calorimeters are heated one degree by means of a pair of variable resistance coils connected in series. The resistance ratio of these coils is adjusted until the two calorimeters are heated at the same rate, as determined by a multiple thermel connected to a high sensitivity galvanometer. The heat capacity of the solution is then calculated from the measured resistance ratio and the known heat capacity of the calorimeter.

Apparatus

General Description.—A general idea of the apparatus may be obtained from the simplified drawing, Fig. 1. The two calorimeters, C, C, of 280-ml. capacity, are enclosed in a water-tight submarine jacket, J, which is completely immersed in the water-bath, B. The stirrers, S, S, are rotated at 215 r. p. m. by a sprocket chain driven from a synchronous motor. The Bakelite thermal insulators (indicated by cross-hatching) in the stirrer shafts prevent leakage of heat into the calorimeters from the bearings above. The water-bath, B, is mounted on a motor-operated, vertical jack-screw so that it can be raised or lowered easily, even when filled with water. It is agitated by two stirrers (not shown in the diagram) which are driven at 215 r. p. m. by the same sprocket chain which operates the calorimeter stirrers. The bath is heated by four bare nichrome coils (not shown in Fig. 1) each of five ohms resistance, connected in series to the 110-volt a. c. circuit. Each coil is 30 cm. long, loosely wound around a heavy copper wire serving as one of the leads, from which it is insulated by a length of glass tubing. The coils are equally spaced and mounted on the brass plate, P, by means of standard attachment plugs so that they project vertically down into the water. A cover, F, and lid, L, fit over the top of the bath. The entire apparatus is insulated with a 5-cm. layer of felt, H. Bare chromel wires, insulated between thin sheets of asbestos, are wound around the cover, lid and bath, under the felt. These surface heaters, connected through a rheostat to the 110-volt a. c. circuit, compensate for loss of heat when working at temperatures higher than that of the room. To maintain temperatures below that of the room, a regulated stream of cold water is allowed to drip into the bath. The surplus water escapes through the outlet tube, R, and the sight glass and overflow, D.

Submarine Jacket.—The heavy copper submarine jacket, J, was nickel plated and burnished on the inside. The bottom was detachable in order to expedite the process of plating and burnishing. Once this was accomplished, a gasket was put in place and the bottom was bolted on permanently. The top of the jacket was rigidly attached to the lid of the bath, P, by the heavy brass tubes through which the stainless steel stirrer shafts extended. The calorimeters were suspended entirely from this top plate, so that the lower part of the submarine jacket was easily detached at the point indicated by the gasket, G.

Calorimeters.—The calorimeters and lids were spun from an alloy of 20% platinum and 80% gold,[2] which combines chemical inertness with adequate mechanical strength. The lids were ground to fit their respective calorimeters and the joints were made vapor-tight by a thin coating of vaseline. Three wells for the thermel and heater cases were gold-soldered to each lid. Only the wells for the main and adiabatic thermels are shown in the horizontal section in Fig. 1. The third well, for the heater, was located directly behind the stirrer. Each lid was also provided with two conical openings. Into the center one was ground the lower end of a glass tube, E, through which passed the stirrer shaft. Toward one side was a second opening, not shown in Fig. 1, fitted with a ground plug. The calorimeter was filled through this second opening. All the ground joints were made vapor-tight by means of a thin coating of vaseline. The 3-stage propeller stirrers, S, S, made of platinum, were screwed into insulating sec-

[2] The calorimeters were made by J. Bishop & Co.

tions machined from transparent Bakelite, indicated by cross-hatching in Fig. 1. This material has a low thermal conductivity. Since tests showed it is almost impervious to water, it is superior to the ivory sections used previously in this Laboratory. Unfortunately, it softens so much that it cannot be used above 40 or 50°. The lower end of the Bakelite was conical to fit a 60° conical seat in the bottom of the glass tube, E.

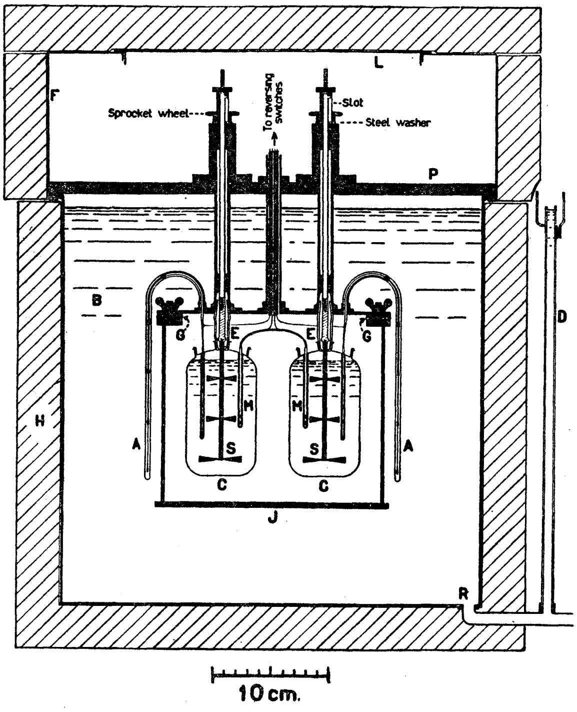

Fig. 1.—Calorimetric assembly.

In assembling the apparatus, the glass tube, E, was fitted into the lid of the calorimeter. The Bakelite section next was put in place and the stirrer screwed to it. The lid, carrying the stirrer, was put on the calorimeter, into which water or solution was then weighed. The conical joint between Bakelite and glass prevented evaporation during this process. The calorimeter was then raised until the top of the glass tube, E, fitted the conical base of the brass tube in the submarine lid, into which it had been ground. A temporary supporting frame held the calorimeter rigidly in this position. The bottom of the stainless steel shaft which carried the sprocket wheel was now screwed into the upper end of the Bakelite section, which was kept from turning by the friction between it and the conical seat in E. Finally the knurled knob above the sprocket wheel was screwed down, raising the shaft to the position shown in Fig. 1, where the Bakelite section is clear of the glass.

Each calorimeter was suspended from the top of the submarine jacket by four equally-spaced pieces of dental floss. The lower ends of these were tied to small wire loops, gold-soldered to the sides of the calorimeters near the top. The upper ends were slipped over small adjustable wire hooks which projected down from the top of the submarine jacket. Above the hook, each wire passed through a hole in the axis of a small machine screw, the lower end of which was knurled so that it could be turned with the fingers. Each screw was threaded vertically into a support fastened to the submarine lid. The top of the wire was bent horizontally, to fit into a vertical slot in the support, so that the hook did not rotate when the screw was turned. When the screws were tightened and the hooks raised, the calorimeters were held tightly against the glass tubes, E, E. Finally the temporary supporting frame was removed, leaving the calorimeters suspended with a very small avenue of heat exchange to the submarine jacket.

Two features in the calorimetric design are important. First, the air space above the liquid level in each calorimeter, including that inside the glass tube, E, is reduced to about 10 ml. This volume is so small that no trouble is caused by evaporation of water when the calorimeter is heated one degree. Second, since the stirrers are easily detachable at the bakelite–stainless steel joints, Fig. 1, the calorimeters and their contents can be removed completely and weighed with no loss of solution or water. The actual evaporation losses determined by this method are usually found to be only 2 or 3 mg. and hence completely negligible.

Thermels.—The constantan wire used in constructing the thermels was tested for homogeneity according to the method recommended by W. P. White[3] and only those sections were used which showed an e. m. f. of less than 1 μ v. over a thermal gradient of 70° in about 3 cm. The 20-junction copper–constantan main thermel, M, M, Fig. 1, was constructed in two halves of 10 junctions each so that the halves could be opposed in the usual manner. The general design is shown in Fig. 2a. Each junction was insulated from the others in a slot cut in a mica form, the No. 34 copper wires running up on one side of the mica and the No. 26 constantan on the other. The mica forms, 0.13 mm. thick, were about one centimeter longer than the corresponding wells in the calorimeter lid. Each 10-

junction unit was dipped in "razo-glass"[4] and sandwiched between two mica insulating strips about 0.08 mm. thick. Snugly fitting copper cases, thick enough for good thermal contact with the calorimeter well and long enough to cover the mica, were then slipped over each pair of completed units. The resistance of the insulation between the thermel wires and the copper cases was found to be about 100,000 megohms (50% relative humidity).

The five junctions of each adiabatic control thermel (A, A, Fig. 1) were staggered as shown in Figs. 1 and 2a in order to obtain a comparison of the average bath temperature with the average temperature inside the calorimeters.

The thermels were connected to the galvanometers through copper reversing switches by which parasitic currents in the galvanometer circuit could be eliminated.

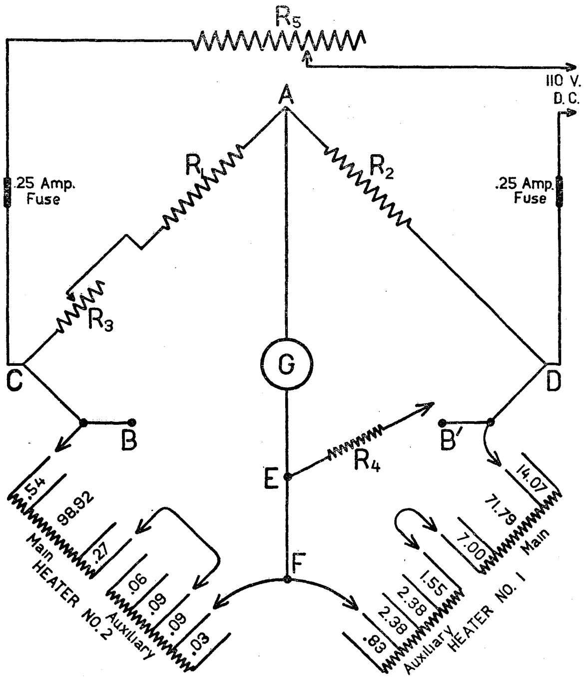

Fig. 3.—Bridge for measuring resistance ratio.

Variable Resistance Heaters.—The design of these heaters, allowing a measurement of the resistance ratio during an experiment, was the most important innovation in the present apparatus. Each consisted of 7 units with a total resistance of about 100 ohms. A large resistance, with a smaller one connected to each end, formed the *main heater* which was supplied with 4 leads. Four much smaller units, connected in series and supplied with 5 leads, formed the *auxiliary heater*. This arrangement gave a satisfactory flexibility in resistance with a minimum number of leads. In each main heater, connection could be made to the large resistance alone or in combination with either or both end coils. In order to keep the lead resistance constant, at least one unit of the auxiliary heater was always connected in series with the main. The 9 possible combinations of the auxiliary, combined with the 4 of the main, gave 36 resistances in each heater and 1296 resistance ratios for the two heaters. The values of the individual units, shown in Fig. 3, were so chosen as to give a series of resistance ratios progressing uniformly from 0.9800 to 1.3700 in steps of 0.0003 to 0.0004. In order to obtain a smooth progression, with no gaps, all the smaller steps were put in one heater (No. 2) and the larger in the other (No. 1).

The main and auxiliary heaters were mounted on separate strips of clear mica 0.13 mm. thick. The construction of auxiliary heater number 1 is shown in Fig. 2b, which is a scale drawing. The constantan resistance wires were No. 36 B and S gage, while those in auxiliary heater number 2, were No. 24 B and S gage, bent to shape and flattened to form a ribbon of the same thickness, 0.13 mm. These ribbons were annealed before assembly by the passage of a current of 6 amp. The large resistances of the main heaters were No. 40 B and S gage constantan. All the constantan wires were confined to the lower parts of the mica strips, 2.5 cm. or more below the surface of the liquid in the calorimeter.

The leads to the outside were No. 24 B and S gage copper wires. The lower end of each, flattened to form a ribbon 0.13 mm. thick, was carried down one side of the mica strip. It was fastened to the mica by means of a second copper strip carried down the opposite side and soldered to it in two slots at a and b, Fig. 2b. This arrangement ensured good thermal contact with the walls of the heater case, so that the heat generated in the coils is delivered to the calorimeter. One-centimeter lengths of flattened No. 36 B and S gage copper wire interposed between b and c, Fig. 2b, minimized the conduction of heat to the leads.

The heating units were made with slightly less than the desired resistance, mounted on the mica strips and soldered to the leads, using rosin flux. They were then annealed by passing through them a current appreciably larger than that which was used in the later experiments. The wires were then alternately scraped cautiously with a sharp knife and annealed until they were adjusted to within 0.01 ohm of the calculated value. Finally the heaters were washed thoroughly with carbon tetrachloride, to remove any rosin flux or grease from the hands, and rinsed several times in distilled water, to remove any salts which would increase the surface conduction of the mica. They were carefully dried and sandwiched between insulating strips of clear mica 0.08 mm. thick which had been cleaned in the same way. The total thickness of the heater with its two insulating strips was 0.9 mm. or less. Each heater was pushed into one side of a double case made from sheet copper 0.25 mm. thick, bent in the shape of a flattened S as shown in Fig. 2b and soldered together at the edges. A 1-cm. opening in the case, coinciding with the small wires bc of the heater leads, reduced conduction of heat up the heater case. The two copper sections of the case were held rigidly together by strips of stainless steel, s, s, 0.25 × 1.25 mm., soldered to shallow recesses filed in the edges of the case as shown in Fig. 2b.

The Resistance Ratio.—The heaters were incorporated in a conventional Wheatstone bridge circuit, Fig. 3, the measuring arms of which, AC and AD, consisted of much higher resistances than the heaters. R_1 and R_2 were 4000-ohm coils and R_3 consisted of a series of coils totaling 2000 ohms in series with a precision resistance box, variable in

(4) "Razo-glass" is the trade name of a polymerized coumarone resin, obtained from the Marbro Products Corporation through the courtesy of the late Professor Eric von Gebauer-Fuelnegg. When dissolved in toluene, razo-glass is an excellent insulating varnish.

steps of 0.01 ohm. The individual Leeds and Northrup resistance coils, wound on metal spools, were mounted on brass rods in the usual manner. The coils were calibrated to within 0.01 ohm, using a set of Bureau of Standards type standard resistors as a basis of comparison. Calibration at intervals of several months showed no significant changes except in the 4000-ohm coils.

By means of this Wheatstone bridge, the resistance ratio was measured *during an experiment,* with a current of 0.19 ampere passing through the heaters, but only 0.005 ampere passing through the measuring arms—a current which they were designed to dissipate without an appreciable change in their calibration. The Leeds and Northrup pointer-type galvanometer G was sensitive to a change of 0.0003% in the resistance ratio.

The resistance ratio measured by the bridge is, of course, the ratio of the total resistances of the heater arms, from C to F and from F to D, respectively. The ratio of the resistances *effective in heating the calorimeters* can only be determined by applying a correction for the lead resistance. For this reason, every effort was made to keep the lead resistance small and constant. The 18 lead wires from the heaters were cut equal in length, and their upper ends were soldered to radio tip-jacks mounted on a shielded Bakelite disk immediately above the bath lid, P, Fig. 1. Connection between the jacks was made by short pieces of heavy stranded wire, soldered to phone tips, indicated by arrows in Fig. 3. Potentiometric measurement showed that the contact resistance of a pin-jack and phone-tip combination was about 0.0010 (±0.0002) ohm. This variation was negligible for the four contacts in each heater arm. Plugging all of the phone tips in and out several times in succession never produced a change in the measured resistance ratio of more than 0.0005%. In finding the value of the lead resistance, we assumed that only the lower half of the exposed leads within the air gap of the submarine jacket belonged to the heater and contributed to raising the temperature of the calorimeter. The resistance from this mid-point through the lead wires, phone connectors and external wires to the corners of the bridge made up the lead resistance, l, which we found by potentiometric measurement was 0.103 ohm for each heater. If the effective end of the heater is within 2 cm. of the center of the 9-cm. length of the lead wire in the gap, the uncertainty in l is not more than ±0.006 ohm. It can be shown easily that the *effective* resistance ratio, x' ($= r_2/r_1$) can be calculated from the *measured* resistance ratio X by the equation

$$x' = X + [l(X - 1)]/r_1 \tag{1}$$

where r_1 is the resistance of heater 1. This equation shows that the effective ratio equals the measured ratio when that ratio is unity, and differs by an increasing amount as the lead resistance and the resistance ratio increase. The lead correction amounts to +0.04% with the maximum ratio of 1.37, and the value of l found above. If l is known to 0.005 ohm and r_1 to 2 ohms, the maximum error in the lead correction will not exceed 0.002%.

Theory of the Measurements

In principle, the method consists in finding the balance point of the apparatus, first with equal weights of water (268.330 g. *in vacuo*) in the two calorimeters, and then with the same weight of water in the tare (number 2) and an equal *volume* of solution of known weight in the working calorimeter (number 1). The balance point is the effective resistance ratio for which the two calorimeters rise exactly the same amount when heated over an interval of 1°. Since the resistance ratio cannot be set *exactly* at the balance point, the small galvanometer deflection, Δg (due to a slight difference in temperature rise over a 1° range) is found by the graphical method used in our previous work.[1c] After two or more experiments, the values of Δg are plotted against the corresponding resistance ratios and the balance point is read from the graph, as shown in Fig. 4.

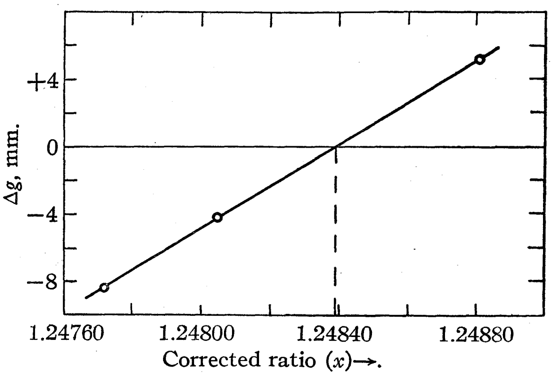

Fig. 4.—Graphical estimation of balance point: ($\Delta g = 0$ at $x = 1.24839$).

If the balance points corresponding to water and solution are designated respectively by x_0 and x, they are defined by the equations

$$x_0 = T/(C_w + c_1) \tag{2}$$

and

$$x = T/(C_s + c_1) \tag{3}$$

where T is the total heat capacity of the tare calorimeter and water, c_1 is the heat capacity of the working calorimeter and C_w and C_s the heat capacities of the weights of water and of solution in calorimeter 1 at balance. Dividing (2) by (3), and rearranging terms gives for the heat capacity of the solution

$$C_s = C_w x_0/x - c_1(x - x_0)/x \tag{4}$$

This equation shows that the effective heat capacity of the working calorimeter, c_1, must be known with an accuracy which becomes greater the more x increases—*i. e.*, the lower the heat capacity of the solution. If x_0 is unity and x has the extreme value of 1.37, c_1 must be known to 0.07 cal. per degree if C_s is to be determined to 0.01%. As the value of x decreases, the error in C_s caused by an error in c_1 becomes correspondingly less. In our experiments, the largest value of x was 1.25, hence an error of 0.1 calorie unit in c_1 causes an error of only 0.004% in C_s.

Although the value of c_1 need not be known more closely than 0.1 calorie unit, it must *remain constant* to 0.01 calorie unit or better. Preliminary experiments showed that the effective heat capacity c_1 decreased nearly linearly by about 0.015 calorie unit per ml. for the first 30 ml. of water removed from the calorimeter. In calculating the results of these experiments a correction was applied for the evaporation of water into the increased air space. The decrease in c_1 was probably due to a lag in the heat reaching the lid of the calorimeter, and an increased heat leakage down the heater leads to the calorimeter. In order to keep c_1 constant, the same volume of liquid (± 0.5 ml.) was always put into the working calorimeter.

In determining c_1, a hollow air-tight copper shell, displacing about 33 ml. of water, was fastened below the surface of the water in the calorimeter, which was then filled up to the usual level. From the balancing ratio x_0', the heat capacity of the water, C_w', and that of the displacer, the value of c_1 was found by eliminating T between equation (2) and a similar equation for x_0'. The heat capacity of the solid parts of the displacer was found by opening it, immersing the parts in the calorimeter filled to the usual volume with water, and finding the balancing ratio. The heat capacity of the air in the displacer was added to this value in calculating the value of c_1. The values of c_1 corresponding to the working volume of 268.3 ml. in the calorimeter, were 10.83 and 10.89 25°-calorie units—an average of 10.86 being used in subsequent calculations in experiments 1–5 inclusive. A slight alteration in one of the heater cases, made before the second series of measurements was started, necessitated a new set of calibration experiments. The new average value of c_1 was found to be 10.73 25°-calorie units. This value was used in all calculations following experiment number five.

The determination of the heat capacity of the calorimeter from the difference of two large heat capacities necessarily increases the percentage error in the value of c_1. However, the effect of this error upon the final results is reduced to negligible proportions, as we have already shown.

A Typical Experiment.—As an indication of the manner in which the measurements were carried out, the important data taken in connection with a typical experiment are given in Table I. The solution used in this experiment was the most concentrated of the series (23.998 molal). The change in galvanometer deflection, Δg, was found as before[1c] by recording the galvanometer deflections at one-minute intervals before and after the experiment and estimating the change graphically. The individual galvanometer deflections are not tabulated here.

TABLE I

Experiment Number 7, 12/24/35–12/26/35

Weight NH_4NO_3 231.670 g.
Weight solution 352.272 g. $m = 23.9978$

Heater settings (Nominal values) $\begin{cases} \text{No. 1} = 71.79 + 7.00 + 0.83 \text{ ohms} \\ \text{No. 2} = 98.92 + 0.54 + 0.06 \text{ ohms} \end{cases}$

	Time	Resistance
Balancing resistance during heating time ($R_1 + R_3$, Fig. 3)	9:43	4992.79 ohms
	44	.78
	45	.75
	46	.74
	47	.73
Average =		4992.76 ohms

Fixed resistance (R_2, Fig. 3) = 4002.47 ohms
Ratio = 4992.76/4002.47 = 1.24741 = X
Ratio, corrected for lead resistance
$= 1.24741 + [0.10(1.2471 - 1)]79.6 = 1.24772 = x_1$
$\Delta g' = -8.4$ mm. (galvanometer deflection for experimental temperature rise)

Platinum resistance thermometer $\begin{cases} \text{Final } R = 28.0808 \text{ ohms} \\ \text{Initial } R = 27.9799 \end{cases}$
$\Delta R = 0.1009$ ohm

$\Delta t = 9.957\Delta R = 1.005° =$ experimental temperature rise
Mean temperature = 24.99°
Δg_1, galvanometer deflection for 1° temperature rise = $-8.4/1.005 = -8.4$ mm.

Similarly, for two additional experiments using different heating ratios

$$\Delta g_2 = +5.2 \text{ mm.}, x_2 = 1.24881$$
$$\Delta g_3 = -4.2 \text{ mm.}, x_3 = 1.24805$$

From Fig. 4, $\Delta g = 0$, at $x = 1.24839$

$$C_s = \frac{1.00009(268.330) + (1.00009 - 1.24839)(10.73)}{1.24839}$$
$$= 212.826$$

$s = 212.826 \div 352.272 = 0.60481$ 25°-cal./deg.
$\Phi(C_{p_2}) = 31.945$ 25°-cal./deg.

Preparation of Ammonium Nitrate.—The ammonium nitrate used in these experiments was synthesized from pure ammonia and nitric acid by two slightly different methods, both based upon the procedure recommended by Archibald[5] for ammonium chloride. In both cases, C. P. nitric acid was distilled through a quartz condenser and the middle third was placed in quartz or platinum dishes. The first portions of ammonium nitrate were prepared by T. R. Rubin, who also measured the heat capacities of the corresponding solutions. The ammonia was obtained as follows. A hot solution of C. P. ammonium sulfate, dissolved in an equivalent weight of pure sulfuric acid, was treated with a few grams of finely powdered potassium permanganate and heated until it was colorless. This treatment ensures the oxidation of any organic matter. The purified ammonium bisulfate was cooled, dissolved in water and neutralized with a suspension of C. P. calcium oxide. It was then put in the bottom of a vacuum desiccator and mixed with excess lime, giving a slow evolution of ammonia. This was absorbed in the dishes of pure nitric acid which were placed on the shelf of the desiccator.

Subsequent tests showed that there were no oxidizable impurities in ammonium hydroxide of synthetic origin; hence the remaining portions were prepared by Robert Mueller using solutions of ammonium hydroxide made from synthetic ammonia in place of the lime and ammonium bisulfate mixture. The heat capacities of these solutions were measured by F. D. Ayres.

The ammonium nitrate resulting from either procedure was twice crystallized from water and dried *in vacuo* at 70–80°. The Hyvac pump was connected through a trap immersed in a mixture of carbon dioxide snow and acetone (about −78°). Pumping was continued until no more moisture collected in the trap. The salt was then ground in an agate mortar and dried again *in vacuo* at the same temperature for about six to ten hours. It was stored in a desiccator.

Experimental Results.

—The results for all the ammonium nitrate solutions are collected in

Table II. The experiments are numbered chronologically. Each solution made from weighed quantities of salt and water is given a consecutive number, while those made by quantitative dilution are designated by letters following the number of the concentrated solution from which they came. Experiments one to five inclusive were carried out by T. R. Rubin; the rest by F. D. Ayres. The molality, m, of the solution (moles solute per kg. water) was determined directly from the weights of the constituents. The molarity, c (moles solute per liter of solution) was then calculated from the equation[6]

$$\frac{c}{m} = d_1\left[1 - \frac{c\Phi(V_2)}{1000}\right]$$

The values of $\Phi\ (V_2)$, the apparent molal volume of ammonium nitrate, were calculated from the equation

$$\Phi(V_2) = 47.558 + 0.966\ c^{1/2} + 0.0474c$$

which was derived[6a] (p. 314) from the accurate density measurements of Adams and Gibson.[7] Successive approximations were made until two consecutive values of c agreed within 0.0001. The process was expedited, especially when successive values diverged, by taking the *average* of the two preceding values of c in making the later approximations. The value of the apparent molal heat capacity $\Phi(C_{p_2})$ was calculated from the usual equation

$$\Phi(C_{p_2}) = \left[\frac{1000}{m} + M_2\right] s - \frac{1000}{m}$$

where M_2 is the molecular weight of ammonium nitrate, 80.047 g. Since s is the specific heat at 25°, $\Phi(C_{p_2})$ is expressed in 25°-calories per degree.

One of our objects in studying ammonium nitrate was to compare the plots of the apparent molal heat capacity against $m^{1/2}$ and $c^{1/2}$ and to see if it was as nearly a linear function of the latter over the whole concentration range as we had already[6a] (p. 314) shown the apparent molal volume to be. Ammonium nitrate is particularly suitable for such a study. Its high solubility and large apparent molal volume give a great difference between the volume and weight concentrations. A plot of $\Phi(C_{p_2})$ against $m^{1/2}$, reproduced in Fig. 5, showed that up to 1.5 m the results could be reproduced with an accuracy of ±0.005% in s by means of the equation

$$\Phi(C_{p2}) = -2.90 + 12.56m^{1/2}$$

Above 1.5m the experimental points lay along a smooth curve which was concave downward.

A plot was next made, using $c^{1/2}$ as abscissa, but a linear equation reproduced the specific heat data adequately to no higher concentration than before. The equation

$$\Phi(C_{p2}) = -3.30 + 13.37c^{1/2}$$

reproduced the specific heats within ±0.004% on the average, up to c = 1.4. At higher concentrations the experimental points again lay along a smooth curve, concave downward, although the curvature was considerably less than in the plot against $m^{1/2}$.

In order to calculate values of the specific heat of the solution and of the partial molal heat ca-

(7) Adams and Gibson, THIS JOURNAL, **54**, 4520 (1932).

pacities of the salt and the water at any desired concentration, an equation connecting the apparent molal volume and the concentration was next sought. Calculations involving the weight concentration are simplest to make, so that we first attempted to obtain the apparent molal heat capacity as a function of the molality. Various equations giving $\Phi(C_{p_2})$ as an explicit function of $m^{1/2}$ were first tried, but none was found to reproduce the curve successfully. The large curvature near the center, with nearly straight portions at each end, suggested a section of a hyperbola.

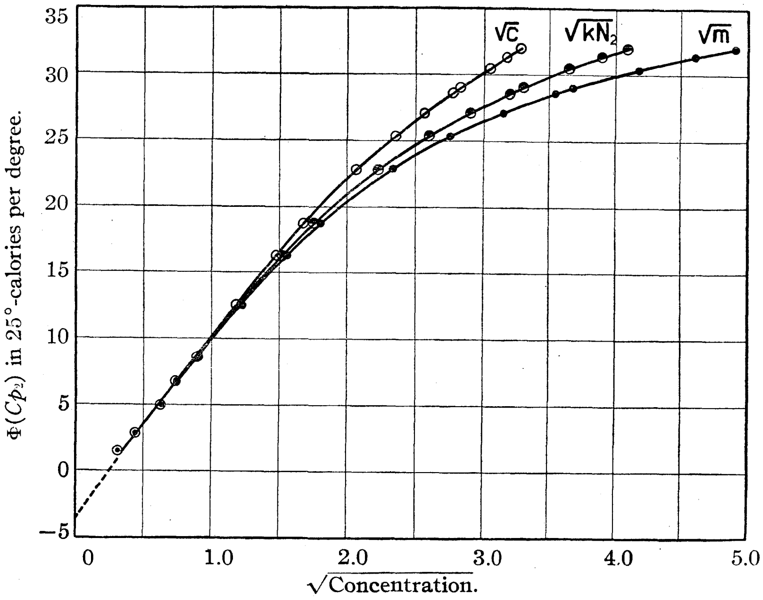

Fig. 5.—A comparison of abscissas.

Accordingly we tried a general equation of the second degree in $\Phi(C_{p_2})$ and $m^{1/2}$, and found that it gave a much better agreement. Such a function reproduced the curve with average deviations of ±0.0085% in s, but there were five deviations of more than 0.01% and the deviations were systematic at both ends of the curve. In order to reduce the curvature, still employing a function of the weight concentration, we next tried the same type of equation with the abscissa $\sqrt{1000\ N_2/M_1}$ where N_2 is the mole fraction of solute, and M_1 the molecular weight of water. This curve coincides with the previous one at low concentrations and in general lies about midway between the plot against $m^{1/2}$ and that against $c^{1/2}$ (see Fig. 5). The agreement was not appreciably improved. Finally we tried the equation

$$\Phi^2 + ac + b\Phi c^{1/2} + dc^{1/2} + e\Phi + f = 0$$

Substituting five values of the variables we evaluated the coefficients a, b, d, e, f. The equation was solved for Φ by the general algebraic formula. Calculated values of Φ were then compared with the experimental ones, and several successive solutions were tried to obtain the coefficients which gave best agreement at every point on the curve. The equation which we finally obtained was

$$\Phi(C_{p2}) = 6.036 + 9.991c^{1/2} - [93.644 - 78.79c^{1/2} + 19.683c]^{1/2}$$

From this equation we calculated the values of Φ which are included in Table II. The average deviation in the specific heat, Δs, is ±0.0075%, with only one of the seventeen observations showing a deviation exceeding 0.011%. In order to check this value, a final experiment, No. 9, was made at almost exactly the same concentration. It gave a value of the specific heat about 0.02% higher than the former one, but still 0.01% lower than the curve at this point. Since this was the largest discrepancy in the whole series, we may conclude that the experimental results, obtained by two experimenters using different samples of ammonium nitrate and making up solutions independently, are in very satisfactory agreement.

Using the last equation, we calculated the values of the apparent molal heat capacity of the salt at even values of c, which are collected in Table III. We also included the corresponding values of the molality and of the partial molal

heat capacities of the solute and solvent. The partial molal heat capacity of the solute, $\bar{C}_{p_2}$, was obtained from the general equation which had been derived previously,[6a] namely

$$\bar{C}_{p2} = \Phi(C_{p2}) + \left[\frac{1000 - c\Phi(V_2)}{2000 + c^{3/2}\dfrac{\partial\Phi(V_2)}{\partial c^{1/2}}}\right] c^{1/2}\,\frac{\partial\Phi(C_{p2})}{\partial c^{1/2}}$$

Values of $\Phi(V_2)$ were calculated from the equation previously given, and $\partial\Phi(V_2)/\partial c^{1/2}$ from its derivative

$$\partial\Phi(V_2)/\partial c^{1/2} = 0.966 + 0.0948c^{1/2}$$

The values $\partial\Phi(C_{p_2})/\partial c^{1/2}$ were obtained from the derivative of our equation, which was

$$\frac{\partial\Phi(C_{p2})}{\partial c^{1/2}} = 9.991 + \frac{39.395 - 19.683c^{1/2}}{[93.644 - 78.79c^{1/2} + 19.683c]^{1/2}}$$

The partial molal heat capacity of the water was obtained from the equation

$$\bar{C}_{p1} = \bar{C}^{\circ}_{p1} - \frac{M_1}{d_1}\left[\frac{c}{2000 + c^{3/2}\dfrac{\partial\Phi(V_2)}{\partial c^{1/2}}}\right] c^{1/2}\,\frac{\partial\Phi(C_{p2})}{\partial c^{1/2}}$$

where M_1 is the molecular weight (18.0156 g.) of water and d_1 is its density (0.997077 g./ml.) at 25°. This equation is perfectly general, and would apply to any other partial molal property as well as to the heat capacity. In the case of the partial molal volume of the solute, it reduces to an equation analogous to that derived by Gibson[8] for the partial specific volume. Calculations involving the volume concentration are more complicated than those involving the weight concentration, but their use is justified when the apparent molal property may be expressed more exactly as a function of the volume than of the weight concentration.

In Fig. 6 we have plotted $\Phi(C_{p_2})$, $(\bar{C}_{p_2})$ and $\bar{C}_{p_1}$. The apparent molal heat capacity of the solute starts from the value −3.6 calories per mole per degree at zero concentration, with an initial slope of $\partial\Phi(C_{p_2})/\partial c^{1/2} = 14.06$, which decreases to 6.287 at $c = 11$. The corresponding partial molal heat capacity starts from the same point, with a slope half again as great. It is always greater than the apparent molal heat capacity, but the difference is greatest (8.3 calories per degree) at 3 molar and decreases steadily to 4.4 at 11 molar, where the *slope* of the curve is only about 55% of that of the apparent molal heat capacity curve.

The partial molal heat capacity of the water decreases regularly from the value in pure water, $\bar{C}^{\circ}_{p_1}$ = 18.0156 25°-calories per degree, to a value of 15.9907 in a saturated solution of ammonium nitrate (11 molar): a decrease of 11%.

Acknowledgments.—It is a pleasure to acknowledge our indebtedness to the National Research Council for a Grant-in-Aid which defrayed part of the cost of the apparatus used in this work; to Professor R. G. Bigelow and Mr. M. L. West of the Northwestern Engineering School for their advice and assistance in the construction of many parts of the apparatus; and to Mr. Robert J. Mueller who, working under an N. Y. A. project, assisted in the purification of much of the ammonium nitrate.

Summary

We have described the construction and operation of a new modification of the twin calorimetric apparatus for measuring specific heats. Special electrical heaters with resistances variable in small increments, mounted on mica strips, are used to supply energy proportional to the heat capacity in each calorimeter. The resistance ratio is measured during the experiment.

Solutions of ammonium nitrate were made from weighed amounts of purified dried salt and water, or from a single quantitative dilution. The specific heats of seventeen of these solutions, over

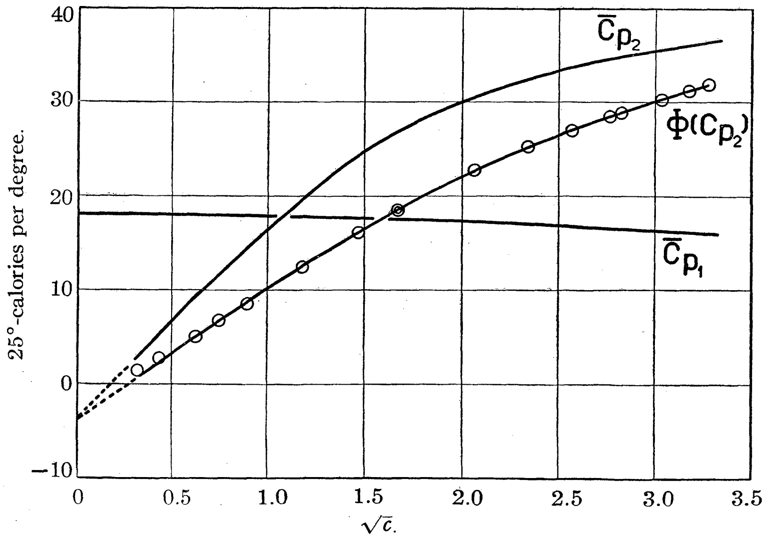

Fig. 6.—Apparent and partial molal heat capacities in solutions of ammonium nitrate at 25°.

---

(8) Gibson, *J. Phys. Chem.*, **38**, 319 (1934).

the concentration range 0.1 to 10.75 moles per liter, were measured at 25°.

The apparent molal heat capacity is a linear function of $c^{1/2}$ (or $m^{1/2}$ or $N_2^{1/2}$) only up to about a 1.5 molal solution, above which the relation found by Randall and Rossini fails. A hyperbolic second degree equation for the apparent molal heat capacity as a function of the square root of the volume concentration reproduces the specific heats with an average deviation of ±0.0075%. Values of the partial molal heat capacity of the salt at round concentrations were calculated from an equation previously derived and values of the partial molal heat capacity of the water were calculated from a new equation which is generally applicable to all molal quantities. These values are tabulated, along with those of the specific heats of the same solutions.

The Thermodynamics of Aqueous Indium Sulfate Solutions[1]

BY ERWIN M. HATTOX AND THOS. DE VRIES

Very little work has been done on the activity coefficients and other thermodynamic properties of aqueous solutions of the ter-bivalent salts. Hovorka and Rodebush[2] determined the freezing point lowering of dilute solutions of lanthanum sulfate, and from these data calculated the activity coefficients. Since their results dealt only with dilute solutions, it seemed desirable to study the behavior of indium sulfate in aqueous solutions over a wider range of concentrations and at several temperatures. E. m. f. measurements were made on cells of the type In (s) | $In_2(SO_4)_3$ (m) | Hg_2SO_4–Hg at 0, 15, 25 and 35°, and freezing point lowerings were determined for a few dilute solutions of indium sulfate. The degree of hydrolysis was also determined at room temperature.

Materials and Apparatus

All materials used in this investigation were very carefully purified. The water used for making the solutions and for making ice was prepared by double distillation of the ordinary laboratory distilled water. The first distillation was made from alkaline permanganate and the second from barium hydroxide. The water thus purified was stored in glass-stoppered Pyrex bottles.

Commercially pure indium (98.9%), obtained from W. S. Murray, Ithaca, New York, was purified in the following manner. The metal was dissolved in concentrated nitric acid, the solution diluted, and precipitated as indium hydroxide with dilute ammonium hydroxide. This was washed several times and dissolved in dilute hydrochloric acid. Spongy indium was plated out from this solution, using platinum electrodes and a current of about 0.3 ampere. The washed, spongy mass then served as an anode in another dilute hydrochloric acid solution, the indium being redeposited by electrolysis on a platinum cathode.[3] Indium sulfate was prepared from this indium by slowly evaporating a strong sulfuric acid solution of it at about 50°, washing the crystals that separated out with glacial acetic acid, and then heating in a furnace to a temperature of 450–500° for six hours.[4] By gravimetric analysis the product was shown to be anhydrous indium sulfate.

The mercury was purified by washing for several days with dilute nitric acid and distilling twice under reduced pressure in a current of air.

Mercurous sulfate was prepared by electrolysis from dilute sulfuric acid using a mercury anode and a platinum cathode, and a current density of 0.5 ampere per square decimeter. In order to prevent the formation of a yellow basic salt due to hydrolysis, the mercurous sulfate, along with the finely divided mercury mixed with it, was washed first with alcohol, then with ether. The product was dried and kept in a desiccator until ready for use.

The most concentrated indium sulfate solution was made up by weight from the prepared anhydrous salt. All the solutions of lower concentrations were made by successive weight dilutions, using an analytical balance of 2-kg. capacity.

After experimenting with complicated cells in which the air could be replaced by hydrogen, a simple cell was developed, made by sealing a platinum wire in the bottom of a 16-mm. Pyrex tube, and having a side-arm in which the indium electrode was placed.

The thermostat temperatures were maintained within ±0.01°. A two-liter size Dewar flask with crushed ice served very satisfactorily for the 0° bath. All temperatures were established with standard thermometers.

Electromotive forces of the cells were measured on a Leeds and Northrup Type K potentiometer.

Apparatus for the freezing point measurements was

[4] Seward, *ibid.*, **55**, 2740 (1933).

essentially the same as that described by Hovorka and Rodebush,[2] the only change being that the two Dewar flasks were not sealed together. A twelve-junction thermel, carefully calibrated, and having a potential change of 461 microvolts per degree at 0°, was used for the determinations of the temperature differences. A very sensitive galvanometer set-up was arranged by making use of a lens of 1.22 meters focal length and focusing a straight edge image from the galvanometer mirror onto a ground glass plate. The distance from light source to the galvanometer, the same as that from the galvanometer to the plate, was 3.2 meters. The scale on the glass plate was calibrated and it was found that readings could be made with a precision of about 0.0001°. A White potentiometer, with the lower dials marked in 10 and 1 microvolts, was used to measure the voltage of the thermel.

Experimental

Mercury was placed in the bottom of the completely dried cell, and was then covered with a thin layer of the dry mercurous sulfate. The solution was poured down the side arm until it reached a height of about 2.5 cm. in the arm. After the cell had been tightly stoppered, it was allowed to stand for a period of from twenty-four to forty-eight hours in order for equilibrium to be reached. This time was found by experiment. When this time had elapsed, an indium electrode was prepared by plating a thin layer of the metal on a platinum spiral sealed in the end of a glass tube, using a current of about 0.2 ampere. After the electrode was washed and dried in a stream of air, it was placed in position in the side-arm, and held there by means of a rubber tubing which also served to keep the cell closed to the atmosphere. The cell was then placed in the 15° thermostat and allowed to reach equilibrium at that temperature, which usually required from three to six hours. After all the needed data at 15° had been recorded, the cell was transferred successively to the 25 and 35° thermostats. A separate cell was prepared for the measurements at 0°, but the procedure followed was the same.

The experimental technique used by Hovorka and Rodebush[2] was employed for the freezing point determinations.

Discussion of the Results

The molalities of the solutions used and the corresponding e. m. f.'s observed at the different temperatures are given in Table I. Two or more values were obtained for each concentration at each temperature. The voltages were reproducible to ±0.2 mv. in the concentrated solutions, but the deviations in the dilute solutions were about ±0.3 mv. The e. m. f.'s of the individual cells usually remained constant for eight to ten hours or longer.

In order to determine the absolute value of the activity coefficients, E_0 must be evaluated. This requires an extrapolation to infinite dilution, and the voltages of the dilute solutions are less reliable than those of the concentrated solutions. Evidently, then, an extremely accurate value of E_0 cannot be expected. However, from freezing point measurements the activity coefficients can be determined with considerable accuracy. Due to the formation of a precipitate resulting from hydrolysis it was possible to obtain only one point of any significance from such measurements. A 0.00631 molal solution gave a depression of 0.0316°, but solutions of 0.00198 molal and less developed precipitates upon standing. The one point that we were able to determine fits the data of Hovorka and Rodebush within the limits of experimental error. Assuming that indium sulfate and lanthanum sulfate give identical freezing point curves in very dilute solutions, which seems to be logical, we used 0.150 as the activity coefficient in 0.01 molal solution[5] and calculated E_0 to be 0.9747 volt at 0°. This agrees well with 0.974 obtained by an extrapolation from e. m. f. data.

The electromotive force of the cell at any temperature T may be given by the equation

$$E = E_0 - (RT/6F) \ln 108\gamma^5 m^5 \qquad (1)$$

which may be written

$$k \log \gamma = E_0 - E - 0.4067k - k \log m \qquad (2)$$

In dilute solutions the logarithm of the activity coefficient may also be expressed by $\log \gamma = -6\,A\,\sqrt{\mu} + B\,\mu$ in which A and B are constants and μ is the ionic strength. When this relation is used in (2), the following expression is obtained

$$E + 0.4067k + k \log m - 6kA\sqrt{\mu} = E_0 - kB\mu \qquad (3)$$

Designating the left side of this equation as E_0', and plotting it against m, a curve is obtained for each temperature which may be extrapolated to

---

[5] Rodebush, THIS JOURNAL, 48, 709 (1926).

infinite dilution to give a value for E_0. Harned and Ehlers' values[6] of A were used in evaluating E'_0. Curves of this type were drawn for the four temperatures. Although these were nearly straight lines and the curves did not have to be extrapolated very much, E_0 was not evaluated closer than 1 mv. The values are given in Table I. These were used in equation (1) to calculate the activity coefficients. Because of the uncertainty as to the degree of hydrolysis of indium sulfate, it is not feasible to determine the "true" activity coefficients. The "stoichiometrical activity coefficients"[7] were therefore determined. They are collected in Table II. The values, including those calculated by Rodebush[5] from the freezing point data for lanthanum sulfate, lie on a smooth curve when log γ is plotted againt $\sqrt{m}$. Since Halpern[8] questions the reliability of the La Mer, Gronwall and Greiff extension of the Debye–Hückel theory[9] to unsymmetric valence type of electrolytes, no attempt was made to make the Debye–Hückel equations fit the data. When extrapolated values of the La Mer, Gronwall and Greiff formulas were used, a value of about 5 Å. was obtained for "a," the mean distance of approach of the ions.

The normal potential of the In, In^{+++} electrode at 25° is +0.340 if the value −0.614 is used for the $Hg–Hg_2SO_4$, $SO_4^=$ electrode.[10]

The Partial Molal Heat Content

The partial molal heat content relative to the 0.01 M solution was computed by the Gibbs–Helmholtz equation

$$(\overline{H}_m - \overline{H}_{0.01}) = NF(E - TdE/dT) \quad (4)$$

The temperature coefficient of the cell was nearly constant. Since an error of ±0.01 mv. in the temperature coefficient means an error of approximately ±100 calories, the values given in Table III are merely good approximations. Because of insufficient data it was not possible to calculate $\overline{L}_2$, the relative partial molal heat content.

TABLE III

Hydrolysis of Indium Sulfate

The pH values of nine solutions were determined at room temperature, 23°, using a quinhydrone electrode with a 0.1 N calomel cell as reference electrode.

Two series of hydrolysis constants were calculated from the pH values found at various molalities. These are designated in Table IV as K_h and K_h'. The K_h' was calculated on the assumption that the hydrolysis of In^{+++} may be represented

$$In^{+++} + H_2O \rightleftharpoons InO^+ + 2H^+ \quad (5)$$

The computed values of K_h' vary considerably at the different concentrations. If, however, the hydrolysis reaction is written

$$In^{+++} + H_2O \rightleftharpoons In(OH)^{++} + H^+ \quad (6)$$

and the constant calculated for this reaction, a much nearer approach to a constant value is obtained. The values headed K_h are the results

obtained. The results are not constant, but such could hardly be expected, since molalities instead of activities were used. There is indication, however, that a constant value will be approached in a very dilute solution.

Summary

1. Using cells of the type In(s), $In_2(SO_4)_3(m)$, Hg_2SO_4–Hg electromotive force measurements have been made at 0, 15, 25 and 35°.

2. The freezing points of dilute solutions of indium sulfate were investigated.

3. Calculations have been made of the activity coefficients of indium sulfate in aqueous solution, and of the partial molal heat contents relative to the 0.01 M solution.

4. *p*H values of solutions of indium sulfate have been determined at room temperature, using the quinhydrone electrode.

5. The constant for the hydrolysis of indium sulfate has been calculated assuming the reaction to be

$$In^{+++} + H_2O = In(OH)^{++} + H^+$$

The Presence of Free Radicals in the Thermal Decomposition of Diethyl Ether

BY C. J. M. FLETCHER AND G. K. ROLLEFSON

The decomposition of diethyl ether is a reaction for which a chain mechanism involving free radicals has been postulated.[1] The experimental results of previous investigations,[2–6] except for the recent results on the inhibition of the rate of reaction by small quantities of nitric oxide,[7] do not enable any decision to be made between the alternative theories of molecular rearrangement and such a chain mechanism. The present investigation provides definite evidence for the presence of free radicals since small amounts of ether are found to catalyze the decomposition of acetaldehyde. Quantitative estimations of the aldehydes, which are formed as intermediates, and a more detailed study of the kinetics of the over-all reaction have enabled the kinetics of the ether decomposition to be separated from those of secondary reactions.

Experimental Details.—The thermal reactions were studied in a Pyrex bulb, approximately 500 cc. in volume, placed in an electrically heated furnace. Fluctuations of the voltage were reduced by the use of Radiatron ballast tubes (U. V. 886 and 876), and the temperature was controlled by hand to within one degree. Pressures greater than 20 mm. were measured on a mercury manometer made from capillary tubing and heated by nicrome wire to prevent the condensation of organic vapors. The dead-space outside the furnace did not amount to more than 2% of the volume of the bulb. Pressures of less than 20 mm. were measured with a sulfuric acid manometer separated from the reaction by a click-gage. It was found that pressure equilibrium between the bulb and click-gage was not established instantaneously, so that the time lag was estimated with different pressures of air and a correction applied.

The reaction vessel was evacuated through a liquid air trap by a mercury vapor pump and oil pump to pressures of less than 10^{-3} mm. If at any time air was admitted to the reaction vessel, it was well washed out with the vapor of the substance in use.

The substances used were stored, if liquids, in small bulbs attached to the system; if gases, in a reservoir over mercury. Mixtures were made in a reservoir over mercury, and could be thoroughly mixed by changing the mercury level.

Gas analyses were carried out according to the micro methods of Blacet and Leighton.[8] The greater part of any aldehyde or ether present was removed in a trap at −70°. As it was found that the beads slowly absorb other gases than that for which they are used (*e. g.*, fuming sulfuric acid slowly absorbs carbon monoxide), the times of contact were carefully controlled.

In order to determine the amounts of aldehydes present the gas was withdrawn, shaken with water and (a) the total aldehydes found by titration with sodium bisulfite; (b) the formaldehyde estimated by the potassium cyanide method.[9] The bisulfite solution was stabilized with ethyl alcohol and frequently standardized against iodine. Blank experiments with acetaldehyde showed that it also slowly reacts with potassium cyanide for which interaction a correction was applied. Experiments with undecomposed acetaldehyde vapor withdrawn from the furnace showed the bisulfite method to be accurate.

Diethyl ether (99.5%) was dried over sodium and freshly distilled in an all-glass apparatus. Acetaldehyde (Eastman Kodak) was distilled and the fraction boiling between 20.5 and 21° collected for use. A particularly pure specimen of helium, prepared for cryogenic work, was used. Ethylene was purified by fractionation at liquid air temperatures.

Experimental Results.—Analyses of the gaseous reaction products were made on samples for which the initial pressure, p_0, was 200 mm. at 507°, and which were allowed to proceed to various stages of completion, $\Delta p/\Delta p_\infty$. The results are given in Table I.

TABLE I

Gas Analyses: p_0 = 200 mm., Temp. = 507°

$\frac{\Delta p}{\Delta p_\infty}$	Hydrocarbons, % Unsatd.	Satd.	H_2, %	CO (obsd.), %	CO (calcd.), %
0.05	7.6	77.4	7.4	7.6	10
.075	10.0	74.8	7.0	8.2	12
.25	9.5	68.2	5.3	17.0	20

.50	10.5	60.9	4.3	24.3	25
.90	8.5	57.9	4.3	29.3	32

It is known that formaldehyde and acetaldehyde are formed during the decomposition of diethyl ether,[3] and as their rates of decomposition are of the same order of magnitude as that of the ether, considerable quantities of the aldehydes are built up in the system. Quantitative estimations were carried out (a) at 507 and 552° for an initial pressure of 200 mm., and (b) at 552° for an initial pressure of 20 mm. In Fig. 1 the percentages of total aldehydes relative to the amount of ether originally present are plotted for comparable stages of completion. The ratio of formaldehyde to the total aldehydes is in each case from 20 to 25%. The almost exact agreement between the two curves for 200 and 20 mm. means that the order of the reaction that produces the aldehyde is the same as that by which it decomposes: results to be described later show that the former is 1.4. The amounts of aldehyde present do, however, show a definite increase with temperature (Table II) for which allowance must be made in deriving the energy of activation of the ether decomposition from pressure measurements.

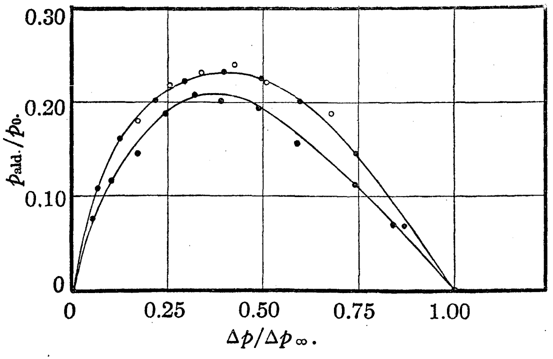

Fig. 1.—Amounts of aldehydes built up at different stages of completion: ●, p_0 200 mm., temp., 552°; ⊙, p_0 20 mm., temp., 552°; ◉, p_0 200 mm., temp., 521°.

Irrespective of the mechanism by which the ether decomposes, it is possible, *a priori*, (a) that the ether decomposes directly to carbon monoxide, *e. g.*

$$C_2H_5OC_2H_5 \longrightarrow C_2H_6 + CH_4 + CO$$

or (b) that an aldehyde is formed as an intermediate, *e. g.*

$$C_2H_5OC_2H_5 \longrightarrow CH_3CHO + C_2H_6$$

and that the aldehyde subsequently decomposes to carbon monoxide and methane. If all the ether decomposes in the former manner, the percentage of carbon monoxide in the products would be constant throughout the reaction; if all in the latter manner, the percentage would be very small in the early stages and increase as the reaction proceeds. Further, assuming that all the ether does actually form an aldehyde as an intermediate, it is possible, knowing the amounts of aldehyde present (Fig. 1), to calculate at any stage of the reaction the amount of aldehyde which has decomposed and therefore the percentage of carbon monoxide in the reaction products. The agreement between the calculated and observed amounts of carbon monoxide (Table I) justifies the conclusion that virtually all the ether forms an aldehyde as an intermediate step in its decomposition.

The question arises as to whether the aldehydes decompose at the same rate as in the pure state. At 552°, the maximum amounts of aldehyde are present when the pressure increase is 40% complete: at this stage the rate of production of aldehyde equals its rate of destruction. For an initial ether pressure of 197 mm. the rate of destruction of ether, which equals the rate of formation of aldehyde, is 0.374 mm./sec. From Fig. 1 it is seen that $p_{\text{ald.}}/p_0$ is 0.234, so that the aldehyde pressure is 46.1 mm. For this temperature and pressure it may be calculated from the results on the decomposition of pure acetaldehyde[10] that the rate of aldehyde disappearance is 0.122 mm./sec.; for formaldehyde the value is very similar.[11] When, therefore, these aldehydes are formed as intermediates in the decomposition of ether they react at a rate approximately three times greater than in its absence. This is too great a difference to be accounted for by cross activation by collisions with ether, and indicates a definite catalytic action of ether which has been confirmed by comparing the rates of decomposition of pure acetaldehyde with those of mixtures containing small percentages of ether.

The Decomposition of Acetaldehyde Catalyzed by Diethyl Ether.—Experiments with acetaldehyde were alternated with those of the aldehyde–ether mixtures. In both cases, after allowing for the ether decomposition, the shapes of the pressure–time curve were similar, and the end-point was nearly double the initial pressure. The rates have, therefore, been compared from the half-times, after applying a correction for the rate of decomposition of the ether: this is comparatively small as the rates of reaction of ether and acetaldehyde are similar (at 552° and 200 mm. they are 0.79 mm./sec. for ether and 1.15 mm./sec. for acetaldehyde). Table III gives the temperature, the percentage of ether to the total gas, the initial acetaldehyde pressure and the ratio of $1/t_{1/2}$ to that for the same initial pressure of pure acetaldehyde. The increase in $1/t_{1/2}$, which represents the catalyzed reaction, is independent of temperature, and nearly proportional to the percentage of ether. It may be noted that the addition of 5% of acetaldehyde does not change the initial rate of the ether decomposition.

TABLE III

THE CATALYSIS OF ACETALDEHYDE BY DIETHYL ETHER

Temp., °C.	% Ether	$p_{\text{ald.}}$, mm.	% increase $1/t_{1/2}$
552	1.9	179	5.3
	5.2	161	15.5
	5.2	90	21.7
	5.2	20.3	25.0
	18.5	156	55.2
507	5.2	178	15.8
	11.3	164	32.2
	11.3	85	38.9
	11.3	23.2	40.0
490.5	5.2	174	16.1

The catalysis of acetaldehyde by ether may be explained on the hypothesis that the decomposition of ether produces free radicals which then set up a chain in acetaldehyde. The uncatalyzed reaction of acetaldehyde cannot involve free radicals to any appreciable extent or the introduction of a few free radicals from ether, at temperatures at which the acetaldehyde is already decomposing as fast as the ether, would not increase the rate appreciably. At temperatures around 550°, therefore, the uncatalyzed reaction is

$$CH_3CHO \longrightarrow CH_4 + CO$$

If free radicals are present, however, the chain decomposition

$$CH_3CHO + R \longrightarrow CH_4 + CH_3CO$$
$$CH_3CO \longrightarrow CH_3 + CO$$

can also occur.

The chain length, λ, can be found in terms of the fraction of free radicals, x, produced from ether. At 552° the addition of 9 mm. of ether to 161 mm. of aldehyde causes an increase in $1/t_{1/2}$ of 15.5%: the initial rate may be assumed to increase by the same amount. In the absence of ether this rate is 0.82 mm./sec., so that the increase is 0.13 mm./sec. The initial rate of disappearance of ether, assuming no cross activation by acetaldehyde, is 0.011 mm./sec.; if collisions with acetaldehyde are equally as effective as collisions with ether in causing activation, the rate of disappearance is 0.031 mm./sec. The value of λ therefore lies between $12/x$ and $4/x$. The results with nitric oxide on ether[7] indicate that at this temperature the inhibited reaction is about 0.3 of the total reaction, so that for ether the chain length is $0.7/x$. The value of x may be very considerably smaller than 0.3 as ether molecules not only produce free radicals but also decompose directly to molecules without the formation of such radicals.

The Rate of Pressure Increase.—Deductions about the rate of disappearance of ether can only be made from measurements on the rate of pressure increase if (a) the final pressure increase at any temperature and pressure is known, and if (b) allowance is made for the undecomposed aldehydes present. Newitt and Vernon[3] at pressures

[10] Fletcher and Hinshelwood, *Proc. Roy. Soc.* (London), **A141**, 41 (1933).

[11] Fletcher, *ibid.*, **A146**, 357 (1934).

greater than atmospheric have estimated the aldehydes and corrected for them.

The final pressure increase, Δp_∞, at any initial ether pressure, p_0, does not vary with temperature, but at any temperature there is a marked decrease with pressure. The values obtained at different pressures at temperatures from 495 to 565° are plotted in Fig. 2. A similar variation has been found for other molecules[11] and has been correlated with condensation reactions.

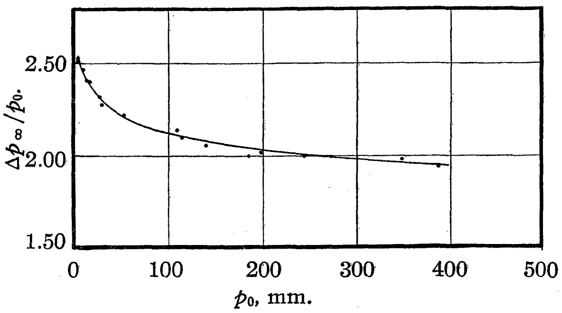

Fig. 2.—Variation of end-point with initial pressure.

The rates at different initial pressures were compared by taking the times, $t_{1/4}$ and $t_{1/2}$, in seconds, for one-quarter and one-half of the pressure increase at completion. The variations of $1/t_{1/4}$ with p_0 at 552 and 521° are plotted in Fig. 3.

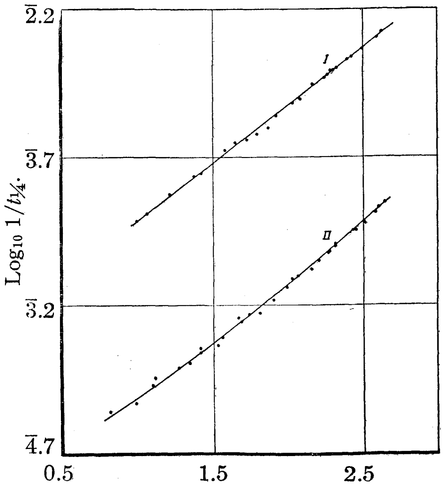

Fig. 3.—I, 552°; II, 507°.

As the amounts of aldehydes present throughout the reaction have been estimated, a pressure–time curve, such as would be obtained if the aldehyde present were completely decomposed, can be constructed (it has been assumed that unit pressure of aldehyde gives 1.95 units of products). This has been done in Fig. 4 for p_0 = 198 mm. at 552°, and it is seen that the induction period noticeable in the uncorrected curve is in this way removed. The uncorrected values of $t_{1/4}$ and $t_{1/2}$ are 102 and 232.5 sec., respectively; from the corrected curve they are 68.2 and 167 sec., so that as the correction for the aldehydes at this temperature is the same at all pressures (Fig. 1), the observed values of $t_{1/4}$ at 552° must all be decreased by the factor 68.2/102 = 0.669. The corrected value of $t_{1/2}/t_{1/4}$ is 2.45, which is very close to that for a unimolecular reaction (2.41). The unimolecular constant, $k_{\text{uni.}}$, is connected at 552° with $t_{1/4}$ by the relation, $k_{\text{uni.}} = 0.43/t_{1/4}$.

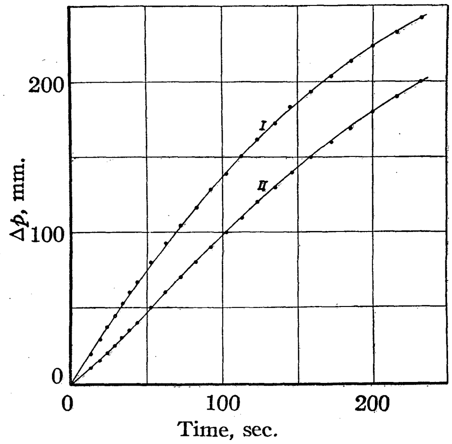

Fig. 4.—Pressure–time curve: p_0 197 mm., temp. 552°; I, corrected for aldehydes present; II, uncorrected for aldehydes.

The slope of log $1/t_{1/4}$: log p_0 (Fig. 3) gives directly the order of the ether decomposition with respect to the initial pressure, as the correction to be applied for the aldehydes is the same at all pressures. This gives an order of 1.40 at 552°, and at 521° a similar value, though at this temperature the order increases somewhat with pressure, as has been found by Rice and Sickman at lower temperatures and pressures.[5] It is known that the non-chain reaction, *i. e.*, that in which small quantities of nitric oxide eliminate the chain reaction, varies with the initial pressure from 50 to 500 mm. in the same manner as the uninhibited reaction.[7] It follows, therefore, that the orders of both the chain and non-chain reactions are approximately 1.4. At much higher pressures (30 to 300 atm.), Steacie, Hatcher and Rosenberg[6] derive an order of 1.35, though they make no allowance for any variation in the end-points.

The Variation of the Energy of Activation with Pressure.—Theories of quasi-unimolecular reactions predict an increase in the energy of activation with pressure, which have been verified for azomethane.[12] In other cases, *e. g.*, the aldehydes,[13] the reverse has, however, been found, and has been correlated with chemical and physical complexities of the reactions. For diethyl ether, in which the greater number of molecules decompose by a chain mechanism, our results show that the energy of activation, E_1, decreases slightly but definitely with pressure (Table IV). The values of E are those derived directly from the slopes of $\log 1/t_{1/4}$ against $1/T$; the quarter times for constant concentrations were compared (Fig. 5). These energies of activation represent composites of the individual energies of activation of the reactions which contribute to the pressure increase. The smaller amounts of aldehydes formed at lower temperatures indicate a lower energy of activation for their destruction than for their formation. At 552° it has been found that $k = 0.43/t_{1/4}$; a similar calculation for $p_0 = 200$ mm. at 507° gives $k = 0.412/t_{1/4}$. If $k = x/t_{1/4}$, the energy of activation, E_1, for the initial decomposition of ether is

$$\begin{aligned} E_1 &= (E + R)\ \mathrm{d} \ln x/d(1/T) \\ &= E + 1200 \text{ cal.} \end{aligned}$$

and at 200 mm., $k = 1.6 \times 10^{13}\ e^{-58,600/RT}$.

TABLE IV

THE ENERGY OF ACTIVATION OF DIETHYL ETHER

p_0, mm.	E, cal.	E_1, cal.
400	56,900	58,100
200	57,400	58,600
100	58,200	59,400
50	58,700	59,900
25	59,000	60,200
12	58,700	59,900

Our results lie between those of Hinshelwood[2] (53,000 cal.), and those of Rice and Sickman[5] (62,000 cal.).

Discussion

The decomposition of diethyl ether was at first thought to be a simple quasi-unimolecular reaction;[2] later Rice and Sickman[5] postulated the existence of two or more unimolecular reactions or selective types of internal activation. The chain mechanism of Rice and Herzfeld[1] can now in part be accepted as the present work has demonstrated the existence of free radicals, and the retardation by nitric oxide shows that chains are set up by the radicals.[7] We have also found that the retardation of the rate by the reaction products[2] is due to ethylene, which can act as a chain breaker. Further, it is known that free radicals produced photochemically from acetone[14] or thermally from ethylene oxide[15] can also set up chains in diethyl ether at lower temperatures.

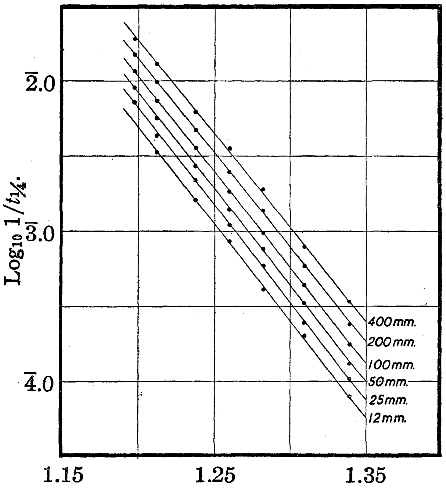

Fig. 5.—Variation of energy of activation with initial pressure.

Although the chain mechanism is thus firmly established, there is evidence that a certain fraction of ether molecules decompose by an intramolecular rearrangement directly to an aldehyde and other molecules.[15] Thus there are three general ways in which ether molecules may break down:

(1) By rearrangement to molecules

$$C_2H_5OC_2H_5 \longrightarrow C_2H_6 + CH_3CHO$$
$$C_2H_5OC_2H_5 \longrightarrow C_2H_4 + CH_4 + HCHO$$

(2) By the formation of free radicals

$$C_2H_5OC_2H_5 \longrightarrow C_2H_5 + C_2H_5O$$

(3) By interaction with free radicals (R)

$$R + C_2H_5OC_2H_5 \longrightarrow RH + C_2H_4OC_2H_5$$

followed by

$$C_2H_4OC_2H_5 \begin{cases} \nearrow CH_3CHO + C_2H_5 \\ \searrow HCHO + CH_3 + C_2H_4 \end{cases}$$

and subsequent chain decomposition of the aldehydes. Our results indicate that an aldehyde is always formed as an intermediate, so that there is no direct production of carbon monoxide from such a reaction as

$$C_2H_5OC_2H_5 \longrightarrow C_2H_6 + CH_4 + CO$$

[15] Fletcher and Rollefson, *ibid.*, **58**, 2135 (1936).

The proportion of the three types of reaction will vary with the pressure and temperature; thus from the relative energies of activation the chain reaction predominates more at lower temperatures.[7] The formation of free radicals by a unimolecular process, and chain termination by the recombination of two small (ethyl and methyl) radicals best accounts for the observed order of the chain reaction of approximately 1.4.[16] The inhibited reaction is probably composed of a number of quasi-unimolecular components of types 1 and 2, so that the order with respect to the initial pressure will, as in the aldehydes,[10] have no simple value. It is at first sight surprising that the order during the course of a run is first order, as the ethylene produced, which retards the rate of reaction, would be expected to raise the order. However, as the reaction proceeds there will be an increase in the relative proportions of methyl to ethyl radicals due to such a reaction as

$$C_2H_5 + CH_3CHO \longrightarrow C_2H_6 + CO + CH_3$$

and methyl radicals may react more easily with ether than do ethyl radicals.

The indecisive influence of inert gases is in agreement with the complex nature of the reaction. Such gases have been found slightly to retard the rate of chain reactions,[15] while they accelerate that of quasi-unimolecular reactions.[17] We have found that helium, when present in a 2:1 ratio, does not change the rate by more than ±2%.

The Evidence for Chains in Related Compounds.—The decomposition of dimethyl ether has been studied by Hinshelwood and Askey,[18] and the results justify a chain mechanism. Formaldehyde is formed as an intermediate ($CH_3OCH_3 \longrightarrow CH_4 + HCHO$) and its rate of decomposition is considerably faster than that of the pure substance. Making a calculation similar to that for diethyl ether, it is found that for an initial ether pressure of 312 mm. at 504°, the rate of disappearance of formaldehyde when its pressure is 38 mm. is 0.10 mm./sec. If it is assumed that there is no cross-activation by other molecules, the value extrapolated from the data on pure formaldehyde[11] is 6.8×10^{-3} mm./sec., *i. e.*, some fifteen times slower. Free radicals will account for the catalysis of the formaldehyde decomposition which does not normally involve a chain mechanism: part of the dimethyl ether reacts therefore through a chain mechanism, as it has been found that chains exist in the presence of free radicals.[14] As in other chain reactions the rate is retarded by inert gases.

Quantitative analyses of the amounts of acetaldehyde present at different stages of the reaction have not been made for methyl ethyl ether. Ure and Young[19] assumed that 65% of the ether decomposed to acetaldehyde, and in this way obtained a rate constant for the aldehyde decomposition similar to that from direct measurement. If, as in the other simple ethers, virtually all the ether forms an aldehyde as an intermediate, the velocity constant for the aldehyde will be greater than in the absence of ether, in agreement with a free radical mechanism. Glass and Hinshelwood[20] found that both methyl ethyl and methyl propyl ether decompose more rapidly in the presence of their respective reaction products. This effect may not have been due to inert gases but rather to traces of iodine compounds, introduced during the preparation of the ethers.

Methyl alcohol bears a structural resemblance to the methyl ethers, and formaldehyde is formed in the course of its decomposition.[21] Its rate of reaction has, however, been explained without postulating the existence of free radicals. The reaction of methyl alcohol in the presence of ethylene oxide shows that the alcohol does not easily form chains even in the presence of comparatively large concentrations of free radicals:[15] further, the decomposition of methyl alcohol is not retarded by nitric oxide and decomposes faster in the presence of its reaction products.[22] There is no evidence, therefore, for a chain mechanism though the formation of free radicals has not been disproved definitely.

The kinetics of the individual reactions which constitute the different steps in the chain decompositions of the ethers must await the determination of the chain-lengths and the percentage of molecules which produce free radicals. In view of the considerable proportion of molecules which decompose without interacting with free radicals, the values assumed by Rice and Herzfeld for the separate steps may need considerable modification.

Summary

The decomposition of diethyl ether has been studied over the pressure range of 6 to 450 mm., and at temperatures from 473 to 562°. Gas analyses indicate that an aldehyde is always formed as an intermediate, and from the amounts of aldehydes present it is found that their rates of decomposition are greater than in the pure state. In confirmation of this the decomposition of acetaldehyde is catalyzed by small amounts of ether, which is explained by the formation of free radicals from diethyl ether, and the initiation of a chain decomposition of the aldehyde. The ether decomposition is interpreted in terms of the three simultaneous processes of molecular rearrangement, free radical formation and chain decomposition, and the importance of these processes in the decomposition of analogous substances is discussed.

The Production of Free Radicals from Ethylene Oxide and the Catalysis of Other Reactions by Them

BY C. J. M. FLETCHER AND G. K. ROLLEFSON

The investigations of F. O. Rice and his coworkers have shown that free radicals are produced from a number of organic substances when they are passed through a hot tube. In the majority of cases the energy of activation for the production of the free radicals is considerably higher than that for the thermal decomposition of the substance, but for ethylene oxide the two energies of activation are similar.[1] Therefore, the fraction of free radicals present in the thermal decomposition of ethylene oxide should be relatively higher than in other compounds. In confirmation of this, we have found that small amounts are very effective in promoting the chain decomposition of other compounds,[2] and can be used to initiate chain reactions from 400 to 450°, just as azomethane has been used around 300°.[3] The catalysis of acetaldehyde by ethylene oxide is of special interest, firstly, as it is formed from ethylene oxide by isomerization and so any investigations on the decomposition of ethylene oxide must necessarily consider the chain decomposition of acetaldehyde, and secondly, because the kinetics are simplified by the fact that only one type of radical, the methyl radical, need be considered.

The kinetics of the decomposition of ethylene oxide were first studied by Heckert and Mack[4] and their results have recently been interpreted in terms of the free radical theory.[5] Thompson and Meissner[6] have shown that the decomposition is not a simple unimolecular reaction and that the variation of the rate with the initial pressure indicates a number of simultaneous reactions.

Experimental Procedure.—The reactions were followed in a manner similar to those described with diethyl ether.[7] The organic materials were purified by distillation, except for ethylene which was purified by fractionation after condensation at liquid air temperatures. Nitric oxide was formed *in situ* in the reaction vessel from ethyl nitrite, which under the experimental conditions decomposes instantaneously.[8]

$$2C_2H_5ONO \longrightarrow 2NO + CH_3CHO + C_2H_5OH$$

The Decomposition of Ethylene Oxide.—The pressure increase at completion is equal to the initial pressure, and the reaction is strictly homogeneous.[4] Aldehydes are formed as intermediate products of the decomposition and in order to obtain sufficiently large amounts with which to carry out tests, moderately large pressures were used and the gases removed at an early stage of the reaction. Acetaldehyde was detected by Rimini's test, formaldehyde by the resorcinol test, while a solution had a definite odor of acrolein; the ratios of unsaturated aldehydes and of formaldehyde to acetaldehyde were small. For an initial pressure of 380 mm., the total aldehyde

428	53.3	.386	1.86	.28
414	52.1	.178	1.85	.13

The rate, as measured by the reciprocal of the half-time, $1/t_{1/2}$, is seen from Table I to decrease with the initial pressure, p_e; Heckert and Mack's results indicate that the rate is more nearly first order above 300 mm. The results of Table I have been used (Fig. 1) to calculate the energy of activation for initial pressures of 50 mm., and give the value 53,300 ± 800 cal., while at different temperatures

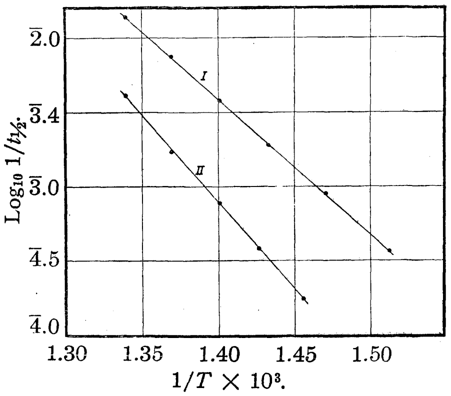

Fig. 1.—I, Acetaldehyde and ethylene oxide; II, ethylene oxide.

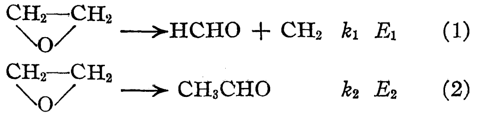
$$1/t_{1/2} = 1.8 \times 10^{13} \times e^{-53{,}300/RT}\ \text{sec}^{-1}$$

The pressure–time curves show an induction period at the beginning of the reaction similar to that in other decompositions (*e. g.*, ethers, methyl alcohol) in which aldehydes are formed as intermediates. With ethylene oxide, however, its duration is proportionately less in agreement with the small fraction of aldehydes formed.

The kinetics may be interpreted on the assumptions that ethylene oxide partly decomposes to formaldehyde, and partly isomerizes to acetaldehyde: small amounts of acrolein may be produced as a side reaction by the decomposition of dioxane formed by a polymerization reaction.



No methylene radicals have been detected,[9] so that they probably react extremely rapidly to form methyl radicals, which in turn lead to a chain decomposition of the aldehydes.

$$CH_2 + C_2H_4O \longrightarrow 2CH_3 + CO \qquad k_3\ E_3 \quad (3)$$
$$CH_3 + CH_3CHO \longrightarrow CH_3 + CH_4 + CO \quad k_4\ E_4 \quad (4)$$

Methyl radicals may be removed by direct recombination either alone or in the presence of a third body.

$$2CH_3 \longrightarrow C_2H_6 \qquad k_5\ E_5 \qquad (5)$$
$$2CH_3 + M \longrightarrow C_2H_6 + M \quad k_6\ E_6 \qquad (6)$$

Sickman[5] has assumed that methyl radicals recombine only at ternary collisions; the experimental results on the induced decomposition of acetaldehyde indicate, however, that a direct bimolecular association also occurs. Let the pressure of ethylene oxide be x_1, of methylene radicals be x_2, of acetaldehyde be x_3, of methyl radicals be x_4, and let the total pressure, including that of inert gases, be P; then, when steady concentrations of methylene and methyl radicals are established, if reaction 1 is first order

$$x_4 = \sqrt{\frac{2k_3x_1x_2}{k_5 + k_6P}} = \sqrt{\frac{2k_1x_1}{k_5 + k_6P}} \qquad (1)$$

It is justifiable to assume that $k_2 > k_1$, as the ratio of formaldehyde to acetaldehyde is small, and the amount of hydrogen, which would be formed from the decomposition of formaldehyde, is only 7% of the reaction products. Furthermore, as the amounts of aldehyde built up are in general agreement with the assumption that there is no direct formation of carbon monoxide and methane from ethylene oxide (see later), it is apparent that the pressure increase is mainly due to reaction 4. The observed rate of pressure increase, (dp/dt), is thus given by

$$\left(\frac{dp}{dt}\right) \sim k_4x_4x_3 \sim k_4x_3\sqrt{\frac{2k_1x_1}{k_5 + k_6P}} \qquad (2)$$

This rate increases (during which time there is an induction period) until the acetaldehyde pressure

---

[9] F. O. Rice and K. K. Rice, "The Aliphatic Free Radicals," The Johns Hopkins Press, Baltimore, Maryland, 1935 ,p. 161.

is a maximum, x_3'. As this occurs at a very early stage, one may put $x_1 = p_e$, and at this time, $t_{\text{max.}}$

$$k_2p_e = k_4x_4x_3' \qquad (3)$$

so that

$$x_3' = \frac{k_2p_e}{k_4}\sqrt{\frac{k_5 + k_6P}{2k_1p_1}} \qquad (4)$$

and

$$(\mathrm{d}p/\mathrm{d}t)_{\text{max.}} \sim k_2p_e \qquad (5)$$

The maximum rate is actually (see Table I) proportional to rather more than the first power of the ethylene oxide pressure, and so inert gases may slightly increase $(\mathrm{d}p/\mathrm{d}t)_{\text{max.}}$ if they help to maintain the Maxwell–Boltzmann distribution of activated molecules. Hydrogen, which is usually far more effective in this way than other gases, has been found to increase the rate of reaction. On the other hand, it follows from equation 4 that inert gases which contribute to the term P, or substances such as nitric oxide which remove free radicals,[10] should increase the maximum amounts of aldehydes and, therefore, of $t_{\text{max.}}$ and of $t_{1/2}/t_{1/3}$. The effect of inert gases found by Heckert and Mack,[4] and the results with small amounts of nitric oxide, p_{NO}, given in Table II are in agreement with these deductions. The fact, however, that $(\mathrm{d}p/\mathrm{d}t)_{\text{max.}}$ is not changed by small amounts of nitric oxide, indicates that not the isomerization of ethylene oxide, but only the subsequent decomposition of acetaldehyde is a chain reaction.

The Catalysis of Organic Reactions by Ethylene Oxide.—As ethylene oxide produces relatively to most other organic compounds a copious supply of free radicals, it is extremely suitable for the study of the extent to which chain reactions involving free radicals may occur. It is possible to invent a chain mechanism for the decomposition of nearly every organic molecule but without knowledge of the kinetics of the separate steps it is often impossible to predict whether such mechanisms will take place. Our experiments contrast the ease with which acetaldehyde and diethyl ether may be made to undergo chain decompositions, compared to the difficulty with which acetone and methyl alcohol decompose in the presence of free radicals. The induced decomposition of acetaldehyde has been used to test for chain-breakers as well as to illustrate the efficiency of inert gases in promoting the recombination of methyl radicals at ternary collisions.

(1) The Decomposition of Acetaldehyde.—Mixtures were made up in which the ratio of the pressure of ethylene oxide, p_e, to acetaldehyde, p_a, was small, and the rates of pressure increase were measured at a number of different initial pressures, p_0. The rate of the uncatalyzed acetaldehyde decomposition was always negligible in comparison with that of the catalyzed reaction. The relative rates of reaction have been compared from the half-times, *i. e.*, the times for a pressure increase of 50%, as the "end-points" are double the total initial pressure, p_0. Figure 2 shows the variation of $1/t_{1/2}$ with p_0 at 441°, and it is seen from Table III that $1/t_{1/2}$ is proportional to the square root of the ethylene oxide pressure, but for a constant ethylene oxide pressure decreases slightly with p_0. It has been shown previously that some recombination of free radicals occurs at ternary collisions, and the present results indicate that ethylene oxide or acetaldehyde can act as the third body. Substituting in equation 2, the initial rate, $(\mathrm{d}p/\mathrm{d}t)'$, of the induced reaction is given by

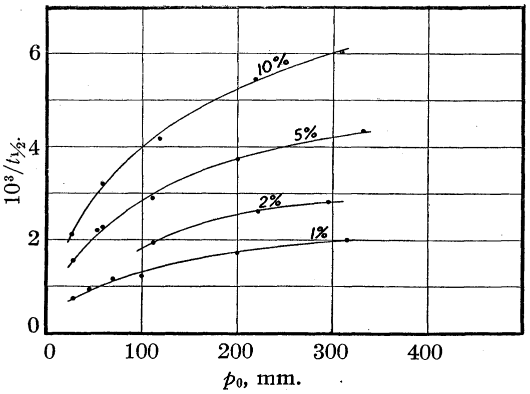

Fig. 2.—Rates of reaction of acetaldehyde with various percentages of ethylene oxide. Temp. 441°C.

$$\left(\frac{\mathrm{d}p}{\mathrm{d}t}\right)' = k_4\sqrt{p_e} \times p_a \times \sqrt{\frac{2k_1}{k_5 + k_6p_0}} \qquad (6)$$

Approximate values of the constants may be obtained by a comparison with the experimental

[10] Staveley and Hinshelwood, *Proc. Roy. Soc.* (London), **A154**, 335 (1936).

results, on the assumption that the correction due to the decomposition of the ethylene oxide is small. The mean values of $1/(t_{1/2}\sqrt{p_e})$ may be expressed in the form

$$\frac{1}{t_{1/2}\sqrt{p_e}} = \frac{1.39 \times 10^{-3}}{(1 + 1.93 \times 10^{-3} p_0)^{1/2}} \qquad (7)$$

from which the calculated results of Table III have been derived. As the initial rate is found by experiment to equal approximately 0.77 $p_a/t_{1/2}$, it follows that

$$k_4\sqrt{2k_1}/\sqrt{k_5} = 1.07 \times 10^{-3}, \text{ and } k_6/k_5 = 1.93 \times 10^{-3}$$

		.048	97.8	100.5	327	.45
		.048	94.7	100.8	325	.45

The term k_6P of equation 1 is composite when more than one type of molecule is present, but the value of k_6/k_5 just obtained will refer predominantly to acetaldehyde. The rate of reaction has been found to be retarded by helium (Table IV), and the increase in $t_{1/2}$ by approximately 10% with a 2–1 helium ratio, indicates that for helium k_6/k_5 is 1.4×10^{-3}. It follows from equation 7 that for the pressures used, the number of free radicals which combine at ternary collisions is rather smaller than the number which combine directly either on the surface or in the gas phase.

Experiments carried out at 446° in a reaction vessel packed with tubes showed the rate to be slower by about 30%, although the surface–volume ratio was increased by a factor of eleven: it is evident, therefore, that at this temperature the recombination of free radicals is mainly a homogeneous reaction. At temperatures around 300°, Allen and Sickman[3] have found that the induced decomposition of acetaldehyde is retarded by over 50%. This decrease in the retardation by the surface at higher temperatures agrees with the investigations of Paneth, Hofeditz and Wunsch[11] who have found that the heterogeneous recombination of free radicals decreases with the temperature. At temperatures and pressures sufficiently low for heterogeneous recombination to predominate, inert gases, by impeding the diffusion of radicals to the walls will, therefore, increase and not decrease the rate of reaction.

The energy of activation of the induced reaction was determined for a mixture containing 5% of ethylene oxide at initial pressures of approximately 200 mm. (Fig. 1). The half-times satisfy the equation

$$1/t_{1/2} = 2.1 \times 10^{10} \times e^{-41,500/RT} \text{ sec.}^{-1}$$

The energy of activation (41,500 ± 500 cal.) can be lower than that for ethylene oxide as the rate has been found to depend upon the square root of the ethylene oxide concentration.

Now that the rate of the induced acetaldehyde decomposition is known, it is possible to compare the amounts of acetaldehyde actually formed from ethylene oxide with those calculated on the assumption that practically all of the ethylene oxide isomerizes to acetaldehyde. From equations 1, 3, 5 and 6, the initial rate of the induced reaction, and the maximum rate of the ethylene oxide decomposition with the same ethylene oxide pressure are related by the expression

$$\left(\frac{dp}{dt}\right)' \Big/ \left(\frac{dp}{dt}\right)_{\text{max.}} \sim p_a/x_3'$$

Comparing these rates at 441° for p_e = 30 mm., $x_3' \sim 3$ mm. However, from equation 4, it follows that x_3' is roughly proportional to $\sqrt{p_e}$, so that for p_e = 380 mm., $x_3' \sim 11$ mm. The aldehydes determined experimentally at an early stage of the reaction were 8.8 mm. for this initial pressure.

The chain length of the acetaldehyde induced reaction may be expressed in terms of the fraction,

---

(11) Paneth, Hofeditz and Wunsch, *J. Chem. Soc.*, 372 (1935).

z, of methyl radicals produced from ethylene oxide. At 441° with a mixture containing 20 mm. of ethylene oxide and 180 mm. of acetaldehyde $(dp/dt)' = 1.34$ mm./sec. At the same temperature extrapolation of the results with ethylene oxide alone gives for $p_e = 20$ mm. a maximum rate of 0.012 mm./sec. Therefore, the chain length is approximately $100/z$. Assuming that the hydrogen and ethane that are present in the reaction products from ethylene oxide are formed solely by way of reaction 1, the observed products (CO, 50%; CH_4, 36%; H_2, 7%; C_2H_6, 7%) would indicate that 14% of the ethylene oxide decomposes to methylene and formaldehyde. The fraction decomposing in this way may, of course, vary with the initial pressure, but if it is not very different at lower pressures, z will be approximately 0.3 as two methyl radicals are formed by reaction 3 from each methylene radical.

It has recently been found that small quantities of nitric oxide can retard certain reactions, due to the elimination of any chain reactions by the removal of free radicals by the nitric oxide.[10] Table IV, which gives the ratio of the half-time, $t_{1/2}'$, in the absence of nitric oxide to the half-time, $t_{1/2}$, in the presence of nitric oxide, shows that the chain decomposition of acetaldehyde is retarded markedly. Organic substances such as acetone and methyl alcohol, when present in large quantities, can also act as chain-breakers (Table IV); this indicates that they can compete effectively with acetaldehyde for methyl radicals, but that the re-formation of a methyl radical is less frequent, either on account of the relative stability of the radicals CH_3O and CH_2COCH_3, or due to their relative ease of recombination with other radicals, *e. g.*

$$CH_3 + CH_3OH \longrightarrow CH_4 + CH_3O$$
$$CH_3O \longrightarrow HCHO + H$$
$$CH_3O + CH_3 \longrightarrow CH_3OCH_3$$

Ethylene also retards the rate of pressure increase but its influence is complicated by the decrease in pressure which must occur from its polymerization.

(2) **Diethyl Ether.**—With a mixture containing 5% of ethylene oxide the initial rate at 441° for an ether pressure of 180 mm. is increased by a factor of twenty and the reaction goes 82% toward completion. If the chain length of the ethylene oxide catalyzed reaction is not very different from that of the chains in the normal ether decomposition, it is apparent that the proportion of free radicals produced directly from ether is only about one four-hundredth of the proportion from ethylene oxide: considerably less than one ether molecule in a thousand, therefore, forms a free radical. Extrapolation of the ether decomposition inhibited by nitric oxide[10] indicates that some 15% of the ether decomposes by a non-chain reaction, so that it follows that in the uncatalyzed reaction there is an appreciable decomposition which takes place neither to free radicals nor by a chain reaction, but rather by a direct molecular rearrangement.[7] Further, the chains must be few and long rather than numerous and short.

(3) **Ethylene.**—The rate of polymerization of 176 mm. of ethylene is twenty times greater in the presence of 3.7 mm. of ethylene oxide at 441°.

(4) **Acrolein.**—The rate of decomposition at 470° is increased by a factor of four with 10% of ethylene oxide.

(5) **Methyl Alcohol.**—Some interaction between free radicals and methyl alcohol occurs which (a) decreases the rate of pressure increase as compared to that for the pure ethylene oxide, and (b) leads to the decomposition of some fraction of the methyl alcohol. Thus at 465° for $p_e = 98$ mm., $t_{1/3} = 173$ sec. In the presence of 105 mm. of methyl alcohol, $t_{1/3} = 211$ sec., but the final end-point indicates that 24.5% of the methyl alcohol has decomposed. The uncatalyzed reaction is inappreciable at this temperature.[12]

We wish to thank Dr. O. K. Rice for many helpful discussions, and one of us (C. J. M. F.) is grateful to the Commonwealth Fund for a Fellowship, which has made this work possible.

Summary

The main reaction of ethylene oxide when heated to temperatures around 450° is an isomerization to acetaldehyde. Free radicals are also formed at the same time and decompose the acetaldehyde by a chain mechanism though they do not affect the isomerization process. Though the fraction of free radicals formed from ethylene oxide is comparatively small, it is relatively much higher than for most other organic compounds, and small amounts effectively catalyze the decomposition of other substances. The induced decomposition of acetaldehyde has been studied in detail, and the rate varies with the square root of the ethylene oxide concentration and with rather less than the first power of the acetaldehyde concentration; it is retarded slightly by helium,

---

(12) Fletcher, *Proc. Roy. Soc.* (London), **A147**, 119 (1934).

moderately by acetone and methyl alcohol and considerably by nitric oxide. The energy of activation of this induced reaction is 41,500 ± 500 cal., and the kinetics have been explained by a chain decomposition initiated by free radicals, which disappear partly at ternary collisions and mainly in the gas phase.

The Photochemical Reaction of Chlorine with Formic Acid

BY HELEN L. WEST[1] AND G. K. ROLLEFSON

Introduction

A study of the photochemical reaction between formic acid and chlorine was undertaken because it offered the possibility of proceeding in stages involving the formation of an intermediate substance, less stable than that found in the formaldehyde chlorine reaction,[2] but stable enough to exist in appreciable concentrations in the reacting mixture. Furthermore, on account of the measurable equilibrium existing between single and double molecules of formic acid, it was possible to test the relative reactivity of the two forms. The results presented in this paper show the formation of the expected intermediate, chloroformic acid, but do not show any appreciable difference in reactivity between the single and double molecules.

Materials and Apparatus

Anhydrous formic acid was prepared from Merck 90% C. P. acid by a preliminary dehydration with copper sulfate followed by repeated distillations *in vacuo* from finely pulverized boric anhydride. Before each of three distillations the acid remained in contact with the boric anhydride for at least one day. In order to prevent any slow thermal decomposition, the purified formic acid was kept in a trap immersed in a liquid air bath. The purity of the acid was evidenced by the agreement of the vapor pressures with those reported by Ramsperger and Porter[3] and Coolidge.[4]

The melting point determined from the vapor pressure-temperature curve was 8.3 ± 0.05°.

The chlorine was prepared by heating anhydrous cupric chloride. The supply used for the second series of experiments was purified by fractional distillation and stored in a three-liter bulb. It was admitted to the reaction vessel by means of a stopcock lubricated with Shell Apiezon grease (this was found to be practically inert toward both chlorine and formic acid). The absorption coefficient of this chlorine was found to be 26 at 3650 Å. in good agreement with the values given by Gibson and Bayliss.[5]

Comparison of data obtained under similar conditions using this chlorine and also chlorine prepared directly from copper chloride showed no essential differences provided the copper chloride had been heated to the decomposition temperature numerous times. Unless this treatment were followed, an inhibitory effect upon the reaction resulted.

A sample of Eastman Kodak Co. C. P. methyl formate was vacuum distilled from phosphorus pentoxide.

In the first series of experiments a spherical Pyrex reaction vessel of 250 cc. capacity was employed. Although the temperature coefficient of the reaction is negligible, some thermostating was necessary to prevent variations in the equilibrium constant for the relation of single to double molecules of formic acid. Water at temperatures from 20–25° was allowed to run over the cell. The light source was a 500-watt tungsten lamp, placed 80 cm. from the reaction bulb. The course of the reaction was determined by the pressure change. Due to the reactivity of formic acid, the pressure had to be read indirectly by means of a click gage connected externally to a sulfuric acid manometer. All pressures are recorded in cm. of sulfuric acid.

In order to provide an independent method for the determination of the amount of chlorine which had reacted, a second series of experiments was performed in which in addition to measuring the pressure change a simultaneous measurement of the absorption of light by chlorine could be made. These experiments were carried out using a cylindrical Pyrex reaction vessel, 15 cm. long with plane windows at the ends, which was immersed in a water-bath. The bath could be thermostated accurately at any desired temperature between 20 and 30°. The light both for the absorption measurements and the photoactivation process was supplied by a quartz Hereaus mercury arc focused by a pair of quartz lenses and passed through a Corning violet ultra filter No. 586 so as to isolate the groups of lines near 3650 Å. After the light had passed through the reaction vessel, it was focused on a Moll surface thermopile connected to a sensitive galvanometer. Variations in intensity of the arc were corrected for by taking simultaneous readings on another thermopile illuminated by a beam which had not passed through the reaction vessel. Quantum yields were calculated from these data after the

surface thermopile had been calibrated by means of a standard lamp.

Results and Discussion

The net reaction between formic acid and chlorine may be represented by the equations

$$HCOOH + Cl_2 = 2HCl + CO_2 \qquad (1)$$
$$(HCOOH)_2 + 2Cl_2 = 4HCl + 2CO_2 \qquad (2)$$

Both of these equations and the equilibrium between the two types of molecules must be taken into consideration in order to calculate the composition of the mixture after any observed pressure change. These reactions are strictly photochemical at the temperatures used, and blank tests showed that formic acid is not affected by light of the wave lengths involved in these experiments.

That hydrogen chloride and carbon dioxide are the only products formed in appreciable amounts is shown by the fact that under no conditions were any gases obtained which could not be condensed by liquid air. In addition, the equilibrium constants $K = (HCOOH)^2/((HCOOH)_2)$ calculated on the assumption that the products are as shown above compare favorably with those reported by Ramsperger and Porter.[3] These constants were computed from the over-all pressure change in experiments carried to completion in the presence of excess chlorine.

A comparison of the amounts of chlorine which have reacted at various stages of the reaction as determined from the change in light absorption and from the over-all pressure change is given in Table II. The fourth column gives the difference between the actually observed deflection of the thermopile galvanometer and that which would have been observed if an amount of chlorine had reacted corresponding to the observed pressure change. The first example shows no discrepancies other than might be expected due to experimental errors; the second shows a definite difference which starts at zero and increases regularly as the reaction progresses; the third shows a discrepancy which increases to a maximum and then disappears as the reaction goes to completion. Whenever such a difference appears it is always such that the residual chlorine pressure as calculated from the pressure change is greater than that found by the absorption measurements. This behavior could be expected if the first reaction forms an intermediate substance such as chloroformic acid which then decomposes to give the final products, carbon dioxide and hydrogen chloride. If the conditions are such that the rate of decomposition of this intermediate is sufficiently slow compared to the rate of formation, an appreciable amount of it will be built up during the course of the reaction. By analogy to the behavior of formyl chloride in the reaction between formaldehyde and chlorine, we expect the decomposition of chloroformic acid to be catalyzed by chlorine in the light and by the walls of the reaction vessel. If such conditions prevail, we should expect the greatest discrepancy in the presence of excess formic acid as is actually the case. The variability of the behavior with excess chlorine as shown by experiments 1 and 3 in Table II may be attributed to variations in the rate of the heterogeneous reaction similar to that found with formyl chloride.

Another fact which supports the hypothesis of an unstable intermediate was obtained by heating the reaction vessel after a reaction had been run with relatively low chlorine. Under these conditions, an additional pressure change of approximately one centimeter was observed. Blank experiments showed that this change could not be ascribed to the excess formic acid.

The pressure–time curves (*cf.* Fig. 1) are essentially the same whether excess chlorine or excess formic acid were present. Under no conditions

do they show an initial "foot" which could be attributed to the time required to build up the intermediate (*cf.* the reaction between formaldehyde and chlorine[2]). This is in accord with the data in Table II which show that the concentration of the intermediate does not attain its maximum value until a considerable amount of reaction has occurred.

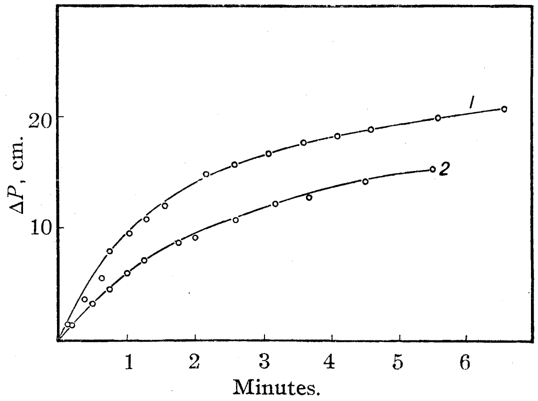

Fig. 1.—Pressure change–time curves: (1) initial pressure, 20.3 cm. formic acid, 19.3 cm. Cl_2; (2) initial pressure, 10.5 cm. formic acid, 19.5 cm. Cl_2.

The rate law for the reaction was deduced from an analysis of the data represented by curves of the type shown in Fig. 1, and separate tests in which the light intensity was varied by the use of calibrated screens. The constants tabulated in Tables I and II are calculated from the equations

$$\frac{-\mathrm{d}(Cl_2)}{\mathrm{d}t} = k_I(I_{abs.})^{1/2}(HCOOH) = k_I(I_0)^{1/2}(Cl_2)^{1/2}(HCOOH) \quad (1)$$

$$\frac{-\mathrm{d}(Cl_2)}{\mathrm{d}t} = k_{II}(I_{abs.})^{1/2}[H(COOH) + (HCOOH)_2] = k_{II}(I_0)^{1/2}(Cl_2)^{1/2}[(HCOOH) + (HCOOH)_2] \quad (2)$$

The exponent of $(I_{abs.})$ was found to change from one-half to one as the chlorine pressure or the light intensity was lowered. This effect manifests itself in the data shown in the tables as a falling off in the values of k_I and k_{II}. The results in brackets in Table I and those in Table II illustrate this behavior. The decrease in the constants can be attributed partly to the formation of chloroformic acid which makes the actual chlorine less than that calculated from the pressure change and the initial pressure. In experiments in which relatively large amounts of the intermediate appear, this effect is especially noticeable. It is obvious, however, that the influence of the change of the exponent of $I_{abs.}$ is much greater. With light intensities such as were used in these experiments, the square root law held for chlorine pressures of 10–15 cm. of sulfuric acid or greater.

A comparison of values of k_I and k_{II} listed in Tables I and II shows a slight preference for the law involving k_{II}. The most strenuous tests are those experiments with excess chlorine in which a large fraction of the formic acid was used up (1 and 3, Table II). In these both constants show a decrease as the run progresses but k_I shows a drop of roughly 45% over the same range that k_{II} drops only 25%.

These constants are calculated by plotting the residual chlorine pressure against time, drawing tangents to the curves at the desired points and using the slopes of these tangents in the rate laws (1) and (2). They represent constants derived from differential rates rather than averages over the range indicated. It is concluded from the data which have been acquired that the single and double molecules react with approximately the same speed.

As has been mentioned, the second experimental arrangement used, permitted a determination of the quantum yield. Some of the values obtained are listed in Table III. It is to be noted that even at the relatively low pressures employed in these experiments, the maximum quantum yields are around two thousand. This value is comparable with the chain length of the hydrogen–chlorine reaction under similar conditions.

The light sensitized reaction between methyl formate and chlorine has been reported[6] as forming methyl chloroformate followed by substitution in the methyl groups in the presence of excess chlorine. Therefore, a quantitative study of this reaction was undertaken in the possibility of observing the stages in the chlorination of the formate radical in a case the intermediate of which had been isolated. A typical chlorine–time curve is shown in Fig. 2. From this curve it is apparent that no discrete steps in the chlorination can be detected. Substitution is occurring in the methyl group simultaneously with substitution in the formate radical. The absence of any pressure change indicated that there was no decomposition of the chlorine derivatives.[7] The quantum yields for the chlorine–methyl formate experiments are of the same order of magnitude as those of the formic acid reaction.

The facts which have been presented show that the photochemical reaction between chlorine and formic acid is a chain reaction which proceeds at least partially through chloroformic acid; the final products are carbon dioxide and hydrogen chloride. The following set of reactions will account for all of the observed facts including the rate laws

$$Cl_2 + h\nu = Cl + Cl^* \qquad (1)$$
$$Cl + HCOOH = COOH + HCl \qquad (2)$$
$$COOH = CO_2 + H \qquad (3a)$$
$$COOH + Cl_2 = ClCOOH + Cl \qquad (3b)$$
$$H + Cl_2 = HCl + Cl \qquad (4a)$$
$$ClCOOH = CO_2 + HCl \qquad (4b)$$
$$Cl + Cl + (M) = Cl_2 \qquad (5)$$

Step (5) becomes $Cl + (M) = {}^1/_2Cl_2$ when $I_{abs.}$ replaces $I_{abs.}{}^{1/2}$. For the double molecules (2) and (3) are replaced by

$$(HCOOH)_2 + Cl = (HCOOH)(COOH) + HCl \qquad (2')$$
$$(HCOOH)(COOH) = (HCOOH) + CO_2 + H \qquad (3'a)$$
$$(HCOOH)(COOH) + Cl_2 = HCOOH + ClCOOH + Cl \qquad (3'b)$$

The failure to obtain higher concentrations of chloroformic acid may be attributed to 3a and 3′a since they supply a path to the final products which does not involve this intermediate. The competition between 3a and 3b and 3′a and 3′b requires that larger amounts of chloroformic acid should be obtained with high chlorine concentrations unless there is a chlorine catalyzed decomposition as well. Apparently such a situation exists as is shown by experiments made in the presence of excess chlorine.

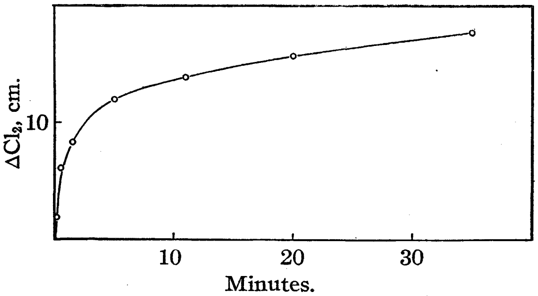

Fig. 2.—Chlorine reacted–time curve for initial pressures: 15.3 cm. $HCOOCH_3$, 58.5 cm. Cl_2.

The theoretical rate law calculated from the mechanism by the usual procedure is

$$\frac{-d(Cl_2)}{dt} = \frac{\sqrt{2}k_2}{\sqrt{k_5}} (I_{abs.})^{1/2} (HCOOH) \text{ or}$$
$$(\sqrt{2}k_2'/\sqrt{k_5}) (I_{abs.})^{1/2} ((HCOOH)_2)$$

Since reactions 3, 3′ and 4 do not affect the final form of the rate law, they may be replaced by any others which will allow for the formation of some chloroformic acid and give carbon dioxide and hydrogen chloride as the final products.

Summary

An investigation of the photochemical reaction between chlorine and formic acid has shown (1) there is no marked difference in the reactivity of the single and double molecules, (2) the reaction proceeds through a chain mechanism involving

[6] Kling, Florentin, Lassieur and Schmutz, *Compt. rend.*, **169**, 1046 (1919).

[7] A small white deposit appeared on the walls of the reaction vessel when water vapor was admitted after the reaction of chlorine with either formic acid or methyl formate had started. No effect was observed with moisture and the initial reactants. Amounts of this white substance sufficient for analysis could not be obtained, and its formation affected the reaction chiefly through a diminution in rate.

the formation of appreciable quantities of an intermediate, probably chloroformic acid. If excess chlorine is present or if the reaction vessel is heated to destroy any residual intermediate, the products are solely carbon dioxide and hydrogen chloride. A mechanism which will account for the observations has been presented.

The Heat Capacity and Entropy of Potassium Permanganate from 15 to 300° Absolute. The Entropy and Free Energy of Permanganate Ion

By Oliver L. I. Brown, Wendell V. Smith and Wendell M. Latimer

As part of a general program for the evaluation of the entropies of the common inorganic ions, the entropy of potassium permanganate has been determined.

Material.—Kahlbaum "For analysis with guarantee" grade potassium permanganate was used in the first series of heat capacity runs. These measurements demonstrated that the sample contained water. The material was removed from the calorimeter, ground in a mortar, and dried over sulfuric acid in a darkened desiccator. The sample was then analyzed by titration with sodium oxalate solution. Within experimental error (±0.1%) the sample was 100% potassium permanganate.

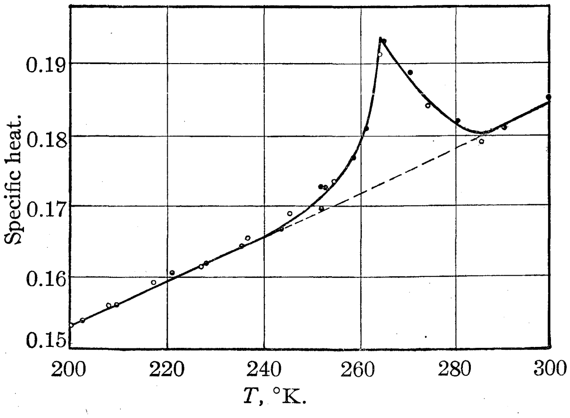

Fig. 1.—Specific heat of wet sample of potassium permanganate.

Heat Capacity Measurements.—The heat capacities were determined by the experimental method used by Latimer and Greensfelder.[1] One calorie was assumed equal to 4.1833 int. joules. The molecular weight of potassium permanganate was taken as 158.03. Measurements on Series I were made on a sample of 133.034 g. (weight *in vacuo*). An anomaly was found in the heat capacities, which appeared to be due to the presence of considerable water included in the sample. On removing the sample from the calorimeter the crystals were found to decrepitate upon heating, confirming the presence of water. The specific heats of the sample in the neighborhood of the melting point of water are presented in Table I and plotted as a function of temperature in Fig. 1. The half filled circles represent runs 1–7 (Oct. 14, 1933), the filled circles runs 8–16 (March 28–29, 1934), the open circles runs 17–26 (April 4, 1934). The area between the dotted curve and the solid curve corresponds to 0.28 cal., and after subtracting 0.02 cal. for the heat absorbed by the solution of potassium permanganate in the liquid water formed, corresponds to the melting of 0.0033 g. of water in each gram of sample. Although the eutectic of ice and potassium permanganate occurs at about 272.5°K., the maximum of the observed "hump" occurs at 265°K. and the abnormal specific heats persist even down to about 245°K. In view of the large amount of water present it was decided to dry the sample as described above, and repeat the entire series of measurements, even though it appeared reasonable that the heat capacity of dry potas-

sium permanganate could be calculated by correcting these measurements for the amount of water present.

Series II (made on the dry sample) is shown in Table II and plotted as a function of temperature in Fig. 2. The measurements on series I, after being corrected for 0.33% of water,[2] are shown in Table III. A few of these measurements selected at random are plotted as filled circles in Fig. 2. The measurements on the wet sample were not used in computing the entropy, but the excellent concordance of these two sets of data indicates that it is quite feasible to correct for water impurity in a salt crystal by assuming the water present as ice. This conclusion is important in cases where the instability of the substance under investigation precludes rigorous drying, although working with wet samples is not recommended as a general practice.

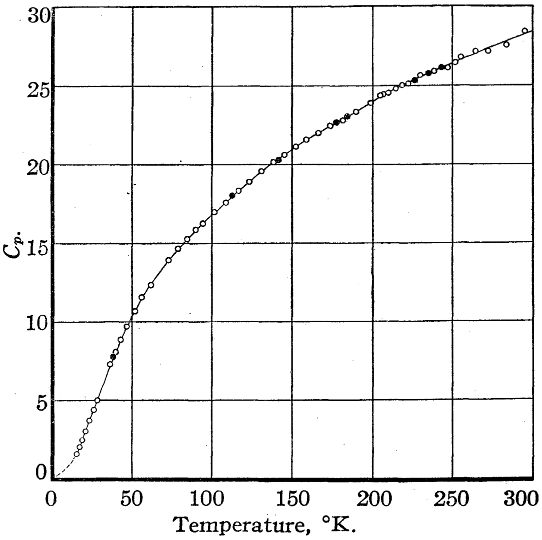

Fig. 2.—Molal heat capacity of potassium permanganate.

Entropy of Potassium Permanganate.—The entropy was calculated by graphical integration of the integral $S = \int_0^T C_p \, d \ln T$ combined with an extrapolation using the Debye specific heat equation. A summary of the entropy calculation is given in Table IV.

TABLE IV

MOLAL ENTROPY OF POTASSIUM PERMANGANATE

0–14.79°K.	Debye extrapolation	0.53
14.79–298.1°K.	Graphical from data	40.51 ± 0.1
	Entropy at 298.1°K.	41.04 E. U.

Heat and Free Energy of Solution.—Roth and Becker[3] have measured the integral heats of solution of potassium permanganate at several different temperatures and concentrations. Heats of dilution to very low concentrations have been determined[4] for the similar salt, potassium perchlorate, but not for potassium permanganate. Since the heats of dilution calculated from the measurements of Roth and Becker are almost identical with those for potassium perchlorate over the same range of concentration, we may assume that the heats of dilution remain the same down to very low concentrations. The heat of

(4) Andauer and Lange, *ibid.*, **A165**, 89 (1933).

solution of potassium permanganate in an infinite amount of water is, then, 10,620 cal. per mole at 298.1°K.

The solubility[5] of potassium permanganate in water at 298.1°K. is 0.482 M. By extrapolation of the activity coefficients of potassium permanganate obtained from freezing point lowering,[6] γ at 0.482 M is 0.49. The free energy change when potassium permanganate dissolves to form a hypothetical one molal solution is, therefore

$$\Delta F^0_{298.1} = -1363.8 \log (0.482 \times 0.49)^2 = 1710 \text{ cal./mole}$$

Entropy of Solution.—Substituting the above values in the equation $\Delta S^0 = (\Delta H^0 - \Delta F^\circ)/T$ we have for the reaction $\text{KMnO}_4\text{(s)} = \text{K}^+ + \text{MnO}_4^-$ (hypothetical one molal solution); $\Delta S^0_{298.1} = 29.9$ E. U.

Entropy of Permanganate Ion.—The entropy of potassium ion has previously been taken[7] as 24.6 E. U. as an average of the values obtained from the entropies of solution of potassium chloride and potassium bromide, and the entropy change of the potassium electrode reaction. Since the time that this value was calculated, improved data for the first two reactions have become available, so that we now regard the entropy change of the potassium electrode as inferior in accuracy to the values 24.3 E. U. and 24.1 E. U. calculated from the entropies of solution of potassium chloride and potassium bromide, respectively.[7b] As an average we shall adopt 24.2 E. U. as the entropy of potassium ion. The entropy of permanganate ion is given by the expression

$$S^0_{\text{MnO}_4^-} = \Delta S^0 + S_{\text{KMnO}_4} - S_{\text{K}^+} = 29.9 + 41.0 - 24.2 = 46.7 \text{ E. U.}$$

This value, as well as the value of the entropy of potassium permanganate, may be somewhat in error due to the possibility that the paramagnetic nature of potassium permanganate may contribute to the heat capacity below the lowest temperatures obtained in this investigation. No trace of this behavior was found, and the heat capacity appeared to be rapidly approaching the limiting T^3 law. The paramagnetism of potassium permanganate is without temperature coefficient, and no theory has yet been proposed which adequately accounts for this type of magnetic behavior. Further work on the entropies of paramagnetic ions, and particularly the study of reactions in which the products have a different magnetic behavior than the reactants, should help to settle this difficult question of magnetic entropy.

Free Energy of Potassium Permanganate and Permanganate Ion.—Bichowsky and Rossini[8] have selected −192,900 cal. as the ΔH of formation of solid potassium permanganate at 18°. Since the correction to 25° amounts to only 14 cal. it may be neglected. Using the entropies of potassium, manganese and oxygen as given by Kelley[9] we find ΔS of formation to be −79.5 E. U., from which the free energy of formation of solid potassium permanganate is −169,200 cal. per mole. Combining this value with the free energy of solution computed above, and subtracting the free energy of potassium ion[10] (−67,431), the free energy of formation of permanganate ion is found to be −100,060 cal./mole.

The authors wish to thank Dr. Philip W. Schutz of this Laboratory for assistance in the experimental work and calculations on Series I.

Summary

The heat capacity of potassium permanganate has been measured from 15 to 300°K., and the entropy of the salt determined by graphical integration to be 41.04 E. U. Coupling this value with the entropy of solution, and the entropy of potassium ion herein adopted, the entropy of permanganate ion has been determined to be 46.7 E. U.

The free energy of formation of potassium permanganate and of permanganate ion have been computed from the known entropies and heat of formation.

The Action of Diethylmagnesium upon the Methyl Substituted Derivatives of Epoxyethane[1,2]

BY F. H. NORTON AND H. B. HASS

Recently, Bartlett and Berry[3] have shown that dimethyl- and diethylmagnesium react with 1,2-epoxycyclohexane to form when hydrolyzed the products *trans*-2-methyl- and *trans*-2-ethylcyclohexanol. The present paper presents the results obtained by extending the use of dialkylmagnesium as a reagent into the field of epoxyalkanes.

The reactions of epoxyalkanes with Grignard reagents may be summarized as follows. Epoxyethane and 1,2-epoxypropane are known to react by simple splitting of the oxygen-to-carbon linkage; but the more highly substituted epoxyalkanes rearrange to produce alcohols which can be obtained from the corresponding aldehyde or ketone by use of the same alkylmagnesium halide.[4]

The authors have allowed diethylmagnesium to react with the methyl substituted derivatives of epoxyethane. Their purpose was to discover whether or not there is rearrangement when a dialkylmagnesium is allowed to react with epoxyalkanes and to determine the difference in activity of the two carbon to oxygen valences in the epoxyalkane. To ensure identification of the alcohols synthesized by this method, the authors allowed ethylmagnesium bromide to react with the same epoxyalkanes. Reference alcohols also were prepared by other Grignard reagents.

Quite accidentally, the authors discovered and separated *cis* and *trans* 2,3-epoxybutane. The identification was performed before the authors ascertained through a private communication that Lucas and Wilson[5] had synthesized these compounds in order to prove Lucas' identification of *cis* and *trans* 2-butenes.

Experimental

Purification of Organic Liquids.—All organic liquids were carefully rectified at atmospheric or reduced pressure in a Podbielniak column or in a rectifying column[6] packed with Penn State glass spirals. A reflux ratio of 20 to 1 or higher was maintained in all distillations.

Cis and trans 2,3-epoxybutane were synthesized from 2-butanol. Eight hundred and fourteen grams of 2-butanol was converted to *cis* and *trans* 2-butene.[7] The mixture of butenes was allowed to react with a cold solution of hypochlorous acid to form 3-chloro-2-butanol, 245 g., b. p. 76–79° at 100 mm.;[8,9] yield 20.6%. The crude 2,3-epoxybutanes were prepared by treatment with solid potassium hydroxide,[10] and were separated by rectification. Sixty-one and one-half grams of *trans*-2,3-epoxybutane distilled from 52–53° at 741 mm., and 43.5 g. of *cis*-2,3-epoxybutane boiled from 58–59° at 745 mm. (yield of combined *cis* and *trans* isomers, 66% based on chlorohydrin).

2,3-Epoxy-2-methylbutane was prepared from 2-methyl-2-butanol by pyrolysis[11] to 2-methyl-2-butene which was converted to the epoxyalkane as described above. Ninety-six grams of 2,3-epoxy-2-methylbutane distilled from 73.0–74.2° at 753 mm.; yield, 8.6% based on alcohol; 74% based on chlorohydrin.

2,3-Dimethyl-2,3-epoxybutane was prepared from acetone. The following reactions were carried out: the conversion of acetone to pinacol hydrate,[12] the dehydration of pinacol hydrate by a benzene distillation,[13] the treatment of 909 g. of anhydrous pinacol with molar proportions of anhydrous hydrogen chloride,[14] crystallization and filtration of the resulting chlorohydrin, 3-chloro-2,3-dimethyl-2-butanol[15] and treatment as above with potassium hydroxide to produce the corresponding epoxyalkane. One hundred and fifteen grams of 2,3-dimethyl-2,3-epoxybutane distilled from 90.2–91.4° at 753 mm. Yield of oxide was 15% based on anhydrous pinacol.

Preparation of Diethylmagnesium.—An ether solution of diethylmagnesium was prepared from ethylmagnesium bromide made from 109 g. of bromoethane, 24.5 g. of magnesium and 150 ml. of ether. The Grignard reagent was treated while refluxing with 110 g. of 1,4-dioxane in 300 ml. of ether.[16, 17] The mixture was centrifuged, the clear ether layer decanted and analyzed for diethylmagnesium[18] and for bromide ion. The solution was concentrated by distillation of about 60% of the ether.

Reactions of Diethylmagnesium upon Epoxyalkanes (Table I).—A general procedure was used in this reaction, typified by the case of 1,2-epoxypropane. The sample of epoxypropane in an equal volume of ether was added

slowly to the diethylmagnesium which had been prepared from bromoethane. The mixture was refluxed for twenty minutes, cooled, poured into ice, treated with only enough dilute sulfuric acid to dissolve the precipitate and then separated. The water layer was extracted with ether. The combined ether solutions were dried with anhydrous potassium carbonate for twelve hours. The ether was distilled off slowly in a packed column and the residue then rectified in a Podbielniak column, the fraction distilling from 113–120° being again distilled.

Reaction of Ethylmagnesium Bromide upon the Epoxyalkanes.—The epoxyalkanes (Table I) were allowed to react with ethylmagnesium bromide. The products were treated in the same manner as for those formed with diethylmagnesium (Table II).

Determination of Physical Constants.—The boiling point at atmospheric pressure,[19] the density at 25° (Ostwald pycnometer, vol. 1.1134 ml.), and the refractive index (Abbé) at 25° of all the alcohols were determined in a ten-day period. The reaction rate with zinc chloride-hydrochloric acid was determined at 27.4° in a three-hour period. The reagent was prepared as described in the literature.[10]

It is very evident from this table that diethylmagnesium reacts with the epoxyalkane to produce 2-pentanol. In the case of the corresponding Grignard reagent there is evidence that two products are formed. The alcohol prepared from ethylmagnesium bromide was rectified repeatedly and still gave a 3,5-dinitrobenzoate melting at 72°. A mixture of this derivative and the 3,5-dinitrobenzoate of 3-pentanol melted from 69–71°, which is very nearly the melting point of both derivatives. The 3-pentanol was a commercial product prepared by a distillation of a mixture of pentanols. It probably contained 2-pentanol.

---

(19) Willard and Crabtree, *Ind. Eng. Chem., Anal. Ed.*, **8**, 79 (1936).

It is apparent from Table V that diethylmagnesium and ethylmagnesium bromide form different alcohols when they react with 1,2-epoxy-2-methylpropane.

Table VI is the basis for the following discussion. 3-Methyl-2-pentanol is the only alcohol obtained from *cis* or *trans* 2,3-epoxybutane and diethylmagnesium. There are four possible isomers: the *cis* should give one set of racemic forms while the *trans* yields the other set. The reference compound should be a mixture of the four isomers. The physical properties of the 3-methyl-2-pentanols check each other closely. The melting points and mixed melting points of their derivatives also tend to show that they are 3-methyl-2-pentanols.

3-Methyl-2-pentanol is obtained from ethylmagnesium bromide. All of the physical properties are very nearly identical with the exception of the boiling point of the alcohol produced from the *cis* form. In this case only 3.5 g. of the alcohol was obtained from the distillation at reduced pressure. This quantity was insufficient for an accurate determination of the boiling point.

The alcohols listed in Table VIII are identified entirely by their physical properties. All the alcohols which were isolated were tertiary derivatives, as shown by the zinc chloride–hydrochloric acid method.

It is evident from the data compiled in Table V that diethylmagnesium reacts with 2,3-dimethyl-2,3-epoxybutane to produce 2,3,3-trimethyl-2-pentanol. Ethylmagnesium bromide, on the other hand, forms 2,2,3-trimethyl-3-pentanol.

In the reaction of diethylmagnesium upon the unsymmetrical expoxyalkanes only one product was isolated. In every case there is a possibility of two products. The alcohol formed by the reaction is tertiary if possible, and secondary if there is a choice and tertiary is impossible.

Summary

1. Dialkylmagnesiums react with epoxyalkanes to form addition products which yield alcohols when hydrolyzed. These alcohols are the result of the splitting of the oxide linkage and not of rearrangement such as occurs with alkylmagnesium halides.

2. Diethylmagnesium reacts with 1,2-epoxypropane to give 2-pentanol, 1,2-epoxy-2-methylpropane to form 2-methyl-2-pentanol, *cis*-2,3-epoxybutane to produce a stereoisomeric mixture of 3-methyl-2-pentanols, *trans*-2,3-epoxybutane to yield a different racemic mixture of 3-methyl-2-pentanols, 2,3-epoxy-2-methylbutane to make 2,3-dimethyl-2-pentanol, and 2,3-dimethyl-2,3-epoxybutane to engender 2,3,3-trimethyl-2-pentanol.

3. When there is a difference between the two carbon valences holding the epoxy oxygen atom, the primary valence breaks rather than the secondary or tertiary and the secondary rather than the tertiary.

4. Ethylmagnesium bromide reacts with 2,3-dimethyl-2,3-epoxybutane to produce 2,2,3-trimethyl-3-pentanol.

5. Certain physical properties of ten alcohols have been determined.

6. A new alcohol, 2,3-dimethyl-2-pentanol, has been synthesized for the first time.

7. The synthesis of Bartlett and Berry, namely, the reaction of dialkylmagnesium upon an alpha epoxy compound has been extended to the epoxyalkanes and has been shown to be widely applicable as a method of synthesizing secondary and tertiary alcohols free from isomers.

The Compound of Cuprous Chloride with Phosphorus Trichloride[1]

BY TENNEY L. DAVIS AND PERCY EHRLICH

More than fifty years ago in a series of brilliant papers Schutzenberger,[2] and Schutzenberger and Fontaine,[3] described the preparation of carbonyl derivatives of platinous chloride and reported that phosphorus trichloride displaced carbon monoxide from these substances to form compounds which retained their essential structure through a variety of chemical transformations. Their experiments, demonstrating the chemical equivalence of carbon monoxide and phosphorus trichloride in complex formation, suggest that phosphorus trichloride may perhaps in general displace carbon monoxide from the carbonyls and that it may in general combine with the elements and compounds with which carbon monoxide enters into direct combination. The interesting possibilities do not appear to have been investigated.

Cuprous chloride forms complex compounds with ammonia and with carbon monoxide. Tropsch and Mattox[4] have recently reported that it combines with ethylene in which, it may be noted, the two valences available for coördination are on different atoms. Phosphorus trichloride, like ammonia and carbon monoxide, has two available valences on its central atom. We find that it also combines directly with cuprous chloride. When phosphorus trichloride is poured upon a quantity of cuprous chloride in a test-tube, the solid immediately commences to swell, heat enough is evolved to produce incipient boiling, and at the end of two hours the solid material occupies two or three times its original volume. On standing overnight, if an excess of phosphorus trichloride is present, the material swells still further, but the reaction appears to be complete after twenty-four hours. In certain experiments in which bottles were used, the material formed hard cakes which by their swelling broke the bottles. Some samples of cuprous chloride reacted more readily than others. When purified cuprous chloride was used, the complex was procured as a white powder having a strong odor of phosphorus trichloride. Washed with benzene or with some other inert solvent, warmed in a stream of carbon dioxide or left to itself in a vacuum desiccator, the compound lost much of its phosphorus trichloride.

The complex is attacked by atmospheric moisture, and cannot be weighed in the ordinary manner because of its high dissociation pressure. Samples for analysis were secured by allowing cuprous chloride undersaturated with phosphorus trichloride to take up more of that material from the vapor phase, and by allowing cuprous chloride oversaturated with phosphorus trichloride to give up a portion of that material through the vapor phase to other cuprous chloride and by introducing samples of the resulting materials into weighing tubes at the temperature of dry ice. The results of analysis showed that the complex has the composition $(CuCl)_2 \cdot PCl_3$.

The dissociation pressures of the complex at various temperatures were determined by the static method which has been used in this Laboratory for determining the dissociation pressures of metal pyridine thiocyanates, etc.[5] The measurements were rendered difficult by the circumstances (1) that the phosphorus trichloride attacked the mercury of the manometer, and (2) that the rate of dissociation of the complex when it was warmed was much greater than the rate of re-association of the components when they were cooled together. The first difficulty was met to some extent by working rapidly, but the second difficulty became more important when the work was rapid. The experimental results were plotted, a smooth curve drawn, and the figures for the dissociation pressures at the even temperatures were read from the curve and found to be 16 mm. at 0°, 28 mm. at 10°, 47 mm. at 20°, 73 mm. at 30°, 117 mm. at 40° and 170 mm. at 50°. These data plotted on a semilogarithmic chart, ln p *vs.* $1/T$, gave a straight line practically parallel with the straight line corresponding to Regnault's[6] data

for the vapor pressure of phosphorus trichloride, a fact which shows that the affinity which holds the phosphorus trichloride in combination with the cuprous chloride is practically constant over the temperature range 0 to 50°.

The complex reacts violently with a small quantity of water and goes entirely into solution. With a solution of aniline in benzene its reaction is vigorous enough to cause the benzene to boil. It reacts vigorously with methyl and ethyl alcohols, less vigorously with isopropyl, *n*-butyl and isoamyl alcohols, and with phenol in benzene solution only very slowly in the cold and more strongly on warming. The product of the reaction with methyl alcohol is a mixture of cuprous chloride with a compound having the formula $CuCl \cdot P(OCH_3)_3$, m. p. 216–217°, crystals from acetone or methyl alcohol, identical with the material prepared by Arbusow[7] by the direct combination of cuprous chloride with methyl phosphite. Arbusow reported m. p. 190–192°. He reported complexes of cuprous chloride, bromide and iodide with a number of alkyl phosphites, complexes generally having the formula $CuX \cdot P(OR)_3$, but in a few cases the formula $CuX \cdot [P(OR)_3]_2$. In our experiments with alcohols other than methyl, no solid products except cuprous chloride could be isolated from the reactions of $(CuCl)_2 \cdot PCl_3$ with the alcohols.

The white crystalline compound $CuCl \cdot P(OCH)_3$ oxidizes slowly in the air, turning green and finally black, but appears to be otherwise stable and odorless. The tendency toward its formation is so great that powdered cuprous chloride added to an ether solution of methyl phosphite wholly deprives it of its offensive odor. The compound dissolves in ammonia water to yield a colorless solution which quickly turns blue in the air, and it produces at the same time an extremely offensive carbylamine-like odor. It dissolves in warm aniline or dimethylaniline without the production of any odorous substance, and the solution on boiling deposits a copper-colored material. It hisses with strong nitric acid. On pyrolysis the compound does not decompose into cuprous chloride and methyl phosphite as might be expected, but leaves a residue which contains metallic copper, and produces methyl chloride and volatile compounds of phosphorus. The latter are now being studied further in this Laboratory.

Experiments

Analysis of the Complex $(CuCl)_2 \cdot PCl_3$.—Although it was not found possible to procure the complex in a state of complete purity, satisfactory indications of its composition were secured by approaching the equilibrium from both sides and analysing the resulting materials. A quantity of freshly purified, finely powdered cuprous chloride was introduced into a short tube open at the top and this was placed within a wide tube which contained some liquid phosphorus trichloride; the wide tube was stoppered and allowed to remain in the refrigerator for ten days. A similar arrangement was set up with cuprous chloride in the outer tube and cuprous chloride plus an excess of phosphorus trichloride in the inner one. After ten days the smaller tubes which contained the complex were removed and cooled in dry ice. Samples of the complex were introduced quickly into previously weighed small glass tubes which had also been cooled in dry ice. These tubes were immediately sealed at the blast lamp, weighed again and marked with identifying marks. In making the analyses, the tubes were scratched with a file, warmed at the scratch with a blowpipe flame and dropped into strong ammonia water, whereupon they cracked open and the contents dissolved in the liquid. Chlorine was determined in the usual way by precipitation as silver chloride in the presence of dilute nitric acid. The samples to be analyzed for copper and phosphorus were evaporated to dryness; concd. nitric acid was added and the mixtures were again evaporated to dryness, the residues were taken up in dilute nitric acid, and the copper in them was determined electrolytically. Phosphorus was determined in the residual solution by precipitation as magnesium ammonium phosphate and the ignition of this material to magnesium pyrophosphate. The results of the analyses, indicated in Table II, correspond fairly closely to the composition, two molecules of cuprous chloride and one of phosphorus trichloride, and differ widely from the composition, one molecule of each of the two.

TABLE I

ANALYSIS OF THE COMPLEX, $(CuCl)_2 \cdot PCl_3$

	Found, %				
					Average
Chlorine	51.88	53.91	51.02	49.75	51.39
Copper	36.33	35.80	40.52	40.79	38.36
Phosphorus	9.71	9.00	8.13	8.23	8.77

	Calcd. for	
	$(CuCl)_2 \cdot PCl_3$	$CuCl \cdot PCl_3$
Chlorine	52.89	59.99
Copper	37.88	26.88
Phosphorus	9.23	13.13

The Complex Methyl Ester $CuCl \cdot P(OCH_3)_3$.—When the complex $(CuCl)_2 \cdot PCl_3$ was treated with absolute methyl alcohol, a violent reaction ensued, clouds of hydrogen chloride were evolved and a heavy, white, crystalline powder remained in the bottom of the vessel. Extraction of the solid with boiling methyl alcohol, ethyl acetate or acetone yielded liquids which on cooling deposited white prismatic crystals of the crude complex ester. Acetone is the best solvent which we have found; on cooling it deposited, sometimes in handsome needles, about one-

---

(7) Arbusow, *Ber.*, **38**, 1121 (1905).

half of the material which it dissolved at boiling temperature. In methyl alcohol or ethyl acetate solution the methyl ester tended to oxidize readily and to turn green. The crude ester melted at about 180–190° and did not appear to decompose at this temperature. At distinctly higher temperatures it decomposed to yield a red residue and to produce a very offensive odor. Recrystallization from acetone or methyl alcohol raised the melting point of the material, 197–202°, 202–207°, 203–209°, etc., and in one instance 216–217°. The latter material showed almost no red color when heated to its melting point.

Chlorine was determined by dissolving a sample of the ester in ammonia water and precipitating as silver chloride in the presence of dilute nitric acid. Copper was determined electrolytically in the solution which resulted from treating the ester with concd. nitric acid and diluting with water. The residual liquid gave no test for phosphate with ammonium molybdate, for the trivalent phosphorus had not been oxidized by the cold concd. nitric acid. Experiment showed that evaporation to dryness with concd. nitric acid, or evaporation to fuming with concd. sulfuric acid, would not accomplish the result. Satisfactory phosphorus determinations were finally made by evaporating the sample with a mixture of nitric and sulfuric acids until fumes of sulfuric acid were given off, or by evaporating with fuming sulfuric acid until the liquid boiled freely, and then diluting with water, precipitating as magnesium ammonium phosphate, etc.

Anal. Calcd. for $CuCl \cdot P(OCH_3)_3$: Cl, 15.89; Cu, 28.49; P, 13.91. Found: Cl, 15.36, 16.26, 16.00; Cu, 28.69, 28.63; P, 13.60, 13.59, 14.22, 13.87, 13.41.

Summary

Phosphorus trichloride combines directly with cuprous chloride to form the compound $(CuCl)_2 \cdot PCl_3$.

The dissociation pressure of this compound has been measured from 0 to 50°. The affinity which holds the phosphorus trichloride in combination with the cuprous chloride is practically constant over that temperature range.

The complex reacts with methyl alcohol, losing one of its molecules of cuprous chloride and forming a complex ester $CuCl \cdot P(OCH_3)_3$.

The pyrolysis of the complex ester yields metallic copper, methyl chloride and volatile compounds of phosphorus which we have not yet identified.

Metal Pyridine Complex Salts. V.[1] Volume Change During Formation of Cyanates and Thiocyanates

BY TENNEY L. DAVIS AND ALBERT V. LOGAN

The fact that cobaltous thiocyanate forms compounds only with two and with four molecules of pyridine, while cobaltous cyanate forms compounds with two, with four, and with six molecules, has suggested that the affinity of pyridine for the metal in complex thiocyanates is probably less than it is in the complex cyanates. Experiments reported in the second and third papers of this series showed that cobaltous, cupric and nickelous pyridine cyanates have lower dissociation pressures than the corresponding thiocyanates containing the same number of pyridine molecules—and support the conclusion that the pyridine coördinately attached to the metal is held in the complex cyanates by a stronger affinity than it is held in the complex thiocyanates. The substitution of an oxygen atom in place of a sulfur at the remote end of the electrovalently connected acid radical considerably increases the residual affinity of the metal atom available for combination with pyridine through its coördination valence.

We now find that the greater forces of affinity at work in the complex cyanates, by pulling the parts of the molecules more closely together, produce greater contractions than do the forces which hold together the complex thiocyanates. The proportionate decrease in volume when the complex cyanate is formed from the simple salt plus pyridine is greater than when the complex thiocyanate is similarly formed. The cyanate radical, then, exhausts to a less extent than the thiocyanate radical the total affinity of the metal atom, and leaves more of it available for holding the pyridine with those internal forces which reduce both the dissociation pressure and the volume of the resulting compounds.[2]

The fact that water and all organic liquids (ex-

---

[1] Earlier papers of this series: I, Davis and Logan, THIS JOURNAL, **50**, 2493 (1928); II, Davis and Batchelder, *ibid.*, **52**, 4069 (1930); III and IV, Davis and Ou, *ibid.*, **56**, 1061, 1064 (1934).

[2] Compare the ideas of T. W. Richards on compressible atoms developed in his Faraday Lecture, delivered before the Chemical Society of London June 14, 1911, and in his Presidential Address to the American Chemical Society, published in THIS JOURNAL, **36**, 2417–2439 (1914), where a bibliography of his papers on the subject is also printed.

cept pyridine) which we have tried removed some of the pyridine from the complex salts, and also dissolved more or less of them, greatly limited the choice of liquids which might be used in the density determinations, and practically confined the choice to saturated solutions of the complexes in pyridine itself. This meant that it was generally possible to work only with the most highly pyridinated of the compounds. We have therefore determined the densities at 25° of cupric, nickelous and cobaltous hexapyridine cyanates and tetrapyridine thiocyanates, by measuring in a pycnometer the amount of a saturated solution of the complex in pyridine (the density of that solution having been determined previously) which was displaced by a known weight of each of the complex salts. The densities of the simple cyanates and thiocyanates were determined similarly under benzene. From the densities, the molecular volumes at 25° of the complexes, of the simple salts, and of the pyridine with which the latter combine to form the complexes have been calculated, and the shrinkages which occur during the formation of the complexes have been determined, and are reported in Table I.

TABLE I

VOLUME CHANGE DURING FORMATION OF COMPLEX CYANATES AND THIOCYANATES

	Molecular volumes at 25°, cc.					
	Components					
	Pyridine	Salt	Total	Complex	Volume Decrease	Decrease, %
$Cu(NCO)_2 \cdot 6Pyr.$	485.0	61.0	546.0	486.3	59.7	10.9
$Co(NCO)_2 \cdot 6Pyr.$	485.0	58.8	543.8	474.7	69.1	12.7
$Ni(NCO)_2 \cdot 6Pyr.$	485.0	62.0	547.0	469.2	77.8	14.2
$Cu(NCS)_2 \cdot 4Pyr.$	323.3	76.2	399.5	366.7	32.8	8.2
$Co(NCS)_2 \cdot 4Pyr.$	323.3	73.9	397.2	354.5	42.7	10.7
$Ni(NCS)_2 \cdot 4Pyr.$	323.3	73.2	396.5	352.7	43.8	11.1

From these data it appears that the absolute shrinkage in cc. and the per cent. shrinkage calculated on the basis of the volume of the components are both greater for the hexapyridine cyanates than for the tetrapyridine thiocyanates. The per cent. shrinkage during the formation of cupric hexapyridine cyanate (10.9) is 1.33 times the per cent. shrinkage during the formation of cupric tetrapyridine thiocyanate (8.2); the ratio for the cobaltous compounds is 1.19, for the nickelous compounds 1.28; average 1.27; that is, the per cent. shrinkage during the formation of cupric, cobaltous and nickelous hexapyridine cyanates from the simple salts and pyridine is about 1.27 times the per cent. shrinkage during the formation of the corresponding tetrapyridine thiocyanates. The shrinkage, however, in the case of the hexapyridine cyanates involves six molecules of pyridine while that in the case of the tetrapyridine thiocyanates involves only four. If each molecule of pyridine in all of the compounds were compressed by the respective chemical forces in exactly the same amount, the absolute shrinkage in cc. during the formation of the hexapyridine cyanates would be 1.5 times the absolute shrinkage during the formation of the tetrapyridine thiocyanates. The ratios calculated from the data are for the cupric compounds 1.82, for the cobaltous 1.62, and for the nickelous 1.78; average 1.74, or about 16% more shrinkage for each molecule of pyridine combined in the complex cyanates than for each molecule combined in the complex thiocyanates. The absolute shrinkages per mole of combined pyridine are shown in Table II where they are compared with the dissociation pressures of the several substances.

TABLE II

SHRINKAGE DURING COMBINATION WITH PYRIDINE COMPARED WITH DISSOCIATION PRESSURE OF THE COMPLEX

	Shrinkage, cc., per mole of combined pyridine	Dissociation pressure, mm.			
		20°	25°	30°	50°
$Cu(NCO)_2 \cdot 6Pyr.$	9.9	7.0	10.0	13.4	49.6
$Co(NCO)_2 \cdot 6Pyr.$	11.5	5.8	(7.7)	10.0	25.7
$Ni(NCO)_2 \cdot 6Pyr.$	13.0	...	5.0	..	7.3
$Cu(NCS)_2 \cdot 4Pyr.$	8.2	5.1	(8.4)	12.0	58.0
$Co(NCS)_2 \cdot 4Pyr.$	10.7	1.9	(2.6)	3.4	10.6
$Ni(NCS)_2 \cdot 4Pyr$	11.0	5.0	(5.4)	6.1	9.8

The shrinkage per mole of pyridine during the formation of the complexes of the three metals is least for the cupric salt, next for the cobaltous, and most for the nickelous salt—both in the hexapyridine cyanate and in the tetrapyridine thiocyanate series. For the cyanates the dissociation pressures at 25° (the figures in parenthesis being estimated) fall in the inverse order; the complex showing the greater shrinkage has the lower dissociation pressure. The dissociations of the thiocyanates at 25° do not fall in line; at 50°, however, they are in the inverse order of the shrinkages.

Correction.—The facts that cupric, cobaltous, and nickel cyanates behave alike in forming complexes with six molecules of pyridine, and that cobaltous and nickelous thiocyanates behave alike in forming complexes with four, have led us to believe, contrary to previously existing information, that cupric thiocyanate also forms a complex with four molecules of pyridine. In the second paper of this series Davis and Batchelder[1] reported analyses and dissociation pressures for the complexes of cupric thiocyanate with one and with two molecules of pyridine. We now find that the dissociation pressures which they reported for the dipyridine compound are actually those of the tetrapyridine compound. They isolated and analyzed the dipyridine compound but failed to observe its dissociation pressure. Their data for the monopyridine compound are correct. The correct data for the three complexes are now summarized in Table III.

TABLE III

DISSOCIATION PRESSURES OF CUPRIC PYRIDINE THIOCYANATES

	Dissociation pressures, mm.					
Temp., °C.	20	30	40	50	60	70
$Cu(NCS)_2 \cdot 4Pyr.$	5.1	12.0	27.0	58.0	106.0	..
$Cu(NCS)_2 \cdot 2Pyr.$	...	5.0	10.0	23.0	...	..
$Cu(NCS)_2 \cdot Pyr.$	...	3.4	5.0	10.1	20.0	36.0

Experiments

The pyridine was fractionated twice, and the portion boiling between 115.25 and 115.40° taken for the density determination.

The complex salts were prepared as described in earlier papers, crystallized from chloroform containing pyridine, dried superficially between filter papers, and kept in desiccators containing pyridine and potassium hydroxide.

Cupric tetrapyridine thiocyanate exists in very dark moss-green crystals which lose pyridine rapidly in the air to produce the dipyridine compound. *Anal.* Calcd. for $Cu(NCS)_2 \cdot 4Pyr$: Cu, 12.82; pyridine, 63.77. Found: Cu, 13.05, 12.99; pyridine, 63.98, 64.96. Cupric dipyridine thiocyanate has an emerald-green color and loses pyridine slowly to form the monopyridine compound. *Anal.* Calcd. for $Cu(NCS)_2 \cdot 2Pyr$: Cu, 18.80. Found: Cu, 18.74, 18.90. The change to the monopyridine compound is hastened by subjecting the dipyridine compound to reduced pressure. *Anal.* Calcd. for $Cu(NCS)_2 \cdot Pyr$: Cu, 24.58. Found: Cu, 24.34, 23.56. The compounds are only moderately soluble in chloroform, but dissolve more readily if pyridine is added. The substances which were described by Davis and Batchelder were the mono- and dipyridine compounds.

Cupric, cobaltous and nickelous cyanates were prepared by warming the complex salts and pumping off the pyridine. It was found that temperatures above 80° caused decomposition with the production of carbon dioxide and the cyanides of the metals. At lower temperatures it was necessary to continue the pumping for several days in order to remove all of the pyridine. Cupric cyanate has a dark moss-green color, nickelous cyanate pale green, and cobaltous cyanate pale lavender.

Cobaltous thiocyanate was prepared as a yellow-brown powder by heating the pyridine complex in vacuum at about 300° at which temperature no decomposition of the salt was found to occur. Nickelous thiocyanate, mustard yellow, was procured by heating the pyridine complex in a well ventilated oven at 250° for two or three hours.

Cupric thiocyanate could not be prepared by any of these methods. It breaks down at slightly elevated temperatures to produce a reddish-brown compound which has been described by Speter[3] as having the composition $Cu(CNS)_2 \cdot CuCNS$. When precipitated from aqueous solution, it decomposes to a greater or less extent forming cuprous thiocyanate. We have prepared the substance by treating freshly precipitated and moderately dry cupric hydroxide with the very strong thiocyanic acid procured by distilling potassium thiocyanate, phosphorus pentoxide and concd. sulfuric acid in an atmosphere of hydrogen at about 60 mm. pressure.[4] The intensely black cupric thiocyanate was transferred quickly to a suction filter, the excess acid was removed, and the unwashed solid was dried in a desiccator over concd. sulfuric acid.

The composition of the salts was verified by analysis for the metals. Cobalt was determined as sulfate, copper by titration with iodide and sodium thiosulfate, and nickel by titration with potassium cyanide. Results are summarized in Table IV.

TABLE IV

ANALYSIS OF CYANATES AND THIOCYANATES

	Metal, % Found			Calcd.
Cupric cyanate	42.84	43.47	...	43.08
Nickelous cyanate	41.24	41.09	41.51	41.13
Cobaltous cyanate	41.16	41.98	...	41.23
Cupric thiocyanate	35.59	35.50	...	35.40
Nickelous thiocyanate	33.50	33.57	33.70	33.59
Cobaltous thiocyanate	33.61	33.55	...	33.69

The densities at 25° of the simple salts, and of the complexes except nickelous tetrapyridine thiocyanate, were determined as has been described briefly in the early part of the present paper. Nickelous tetrapyridine thiocyanate when allowed to stand in contact with pure pyridine forms the heptapyridine derivative which has been described in the second paper of this series.[1] It is unaltered even by long standing in contact with its solution in a 60/40 mixture of pyridine and benzene, and its density was determined by the use of this solution. The density determinations are summarized in Table V.

TABLE V

DENSITIES AT 25°

	Experimental values		Average
Pyridine	0.9774	0.9772	0.9773
$Cu(NCO)_2$	2.4195	2.4172	2.418
$Ni(NCO)_2$	2.3018	2.3021	2.302
$Co(NCO)_2$	2.4325	2.4322	2.432
$Cu(NCS)_2$	2.3589	2.3536	2.356
$Ni(NCS)_2$	2.3866	2.3845	2.386
$Co(NCS)_2$	2.3673	2.3656	2.366

Summary

The decreases in volume which occur at 25° when cupric, cobaltous and nickelous cyanates and thiocyanates combine with pyridine to form hexapyridine cyanates and tetrapyridine thiocyanates have been determined.

The shrinkage in cc. during the formation of the hexapyridine cyanates is about 1.74 times as great as during the formation of the tetrapyridine thiocyanates. This corresponds to about 16% more shrinkage for each molecule of pyridine in the complex cyanates than for each molecule in the complex thiocyanates. This fact, and the fact that the complex cyanates have the lower dissociation pressures, both indicate that the pyridine in the complex cyanates is held by greater forces of chemical affinity than in the complex thiocyanates. The thiocyanate radical to a greater extent than the cyanate radical exhausts the total affinity of the metal atom and leaves less of it available for coördinative combination with pyridine.

For the three cyanates and thiocyanates alike, the shrinkage during combination with pyridine is least in the case of the cupric compounds, next in the case of the cobaltous, and most in the case of the nickelous compounds.

The Heats of Dissociation of Hexaarylethanes

BY CHARLES BUSHNELL WOOSTER

In a recent paper Conant[1] has estimated the heats of dissociation of a number of substituted ethanes from cryoscopic data on the basis of the following assumptions: (1) that the heat of dissociation, ΔH, the free energy of dissociation, ΔF, and the corresponding entropy change, ΔS, were all approximately independent of the nature of the solvent in which the ethane was dissolved; (2) that ΔH and ΔS were independent of the temperature over the range involved in the experiments and (3) that ΔS was independent of the substituents attached to the two carbon atoms which dissociate from each other, at least in solution in organic solvents. The work of Ziegler,[2] on hexaphenylethane had furnished confirmation of the first two assumptions, but Conant offered no experimental basis for the third. The last assumption has also been made by Pauling and Wheland[3] but, on the other hand, Hückel[4] states that variations in the entropy change may be expected to accompany alterations in the structure of the molecules.

As a matter of fact, it is possible to calculate values for the heats of dissociation of four hexaarylethanes by independent and somewhat more direct methods from data at present available in the literature. It is the purpose of this paper to present and discuss the results of such calculations.

The Heat of Dissociation of Di-β-naphthyltetraphenylethane.—Gomberg and Sullivan[5] have measured the intensity of color of solutions of di-β-naphthyltetraphenylethane over a wide temperature range in toluene and in chloroform solutions. A sufficiently close approximation to the dissociation constant K, expressed in mole fractions, may be obtained from these measurements by the use of equation 1

$$K = \frac{4N(I/I_0)^2}{1 - I/I_0} \qquad (1)$$

where N is the concentration in moles of the ethane per mole of solvent, I is the intensity of color per mole of the ethane (in arbitrary units) and I_0 is the limiting value of I on dilution.[6] In order to test the consistency of the data, ΔH is best determined graphically by plotting values of $-\log K$ against $1/T$ which should yield a straight line in accordance with equation 2

$$-\log K = (\Delta H/2.303RT) + \text{const.} \qquad (2)$$

when ΔH is independent of the temperature. The value $I_0 = 195$ was obtained from equation 1 by setting K equal to the value 3.50×10^{-4} based on Ziegler's photometric measurements at 20° in

[5] Gomberg and Sullivan, THIS JOURNAL, **44**, 1810 (1922).

[6] The value of I_0 is assumed to be independent of the temperature and of the nature of the solvent. These assumptions were also made by Ziegler in his study of hexaphenylethane.

cyclohexane[7] and substituting the observed value of I at that temperature. A plot of $-\log K$ against $1/T$ appears in Fig. 1. The points obtained in the two solvents lie on the same curve which is linear within the limits of error over a range of 56° in toluene and 52° in chloroform. The value of ΔH corresponding to the slope of this line is 12.9 kcal.

The method suggested for the estimation of I_0 neglects any variation in K which might occur as a result of changing the solvent from cyclohexane to toluene and to chloroform. Some justification for neglecting this variation may be found in the correspondence between the measurements in toluene and chloroform which shows that the values of K in these two solvents do not differ sufficiently to influence appreciably the value of ΔH. However, Ziegler found much wider differences in the values of K for hexaphenylethane in various solvents, so it is necessary to examine carefully the influence of the choice of I_0 on the value of ΔH as calculated from the data of Gomberg and Sullivan.

As a matter of fact, ΔH is not very sensitive to the choice of I_0 when this constant is not too small. The expression for ΔH may be written

$$\Delta H = RT^2(\mathrm{d}\ln K/\mathrm{d}T) = RT^2\frac{\mathrm{d}}{\mathrm{d}t}[2\ln I - \ln(1 - I/I_0)] \qquad (3)$$

and in the limiting case when I_0 is sufficiently great, $1 - I/I_0$ may be replaced by unity so that on integration a linear relation between $\log I$ and $1/T$, similar in form to equation 2, is obtained.

$$-\log I = (\Delta H/4.606RT) + \text{const.} \qquad (4)$$

Plots of $\log I$ against $1/T$ for the β-naphthyl compound in toluene and in chloroform are actually linear in accordance with equation 4 and the value of ΔH thus obtained is 12.3 kcal. The term $1-I/I_0$ cannot exceed unity so the neglected term always makes a positive contribution to ΔH when I increases with the temperature. Therefore, the value 12.3 kcal. may be regarded as a reliable *minimum* within the limits of experimental error, regardless of the true value of I_0.[8]

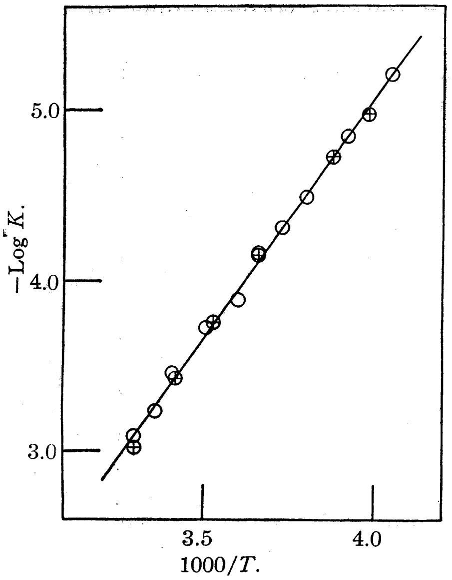

Fig. 1.—Plot of $-\log K$ against $1/T$ for di-β-naphthyltetraphenylethane in toluene (open circles) and in chloroform (crossed circles).

A third method of approximation may be used to set a maximum limit for ΔH. Gomberg and Sullivan also gave data regarding the intensity of color of solutions of the ethane in *cyclohexane* at its freezing point 5.8°. Taking the value of K in cyclohexane at 293°K. as 3.50×10^{-4} and using the minimum value of $\Delta H = 12.3$ kcal., a maximum value of 1.22×10^{-4} may be calculated for K in cyclohexane at 279°K. By the use of equation 1 the value of I_0 may be determined[9] from the values of I in cyclohexane at 5.8°. Unfortunately, these values of I and consequently the resulting values of I_0 are not expressed in the same units as those given for the toluene and chloroform solutions. This difficulty may be circumvented in the following way. From the data on benzene solutions at the freezing point, 5.3°, neglecting the temperature difference of 0.5°, the

---

[7] This value of the equilibrium constant is somewhat uncertain because Ziegler did not determine the concentration of his solution by direct analysis. The concentration has been estimated from the amount of triarylmethyl chloride used, assuming a theoretical yield of the ethane. Since Gomberg and Sullivan obtained the yields 99.6, 102 and 100% in three quantitative studies of this reaction, it is believed that the error thus introduced is actually quite small; in any event, this value of K in cyclohexane may be regarded as a reliable *maximum*.

[8] The solutions used by Gomberg and Sullivan were about 0.034 molar with respect to the ethane and the values of I increased approximately ten-fold in passing from the lowest to the highest temperature so that the degree of dissociation, $\alpha = I/I_0$, in toluene, calculated on the basis $I_0 = 195$, varies from 0.0205 at −26° to 0.2100 at +30°. Although it may seem a very arbitrary procedure to set $1-\alpha$ equal to unity when $\alpha = 0.21$, this simplification is justified by the fact that the extreme variation in $1-\alpha$ from 0.979 to 0.790 is accompanied by a variation in α^2 from 4.2×10^{-4} to 4.4×10^{-2} and, accordingly, the neglected variation in $1-\alpha$ contributes but 4.4% of the total variation in $-\log K$.

[9] It has been pointed out previously [Wooster, THIS JOURNAL, **51**, 1163 (1929)] that these measurements are not sufficiently accurate to permit the determination of I_0 by direct extrapolation because the concentration range is so narrow that the moderate experimental errors are greatly magnified by the process of extrapolation. A similar magnification of the experimental errors is not involved in the direct calculation of I_0 from I and K.

ratio of K_b (the dissociation constant in benzene) to K_c (the dissociation constant in cyclohexane) may be calculated by the use of equation 5.

$$K_b/K_c = (N_b/N_c)(I_b/I_c)^2(I_0 - I_c)/(I_0 - I_b) \quad (5)$$

where I_b and I_c are the color intensities in the respective solvents corresponding to the concentrations (in moles ethane per mole solvent) N_b and N_c. The three available intercomparisons yield the value $K_b/K_c = 1.14 \pm 0.06$.

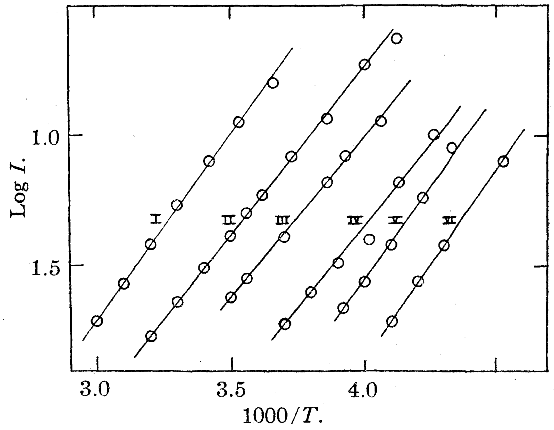

Fig. 2.—Plot of log I against $1/T$ for symmetrical tetramethoxyhexaphenylethanes. Curve I is plotted with respect to the horizontal scale given. Each succeeding curve is displaced two-tenths of a unit to the right with respect to this scale. The vertical scale is the same for all six curves: I, the 2,5-compound in toluene; II, the 2,5-compound in bromobenzene; III, the 3,4-compound in bromobenzene; IV, the 3,4-compound in toluene; V, the 2,4-compound in toluene; VI, the 2,4-compound in bromobenzene.

Since the color intensities of the toluene solutions (concentration 2 g. per 100 cc.) were determined by matching a 17-mm. column against a column of a standard solution of the same free radical in benzene (concentration 0.5 g. per 100 cc.) at room temperature (21–22°) and the diameters of the two tubes of the colorimeter were equal, the ratio K_t/K_b (K_t = the dissociation constant in toluene) at this temperature may be calculated from these data by using a simplified form of equation 5.

$$K_t/K_b \overset{=}{<} (N_t/N_b)(I_t/I_b)^2 \quad (6)$$

The simplification is possible because at the temperature in question $I_t < I_b$ so that $(I_0 - I_b)/(I_0 - I_t)$ is less than unity; consequently the simplified expression yields a *maximum* value for K_t/K_b at that temperature. The value of I_t/I_b is equivalent to the height of the benzene solution divided by four times the height of the toluene solution, since the latter contains four times as much solute as the former. At 22° the height of the benzene solution would be 30 mm.[10] so $K_t/K_b \overset{=}{<} 0.925$. If ΔH is independent of the nature of the solvent K_b/K_c will have the same value at 22° as at 6° and $K_t/K_c \overset{=}{<} 1.06 \pm 0.06$. The maximum variation in ΔH due to the nature of the solvent observed by Ziegler with hexaphenylethane was 1.5 kcal. Assuming that ΔH for the β-naphthyl compound in benzene exceeds by 1.5 kcal. the value in cyclohexane, the ratio K_b/K_c would become 1.32 ± 0.07 at 22° so it is reasonable to conclude that K_t/K_c does not exceed 1.30 at the latter temperature. The difference between this ratio and the value of unit previously assumed is negligible for the purpose of calculating ΔH since it changes the result by less than 0.1 kcal. Therefore, as far as uncertainties in the value of I_0 are concerned ΔH for the β-naphthyl compound probably lies between the limits 12.3 and 12.9 and, making allowance for experimental error, it may be taken as 12.9 ± 1.[11]

The Heats of Dissociation of Tetramethoxyhexaphenylethanes.—Similar colorimetric measurements have been made by Gomberg and Forrester[12] with three symmetrically substituted tetramethoxyhexaphenylethanes. A plot of log I against $1/T$ appears in Fig. 2. The curves are nearly linear at the higher temperatures and the slopes correspond to the following *minimum* values of ΔH in kcal.: di-(2,5-dimethoxyphenyl)-tetraphenylethane in toluene 12.8, in bromobenzene 11.6; di-(3,4-dimethoxyphenyl)-tetraphenylethane in toluene 11.4, in bromobenzene 11.3; di-(2,4-dimethoxyphenyl)-tetraphenylethane in toluene 12.7, in bromobenzene 13.0. The measurements at the lower temperatures have been disregarded because when the color intensities are low the experimental errors produce larger deviations in the plot. The behavior of the 2,4-compound in bromobenzene is exceptional, the color intensities, for some unexplained reason, pass through a minimum at about 5° and rise rapidly

---

(10) Obtained from the value 28 mm. at 20° by interpolation using the *experimentally* observed linear relation between log I and $1/T$.

(11) The temperature of the standard benzene solution was not given directly by Gomberg and Sullivan who stated that it was at "room temperature." In order to obtain the most probable value for the ratio K_t/K_b, the value 21–22° for the room temperature given elsewhere in the same paper has been used. However, it is practically certain that the temperature of the standard did not exceed 30°, the highest temperature employed in the measurements. Since at that temperature the height of the standard was 41 mm., $(K_t/K_b)_{303} \overset{=}{<} 1.73$, $(K_t/K_c)_{303} \overset{=}{<} 2.56$, $(K_t/K_c)_{293} \overset{=}{<} 2.78$ and $\Delta H \overset{=}{<} 13.3$, which is within the limits of error of the final value.

(12) Gomberg and Forrester, THIS JOURNAL, **47**, 2373 (1925).

at lower temperatures. Nevertheless, the measurements above 10° yield a linear plot and correspond to the same value of ΔH as those made in toluene where the color intensities do not exhibit a minimum. In any event, the discrepancies at low temperatures cannot be ascribed to the failure of the approximation involved in equation 4, because such effects would be most pronounced at the higher temperatures.

Discussion of Results

The averaged values of ΔH are collected in Table I together with the corresponding values ΔH^* estimated according to Conant's method by setting $\Delta S = 17$ E. U. in the expression[13]

$$\Delta H = \Delta F + T\Delta S \qquad (7)$$

TABLE I

HEATS OF DISSOCIATION OF HEXAARYLETHANES–TETRAPHENYL SERIES OF THE GENERAL FORMULA

$(C_6H_5)_2\underset{R}{C}-\underset{R}{C}(C_6H_5)_2$

R	ΔH, kcal.	ΔH^*, kcal.	ΔF, kcal.	ΔS, E. U.
β-Naphthyl	12.9	8.9	4.5	28
2,5-Dimethoxyphenyl	12.2	9.3	4.4	26
3,4-Dimethoxyphenyl	11.3	9.3	4.3	23
2,4-Dimethoxyphenyl	13.9	9.4	4.6	28

The values of ΔH^* are all low and the actual discrepancies for the methoxy compounds may be even greater, since values of I_0 sufficiently low to alter appreciably the values of ΔH based on equation 4, would correspond to *higher* values of ΔH and *lower* values of ΔF. The discrepancies may be due in part to errors inherent in the cryoscopic method of determining ΔF, but use of the value of ΔF for the β-naphthyl compound computed from Ziegler's photometric measurements reduces the difference between ΔH and ΔH^* by only 0.6 kcal. The value of $\Delta S = 17$ is approximately the mean value for hexaphenylethane; the extreme limits in the nine different solvents investigated by Ziegler, obtained by combining the highest ΔF with the lowest ΔH and *vice versa*, are 12.4 and 22.5. Since all of the values in Table I exceed the highest limit, it seems likely that the entropy of dissociation is not entirely independent of structural influences.

For the sake of completeness, a number of assumptions have been introduced in order to estimate the most probable value of ΔH for the β-naphthyl compound. However, the *minimum* values based on equation 4 are dependent on but two assumptions, namely, that the variations in color are due to a simple binary dissociation of colorless ethane molecules into colored free radicals (equation 1) and that I_0 is independent of the temperature. Of course, the conclusions drawn from these values are subject to the validity of these two assumptions, but, since the same two assumptions are involved in all of Conant's calculations, the minimum values of ΔH may properly be employed to test whether or not the results of Conant's method are entirely consistent with *all* the assumptions which he has made. Furthermore, Ziegler has shown that the absorption of the β-naphthyl compound is actually in quantitative agreement with the requirements of a binary dissociation over a dilution range of approximately 100–8850 liters in cyclohexane at 20°.

Pauling and Wheland's Theory.—Pauling and Wheland[3] have suggested that the low heats of dissociation of the hexaarylethanes are due entirely to a stabilization of the free radicals by resonance[14] and pointed out that the dissociation qualitatively paralleled the calculated resonance energy for a number of substituted ethanes as was to be expected if these ethanes had the same entropy of dissociation. It has just been shown that this condition may not be generally fulfilled.

They took 84 kcal. as the heat of dissociation of the normal C–C bond and gave the values 1.1078 α and 1.1715 α for the resonance energies of the triphenylmethyl and diphenyl-β-naphthylmethyl radicals, respectively. The symbol α represents the single exchange integrals involving adjacent atoms which are necessarily equal for the symmetrical benzene molecule and have been assumed equal in all other molecules. Using Ziegler's value of ΔH for hexaphenylethane in solution, Pauling and Wheland found $\alpha = -32.8$ kcal., in rough agreement with values of α from other sources. Since this experimental evidence[2] also presupposes the independence of T and I_0, it is a fair test to compare the value 7.0 kcal., calculated according to Pauling and Wheland's method for the β-naphthyl compound, with the experimental minimum value 12.3 kcal. This discrepancy certainly casts doubt on the significance of the rough agreement in the values of α noted above. As a matter of fact, Ziegler's studies on pentaphenylcyclopentadienyl[2] indicate that the varia-

---

(13) The value of ΔH^* for the β-naphthyl compound is taken from Conant's paper and was based on ΔF as calculated from Gomberg and Sullivan's cryoscopic data in naphthalene solution. The other values have been calculated in the same manner from the cryoscopic data of Gomberg and Forrester in dichlorobenzene.

(14) See, however, Bent and co-workers [THIS JOURNAL, **57**, 1242 (1935); **58**, 165, 170 (1936)] for evidence regarding the importance of other factors than resonance.

tion of the absorption curve with the temperature is not sufficient to affect the values of ΔH by more than about 1 kcal. Accordingly, it seems very unlikely that the theory of Pauling and Wheland can be applied without modification to the calculation of heats of dissociation of hexaarylethanes in solution.

Summary

1. The heat of dissociation of di-β-naphthyltetraphenylethane and minimum values for the heats of dissociation of three other hexaarylethanes have been calculated from data available in the literature.

2. The results indicate that the entropy of dissociation of hexaarylethanes is not entirely independent of the nature of the aryl groups.

3. The heat of dissociation of di-β-naphthyltetraphenylethane in solution does not agree with the value calculated on the basis of Pauling and Wheland's resonance theory.

Preparation and Properties of Cobalt Nitrosyl Carbonyl and of Cobalt Carbonyl Hydride

BY GEORGE W. COLEMAN AND ARTHUR A. BLANCHARD

Blanchard and Windsor[1] in summarizing the properties of the volatile carbonyls, nitrosyl carbonyls and carbonyl hydrides of the metals, noted that in the volatile $CoNO(CO)_3$ the total of the atomic numbers is the same as in the volatile $Ni(CO)_4$; also that in the suspected volatile $HCo(CO)_4$ the same total of atomic numbers prevails.

In order to add further evidence of the similarity of the structure of $Ni(CO)_4$ and $CoNO(CO)_3$ the present study was undertaken to determine whether the action of bromine would liberate nitric oxide as well as carbon monoxide

$$Br_2 + Ni(CO)_4 \longrightarrow NiBr_2 + 4CO$$
$$Br_2 + CoNO(CO)_3 \longrightarrow CoBr_2 + NO + 3CO$$

Complete proof has been found that bromine does, in fact, give the expected reaction.

Incidentally, in preparing an additional supply of cobalt nitrosyl carbonyl, a greatly improved procedure has been worked out through adapting methods employed by Schubert[2] in studying the action of carbon monoxide with cysteine complexes of cobalt.

Also in the course of this procedure it has been possible to isolate the volatile hydride of cobalt carbonyl, $HCo(CO)_4$, in pure form and contribute to a knowledge of its properties.

Windsor and Blanchard[3] and Blanchard, Rafter and Adams[4] studied the formation of carbonyls when alkaline suspensions of nickel and cobalt sulfides and cyanides are treated with carbon monoxide. They did not attempt to identify intermediate complexes. Schubert, using cysteine compounds instead of sulfides or cyanides, isolated the intermediate stages, and defined the course of the reaction with cobalt salt with the equations, in which R = [$-CH_2CHNH_2COO-$]:

$$CoCl_2 + 2HSRH \cdot HCl + 6KOH \longrightarrow K_2Co(SR)_2 + 4KCl + 6H_2O$$
$$9K_2Co(SR)_2 + 8CO + 2H_2O \longrightarrow 6K_3Co(SR)_3 + 2HCo(CO)_4 + Co(OH)_2$$
$$K_3Co(SR)_3 + 6CO + 7KOH \longrightarrow HCo(CO)_4 + 2K_2CO_3 + 3K_2RS + 3H_2O$$

The present authors would make a summation of the above steps in the equation

$$2CoCl_2 + 12KOH + 11CO \longrightarrow 2KCo(CO)_4 + 3K_2CO_3 + 4KCl + 6H_2O \quad (1)$$

which shows a complete regeneration of the cysteine, a reduction of cobalt and a corresponding oxidation of carbon monoxide.

Schubert acidified the alkaline solution containing the complex $KCo(CO)_4$, and noted that a very bad odor was produced and that crystals separated which he identified as the dimeric cobalt tetracarbonyl $Co_2(CO)_8$. He was unable to detect either free hydrogen or any product to account for the hydrogen liberated from the postulated hydride $HCo(CO)_4$.

Experimental

Auxiliary Substances Promoting Absorption of Carbon Monoxide.—Several auxiliary substances other than

cyanides, sulfides and cysteine were tried, and the rate of absorption of carbon monoxide by an alkaline solution or suspension of cobaltous salt in the shaking apparatus[5] was measured. The results are shown in the tabulation. The shaking apparatus was filled with carbon monoxide, concentrated solutions of the various ingredients were run in, the volume was made up to 80 cc. and shaking was started with the cock open from the carbon monoxide reservoir. Concentrations are given in f. w. of the added substance per liter of the final volume of the mixture.

Cyanide, tartrate and cysteine produced the most notable absorption. Following the absorption of carbon monoxide, treatment of the alkaline cyanide solution with nitric oxide immediately produced brown vapors of cobalt nitrosyl carbonyl as already noted by Rafter and Adams, but similar treatment of the tartrate and cysteine solutions with nitric oxide was without effect.

Acidification of the cysteine solution following treatment with carbon monoxide and nitric oxide produced brown vapors which, when swept with carbon monoxide and nitric oxide through a tube filled with phosphorus pentoxide, and through a trap immersed in solid carbon dioxide and alcohol, condensed in the latter to a yellow solid which melted to a deep red liquid. When this liquid came to room temperature it very quickly changed to a dark colored crystalline mush. In this run the vapors blackened the connecting tubes and the phosphorus pentoxide tube through which they passed on the way to the trap. In the runs described later this blackening did not occur. Later experiments confirmed the conjecture that the dark red vapors contained both $Co(CO)_3NO$ and $HCo(CO)_4$.

$Co(NO_3)_2$	Auxiliary substance and concentration		KOH	Absorption of CO

Preparation of Cobalt Nitrosyl Carbonyl

First Run.—Sixty cc. of a solution 0.5 formal in cobalt nitrate, 0.75 formal in cysteine hydrochloride and 16 formal in potassium hydroxide absorbed carbon monoxide in the shaker at the rate of 160 cc. per hour at the start and the rate had diminished to 5 cc. per hour at the end of one hundred and forty-nine hours. In all, 5500 cc. of carbon monoxide was absorbed (4100 calculated according to equation (1)). One half of this solution was run into another tube for a later experiment (air being at all times excluded), and the half left in the shaking apparatus was treated with concentrated hydrochloric acid. Violent local effervescence took place at first, the carbon dioxide redissolving in the rest of the solution on shaking. Finally, the gas came off violently and one-half of the solution was lost by being blown out of the apparatus. The odor was so noxious that work had to be suspended until the laboratory was thoroughly ventilated.

After a slight excess of acid had been added to the one-half of the solution that was saved, the color was yellow and a black scum floated on top. Not more than a trace of solid had been collected in the trap during the acidification. A new trap was now introduced, and nitric oxide was run into the shaking apparatus which immediately became filled with reddish-brown vapors. The vapor was swept with nitric oxide through a phosphorus pentoxide tube into the trap cooled with dry ice, where a yellow solid collected. Thirty minutes later more reddish-brown vapors had collected which were again swept into the trap. The reddish-brown vapors continued to form for several days and were occasionally swept into the trap. In all 0.7 g. of yellow solid, melting sharply at approximately −11° to a deep red liquid, was collected. Thus a yield of $Co(NO)(CO)_3$ of about 54% based on the cobalt nitrate taken, was obtained.

Preparation of Cobalt Carbonyl Hydride

First Run.—The one-half of the solution reserved in the first part of the first run as above described was again introduced into the shaking apparatus without coming in contact with air. The train of phosphorus pentoxide tube and trap cooled with dry ice was again attached. Concentrated hydrochloric acid was added, this time with very great caution until an additional 1 cc. produced no more effervescence. After five minutes of shaking, a very pale yellow gas was noted, and this, swept with carbon monoxide into the trap, condensed to a pale yellow solid. Addition of more acid gave rise to more yellow gas. In all 11 cc. of normal hydrochloric acid was used before the yellow

---

(5) Rafter, Thesis, Massachusetts Institute of Technology, 1932.

gas ceased to be produced (thus making the solution about 1 normal in free hydrochloric acid). The remaining solution was yellow with some black scum ($Co_2[CO]$) floating on top. The yellow solid collected in the trap melted sharply at −33° to a sulfur yellow liquid; after it was resolidified it was yellow; it became somewhat reddish after a few remeltings. At room temperature it showed effervescence and soon changed to a brown solid. This solid was then heated to 51° at which temperature it melted. Of the total gas evolved up to 51° a sample of 24.8 cc. was collected. Of this 10.3 cc. was absorbed by ammoniacal cuprous chloride, thus indicating 41.6% of carbon monoxide, and explosion with oxygen indicated 48.8% of hydrogen. The gas evolved on thus warming the hydride had a pale yellow color. Surrounding the upper part of the eudiometer with a cooling bath a thin deposit of yellow solid appeared at −23° and the remaining gas was colorless. This solid had completely revaporized when the bath temperature reached −11°. The volume decrease, due to the lowering of temperature of the upper one quarter of the gas tube and the condensation of the yellow constituent, was only 0.8 cc. Heating the tube to 250° caused no deposition of a cobalt mirror. This yellow constituent of the gas was not absorbed by concentrated potassium hydroxide nor by ferrous sulfate solution but it was removed by ammoniacal cuprous chloride solution.

The brown residue left after warming the hydride weighed 0.6605 g. It melted again at 51° and gave off gas freely at 60°; after it was heated to 250°, a brilliant black mirror covered the inside of the entire heated part of the tube; weight of mirror 0.2408 g. Calcd. for Co in $Co_2(CO_8)$, 0.2275. Volume of gas (all absorbed by ammoniacal CuCl) 385.5 cc. Calcd. for CO, 371 cc. Yield of $HCo(CO)_4$ = 26% based on $Co(NO_3)_2$ taken.

Second Run.—Fifty cc. of a solution 0.5 formal in cobalt nitrate; 0.3 formal in cysteine hydrochloride and 16 formal in potassium hydroxide absorbed a total of 4445 cc. of carbon monoxide [3400 calculated according to equation (1)]. Adding 12 normal hydrochloric acid until the solution was acid caused only a slight deposition of the hydride in the trap. On adding 20 cc. excess of 12 *N* hydrochloric acid and sweeping with carbon monoxide a yield of 0.4215 g. of the hydride was collected in the trap (10% yield). Again only a part of the gas from the decomposition of the hydride was collected and this proved to contain 50% hydrogen, and 50% carbon monoxide. This gas also contained the same yellow constituent as in the first run.

Third Run.—Fifty cc. of a solution 0.5 formal in cobalt nitrate; 2.0 formal in tartaric acid and 16 formal in potassium hydroxide absorbed 1700 cc. of carbon monoxide in one hundred and forty-four hours. The solution was a clear cherry red. Strong acidification and sweeping with carbon monoxide gave 0.2074 g. of the hydride or a 10% yield. The remaining solution was pink. The melting point and the odor of the hydride were identical with those of the product obtained in the first and second runs with cysteine. On letting the trap warm up to room temperature, 18.4 cc. of a light yellow gas was obtained. The light yellow constituent again condensed to a solid at −11°. Analysis gave 3.4 cc. of carbon monoxide and 12.8 cc. of hydrogen; calculated for 0.2074 g. of $HCo(CO)_4$ = 14.9 cc. H_2.

Treatment of Cobalt Nitrosyl Carbonyl with Bromine

Experiment 1.—0.0208 gram of $Co(NO)(CO)_3$, prepared by Adams by the cyanide method = 0.000122 f. w., dissolved in 5 cc. of carbon tetrachloride. Add 0.0750 g. Br_2 = 0.00041 f. w., dissolved in 15 cc. of carbon tetrachloride. Effervescence was noted. Found, 2.6 cc. NO; calculated for $Co(NO)(CO)_3$, 2.9 cc. Found 8.7 cc. CO; calcd., 8.7 cc.

Experiment 2.—0.0624 gram of $Co(NO)(CO)_3$, prepared by Adams by the cyanide method = 0.000361 f. w., dissolved in 15 cc. of CCl_4. Add 0.225 g. Br_2 = 0.0015 f. w. dissolved in 15 cc. of CCl_4. Found, 8.4 cc. NO; calcd. 8.7 cc. Found, 25.9 cc. CO; calcd. 26.2 cc.

Experiment 3.—0.2129 gram of $Co(NO)(CO)_3$, prepared by the cysteine method in first run above = 0.00123 f.w., dissolved in 15 cc. of CCl_4. Titrated with a solution of Br_2 in CCl_4 containing 0.01855 g. of Br_2 per cc. The end-point is the disappearance of the red color of the nitrosyl carbonyl followed by the appearance of the red color of bromine. It is difficult to observe because of the green precipitate of anhydrous $CoBr_2$. End-point at 10.65 cc. = 0.00123 f. w. Br_2; added 1 cc. more Br_2. Found, 26.0 cc. NO; calcd., 29.5 cc. Found, 88.4 cc. CO; calcd. 88.7 cc. Found, 0.260 g. $CoBr_2$; calcd., 0.268 g.

Experiment 4.—0.2163 gram = 0.00125 f. w. of $Co(NO)(CO)_3$, dissolved in 15 cc. of CCl_4. Add 0.2022 g. of Br_2, dissolved in 10.9 cc. of CCl_4 = 0.00126 f. w., which just gave end-point. Found, 29.9 cc. NO; calcd. 30.1 cc. Found, 89.3 cc. CO, calcd., 90.3 cc. Found, 0.2743 g. $CoBr_2$; calcd., 0.2735 g.

The above experiments show that nitric oxide and carbon monoxide are dislodged quantitatively by bromine both when the exact amount and when an excess of the latter is used. The same results were obtained with samples of cobalt nitrosyl carbonyl prepared by different methods.

Comments

The small amount of yellow gas admixed with the hydrogen obtained on warming $HCo(CO)_4$ to room temperature is very perplexing. Its melting point at above −23° is too high for it to be some undecomposed hydride. Since it does not give a cobalt mirror even at 250°, it is unlikely that it contains cobalt. One might surmise that it came from some side reaction of the cysteine, were it not for the fact that it is also obtained when tartaric acid instead of cysteine is used as the auxiliary substance. Its amount is small and its presence does not invalidate the main conclusion as to the formation of the volatile hydride and the decomposition of the latter into hydrogen and dimeric cobalt tetracarbonyl. Nevertheless its nature should be studied as soon as opportunity offers.

It appears that cobalt carbonyl hydride is a somewhat stronger acid than carbonic acid, for it is hardly displaced from its salt at all by carbonic acid, and it is not wholly driven from the solution until free hydrochloric acid in 1 N concentration is present.

The net result of the use of tartaric acid appears to be the same as that from the use of cysteine and can be represented by the same equation (1). Probably intermediate complexes of a similar nature are formed.

The metering of the carbon monoxide was only approximate. If in the first and second runs the excess of CO absorbed over that required by equation (1) is real, it is doubtless due to the formation of some potassium formate. Blanchard and Gilliland[6] noted the formation of a little nickel formate in the slow oxidation of nickel carbonyl by air where the principal reaction was

$$Ni(CO)_4 + {}^1/_2O_2 + H_2O \longrightarrow Ni(OH)_2 + 4CO$$

Summary

Bromine reacts quantitatively with cobalt nitrosyl carbonyl, displacing nitric oxide and carbon monoxide.

The absorption of carbon monoxide by alkaline cobalt salt solutions is promoted by the presence of cysteine, tartrate and several amino acids as well as the presence of cyanide and sulfide.

Acidification of the $KCo(CO)_4$ solution obtained by treating alkaline cobalt salt solution containing cysteine or tartrate with carbon monoxide sets free the very volatile hydride $HCo(CO)_4$. This hydride can be condensed to a light yellow crystalline solid which melts at −33° to a sulfur yellow liquid and decomposes at room temperature into the non-volatile dimeric cobalt tetracarbonyl and hydrogen. The hydride is distinctly an acid, its acid strength being markedly greater than that of carbonic acid.

Cobalt nitrosyl carbonyl is most advantageously prepared by the use of cysteine as above: after acidification, the hydride is allowed to decompose in the shaking apparatus, then treatment with nitric oxide yields the nitrosyl carbonyl.

The Action of Bromine in Methyl Alcoholic Solution on Phenanthrene; a New Route to 9-Phenanthrol and 9-Phenanthrylamines[1]

BY L. F. FIESER, R. P. JACOBSEN[2] AND C. C. PRICE

In connection with a study of the reaction between phenanthrene and bromine in carbon tetrachloride solution,[3] a trial was made of the action on the hydrocarbon of a solution of bromine in methyl alcohol. Considering the ready formation of phenanthrene dibromide, and in analogy with known cases of the addition of methyl hypobromite to aliphatic and alicylic ethylenic linkages,[4] it seemed possible that the hydrocarbon might add the reagent in a similar fashion.

In the first experiments fine, colorless needles of a reaction product were observed to separate after mixing methyl alcoholic solutions of bromine and phenanthrene at room temperature, but the yield was poor. The results were somewhat improved by working at a lower temperature and by using a large excess of bromine, and it was found that the yield is increased very substantially by carrying out the reaction in the presence of sodium acetate to displace the bromine equilibrium in favor of the hypobromite. Eventually an easily reproducible procedure was developed by means of which a colorless product can be obtained in a quantity amounting to about one and one-third the weight of hydrocarbon employed. This material was granular and possibly different from that first observed. Purified by careful recrystallization, the substance melted at 107.5–108°, dec., and when stored in the cold room (5°) it remained apparently unaltered for about one day. At room temperature decomposition set in after a few hours. Although the analysis of the unstable substance presented difficulties, the results for carbon, hydrogen, bromine and methoxyl all point to the formula of a molecular compound composed of equivalent parts of phenanthrene

---

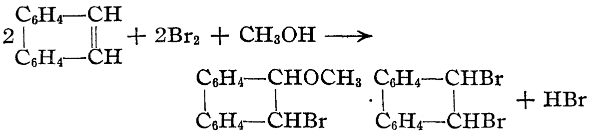
[1] The bromination reaction described in this paper was discovered in the course of other work by C. C. Price, who made a preliminary study of the formation of the product and of its conversion to 9-methoxyphenanthrene (Dissertation, 1936). A more detailed investigation of the formation, nature and preparative uses of the compound was subsequently made by R. P. Jacobsen, and these experiments form the basis of the present report.—L. F. F.

[2] Du Pont Research Fellow.

[3] Price, THIS JOURNAL, **58**, 1834 (1936).

[4] Conant and Jackson, *ibid.*, **46**, 1727 (1924); Jackson, *ibid.*, **48**, 2166 (1926); Jackson and Pasiut, *ibid.*, **49**, 2071 (1927); Meinel, *Ann.*, **510**, 129 (1934).

methoxybromide and phenanthrene dibromide, and the reaction thus appears to proceed as follows.



$$2\begin{array}{l}C_6H_4\text{—}CH\\ |\qquad\quad \|\\ C_6H_4\text{—}CH\end{array} + 2Br_2 + CH_3OH \longrightarrow \begin{array}{l}C_6H_4\text{—}CHOCH_3\\ |\qquad\quad |\\ C_6H_4\text{—}CHBr\end{array}\cdot\begin{array}{l}C_6H_4\text{—}CHBr\\ |\qquad\quad |\\ C_6H_4\text{—}CHBr\end{array} + HBr$$

This formulation is consistent with such observations as have been made of the properties of the substance. When warmed with a solution of potassium hydroxide and potassium acetate in methyl alcohol, it yielded a mixture of about equal parts of 9-methoxyphenanthrene and phenanthrene. The former substance presumably is produced by the elimination of hydrogen bromide from the methoxybromide component, while the latter evidently comes from the dibromide by loss of bromine When treated in the same way, pure phenanthrene dibromide afforded bromine-free phenanthrene in nearly quantitative yield. While the mixture of the ether and the hydrocarbon is not readily separated, pure 9-phenanthrol can be obtained very easily by short treatment of the crude mixture with hydrobromic–acetic acid followed by extraction with alkali, and the phenanthrene can be recovered in a satisfactory state of purity. Since the most satisfactory of the previous methods of preparing 9-phenanthrol (through phenanthrenequinone and dichlorophenanthrone[5]) leaves much to be desired, the new reaction series was studied with a view to the development of a better source of the hydroxy compound. It was found that all three reactions can be carried out rapidly with reasonably large amounts of material and that 9-phenanthrol can be obtained with regularity in a pure condition in over-all yields of 28–30%, based on the phenanthrene consumed. In its present state the process seems to have definite advantages over previous methods, and it is not impossible that further improvements can be made.

With 9-phenanthrol more readily available, the use of this material as a source of 9-phenanthrylamines was investigated. Such substances are of particular interest because of the structural relationship, in at least one important respect, to morphine. The conversion of 9-phenanthrol into 9-phenanthrylamine is described in the early literature, but the results were unsatisfactory (25% yield),[6] and methods of preparing the amine through 9-nitro-,[7] 9-nitro-10-bromo-,[8] or 9-acetylphenanthrene[9] all suffer from the fact that the starting materials are not easily available. Following the general procedure of Bucherer,[10] we obtained the amine from 9-phenanthrol in 90% yield. N-Alkylphenanthrylamines (methyl, ethyl, *n*-propyl and *n*-butyl) were obtained in about 70% yield by heating 9-phenanthrol with the appropriate primary amine and aqueous sodium bisulfite at 135–140° for about one day. N-(β-Hydroxyethyl)-9-phenanthrylamine was prepared from 9-phenanthrylamine and ethylene oxide, but only in poor yield.

The investigation of the bromination reaction is being continued and the preparation of further 9-amino derivatives more closely related to the alkaloids of the morphine group is in prospect.

Experimental Part[11]

Preparation of the Complex.—After a number of trials at different temperatures and varying the amounts of the reagents, the following procedure was adopted as the most satisfactory both as to yield and quality of the product. For efficient washing of the product, larger amounts are best handled in portions of the size indicated.

A solution of 50 g. of phenanthrene (m. p. 97.5–98°) and 15 g. of anhydrous sodium acetate in 900 cc. of warm methyl alcohol was cooled quickly to about 35–40° without allowing much phenanthrene to crystallize, and a solution of 25 g. of bromine in 100 cc. of cold methyl alcohol was added all at once. The mixture was cooled rapidly in a salt–ice bath and the temperature was brought to $-5°$. The complex began to separate from the red-brown solution during the cooling process, and after standing at $-5°$ for twenty to thirty minutes the yellow solid was collected and washed, after removing the filtrate, with three 100-cc. portions of a 5% solution of sodium acetate in 70% methyl alcohol. This removed the yellow color and left a nearly white solid. The original filtrate was treated with 75 cc. of 20% aqueous sodium acetate solution and an additional 15-cc. portion of bromine in 50 cc. of cold methyl alcohol, and cooled to $-10°$ for thirty minutes. A second crop of the complex separated, about equal in amount to the first, and it was washed as before. The total product weighed 63–65 g. (71–74%, calculated on the basis of the formula indicated) and melted at 105–107° with loss of hydrogen bromide. This crude product was employed in the next step without purification.

The material prepared in this way did not appear to undergo change when crystallized from ether–petroleum

[11] All melting points are corrected. Analyses by Mrs. G. M. Wellwood.

ether, using Norite for clarifying the solution and avoiding undue heating, and after several recrystallizations it was obtained as a colorless, granular solid, m. p. 107.5–108°, dec. One sample melted at this temperature without showing signs of decomposition. Samples dried in vacuum and kept at room temperature began to turn brown within a few hours, and the sample used for the following analyses was prepared the evening before it was used and stored at 5°. All of the analyses were made on the same sample, but this was recrystallized prior to the second methoxyl determination (the last of the series reported), although no darkening had been observed.

Anal. Calcd. for $C_{14}H_{10}Br_2 \cdot C_{14}H_{10}(OCH_3)Br$: C, 55.51; H, 3.70; Br, 38.24; OCH_3, 4.95. Found: C, 56.11, 56.23; H, 4.62, 4.97; Br, 38.06, 36.74; OCH_3, 4.96, 5.49.

The lack of concordance in the results may be connected with the difficulty in drying the sample completely at a low temperature, with its instability, or, particularly in the case of the carbon–hydrogen determinations, with a difficulty inherent in the combustion itself. The bromine content is about 10% higher than that calculated for the pure methoxybromide and this fact, and the definite methoxyl content found, provide convincing indications of the presence of the two components.

One sample, prepared at an earlier stage of the work, crystallized from ether in fine needles, m. p. 113–115°, uncorr., and the carbon value found in a single determination was about 5% higher than found above, but other analyses were not made and it is not known if this was the same or a different product.

In bromination experiments conducted at room temperature in methyl alcohol containing no sodium acetate the yields of the solid product which separated ranged from 20 to 30%. When the solution was cooled to 0° soon after mixing the reagents the yield was increased to 50%.

Debromination.—The crude, undried complex prepared in four lots from 200 g. of phenanthrene was suspended in 1 liter of methyl alcohol containing 40 g. of potassium hydroxide and 10 g. of potassium acetate. The mixture was heated with stirring at 50–55° for one hour, after which the temperature was raised to 60° for thirty minutes. The warm, deep yellow-red solution was decanted from precipitated potassium bromide, the latter being washed with methyl alcohol, and the solutions were combined and diluted with 200 cc. of water and cooled. The oil which separated soon solidified and the material was crystallized from methyl alcohol, using Norite. An additional quantity of material was obtained by further dilution of the mother liquor, and recrystallized. The total yield of material, consisting of a mixture of plates and needles and melting indefinitely at 60–80°, was 110 g. This was found from the subsequent treatment described below to be composed of nearly equal amounts of phenanthrene and 9-methoxyphenanthrene.

In two early experiments by different workers, both using sodium acetate in methyl alcoholic solution, 9-methoxyphenanthrene, m. p. 93–94° (calcd.: C, 86.50; H, 5.76. Found: C, 86.16; H, 5.76) was obtained as the sole product, but the results could not be repeated later. The starting materials were not fully analyzed and may have been different from that described above.

As the formation of phenanthrene from the dibromide component seemed surprising, a test experiment was made with the phenanthrene dibromide prepared by adding 5 g. of bromine to 5 g. of phenanthrene in 25 cc. of carbon tetrachloride solution and cooling. The crystalline product was washed well and heated for thirty minutes with a solution of 4 g. of potassium hydroxide and 0.5 g. of potassium acetate in 50 cc. of methyl alcohol. On decanting the solution and adding an equal volume of water, 4 g. of halogen-free phenanthrene separated as small leaflets. Once recrystallized it melted at 95.5–97° and gave no depression when mixed with authentic phenanthrene.

9-Phenanthrol.—The crystalline mixture (110 g.) obtained as described above was heated under reflux with 400 cc. of glacial acetic acid, and 60 cc. of 48% hydrobromic acid was added gradually. After boiling the mixture for two hours an equal volume of water was added and the precipitate was collected after cooling, washed, and the moist product was taken up in 300 cc. of ether. After thorough washing with water, the ethereal solution was extracted with three 50-cc. portions of 10% sodium hydroxide and the green alkaline extract, after one washing with ether, was acidified and extracted with 100 cc. of ether. The washed ethereal solution, after dilution with 25 cc. each of benzene and hexane, was dried over sodium sulfate and decolorized by filtration through a column of activated alumina. An impurity giving the solution an orange color was retained in a greenish band, and from the filtrate 48–50 g. of 9-phenanthrol was obtained in the form of faintly salmon-colored needles melting at 153–155°. From the washed ethereal solution remaining after extraction with alkali, 45 g. of crude phenanthrene was recovered, making the over-all yield of 9-phenanthrol 28–30%, based on material consumed. The crude phenanthrene after being distilled in vacuum and crystallized once from methyl alcohol was satisfactory for use in the bromination reaction.

9-Phenanthrylamine.—A mixture of 10 g. of 9-phenanthrol, 50 g. of 40–45% ammonium sulfite, and 50 cc. of concentrated ammonium hydroxide solution was heated in a sealed tube at 135–140° for twenty to twenty-five hours. The cooled mixture was extracted with ether and the solution, after being washed with dilute sodium hydroxide and with water, was dried over sodium sulfate, decolorized with Norite and concentrated somewhat. On adding hexane and cooling, there was obtained 9.1 g. (90%) of 9-phenanthrylamine, m. p. 135–136.8°. One recrystallization from ether–petroleum ether or benzene–hexane gave very faintly yellow needles, m. p. 137.5–138.5°.

In similar experiments conducted at 100° the yield of amine after heating for five hours was 20%, after twenty to twenty-five hours it rose to about 50%.

N-Alkyl-9-phenanthrylamines.—For the preparation of these substances a mixture of 2 g. of 9-phenanthrol, 10 g. of sodium bisulfite and either 10 cc. of water and 10 cc. of a 33% aqueous solution of the amine, or a mixture of 20 cc. of water and 5 cc. of the pure amine, was heated in a sealed tube at 135–140° for twenty to twenty-five hours. The reaction products, recovered as above, were obtained directly in a good condition and the melting point subsequently rose only 1–3° on further recrystallization. The first three substances were crystallized from benzene–ligroin or ether–petroleum ether, while 80% methyl alcohol was used in the case of the butyl compound. The amines all form heavy, pale yellow needles.

N-ALKYL-9-PHENANTHRYLAMINES

Alkyl group	Yield, %	M. p., °C.	% C Calcd.	% C Found	% H Calcd.	% H Found
Methyl	70	88.5– 89.5	86.91	86.85	6.33	6.27
Ethyl	70	97 – 98	86.87	86.96	6.84	7.11
n-Propyl	70	109.5–110.5	86.76	86.61	7.29	7.09
n-Butyl	62	102 –103	86.69	86.52	7.69	7.51

N-(β-Hydroxyethyl)-9-phenanthrylamine.—After heating a mixture of 2 g. of 9-phenanthrylamine, 5 cc. of benzene and 10 cc. of ethylene oxide in a sealed tube at 100° for seven hours, the excess ethylene oxide was expelled and the residue was extracted with ether. The solution was dried, decolorized and treated with petroleum ether, when 0.25 g. (10%) of a solid was obtained in the form of fine needles melting at 99.5–101°. The substance has a tendency to separate in a gelatinous condition. After two recrystallizations from ether–petroleum ether it was obtained as long, slender, colorless needles, m. p. 101–102°.

Anal. Calcd. for $C_{16}H_{15}ON$: C, 80.97; H, 6.38. Found: C, 81.22; H, 6.34.

When the reaction mixture was heated at 100° for only five hours considerable 9-phenanthrylamine was recovered along with some of the β-ethanol derivative. On conducting the reaction at 135–140° for either ten or twenty hours the ethereal extract of the product yielded only a resinous residue on evaporation. This distilled without apparent decomposition at about 250° (2 mm.) but the viscous, pale yellow distillate set to a glass and did not crystallize.

Summary

Treated with bromine in methyl alcoholic solution, phenanthrene is converted in about 70% yield into a very unstable substance which appears to be a complex containing one molecule each of phenanthrene methoxybromide and phenanthrene dibromide. The complex yields 9-methoxyphenanthrene and phenanthrene when warmed with alcoholic potassium hydroxide–acetate, and 9-phenanthrol is easily obtained from the mixture in a sufficiently satisfactory over-all yield to make this a useful preparative method. 9-Phenanthrylamine and typical N-alkyl derivatives can be obtained in good yield from 9-phenanthrol by the Bucherer reaction.

The Acylation and Alkylation of Beta Diketones and Beta Sulfonyl Ketones

BY E. P. KOHLER AND H. A. POTTER

In a recent paper,[1] in which we described the action of benzoyl chloride on the magnesium derivatives of a series of monoketones, we showed that there is a conspicuous difference in the behavior of phenyl and mesitylenic ketones, the former being converted into diketones and the latter largely into benzoates. We have now extended the comparison to the corresponding β-diketones and, as these diketones form copper derivatives which can be purified by crystallization, we were able to compare the behavior of phenyl and mesitylenic ketones when they are benzoylated by means of metallic derivatives that are very different from the magnesium compounds in their activity.

We also included in the comparison the corresponding β-sulfonyl ketones—tosyl acetophenone and tosyl acetomesitylene. These compounds are of special interest because the sulfonyl group increases the acidity of the hydrogen on an adjoining carbon atom but is incapable of participating in any process akin to enolization.

The nature of the products and the yields in which they were obtained are shown in the following table. In many cases the primary benzoylation products deprived some of the initial metallic derivatives of their metal and thus prevented complete acylation; the proportion of C-benzoyl to O-benzoyl derivatives is therefore more significant than the total yield. In the case of the copper compounds the great differences in solubility introduce an additional complication because in the very slow reactions a part of the initial material is lost through halogenation by the mechanism recently established by Michael and Carlson.[2] An attempt to obviate this difficulty by substituting benzoyl bromide for the chloride—in the cases marked with an asterisk—was unsuccessful because, while the bromide reacts far more rapidly than the chloride, the resulting cupric bromide is also a much better halogenating agent than the chloride.

An examination of this table shows that the difference in the mode of benzoylation of phenyl

and mesitylenic ketones is just as marked in the β-diketones and the β-sulfonyl ketones as it is in the monoketones. It shows also that the course of the benzoylation of the metallic derivatives of these compounds is not greatly affected by the nature of the metal; it depends almost entirely on the character of the hydrocarbon residues and the mesityl group effectively promotes O-benzoylation.

For reasons stated earlier, the β-sulfonyl ketones are especially interesting. As they behaved toward benzoylating agents essentially like the polyketones, we also examined the behavior of tosyl acetomesitylene in reactions involving alkylation. In alcohol the sodium compound reacted rapidly with methyl iodide and the sole product of the reaction was the C-alkyl derivative. We were unable to induce either the magnesium or the sodium compound to react with methyl iodide in ether or benzene but both reacted with dimethyl sulfate in these non-polar solvents and formed O-methyl derivatives exclusively. Mesitylenic ketones, therefore, differ from phenyl ketones also in their tendency to form O-alkyl derivatives.

These β-sulfonyl ketones also provided a means of examining the view that sulfonyl groups do not promote the enolization of a carbonyl group in the β-position because they cannot serve as partners in conjugation. In support of this view Arndt and Martius[3] described the behavior of a series of mono- and disulfonyl compounds toward alcoholic ferric chloride. The behavior of our series of sulfonyl compounds in solutions of ferric chloride in methyl alcohol—or better in freshly prepared solutions in acetone—was as follows: with $C_7H_7SO_2CH_2COC_6H_5$, $C_7H_7SO_2CH_2COC_6H_2(CH_3)_3$ and $(C_7H_7SO_2)_2CHCOC_6H_5$ the tests were negative; $C_7H_7SO_2CH(COC_6H_5)_2$ slowly developed a red color which was feeble in alcohol, stronger in acetone; both $C_7H_7SO_2CH(COC_6H_5)COC_6H_2(CH_3)_3$ and $(C_6H_5SO_2)_2CHCOC_6H_2(CH_3)_3$ rapidly developed deep red colors in both solvents.

---

(3) Arndt and Martius, *Ann.*, **499**, 244 (1932).

The view that sulfonyl groups cannot promote enolization is manifestly no longer tenable because the difference between acetomesitylene which does not respond to any tests for enolization and disulfonyl derivative which enolizes must be due to the two phenylsulfonyl groups. It is doubtless true that the sulfonyl group is far less effective than the carbonyl group in promoting enolization; the introduction of another benzoyl group into the completely enolic dibenzoylmethane merely stabilizes the ketonic form while the introduction of a tosyl group completely inhibits enolization. But when the same group is introduced into benzoyl acetomesitylene, the product still enolizes in solution—an indication that the tendency to enolize is much more pronounced in mesitylenic than in phenyl ketones.

From the foregoing account and the facts presented in the earlier paper it is evident that all types of ketones which contain the group $CH-COC_6H_2(CH_3)_3$ differ from those which have the group $CH-COC_6H_5$ in that they have a greater tendency to enolize and to form acyl and alkyl derivatives of the enolic modification. The reason for this peculiarity is not clear but it appears probable that the predominant O-acylation and O-alkylation is associated with the tendency to enolize.

Experimental Part

I. Preparation of Materials

The diketones and their copper derivatives which were known were prepared by conventional methods but the copper derivative of dibenzoylmethane was recrystallized before use by solution in pyridine and reprecipitation with ether. Tosyl acetophenone was made by Arndt and Martius[3] (p. 281) by treating chloroacetophenone with sodium toluene sulfinate. In order to secure the intermediates, we undertook to prepare it by means of a series of reactions which can be represented as follows

$$C_7H_7SNa + ClCH_2COC_6H_5 \longrightarrow C_7H_7SCH_2COC_6H_5 \longrightarrow C_7H_7SOCH_2COC_6H_5 \longrightarrow C_7H_7SO_2CH_2COC_6H_5$$

We found, however, that, owing to oxidation and reduction in the alkaline solution, the principal products of the first step were the sulfoxide and acetophenone. The procedure was as follows.

A solution of 172 g. of chloroacetophenone in boiling methyl alcohol was treated with an equivalent quantity of sodium *p*-thiocresolate. The mixture was boiled for several hours, then freed from most of the methyl alcohol by distillation. An ethereal extract of the residue, distilled under diminished pressure, gave 50 g. of acetophenone and 168 g. of the sulfoxide. The sulfoxide melts at 46° and boils at 182–184° (5 mm.). It is oxidized to the sulfone by hydrogen peroxide.

Anal. Calcd. for $C_{15}H_{14}O_2S$: C, 69.7; H, 5.6. Found: C, 69.6; H, 6.0.

Tosyl Acetomesitylene: $C_7H_7SO_2CH_2COC_6H_2(CH_3)_3$.—Sodium toluene sulfinate reacts much less readily with chloroacetomesitylene than with chloroacetophenone. The best results were obtained by heating equivalent quantities of the reactants and a small quantity of alcohol (about one-third of the volume of the solids) in sealed tubes for seventy-five hours at 100°. The contents of the tubes were acidified with dilute acid and extracted with benzene. The benzene solution, in turn, was extracted with bicarbonate to remove sulfinic acid and finally with normal aqueous sodium hydroxide. From the yellow alkaline solution acids precipitated the sulfonyl ketone. It crystallized from methyl alcohol in needles and it melted at 180°. The yield was about 50%.

Anal. Calcd. for $C_{18}H_{20}O_3S$: C, 68.4; H, 6.3. Found: C, 68.2; H, 6.3.

Tribenzoyl Methyl Chloride: $(C_6H_5CO)_3CCl$.—A slow stream of chlorine was passed through a suspension of tribenzoylmethane until all of the solid disappeared. The chloroform was evaporated and the residue was recrystallized from methyl alcohol. The product separated in needles melting at 122°.

Anal. Calcd. for $C_{22}H_{15}O_3Cl$: C, 72.8; H, 4.1. Found: C, 72.5; H, 4.2.

The chloride did not serve the purpose for which it was made because sodium toluene sulfinate reduced it rapidly and quantitatively to tribenzoylmethane and when it was treated with sodium thiocresolate in benzene it reacted in accordance with the equation

$$(C_6H_5CO)_3CCl + 2NaSC_7H_7 \longrightarrow NaCl + (C_6H_5CO)_3CNa + C_7H_7S{-}SC_7H_7$$

II. Benzoylation

In order to get significant results with the magnesium derivatives it was necessary to prepare and benzoylate them in ether at low temperatures because at higher temperatures both the magnesium derivatives themselves and their benzoylation products are cleaved in part into new magnesium derivatives which then undergo further benzoylation. Thus when the magnesium derivative of benzoyl acetomesitylene was benzoylated in boiling benzene the principal products were the magnesium derivatives of dibenzoyl and tribenzoyl methane.

For manifest reasons some diketone or sulfo ketone was regenerated in all cases in which one of the products was formed by C-benzoylation. In many of these cases also—especially in the benzoylation of the sulfonyl compounds—the primary product suffered further benzoylation. The final result, therefore, was a mixture which might contain diketone and one or more of its stereoisomeric benzoates, triketone and its benzoates, and the excess of acid chloride. And, in the case of the copper compounds, usually it also contained a halogen derivative of the diketone.

The separation of these mixtures, frequently troublesome, was in part chemical. In general ether, when present, was removed and replaced with benzene. The benzene solutions were boiled with water to decompose excess of chloride or bromide, then cooled and extracted with dilute bicarbonate until free from benzoic acid. The benzene layer was then shaken with sodium carbonate which converted a part of the triketone into the sparingly soluble ketonic modification and removed the remainder as a soluble sodium salt. Extraction with aqueous sodium hydroxide then removed both the regenerated diketone and its halogen compound and these substances were separated either by crystallization or when necessary by converting the diketone into its copper derivative. The benzene solution then contained only benzoates. The separation of the isomeric benzoates by crystallization was always troublesome and sometimes impossible but the nature of the products and the quantities in which they were present could always be established by hydrolysis with cold dilute methyl alcoholic sodium hydroxide. The important constants of the new products are recorded in the following table. The Roman numerals refer to structural formulas in Table I.

TABLE II

Formula	Crystal form	M. p., °C.	Composition, % Calcd. C	Calcd. H	Found C	Found H

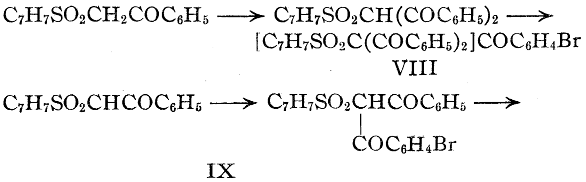
III. Proof of Structure

In most cases the products formed by O-acylation were readily distinguished from the C-acyl derivatives by their lack of solubility in aqueous alkali. This test, however, was not applicable to those tosyl compounds which contained four acyl groups. There was little doubt concerning the structure of these compounds because they were readily formed also by benzoylation in pyridine but we nevertheless decided to establish with certainty the manner in which the fourth acyl group enters the molecule. To this end we employed *p*-bromobenzoyl chloride in accordance with the scheme

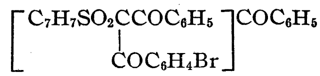


$$C_7H_7SO_2CH_2COC_6H_5 \longrightarrow C_7H_7SO_2CH(COC_6H_5)_2 \longrightarrow [C_7H_7SO_2C(COC_6H_5)_2]COC_6H_4Br$$

VIII

$$C_7H_7SO_2CHCOC_6H_5 \longrightarrow C_7H_7SO_2\underset{\substack{|\\COC_6H_4Br}}{C}HCOC_6H_5 \longrightarrow$$

IX



$$\left[C_7H_7SO_2\underset{\substack{|\\COC_6H_4Br}}{C}COC_6H_5\right]COC_6H_5$$

X

As the final products of the two series are different, the fourth group evidently enters as benzoate. The constants of these compounds have been included in Table II.

IV. Alkylation of Tosylacetomesitylene

Alkylation with Diazomethane: $C_7H_7SO_2CH{=}C(OCH_3)$-$C_6H_2(CH_3)_3$.—An excess of diazomethane was passed into a solution of the sulfonyl ketone in cold benzene. The solution evolved gas slowly but regularly. It was left to itself overnight, then diluted with petroleum ether. The product crystallized from benzene–petroleum ether in large prisms and it melted at 137°. The yield was 93%.

Anal. Calcd. for $C_{19}H_{22}O_3S$: C, 69.1; H, 6.7. Found: C, 69.2; H, 6.8.

This product is evidently an ether because it is insoluble in alkalies and regenerates the sulfonyl ketone when it is digested with hydrochloric acid. When it was heated for six hours to 130° in a vacuum it was transformed into an isomer which crystallized from methyl alcohol in sparkling cubes and melted at 147°. This isomer likewise is an ether; it also is insoluble in alkalies but is hydrolyzed by acids. Neither of these ethers was rearranged to the C-methyl derivative by prolonged boiling with alcoholic sodium methylate.

Anal. Calcd. for $C_{19}H_{22}O_3S$: C, 69.1; H, 6.7. Found: C, 69.0; H, 6.7.

Alkylation of the Magnesium Derivative.—A solution of 6.3 g. of the tosyl compound in benzene was added to a small excess of ethylmagnesium bromide and the solution was distilled until all of the excess ethyl bromide and the ether had been expelled. It was then treated cautiously with excess of dimethyl sulfate, boiled for seven hours and decomposed in the usual manner. The benzene layer contained 6.2 g. of the methyl ether melting at 147°—a yield of 94%.

Alkylation of the Sodium Derivative in Benzene.—A solution of 3.2 g. of the tosyl compound in benzene was treated with an equivalent quantity of sodium and left to itself until all of the metal had disappeared. Excess of dimethyl sulfate was added then and the mixture was boiled for four hours and decomposed in the usual manner. The benzene layer contained 3 g. of the methyl ether melting at 137°—a yield of 90%.

Alkylation with Methyl Iodide in Alcohol: $C_7H_7SO_2CH$-$(CH_3)COC_6H_2(CH_3)_3$.—A boiling methyl alcoholic solution of 3.2 g. of the tosyl compound and 3 g. of methyl iodide was treated gradually with two equivalents of sodium methylate and boiled for two hours. The solution remained clear until it was diluted with ice water. It then deposited a very sparingly soluble product which was recrystallized from acetone–methyl alcohol. It separated in lustrous needles melting at 171°. The yield was 96%.

Anal. Calcd. for $C_{19}H_{22}O_3S$: C, 69.1; H, 6.7. Found: C, 69.2; H, 6.9.

The methyl derivative is extracted from its ethereal solution by aqueous sodium hydroxide and although very slightly soluble in methyl alcohol it dissolves freely in methyl alcoholic sodium hydroxide. The crude product contained no material that was not extracted from ether by aqueous sodium hydroxide; it therefore contained neither ethers nor dimethyl derivatives.

Summary

This paper contains an account of the results obtained in a study of the acylation and alkylation of a series of β-diketones and β-sulfonyl ketones.

Reduction of Nitroguanidine. VII. Preparation of Aminoguanidine by Catalytic Hydrogenation

BY EUGENE LIEBER AND G. B. L. SMITH

The catalytic hydrogenation of nitroguanidine to nitrosoguanidine with nickel and platinum catalysts in neutral media has been reported.[1] The further reduction to aminoguanidine has not been studied extensively.[2] Recently McGill[3] has suggested the manufacture of aminoguanidine by catalytic hydrogenation with a catalyst of nickel dispersed on kieselguhr (all of the ordinary hydrogenating catalysts are also claimed) at temperatures between 25 and 125° (the preferred temperature is 80°) in the *absence* of any substantial amounts of acid. However, it has been found that the optimum conversion to aminoguanidine is obtained in media of relatively high acid concentration. McGill,[3] in the examples cited in the patent, gives no yields but claims that for nickel catalyst the use of elevated pressure is essential for increased yields. We have found that the yields for a nickel catalyst are conditioned not solely by pressure but by the type of solvent used.

The molar ratio of hydrogen to hydrogen acceptor obtained in the catalytic hydrogenation of nitroguanidine depends upon the environmental conditions of the solvent. For the first molar proportion of hydrogen the reduction proceeds as follows.

Media	Principal product	Ratio, H_2 : Acceptor
Neutral	Nitrosoguanidine	1:1
Basic	Nitrosoguanidine	1:1
Acid	Aminoguanidine	3:1

In acid media of such a concentration that the molar ratio of nitroguanidine to acid is one or higher the reduction proceeds without the formation of nitrosoguanidine. This is a new observation and is of significant importance for the preparation of aminoguanidine by catalytic hydrogenation. If the molar ratio of acid to nitroguanidine be below one then the distribution of reduction products depends upon the acid concentration. At ratios of acid above one, the hydrazino formation was found to be linear with hydrogen absorption.

Raney nickel catalyst can be used in both neutral and alkaline media. The Adams platinum oxide catalyst can be used in neutral and acid media but is completely poisoned in alkaline media of even low concentrations. The reduction in neutral aqueous media at atmospheric pressure and room temperature gives low yields of aminoguanidine, the principal products appearing to be ammonia and guanidine. At higher hydrogen pressures superior yields of aminoguanidine are obtained with platinum oxide in 15% aqueous acetic acid as compared with Raney nickel in neutral solvents. With increasing temperatures to 125° the yields of aminoguanidine with Raney nickel fall off more rapidly than with platninum oxide as shown by Fig. 1. This also illustrates the effect of type of solvent, especially at 75°.[3]

Experimental

Method.—The Adams platinum oxide and Raney nickel catalysts were prepared in the usual manner. The apparatus employed has been described previously,[1] while the high pressure equipment was of the Adkins type.

The experimental technique and procedures devised for the recovery of the aminoguanidine with minimum loss will be made clear by the description of typical reductions obtained with platinum and nickel catalysts.

Reduction in Acid Media with Platinum Oxide Catalyst.—20.8 g. of nitroguanidine and 1 g. of platinum oxide are suspended in 125 ml. of 15% aqueous acetic acid. The reduction is carried out at 125 atm. and room temperature

---

[1] Lieber and Smith, THIS JOURNAL, **57**, 2479 (1935).

[2] Audrieth and Schmidt, University of Illinois, private communication, used Raney nickel in ethyl alcohol and identified the aminoguanidine through the melting point of the benzalazine obtained by hydrolysis of the reduction mixture.

and is allowed to continue until no further hydrogen is absorbed. Slightly more than 3 molar quantities of hydrogen is usually taken up. A small amount of Norit is added and the solution filtered from catalyst into a 500-ml. volumetric flask. After washing the filter paper the volume is adjusted and a 2-ml. portion is titrated with 0.1 *N* potassium iodate solution.[4] From the titer required the titration yield of aminoguanidine was found to be 81.8%. From these data the amount of sulfuric acid required for the formation of aminoguanidinium sulfate is calculated (the addition of too large an excess of sulfuric acid causes the formation of the less easily crystallizable primary salt) and is added after concentrating the solution of the acetate under 10 mm. pressure on a water-bath maintained at 50–60°. The sulfate should be reconcentrated until crystallization of the salt takes place in the warm solution. An equal volume of ethyl alcohol is added and after cooling the white crystals are filtered on a Büchner funnel, pressed dry and washed with a small amount of cold absolute alcohol, dried in a vacuum desiccator and then at 100° for three hours to remove the water of crystallization; yield 16.8 g. or 68.3%; m. p. (Dennis bar) 206°. *Anal.* Calcd. for $(CH_6N_4)_2H_2SO_4$: H_2SO_4, 39.84; N_2H_4, 26.02. Found: H_2SO_4, 39.77; N_2H_4, 26.11, 26.07.

Benzal-aminoguanidine.—$C_6H_5CH{=}NNHC(NH)NH_2$; m. p., found, 177–78°, reported 178°.[5] *Anal.* Calcd. for $C_8H_{10}N_4$: C, 59.26; H, 6.17; N_2H_4, 19.75. Found: C, 59.60; H, 6.79; N_2H_4, 20.16, 20.02.

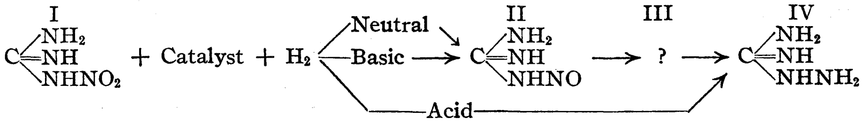
Reduction in Absolute Methyl Alcohol with Raney Nickel.—20.8 g. of nitroguanidine and 10 g. of Raney nickel are suspended in 125 ml. of methyl alcohol and reduced at 125 atm. and room temperature. The reduction mixture is treated with Norit and filtered. The solution is saturated with carbon dioxide for several hours and the voluminous white precipitate which forms is filtered and washed with alcohol and ether; yield 15 g. or 55.2%. *Anal.* Calcd. for $CH_6N_4H_2CO_3$: N_2H_4, 23.53. Found: N_2H_4, 22.78.

Distribution of Reduction Products with Acid Concentration.—Ten grams of nitroguanidine and 0.5 g. of platinum oxide are suspended in 100 ml. of water, 0.1 and 1 *N* hydrochloric acid, respectively, and reduced at 1 atm. until 1 molar proportion of hydrogen has been absorbed (2300 ml.). The reduction mixture was examined for nitrosoguanidine, aminoguanidine and unreacted nitroguanidine. The results obtained were:

Molar ratio HCl/nitroguanidine	0	0.1	1.0
Acid concentration, *N*	0	.1	1
Reduction products:			
% Nitrosoguanidine	59	17.5	Absent
% Aminoguanidine	None	Present	46.2
% Nitroguanidine recovered	None	11.5	61.5

Discussion

The catalytic hydrogenation of nitroguanidine may be summarized as follows



$$\underset{\text{I}}{\text{C}\begin{smallmatrix}\text{NH}_2\\=\text{NH}\\\text{NHNO}_2\end{smallmatrix}} + \text{Catalyst} + \text{H}_2 \xrightarrow[\text{Basic}]{\text{Neutral}} \underset{\text{II}}{\text{C}\begin{smallmatrix}\text{NH}_2\\=\text{NH}\\\text{NHNO}\end{smallmatrix}} \longrightarrow \underset{\text{III}}{?} \longrightarrow \underset{\text{IV}}{\text{C}\begin{smallmatrix}\text{NH}_2\\=\text{NH}\\\text{NHNH}_2\end{smallmatrix}}; \quad \text{I} \xrightarrow{\text{Acid}} \text{IV}$$

In neutral and basic media, nitrosoguanidine is the first product of reduction and may be readily isolated in good yield,[1] while in acid media the reduction proceeds directly to aminoguanidine. Of the substances I and II, nitrosoguanidine is the least stable and it is therefore reasonable that route I to IV by way of II should yield less of IV, than its direct formation in acid media in which II does not appear as an intermediate reduction product. The increased yields of IV with Raney nickel using alcohol as a solvent may be explained on the basis that II is less subject to dearrangement in alcohol than it is in water. The products obtained in the reduction of II with *one* molar proportion of hydrogen (II ⟶ III) have never been studied and we are at present engaged upon that phase of this investigation. Preliminary experiments have yielded small quantities of unknown reduction products of nitroguanidine including a reddish-orange substance having dye and indicator properties.

The Condensation of Certain Aromatic Methyl Ketones

BY DANIEL B. CLAPP AND AVERY A. MORTON

Bernhauer, Müller and Neiser[1] have studied recently the condensation of aromatic methyl ketones by means of potassium pyrosulfate and sulfuric acid. They were successful by this method, in obtaining 1,3,5-tri-*p*-diphenylbenzene from *p*-acetyldiphenyl, but failed in an attempt to prepare 1,3,5-tri-α-naphthylbenzene and 1,3,5-tri-β-naphthylbenzene from α- and β-acetylnaphthalene, respectively. In the course of other work we have prepared the above three compounds by the method of Reddelien,[2] which involves the use of aniline and aniline hydrochloride. This method is more suitable for the preparation of 1,3,5-tri-*p*-diphenylbenzene than that with potassium pyrosulfate, since in the former case purification involves only a few recrystallizations of the crude product.

Experimental

1,3,5-Tri-*p*-diphenylbenzene.—*p*-Acetyldiphenyl (120 g., 0.61 mole), aniline hydrochloride (6.4 g.), and freshly distilled aniline (86 g.) were heated together at 175° under a carbon dioxide atmosphere for three hours. The aniline was removed by distillation, and the residue was poured, while still hot, into a pan, where it quickly set to a brittle, red-brown resin. On grinding the resin in a mortar with ether, and filtering, 43.5 g. of crude product was obtained. Three recrystallizations from toluene gave 25 g. of pure 1,3,5-tri-*p*-diphenylbenzene; yield 23%; white needles; m. p. 230.5–231°; gives no color with cold concentrated sulfuric acid; almost insoluble in ether, alcohol and acetone; slightly soluble in glacial acetic acid; soluble in benzene and toluene.

Anal. Calcd. for $C_{42}H_{30}$: C, 94.34; H, 5.66; mol. wt., 534. Found: C, 94.50, 94.31; H, 5.71, 5.68; mol. wt. (Rast), 536, 538.

1,3,5 - Tri - α - naphthylbenzene.—α - Acetylnaphthalene[3] (26 g., 0.153 mole), aniline (21.4 g.) and aniline hydrochloride (1.6 g.) were heated for one and one-half hours under carbon dioxide at 175°. The aniline was then removed by distillation under atmospheric pressure, and the remaining tar refluxed with 100 cc. of glacial acetic acid for one hour. On cooling, 4 g. of solid separated, which gave 2.8 g. of pure material after four recrystallizations from a mixture of equal parts of glacial acetic acid and acetic anhydride; yield 18%. In preparations in which impure α-acetylnaphthalene (contaminated with the β-isomer) was used, only tars separated from the acetic acid solution on cooling. However, it was found that an attempt to purify the acetic acid solution by boiling with decolorizing carbon caused the adsorption of the 1,3,5-tri-α-naphthylbenzene on the carbon, from which it could be recovered in a relatively pure condition by extraction with a glacial acetic acid–acetic anhydride mixture. The substance crystallizes in white, flat needles with rounded ends; m. p. 190.5–191°; it gives no color with concentrated sulfuric acid.

Anal. Calcd. for $C_{36}H_{24}$: C, 94.69; H, 5.31; mol. wt., 456. Found: C, 94.61; H, 5.40; mol. wt. (Rast), 466, 450.

1,3,5 - Tri - β - naphthylbenzene.—β - Acetylnaphthalene (Eastman Kodak Co.) (19.2 g., 0.113 mole), aniline (15.6 g.) and aniline hydrochloride (1.2 g.) were heated for four and one-half hours under carbon dioxide at 175°. After the reaction mixture had stood in the ice box for one day, 5.5 g. of crystalline material had separated. Three recrystallizations from toluene gave 3.4 g. of pure substance; yield 20%; white needles; m. p. 234–235°; gives no color with cold concentrated sulfuric acid; less soluble than tri-α-naphthylbenzene in common solvents.

Anal. Calcd. for $C_{36}H_{24}$: C, 94.69; H, 5.31; mol. wt., 456. Found: C, 94.58; H, 5.38; mol. wt. (Rast), 462, 468.

Summary

1,3,5-Tri-*p*-diphenylbenzene, 1,3,5-tri-α-naphthylbenzene and 1,3,5-tri-β-naphthylbenzene have been prepared from *p*-acetyldiphenyl, α-acetylnaphthalene and β-acetylnaphthalene, respectively, by the action of aniline and aniline hydrochloride.

Studies in the Physical Chemistry of Amino Acids, Peptides and Related Substances. VII. A Comparison of the Solubility of Amino Acids, Peptides and their Derivatives

BY THOMAS L. MCMEEKIN, EDWIN J. COHN AND JOHN H. WEARE

I. Introduction

The solubilities of α-amino acids[1] and certain of their derivatives[2] in water and ethyl alcohol have been reported previously. Although the solubility measurements themselves suggest certain generalizations, such as that solubility in water increases with the dipole moment, and diminishes with the length of the paraffin chain, the exceptional behavior of certain molecules has been noted and associated with differences in crystal lattice energy. If the ratio of solubility in two solvents be compared, this disturbing factor is eliminated and more precise rules may be deduced. One of these states that the ratio of the solubility in alcohol to that in water is increased threefold for each CH_2 group in hydrocarbon chains terminating in methyl groups. This rule holds not only for amino acids but for other sufficiently insoluble compounds such as the formyl amino acids, hydantoins and hydantoic acids.[2] In terms of mole fraction of solute in water, N_0, and ethanol, N_A, it may be written

$$\log N_0/N_A = K_2 + 0.49\ (CH_2)_n \qquad (1)$$

where n is the number of CH_2 groups and K_2 a constant depending upon the nature of the polar groups.

A further rule is implicit in the above equation, for it suggests that changes in the logarithm of the solubility ratio are additive not only for non-polar but for polar groups. Thus the change in the ratio of solubility from water to alcohol, tentatively ascribed to dipolar ionization, has been estimated by a comparison of α-amino acids and their hydantoic acids. Subtracting the logarithm of the solubility ratio of the uncharged hydantoic acids ($N\mu_A/N\mu_0$) from that of α-amino acids (N_{zA}/N_{z0}), we obtained

$$\log f_e = \log N_{zA}/N_{z0} - \log N\mu_A/N\mu_0 = 3.85 - 1.12 = 2.73 \qquad (2)$$

This calculation neglects the influence of the amide linkage and also the movement of the proton which results in the dipolar ion structure of amino acids and peptides. The amide group and the peptide linkage, which generally decrease solubility, are further considered in the present investigation, in which the above rules are extended to both solvents and solutes of different dipole moments. On the one hand, we have extended equation (1) to a variety of solvents, including higher alcohols, acetone and a solvent more polar than water, namely, formamide. On the other, we have extended the applicability of equation (2) to amino acids and peptides of long dipole moments.

II. Methods and Materials

The same methods of determining solubility were employed as have been described previously.[1,2] The concentrations of the hydantoic acids were usually determined by direct titration, advantage being taken of their acidic properties. The concentrations of the amino acids and peptides were determined by dry weight, or by Kjeldahl nitrogen analysis. In cases where the solubilities were very small, the concentrations were determined by digestion followed by direct Nesslerization. The solubility of amino acids in formamide was determined by precipitating the amino acids with one volume of alcohol and four volumes of ether. After standing for twenty-four hours, and washing, the insoluble amino acids were weighed. Nitrogen analyses and melting point determinations on the precipitates from formamide demonstrated that they were pure amino acids.

Solvents.—Density or boiling point determinations were always used to verify the purity of the solvents employed. In all cases the appropriate blank determination was made on the solvent. The butanol was redistilled and the fraction used boiled at 117–118°. The formamide prepared by crystallization at $-5°$ was neutral in reaction, free from ammonium salts, melted from -3 to $-1°$ and had a specific conductivity of 4×10^{-5}.

Substances.—The purification of the α-amino acids and the preparation of hydantoic acid, methylhydantoic acid, formylglycine and formylaminobutyric acid have been described previously.[1,2] The same method sufficed for all the hydantoic acids, save those of peptides. In the case of peptide hydantoic acids the reaction was carried out at room temperature for two hours before acidification. For convenience in comparing amino acids with their corresponding uramido acid derivatives, the uramido acid is designated as a hydantoic acid of the amino acid. The more accurate chemical names are given in parentheses in the description of preparations.

β-Alanine Hydantoic Acid (β-Uramidopropionic Acid).—There was a slight variation in the solubility of this compound, indicating decomposition during the solubility determination, or an impure product. The preparation

was repeated a number of times, always giving a product of the same properties, and melting between 168–169°.

Anal. Calcd. for $C_4H_8O_3N_2$: N, 21.2; eq. wt., 132.07. Found: N, 21.1; eq. wt., 132.1.

α-Aminocaproic Hydantoic Acid (α-Uramidocaproic Acid).—The pure substance melted at 169–170°.

Anal. Calcd. for $C_7H_{14}O_3N_2$: N, 16.08; eq. wt., 174.1. Found: N, 16.0; eq. wt., 174.2.

ϵ-Aminocaproic Hydantoic Acid (ϵ-Uramidocaproic Acid).—The pure substance melted at 179–180°.

Anal. Calcd. for $C_7H_{14}O_3N_2$: N, 16.08; eq. wt., 174.1. Found: N, 16.1; eq. wt., 174.6.

δ-Aminovaleric Hydantoic Acid (δ-Uramidovaleric Acid).—The pure substance melted at 179–180°.

Anal. Calcd. for $C_6H_{12}O_3N_2$: N, 17.49; eq. wt., 160.1. Found: N, 17.4; eq. wt., 160.8.

Diglycine Hydantoic Acid (Carbamidoglycylglycine).—The substance melted at 194–195°.

Anal. Calcd. for $C_5H_9O_4N_3$: N, 24.0; eq. wt., 175.09. Found: N, 23.9; eq. wt., 175.0.

Triglycine Hydantoic Acid (Carbamidodiglycylglycine). The substance melted at 204–205°.

Anal. Calcd. for $C_7H_{12}O_5N_4$: N, 24.1; eq. wt., 232.08. Found: N, 24.0; eq. wt., 231.9.

β-Alanine was prepared by a modification of the method of Mulder.[3] β-Bromopropionic acid was allowed to stand for seven days with a large excess of ammonia. The ammonia was removed and the substance purified by crystallization. After three crystallizations from alcohol–water mixtures the pure substance melted at 197–198°. Nitrogen: found, 15.5; calcd., 15.7.

ϵ-Aminocaproic acid was prepared by the method of Wallach.[4] Later samples were obtained from the University of Illinois. After three crystallizations, the substance melted at 201–202°. Nitrogen: found, 10.56; calcd., 10.69.

Triglycine was prepared by the method of E. Fischer.[5] Nitrogen: found, 22.1; calcd., 22.2.

III. Experimental Results

The solubility measurements upon amino acids and peptides are recorded in Table I and those upon their derivatives in Table II. Apparent molal volumes, calculated from the densities of many of the solutions studied, are recorded in Table III. The values previously ascribed to the CH_2, CONH, COOH and NH_2 groups[6] yield satisfactory estimates of the apparent molal volumes, Φ, of the hydantoic acids.

The observed apparent molal volumes of the amino acids and peptides are smaller than those calculated, as a result of the electrostriction of solvent molecules due to the charged groups of dipolar ions.[6]

Triglycine hydantoic acid	48.9	60.0	40.7	149.6	149.5

The aminocaproic hydantoic acids are so insoluble in water that no great confidence can be placed on the values of Φ estimated for this solvent. The apparent molal volumes of those molecules, sufficiently soluble to be studied in more than one solvent, vary to a small extent in the different solvents employed (Table IV).

Solubility in Alcohol–Water Mixtures.—Our previous communications have been concerned largely with α-amino acids and their derivatives. Two series of molecules, in which the ammonium groups are at a greater distance from the dissociated carboxyl groups, are here reported. In the one only non-polar CH_2 groups intervene between the charged groups, in the other (peptide) series, there is an alternation of CH_2 and CONH groups. Solubility in the first series appears to increase with increase in the dipole moment. Peptides of glycine on the other hand are less soluble the larger the number of glycine residues in the chain. This would appear to depend, at least in part, on close packing in the crystal lattice since peptides containing side chains of unequal lengths are often more soluble than those of glycine.[7] The hydantoic acids of both series

---

(7) Fischer, "Untersuchungen über Aminosäuren, Polypeptide und Proteine," Julius Springer, Berlin, 1906, Vol. I, p. 333.

have been prepared and are far less soluble in water than the dipolar ions from which they were derived.

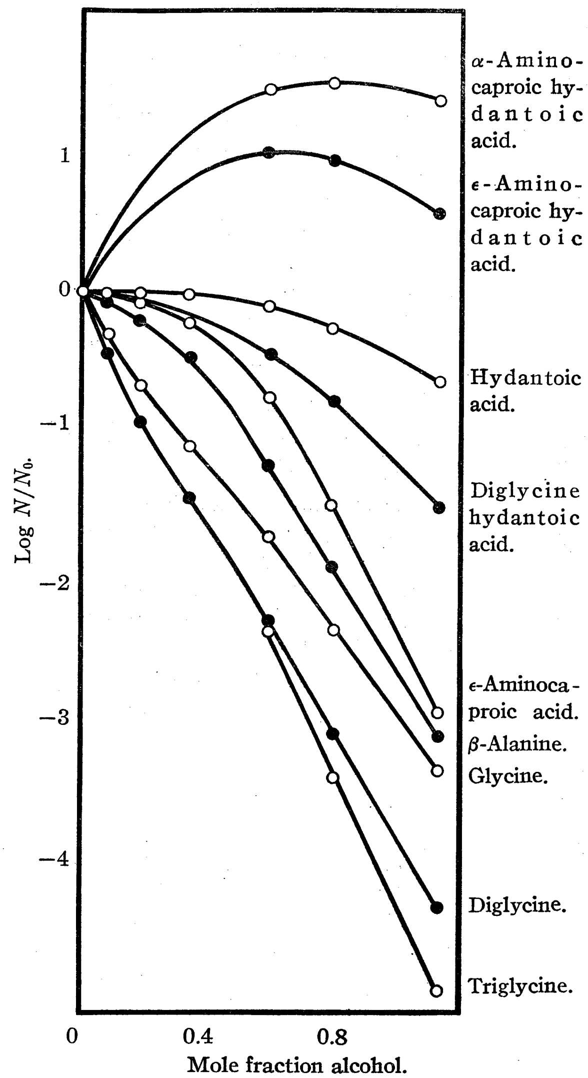

Fig. 1.

The ratio of the solubility, N, of these three classes of molecules in alcohol–water mixtures, to that in water, N_0, is plotted in Fig. 1 against mole fraction alcohol. The shapes of the glycine, diglycine and triglycine curves are very similar. All have steep segments at low mole fractions of alcohol, with comparable points of inflection in the range in which the solvent molecules are approximately equal in number. In systems containing larger amounts of ethanol the logarithm of the solubility may as a first approximation be considered to vary inversely as the mole fraction of alcohol. Straight lines have been drawn through these segments of the curves of glycine and its peptides.

TABLE IV

APPARENT MOLAL VOLUMES OF HYDANTOIC ACIDS AT 25°

Solvent	Concentration, moles per liter	Molal volume, cc.
	Hydantoic acid	
Formamide	0.837	79.8
Water	.250	77.6
Methanol	.0797	68.2
80% Ethanol	.1256	75.7
90% Ethanol	.071	76.1
Ethanol	.0242	(63.2)[a]
	α-Aminocaproic hydantoic acid	
Formamide	0.165	150.6
Water	.0069	(146.4)[a]
Methanol	.1123	139.2
80% Ethanol	.0867	144.8
90% Ethanol	.0803	146.7
Ethanol	.0477	138.5

[a] Concentration too low for accurate measurements of molal volume.

The curves describing the behavior of hydantoic acids in alcohol–water mixtures also form a family though their shape is quite different from that of the amino acids and peptides from which they were derived. The additional peptide linkage in the hydantoic acid of diglycine, as compared with hydantoic acid, is reflected in decreased solubility; and the additional CH_2 groups of α-aminocaproic hydantoic acid in increased solubility in systems rich in alcohol. The curve of the latter substance is very similar to that of formylleucine or benzamide. The isomer, ε-aminocaproic hydantoic acid, in which the CH_2 groups all lie between polar groups, behaves far more like formyl-α-aminobutyric acid, that is to say, like a molecule with two less CH_2 groups. Its solubility in 80% ethanol is approximately tenfold that in water and threefold that in ethanol, a type of behavior characteristic of a class of proteins, the prolamines.

The measurements on β-alanine and ε-aminocaproic acid cannot be considered as accurate as those upon the other substances studied, in part because their large dipole moments render difficult their purification, in part because the great solubility which results from these moments renders difficult accurate solubility measurements.

The curves for β-alanine and ε-aminocaproic acid clearly belong to a third family. In systems rich in alcohol these curves approach the straight lines characteristic of glycine and its peptides. Small amounts of ethanol, however, have but very slight precipitating action on these amino acids of long dipole moment, presumably because of their very great solubility and, therefore, the very high dielectric constants of their saturated solutions in water. Assuming that the dielectric constant increments of these two substances remain the same in concentrated as in dilute solution,[8] the dielectric constants of a saturated aqueous β-alanine solution would be 300 and of ϵ-aminocaproic acid 370, or more than four times that of water. A comparable calculation yields an estimate of 72 for the dielectric constant of 80% ethanol saturated with ϵ-aminocaproic acid. Only at alcohol concentrations higher than these do the compositions of the solutions containing these amino acids approach those of the pure solvents. The shapes of these curves in solutions containing small amounts of alcohol appear to depend in large part upon the high dielectric constants of the solutions.

Solubility in Pure Solvents.—The conditions that obtain in pure solvents are simpler than those in alcohol–water mixtures. Water is by far the best solvent for the amino acids. Their solubility in alcohols is smaller the longer the hydrocarbon chain of the latter, but is smaller in acetone than in butanol, although the former has a higher dielectric constant. The solubilities of the amino acids are also smaller in formamide than in water, despite its higher dielectric constant.

Certain of the less polar derivatives of the amino acids are more soluble in other solvents than in water. Thus hydantoic acid is more soluble in formamide than in water, as is the hydantoic acid of α-aminocaproic acid which is moreover more soluble in all of the alcohols than in water. The influence of the hydrocarbon chain of the solute in increasing solubility in a solvent with a hydrocarbon chain of somewhat the same length is also reflected by the measurements upon formyl α-aminobutyric acid.

Influence of the Hydrocarbon Chain.—The influence of the hydrocarbon chain is more readily examined, as we have previously shown[1,2] if we consider the solubility ratio. Values of log N/N_0 are plotted against the number of CH_2 groups, in the molecule $n\mathrm{CH_2}$ in Fig. 2. The values for glycine, alanine, diglycine and hydantoic acid are from Studies II and III of this series.[1,2] Straight lines are drawn connecting the experimental values even when only two members of the series have been studied, since no exception has been found to the rule that provided CH_2 groups are in hydrocarbon chains terminating in methyl groups, the increase in log N/N_0 for each additional CH_2 group is, within the limits of error, identical, whether we are comparing amino acids or their derivatives (Table V). This influence of the CH_2 group is smaller for formamide than for methanol, and for methanol than for ethanol. There is no significant difference between the previously published coefficient for CH_2 groups between water and ethanol, 0.49,[1] and that for acetone. The coefficient for the higher alcohols is slightly greater. The value of 0.53 appears to be reached with butanol, and is not increased by further increase in the CH_2 groups of the solvent. It is probable that still greater influences of the CH_2 groups of the solvent might, however, be observed were we to study solutes of longer hydrocarbon chains.

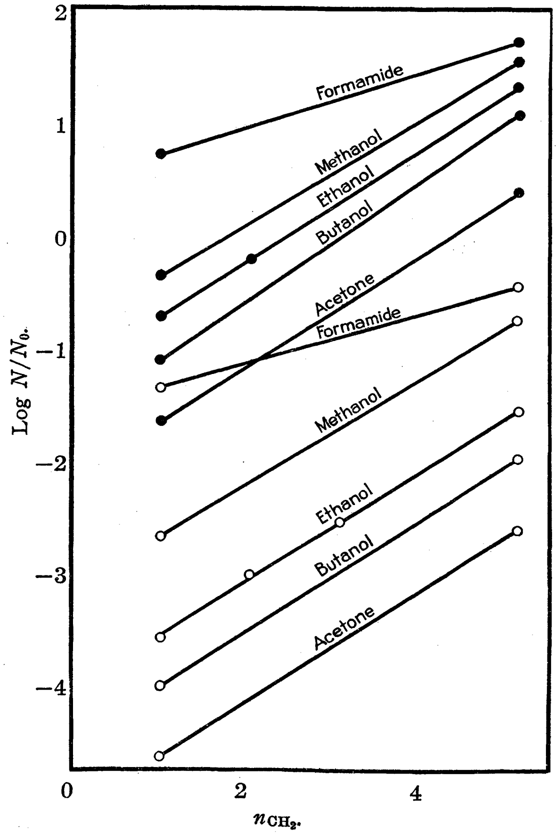

Fig. 2.—Solubility ratios of amino acids ○, and hydantoic acids prepared from them ●, in different solvents.

The influence of the CH_2 groups would appear to increase inversely as the dielectric constant of the solvent (Table IX), were we considering only the alcohols and acetone. Formamide, however,

α-Aminocaproic hydantoic acid	5	+1.118	.532
Heptanol			
Formylglycine	1	−0.880	
Formyl α-aminobutyric acid	3	+0.173	0.527

has a higher dielectric constant than water, and we must therefore conclude that its behavior in these studies is determined, at least in part, by factors other than the dielectric constant.

Influence of Dipolar Ion Structure.—The same solubility ratios may be employed in estimating the influence of dipolar ion structure, by means of equation (2). This calculation is carried out in Table VI, which in conjunction with Table V demonstrates the additivity of the influence of the paraffin chain and of dipolar ionization. The value of 2.73, derived from the previous comparison[1] of all α-amino acids (corrected for the influence of the CH_2 group) with hydantoic and methyl hydantoic acid, holds also for the measurements in Table VI.

The comparison of the peptides of glycine with their hydantoic acids reveals no difference in the free energy change from water to ethanol with change in the dipole moment. This is contrary to what was expected on the basis of theoretical calculations, which suggested that this quantity would increase with increase in the dipole moment[1] (p. 2275).[9,10] The influence of dipolar ionization does not appear to be greater in the case of triglycine than of diglycine, or of diglycine than of glycine.

Influence of the Amide Group.—Hydantoic acids terminate in an amide group not present in the amino acids or peptides from which they are derived. In this, as in previous calculations, we have considered that the terminal $CONH_2$ group has but very small influence. This notion was deduced from a comparison of the solubility in water and ethanol of glycine with glutamine and asparagine. The measurements upon asparagine

Acetone		
Glycine	−4.401	
Hydantoic acid	−1.520	−2.88
α-Aminocaproic acid	−2.432	
α-Aminocaproic hydantoic acid	+0.437	−2.87

TABLE VII

SOLUBILITY RATIOS OF DIPOLAR IONS IN WATER AND ETHANOL

	Log N_A/N_0	Δ Log N_A/N_0
Glycine	−3.391	
Asparagine	−3.402	−0.011
Glutamine	−3.466	− .064
Diglycine	−4.367	− .976
Triglycine	−4.965	−1.574

are perhaps the more accurate and the difference between its solubility ratio and that of glycine must be considered within the errors of experiment. The influence of the amide group was, therefore, considered negligible.

If we assume the influence of dipolar ion structure on the solubility ratio to be that estimated in Table VI, we may subdivide the influence of the amide group into two parts. Thus, subtracting 2.73 from the value for glycine should yield −0.66 for its hypothetical uncharged isomer; a value not very different from that determined for glycol amide, which has the same composition though a different structure. The value for formylglycine is −0.33. The difference +0.33 might be considered to yield the effect of the carbonyl group. Comparable calculations could be made by comparing the other formyl compounds that have been studied with the corresponding amino acids.

Formylglycine and hydantoic acid differ by an NH group. The change in their solubility ratios is given below:

	Log N_A/N_0	Δ Log N_A/N_0
Formylglycine	−0.33	
Hydantoic acid	− .63	−0.30

According to this calculation the influences of the CO and NH groups are opposite in sign, as might have been expected from the small apparent influence of terminal amide groups on the solubility ratios reported.

Influence of the Peptide Linkage.—Quite different is the influence of the peptide linkage. Glycylglycine and asparagine are isomers. The comparison of glycine and its peptides with their hydantoic acids (Table VI) indicates that variation in the dipole moment of the molecule has no measurable influence on the change in free energy in passing from water to ethanol. The great difference in Δ log N_A/N_0 between glycine and its peptides (Table VII) would therefore appear to be due to the CONH group between polar groups. The negative value of log N_A/N_0 for diglycine is larger than that for glycine by −0.976. The comparable value for triglycine, −1.574, is only −0.598 larger. The smaller influence of the second peptide linkage presumably is related to the greater distance of CH_2 and CONH groups in the larger molecule from the polar terminal groups.

Influence of CH_2 Groups between Polar Groups.—That CH_2 groups situated between polar groups have but slight influence on the solubility ratio has previously been demonstrated by comparison of aspartic with glutamic acid, and of asparagine with glutamine. Since there is no appreciable change in the solubility ratio, when instead of one CH_2 group two are present between polar groups, we assumed that the first also behaved as though it was not subject to the rule valid for CH_2 groups in the paraffin chain. With increase in the number of groups between polar groups intermediate behavior should obtain. This phenomenon has been investigated by studying the hydantoic acids of α, β, δ, and ε-amino acids. It will be observed that the larger the number of CH_2 groups between polar groups the greater the influence of each upon the solubility ratio (Table VIII). The coefficient per CH_2 group between the hydantoic acid of an α- and β-amino acid is but 0.167, whereas that between comparable δ- and ε-compounds is more than twice as great, namely 0.397, approaching that characteristic of the paraffin chain.

TABLE VIII

INFLUENCE OF THE POSITION OF GROUPS UPON THE SOLUBILITY RATIO IN ETHANOL AND WATER

	Number of CH_2 groups, n	Log of soly. ratio, $\log N/N_0$	$\frac{\Delta \log N/N_0}{\Delta n_{CH_2}}$
Hydantoic acid	1	−0.630	0.167
β-Alanine hydantoic acid	2	− .463	.308
δ-Aminovaleric hydantoic acid	4	+ .152	.397
ε-Aminocaproic hydantoic acid	5	+ .549	.495
α-Aminocaproic hydantoic acid	5	+1.352	

Comparison of the solubility ratio of ε-aminocaproic acid in water and ethanol with that of its hydantoic acid constitutes the one exception noted thus far to the rule deduced in Table VI, and suggests that CH_2 groups between the charged groups of a dipolar ion have a smaller influence than those between other polar groups at this distance from each other. This is not unexpected since the moment of the former is more than ten times that of the widely separated polar groups of this hydantoic acid.

	$\log N_A/N_0$	$\Delta \log N_A/N_0$
ε-Aminocaproic acid	−2.972	
ε-Aminocaproic hydantoic acid	+0.549	−3.521

Discussion.—The influence of the polar and non-polar groups of molecules upon solubility has been stressed previously.[11–13] "A comparison of various insoluble substances has proved that the spreading tendency depends upon the presence of certain active groups of radicles in the organic molecule, these being the groups which tend to increase the solubility of organic substances in water. For example, pentane, C_5H_{12}, is practically insoluble in water, but amyl alcohol, $C_5H_{11}OH$, is relatively soluble. Thus the hydroxyl groups in organic molecules exert strong attractive forces on the hydroxyl groups in the water molecules and these manifest themselves by an increase in solubility. Similarly the carboxyl group, COOH, tends to make the lower fatty acids much more soluble in water than the corresponding hydrocarbons"[13] (p. 161).

"Traube found that with molecules of aliphatic compounds having different lengths of hydrocarbon chains" the decrease in the surface tension of the pure liquid, divided by the osmotic pressure of the dissolved substance in the underlying solution, "for dilute solutions increases about threefold for each CH_2"[13] (p. 164). Our investigations confirm the applicability of Traube's rule[14] to the ratio of solubility in water and organic solvents.

The accuracy with which the above rule appears to hold even when solubility is not very low was, however, not foreseen. Thus in all the solvents studied there was no appreciable difference between the coefficient for the CH_2 group calculated from glycine and α-aminocaproic acid and from the far less soluble hydantoic acids (Table V), despite the high solubility of glycine and the high dielectric constant of its aqueous solution. This result may mean that the logarithm of the activity coefficient of glycine in saturated aqueous solution is not very large. Scatchard[15] estimates this quantity to be about −0.15 from freezing point determinations.

The CH_2 rule appears to hold for monoamino monocarboxylic α-amino acids as well as for their derivatives, but not for dicarboxylic acids, where the hydrocarbon chain terminates in a carboxyl group. The study of the hydantoic acids of β-, δ- and ε-amino acids suggests that interaction between the carboxyl, amide and CH_2 groups extends to the neighboring CH_2 groups, but not very much farther. The term interaction is used since the present studies yield no evidence as to whether polar groups are masking the effect of non-polar groups, or non-polar those of polar groups.

This interaction appears to extend to a greater distance, in the case of CH_2 groups between the charged groups of a dipolar ion. None the less, the fields of force set up must be restricted largely to the intervening atoms and cannot extend very far beyond them. Otherwise, the simple CH_2 rule would not apply to α-amino acids, for the co-

efficient relating glycine and alanine would be different from that relating norvaline and norleucine.

Finally the results reported as solubility ratios may be transformed into calories and compared with the studies of Butler and his co-workers,[16] who have considered the free energy change, ΔF, from the gaseous state to aqueous solution. Our results recalculated (Table IX) suggest that the free energy increment for the CH_2 group in aqueous solutions referred to alcohols, ranges from 600 to 700 calories. Butler estimates the free energy in aqueous solution referred to the gaseous state as 200 calories per CH_2 group. Butler further estimates a change in free energy of about 6000 calories if NH_2 be substituted and 7400 calories if COOH be substituted in the paraffin chain.

The free energy in aqueous solution referred to alcohols due to dipolar ionization we estimate at -3000 to -4000 calories. This estimate is based on the comparison of the amino acids and the hydantoic acids and includes, as has previously been pointed out, effects due to the amide group and to the movement of the proton from the carboxyl to the ammonium group.

TABLE IX

Solvent	Dielectric constant[a]	Influence of CH_2 groups $\Delta \log N/N_0$	ΔF, cal.	Influence of dipolar ionization $\Delta \log N/N_0$	ΔF, cal.
Formamide	>84	+0.23	314	−2.03	−2768
Methanol	32.71	+ .44	600	−2.24	−3054
Ethanol	24.28	+ .49	668	−2.73	−3722
Acetone	20.83	+ .49	668	−2.87	−3913
Butanol	17.51	+ .53	723	−2.82	−3845
Heptanol	9.33	+ .53	723	....	....

[a] We are indebted to Dr. Wyman for measuring the dielectric constants of the solvents employed. The value for formamide is taken from "Int. Critical Tables," Vol. VI, p. 83.

These quantities define all the solubility measurements reported. They reveal no exceptional behavior such as was expected, due either to interaction between dipolar ions in concentrated aqueous solution, or to the changing ratio of dipolar ions and uncharged molecules in solvents of low dielectric constant. Moreover they do not reveal change in $\Delta \log N/N_0$ or of ΔF with change in the reciprocal of the dielectric constant, such as would be expected. The relations that obtain, however, appear to be far simpler than could have been predicted.

Summary

1. The solubilities of amino acids and peptides of different dipole moments have been studied in various solvents at 25°.

2. The logarithm of the ratio of solubility in any solvent, N, to that in water, N_0, is increased by a constant amount for each CH_2 group in hydrocarbon chains terminating in methyl groups. This amount is 0.53 for butanol and heptanol, 0.49 for acetone and ethanol, 0.44 for methanol and 0.23 for the most polar solvent studied, formamide.

3. When only one or two CH_2 groups are situated between polar groups the solubility ratio is but little affected. The larger the number of CH_2 groups situated between polar groups the more nearly the solubility is influenced, as in hydrocarbon chains ending in methyl groups.

4. CH_2 groups situated between the charges of a dipolar ion influence the solubility ratio far less than those between other polar groups. The electric moments of dipolar ions are generally more than fivefold as great as the moments of the carboxyl, hydroxyl, amine or amide groups.

5. Solutions of dipolar ions such as β-alanine and ϵ-aminocaproic acid are so concentrated and have such high dielectric constants that conditions existing in them must be considered different from those in the pure solvent.

6. The peptides of glycine are all less soluble than glycine and so are other α-amino acids and the hydantoic acids derived from them. Comparison of the solubility ratios of these dipolar ions with their hydantoic acids yields, as estimates of the influence of dipolar ionization upon the logarithm of the solubility ratio, -2.03 from water to formamide, -2.24 to methanol, -2.73 to ethanol, -2.82 to butanol and -2.87 to acetone.

7. The comparison of the peptides of glycine with their hydantoic acids has revealed no change in solubility ratio with change in the dipole moment of the peptide.

Acid Catalysis in Sulfuric Acid–Acetic Acid Solutions. The Rate of Bromination of *m*-Nitroacetophenone[1]

BY MARTIN A. PAUL AND LOUIS P. HAMMETT

Previous papers have given applications of indicator measurements to the study of acid catalysis in solutions containing water.[2-4] Over wide ranges of composition, direct proportionality was found between the acidity of the medium as measured by simple basic indicators[2] and the speeds of certain reactions. These results led us to make a similar investigation in a solvent, glacial acetic acid, which is of great utility as a medium for organic reactions and in which the pioneer work of Hall and Conant[5] on super-acid solutions was carried out.

The reaction studied was the bromination of *m*-nitroacetophenone, which proceeds at a rate suitable for measurement in dilute solutions of sulfuric acid in acetic acid. It is a case of the frequently studied acid-catalyzed ketone halogenation.[6] It is characteristic of this type of reaction that the rate is independent of the halogen concentration, but is proportional to the concentration of ketone. The reaction in dilute aqueous solutions exhibits the phenomena of general acid catalysis in the Brönsted sense and is also subject to a pronounced catalysis by bases.

With this ketone and under the conditions of low ketone concentration necessary to keep the rate within reasonable limits at the high acidities encountered, the method used by previous investigators,[6] namely, dilution of a sample of the reaction mixture with water containing a small excess of potassium iodide and some sodium acetate and titration with thiosulfate of the liberated iodine, was entirely unsatisfactory. The difficulty arises from the fact that the monobrominated acetophenone derivative halogenates further in the diluted aqueous solution at a rate which seriously affects the titers obtained. The same phenomenon exists with ω-bromoacetophenone as with its nitro derivative, but the magnitude of the effect is smaller. In the original sulfuric–acetic acid mixtures, the rate of bromination of these brominated ketones is small relative to that of the unbrominated compounds while the latter use up iodine at a negligibly small speed in the solutions diluted with water. Apparently bromine substitution in the methyl group of these compounds shifts the catalytic minimum (the acid concentration separating the region of predominantly acid catalysis from that in which basic catalysis is most important) to quite high acidities, especially for the ketone brominating more slowly. This is in accord with the trend noted by Watson and Yates[6l] for the brominated acetones. An aqueous acetate buffer acts therefore as a powerful basic catalyst for the halogenation of ω-bromo-*m*-nitroacetophenone. Applied to Watson's data[6m,n] on halogenation in an acetic acid, water, hydrochloric acid mixture, our observations indicate that, for the ketone *m*-nitroacetophenone, toward the end of a run the rate of disappearance of iodine from the solutions diluted for titration may have been nearly as great as the rate of disappearance of bromine from the undiluted reaction mixture. Unless only initial titers were used in computing rate constants, his value for this ketone may therefore be high.

A colorimetric method of the sort used by Bartlett and Vincent[7] in the study of the iodination of menthone proved entirely satisfactory and was therefore used throughout this work.

Experimental

Apparatus.—The colorimeter was the Bausch and Lomb instrument used in previous work.[8] The mirror was replaced by an illuminator similar to that described by Beaver.[9] The scales were calibrated and had no error exceeding ±0.1 mm. For indicator measurements in acetic acid solutions, a closed cell with plane parallel ends, described by Hammett and Deyrup,[2] was employed.

For the rate measurements, one cup of the colorimeter was fitted with a jacket having a bottom made of optically clear glass (Fig. 1). Water from a thermostat was circulated through it by means of an air-lift pump and, with suitable insulation, the contents of the cup could be kept at 25.00 ± 0.01°. This precision was quite adequate for our purpose, estimating the temperature coefficient of the bromination of acetophenone derivatives in solution to be about 20% per degree.[6n]

To reduce evaporation of bromine, each cup had a closely fitting glass cap with a hole bored through of diameter slightly larger than that of the plungers. Loss of bromine from the cups so equipped was less than 2% per hour, negligible since no runs lasted longer than an hour.

Method: Indicator Measurements.—Indicator measurements were made essentially according to the method of Hammett and Deyrup.[2] The reference solution was acetic acid containing enough sodium acetate (about 0.5 molar) to completely convert the bases to their colored uncharged forms. Absorption of water from the atmosphere by this solution during a set of observations was found to be too small to affect readings.

Method: Rate Measurements.—As a reproducible color standard for measuring the concentration of bromine in acetic acid solutions, bromine water prepared freshly as needed from a standard potassium bromate solution by addition of potassium bromide (100% excess) and sulfuric acid (final concentration about 0.5 molar) was adopted. The specific color intensities of bromine in the two media are different due, no doubt, to a shift in the absorption spectrum, but the yellow colors nevertheless may be matched without difficulty.[10] Accordingly, solutions of bromine in acetic acid were made up and their concentrations determined by titration. The apparent concentrations of 0.00500 and 0.00250 molar bromine water were determined against each of these by colorimetric comparison. These experiments tested the constancy of the concentration–color intensity ratio (Beer's law) for bromine dissolved in acetic acid. For six concentrations of bromine covering the range 0.006–0.001 molar, the concentration c_S of bromine in glacial acetic acid colorimetrically equivalent to 0.00500 molar bromine water was 0.00381 ± 0.00004 molar and to 0.00250 molar bromine water, 0.00191 ± 0.00003 molar. Deviation from Beer's law in the range examined is thus within the precision of matching (2–5%). The 0.00500 molar bromine water was found to be equivalent to 0.00415 molar bromine in the mixed solvent acetic acid–water in the mole ratio 1–1.

The precedure was to make up a solution of ketone, sulfuric acid and acetic acid by weight in a 25-ml. glass-stoppered volumetric flask and to bring to mark with acetic acid at 25°. The flask was then kept in the thermostat for at least fifteen minutes while water was circulated through the jacket of the reaction cup. Standard bromine water was prepared and introduced into the other cup of the colorimeter. A drop of bromine was then added to the flask, a stop watch (calibrated by telephone time) started, the solution thoroughly shaken and a sample poured into the jacketed cup. The latter was immediately racked to a convenient height, r, and left there during the run. Readings of the length, h, of the standard solution required to balance colorimetrically the "unknown" were taken at times, t, read to the nearest one-tenth minute. The first reading could be made within one and one-half to two minutes after addition of the bromine, while mixing and transfer of the solution took about one-half minute. The initial ketone concentration, c^0_K, was between 0.005 and 0.05 molar and was always so chosen as to have the run last between twenty and sixty minutes.

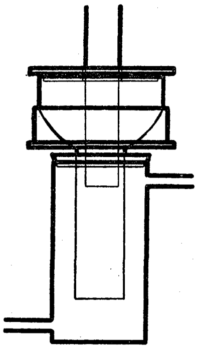

Fig. 1.—Diagram of colorimetric reaction cup.

Rate Calculations.—Previous investigators have used ketone concentrations so much larger than the bromine concentration that the reaction rate, which is independent of the latter concentration, is essentially constant throughout the run. This procedure would give rates at the higher acidities much too large to be measured, but its abandonment requires some variations in the usual calculation of the rate constant. The fundamental equation is

$$-\frac{dc_K}{dt} = -\frac{dc_{Br_2}}{dt} = kc_K \qquad (1)$$

where c_K is ketone concentration and c_{Br_2} is bromine concentration. Using superscript zero to denote initial concentrations at time zero we have

$$-dc_{Br_2}/dt = kc_K = k\ \{c^0_K - (c^0_{Br_2} - c_{Br_2})\} \qquad (2)$$

The integrated equation is

$$\ln\left(1 - \frac{c^0_{Br_2} - c_{Br_2}}{c^0_K}\right) = -kt \qquad (3)$$

Experimentally the bromine concentration is given by

$$c_{Br_2} = c_S(h/r) \qquad (4)$$

where h and r are the previously defined colorimeter readings. Substituting in (3) we obtain

$$\ln\ \{1 - (h_0 - h)\ (c_S/rc^0_K)\} = -kt \qquad (5)$$

For the initial readings ($h_0 - h$ small) this reduces to

$$(h_0 - h)\ (c_S/rc^0_K) = kt \qquad (6)$$

In calculating the constant for a run, equation 6 was applied to the initial experimental points and the value of h_0 thus obtained was used in equation 5 to obtain the value of k, all experimental points being used. Both calculations were made by the method of least squares. In no case did the mean error in k from a single run exceed 5%. Figure 2, in which h and the quantity $c \equiv -\log\ \{1 - c_S\ (h_0 - h)/rc^0_K\}$ are plotted against t, is a graphical representation of the re-

sults of a typical experiment. Conformity of the data with equation (5) for different initial ketone and bromine concentrations establishes the validity of the assumptions that the rate of reaction is independent of the latter and proportional to the former. That ω-bromo-*m*-nitroacetophenone is the product was proven by obtaining this compound on dilution with water when a run was tried using a relatively high concentration of *m*-nitroacetophenone. In the range of acidity studied, the rate of bromination of this product is negligibly small at the concentrations at which it was present, but at higher acidities, it is great enough to make independent measurements of the rate for the unbrominated ketone impossible. Lower acidities were not tried for fear of auto-catalysis by hydrobromic acid.

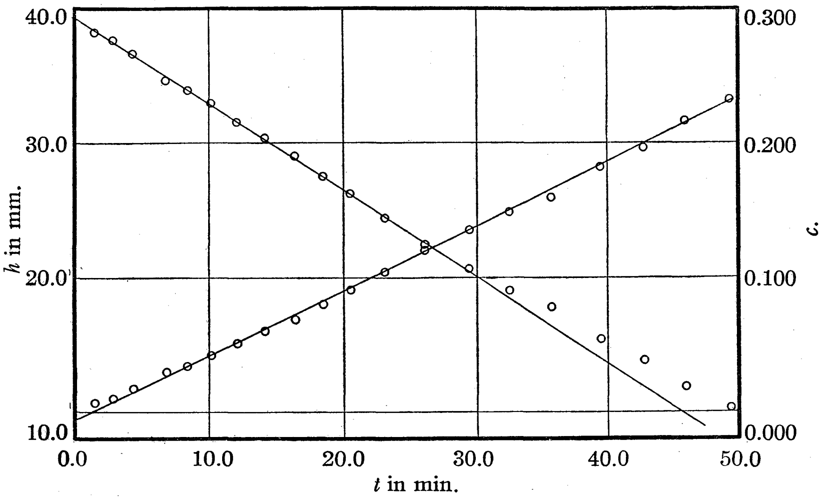

Fig. 2.—Graphical representation of typical bromination experiment: $c°_K$ = 0.01015 mole/liter; $c_{H_2SO_4}$ = 0.0609 mole/liter.

Materials.—Acetic acid was prepared from commercial 99.5% reagent by the method of Orton and Bradfield.[11] Samples reacting with bromine were rejected. The water content, estimated by the freezing-point method, was between 0.3 and 0.1%. No extraordinary precautions other than rapid manipulation were taken to keep out water from the atmosphere during experiments. No effect on the measurements from this source could be detected. In fact, many of the runs were made with just sufficient acetic anhydride (prepared by fractional distillations of the commercial C. P. reagent) added to react with the quantity of water present. Orton and Jones[12] have shown that this reaction is very rapid in acetic acid in the presence of a small concentration of sulfuric acid. No significant difference could be detected between rates of bromination in this medium and in 99.8% glacial acetic acid. Of course, measurements were impossible on very humid days.

Sulfuric acid was prepared by distillation of 50% fuming acid into C. P. concentrated reagent and dilution with more of the latter to maximum freezing point.

m-Nitroacetophenone was recrystallized to constant melting point, 77.3° from ethyl alcohol and water.

Bromine was of analytical reagent grade.

Potassium bromate was recrystallized twice from water and dried at 180°. Its equivalent weight was within 0.1% of the theoretical value when checked with that of potassium iodate purified in the same way. The latter was used as primary standard for calibration of thiosulfate solutions. Potassium bromide was recrystallized from water and was bromate free.

Results

Table I contains the results of indicator measurements in sulfuric acid–acetic acid solutions. *M* is molality of sulfuric acid, c_{BH^+} and c_B are concentrations of indicator acid and base, and H_0 is the acidity function. The pK' of −0.17 for *o*-nitroaniline is from previous work.[8] The difference in basic strength of the two indicators employed is the same within experimental error as for aqueous solutions of strong acids.[2,3] Data for solutions containing sodium bisulfate (prepared by mixing an acetic acid solution of sodium acetate with excess of a solution of sulfuric acid in acetic acid) and for solutions of sulfuric acid in the mixed solvent, acetic acid–water in mole ratio 1–1, are included. Table II gives mole fractions of sulfuric acid required to produce the same simple basic indicator acidity in the three media, water, acetic acid and their equimolar mixture.

Table III summarizes the results of measurements of the rate of bromination of the ketone *m*-nitroacetophenone in sulfuric acid–acetic acid solutions. The unimolecular velocity constants, *k*, are expressed in natural logarithms and minutes. Measurements in solutions containing the salt sodium bisulfate and in solutions of sulfuric acid in mole-to-mole acetic acid–water are also given. In Fig. 3, log *k* is plotted against H_0 of the medium. We have measured the reaction rate in the medium used by Evans, Morgan and Watson,[6n] 0.5 molar hydrochloric acid in 75% acetic acid–water by volume and our value for *m*-nitro-

RATE OF BROMINATION OF *m*-NITROACETOPHENONE IN 0.5 MOLAR HCl IN THE MEDIUM 75% ACETIC ACID IN WATER BY VOLUME

$$k = 0.000396 \pm 0.000005$$
$$.000395 \pm .000007$$

In terms of "fall of 0.02 *N* thiosulfate titer per minute per 20 cc. of solution containing 0.1 molar ketone concentration," this constant would have the value 0.079. Evans Morgan and Watson[6n] have reported 0.099.

Discussion

As was to be expected and has been reported by Hall and Spengeman[13] on the basis of more extensive data than ours, a solution of sulfuric acid in glacial acetic acid is much more acid than one of the same sulfuric acid concentration in water. Our measurements on solutions in the equimolar mixture of the two solvents show that this medium resembles water much more nearly than it does acetic acid. This is true no matter what concentration scale is used, but is especially true, as Table II shows, on the basis of mole fractions. The mole fraction of sulfuric acid necessary to produce a given value of H_0 in the mixed solvent is nearly identical with that required to produce the same acidity in water alone, whereas a much smaller mole fraction of the strong acid is required in glacial acetic acid.

Qualitatively the behavior of the reaction rates is parallel. The concentration of sulfuric acid required to produce a given rate is much higher in the mixed solvent than in glacial acetic acid, and in either solvent an increase in H_0 is accompanied by an increase in rate. The kind of simple quantitative correlation between reaction rate and indicator acidity which we have previously found in mixtures of strong acids with water is however lacking. In the first place, we note that two solutions, one in glacial acetic acid, the other in the equimolar acetic acid–water mixture, which possess the same value of H_0, do not necessarily give rise to equal reaction rates. Obviously we have to deal with specific effects of the solvent upon the rate.

Furthermore, the plot (Fig. 3) of log *k* against H_0 for the experiments in glacial acetic acid, while satisfactorily linear, possesses a slope considerably greater than unity (about 1.6), a phenomenon not susceptible to any simple interpretation. Barring specific solvent effects, a reaction of ketone with solvated hydrogen ion would lead to unit slope in this plot, and unit slope has, indeed, been found for a number of reactions in mixtures of strong acids with water.[2–4] Although the data are too scanty for assurance, our few measurements in the mixed acetic acid–water solvent are not inconsistent with unit slope in this medium also. That the effect is due to catalysis by molecular sulfuric acid seems improbable for two reasons. In the first place, the activity of molecular sulfuric acid in the solvent acetic acid is known from the measurements of Hutchison and Chandlee,[14] and is fairly closely proportional to the molality of the sulfuric acid in dilute solutions. Our reaction rates, on the other hand, increase considerably more rapidly than the first power of the sulfuric acid molality. Furthermore, the magnitude of a catalysis by molecular acid should be increased by the addition of sodium bisulfate, and our results show that the salt has relatively little effect upon the rate.

It follows that specific effects are present in these acetic–sulfuric acid solutions which were absent in the aqueous solutions in which we have found simple proportionality between rate and acidity.[2–4] Further work will be necessary in order to determine the region within which these simple relations apply and to account for the existence of the specific effects.

Summary

By a colorimetric method the rate of bromination of the ketone *m*-nitroacetophenone has been measured in solutions of sulfuric acid in acetic acid of concentration varying from 0.016 to 0.15 molal. Measurements to establish the effect of sodium bisulfate upon the rate of the reaction in these solutions and a limited series of measurements in solutions in a mixed acetic acid–water solvent have also been made.

It has been found that in the acetic acid solution the rate of reaction increases with increasing sulfuric acid concentration more rapidly than does either the acidity function H_0, the stoichiometric concentration of sulfuric acid, or the activity of sulfuric acid.

Energy Levels in Electrochemistry. II

BY WILDER D. BANCROFT AND JAMES E. MAGOFFIN

In aqueous solutions sulfuric acid can only be reduced electrolytically when the concentration is very high. Raising the temperature is equivalent to increasing the concentration. Sodium sulfate and ammonium sulfate solutions cannot be reduced electrolytically at any concentrations and temperatures that can be reached in open vessels.

On the other hand sulfurous acid and sodium sulfite can easily be oxidized electrolytically to sulfuric acid and sodium sulfite. A sulfite–sulfate electrode is therefore a one-way electrode, the reaction being irreversible electrolytically.[1] It was shown in our previous paper[2] that at constant temperature and constant *p*H, the potential difference at a sulfite–sulfate electrode should be a function of the concentration of the sulfite and independent of the concentration of the sulfate as an oxidation product. Lewis, Randall and Bichowsky[3] found that at constant temperature and constant *p*H the change of electromotive force with change of concentration of sulfurous acid was described very well by the theoretical formula. They did not find that sulfate concentration had no effect because they varied the *p*H at the same time. This gap was filled by Noyes and Steinour[4] who showed that, "provided the hydrogen-ion concentration is nearly the same, hydrochloric acid and sulfuric acid produce (in association with sulfurous acid) substantially the same electromotive force."

Schaum[5] and von der Linde[6] found that the electromotive force of a sodium sulfite electrode varies with the concentration as it should, and that it makes no difference whether one dilutes with water or with sodium sulfate. The addition of a drop of benzyl alcohol was found to shorten the time necessary to reach equilibrium. We have not been able to confirm this effect of benzyl alcohol; but our experiments were made with smooth platinum electrodes and not with platinized electrodes.

The case of the cysteine–cystine electrode is more striking, because the same general results have been obtained by all workers. Dixon and Quastel[7] found that the electromotive force of this electrode at constant temperature and constant *p*H is a function of the concentration of cysteine and is independent of the concentration of cystine. This is the more interesting because cystine can be reduced to cysteine with tin and hydrochloric acid. The discrepancy between the potential difference generated by cysteine and that necessary to reduce cystine to cysteine is therefore not very large; but it is sufficient to change the electrode from the reversible to the irreversible class. Dixon thought that cysteine was a stronger reducing agent at a mercury electrode by about 200 mv. than at a gold electrode. He ascribed this, apparently erroneously, to the high hydrogen over-voltage which can be observed at a mercury electrode.

Dixon found that glutathione behaved like cysteine. Michaelis and Flexner[8] have confirmed Dixon on the important points; but they offer a different and apparently better explanation for

the behavior of a mercury electrode. They report, p. 721, that "a solution of cysteine in absence of oxygen establishes a definite potential at an indifferent electrode. This potential is independent of the concentration of cystine and depends logarithmically on the concentration of cysteine [over the range from 0.1 to 0.002 M at a pH of 4.6] and of hydrogen ions. The potential is identical at electrodes of blank platinum, gold-plated platinum, and mercury, and reproducible to within 5 mv. Slight traces of oxygen displace the potential to the positive side. Mercury is much less sensitive to oxygen than platinum or gold-plated platinum and has the advantage of yielding final values in a relatively short time."

If the explanation offered by Michaelis and Flexner for the behavior of mercury electrodes is right, it should be general and should apply to all reducing agents. This is the more important because many measurements of the electromotive forces of reducing agents are made in the presence of air. The measurements given in our previous paper in Table II were repeated, using mercury electrodes instead of smooth platinum ones. The results are given in Table I.

TABLE I

Pt | M Na_2SO_3 + A | Calomel electrode: A = concentration of other salt; B = E_c with smooth platinum electrode; C = E_c with mercury electrode. The calomel electrode is always cathode

A	B	C
Zero	0.146	0.313
M/10 Na_2SO_4	.153	.320
M $NaSO_4$	.149	.310
M NaCl	.182	.323
M NaBr	.188	.341
M NaCNS	.228	.347
M NaOH	.271	.278
M NaI	.302	.499

The electromotive forces obtained with the mercury electrodes, with the exception of the cell containing sodium hydroxide, are 120–200 mv. higher than the corresponding ones with platinum electrodes. This agrees with the results of Dixon and of Michaelis. The constant values are reached much more quickly with mercury than with platinum, so that a mercury electrode is more convenient to use than a platinum one. Mercury electrodes should be tried in measurements of photographic developers.

It seemed desirable to know something about the temperatures at which sodium sulfate and some other salts could be reduced by so energetic a reducing agent as metallic sodium. A small oven was constructed of asbestos board and a glow-coil heater installed. The dry salts were mixed with approximately an equal weight of metallic sodium and placed in a hard-glass test-tube which was lowered into the oven through a small aperture in the roof. The mixture was stirred thoroughly throughout the heating, and the temperature was measured by inserting the bulb of a thermometer into the salt–sodium mixture. No correction was made for emergent stem and the temperatures given are only first approximations. After heating, the apparatus was allowed to cool and the mixture was then poured into water to decompose any excess sodium. The resulting solution was made acid with nitric acid and tested for reduction products. In the case of the sulfates and sulfites the test was made for sulfides, while chlorides were tested for in the case of chlorates and perchlorates. Reduction of potassium chlorate was also attempted with a 0.7% sodium amalgam at temperatures below the melting point of sodium. The data are given in Table II.

TABLE II

APPROXIMATE REDUCTION TEMPERATURE WITH SODIUM

Salt	Temp., °C.
Sodium sulfate	370
Sodium sulfite	300
Potassium perchlorate	280
Potassium chlorate	100 (70)

The temperatures of reduction given in Table II show that sulfites are reduced more readily than sulfates and chlorates than perchlorates. This was to be expected, because chlorates break down when heated at a lower temperature than perchlorates and because sulfates seem to go direct to sulfides when heated. It would be possible to do decomposition-voltage measurements for sodium sulfate in the presence of fused caustic soda; but this delightful task was left for somebody else. It was hoped to determine the approximate temperature at which hydrogen reduces platinized sodium sulfate; but the time at our disposal did not permit of this.

Potassium chlorate can be reduced by sodium amalgam at temperatures below the melting point of sodium; but the reduction is very slow, only traces of chloride being formed on heating for three hours at 70°. At 100° sodium amalgam reduces potassium chlorate quantitatively in a few minutes.

In the light of what we now know, Quastel, Stephenson and Whetham[9] were very close to the truth a dozen years ago. "It was found [by Quastel and Whetham[10]] that in the presence of resting bacteria succinic acid donates hydrogen to methylene blue with the production of fumaric acid. It was also found that in the presence of the bacteria fumaric acid oxidizes leucomethylene blue, so that finally an equilibrium is established between succinic acid, fumaric acid, methylene blue and leucomethylene blue."

Bernheim and Dixon[11] made use of the same concept in their study of the reduction of nitrates to nitrites in animal tissues. "If it is assumed that the nitrate invariably requires activation before it can be reduced in the tissues, it is clear that the catalyst responsible must be associated in a very special way with the particular oxidase systems in the cell. . . .

"Nitrates differ from methylene blue in giving no oxidation potential at a platinum electrode, in this respect resembling the aromatic nitro-compounds. The latter are nevertheless easily reduced, both *in vitro*, for example by –SH compounds (cysteine, glutathione, etc.) and also by the dehydrases. Nitrates are not reduced by cysteine unless a nitrate-activating catalyst is present (Quastel, Stephenson and Whetham)."

The colloid chemist—and still more the physical chemist—is not yet accustomed to considering "resting" bacteria, of which he has never before heard, as acting as catalytic agents to succinic acid in something the same way that platinum does to hydrogen. It is evident, however, that some day there will be an extensive study of the catalytic action of "resting" bacteria.

From our point of view the formulation of all oxidation–reduction systems is very simple. If a substance does not pass through a more strongly reducing stage while being oxidized, it will give an electromotive force with an inert electrode quite apart from any catalytic action of the electrode or of the solution. If the substance does pass through a more strongly reducing stage while being oxidized, it will not act electromotively as a reducing electrode unless the electrode metal or the solution is a sufficiently powerful catalytic agent to eliminate the effect of the energy hump. The converse is also true. If a substance does not pass through a more strongly oxidizing stage while being reduced, it will give an electromotive force with an inert electrode quite apart from any catalytic action of the electrode or of the solution. If the substance does pass through a more strongly oxidizing stage while being reduced, it will not act electromotively as an oxidizing electrode unless the electrode metal or the solution is a sufficiently powerful catalytic agent to eliminate the effect of the energy hump.

Any given oxidation–reduction system may be reversible both ways as with the ferrous–ferric electrode; it may be reversible one way as with the cysteine–cystine electrode; or it may be irreversible both ways as with the chloride–chlorate or chlorate–perchlorate electrode.

This accounts for potassium nitrate, nitrobenzene and acetic acid not giving oxidation potentials, and for ammonia, aniline, and alcohol not giving reduction potentials. On the other hand, phenylhydroxylamine and nitrosobenzene is a completely reversible system and so is hydroquinone and quinone.[12]

Summary

The general results of this paper are:

1. Since the reduction of cystine to cysteine is not strictly reversible, the electromotive force of a cysteine–cystine electrode is theoretically a function of the temperature, the *p*H and the concentration of cysteine but not a function of the concentration of cystine.

2. If an electron transfer between an inert metal and an oxidizable or reducible substance involves passing through an energy hump under the conditions of the experiment, a reducing potential or oxidizing potential characteristic of that substance will not be set up; otherwise, it will.

3. "Resting" bacteria are catalytic agents for some systems and we shall some day have a bacterial chemistry based on this property.

The Effect of Halogen Substituents on the Rearrangement of Allyl Aryl Ethers. II. Ethers which Behave Abnormally

BY CHARLES D. HURD AND CARL N. WEBB

The previous paper[1] of this series dealt with three halogen-substituted allyl aryl ethers which rearranged normally into allylphenols. Eleven related compounds, nine ethers and two phenols, are taken up in this paper. The list is given in Table I.

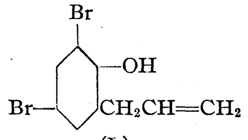
TABLE I

COMPOUNDS STUDIED

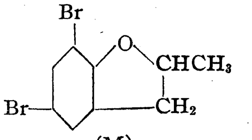
Symbol	Name	Formula
A	Allyl 2,4,6-tribromophenyl ether	$CH_2{=}CHCH_2{-}O{-}C_6H_2Br_3$
B	Allyl 2-methyl-4,6-dibromophenyl ether	$CH_2{=}CHCH_2{-}O{-}C_6H_2MeBr_2$
C	Allyl 2,6-dibromophenyl ether	$CH_2{=}CHCH_2{-}O{-}C_6H_3Br_2$
D	Allyl 2-methyl-6-bromophenyl ether	$CH_2{=}CHCH_2{-}O{-}C_6H_3MeBr$
E	β-Chloroallyl phenyl ether	$CH_2{=}CCl{-}CH_2{-}O{-}C_6H_5$
F	β-Bromoallyl phenyl ether	$CH_2{=}CBr{-}CH_2{-}O{-}C_6H_5$
G	γ-Chloroallyl phenyl ether	$CHCl{=}CHCH_2{-}O{-}C_6H_5$
H	γ-Chloroallyl *p*-tolyl ether	$CHCl{=}CHCH_2{-}O{-}C_6H_4CH_3$
I	γ-Bromoallyl phenyl ether	$CHBr{=}CHCH_2{-}O{-}C_6H_5$
J	*o*-(β-Chloroallyl)-phenol	$HO{-}C_6H_4{-}CH_2CCl{=}CH_2$
K	*o*-(γ-Chloroallyl)-phenol	$HO{-}C_6H_4{-}CH_2CH{=}CHCl$

The results show that none of the nine ethers rearranges in the normal fashion. All give greater or less amounts of hydrogen halide and polymeric products. No C_3- or C_6-hydrocarbons were liberated, a matter of some significance[2] with A and B. Differing from the three ethers mentioned in the previous paper, none of the ethers A-D possessed unsubstituted ortho positions but C and D possessed available para positions. Therefore, they might be expected to give normal rearrangement products. Actually D did rearrange in part to 2-methyl-4-allyl-6-bromophenol. In the case of C, the phenolic mixture which was obtained seemed to be a mixture of 4-allyl-2,6-dibromophenol[3] and 2-allyl-6-bromophenol but it could not be separated satisfactorily.

That the ortho bromine may be replaced by the incoming allyl group was definitely established with the tribromo ether (A) since 2-allyl-4,6-dibromophenol (L) was a reaction product. An isomeric product, probably 2-methyl-5,7-dibromocumarane (M), was also isolated. It will be recalled that none of it was formed from allyl 2,4-dibromophenyl ether during pyrolysis[1] in spite of the large yield of L, but in this case hydrogen bromide was absent. With hydrogen bromide present the change, in part, of L into M would be anticipated.[4] The rearrangement of L into M by hydrogen bromide was confirmed by experiment. The transformation of A into L involves a dehydrogenation of the solvent or reactant: (A) + 2H ⟶ (L) + HBr.



(L)



(M)

The haloallyl aryl ethers (E-I) apparently underwent rearrangement as an initial effect but only with E was the isomeric phenol (J) isolable. In this case also much of it isomerized to 2-methylcumarone (N). Part of the N polymerized but the fact that some of it was isolable was due to its comparative dilution, since when pure

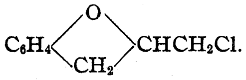
TABLE II

PROPERTIES OF THE ETHERS

Ether	B. p.			Analyses, %			Moles of HX envolved per mole of ether
	°C.	mm.	n^{20}_D	Halogen	Calcd.	Found	
A	—	—	(a)	Br	64.67	64.72	0.74
B	137–141	4	(b)	Br	52.26	52.40	.58
C	112–113	2	1.5830	Br	—	—	.62
D	81–85	0.5	1.5451	Br	35.22	35.68	.15
E	89–91	12	1.5329	Cl	21.04	21.28	.54
F	83–88	7	1.5557	Br	—	—	.39
G	122–127	27	1.5421	Cl	21.04	21.15	.24
H	101–106	7	1.5360	Cl	19.42	19.41	.44
I	101–103	7	1.5620	Br	37.52	37.68	.03

[a] M. p. 76–77°. [b] M. p. 34–37°.

J was pyrolyzed only the polymers were found. Considerable search was made for *o*-(β-bromoallyl)-phenol from F but none was found, contrary to von Braun.[5] Complex phenols were found in 18–29% yields and also neutral polymers but phenol itself was the only phenol actually isolable. The N formed from G contained a persistent chlorine-containing impurity. It was formed normally *via* *o*-(α-chloroallyl)-phenol, and not *via* K. On heating, the chief reaction of K was isomerization to 2-(chloromethyl)-cumarane,



Significant amounts of phenol and 1,3-dibromopropene were formed from (I), evidently by reaction of the liberated hydrogen bromide on the unused ether: $C_6H_5OCH_2CH{=}CHBr + HBr \longrightarrow C_6H_5OH + BrCH_2CH{=}CHBr$.

Experimental Part

Eastman 2,3-dibromopropene and tribromophenol were used in this work. The 2-methyl-6-bromophenol[6] was generously supplied by Dr. R. C. Huston of Michigan State College. It was redistilled before use: b. p. 204–207° (742 mm.). The 1,3-dibromopropene,[7] 2,6-dibromophenol[8] and 2-methyl-4,6-dibromophenol[8] were prepared by methods described in the literature; the percentage yields, respectively, were 23, 35 and 82.

2,3-Dichloropropene.—Although this is not new, there are no satisfactory directions for its preparation. It was found that the excellent directions for 2,3-dibromopropene[9] were adaptable. The following procedure, out of several tried, gave the best results. A mixture of 144 g. of trichloropropane, 13 g. of water and 90 g. of crushed (not powdered) sodium hydroxide was placed in a 500-cc. round-bottomed flask under a 3-ball Snyder floating-ball column. The mixture was heated with a smoky flame at such a rate that slow distillation took place. The distillate was washed with water, dried and fractionated through the column. That portion which was collected at 92.5–97° weighed 86 g. (80% yield). Redistillation gave these constants: b. p. 93–96°, n^{21}_D 1.4600.

Trichloropropane.—Several modifications of the directions of Pfeffer and Fittig[10] were used. Distilled glycerol dichlorohydrin (b. p. 170–176°) was used instead of the crude material. After treatment of this with phosphorus pentachloride most of the phosphorus oxychloride was distilled off before washing the product with water. From 170 g. of dichlorohydrin, 110 g. of trichloropropane (57% yield) was obtained; b. p. 153–158°.

1,3-Dichloropropene.—This was made by the method of Hill and Fischer[11] but in much lower yields. The best yield obtained was 34% for material boiling at 106–109°, or 39% for material boiling at 106–112°. Much larger amounts of trichloropropane and recovered glycerol dichlorohydrin were obtained than Hill and Fischer reported. Also, there was 60–65 g. of a high-boiling residue from 330 g. of dichlorohydrin.

Preparation of the Ethers

The ethers were prepared as before.[1] In the case of the chloroallyl and bromoallyl ethers, the limiting factor for yield was the dihalopropene rather than the phenol. In these cases 1.1 moles of the phenol was used for each mole of halide. Slight modification was necessary in the case of (A). It, being a solid and insoluble in ether, was worked up by solution in chloroform, and was recrystallized therefrom for purification.

In the synthesis of B, dibromo-*o*-cresol acted peculiarly. When the potassium carbonate was added to it in acetone solution, the mixture warmed, a gas was evolved and a sticky, brown precipitate formed. After the subsequent nine hours of refluxing with allyl bromide, much of the latter was unused. The yield of ether was very low and there was much tar.

Ethers A,[12] C,[3] F,[5] G[13] and H[13] have been made previously and analyzed. Ether A was prepared in a 0.7-mole run, and E in a 1.0-mole run. The other runs were 0.2–0.5 molar. The percentage yields, respectively, for the various ethers (A to I) were: 91, 11, 91, 77, 60, 85, 72, 65, 77. The constants and analytical data are summarized in Table II.

Pyrolyses

The apparatus and procedure were the same as described in the previous paper.[1] Experiments were performed at 200–220°, usually for two hours. Ethers E and H were heated without solvents, ethers A, F, G, I both with and without solvents (tetralin, decalin, fluorene), and ethers B, C, D only with solvents. The HX evolved was absorbed in 0.5 *N* alkali. Solvents, in the case of A, F, G, I, did not affect the quantity of hydrogen halide evolved (see Table II). An exothermic reaction was noticed only in the case of A, but the other allyl ethers (B, C, D) might have behaved similarly had no solvent been present. The maximum temperature attained on a 25-g. sample of A, heated by a bath at 202–223°, was 270°. The inside temperature of the chloro- or bromoallyl ethers (E-I) always lagged below the bath temperature.

In all the runs, phenolic and neutral tars were produced. Also, from A, C, and D a liquid product was formed in traces which appeared to be allyl bromide. A similar product, namely, 1,3-dibromopropene, was formed in greater quantity from (I). Results with the various ethers will be listed.

Allyl 2,4,6-Tribromophenyl Ether.—A 25-g. portion of the ether was heated for two hours at 197–211° in 63 g. of tetralin. The principal phenolic product distilled at 125–130° (2 mm.); 13.5 g., 68% yield. It was essentially 2-allyl-4,6-dibromophenol. When treated with chloroacetic acid it gave 2-allyl-4,6-dibromophenoxyacetic acid,[1] m. p. 114–116°.

The neutral fraction weighed 6.6 g., about half of which was 2-methyl-5,7-dibromocumarane, b. p. 130–135° (1 mm.). This was synthesized for comparison. When (A) was heated without a solvent, the only identifiable product was a small amount of tribromophenol.

2-Methyl-5,7-dibromocumarane.—A sample of 2-allyl-4,6-dibromophenol was boiled for two hours with an aqueous acetic acid solution of hydrogen bromide according to Claisen's general method.[4] The cumarane (M) was collected in 47% yield at 129–134° (1 mm.); $n^{20}\text{D}$ 1.6075.

Anal. Calcd. for $C_9H_8OBr_2$: Br, 54.77. Found: Br, 54.75.

Allyl 2-Methyl-4,6-dibromophenyl Ether.—Sixteen grams of (B), mixed with 24 g. of tetralin and heated for two hours, yielded 5.5 g. of phenolic products and 8.1 g. of neutral material. No pure products were isolable from the fractions.

Allyl 2,6-Dibromophenyl Ether.—From 47 g. of (C), heated with 66 g. of tetralin, there was isolated 17.2 g. of crude phenolic material. Distillation at 2 mm. gave these fractions (°C., g., $n^{20}\text{D}$, % Br): 96–98, 2.9, 1.5784, 39.97; 98–104, 6.2, 1.5842, (no anal.); 107–112, 2.4, 1.5953, 44.61; 112–117, 2.3, 1.6057, 46.14; residue, 3 g. The lowest fraction appeared to be chiefly 2-allyl-6-bromophenol (calcd. Br, 37.54), and the highest fraction chiefly 4-allyl-2,6-dibromophenol (calcd. Br, 54.77).

Distillation of the neutral products at 1–2 mm. yielded 3 g. of naphthalene (formed by dehydrogenation of the tetralin), and 7.4 g. of the recovered ether, b. p. 102–112°.

Allyl 2-Methyl-6-bromophenyl Ether.—Thirty-three grams of (D), mixed with 33 g. of tetralin, yielded 7.7 g. (23%) of 2-methyl-4-allyl-6-bromophenol; b. p. 101–110° (1.5 mm.), $n^{20}\text{D}$ 1.5711.

Anal. Calcd. for $C_{10}H_{11}OBr$: Br, 35.2: Found: Br, 35.3.

Evidence was obtained for about 1 g. of 2-methyl-6-bromophenol but there was no evidence for 2-methyl-6-allylphenol, which would be anticipated if there were replacement of the bromine in (D) as in (A). No pure products were isolated from the 14.2 g. of crude neutral material.

β-Chloroallyl Phenyl Ether.—When heated for two hours at 216–223°, this ether (52 g.) yielded a colorless phenolic oil (12.4 g.) which boiled at 130–134° (12 mm.); $n^{20}\text{D}$ 1.5778. Analysis showed this to have the composition of *o*-(β-chloroallyl)-phenol. When allowed to stand, this material gradually became viscous and finally changed to a solid.

From the neutral material, 8 g. of 2-methylcumarone was isolated; b. p. 190–193°, b. p. 56–57° (8 mm.), $n^{20}\text{D}$ 1.5590.

Anal. Calcd. for C_9H_8O: C, 81.8; H, 6.06. Found: C, 81.4; H, 6.21.

This material reacted with bromine in carbon disulfide to give an oil; b. p. 116–119° (15 mm.); $n^{20}\text{D}$ 1.5873. 2-Methylcumarone (b. p. 190–193°, $n^{25}\text{D}$ 1.5552) and its bromination product (b. p. 114–118° (15 mm.); $n^{20}\text{D}$ 1.5875) were prepared for comparison by the method of Adams and Rindfusz.[14]

β-Bromoallyl Phenyl Ether.—When this ether was heated without a solvent, only a tar resulted. When 15 g. of (F) was heated with 3 g. of decalin or 5 g. of fluorene, 2–3 g. of a bromine-containing, infusible solid resembling carbon accumulated on the sides of the flask. Considerable phenolic substances (18–29%) were extracted from the reaction mixture. Distillation gave rise to a trace of phenol, identified as tribromophenol. Nothing distilled at 135° (14 mm.), the b. p. of *o*-(β-bromoallyl)-phenol. The residue was a tar.

Less than 1 g. of (F) was recovered on attempted distillation of the neutral material. The thick tarry residue weighed 3.5 g.

γ-Chloroallyl Phenyl Ether.—Fourteen different runs were carried out with (G). Practically no phenolic products were obtained except in the runs with fluorene as solvent. Thus, from 31–33 g. of G (in 11–14 g. of fluorene), heated for forty, ninety and four hundred forty minutes, there was formed 0.5, 1.2 and 2.3 g. of phenols. The 0.5 and 1.2-g. portions were thick, dark oils which gave good chlorine tests. The 2.3-g. portion yielded 0.53 g. of phenol (identified as tribromophenol) on steam distillation.

The principal product from (G) was a neutral material of lower b. p. It could not be separated completely from unchanged G either by vacuum distillation or by chemical means. On distillation at atmospheric pressure, it polymerized. Data from two runs will be listed, with and without a solvent.

Without Solvent.—In this run, 30.8 g. of G, $n^{21}\text{D}$ 1.5424, was heated for three hours at 215–225°, then distilled at 27 mm. (°C., g., $n^{21}\text{D}$): 103–112, 0.5, 1.5606; 112–115, 3.5, 1.5598; 115–118, 3, 1.5573; 118–120, 4, 1.5493; dark residue, 17 g. The 3.5-g. fraction (112–115°) possessed a

---

(14) Adams and Rindfusz, THIS JOURNAL, **41**, 648 (1919). See also Claisen, *Ann.*, **418**, 84 (1919); *Ber.*, **53**, 322 (1920).

refractive index 0.0174 higher than G. Analysis (Cl, 12.8%) indicated 39.4% of chlorine-free material.

With Solvent.—In this run, 30.8 g. of G, n^{23}D 1.5392, admixed with 11.5 g. of fluorene, was heated at 250–255° for forty minutes. From it there was collected at 9 mm. about 23 g. of distillates (°C., g., n^{23}D). 68–74, 1.9, 1.5718; 74–77, 3.3, 1.5657; 78–82, 5.0, 1.5572; 83–85, 8.7, 1.5468; 85–88, 4.8, 1.5437. The residue, nearly colorless, was chiefly fluorene. None of the fractions, in common with G, possessed activity toward alcoholic or ammoniacal silver nitrate. This and other evidence suggests that the chlorine-containing impurity in the fractions is (G). The 1.9-g. fraction (68–74°) possessed a refractive index 0.0326 higher than the original ether. Analysis (Cl, 7.72%) indicated 63.3% of chlorine-free material.

γ-Chloroallyl *p*-Tolyl Ether.—From 25 g., only 0.3 g. of phenolic material was found. In the neutral portion, 10.4 g. of (H) was recovered. There was 10.8 g. of a black residue the mol. wt. of which, determined cryoscopically in benzene, was 424. This suggests a trimer of 2,5-dimethylcumarone (mol. wt., 438).

γ-Bromoallyl Phenyl Ether.—From 18.9 g. of (I), the most interesting neutral material was 1.41 g. of liquid, b. p. 157°, which was satisfactory for 1,3-dibromopropene. About 27% of (I) was recovered. The neutral tar weighed 2 g. The only recognizable phenolic product from this ether was phenol itself, formed in 9–18% yields.

The *o*-Chloroallylphenols

o-(β-Chloroallyl)-phenol (J), b. p. 95–100° (1 mm.), 130–134° (12 mm.), was a product of pyrolysis of β-chloroallyl phenyl ether (E).

Anal. Calcd. for C_9H_9OCl: Cl, 21.04. Found: Cl, 21.02.

o-(γ-Chloroallyl)-phenol (K) was prepared in 17% yield by reaction of 47 g. of phenol, 11.5 g. of fine sodium, 250 cc. of dry benzene and 56 g. of 1,3-dichloropropene for seventeen hours. The first half of the reaction was performed at room temperature, the last half at refluxing temperature. On working up the products (alkali-extraction and vacuum distillation), 14.5 g. of (K) was obtained; b. p. 151–156° (31 mm.), n^{23}D 1.5638. Concurrently, 4.5 g. of the isomeric ether (G) was obtained from the alkali-insoluble portion. The phenol (K) was analyzed.

Anal. Calcd. for C_9H_9OCl: Cl, 21.04. Found: Cl, 21.05.

Pyrolyses.—Phenols J and K were heated without solvents in the manner described above for the ethers. The hydrogen chloride evolved from J was 0.73 mole (per mole of J) during ninety minutes, whereas that from K was only 0.023 mole during two hundred minutes.

Approximately equal amounts of molasses-like phenolic and neutral products were formed from J. The phenolic material gradually became quite hard and resinous. There was 54% recovery of K. From a 6-g. run, the principal product was 1.03 g. of a neutral, halogen-containing material; b. p. 106–108° (9 mm.), n^{23}D 1.5595. Analysis and comparison with synthetic material showed it to be 2-(chloromethyl)-cumarane.

Anal. Calcd. for C_9H_9OCl: Cl, 21.04. Found: Cl, 20.15.

Synthetic 2-(Chloromethyl)-cumarane.—Five grams of K, mixed with 20 cc. of acetic acid and 10 cc. of 48% hydrobromic acid, was heated for two hours. This is Claisen's method[4] of ring-closure. There was 2.3 g. of K recovered. From the neutral material, 1.5 g. of the desired cumarane was collected between 140–155° (28 mm.), two-thirds of which was collected at 145–155°. This fraction, n^{24}D 1.5615, was analyzed.

Anal. Calcd. for C_9H_9OCl: Cl, 21.04. Found: Cl, 20.94.

Summary

Allyl aryl ethers were prepared wherein the aryl groups were 2-methyl-6-bromophenyl, 2,4-dibromophenyl, 2-methyl-4,6-dibromophenyl and 2,4,6-tribromophenyl. Also, "allyl" phenyl ethers were synthesized wherein the "allyl" group represented β- and γ-chloroallyl, β- and γ-bromoallyl. γ-Chloroallyl *p*-tolyl ether was also studied. All nine of these ethers evolved hydrogen halide on heating and gave rise to a complex mixture of products. The only cases which rearranged into isolable phenolic isomers were allyl 2-methyl-6-bromophenyl ether, β-chloroallyl phenyl ether and possibly allyl 2,6-dibromophenyl ether. Other phenolic products and neutral materials were formed. Cyclization was encountered in many cases and tarry polymeric products invariably were formed.

The chief organic products formed during the pyrolysis of allyl tribromophenyl ether were 2-allyl-4,6-dibromophenol and 2-methyl-5,7-dibromocumarane.

For purposes of comparison, study was also made of the pyrolysis of *o*-(β-chloroallyl)-phenol and *o*-(γ-chloroallyl)-phenol.

Phenanthrene Derivatives. VI. The Preparation of 1-, 2- and 3-Phenanthryl Halides

BY W. E. BACHMANN AND CHARLOTTE H. BOATNER[1]

During the sixty-four years that have elapsed since the discovery of phenanthrene only one mono-halogen derivative, other than the 9-phenanthryl halides, has been prepared. This is not due to lack of effort, for numerous attempts have been made to obtain these compounds. An extensive study of the halogenation of phenanthrene and of phenanthrene derivatives was undertaken by Sandqvist[2] who succeeded in obtaining 3-chlorophenanthrene from 3-phenanthrenesulfonic acid. The attempts at the total synthesis of the phenanthryl halides met with no more success. Pschorr[3] applied his method of synthesis to the preparation of 1- and 3-bromophenanthrene but the attempt failed in the last step of the process. Berger[4] likewise was unable to prepare 2-bromophenanthrene by a similar procedure. Nylen,[5] somewhat more successful, obtained a small amount of 3-chlorophenanthrene by the Pschorr synthesis.

The idea of preparing the phenanthryl halides through the diazo reaction was first conceived by Schmidt[6] but he abandoned the investigation because of the difficulty of obtaining the phenanthryl amines. Werner and Kunz[7] reported that 3-aminophenanthrene could not be diazotized. Although Schmidt[8] reported the successful diazotization of this amine, he did not state the yield of the coupling product obtained with β-naphthol, and his method of diazotization is laborious. In view of these results no attempt was made in the present investigation to use the ordinary methods of diazotization. Instead, we resorted to the method of de Milt and van Zandt[9] which was developed recently for the diazotization of weakly basic and insoluble amines. Using their procedure we were able to diazotize 1-, 2- and 3-amino-phenanthrenes successfully.

Although the iodophenanthrenes were obtained by treating the phenanthrene diazonium sulfates with potassium iodide, the Sandmeyer reaction proved to be unsatisfactory for the preparation of the chloro- and bromophenanthrenes. These halides were obtained by using the procedure of Schwechten,[10] which involves the intermediate formation and subsequent decomposition of a complex formed by interaction of the diazonium compound and mercuric halide and potassium halide. In Table I are presented the yields and properties of the phenanthryl halides that were prepared. By heating the aqueous solutions of the diazonium salts the corresponding 1-, 2- and 3-phenanthrols were obtained. We are now engaged in the preparation of the 4-phenanthryl halides and are also investigating other methods of preparation.

Experimental Part

Preparation of Chlorophenanthrenes and Bromophenanthrenes.—The 1-, 2- and 3-aminophenanthrenes[11] were all diazotized in exactly the same manner. One and five-tenths grams of sodium nitrite was added with stirring to a cold mixture of 7.5 cc. of water and 15 cc. of concentrated sulfuric acid. The mixture was then heated with stirring on a steam-bath until a clear solution of nitrosylsulfuric acid was obtained. This solution was cooled to 0° and stirred mechanically as a solution of 1.93 g. (0.01 mole) of aminophenanthrene (1-, 2- or 3-isomer) in 10 cc. of pyridine was added drop by drop in the course of an hour. After addition was complete the mixture was stirred for one hour longer; it was then diluted to a volume of 200 cc. by addition of ice and water and treated with a solution of 1 g. of urea in 25 cc. of water in order to destroy the excess of nitrous acid. After the solution had been stirred at 0° for another hour, the diazonium salt solution was ready for reaction.

To the yellow solution of the phenanthrene diazonium sulfate from 1.93 g. of aminophenanthrene was added a solution of 11 g. of mercuric chloride and 11 g. of potassium chloride in 50 cc. of water. The mixture was allowed to stand in the cold for an hour in order that the deeply colored (yellow, orange or orange-red) precipitate of the double salt which formed could coagulate. The precipitate was filtered off, washed with water and air-dried for twelve to twenty hours. The dry double salt (6 g.) was intimately mixed with 12 g. of potassium chloride and the mixture was heated cautiously in a 50-cc. distilling flask with a free flame, keeping the temperature just high

TABLE I

PHENANTHRYL HALIDES

All of the compounds were obtained as colorless crystals by recrystallization from alcohol.

Compound	Cryst. form	M. p., °C.	Yield, %	Formula	Analyses, % Calcd.	Found
1-Chlorophenanthrene	Plates	120–120.5	41	$C_{14}H_9Cl$	Cl 16.7	16.7
2-Chlorophenanthrene	Plates	85.5–86	42			16.7
3-Chlorophenanthrene	Needles	80.5–81.5[a]	48			16.9
1-Bromophenanthrene	Needles[b]	109.5–110	72	$C_{14}H_9Br$	Br 31.1	30.6
2-Bromophenanthrene	Plates	95–96	70			31.2
3-Bromophenanthrene	Needles	83–84	70			31.1
1-Iodophenanthrene	Fine needles	112.5–113	53	$C_{14}H_9I$	I 41.8	41.0
2-Iodophenanthrene	Prisms	116–116.5	47			40.9
3-Iodophenanthrene	Stout needles	83.5–84	47			41.8

[a] Nylen[5] reported a melting point of 80–81° for the product obtained by the Pschorr synthesis. Sandqvist[2] reported the two values, 70.5–71 and 81°, for the product prepared by interaction of 3-phenanthrenesulfonyl chloride and phosphorus pentachloride. [b] The compound also crystallizes in the form of plates.

enough for evolution of nitrogen to take place. When no more nitrogen was evolved, the chlorophenanthrene was distilled from the mixture under reduced pressure (4 mm.). The distillate was extracted with benzene in order to remove inorganic salts, the benzene solution was boiled with charcoal, filtered and evaporated and the residue of chlorophenanthrene was then recrystallized from alcohol. All of the halides are readily soluble in benzene and in acetone but only slightly soluble in cold alcohol.

The bromophenanthrenes were prepared in a similar manner. For larger runs the procedure was modified somewhat. Thus, the double salt (63 g.), which was obtained by addition of a solution of 55 g. of mercuric bromide and 55 g. of potassium bromide in 200 cc. of water to the diazonium salt solution from 9.65 g. of 2-aminophenanthrene, was mixed with twice its weight of potassium bromide, and the mixture was then heated cautiously in an evaporating dish on a sand-bath until evolution of nitrogen had ceased. The reaction product was digested with hot water, the residue was taken up in benzene, the filtered benzene solution was evaporated and the residue of 2-bromophenanthrene was purified by distillation, b. p. 185° (4 mm.), followed by recrystallization from alcohol; yield 9.0 g.

Preparation of Iodophenanthrenes.—A pale yellow precipitate was formed on addition of 10 g. of potassium iodide in 25 cc. of water to the diazonium salt solution from 9.65 g. of 3-aminophenanthrene (or its 1- or 2-isomer). After standing overnight at room temperature the reaction mixture was heated at 100° until no more nitrogen was evolved. The precipitate which had formed was filtered from the cooled solution and dissolved in benzene; the benzene solution was washed with a solution of sodium bisulfite and with water and then evaporated to dryness. The residue of 3-iodophenanthrene was purified by distillation, b. p. 190° (4 mm.), followed by recrystallization from alcohol; yield 7.2 g. By using the procedure involving the intermediate formation and subsequent decomposition of a double salt with mercury iodide and potassium iodide a 31% yield of 3-iodophenanthrene was obtained.

Preparation of Phenanthrols.—The phenanthrene diazonium sulfate solution from 1.93 g. of aminophenanthrene was diluted to a volume of 400 cc. and heated at 100° until decomposition was complete. The precipitate of phenanthrol was filtered off and purified through its water-soluble potassium salt. The yields were: 1-phenanthrol, 11%; 2-phenanthrol, 40%; 3-phenanthrol, 39%. The properties of the compounds agreed with those described in the literature.

Summary

By means of the diazo reaction 1-, 2- and 3-chlorophenanthrene, 1-, 2- and 3-bromophenanthrene, 1-, 2- and 3-iodophenanthrene and 1-, 2- and 3-phenanthrol have been prepared.

Heats of Adsorption at −183°. Carbon Monoxide on Copper

BY RALPH A. BEEBE, GEORGE W. LOW, JR., AND SEYMORE GOLDWASSER

Recent investigation[1] has shown that the reaction $H_2 + D_2 = 2HD$ is catalyzed by chromium oxide and supported nickel at temperatures as low as −183°, giving evidence for an activated as well as a van der Waals adsorption even at this low temperature. Because in general the magnitude of the heat effect is approximately one order higher for activated adsorption than for van der Waals, experimental data on heats of adsorption have been considered important in deciding which type is predominant in any given case. However, Gould, Bleakney and Taylor,[1] by indirect reasoning from their results on the catalytic activity of chromium oxide at low temperatures, have suggested that the heat of activated adsorption of hydrogen on this catalyst is very small at −183° and therefore of the magnitude commonly believed to attend van der Waals adsorption. For a more complete understanding of the phenomena at −183° it is apparent that experimental data on the heats of adsorption are needed. These are often calculated by application of the Clapeyron–Clausius equation to pressure data at two temperatures; however, this procedure cannot be used if the residual pressure is too small to measure as is often the case especially for the initial portions of the surface covered. The authors have therefore considered it important to develop a direct calorimetric method for measuring the heat values at low temperatures.

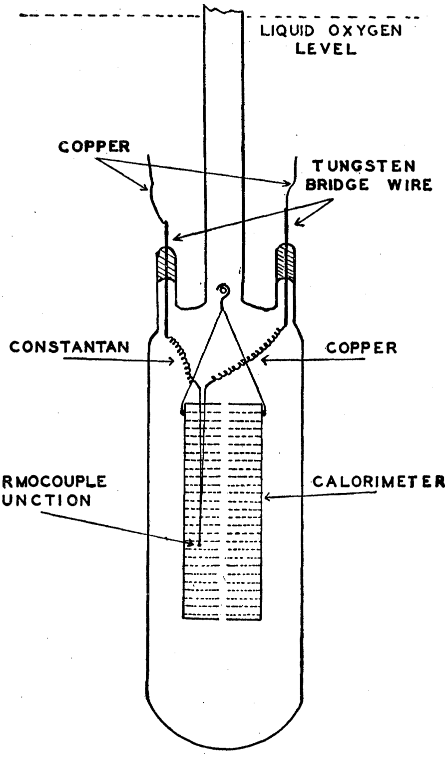

Fig. 1.

Because the problems attendant upon the heat measurements at 0° have been studied carefully by one of us[2] for carbon monoxide on copper, this case has been chosen as a point of attack in developing a method at −183°.

Experimental

Apparatus.—The apparatus was identical with that of Beebe and Wildner[2b] except for the method of leading in the thermocouple wires. In one method (Fig. 1) tungsten wire bridges were substituted for the "Picein" seals which had been satisfactory at 0° but would not hold the vacuum at −183°. Because it seemed reasonable to question the reliability of results for which the tungsten bridge wires were used, a second method (Fig. 2) was also employed. In this method, the copper–constantan thermo-junction, inserted at the point A, was pushed to the bottom of the platinum finger F, which was closed at its lower end. The platinum finger fitted loosely into a thin-walled copper sleeve which was embedded in the catalyst, the loose fit being necessary to facilitate the assembly of the apparatus. A reference junction not shown in Fig. 2 was inserted into the heavy copper jacket mentioned below. This calorimeter had the advantage that the gases never came in contact with the thermoelement. Both calorimeters contained the copper adsorbent granules in layers separated by copper gauze disks to improve the conditions for heat distribution.[2b] A heavy copper jacket

1.1 cm. thick, suspended in the liquid oxygen bath and fitting closely around the Pyrex calorimeter chamber, served to integrate local variations in the bath temperature. The liquid oxygen[3] was contained in a large Dewar flask of 4.5 liters capacity. This large volume of liquid was essential to maintain sufficient constancy and uniformity of bath temperature.

The sensitivity of the single junction copper–constantan thermoelement was of course much less at −183° than at 0°; but this unfavorable factor was partially compensated because of the lower heat capacity of copper at the lower temperature. In the case of cylinder 1, for instance, the water equivalent was 3.93 as compared to 6.59 calories at 0°. The galvanometer deflection was 1 mm. per 0.0069° at a distance of one meter. The voltage sensitivity of the thermocouple in the region of −183° was calibrated against a secondary standard copper–constantan couple kindly provided by Professor Evald Skau of Trinity College, Hartford, Conn.

Materials.—In all, four different calorimeter cylinders filled with copper granules were used. Cylinder 1 with its charge of copper had been used for the measurements at 0° reported by Beebe and Wildner.[2b] This active copper, designated as copper 1, had been exposed to the atmosphere for some time, and after again reducing with hydrogen it had lost about 30% of its activity at the time of the previous measurements. At no time had the adsorbent been removed from the cylinder. On this as well as on all the other copper samples used, the rate of adsorption at −183° was practically instantaneous. Copper 2, used in cylinders 2 and 3, came from the same original batch as copper 1 but had been sealed in glass for nearly three years. Its adsorptive capacity was approximately the same as that of copper 1. Copper 4 used in cylinder 4 was prepared at the time of these experiments by reduction of copper oxide granules in hydrogen, first at 120°, and finally at 170°; its adsorptive capacity was about half that of copper 1. Cylinders 1 and 2 were used in method 1 (Fig. 1), and cylinders 3 and 4 in method 2 (Fig. 2). Because all the cylinders had the same dimensions, their weight when assembled varied little from that of cylinder 1 which was 71.5 g., of which 40.0 g. was due to active copper adsorbent.

Procedure.—Before each series of measurements the catalyst was outgassed for five hours at 170°. To hasten the establishment of thermal equilibrium between the calorimeter and its surroundings a small pressure of pure helium was admitted to the calorimeter which was then allowed to stand overnight in the liquid oxygen bath. In experiments by method 1, this helium was pumped out before the first increment of carbon monoxide was admitted, but with method 2 it was necessary to leave a small helium pressure (0.02 mm.) in the calorimeter vessel at the start of a series; otherwise the rate of transfer of heat from the active copper mass to the platinum finger containing the thermocouple was too slow to produce satisfactory time–temperature curves. In method 1 the uninsulated copper wire of the thermocouple was crowded against the copper gauze cylinders of the calorimeter probably in several places making much better thermal contact between the calorimeter and the thermocouple than the loosely fitting platinum finger of method 2. As in the previous work[2b] the time–temperature curves were photographically recorded.

Discussion of the Method

Previous experiments[2a] have demonstrated that two factors, (a) slow conduction of heat and (b) non-uniform adsorption, are unfavorable to satisfactory conditions for the heats of adsorption measurements; and the efficiency of our calorimeter in minimizing the effects of these factors at 0° has been discussed.[2b] Compared to 0°, effective heat transfer is favored at −183° by the greater thermal conductivity of copper at that low temperature; but this favorable factor is offset by the much lower rate of heat transfer by radiation and by the residual gases in the calorimeter. Judging from the similarity in form between the time–temperature curves obtained at the two temperatures, it would seem that the factors favorable and opposed to good heat distribution just about balanced each other. For the initial stages of adsorption at 0°, it was shown by experiment that the process was non-uniform, *i. e.*, adsorption occurred on those successive layers of adsorbent with which the carbon monoxide first came into contact.[2a] Although not demonstrated experimentally, it is probable that the same phenomenon is present at −183°. The calorimeter is designed to minimize, but does not completely eliminate, this effect with the result that the differential heats for the initial increments measured and reported below, are probably lower than the true differential heats for reasons previously given.[2b]

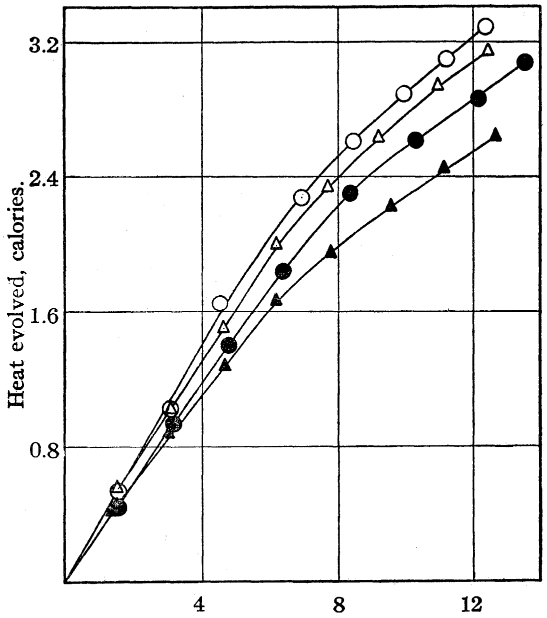
The time–temperature curves obtained by method 1 (Fig. 1) were similar to those at 0°, having the form of curves I, II and III in Fig. 2 of the paper by Beebe and Wildner,[2b] for initial, intermediate, and final increments of carbon monoxide added to the surface. Using method 2, all the time–temperature curves had the form of curve III mentioned above, the more rapid rise to a maximum and the subsequent more rapid cooling being due to the presence of the helium gas (0.02 mm.). Unlike those at 0°, these curves at −183° contained irregularities which were probably due to lack of complete uniformity in temperature of the liquid oxygen bath. The amplitude of these variations varied from 0.5 mm.

---

[3] This liquid oxygen guaranteed 99% pure was purchased from the Air Reduction Sales Company. Because of the high degree of purity of the oxygen and because a relatively small percentage of it was evaporated, no change in its boiling point was noticeable during the measurements.

in most of the curves to 2 mm. in the worst cases. It is roughly estimated that they introduced random errors of 5 to 10% in reading the temperature changes from the curves.

Results



Cc. adsorbed on 40.0 g. of copper.

Fig. 3.—○, Cylinder 2, series 1; △, cylinder 2, series 2; ●, cylinder 3, series 1; ▲, cylinder 3, series 2.

Three series of differential heats were measured for cylinder 1, and two each for cylinders 2, 3 and 4, making nine series in all. The results for the four series on copper 2 are shown in Fig. 3 in which the total heat evolved is plotted against cc. of carbon monoxide adsorbed. The total heat was calculated by summation of the measured heats for separate successive increments of gas. It is important to observe that method 1 (Fig. 1) was used in the measurements on cylinder 2, but that method 2 (Fig. 2) was used for cylinder 3; however, copper 2 was used in both cylinders. The fair concordance of the data obtained by the two methods is evidence for the reliability of both methods of measurement. The failure of the results for the four series to check more closely than they do is probably due to the lack of complete similarity of the copper surfaces used in the two cylinders, although they came originally from the same batch of copper, and also to the lack of complete reproducibility of these surfaces in successive series. In Table I is given a comparison of the volumes adsorbed at the arbitrarily chosen pressure of 0.8 mm. This table does not of course give any information concerning the relative percentages of active points in the surfaces used. In Table II are shown more complete details of two typical series. After the completion of series 2, cylinder 1 (Table II), the copper was outgassed for two hours at −183°. The increments a, b and c, then added, yielded low differential heats of the order of 3 kcal. per mole. Measurements on copper 4 which had lower adsorptive capacity than the others gave the following differential heats for successive increments: 7.3, 5.5, 4.9, 3.8, 4.0 kcal. per mole.

Discussion

In all our measurements for carbon monoxide on copper at −183° the differential heats for the first few cc. of gas added to the surface have been of the order of 8 kcal. which, although less than the values at 0°,[2b,4] is several times greater than the heat of vaporization of carbon monoxide. It

---

(4) Measurements of differential heats at 0° on copper 1 and copper 2 using the tungsten bridge calorimeter (Fig. 1), confirmed the previous work of Beebe and Wildner which showed that the heats were of the order of 19 to 14 kcal. per mole.

therefore seems probable that the adsorption is a combination of activated and van der Waals adsorption favoring the former for initial stages but changing in ratio progressively to the latter as successive increments of gas are added to the surface. This is in agreement with the conclusion of Benton and White[5] based upon indirect experimental evidence.

The technique worked out in detail for carbon monoxide on copper should be applicable to other gas–solid combinations at −183°. For reasons given in the introduction, direct experimental measurements of heats of adsorption are needed at low temperatures on chromium oxide. The technique described above is now being applied to the latter adsorbent.

Our thanks are due to the Committee on Grants-in-Aid of the National Research Council for supplying funds for technical assistance in this work.

Summary

1. A method has been described for the direct measurement of the differential heats of adsorption of carbon monoxide on copper at −183°.

2. The differential heats are of the order of 8 kcal. per mole in the initial stages, and decrease to 3 kcal. in the later stages of the adsorption.

3. The results seem to indicate that a considerable part of the adsorption for the initial increments of gas is of the activated type even at the low temperature of −183°.

X-Ray Diffraction Studies of Built Up Films[1]

By G. L. Clark and P. W. Leppla

The development by Langmuir and Blodgett[2] of a technique for the preparation of foliated films of any desired number of molecular layers permits for the first time the study of x-ray diffraction effects produced by a known number of planes. Clark, Sterrett and Leppla[3] reported distinct diffraction patterns from nine or more layers of stearates prepared by Blodgett's method. Langmuir and Schaefer[4] have since shown by chemical analysis of the unimolecular layer skimmed from solutions containing calcium or barium ions that the built up films vary continuously in composition from pure acid at *p*H 2 to pure soap at *p*H 11. In view of the fact that the soaps and the acids crystallize in different systems, and since, furthermore, several modifications of the fatty acids are known, the structure of the composite built up films was investigated by diffraction methods.

Experimental.—Films were prepared of stearates of lead, calcium and barium by means of a motor-driven device to ensure freedom from vibration and the highest possible perfection of the individual layers. To eliminate the necessity for oscillating the specimen in the path of the x-ray beam, curved surfaces were used as originally proposed by Trillat.[5] For the measurement of the long spacing, *d*, a radius of 15 mm. was employed. To each order corrections were applied for the actual position of the origin of the diffracted spot. To increase the intensity of the pattern for the study of films of only a few layers, the radius was increased to a maximum of 50 cm. Copper Kα radiation was used.

A double lining of lacquer overlaid with paraffin was used in the brass trough to prevent contamination of the solutions with copper ions. For the measurement of *p*H an antimony electrode was employed.

Since films do not adhere to glass at low *p*H, lacquered surfaces were used in the acid range. Molecules adhere to glass or metal by their polar groups and exist in an odd number of layers. On lacquer the hydrocarbon end of the chain is attached to the surface and the films exist in an even number of layers.

Composition of the Surface Film.—Unimolecular stearate films were skimmed from the surface of dilute calcium, barium and lead salt solutions at varying hydrogen-ion concentrations, the material air-dried, packed into tiny cells and transmission diffraction patterns registered. Side spacings characteristic of both the acid and the soap appeared in each case, the intensities indicating complete agreement with Langmuir and Schaefer's[4] conclusions.

Structure of the Built Up Films.—From the mechanism of the transfer process the gross structure readily may be inferred to be the alternating

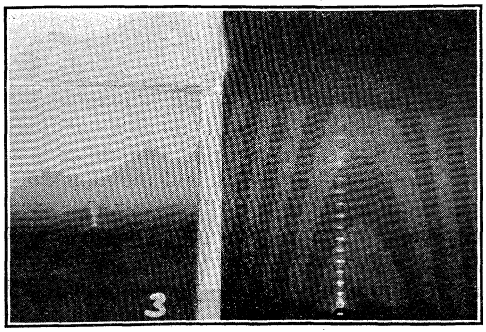
type common to fatty acids and derivatives. In the ordinary crystal modification of stearic acid the chains are tilted at about 27° from the normal to the base and *d* is about 40 Å. In stearates of divalent metals the chains are perpendicular or very nearly so to the base and *d* is approximately 50 Å. The spacings observed for built up films and for ordinary preparations are given in Table I.

Table I

		Å.
Stearic acid	Built up film	39.7 ± 0.2
	Melted on glass	39.5 ± .2
Calcium stearate	Built up film	49.4 ± .2
	Powder by transmission	50.0 ± 0.5
Lead stearate	Built up film	49.6 ± .2
	Powder by transmission	49.7 ± .5

Based upon the spacing observed and the relative intensities of the odd and even orders, it was concluded that the structure of the composite films varies *discontinuously* with the *p*H, being that of the acid below *p*H 3 and that of the soap above *p*H 6. As might be expected from the difference in lattice energies, the stearates power in imposing the soap structure on the film is the greater, and films containing even a relatively high proportion of the acid still have the structure of the soap. At intermediate hydrogen-ion concentrations a pattern was obtained characterized by low intensity of the higher order reflections, indicating a distorted transition structure. Lead stearate films at *p*H 4 gave a totally different pattern indicative of an entirely distinct configuration.



3 layers 50 layers

Fig. 1.—Diffraction patterns of built up films of lead stearate.

By an ingenious method of interference of monochromatic light, Blodgett[2] has measured the over-all thickness of calcium stearate films, obtaining 48.8 Å. per double layer. It has been suggested that comparison of such measurements with those of x-ray diffraction affords a direct approach to absolute x-ray wave length values. No significance can be attached to the discrepancy between Blodgett's value and those of this investigation since different samples of stearic acid were employed, and it has been shown adequately that *d* values for fatty acids vary greatly with the purity of the specimen, and for at least three polymorphic structures.

Pure stearic acid films were transferred to lacquered surfaces from perchloric acid solutions of *p*H 2 to 5. Two side spacings appeared on the photographic film in a position indicating that all the chains were tilted in the same direction, sloping down with respect to the plane in which the surface was raised and lowered during the transfer process.

Intensity Measurements.—The use of a large radius of curvature resulted in such high intensities that good patterns were obtained from as few as three layers of lead stearate. Figure 1 is a reproduction of such a pattern secured in three-fourths hour from a Philips Metalix tube operating at 28 kv. and 25 ma., as compared with a pattern for 50 layers.

From a series of films with increasing numbers of layers the data shown graphically in Fig. 2 were obtained. The intensities were read from micro-

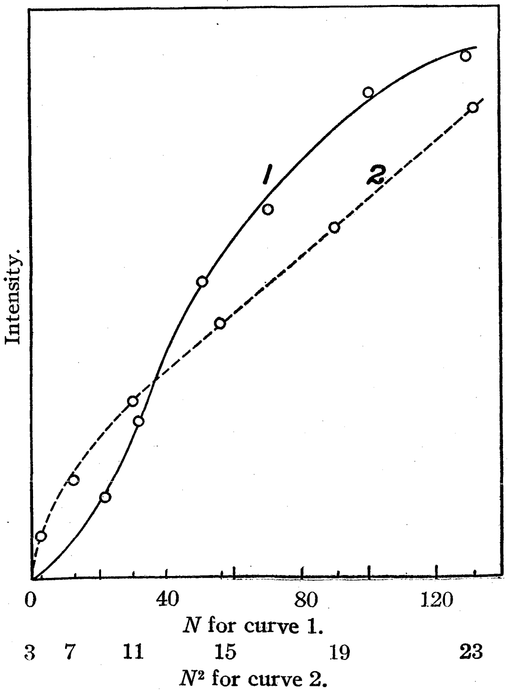


Fig. 2.

photometer traces and a blackening curve established from similar films developed simultaneously. In the experimental series the exposure time was varied systematically from one minute to one hour to keep the blackening between 25 and 50%. If intensities of interferences for the thinnest films are plotted against the *square* instead of the first power of the number of layers, the points between ten and thirty layers fall on a straight line. This is characteristic of an ideally imperfect diffracting medium. From a greater number of layers the intensity falls off, the upper layers shielding those below from the x-ray beam. Thus the irregularity of the first layers applied has become smoothed out and the planes approach perfection.

Test of the Laue Particle Size Equation.—The theoretically derived equation, $B = b + (0.9\ \lambda/D \cos \theta/2)$[6] has been used to calculate particle size in the colloidal range from the observed breadth of x-ray interferences. Until now it has been impossible to test the equation because of a lack of a comparison method. The expression is equally valid for the thickness of a built up film. The results of line breadth measurements are given in Table II. In general, agreement of observed and calculated values is good except for very thin films where the excess broadening observed is attributed to the previously mentioned distorted nature of the first layers applied.

Summary

The structures of Blodgett's composite films of stearic acid and stearates have been investigated by x-ray diffraction methods. The structure and hence the thickness have been found to be that of the constituent present in greater proportion. The *d* spacings agree closely with those of the crystalline material.

Intensity measurements have been made from successively increasing numbers of planes and the degree of perfection inferred therefrom.

Laue's particle size equation has been tested by the use of films of known thickness.

URBANA, ILLINOIS RECEIVED AUGUST 6, 1936

---

[6] B = breadth of interference at points of half-maximum intensity; b = apparatus constant for minimum width under experimental conditions; λ = x-ray wave length; θ = diffraction angle for given interference; D = size of particle, or thickness of film.

Reactions of Nickel Carbonyl with Oxides of Nitrogen[1]

BY J. C. W. FRAZER AND WM. E. TROUT, JR.[2]

M. Berthelot[3] passed nitric oxide into nickel carbonyl and obtained a solid product. Subsequent admission of small amounts of oxygen to the reaction vessel produced another solid. Berthelot characterized both solids as complex compounds but did not give analyses. Some confusion has arisen in the literature concerning these experiments, apparently due to the mistaken translation of "bioxyde d'azote" as nitrogen peroxide.[4] Attempts to determine the nature of the solids have not been wholly successful.[5,6]

This paper reports further observations concerning the reactions of nickel carbonyl with oxides of nitrogen.

Experimental

Nitrogen Peroxide and Nickel Carbonyl.—Nitrogen peroxide and nickel carbonyl reacted exothermally at temperatures as low as −78°. The reaction was carried out

in four ways: (1) nitrogen peroxide was permitted to expand into the vapor of nickel carbonyl at low pressures; (2) the gaseous reactants, transported in carbon monoxide or in nitrogen, were introduced into the reaction vessel in opposing jets; (3) nitrogen peroxide diluted with nitrogen was passed over liquid nickel carbonyl at or near 0°; (4) nitrogen peroxide was admitted to solutions of nickel carbonyl in hexane. Methods 2 and 3 appeared to be most satisfactory. Special care was taken to exclude air and moisture and to purify all materials.[1]

The gaseous products of this reaction contained as much as 97.8% of the carbon monoxide originally combined with the nickel in the reacting nickel carbonyl. Some carbon dioxide was detected, the amount appearing to vary with the rate of admission of nitrogen peroxide, or perhaps with the temperature attained by the glass near the reaction zone.

The solid products of the reaction were obtained as a light, bulky, greenish-yellow solid which adhered to the walls of the reaction vessel. When covered with liquid nickel carbonyl, the product was apparently insoluble and unchanged. Failure to obtain x-ray patterns of the solid suggested that the material was amorphous. The solid was hygroscopic, dissolving in the water absorbed, then appearing to hydrolyze to form a green gelatinous precipitate resembling nickelous hydroxide. When treated with dilute sulfuric acid, the solid readily dissolved and oxides of nitrogen escaped. This reaction was made use of in analysis. Analyses of the solid are indicated in Table I.

TABLE I

ANALYSES OF SOLIDS RESULTING FROM REACTION OF NICKEL CARBONYL WITH NITROGEN PEROXIDE

Numbers refer to methods of preparation listed above.

Sample no.	Percentage composition Ni	N	O
30[2]	36.43	17.55	47.82
31[2]	34.52	18.04	47.44
32[2,a]	35.50	17.26	47.24
34[2]	36.86	18.24	44.90
35[4]	32.25	18.84	48.91
36[4]	32.69	19.09	48.22
37[3]	35.20	17.88	46.92

[a] Adsorbed oxides of nitrogen were removed from this sample before analysis.

The ratio of nitrogen as nitrate to that as nitrite was determined on Sample 37 and was found to be: N (nitrate)/N (nitrite) = 0.7469.

Nitric Oxide and Nickel Carbonyl.—Reaction between these compounds was markedly *inhibited by carbon monoxide.* In the presence of carbon monoxide under partial pressure of approximately half an atmosphere, reaction between nitric oxide and *gaseous nickel carbonyl* was not detected below 62°, at which temperature a bronze film appeared on the heated glass. Addition of moisture to the gases did not alter the results. When nitrogen was substituted for the carbon monoxide, reaction between nickel carbonyl and nitric oxide began immediately but was soon retarded or stopped and was far from complete after twenty-four hours. Pure nitric oxide and gaseous nickel carbonyl reacted rapidly but incompletely at room temperature, although reaction was not detected at 0°.

When nitric oxide was passed over *liquid nickel carbonyl,* a greater pressure of carbon monoxide was necessary to inhibit the reaction than when both reactants were in gaseous form. When pure nitric oxide was passed over liquid nickel carbonyl at 0°, twenty-five and one-half hours were required for the preparation of a maximum yield of 0.2775 g. of the solid product mentioned below.

Reaction took place as usual between nitric oxide and nickel carbonyl at room temperature in a vessel from which the light was carefully excluded.

Analysis of the *gaseous products* of the reaction indicated that most of the carbon monoxide initially combined with the nickel was set free. A trace of carbon dioxide was detected.

Pure nitric oxide and liquid nickel carbonyl reacted at temperatures between −11 and 0° to form a blue gelatinous *solid product* which became pale blue, almost white, on removal of the excess liquid nickel carbonyl. At room temperature the reaction was complicated by the formation of bronze, brown or olive-green solids. Analyses of the solid products showed large variations as shown in Table II. The pale blue solid formed at 0° was insoluble in water, but dissolved readily in dilute sulfuric acid, liberating oxides of nitrogen. Concentrated sulfuric acid reacted slowly with the solid forming a yellow suspension and liberating oxides of nitrogen and traces of carbon monoxide and carbon dioxide. When heated in hydrogen a sample of the solid slowly turned brown: at 140° reaction was rapid, leaving a dark brown solid and liberating nitric oxide. When heated in oxygen another sample of the solid rapidly turned brown at 150° and nitrogen peroxide was formed. It is interesting to note that the similar solid prepared by Mond and Wallis[5] decomposed violently at 90° in an inert atmosphere.

TABLE II

ANALYSES OF SOLIDS RESULTING FROM REACTION OF NITRIC OXIDE WITH NICKEL CARBONYL

9, 10 prepared at room temperature; 11–13b at 0°

Sample no.	Percentage composition Ni	N	O
9	28.83	11.04	60.13
10	25.15	10.61	64.24
11	58.62	13.19	28.65
12	45.94	12.47	41.59
13a	39.19	14.35	46.46
13b	38.89	12.94	48.17

Ammonia, Nitric Oxide and Nickel Carbonyl.—In an attempt to stabilize the initially formed blue solid product of the reaction between nitric oxide and nickel carbonyl, ammonia at a partial pressure of 0.06 atm. was introduced into the nitric oxide and the resulting mixture was passed over liquid nickel carbonyl. Reaction occurred above −14° with the formation of a blue, gelatinous precipitate, lighter in color and more bulky than that obtained with nitric oxide alone. When the excess liquid nickel carbonyl was removed, a finely divided white solid remained, which dissolved readily in dilute sulfuric acid with the liberation of oxides of nitrogen. When exposed to the air the solid turned pink. Analyses of samples are indicated in Table III.

TABLE III

ANALYSES OF SOLIDS FORMED BY THE REACTION OF A MIXTURE OF NITRIC OXIDE AND AMMONIA WITH NICKEL CARBONYL

Sample no.	Percentage composition			
	Ni	NH_3	N (additional)	O
17	27.07	34.82	14.09	24.02
22	25.06	37.23	9.89	27.82

Ammonia and Nickel Carbonyl.—No reaction was detected with either gaseous or liquid reagents. The solubility of nickel carbonyl in liquid ammonia at its boiling point was apparently negligible.

Nitrogen Trioxide and Nickel Carbonyl.—Reaction of nitrogen trioxide with nickel carbonyl took place at −78° with the formation of a bright red solid, apparently formed only at temperatures at which the molecule N_2O_3 exists. The solid slowly lost its bright red color and became reddish-yellow when warmed to 60°. We were unable to analyze the red compound, but obtained a brown solid (apparently formed by the action of nitrogen peroxide on the red solid) which had the composition: Ni, 28.95; N, 22.95; O, 48.10.

Nitrous Oxide and Nickel Carbonyl.—Reaction between these substances was not observed at 0°, and at room temperature the rate of reaction was negligible. A mixture of nitrous oxide and gaseous nickel carbonyl exploded when ignited with a gas flame.

Nitric Oxide, Nickel Chloride and Grignard Reagents.—Nitric oxide was passed through suspensions formed by addition of nickel chloride (1) to an ether and benzene solution of phenylmagnesium bromide,[7] and (2) to an ether solution of ethylmagnesium bromide. The green solution obtained in the latter experiment was not as intense in color as that in the former. Attempts to isolate the green substances were unsuccessful due to their high solubility and sensitivity to air. That Job and Reich,[7] as they suggested, prepared the compound obtained by Mond and Wallis,[5] is made doubtful by the facts that the green substance in solution was not decomposed by dilute sulfuric acid, and that oxides of nitrogen were not liberated by this treatment.

Discussion of Results

The temperatures at which reaction was first detected between nickel carbonyl and oxides of nitrogen studied were roughly in the inverse order of the degree of oxidation of the nitrogen atom: NO_2, −78°; N_2O_3, −78°; NO, −11°; N_2O, above room temperature.

Nitrogen peroxide reacted with nickel carbonyl at −78° and above to form a solid in which the ratio of nitrate to nitrite was in agreement with the assumption that the solid consisted of a mixture of the nickel salts of these ions (calculated for $Ni(NO_2)_2 \cdot 0.7469Ni(NO_3)_2$, Ni, 35.20%: found Ni, 35.71). Most of the carbon monoxide combined with the nickel was liberated as such. The products of the reaction in hexane contained more nitrogen and oxygen than samples obtained by other methods.

Nitrogen trioxide reacted with nickel carbonyl apparently at temperatures at which the molecule N_2O_3 exists. The behavior of this solid suggests the possibility that it is an addition product.

Nitric oxide reacted with nickel carbonyl above −11° to liberate carbon monoxide and traces of carbon dioxide and to form solids which varied greatly in composition, even when prepared in consecutive vessels under the same conditions (13a and 13b, Table II). It will be noticed that the solid obtained at room temperature contained less nickel than that formed at 0° (9, 10, Table II).

The marked inhibiting effect of carbon monoxide on the reaction between nickel carbonyl and nitric oxide is somewhat similar to that reported by Dewar and Jones[8] on the reaction between nickel carbonyl and carbon disulfide. The phenomena in both cases are probably, as these authors suggested, explained by the influence of carbon monoxide on the stability of the nickel carbonyl in accordance with its reversible decomposition.

$$Ni(CO)_4 \rightleftarrows Ni + 4CO$$

for which the equilibrium relationship is

$$K = P_{Ni} \times P^4_{CO}/P_{Ni(CO)_4}$$

The possibility is suggested that the nitric oxide reacts not entirely with the nickel carbonyl but with its products of decomposition.

The appearance, analyses and manner of formation of the solids formed by the action of ammonia and nitric oxide on nickel carbonyl suggests the formation of complex compounds, such as $[Ni(NH_3)_5NO]NO_2$ and $[Ni(NH_3)_5NO]NO_3$ (Ni: calcd., 26.69 and 24.88%; found, 27.07 and 25.06%).

Ammonia did not react with nickel carbonyl at 0°, and the reaction between ammonia, nitric oxide and nickel carbonyl began at the same temperature as that between nitric oxide and nickel carbonyl. These facts suggest that the nickel carbonyl first reacts with the nitric oxide to form a product which further reacts with ammonia to form a complex compound, perhaps as indicated in the tentative equations

$$Ni(CO_4) + 2NO \longrightarrow Ni(NO)_2 + 4CO$$
$$Ni(NO)_2 + 5NH_3 \longrightarrow [Ni(NH_3)_5NO]NO$$

The $[Ni(NH_3)_5NO]NO$ may then be oxidized to form the compounds $[Ni(NH_3)_5NO]NO_2$ and

---

[7] Job and Reich, *Compt. rend.*, **177**, 1439 (1923).

[8] Dewar and Jones, *J. Chem. Soc.*, **97**, 1226 (1910).

$[Ni(NH_3)_5NO]NO_3$. Briner and co-workers[9] have found that nitrogen peroxide is formed slowly in pure nitric oxide under pressure at ordinary temperature, and also in liquid nitric oxide under atmospheric pressure below its boiling point. The presence in the reacting gases of nitrogen peroxide so formed may explain the oxidation of the complex compound first formed, and may also explain the failure to obtain a pure solid product from the reaction of nitric oxide with nickel carbonyl.

In view of the unexplained erratic behavior of oxygen and nickel carbonyl,[10] the observations concerning mixtures of nitrous oxide and nickel carbonyl cannot be taken as final. Nitrous oxide may react equally unpredictably with nickel carbonyl.

Acknowledgments.—The authors wish to acknowledge their indebtedness to Drs. C. B. Jackson and O. G. Bennett for assistance in the preparation of the nickel carbonyl used, and to Messrs. P. M. Goodloe, J. H. Hopkins and J. W. Daum for assistance in the laboratory.

Summary

Some observations have been reported concerning the reactions of nickel carbonyl with nitrogen peroxide, nitric oxide, nitrous oxide, ammonia and a mixture of ammonia and nitric oxide.

The suggested relationship of the results of Job and Reich[7] to those of Mond and Wallis[5] was also investigated.

Antioxidants and the Autoxidation of Fats. VII. Preliminary Classification of Inhibitors[1]

BY H. S. OLCOTT AND H. A. MATTILL

It was recently proposed[2] to give the name "inhibitols" to those as yet unidentified constituents of the unsaponifiable matter of various vegetables and vegetable oils which possess the capacity to delay oxidative rancidity in certain fats. This term indicates their activity as inhibitors and also the invariable occurrence of hydroxyl groups upon which their inhibiting action depends. Methods of preparation of inhibitol concentrates and some of their physical and chemical properties have been described in some detail.[2]

Inhibitol concentrates are effective antioxidants for animal fats and for highly purified unsaturated fatty acids and esters, but they have consistently failed to show any antioxygenic activity when added, even in relatively large amounts, to the vegetable oils from which they were obtained (Table I). The inactivity of inhibitols in vegetable oils is also implied in the experiments of Royce,[3] who added a crude sterol fraction of cottonseed oil to hydrogenated cottonseed oil without observing any prolongation of the induction period, in those of Greenbank and Holm[4] who reported an unsuccessful attempt to isolate an antioxidant from cottonseed oil, using vegetable oils as the assay substrate, and in those of Bau-

mann and Steenbock[5] who found that, in cottonseed oil, carotene losses were not reduced by an inhibitol-containing material like wheat germ oil.

These facts prompted an investigation of the factor or factors in the vegetable oils responsible for their refractoriness to protection by inhibitols and conversely, a study of the types of inhibitors which could protect these oils. The experiments to be described deal with the second of these two questions. Refined and hydrogenated cottonseed oils were used in most of the experiments, but the same phenomena were also demonstrable with palm, sesame, soy bean and other vegetable oils.

The oxygen absorption method which we have used[6] in the study of lard and its protection by inhibitors could not be applied satisfactorily to the study of vegetable oils. Whereas lard demonstrates a definite induction period after which the absorption of oxygen is rapid, vegetable oils absorb oxygen slowly and the end of the induction period is not sharply defined. Furthermore, vegetable oils are more stable than lard so that the oxygen absorption method is time consuming unless high temperatures are used. Since, in our hands, a temperature of 70–80° has proved to be a convenient one at which to measure oxygen absorption, we investigated several methods of reducing the induction period of these oils to convenient lengths at 75°, attempting at the same time to retain the properties of the original oils with regard to inhibitors, especially their absolute refractoriness to protection by inhibitols.

The most satisfactory method proved to be the use of the ethyl esters of the fatty acids, prepared as follows. Two parts of absolute alcohol containing 2–3% hydrogen chloride were added to one part of the fat and refluxed on a steam-bath for eighteen to twenty-four hours. The mixture was cooled and diluted with water. The ester layer was washed repeatedly with water to remove hydrochloric acid and ethyl alcohol, then centrifuged free from occluded water, and finally heated on a steam-bath in a vacuum to remove traces of solvents. Theoretically this light brown, mobile liquid, hereafter referred to as crude esters, contained the ethyl esters of the fatty acids, the unsaponifiable constituents of the original fat and possibly traces of unhydrolyzed glycerides; the glycerol and any water-soluble constituents should have been removed.

The product so obtained from a hydrogenated cottonseed oil could be used to assay inhibitors by the oxygen absorption method, since it had a convenient induction period at 75° (four to sixteen hours), and a rapid rate of oxygen absorption at the end. Furthermore, the protection afforded the crude esters by various inhibitors was qualitatively parallel to that conferred on the original fat; the crude esters were not protected by relatively large amounts of inhibitol concentrates but were protected to a remarkable degree by several substances which have been suggested for use as antioxidants in vegetable fats, namely, oxalic acid,[7] maleic acid,[4] sulfuric and phosphoric acids and their acid salts,[8] and lecithin.[9,10]

The effectiveness of so many substances that are alike only in the possession of an ionizable hydrogen atom prompted an investigation of the antioxygenic activity of other acids, both organic and inorganic. The results, summarized in Table II, permit of no generalizations, but suggest certain interesting relationships. In the aliphatic series, pyruvic acid is the only active compound not containing two free carboxyl groups; the adjacent carbonyl apparently has an activating effect. The two carboxyl radicals must not be separated by more than one CH_2 group unless an active group or groups, such as hydroxyl, or an unsaturated bond is also present. The inactivity of the salts and esters of the dicarboxylic acids indicates that the carboxyl groups must be free. Among the inorganic acids tested, sulfuric and phosphoric acids were the only ones to show marked antioxygenic action. Calcium acid phosphate was effective in contrast to the inactivity of the sodium and potassium salts, presumably due to its greater acidity. Any explanation of the action of these acids must take account of the fact that the medium in which they act is practically anhydrous. The solubility of cephalin doubtless accounts in part for its efficiency.

With the exception of hydroquinone, the phe-

(10) The antioxygenic action of commercial lecithin has been shown to be due to its contained cephalin, and the activity of cephalin in turn, appears to depend on the monobasic phosphoric acid radical [H. S. Olcott and H. A. Mattill, *Oil and Soap*, **13**, 98 (1936)].

Lactic acid
Succinic acid
Adipic acid
Mucic acid
Azelaic acid
Dihydroxystearic acid
Aspartic acid
Benzoic acid
Phthalic acid
Isophthalic acid
α-Naphthoic acid
β-Naphthoic acid
d-Camphoric acid
Tannic acid
Ethyl oxalate
Ethyl malonate
Ethyl tartrate
Sodium bitartrate
Sodium oxalate
Oxamide
Inhibitol concentrates

Active Compounds and Indices[b]

Sulfuric acid (95%)[c]	15–20	Maleic acid	4–6
Phosphoric acid (85%)[c]	15–20	Citric acid	10–15
Calcium dihydrogen phosphate	4–6	Malic acid	8–12
Cephalin	4–6	Pyruvic acid	10–15
Perchloric acid	3	Hydroquinone	1.2–1.6
Arsenic acid	3	Catechol	12
Oxalic acid	15–20	Pyrogallol	26
Malonic acid	10–15	α-Naphthol	9
Tartaric acid	10–15	1,5-Naphthalenediol	5

[a] For the most part these compounds were assayed by adding 1 mg. to 5 g. of the crude esters (0.02%). The induction period of the "protected" sample was never more than twice that of the control sample; in most cases, no antioxygenic action could be observed. When 5 mg. was used (0.1%), some of the compounds exhibited slight antioxygenic activity. Among these were lactic and phthalic acids, sodium and potassium dihydrogen phosphates, and ethyl tartrate.

[b] The index represents the ratio of the induction period with inhibitor to that of the control. For example, the data for several runs of tartaric acid: with inhibitor, 130, 100, 170 hours; without, 6, 9, 10. Most of the inhibitors were assayed at a 0.02% level. 1,5-Naphthalenediol was tested at 0.01%. All results were obtained at 75°.

[c] Dilution of the sulfuric and phosphoric acids with an equal amount of water did not decrease their activity.

nolic inhibitors were relatively as active on the ester preparations as on lard.[11,12]

The reactions of the vegetable oil crude esters to inhibitors thus provided an entirely different picture from that presented by lard and purified fatty acids, in which the acid inhibitors mentioned above are only very slightly antioxygenic if at all, while the phenolic inhibitors and the inhibitols are very efficient.[2] Crude methyl and ethyl esters prepared from lard responded to inhibitors in the same manner as did the original lard (Table III), indicating that the process of esterification was not responsible for the reaction toward inhibitors of the vegetable oil esters. Crude methyl esters of the vegetable oils reacted exactly like those prepared with ethyl alcohol.

TABLE III

THE EFFECT OF INHIBITORS ON LARD AND ON THE CRUDE ESTERS OF LARD

Substrate	% inhibitor added	Induction period, hours: With inhibitor	Induction period, hours: Control
Lard (75°)	0.20 cephalin	8	5
	.20 tartaric acid	15	9
	.20 malonic acid	13	9
	.20 citric	16	11
	.20 phosphoric acid	19	10
	.20 oxalic acid	38	13
	.20 W5-10	62	15
	.01 hydroquinone	410	14
Crude methyl esters of lard (60°)	.20 cephalin	10	9
	.20 tartaric acid	14	9
	.10 W5-10	45	9
Crude ethyl esters of lard (65°)	.10 tartaric acid	4	2
	.10 malonic acid	4	1.5
	.10 citric acid	4	1.5
	.10 phosphoric acid	5	1.5
	.10 oxalic acid	25	2
	.10 W5-10	12	1.5
	.02 hydroquinone	60	2

When the crude esters were distilled *in vacuo*, 95% distilled below 160° at 0.1 mm. The properties of the water-white distillate, with regard to its amenability to protection by various inhibitors, were strikingly different from those of the crude esters. The inhibitols were effective, although not as active as in lard. Hydroquinone was an efficient inhibitor, and the dibasic and inorganic acids were relatively ineffective (Table IV). This table also demonstrates the same significant difference in the reactions of palm oil esters to different inhibitors before and after distillation.

From these results it is apparent that, unless some destruction or alteration occurred during the distillation, the residue should contain compounds which could (a) inhibit the antioxygenic activity of inhibitols and hydroquinone and (b) activate the acid type inhibitors.

It was possible to demonstrate (b) but not (a) by adding small amounts of the residue to the distilled esters. The acid type inhibitors were effec-

tive for this mixed substrate but the antioxygenic action of inhibitols was not suppressed. A series of investigations designed to determine the nature of the compound present in the residue and responsible for the activation of the acid type inhibitors, disclosed that it occurred in the nonsterol unsaponifiable fraction and that it was destroyed by acetylation but not by hydrogenation. These were also properties of the inhibitols, and it was possible to demonstrate that a highly concentrated inhibitol fraction exhibited this remarkable synergism with acid type inhibitors when the distilled esters of hydrogenated cottonseed oil were used for the substrate fat (Table V). Apparently the inhibitol originally present in the vegetable oil and remaining in the residue when the crude esters were distilled, is responsible for the activation of the acid type inhibitors in the crude esters.

This synergistic effect of inhibitol and some one of the acid inhibitors could also be demonstrated in lard, purified fatty acids and esters and octadecene (Table V), but not in vegetable oils.

The close relationship between hydroquinone and the inhibitols led to an investigation of the effect of mixtures of phenolic and acid inhibitors. The synergistic effect could easily be demonstrated, for example, with orcinol and phosphoric acid (Table VI). Other combinations of phenolic and acidic inhibitors varied in their effectiveness. Citric and tartaric acids did not show the synergistic effect with orcinol when assayed on lard fatty acids.

It is thus apparent that the observation of Holmes, Corbet and Ragatz[13] on the superior stabilizing effect of combinations of lecithin and hydroquinone on vitamin A over that of either alone, is only an individual case of a more or less general phenomenon.

Based upon our experiments we have tentatively classified the inhibitors studied into three groups: (1) the acid type inhibitors, (2) inhibitols and hydroquinone, and (3) the phenolic type including α-naphthol, pyrogallol, catechol and others. Table VII outlines the qualitative differences in behavior of these kinds of inhibitors on various substrates. The boundaries between the three types are not especially well defined. For example, oxalic acid has a definite antioxygenic action on lard, greater than that of the other acid type inhibitors. The anomalous behavior of hy-

	.02 orcinol + 0.10% tartaric acid	41	2.5

[a] When discontinued, these samples were still fresh.

droquinone in contrast to the other phenolic inhibitors is in accord with the observations of others concerning hydroquinone in gasoline.[14]

TABLE VII

QUALITATIVE DIFFERENTIATION OF THREE TYPES OF INHIBITORS

	Acid type[a]	Inhibitols and hydroquinone[b]	Phenolic type[c]
Vegetable oils	+	−	+
Crude vegetable oil esters	+	−	+
Distilled vegetable oil esters	−	+	+
Lard and lard esters	−	+	+
Purified fatty acids and esters	−	+	+

[a] Oxalic acid protects lard to an appreciable extent (Table III).

[b] Hydroquinone is effective in vegetable oils, but is included in this grouping because it is relatively ineffective on crude vegetable oil esters.

[c] Includes some natural products, such as gossypol, gallic acid, as well as catechol, pyrogallol, α-naphthol, etc.

In general, any type 1 inhibitor when used with any type 2 or 3 compound, prolongs the induction period of certain fats and other unsaturated compounds to a much greater extent than would be expected from a summation of the effects of each used alone.

There is, of course, an almost infinite number of possible combinations of antioxidants, some of which should be utilizable not only in the edible fat industry, but wherever compounds or mixtures are subject to oxidative deterioration.

In conclusion, it may again be emphasized that the complex reactions which result in rancidity are subject to many factors, some unknown, which operate to make duplication of results uncertain at times. The data recorded in this paper are merely representative of those obtained from a large number of experiments and assays.

Further observations on the causes of the fundamental differences between vegetable and animal fats, with respect to their reactions toward different inhibitors, will appear in subsequent publications.

Acknowledgment.—The authors are indebted to Lever Brothers Company for a grant in support of this work and to Dr. Lyle A. Hamilton for technical assistance.

Summary

The crude esters of hydrogenated cottonseed and other vegetable oils, prepared by refluxing the oil with absolute methyl or ethyl alcohol containing dry hydrogen chloride, are protected to a remarkable degree by oxalic, malonic, maleic, citric and other aliphatic dibasic acids, by phosphoric and sulfuric acids and cephalin, and by some phenolic inhibitors. Hydroquinone is only slightly effective and inhibitol concentrates prepared from the unsaponifiable fraction of vegetable oils are inactive.

When the esters are partially purified by fractional distillation *in vacuo*, they are only slightly protected by the acids or cephalin, but are protected by hydroquinone and the inhibitols.

The acid inhibitors and inhibitol concentrates have a pronounced synergistic effect when used together in the distilled ester preparation; the protection afforded by the mixture is much greater than by either alone. This phenomenon can also be demonstrated in lard, and in purified fatty acids and esters, and also with certain mixtures of phenolic and acid type inhibitors.

Based upon these observations, a tentative classification of inhibitors into three groups is proposed: Group 1, acid type inhibitors; Group 2, inhibitols and hydroquinone; Group 3, other phenolic inhibitors.

The Kinetics of the Benzilic Acid Rearrangement

BY F. H. WESTHEIMER[1]

Introduction

In 1932 Whitmore[2] advanced a general theory which postulated a positive ion as the intermediate in all molecular rearrangements. Not only a large amount of qualitative evidence, but also the quantitative work of Meerwein,[3] support this hypothesis, at least for the Wagner–Meerwein (retropinacol) rearrangement. Ingold,[4] in 1928, put forth another general theory of rearrangements in which a negative ion was assumed as the intermediate; later[5] he pointed out that it is difficult to reconcile Whitmore's views with the facts of the benzilic acid rearrangement. The present work, a quantitative study of the benzilic acid rearrangement, supports Ingold's contention that the intermediate is the negative ion  $C_6H_5\text{—}\overset{\text{O—}}{\underset{\text{HO}}{C}}\text{—}\underset{\text{O}}{\overset{}{C}}\text{—}C_6H_5$. Another study, which will be presented elsewhere, deals with the rearrangement of benzil *o*-carboxylic acid, especially as concerns the salt effect.

Method

Lachman,[6] in 1924, showed that there are three reactions which take place when benzil, in aqueous alcoholic solution, is treated with alkali

$$C_6H_5COCOC_6H_5 + KOH \longrightarrow (C_6H_5)_2COHCOOK$$
$$C_6H_5COCOC_6H_5 + KOH \longrightarrow C_6H_5COOK + C_6H_5CHO$$
$$2C_6H_5COCOC_6H_5 + C_2H_5OH \longrightarrow C_{30}H_{24}O_4$$

The second of these three reactions, a cleavage, goes on only in the presence of alcohol, and to the extent of only a few per cent. when the alcohol is less than half of the total solvent. The third reaction, the production of "ethyl dibenzil," also a minor reaction, again occurs only in the presence of alcohol. The structure of "ethyl dibenzil"[7] is unknown. The first reaction, the rearrangement of benzil to benzilic acid, is quantitative in aqueous solution; in aqueous alcohol yields of 90–95% are obtained. Since benzil, even in the absence of salt, is soluble only to the extent of 0.3 g./l. at 100°, it was necessary to employ 32% alcohol in this kinetic study. The secondary reactions interfered but slightly with the results obtained.

The rate of rearrangement of benzil was measured at 100° in 32% alcoholic solutions of potassium and barium hydroxides, and in phenol-phenolate ion and *o*-chlorophenol-*o*-chlorophenolate ion buffers. While many studies have been made of the *pK* of phenol and chlorophenol at room temperature,[8] the value of these constants at 100° was unknown. In order to ascertain the hydroxyl ion concentrations of the buffer solutions, the hydrolysis constants of phenolate and of *o*-chlorophenolate ions were measured at 100° in 32% alcohol by conductivity.

Ampoules, filled with the reacting solution, were removed from the thermostat at stated times for analysis. Since it would have been difficult if not impossible to determine the concentration of benzilic acid, acidimetrically, by difference, especially in the buffered solutions, an extraction method was employed. The contents of the ampoules were acidified and the organic matter brought into ether using a continuous extractor. Subsequently the ether was distilled off, the benzilic acid taken up in alcohol–water and titrated with 0.01 *M* carbonate-free alkali, using thymol blue as the indicator. When buffered solutions were employed, they were neutralized, bicarbonate solution added, and the mixture extracted. This removed the phenol or *o*-chlorophenol; after acidifying again, the benzilic acid was obtained by a second extraction.

A difficulty, encountered in connection with the buffers, was the air oxidation of the alkaline phenol solution. This produced a red indicator-type dye which effectively obscured the thymol blue end-point. It was impossible to obtain consistent results until the ampoules were evacuated and filled with nitrogen before sealing. The ampoules were of a type which prevented mixing of the phenol with the alkali until they were inverted.

TABLE I

TYPICAL VELOCITY DETERMINATION

Cc. stands for the number of cc. of 0.01 *M* potassium hydroxide used in titration, x, for the concentration of benzilic acid, $a - x$ the concentration of benzil, $b - x$ the concentration of potassium hydroxide present at any time; t is quoted in minutes. The standard equation, employing natural logarithms, was used for the calculation.

Cc.	x	$a - x$	$b - x$	$\text{Log}\,\frac{a\,(b - x)}{b\,(a - x)}$	D		$k \times 10$	Dev.
2.72	0.00149	0.00505	0.0485	0.099				
4.06	.00222	.00432	.0478	.160	0.061	15.2	2.13	0.18
5.00	.00274	.00380	.0473	.211	.112	33.3	1.78	.17
5.91	.00323	.00331	.0468	.267	.168	45.7	1.94	.01
6.62	.00362	.00292	.0464	.319	.220	61.3	1.89	.06
7.48	.00409	.00245	.0459	.389	.290	76.8	2.00	.05
						Average	1.95	0.09 or 5%

Since the analyses proved accurate to 1%, velocity constants could be obtained.

Experimental

The thermostat is a large copper tank designed as in Fig. 1. A hot plate boils water in the lower compartment. Steam fills the boiler, heats the wells (which are filled with paraffin) and the condensate is returned from the reflux to the lower compartment. The cold end of the condenser is attached to a pressure regulator, of the type designed by Coffin,[9] with picein. By maintaining constant pressure, constant temperature was assured. The thermostat, which required no attention whatsoever, operated at 100.04 ± 0.03° for a period of five months. The absolute temperature was determined with a Bureau of Standards calibrated thermometer.

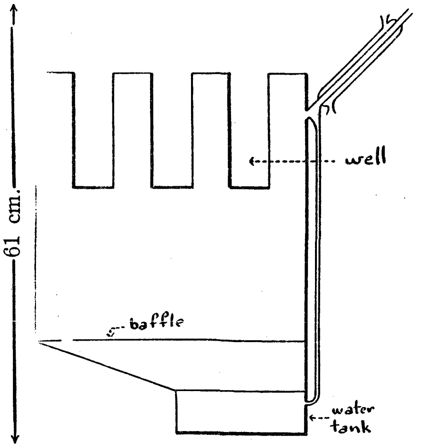

Fig. 1.—The thermostat.

Conductivity Apparatus.—The conductivity cell was a Washburn[10] type B cell, made of Jena glass, with 1.3-cm. smooth platinum electrodes 8 cm. apart. The conductivity apparatus was of the standard Washburn type.

Extractors were designed as in Fig. 2. They were constructed entirely of glass, using interchangeable ground-glass joints. Blanks showed that benzilic acid, introduced with alcohol as in the actual experimental conditions, could be removed quantitatively in one hour. The precision was 1%. When buffers were used, the solution was brought to the methyl orange end-point, and 10 cc. of 0.1 *M* sodium bicarbonate solution added. The solution was extracted for two hours in the case of phenol, three hours in the case of *o*-chlorophenol. Three cc. of 1 *M* hydrochloric acid was then added through the funnel and the solution extracted for one hour after the acid had permeated the entire aqueous layer (as shown by the methyl orange color). Blanks showed that this method removed the benzilic acid from phenol with an accuracy of 1%.

Materials.—The benzil was an Eastman chemical, recrystallized twice from carbon tetrachloride, twice from alcohol. The corrected m. p. was 94.4°. Eastman chlorophenol was three times vacuum distilled from an ordinary Claisen flask; the corrected freezing point was 9.1° over a few hundredths of a degree range. After five vacuum distillations and subsequent fraction freezing, Eastman recrystallized phenol froze at 40.5° over 0.1° range. The alcohol was freed of aldehyde by the method of Dunlap.[11] All salts were recrystallized from water. Only carbonate-free alkali was employed.

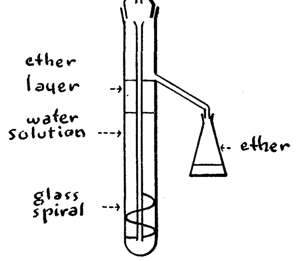

Fig. 2.—Continuous extractor.

Results

The reaction between benzil and OH^- ion is bimolecular. This conclusion is based not only on the fact that a constant is obtained with a bimolecular equation, but also on the fact that the constant remains sensibly the same while the concentrations of the reactants are varied tenfold. The small deviations observed which are outside the possible experimental error may be due to the fact that the side reactions, referred to above,

---

(10) Washburn, *ibid.*, **38**, 2431 (1916); Washburn and Parker, *ibid.*, **39**, 235 (1917).

(11) Dunlap, *ibid.*, **28**, 395 (1906)

are more prominent in one case then in the other. A typical run, in which the average deviation is of the usual magnitude, is recorded.

The rate constants obtained using varying initial concentrations of benzil and of hydroxyl ion (but a constant ionic strength of 0.3) are shown in Table II.

TABLE II

BIMOLECULAR RATE CONSTANT FOR THE BENZILIC ACID REARRANGEMENT

Concn. of benzil	Concn. of KOH	Concn. of KCl	k
0.008	0.15	0.150	2.17×10^{-1}
.006	.05	.250	1.95×10^{-1}
.006	.015	.285	1.79×10^{-1}
.003	.005	.295	2.12×10^{-1}
.02	.05	.250	1.85×10^{-1}

While the variation is somewhat greater than the experimental error, it is indeed small for a tenfold change in the concentration of both reactants. Such variation as there is in the rate constant with change in hydroxyl-ion concentration must be discounted in view of the evidence, reported below, obtained with buffered solutions. A small change in the extent of the side reactions with increasing concentration of benzil would account for that part of the variation in the constant which exceeds the experimental error. The effect of increased salt concentration upon the reaction is small, but positive, as is shown in Table III.

TABLE III

THE SALT EFFECT IN THE REARRANGEMENT OF BENZIL

Concn. of benzil	Concn. of OH⁻	Concn. of KCl	μ	k
0.008	0.05		0.05	1.89×10^{-1}
.006	.05	0.25	.30	1.97×10^{-1}
.007	.05	.70	.75	2.15×10^{-1}

If the reaction is truly a bimolecular one between benzil and hydroxyl ion, the rate should be the same regardless of what metallic hydroxide is employed. In solutions of low ionic strength, the rate with barium hydroxide indeed proved approximately equal to that with potassium hydroxide; there is, however, a large positive salt effect with increased concentration of barium chloride. The results are tabulated below.

TABLE IV

THE SALT EFFECT WITH BARIUM CHLORIDE ON THE REARRANGEMENT OF BENZIL

Concn. of benzil	Concn. of OH⁻	Concn. of $BaCl_2$	μ	k
0.006	0.0100		0.015	2.61×10^{-1}
.007	.0100	0.050	.165	3.69×10^{-1}
.007	.0100	.242	.740	5.13×10^{-1}

In buffered solution, the pseudomonomolecular rate constants drifted to lower values of k as the run progressed. Some, at least, of this effect was due to the fact that the buffer does not hold the hydroxyl ion concentration constant, but this concentration diminishes during the run. It is, however, possible to separate this effect from any real drift which may occur. The following approximation formula was developed to compensate for the change in hydroxyl ion concentration during the course of the reaction

Let x = concentration of benzilic acid
a = original concentration of benzil
b = original concentration of phenolate ion
c = original concentration of phenol
K_h = hydrolysis constant of phenolate ion

$$\frac{dx}{dt} = k(\text{Benzil})(\text{OH}^-) \text{ and } (\text{OH}^-) = K_h \frac{(\text{Phenolate ion})}{(\text{Phenol})}$$

$$\text{So } \frac{dx}{dt} = kK_h(a - x)\frac{(b - x)}{(c + x)}$$

Since b and c are large compared with x, little error is introduced by replacing $(b - x)/(c + x)$ by the expression $\frac{b}{c}\frac{1}{1 + [(b + c)/bc]x}$. Making this substitution, and integrating the resultant equation, we obtain

$$2.303\left(1 + \frac{b + c}{bc}a\right)\log\frac{a}{a - x} - \frac{b + c}{bc}x = \frac{b}{c}kK_h t$$

Here the left side of the equation embodies the correction; the product $(b/c)kK_h$ can be considered a new constant k'. The results obtained with this equation still have, on the average, somewhat of a drift, although this hardly exceeds the experimental error. Typical values for k', obtained over about 50% reaction, are 1.70, 1.31, 1.46, 1.45, 1.38. The values of k' in various buffer solutions are recorded below.

TABLE V

RATE OF REARRANGEMENT OF BENZIL IN BUFFERED SOLUTIONS

Concn. of benzil	Concn. of KCl	Concn. of phenolate ion	Ratio of phenolate ion to phenol	k'
0.012	0.185	0.115	2.00	4.71×10^{-4}
.010	.250	.050	1.00	2.40×10^{-4}
.011	.118	.182	1.00	2.32×10^{-4}
.009		.300	1.00	2.44×10^{-4}
.009	.268	.032	0.50	1.40×10^{-4}
.009	.108	.192	.50	1.46×10^{-4}

Using *o*-chlorophenol and *o*-chlorophenolate ion, the results given in Table VI were obtained.

The results with phenol were easier to reproduce than the very slow rates obtained with *o*-chlorophenol.

TABLE VI

RATE OF REARRANGEMENT OF BENZIL IN BUFFERED SOLUTIONS

Benzil concn.	0.008	0.010
o-Chlorophenolate ion concn.	.026	.190
Ratio of *o*-chlorophenolate ion to *o*-chlorophenol	3.00	3.00
Potassium chloride concn.	0.274	0.110
$k' \times 10^4$	.92	.72

It is at once obvious from these figures that the rate is dependent upon the buffer ratio but not upon the concentration of the phenolate ion present. That is to say, the reaction is not one involving general base catalysis, for, if it were, the rate would increase, at constant buffer ratio, as the concentration of the phenolate ion increases. Furthermore, the change in rate with change in buffer ratio is approximately that which would be predicted if the reaction is strictly between benzil and OH^- ion.

TABLE VII

HYDROLYSIS OF PHENOLATE AND *o*-CHLOROPHENOLATE IONS AT 100° IN 32% ALCOHOL

Compound	Concn.	Compound	Concn.	Resistance
KOH	0.01500			776.8
KOH	.003106			3602.8
Phenolate	.2620	Phenol	0.3640	120.46
Phenolate	.2617	Excess KOH	.00151	107.41
o-Chlorophenolate	.3055	*o*-Chlorophenol	.1670	106.30
o-Chlorophenolate	.3038	Excess KOH	.00150	102.46

Phenolate ion is 7.3% hydrolyzed in the presence of 0.6% excess potassium hydroxide. *o*-Chlorophenolate ion is 1.7% hydrolyzed in the presence of 0.5% excess potassium hydroxide.

The rates in buffered and unbuffered solutions enable us to determine the hydrolysis constant of phenolate and of *o*-chlorophenolate ions. From Table V, the average value for phenol of ck'/b (which is equal to kK_h) is 2.54×10^{-4}, with an average deviation of 8%. Likewise, from Table I, the average value of the bimolecular constant k is 1.98×10^{-1}, with an average deviation of 7%. The value for K_h from kinetic measurements, then, is 1.28×10^{-3} for phenol, and likewise is 1.37×10^{-4} for *o*-chlorophenol.

The hydrolysis constant of a weak acid can be determined independently by measuring, by conductivity, the degree of hydrolysis of the potassium salt. A difficulty arose here in the manner in which the measurements should be made. For, to be comparable to the kinetic data, the conductivity measurements should be made at an ionic strength of 0.3. While these were the experimental conditions used, it is necessary to bear in mind that the conductivities of two salts in the same solution are not necessarily the sum of their separate conductivities, and that there is a certain solvent effect due to the presence of undissociated phenol or *o*-chlorophenol. Furthermore, these effects are magnified in solutions of moderate concentration.[12]

In the calculations using the data of Table VII below, the conductivities of the phenolate and *o*-chlorophenolate ions were corrected for the hydroxyl ions in the buffer solutions before calculating the percentage hydrolysis. $(\text{Phenol})(OH^-)/(\text{Phenolate ion} = K_h$. The final results are, then, given in Table VIII.

TABLE VIII

HYDROLYSIS CONSTANTS OF PHENOLATE AND *o*-CHLOROPHENOLATE IONS

	K_h	
Compound	Kinetics	Conductivity
Phenol	1.28×10^{-3}	1.61×10^{-3}
o-Chlorophenol	1.37×10^{-4}	1.15×10^{-4}

Before the significance of these figures can be appreciated, the possible errors must be evaluated. The error in the quotient of the two velocity constants may well be 10 or 15%. An error of 0.1% in the percentage hydrolysis of phenolate ion would mean an error of about 3% in the value of K_h; a similar error in the case of *o*-chlorophenolate ion would represent an error of a little more than 10%. If, then, there are no errors introduced because of the divergence from ideality of solutions as concentrated as 0.3 molar, we would expect that the constants obtained by the two different methods would agree within about 20%. The disagreement, while a trifle greater than this, is of this order of magnitude, and the pK of phenol and chlorophenol determined by the two methods agree within 0.1 pK unit.

Since the values of the hydrolysis constants determined by the two methods agree as well as

---

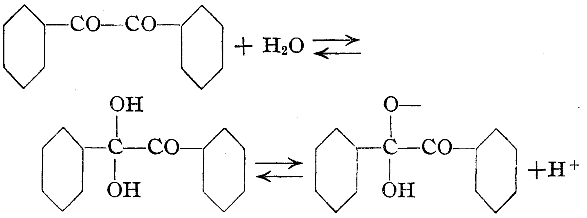
[12] MacInnes, Shedlovsky and Longsworth, *Chem. Rev.*, **13**, 29 (1933).

can be expected, we are justified in the assumption, used in the calculation of the hydrolysis constants from the kinetic data, that the bimolecular rate constant holds throughout the entire range of acidities studied. Essentially, the hydroxyl ion concentration has been varied 425-fold without changing the velocity constant by more than the experimental error.

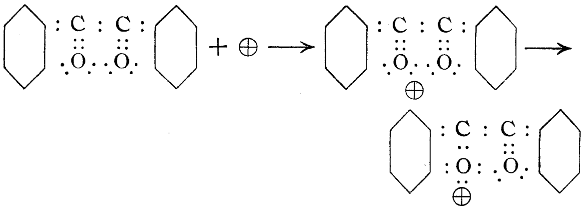
Peroxide Effect.—The work of Kharasch and Foy[13] on the oxygen catalysis of the Cannizzaro reaction suggested that the effect might be present in the benzilic acid rearrangement. Using the same precautions with which the results of Kharasch were repeated, no retardation was noted in the rearrangement. If such a catalysis exists, it levels off too rapidly to invalidate the kinetic data recorded above.

Discussion of Results

In aqueous solution, benzil undoubtedly exists in equilibrium with its hydrate, and with the negative ion which results from the ionization of the hydrate

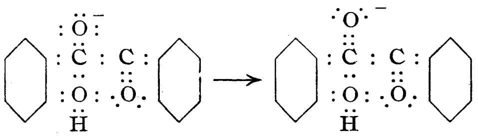


Whitmore[2] suggested that the first reaction is one between a positive ion and benzil, followed by a shift of electrons to form a carbonium ion, the true, unstable intermediate.



However, regardless of whether this primary addition is the slow step, or merely an equilibrium supplying the starting product for some other slow step, the theory would demand a strong positive ion catalysis. Such does not exist, and Whitmore's hypothesis cannot possibly be correct in this case. As a carbonium ion is the most likely intermediate in the Wagner–Meerwein rearrangement,[3] it is necessary to postulate more than one type of ionic intermediate for molecular rearrangements.

Ingold[4] suggested that the negative ion which results from the ionization of benzil hydrate is the first intermediate; a shift of electrons so that ten surround one C atom forms the true, unstable intermediate.



The kinetic data give no indication of whether this second hypothesis is correct, but they do very definitely point to this negative ion as the intermediate.[14] No other assumption would explain the fact that the rearrangement of benzil is bimolecular over more than a four hundredfold change in hydroxyl ion concentration.

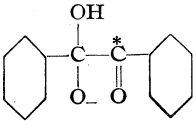
This ion could be formed by one of three mechanisms, namely, by general base catalysis, in which case a base would remove a hydrogen ion from the hydrate, by addition of an hydroxyl ion to benzil, or by direct ionization of the hydrate. The fact that the rate is independent of the concentration of phenolate ion is definite proof that the reaction is not an example of general base catalysis. The kinetic data afford no means of differentiating between the other two possibilities.

Furthermore, the ionization cannot be extensive in any of the solutions studied. For, if it were, a simple calculation shows that the rate would vary with *less* than the first power of the hydroxyl ion concentration; such is not the case. Moreover, a doubly ionized benzil molecule is also impossible, for if such an ion were involved, the reaction would of necessity show a large positive salt effect. Therefore, not only can the reaction adequately be explained on the basis of this ion as intermediate, but most other likely hypotheses can be eliminated definitely.

---

(13) Kharasch and Foy, THIS JOURNAL, **57**, 1510 (1935).

(14) Dr. P. D. Bartlett has pointed out in discussion that the fact that this migration occurs in a negative rather than a positive ion is not so foreign to Whitmore's generalization as might appear. According to this viewpoint, the essential feature of rearrangements is the migration of some group R: with an electron pair to a position having electron-attracting character. In the pinacol rearrangement such a position must be produced by the formation of a positive ion. Benzil, on the other hand, has an electron-attracting center permanently in the starred carbon atom of the carbonyl group:



The appearance of a negative charge on the other CO group facilitates the release of the adjacent phenyl group with its electron pair.

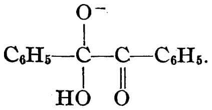
Acknowledgment.—The author owes an especial debt of gratitude to Professor L. P. Hammett for his advice and assistance. He wishes also to thank Professor J. J. Beaver for the use of his conductivity apparatus.

Summary

1. The rate of the rearrangement of benzil to benzilic acid has been measured in solutions of hydroxyl ion and in phenol–phenolate and *o*-chlorophenol–*o*-chlorophenolate ion buffers, all in 32% alcohol at 100%. The reaction is strictly bimolecular.

2. The hydrolysis constants of phenolate and of *o*-chlorophenolate ions have been measured, in 32% alcohol at 100°, by conductivity.

3 The conclusion is drawn that the rearrangement proceeds through the ion



$C_6H_5\text{—}\overset{O^-}{\underset{HO}{C}}\text{—}\underset{O}{C}\text{—}C_6H_5$.

The Rate of Exchange between Chloride Ion and Chlorine in Aqueous Solution

BY F. A. LONG AND A. R. OLSON

Two investigations dealing with the rate of exchange between halide ions and halogens have been published recently. Grosse and Agruss[1] studied the exchange between bromine and bromide ion and Hull, Shiflett and Lind[2] that between iodine and iodide ion. Both of these investigations employed radioactive indicators to follow the reactions. We can conclude from the results of these investigators that considerable interchange takes place during the course of several minutes, but no attempt was made in either investigation to ascertain the order of magnitude of the rate of the interchange reaction.

In studying the mechanism of the rearrangement of chloroacetylaminobenzene, Olson, Porter, Long and Halford[3] found that it was necessary to know whether such an interchange was fast or slow compared to the rate at which chlorine reacts with acetanilide in aqueous solution. Since this latter reaction is itself extremely fast, it is obvious that we could draw no inferences from the published investigations which would be valid in this work. We have therefore determined the relative speed of these two fast reactions by passing non-radioactive chlorine into an aqueous solution of acetanilide and radioactive chloride ion, followed by an examination of the distribution of the radioactivity in the products of the reaction. Radioactivity in the resulting chloroacetanilide will thus indicate that the chlorine has interchanged with the chloride ions before chlorinating the acetanilide. Even though the chlorination of acetanilide is immeasurably fast, we found the exchange reaction to be complete within the limits of experimental error.

Experimental

0.033 Mole of acetanilide was dissolved in 35 cc. of 95% alcohol, 515 cc. of 1 *N* sulfuric acid added and 0.0825 mole of radioactive sodium chloride was dissolved in this mixture. The concentrations in the resulting 550 cc. of solution were thus 0.06 *M* acetanilide and 0.15 *M* chloride ion. Fifty cc. of this solution was withdrawn for radioactive analysis and, to the remaining 500 cc., 0.00617 mole of chlorine was added with vigorous shaking. The chlorine disappeared rapidly and a precipitate of chloroacetanilide appeared almost immediately. The organic matter, chloroacetanilide and unreacted acetanilide, was then extracted with two portions of ether, the ethereal solution evaporated to dryness and the solid material fused with potassium hydroxide in a nickel crucible. The resulting fused mass was dissolved in water and acidified with nitric acid. To this solution, containing chloride ion from the chloroacetanilide only, and to the 50-cc. initial sample, excess silver nitrate solution was added. Weighed amounts of the dried silver chloride precipitates were dissolved in ammonium hydroxide and radioactive determinations were then made by the method described by Olson, Libby, Long and Halford.[4] The control sample was made by using 0.4 g. of silver chloride. From the fusion we were able to obtain only 0.33 g. of silver chloride and so 0.07 g. of non-radioactive silver chloride was added. In comparing the radioactive analyses this factor must be taken into account.

In Fig. 1 we have plotted the time against the logarithm of the net count times the dilution. The circles represent the observed data and the straight lines have been drawn with a slope corresponding to the known half-life of radioactive chlorine (thirty-seven minutes). Our radioactive material exhibited some gamma radiation but

any contribution due to this was ignored in calculating our results. During the run the counting apparatus developed some instability as was shown by a variation of the background count and so the accuracy is not as great as we could have expected for this type of experiment. However, the errors are not large enough to throw any doubt on our conclusions.

Figure 1 shows immediately that considerable interchange must take place since the chlorine in the final product is highly radioactive. A comparison of the readings for the two samples at any given time shows that the activity of the silver chloride from the chloroacetanilide is about 79% of that of the control sample.

Discussion and Calculations

The particular concentrations that we used were chosen, first, so that the ratio of chloride ion to acetanilide would be small enough so that the chlorine would not have too great a chance of interchanging before colliding with an acetanilide molecule, and second, with the ratio of radioactive chloride ion to the amount of chlorine rather large so as to permit simplification in calculating the results. Every molecule of chlorine that reacts with acetanilide forms one molecule of chloroacetanilide and sets free one chloride ion. Thus, if a is the initial amount of radioactive chloride ion and x is the amount of chlorine introduced at any time, then, since all chlorine that goes into solution reacts almost immediately, the total amount of chloride ion, radioactive or non-radioactive, is $a + x$. If all of the chlorine becomes radioactive before reacting with the acetanilide, the amount of radioactive chloride ion in solution would be $a - x$. To correct for the fact that as the reaction progresses the chlorine has a decreasing probability of becoming radioactive, we must alter the above amount to $a - x\ (a - x)/(a + x)$. As the reaction progresses the probability that the chlorine will become radioactive decreases for two reasons: first, because the total amount of chloride ion increases and, second, because the amount of radioactive chloride ion decreases. Thus the probability that a chlorine molecule will become radioactive is equal to $[a - x\ (a - x)/(a + x)]/(a + x)$. Then the decrease in radioactivity of the chloride ion in solution will be very nearly equal to the integral from zero to x of $\frac{a - x(a - x)/(a + x)}{a + x}\,dx$. This, of course, will also be the total amount of radioactivity to be found in the chloroacetanilide. In our experiment the ratio of x to a is 1 to 13.35. Putting these values into the above integral we find that the radioactivity of the chlorine in the chloroacetanilide should be 93% of the original radioactive chloride ion. When we apply the further correction of 33/40 due to the undersized sample we find that the radioactivity of the silver chloride from the chloroacetanilide should be about 77% of that for the control sample, assuming complete interchange between chlorine and chloride ion. This agrees very well with our experimental value of 79%. Therefore we can conclude that the establishment of the equilibrium between chlorine and chloride ions in an acidified aqueous solution is extremely rapid.

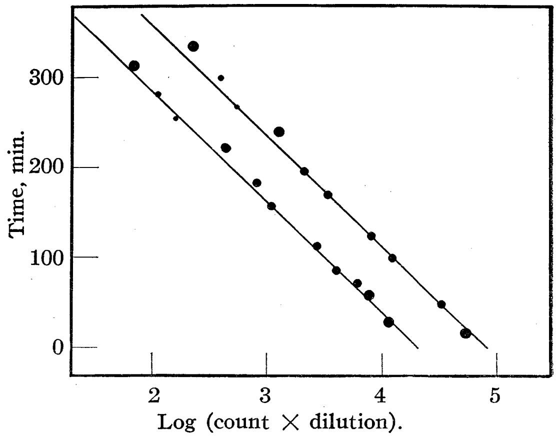

Fig. 1.—The upper curve, which is for the control sample, has been displaced to the right by one-half a unit.

In conclusion we express our indebtedness to Professor E. O. Lawrence and his colleagues for supplying us with the radioactive sodium chloride.

The Activity of Sodium in Dilute Sodium Amalgams

By H. E. Bent and E. Swift, Jr.

The thermodynamic properties of sodium amalgams have been investigated previously by a number of workers.[1] The potentiometric method of Richards and Conant used, as an electrolyte, an aqueous solution of sodium hydroxide. Lewis and Kraus,[2] in determining the standard electrode potential of sodium used a solution of sodium iodide in ethylamine. By combining these two sets of data one can calculate the activity of sodium in dilute sodium amalgams referred to the pure metal as the standard state. Recently, however, it has been shown that the potential of a concentration cell may be affected by the nature of the electrolyte.[3] The explanation for this behavior is not known but presumably the electrolyte either alters the number of equivalents of alkali metal transferred per faraday due to the formation of a complex ion or gives rise to some side reaction. It therefore seemed desirable to check data previously reported by the use of other solvents and with varying concentrations of electrolyte.

A further reason for again studying these amalgams arose in the effort to interpret the shape of the curve obtained by plotting the values of the logarithm of the activity coefficient against the concentration of the sodium. The variation in the values determined for the most dilute solutions on account of reaction with the aqueous electrolyte made it impossible to distinguish between a physical and a chemical explanation for the deviations from Raoult's law in this region.

Finally, it seemed worth while to develop the technique of these measurements to a considerably higher point before studying further amalgams of the other alkali metals. We are interested in having data on the thermodynamic properties of alkali metal amalgams in connection with a program of studying the free energy of formation of various organo metallic compounds with the aid of amalgams.

The most accurate element in this investigation seemed to be the determination of the potential between amalgams of various concentrations. We therefore attempted to bring the various other errors down to the order of 0.01%. We first investigated a number of solvents in order to find one which would dissolve sufficient sodium iodide to give a good conductivity and still not react with the sodium amalgam or metallic sodium. Great care was exercised in filling the cells and in controlling the temperature during measurement. Finally, considerable time was spent in improving the accuracy of the analysis and discovering the sources of error in this determination.

Solvent.—The solvents heretofore used in the study of amalgam concentration cells have been water, ethylamine and ether. Water obviously is far from ideal on account of its rapid reaction with amalgams. Ethylamine, used by Lewis and Kraus, is very much better but even this solvent reacts slowly with metallic sodium. Ether is better from the standpoint of reaction with the metal. However, as shown by Gilfillan, the electromotive forces obtained by dissolving organo metallic compounds in ether are not reproducible and do not agree with those obtained with other solvents.

Dimethylethylamine was prepared by treating dimethylamine with diethyl sulfate at 80° for twenty-four hours. The yield was very poor—about 1%. The product was purified by distillation and dried before using. Dimethylamine, diethylamine and ethylamine were purchased from Eastman Kodak Co. and purified and dried before use. The amine was first dried by distillation onto calcium oxide or activated alumina and then onto sodium benzophenone. It was sealed in glass capsules which were later broken into an evacuated system. The sodium iodide was fused in vacuum in a platinum boat according to the method of Forziati.[4] As will be seen from Table I only ethylamine and dimethylamine dissolve sufficient sodium iodide to be suitable solvents.

These two amines were then compared to determine the relative speed of the reaction with alkali metal. For this purpose sodium–potassium alloy was introduced into a small tube connected to a second tube carrying a pair of platinum electrodes. The amine could be distilled into the tube containing the electrodes to measure its conductivity or the solution could be poured in and the course of the reaction followed by the change in conductivity. It was found that ethylamine reacted about one hundred times faster than dimethylamine and gave solutions which were of the order of one hundred times more conducting as a result of reaction with the alloy. This treatment is probably much more severe than necessary but gives a rapid method of comparing the inertness of the two liquids. The ethylamine very quickly became colored and at times bubbles could be observed rising from the surface of the alloy in contact with this liquid, while the dimethylamine remained perfectly clear. The results of these experiments are recorded in Table II and indicate clearly that dimethylamine is much to be preferred.

1	10^{-9}	5×10^{-8}
24	2×10^{-9}	4×10^{-7}
48	3×10^{-9}	6×10^{-7}

Analysis.—Since the analysis of the amalgams is the part of the problem which introduces the greatest part of the experimental error, a great deal of time was spent in improving this procedure. A great many precautions were taken in standardizing the acid used in the titration and in extracting the sodium from the amalgam. Only a few of these will be mentioned here. The carefully purified sodium carbonate was fused in a stream of dry carbon dioxide. All titrations were carried out in quartz flasks with air, free from carbon dioxide, passing through the flask at the end-point. Weight burets were used, one containing sulfuric acid approximately 0.5 *N* and the other acid approximately 0.01 *N*. Standard base was not used in the titration, the initial alkaline solution being decanted from the amalgam in order that an excess of acid could be added to remove the last of the sodium. The initial alkaline solution was then added and the titration carried just to the end-point with brom thymol blue. All amalgams were prepared by distilling mercury onto sodium which had been filtered through several constrictions. The amalgam was then transferred to storage flasks and capsules which had been baked and evacuated at 450°. Samples were removed for analysis or for the preparation of a cell by means of tips broken by magnetic hammers. The general style of cell was the same as that used by Gilfillan.[5] No stopcocks were used at any point in the line, however. With the aid of the above precautions the precision of the analysis appeared to be 0.02% as judged by the agreement of successive runs.

Thermostat.—The temperature of the thermostat was controlled by means of a 24-junction copper–constantan thermocouple. The potential from this thermocouple was balanced by a small potentiometer which was kept, with dry cells used for its operation, in another thermostat at 25°. When off balance the current generated deflected a spot of light thrown by a spot light onto a galvanometer and reflected to a photocell. The remainder of the control is illustrated in Fig. 1. This use of the thyratron in a phase-shift circuit results in an adjustment of the current sixty times a second. This arrangement was worked out with the details as shown in the figure by Professor W. B. Nottingham of Massachusetts Institute of Technology and proved very satisfactory. There was no tendency of the temperature to oscillate and the temperature could be kept constant at any desired point to 0.01°. Greater precision could have been obtained by using a larger thermostat and a thermocouple with a greater number of junctions or a more sensitive galvanometer. All that was necessary to operate the cell at lower temperature was to adjust the temperature roughly by an increase in the flow of cooling water and then to set the potentiometer for the desired temperature. Switch "G" was added in order to allow the temperature to be raised rapidly.

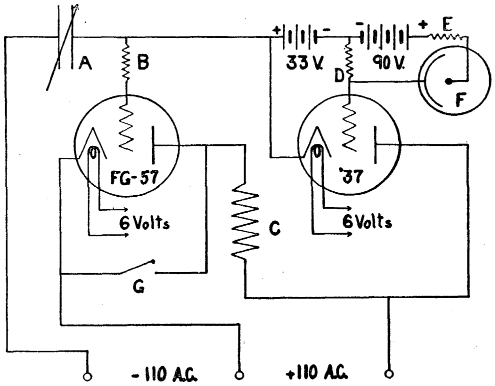

Fig. 1.—Control circuit used for thermostat: A, 0.0001 mfd. variable condenser; B, 50,000-ohm variable resistance; C, 125-watt "lagless" heater (in bath); D, 10-megohm resistance; E, 2-megohm resistance; F, photoelectric cell, type 71-A; G, switch used for rapid heating.

Experimental Results

Seven cells were constructed including eight amalgams of varying concentrations, one of which was two phase. One cell was designed to permit successive dilution of the electrolyte. Over a range of one thousandfold in the concentration of sodium iodide there was no change in the e. m. f. which was greater than the experimental error. However, in the case of the most dilute solutions the resistance was so high that it was difficult to obtain measurements which were reproducible to better than about 1%. This experiment proves that there is no variation in e. m. f. with this electrolyte comparable to the 50% variation found by Gilfillan with ether solutions of organo metallic

compounds. The cross checks obtained by comparing various pairs of amalgams in a single cell were usually good to 0.01 mv. The values for pairs of amalgams occurring in different cells were good to 0.03 mv. From all of these cells data were obtained over many weeks and at 5, 15 and 25°. Two cells contained metallic sodium. The results are given in condensed form in Table III. From these data three equations were obtained by the method of least squares to represent log a_2/N_2 as a function of N_2. The form of expression found satisfactory is of the familiar type, log $a_2/N_2 = a + bN_2 + cN_2^2$, the last term contributing relatively little to the expression. The average deviation of the experimental points from the curve was 0.0015, which corresponds to about 0.06 mv. error in the e. m. f. or about 0.1% in the analysis of the more concentrated amalgams. It was found possible to combine these three equations, obtained by least squares

$$\log a_2/N_{2_{25°}} = -12.81441 + 15.6130N_2 + 7.530N_2^2$$
$$\log a_2/N_{2_{15°}} = -13.32030 + 15.87260N_2 + 7.110N_2^2$$
$$\log a_2/N_{2_{5°}} = -13.86807 + 16.1820N_2 + 5.970N_2^2$$

into a single simple equation involving the temperature without seriously sacrificing the accuracy of the data. This equation is

$$\log a_2/N_2 = \frac{-8387.6}{T^{1.138}} + \frac{338.2}{T^{0.54}} N_2 + 7.0N_2^2$$

Values of log a_2/N_2 calculated by means of this equation usually differed from those calculated by the three separate equations given above by less than 0.001. From this more general equation the following equations have been derived for the partial molal free energy, entropy and heat content of sodium and mercury, following the methods used by Bent and Gilfillan.

$$\overline{F}_2 = 4.57393\ T \log N_2 - \frac{38364.30}{T^{0.138}} + 1546.9N_2T^{0.46} + 32.0N_2^2T$$

$$\overline{S}_2 = -4.57393 \log N_2 - \frac{5294.27}{T^{1.138}} - \frac{711.574}{T^{0.54}} N_2 - 32.0N_2^2$$

$$\overline{H}_2 = \frac{-43658.57}{T^{0.138}} + 835.3N_2T^{0.46}$$

$$\overline{F}_1 = 4.57393\ [T \log N_1 - 169.1N_2^2\ T^{0.46} - (338.2T^{0.46} + 14T) \text{ x } (N_2^3/3 + N_2^4/4\ldots)]$$

$$\overline{S}_1 = -4.57393\ [\log N_1 - \frac{77.786}{T^{0.54}} N_2^2 - \left(\frac{155.57}{T^{0.54}} + 14\right)(N_2^3/3 + N_2^4/4\ldots)]$$

$$\overline{H}_1 = 4.57393\ [-91.3\ N_2^2T^{0.46} - 182.6T^{0.46}\ (N_2^3/3 + N_2^4/4\ldots)]$$

Introducing the values for the e. m. f.'s of sodium to the saturated amalgams into the equation obtained by the method of least squares for each temperature and solving for the concentration, three values were obtained for the solubility of sodium in mercury.

TABLE IV

SOLUBILITY OF SODIUM IN MERCURY

Temp., °C.	Mole fraction of Na
5	0.043955
15	.04870
25	.05380

Our results may be compared first with those of Lewis and Kraus. They report an e. m. f. between an amalgam whose concentration is 0.2062 wt. % sodium and pure sodium of 0.8456 which is equal to 0.8453 international volt.[6] We find from our equation a value for this e. m. f. of 0.8448 using the equation derived from the experimental data at 25° and a value of 0.8449 v. using our more general equation which includes the temperature. The disagreement between our value and that of Lewis and Kraus is considerably more than the experimental error which they attribute to their result. A check on our result has been obtained by A. F. Forziati using entirely different apparatus in work soon to be reported. His measure-

---

ments agree with our results for the e. m. f. between sodium and an amalgam of a given concentration to 0.1 mv. Our agreement with Lewis and Kraus in the temperature coefficient of this cell is not entirely satisfactory. They report a value of −0.0000408 v. per degree for the range 10–35°. As will be seen from Table V the temperature coefficient is changing rather rapidly with the temperature. The average value which we obtained by calculating the activity at 10 and 35° does not agree well with that of Lewis and Kraus and the value at 25° is still further from their value.

TABLE V

CALCULATED VALUES OF dE/dT

Temp., °C.	$-dE/dT$
5	0.000059
15	.000043
25	.000029
10–35	.000032

We have also compared our data with those of Richards and Conant. Their experimental data are shown by crosses on our plot in Fig. 2. They did not determine the potential of any amalgam against sodium. Their points have been placed on our plot by arbitrarily adding a constant to the values of log a_2/N_2 which would give the best agreement with their data. The agreement of their data with those reported in this investigation seems remarkably good considering the difficulties which they encountered in working with water solutions. Their data have been calculated in a similar manner by Bent and Hildebrand but these results do not entirely agree with our present calculations, apparently due to some error in the earlier calculations.

We have also compared our temperature coefficients with those observed by Richards and Conant. The agreement here is remarkably good, probably within our experimental error.

TABLE VI

COMPARISON OF dE/dT WITH DATA OF RICHARDS AND CONANT

Amalgams of R. and C.	dE/dT R. and C.	dE/dT B. and S.
18–20	0.093	0.091
18–19	.156	.151
20–21	.164	.158
21–22	.059	.062

Finally, from our equations we have calculated the free energy of formation of $NaHg_4$ and values for the solubility of sodium in mercury. These data were obtained from measurements on the two-phase amalgam. The potential between the two-phase amalgam and sodium is shown in Fig. 2 and gives, with the aid of the equation for the curve, the concentration of the liquid phase. From the activity of sodium and mercury in this amalgam we then calculate the value −18,296 kcal. for ΔF.

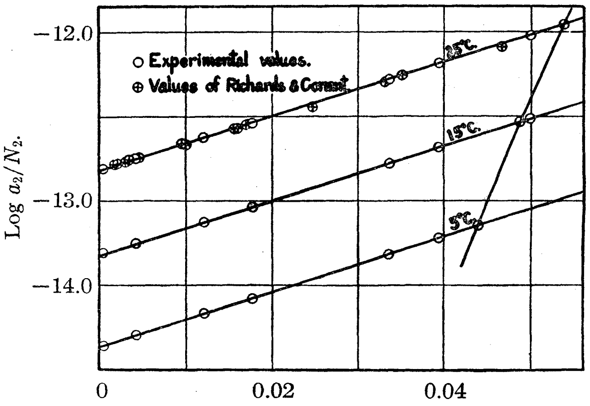

Fig. 2.—○, Experimental values; ⊕, values of Richards and Conant.

The choice of explaining the deviation from ideal solution by either compound formation or a more general physical picture seems to be pretty clearly answered by our data. Whatever compounds may be present at higher concentrations the behavior of the dilute amalgams cannot be explained by such assumptions alone. The plot of log a_2/N_2 is perfectly straight down to our most dilute amalgam. It has been shown by Bent and Hildebrand that even a compound containing as much mercury as $NaHg_{16}$, which is about as much as one can reasonably postulate, still gives a slight upward curvature in the very dilute range of concentration.

Summary

1. The thermodynamic properties of dilute sodium amalgams have been determined by means of concentration cells containing sodium iodide in dimethylamine as the electrolyte.

2. The solubility of sodium in mercury has been determined at 5, 15 and 25°.

3. The experimental results are compared with those of Richards and Conant on concentration cells and Lewis and Kraus on the sodium electrode.

4. The data on very dilute amalgams indicate that deviations from Raoult's law, which can be

largely attributed to the existence of compounds, cannot be quantitatively explained by the assumption that compounds exist which dissolve in mercury to give ideal solutions.

The Activity of Sodium and Mercury in Solid Sodium Amalgams

BY H. E. BENT AND A. F. FORZIATI

The number and composition of the solid phases containing sodium and mercury have been the subject of much difference of opinion.[1] A study of the activity of sodium in the solid phase might well be expected to throw added light on this complex system.

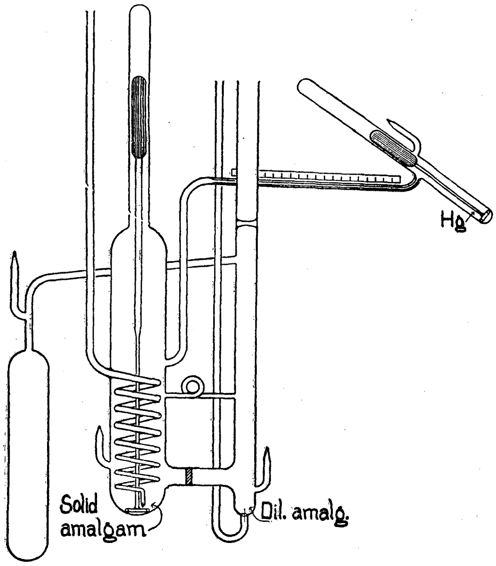

Fig. 1.

A second reason for studying the solid compounds of sodium and mercury arises in connection with the investigation of organo-metallic compounds. It is possible to determine the free energy change associated with the addition of sodium to various organic compounds by shaking the materials to be investigated with liquid sodium amalgams.[2] Many compounds, however, exhibit a stability which would necessitate the use of solid sodium amalgams in such an equilibrium determination. Recently the investigation of unsaturated hydrocarbons[3] has emphasized the need of studying such solid sodium amalgams.

We have constructed cells in which one electrode is a dilute sodium amalgam and the other a solid amalgam, Fig. 1. The solid amalgams may be diluted by small additions of known quantities of mercury, thus covering the whole concentration range with one cell. The electrolyte is a solution of sodium iodide in dimethylamine. This solvent has been found to be well suited to cells of this type.[4] From the activity of the sodium the activity of the mercury can be calculated and the free energy of formation of the various solid phases.

Materials

All materials were handled in carefully evacuated and baked out glass apparatus. Stopcocks were replaced by glass tips to be broken by magnetic hammers.

Mercury was purified by washing with nitric acid and distillation.

Sodium was melted and allowed to flow through several constrictions in order to remove surface impurities. In one cell sodium was prepared by repeated distillation and this material compared with that which had only been filtered. These results justify the procedure of using material which has been subjected only to the removal of surface impurities.

Ethylamine and Dimethylamine.—Ethylamine was used in the earlier cells but is not entirely satisfactory as it reacts slowly with the amalgams. Dimethylamine has been shown by E. Swift, Jr., to be much less reactive and still to dissolve enough sodium iodide to serve as a good electrolyte. The amines were prepared in each case by treating the hydrochloride with sodium hydroxide. Much of the water vapor is removed by a reflux condenser. The amine is dried by allowing it to stand first over calcium oxide or activated alumina and then distilling it into a tube containing benzophenone and sodium–potassium alloy. The ketyl dissolves in the amine and indicates by its intense violet color the absence of all water. The amine is next shaken with fused sodium iodide in order to produce practically a saturated solution.

Sodium Iodide.—This material was first recrystallized and then fused in a covered platinum boat in a vacuum. Considerable difficulty is encountered in the process of fusion unless adequate precautions are taken. The vapor pressure of the iodide is so great at its melting point that it distils out of the platinum boat and condenses over the

surface of the quartz tube. This difficulty was avoided by covering the platinum boat with a tight fitting platinum cover. A small hole in the cover allowed a heavy platinum pin to project above the cover. When the iodide fuses the pin drops down into the boat thus indicating that the process is complete.

Experimental Procedure

The technique of handling cells containing solid sodium amalgams requires some comment as a great deal of difficulty was encountered. The high melting point of some of the amalgams (355°) makes it impossible to melt such an amalgam without distillation of mercury. Furthermore the amalgam adheres to the glass if clean and on cooling will crack even very rugged cells. It is almost impossible to keep amalgams in capsules and then introduce them into the cell as distillation is serious at the melting point and the labor of preparing and analyzing amalgams over the whole concentration range would be almost prohibitive.

Many types of cells were constructed and in most cases some useful data were obtained. The early cells contained ethylamine as the solvent. Later cells contained dimethylamine which is much more inert. Without going into the details of all of the types of cells investigated we will describe only the type used in constructing cells 10 and 11. Figure 1 illustrates the chief features of the cell. Contact is made with the solid amalgam by means of a long spiral which dips into the amalgam at the bottom. This was the only style of cell which was not cracked by the solidification of the amalgam. A stirrer which may be moved magnetically is also included in this cell in order to ensure homogeneity of the amalgam. A sintered Pyrex disk prevents any liquid amalgam from spattering or being dumped into the wrong electrode. A connecting tube above the level of the electrolyte equalizes the pressure on both sides and prevents undue stirring and bubbling of the electrolyte. The chief point of interest, perhaps, in this cell is the dilution device. Two types have been tried in different cells. The first type is perhaps a little more simple to construct but not quite so convenient to operate. By tipping the whole apparatus mercury in the reservoir is allowed to run into a short section of capillary which is within the reservoir. On turning the apparatus rapidly into a vertical position this slug of mercury runs down into a horizontal calibrated section of capillary tubing where it is measured by determining its length. Further tipping then pours this mercury into the cell. By this device it is possible to start with a small amount of a concentrated amalgam and carry it through practically the whole concentration range, admitting either large or small quantities of mercury as desired. A second device which accomplishes the same purpose is a little magnetic lift. In this case the apparatus need not be tipped. The reservoir is set at an angle of about 45° and within the mercury reservoir is a glass cylinder containing soft iron. To the end of this cylinder is attached a glass rod which terminates in a ring of glass which is ground to fit the inside of the tube and to be flat on its upper surface. This gives a right angle at the point of contact of ring and tube. When the cylinder is raised a drop of mercury is carried upward to the point at which it runs into the side-arm and down into the capillary to be measured. After a little practice this was found to be a much easier method of diluting the amalgam.

Other experimental details were very similar to those previously recorded.[5] A type K potentiometer was used with a type HS galvanometer sensitive to 10^{-10} amp. The resistance of the cells was of the order of one megohm. Usually a cell could be measured to 0.01 mv. However, the e. m. f. fluctuated from day to day in the most favorable cases by several hundredths of a millivolt and, in the case of some unstable amalgams to be discussed later, by several hundredths of a volt.

In the case of low melting amalgams the electrolyte was poured into the side bulb before diluting the amalgam. The amine could then be cooled with Dry-Ice while the mercury was being added and the amalgam melted and stirred. The highest melting amalgams could only be studied by admitting nitrogen into the system as otherwise it was impossible to melt the amalgam without a great deal of distillation.

Experimental Results

The experimental results are recorded in Table I and in Fig. 2. It would be impossible to give all of the observations without taking up an inordinately great amount of space. Eleven cells were studied, in some cases over a period of several months. In the early part of the work it seemed almost impossible to discover any meaning in the data. The e. m. f.'s were frequently very fluctuating and often an amalgam gave a higher e. m. f. after adding mercury than it did before. Gradually, however, as data were accumulated, it became evident that cells were likely to be very unstable when the composition was very near that of one of the compounds. When the composition was about half-way between that of two compounds the e. m. f. was usually very satisfactory. Frequently just after diluting an amalgam the e. m. f. would be very low and gradually rise and become steady when it came to the value at which other amalgams had become steady. A possible explanation for this phenomenon would

TABLE I

OBSERVED ELECTROMOTIVE FORCE

Composition of solid electrode	Mole fraction of reference electrode	Obsd. e. m. f.
Na + liq.	0.03270	0.8150
Na_3Hg + Na_3Hg_2	.03270	.7950
Na_3Hg_2 + NaHg	.03270	.7600
NaHg + Na_7Hg_8	.03270	.7400
Na_7Hg_8 + $NaHg_2$	.03270	.6500
$NaHg_2$ + $NaHg_4$	.03206	.1800
$NaHg_4$ + liq.	.03206	.0350

The error in the e. m. f. in most cases is probably not greater than 1 mv. although it may be as large as 5 mv. in the case of the fourth value in the column.

---

[5] Bent and Gilfillan, THIS JOURNAL, **55**, 3989 (1933).

be that on cooling a liquid amalgam a solid solution is first formed which gradually goes over into the two stable crystalline compounds. Another curious phenomenon was that frequently an e. m. f. was observed corresponding to a pair of compounds which could not possibly represent the over-all composition of the electrode. In fact further dilution would in these cases sometimes raise the e. m. f. to that to be expected from the total composition of the electrode, as is shown by the points in Fig. 2. This phenomenon can only mean that, on cooling, the liquid becomes supersaturated with respect to several compounds simultaneously and that it is more or less a matter of chance which compounds are formed. The curious part of this behavior, however, is that these metastable compounds are able to dominate the situation and determine the value of the e. m. f. of the cell.

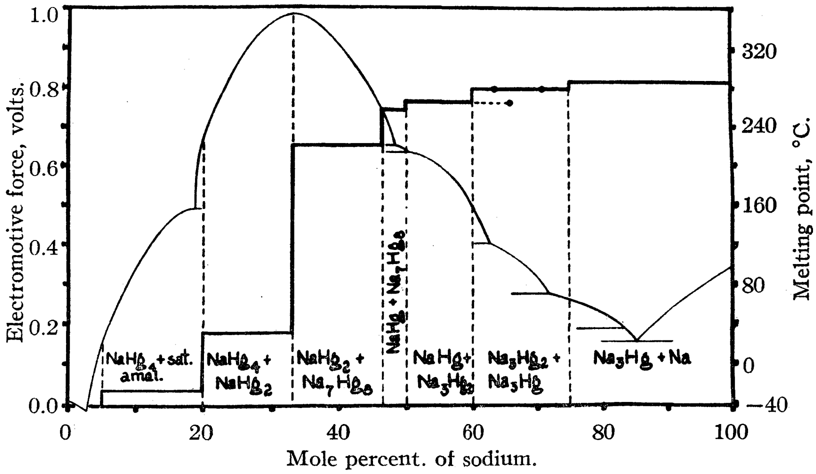

Fig. 2.

The experimental results given in Fig. 2 and in Table I give the e. m. f. produced by the difference in the activity of sodium in a dilute amalgam and a solid amalgam. A typical half cell reaction at the solid amalgam electrode is $2NaHg_2 = NaHg_4 + Na^+ + (-)$ and at the dilute amalgam electrode is $Na^+ + (-) = Na_{\text{dil. amalg.}}$. Since it has been shown[6] that the activity of sodium in a saturated amalgam in which the mole fraction of sodium is 0.857 is the same as that of solid sodium, our measurements may all be referred to pure metal by taking our first electrode as our point of reference. This then gives the activity of sodium in the various two-phase solid amalgams as shown in the first five entries in Table II. These data we hope to use in interpreting reactions involving solid sodium amalgams.

Knowing the activity of sodium over the whole range of concentration one would expect to be able to calculate the activity of mercury by a process similar to that employed in using the partial molal equation[7]

$$\log \frac{a_1}{N_1} = -\int_0^{N_2} \frac{N_2}{N_1} \, d \log \frac{a_2}{N_2}$$

In this case the process is one of summation due to the formation of definite compounds. Table II gives the data for the activity of mercury over the whole range of concentration and also the free energy of formation of the various solid compounds. The first five equations represent the reactions involved in our cells, giving rise to the observed e. m. f.'s. The values of ΔF are calculated from the experimental measurements. The value for reaction 6 has been taken from the data of Bent and Swift.[4] Reactions 7–11 are of interest in indicating the relative stability of the various compounds and are also useful in calculating the activity of mercury in these solid amalgams. Reactions 12–16 describe the changes involved in starting with sodium and adding mercury. If a cell were possible which would be reversible to mercury rather than to sodium the e. m. f. would be determined by these equations. The next-to-the-last column in the table gives the method of computing the various values of ΔF. The numbers in parentheses refer to equations given in the same table. The equations when combined as indicated give the desired reaction and the corresponding value for ΔF.

The last column of the table gives the activity of sodium (a_2) and the activity of mercury (a_1) in solid amalgams of various concentrations. The liquid phase, occurring at 85 atom % sodium is not discussed here as it has been reported previously.[6] The activity of sodium in this liquid amalgam is practically the same as that of the pure metal.

The equations written in Table II are deduced

14	$7NaHg + Hg = Na_7Hg_8$	8.158	$(8) - 7(9)$	1.05×10^{-6}
15	$Na_3Hg_2 + Hg = 3NaHg$	8.616	$3(9) - (10)$	4.8×10^{-7}
16	$Na_3Hg + Hg = Na_3Hg_2$	9.827	$(10) - (11)$	6.2×10^{-8}

partly from the work of Vanstone,[8] Schuller[9] and Kurnakow[10] and partly from the results of this investigation. Vanstone and Schuller agree very well in the formulas to be assigned to the various compounds. Both agree in writing $NaHg_4$, $NaHg_2$, NaHg, Na_3Hg_2 and Na_3Hg. The compound Na_7Hg_8 is perhaps not quite so certain. Schuller writes $Na_{12}Hg_{13}$. Kurnakow agrees with the above list although he does not report either of these last two compounds or Na_3Hg_2.

The results of our investigation agree perfectly with the list of Vanstone. We are not able to contribute anything very definite to the discussion of the compound Na_7Hg_8 although we did have a few points which could most readily be interpreted as due to some such compound. The evidence is very good, however, in the case of the compound $NaHg_4$. The change in e. m. f. was abrupt and large at 20 atom % sodium and the e. m. f. beyond this point is that observed between a saturated amalgam and one in which the concentration of sodium is 3.27 atom %.[4] This clearly indicates that no compound was present such as $NaHg_5$ or $NaHg_6$ as has been previously suggested.

The activities listed in the last column give information which will be useful in studying chemical reactions involving solid amalgams. The activity of mercury gives a measure of the efficiency of sodium in replacing liquid air or Dry-Ice as a mercury trap in a vacuum line.[11] At 25° the vapor pressure of mercury above liquid 85 atom per cent. amalgam is 1.2×10^{-11} mm. while the vapor pressure of mercury at the temperature of Dry-Ice is 10^{-9} mm. Hence this liquid amalgam should be one hundred times as good as Dry-Ice in removing mercury vapor in a vacuum line. We may also conclude from the data in the last column that on heating a solid amalgam the metal which will distil will probably be mercury. This follows from the fact that at room temperature the ratio of the vapor pressure of mercury to that of sodium is about 10^{11}. Consequently, even in amalgams rich in sodium the mercury will have the higher vapor pressure. At elevated temperatures it is not as easy to make predictions. Undoubtedly the mercury will have the higher pressure from all amalgams except possibly those richest in sodium. The higher heat of vaporization of sodium would tend to increase its vapor pressure faster than that of mercury but this would be complicated by the change in the stability of the various compounds which would probably tend to increase the vapor pressure of mercury.

Conclusions

1. A potentiometric method is described for studying intermetallic compounds at room temperature.
2. Values are given for the free energy of formation of $NaHg_4$, $NaHg_2$, NaHg, Na_3Hg_2 and Na_3Hg. The value for Na_7Hg_8 is not so reliable.
3. The activity of mercury and sodium in solid amalgams of all concentrations is computed.

The Stereochemistry of Complex Inorganic Compounds. II. The Reaction of Carbonates with Dichlorodiethylenediaminocobaltic Chloride

BY JOHN C. BAILAR, JR., FRANK G. JONELIS AND E. H. HUFFMAN

The factors which commonly determine whether a Walden inversion will occur when a group attached to an asymmetric atom is replaced by another group are the nature of the reagent, its concentration, the temperature and the solvent. That the first of these factors is effective in bringing about a Walden inversion in the reactions of complex inorganic compounds was shown by the discovery that levo-dichlorodiethylenediaminocobaltic chloride reacts with silver carbonate to give a levo carbonato product, while potassium carbonate gives the corresponding dextro salt[1]

$$[\mathrm{Coen_2Cl_2}]^+ \longrightarrow {}^2[\mathrm{Coen_2CO_3}]^+$$

$$l \underset{\text{alc. HCl}}{\overset{\mathrm{K_2CO_3}}{\rightleftarrows}} d$$

$$l \xrightarrow{\mathrm{Ag_2CO_3}} l$$

The present study had for its purpose the determination of the influence of the second two factors mentioned above, *viz.*, the effect of changing concentration of the reagent and the effect of temperature.

Effect of Concentration.—The dichlorodiethylenediaminocobaltic chloride was treated with varying amounts of silver carbonate and the optical rotation of the product was determined. Table I shows that increasing the number of moles of silver carbonate changed the rotation of the product from dextro to levo.

TABLE I

Molar ratio $\frac{Ag_2CO_3}{\text{complex salt}}$	Specific rotation of product
0.75	+362°
1.12	+288°
1.5	−102°
3.0	−160°
4.5	−180°

The data show that changing the concentration of the reagent silver carbonate is certainly an important factor in determining whether a Walden inversion takes place.

On the other hand, potassium carbonate produced the dextro salt at all concentrations (Table II).

TABLE II

Molar ratio $\frac{K_2CO_3}{\text{complex salt}}$	Specific rotation of product
1.0	+240°
1.5	+140°
3.0	+110°
5.0	+ 80°

The marked racemization during the reaction with the higher concentration of potassium carbonate may be due to the formation of the optically inactive *trans* hydroxy-aquo complex $[\mathrm{Coen_2(H_2O)(OH)}]^{++}$ by the strongly basic solution.

Holmberg[3] and Bancroft and Davis[4] have shown that *l*-bromosuccinic acid and silver oxide react to give *l*-malic acid if the silver oxide is present in limited amount, but *d*-malic acid if it is present in large amount. The rotation of the product is apparently a function of the acidity of the solution. It is evident that neither the acidity nor the carbonate ion concentration is the determining factor in the reaction of carbonates with levo-dichlorodiethylenediaminocobaltic chloride, for the more silver carbonate is present, the more strongly levorotatory the product is, while potassium carbonate, which furnishes an abundance of both hydroxyl and carbonate ions, yields a dextrorotatory product.

Effect of Temperature.—The same reaction was carried out at six different temperatures. The data which are summarized in Table III show that the chief effect of low temperatures is to decrease the rate of reaction, and the effect of higher temperatures is to cause racemization.

TABLE III

Temp., °C.	Specific rotation of product
0	− 10°
15	−100°
25	−106°
50	− 78°

pound prepared at 0° having a smaller rotation than that prepared at 25°.

The reaction of mercurous carbonate with the dichloro salt is of some interest. Mercurous ion and silver ion are both univalent and form insoluble chlorides and carbonates, and they have about the same ionic radii.[5] They might, therefore, be expected to behave similarly. It was found, however, that *l*-dichlorodiethylenediaminocobaltic chloride reacts with an excess of mercurous carbonate to give the dextrorotatory carbonato salt. The reaction is much slower than that with silver carbonate.

The discovery that the amount of reagent employed affects the rotatory power of the product in this reaction suggested a reëxamination of the reaction between oxalates and dichlorodiethylenediaminocobaltic chloride.[1] Varying the relative amounts of the reactants did not bring about an inversion in this case, however, though the magnitude of the rotatory power was varied somewhat.

Experimental

The materials used were prepared as described in the earlier paper. It has been found that the dextro-ammonium-α-bromo-camphor-π-sulfonate used in resolving the dichloro salt can be recovered in 85–90% yield by adding an excess of ammonium carbonate to the solution and evaporating to crystallization. Attempts to recover the complex inorganic salt have not been successful. The levo-dichlorodiethylenediaminocobaltic chloride used in this study had a specific rotation of +650°, as measured for a 0.05% solution for the D line of sodium.[6]

All measurements reported in this paper are for the D line of sodium, and, unless otherwise stated, for solutions having a concentration of 0.1%. In most cases, the carbonato salts were not isolated, but the solutions containing them were simply diluted to the proper concentration.

Effect of Varying the Proportions of $\left[\mathrm{Co}^{\mathrm{en}_2}_{\mathrm{Cl}_2}\right]\mathrm{Cl}$ and Silver Carbonate.—Three grams of levo-*cis*-dichlorodiethylenediaminocobaltic chloride was ground in a mortar with 2.14 g. of silver carbonate (molar ratio 1:0.75). The mixture was shaken in 10 cc. of water until the color change indicated that reaction was complete. The solution was allowed to stand for a day to ensure racemization of the unreacted dichloro salt, and the silver chloride was removed by filtration. One hundred cubic centimeters of absolute alcohol was added to precipitate the carbonatodiethylenediaminocobaltic chloride, which was filtered off at once. On standing, the filtrate yielded a second crop of the material. The first precipitate had very little optical activity; the second had a specific rotation of +362°. The experiments using larger amounts of silver carbonate were carried out in the same way. The negative ion of the complex compound is chloride in some cases, and carbonate in others, but this does not affect the specific rotations.

A sample of the dextro carbonato compound was prepared for analysis by adding 3.8 g. of silver carbonate in small portions to 2.4 g. of levo $[\mathrm{Coen_2Cl_2}]\mathrm{Cl}$ while the mixture was ground with water in a mortar. The complex compound was present in excess until the very end of the reaction. The product had a specific rotation of +370° and showed C, 22.34; H, 6.30, and N, 19.22. Calcd. for $[\mathrm{Coen_2CO_3}]\mathrm{CO_3{\cdot}3H_2O}$: C, 22.29; H, 6.47; N, 18.92. A sample of this material was reconverted to the dichloro salt by alcoholic hydrogen chloride. This salt had a specific rotation (0.05% soln.) of +240°. Chlorine, 37.08. Calcd., 37.37.

A sample of the levorotatory carbonato salt (C, 22.12; H, 6.43; N, 19.08) with a specific rotation of −180° was converted to the dichloro compound (Cl, 37.60) having a specific rotation (0.05%) of −132°.

The Effect of Varying the Concentration of Potassium Carbonate.—Samples of 0.3 g. of *l*-$(\mathrm{Coen_2Cl_2})\mathrm{Cl}$ were mixed with varying amounts (0.145, 0.218, 0.436 and 0.725 g.) of potassium carbonate and dissolved in 10 cc. of water at room temperature. At the completion of the reaction, 1 cc. of each solution was diluted to 33 cc. to give a 0.1% solution and the rotation was taken. The excess carbonate remaining in solution does not affect the rotation, as was shown by adding potassium carbonate to the solutions and taking the rotations again.

The Effect of Changing Temperature.—Intimate mixtures of 0.3 g. *l*-$[\mathrm{Coen_2Cl_2}]\mathrm{Cl}$ and 0.5 g. of silver carbonate were shaken in 10 cc. of water at 0, 15, 25, 50, 75 and 90° until the color of the reaction mixture indicated complete reaction. This required eight hours at 0°, but only a few seconds at 90°. At the three higher temperatures, the solution was cooled as quickly as possible after the reaction was ended. The silver salts were filtered out and 1 cc. of each filtrate was diluted to 33 cc. to give a 0.1% solution.

In the same manner 0.3 g. of *l*-$[\mathrm{Coen_2Cl_2}]\mathrm{Cl}$ was allowed to react with 0.3 g. of silver carbonate at 0 and 25°. In this case the solutions were allowed to stand until the unreacted dichloro salt had racemized. The observed rotations were +0.13 and +0.24°.

The Reaction with Mercurous Carbonate.—An intimate mixture of 0.4 g. of $[\mathrm{Coen_2Cl_2}]\mathrm{Cl}$ and 4 g. of mercurous carbonate was moistened with enough water to make a paste and ground intermittently until the color indicated completion of the reaction. This required about eight hours. Enough water was added to dissolve the complex, the solution was filtered, and the carbonato salt precipitated by adding alcohol and ether. It has a specific rotation of +120°.

The Reaction with Oxalates.—Samples of $[\mathrm{Coen_2Cl_2}]\mathrm{Cl}$, each weighing 0.30 g., were allowed to react with 0.245, 0.49 and 0.735 g. of $\mathrm{K_2C_2O_4{\cdot}H_2O}$ in 10 cc. of water at room temperature. After dilution of 1 cc. of each solution to 33 cc., they showed specific rotations of +160, +200 and +220°. The soluble potassium salts remaining in the solutions do not affect the rotatory power, as was shown by

---

(5) Pauling, This Journal, **49**, 765 (1927).

(6) Mathieu, who confirmed the results of our earlier investigation [*Bull. soc. chim.*, [5] **3**, 495 (1936)], commented on the great discrepancy between the rotation of the dichloro salt as given by us (M_{D} −600°) and as found by him (M_{D} +2500°). This is no doubt due to differences in the concentrations of the solutions, which affect the specific rotatory power enormously, causing a change in sign at about 0.17%. This will be discussed in detail in a subsequent paper.

adding a large amount of potassium oxalate to each of them and taking the rotations again.

Likewise, three samples were ground with 0.31, 0.62 and 0.93 g. of silver oxalate and allowed to react in 10 cc. of water. After filtration and dilution (1 to 33 cc.) the solutions showed specific rotations of +170, +390 and +430°.

Another sample, weighing 0.6 g., was dissolved in 20 cc. of water. Eight-tenths of a gram of silver oxalate was added in small portions while the mixture was ground continuously, so that the complex was present in great excess until the end of the reaction. The solution was diluted as before and showed a rotation of +240°.

Summary

It has been shown that levo-dichlorodiethylenediaminocobaltic chloride reacts with a limited amount of silver carbonate to give the dextro carbonato salt, whereas a larger amount of silver carbonate causes inversion in the direction of rotation to give the levo salt.

The reaction with potassium carbonate gives the dextro salt, no matter what the concentration of the reagent.

It appears that temperature is not an important factor in determining whether a Walden inversion occurs in this reaction.

Mercurous carbonate, present in large excess, reacts with levo-dichlorodiethylenediaminocobaltic chloride to give the dextro-rotatory carbonato salt. In this respect it is like potassium carbonate, and unlike silver carbonate.

The Stereochemistry of Complex Inorganic Molecules. III. The Reaction of Ammonia with Levo-Dichlorodiethylenediaminocobaltic Chloride

BY JOHN C. BAILAR, JR., J. H. HASLAM AND ELDON M. JONES

One of the mechanisms suggested for the Walden inversion postulates that every reaction which involves a single step in the substitution of one group by another on a tetrahedral atom should lead to inversion.[1,2] Accordingly, if the over-all reaction takes place in an odd number of steps the product should be the enantiomorph of the original material, but if it takes place in an even number of steps, the starting material and the product should have the same configuration.

The object of the present study was to see whether this theory might be applied to reactions of the octahedral complex inorganic compounds. The reaction studied was that between ammonia and levo-dichlorodiethylenediaminocobaltic chloride[3]

$$\underset{\text{levo } cis}{[\mathrm{Coen_2Cl_2}]\mathrm{Cl}} \longrightarrow \underset{\substack{trans\text{, levo } cis \\ \text{or dextro } cis}}{[\mathrm{Coen_2(NH_3)Cl}]\mathrm{Cl_2}} \longrightarrow \underset{\substack{trans\text{, levo } cis\text{, or} \\ \text{dextro } cis}}{[\mathrm{Coen_2(NH_3)_2}]\mathrm{Cl_3}}$$

The two chloride groups of the complex ion are attached to the cobalt in exactly the same way and occupy like positions in the molecule. It seems logical to assume, therefore, that the same mechanism functions in their displacement from the complex. If this is correct, the conversion of the dichloro salt to the diammino salt must take place in an even number of steps, and the theory mentioned would allow no inversion. However, as the data in Table I show, the reaction does lead to a Walden inversion, the product prepared at low temperatures being levorotatory while that prepared at higher temperatures is dextrorotatory. It is of some interest to note that this is the first case of a Walden inversion of complex inorganic compounds brought about by a change in temperature.

TABLE I

Reagent	Temp., °C.	$[\alpha]^{25°}_{\mathrm{E}}$ (av.)
Liquid NH_3	−77	−32
Liquid NH_3	−33	−22
Liquid NH_3	+25	+29
Gaseous NH_3	+80	+43
NH_3 in CH_3OH	+25	+31
NH_3 in C_2H_5OH	+25	+29

It is possible, of course, that the displacement of a negative chloride group by a neutral ammonia molecule produces such a profound change in the complex ion that the second step of the reaction does not follow the same mechanism as the first. The theory of Bergmann, Polanyi and Szabo and of Olson might be more applicable if the chloride groups were displaced by other univalent

---

[1] Bergmann, Polanyi and Szabo, *Z. physik. Chem.*, **B20**, 161 (1933).

[2] Olson, *J. Chem. Phys.*, **1**, 418 (1933).

[3] The symbol "en" represents ethylenediamine.

negative groups. A search for an example of the Walden inversion in such a case is now under way. It seems probable that the two steps of the reaction here reported do not follow the same mechanism, or that the theory of Bergmann, Polanyi and Szabo and of Olson cannot be applied to this case.

A study of the octahedral model will show that if the substitution of the ammonia molecules for the chloride groups follows purely mechanical laws, both *cis* and *trans* isomers will be formed at each step of the reaction. The formation of a *trans* form at any point would, of course, cause racemization. Fortunately, the formation of the *cis* isomer is favored under the conditions of this reaction. In no case did the diammino compound contain more than 10% of the *trans* form, and the rotations, while small, were unmistakable.

Experimental

The dichlorodiethylenediaminocobaltic chloride used was prepared and resolved as previously described.[4] Several different batches were used, but all had about the same specific rotation: +650° for a 0.05% solution for the D line of sodium. The diamino compound rotates yellow light very feebly, so rotations on it were taken at the E line (5270 Å.). The instrument used was a Schmidt and Haensch polarimeter graduated to one-thousandth of a degree, and fitted with a prism to select the desired wave length. The solutions used had a concentration of 0.1%.

The amount of *trans* diamino salt formed in the experiments was determined by precipitating it from the mixture with sodium dithionate in acid solution, according to the directions of Werner.[5] The separation afforded by this method is not entirely quantitative, but was deemed satisfactory for the purposes of this investigation. Since the amount of *trans* salt in every case was very small, it was not removed from those samples which were examined for optical activity, but allowance was made for it in making up the solutions. That the presence of the *trans* salt does not affect the rotation of the *cis* salt was shown by polarimetric examination of various mixtures of the two.

The Reaction of Liquid Ammonia and levo cis ($Coen_2Cl_2$)-Cl at −77°.—One-half gram of levo *cis*($Coen_2Cl_2$)Cl was placed in a small flask in a bath of solid carbon dioxide. Fifty cubic centimeters of liquid ammonia was added and the flask was stoppered and allowed to stand until the reaction was complete—forty-eight to sixty hours. It is easy to follow the progress of the reaction as the original purple color of the solution changes to bright red (the chloro-ammino compound) and then to yellowish-brown (the diammino compound). The ammonia was allowed to evaporate, and the material was examined. Four samples gave specific rotations of −35, −29, −30 and −34°.

The Reaction with Liquid Ammonia at −33°.—The reaction was carried out as before, but the ammonia was allowed to evaporate freely from a well insulated flask, which was fitted with a trap to avoid entrance of moisture. The amount of ammonia used for one-half gram of the sample was varied between 10 and 50 cc. without appreciably affecting the results. Specific rotations of −21, −27, −24, −17, −22, −20 and −25° were obtained.

The Reaction with Liquid Ammonia at +25°.—Two-tenths of a gram of the dichloro salt was placed in one arm of a Y-tube and from 6 to 12 cc. of liquid ammonia in the other. After sealing, the tube was allowed to come to room temperature. The salt is deliquescent toward ammonia and some of the gas distilled over before room temperature was reached. When the temperature reached 25°, the whole of the liquid was poured onto the solid. In other respects the experiment was like the preceding ones. Six samples gave specific rotations of +17, +24, +13, +40, +42 and +37°.

The Reaction with Gaseous Ammonia at +80°.—A half gram of finely powdered dichloro salt was placed in a tube in a bath at 80°. Dry ammonia gas was passed over it until the reaction was complete. Six samples gave specific rotations of +31, +43, +40, +53, +56, +49 and +52°.

Samples of the dichloro salt were placed in an atmosphere of ammonia at room temperature over a year ago. The first step of the reaction was complete in about a month—the second step is now progressing very slowly.

The Reaction with Ammonia Dissolved in Absolute Methyl and in Absolute Ethyl Alcohols at +25°.—One-half gram of the dichloro salt was placed in 35 cc. of the saturated alcoholic ammonia solution. The salt did not dissolve appreciably, so the reaction was slow. After three or four days, the alcohol was evaporated, and the residue examined. Four samples prepared in methyl alcohol gave specific rotations of +29, +27, +34 and +36°. The samples prepared in ethyl alcohol gave rotations of +21, +28, +36 and +33°.

We are indebted to Mr. J. P. McReynolds for some of the polarimeter readings.

Summary

It has been shown that a Walden inversion takes place in the reaction of ammonia with levo-dichlorodiethylenediaminocobaltic chloride, the optical rotatory power of the diamminodiethylenediaminocobaltic chloride formed being conditioned by the temperature at which the reaction is carried out. Prepared at the temperature of boiling ammonia or lower, the product is levorotatory; at 25° and higher, it is dextrorotatory.

It seems probable that the two steps of the reaction do not follow the same mechanism, or that the mechanism of the Walden inversion proposed by Bergmann, Polanyi and Szabo and by Olson is not applicable to this case.

The Heat Capacity of Lithium Carbonate from 16 to 300°K. The Entropy and Heat of Solution of Lithium Carbonate at 298°K. The Entropy of Lithium Ion

BY OLIVER L. I. BROWN AND WENDELL M. LATIMER

The heat capacity of lithium carbonate has been determined from 16 to 300°K. in order to evaluate more accurately the entropy of lithium ion in aqueous solution.

Material.—A C. P. grade of lithium carbonate was shaken with distilled water saturated with carbon dioxide. The solution was filtered through sintered glass and the filtrate boiled to precipitate lithium carbonate. This procedure was repeated with the product thus obtained. The final product was dried at 110° and for a short time at 200°. The carbonate was definitely crystalline, and analysis by titration with weight burets, using sulfuric acid standardized against sodium carbonate, showed 99.82, 99.82 and 99.79% lithium carbonate.

Heat Capacity Measurements.—The measurements were made with a calorimeter and cryostat similar to that previously described.[1] One calorie was assumed equal to 4.1833 int. joules. The molecular weight of lithium carbonate was taken as 73.88. Measurements were made on a sample of 61.814 g. (weight *in vacuo*). The heat capacity measurements are summarized in Table I, and are plotted as a function of temperature in Fig. 1.

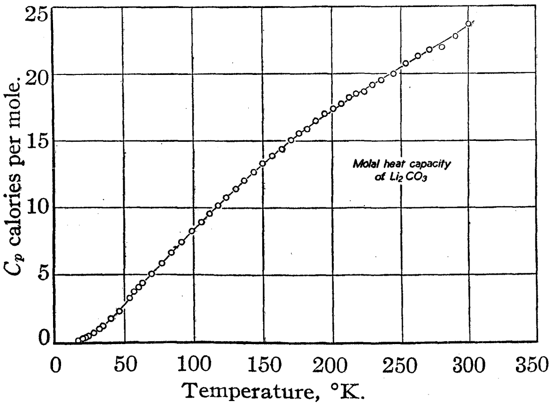

Fig. 1.—Molal heat capacity of lithium carbonate.

Entropy of Lithium Carbonate.—The entropy at 298.1°K. was obtained by graphical integration of the integral $S = \int C_p d \ln T$ between 16.68 and 298.1°K. combined with an extrapolation from 16.68 to 0°K. using the Debye specific heat equation. The calculation is summarized in Table II.

TABLE I

MOLAL HEAT CAPACITY OF LITHIUM CARBONATE

	Entropy at 298.1°K.	21.60 E. U.

Heat of Solution of Lithium Carbonate.—The heat of solution of lithium carbonate was determined with the calorimeter previously described.[2]

The integral heat of solution of one mole of lithium carbonate in 1900 moles of water at 298.1°K. was found to be −3371 and −3395 cal. The average value −3383 cal. was corrected for the heat of hydrolysis of carbonate ion and extrapolated to infinite dilution on the assumption that the heat of dilution was the same as for lithium sulfate. In this way the theoretical heat of solution of lithium carbonate in an infinite amount of water with no hydrolysis was found to be −4200

---

[1] Latimer and Greensfelder, THIS JOURNAL, **50**, 2202 (1928).

[2] Brown, Smith and Latimer, *ibid.*, **58**, 1758 (1936).

cal./mole. The probable error resulting from these corrections is difficult to estimate, but may be as high as 200 cal.

Entropy of Solution of Lithium Carbonate.—Seyler and Lloyd[3] measured the solubility of lithium carbonate at 298.1°K., in water solutions containing various amounts of carbon dioxide. They measured the total carbonate and bicarbonate by titration. By plotting the reciprocal of the mean molality of lithium ion and carbonate ion against the square root of the ionic strength, a fairly good straight line was obtained, from which the activity coefficient of lithium carbonate at saturation was found to be 0.59. The calculation is not of high accuracy but fortunately this does not affect greatly the free energy of solution. For example, a change of 10% in the activity coefficient would change the free energy of solution only about 180 cal., which corresponds to 0.3 E. U. in the entropy of lithium ion. The solubility of lithium carbonate in pure water is 0.169 *M* according to the same authors, so that $\Delta F^\circ = 3280$ cal./mole.

The entropy change when the solid salt dissolves to form a hypothetical one molal solution is given by the expression

$$\Delta S^\circ = (\Delta H - \Delta F^\circ)/T = (-4200 - 3280)/298.1 = -25.1 \text{ E. U.}$$

Entropy of Lithium Ion.—The entropy of carbonate ion[4] is −12.7 E. U., so that the entropy of lithium ion is given by the expression

$$S^\circ_{\mathrm{Li^+}} = {}^1/_2(\Delta S^\circ + S^\circ_{\mathrm{Li_2CO_3}} - S^\circ_{\mathrm{CO_3^{--}}}) = {}^1/_2(-25.1 + 21.6 + 12.7) = 4.6 \text{ E. U.}$$

Because of the absence of calorimetric data on lithium compounds, the entropy of lithium ion previously has been calculated from the entropy change of the lithium electrode reaction, even though the uncertainties were quite large.[5] The value thus obtained (−1.8 E. U.) differs by 6.4 E. U., or about 1900 calories, from the value calculated above. Since we believe the possible uncertainty introduced into the entropy of solution of lithium carbonate by the troublesome corrections for hydrolysis are not greater than one E. U. in $S^\circ_{\mathrm{Li^+}}$, we must conclude that the discrepancy is due to errors in the entropy change of the electrode reaction.

Summary

The heat capacity of lithium carbonate has been measured from 16 to 300°K. The entropy of lithium carbonate at 298.1°K. obtained from these data is 21.60 E. U. The heat of solution in water at 298.1°K. has been determined. The entropy of lithium ion calculated from these and other data has been found to be 4.6 E. U.

The Boyle Temperature and a General Equation of State

BY GEORGE WOOLSEY

If a general equation of state is possible the Boyle temperature, the temperature at which $\left(\frac{\partial PV/T}{\partial P}\right)_T = 0$, at zero pressure must be either the same temperature or a function of RT_c/p_cv_c (*n* in my notation) for all pure non-associating and non-dissociating substances. Empirically the older data seem to indicate that the Boyle temperature, T_B (reduced), is a function of *n*. For example, taking T_B as the temperature for which the second virial coefficient equals zero, Holborn and Otto[1] found

Substance	Ne	He	H_2	O_2	A	N_2
T_B	3.00	3.65	3.21	2.72	2.73	2.56
n	3.254	3.261	3.282	3.423	3.424	3.428

Recomputing the values for oxygen and argon, using more recent values for critical temperatures, gives 2.74 and 2.72, respectively. These figures seem to indicate quite definitely that T_B is a function of *n*.

However, using data compiled by Beattie and Bridgeman,[2] approximate values of T_B are obtained which indicate that the other possibility, that T_B is a constant, is the correct one.

Substance	Ne	H_2	O_2	A	N_2	CH_4
T_B	<2.77	Between 3.7 and 2.5	>2.4	2.5	Between 2.56 and 2.33	2.48
n	3.245	3.282	3.423	3.424	3.428	3.448

---

An additional value is found from the work of Bartlett, *et al.*, THIS JOURNAL, **52**, 1363–1374 (1930).

Substance	CO
T_B	Between 2.78 and 2.41
n	3.404

These data indicate that the value $T_B = 2.5$ for all of these substances is very nearly correct. The use of this relationship, $T_B = 2.5$, enables the constants of the equation[3]

$$PV + \frac{AV - AB}{T^xV^2 + CT^yV + DT^z} = nT + (B + K)\,P + q\log(P + 1)/T^w$$

to be determined in a way which is much more convenient than that used before. (The equation as given here contains the expression T^w which was not previously used. Work with the equation indicates that the logarithmic term should be an inverse function of the temperature.)

To make use of the above relationship the equation is divided by T and the expression for $(\partial PV/T/\partial P)_T$ is obtained by differentiation and set equal to zero at $P = 0$ when $T = T_B$. Two substitutions, $PV = nT$ when $P = 0$ and $dV/dP = T/P(\partial PV/T/\partial P)_T - V/P$ are used to obtain the final expression. This is

$$q = 2.30259\ T_B^w\ \{A/nT_B^{(x+1)} - (B + K)\}$$

Letting $n = n_0 = 3.25$, $T_B = 2.5$, $A = C^2 + 3C + 3 - D$ and $B + K = C + 3 - n - 0.30103\,q$, the following expressions for q are found for various values of x and w.

x	w	$-q$
0	1	$0.966720\,(C^2 - 5.125C + 5.03125 - D)$
0.5	1	$.61140\,(C^2 - 9.8467C + 6.21168 - D)$
1	1	$0.386691\,(C^2 - 17.3125C + 8.078125 - D)$
0	1.5	$.643843\,(C^2 - 5.125C + 5.03125 - D)$
0.5	1.5	$.407191\,(C^2 - 9.8467C + 6.21168 - D)$
1	1.5	$.257535\,(C^2 - 17.3125C + 8.078125 - D)$

Work with $w = 0$ or 0.5 is found to lead to unusable results.

The constants for the equation of state are determined for the various values of x, w and q from this table by substituting $V = 0.36$ at $P = 20$ and $V = 0.4$ at $P = 10$, with $T = 1$ for both, and solving the resulting simultaneous equations for C and D. These values are then checked at three points on the critical isotherm as indicated.

x	w	C	D	q	$(B + K)$	A	$-AB$
0	1	0.9237	2.4824	1.2875	0.2861	4.1419	8.7402
0.5	1	.8390	0.2943	1.0027	.2871	5.9266	0.1298
1	1	.9859	−4.1268	1.5046	.2829	11.0564	−17.4489
0	1.5	.9298	+3.1629	1.3085	.2859	3.4910	+11.4296
0.5	1.5	.8973	1.1216	1.1972	.2869	5.3753	3.3713
1	1.5	1.0210	−2.2272	1.6299	.2804	9.3327	− 9.9556

		P (calcd.) at			
			P exp.	0.5	5	2
			V	5.2[a]	0.454	0.55
x	w		T	1	1	1
0	1			0.544	4.9	1.85
0.5	1			.499	4.95	2.00
1	1			.417	8.24	Impossible
0	1.5			.539	4.86	1.78
0.5	1.5			.511	4.94	1.94
1	1.5			.455	12.5	Impossible

[a] Additional data obtained since the preceding paper[3] indicate that $V = 5.2$ at $P = 0.5$ is a better value than the previously used $V = 5.4$.

This table shows that $x = 0.5$ is a much better value than $x = 0$ or $x = 1$. A point in the liquid phase in equilibrium with the vapor, $T = 0.85$, $P = 0.3745$ and $V = 0.49048$, is used to determine one relation between y and z. When these values are substituted in the equation of state the equations $0.85^y + 0.7152 \times 0.85^z = 2.0509$ when $w = 1$ and $0.85^y + 2.5484 \times 0.85^z = 4.2074$ when $w = 1.5$ are obtained. Another relation between y and z is obtained by making use of the fact that for $V = 1$ the $(AV - AB)/(T^{1/2}V^2 + CT^yV + DT^z)$ term must be a maximum at the critical temperature. Differentiating the denominator with respect to T and setting it equal to zero gives the relation $0.5 + yC + zD = 0$. Solving these two equations in y and z gives $y = 0.333$ and $z = -2.67$ when $w = 1$; and $y = 1.8$ and $z = -1.88$ when $w = 1.5$. The table below shows that the values with $w = 1.5$ give the better solution.

---

(3) Woolsey, THIS JOURNAL, **58**, 984–987 (1936).

T	8	8	4	4	0.85	0.85
V	1.56	2.80	0.91	1.54	5.8264	.49048
P (calculated) ($w = 1$)	19.77	10.15	18.3	9.50	0.355	(.373)
P (calculated) ($w = 1.5$)	20.34	10.31	20.04	10.07	.366	(.379)
P (experimental)	20	10	20	10	.3745	.3745[a]

[a] Used to obtain the relation between y and z.

The use, then, of the Boyle temperature has resulted in a modification of the form of the general equation of state by showing that the logarithmic term is a function of T and it has simplified considerably the determination of the constants of the equation. Using the critical point, the ideal gas value at low pressure, two points on the critical isotherm at high pressure, the Boyle temperature, one point in the liquid phase and the second term maximum at the critical point, an equation

$$PV + \frac{5.3752V + 3.3713}{T^{0.5}V^2 + 0.8973T^{1.8}V + 1.1216T^{-1.88}} = 3.25T + 0.2869P + 1.1972T^{-1.5}\log(P + 1)$$

is found which fits fairly closely at the eight other widely divergent points which were tested.

Age and the Chemical Composition of White Fir Wood

BY IRVING H. ISENBERG

The effect of age on the chemical composition of wood has been studied by few investigators. The composition of sapwood and heartwood has been compared,[1–4] separate trees examined[4,5] or a single constituent determined in one tree.[6,7] It would seem that differences due to age may be studied best by demarking zones of various ages on a cross-section from a definite height in a selected tree, in order to eliminate environmental factors as far as possible. The material should be examined for all important constituents.

Selection of Material

In the past, little effort has been made to record data on the environment in which the wood to be analyzed was grown. Since there is a possibility that environment and chemical composition may be correlated, such data may be of value in the future.

The wood used for this study was obtained from a white fir tree (*Abies concolor*) growing in a mixed conifer stand near Quincy, California. It was a healthy tree, approximately 100 feet tall and 185 years old. The diameter, breast high, was 23 inches (58 cm.). Classed as a dominant number three,[8] it had a long, pointed crown of medium width. The site was such that a tree dominant throughout its life had an average height of 125 feet (38 meters) at 300 years of age; the elevation 3900 feet (1150 meters); the slope 50%; and the exposure northwesterly. The average annual precipitation is 35 to 40 inches (89 to 101 cm.), with little during the summer season.

Preparation of Material

A section 7 inches (17.8 cm.) thick and 17 inches (43 cm.) in diameter, without the bark, was sawed from the white fir tree described above, at a point 12 feet (3.66 m.) above the ground level. The age at this point was one hundred and sixty years. This cross-section was carefully marked, following the 15th, 40th, 85th and 125th annual ring from the periphery, thus dividing the piece into five bands or zones. These zones were chiseled to sticks approximately 0.2 × 0.2 × 3.5 inches (0.51 × 0.51 × 8.9 cm.) and after drying at room temperature, chopped in a Wiley mill until all the sawdust passed a 60-mesh screen. In common with standard procedure, all sawdust passing an 80-mesh screen was discarded. Knots and compression wood areas were eliminated.

Data concerning these zones are listed in Table I. The total (T) was mixed from weighted proportions of the zones. The wood was 65.4% sapwood and 34.6% heartwood. The average apparent specific gravity of the sapwood was 0.425 and of the heartwood 0.440.

TABLE I

MEASUREMENTS ON AGE ZONES

No. of rings from periphery	Symbol	Sap- or heart-wood	Radial width of zone, in.	Area of zone, sq. in.	% of total	% of sap- or heart-wood
1–15	A	S	0.5	23.0	10.1	15.5

Methods

Methods of the Forest Products Laboratory[9] were used to determine ash, solubility in cold water, hot water, 1% sodium hydroxide, ether, and alcohol–benzene, pentosans (thiobarbituric acid used as precipitant), cellulose and lignin.[10] Nitrogen was determined by the method given in Schorger.[11] The Zeisel method, as modified by Dore,[12] was used to determine methoxyl content. Acetic acid was determined by the toluenesulfonic acid method of Freudenberg.[13]

Carbon dioxide determinations, using Dore's modification[14] of the LeFevre method for the determination of uronic acid, were made on the total sawdust. Mannan was determined on this material by Schorger's method[11] (p. 537).

Results

The averages for all data collected on age zones are gathered in Table II. In each case the value calculated for the total from the zones is listed so that it may be compared with the figure determined experimentally. All results are the average of at least two check determinations. Values are expressed in per cent. of oven-dry (105°) weight of the wood.

TABLE II

SUMMARY OF RESULTS

		Solubility in					
Zone	Ash	Cold water	Hot water	Ether	Alcohol–benzene	1% NaOH	Acetic acid
A	0.38	1.46	2.35	0.21	0.92	11.28	1.64
B	.37	0.51	1.29	.19	.96	10.66	1.70
C	.38	.21	1.19	.20	.94	9.95	1.71
D	.63	2.16	2.83	.26	1.74	11.72	1.33
E	.64	1.55	2.04	.22	1.49	10.77	1.25
T	.43	1.12	1.89	.23	1.43	11.38	1.64
Calcd. T	.46	1.04	1.83	.22	1.20	10.79	1.56

Zone	Methoxyl	Nitrogen	Pentosan	Lignin	Cellulose	Pentosan-in-cellulose
A	4.68	0.08	8.68	26.62	64.63	6.96
B	4.62	.06	8.46	27.29	64.56	6.33
C	4.40	.06	8.62	27.65	64.60	7.18
D	4.68	.06	8.83	27.31	64.53	5.75
E	5.06	.06	10.98	28.00	63.65	9.16
T	4.57	.06	8.86	27.43	64.47	7.31
Calcd. T	4.62	.06	8.73	27.40	64.49	..

The total sawdust contained 5.98% mannan and yielded 0.86% carbon dioxide in the uronic acid determination. The methoxyl content of the lignin isolated from total sawdust was 14.81%, or 4.06% calculated on the total wood. Compared to 4.57%, 89% of the methoxyl content was retained in the lignin.

Discussion

No previous data have been reported in the literature for the proximate analysis of the wood of white fir. The values found for the total wood, *i. e.*, the sample commonly used for analysis, compared favorably with the data recorded for other coniferous woods[11] (p. 34). In many points the composition of white fir resembled that of white spruce.

The carbon dioxide from total sawdust amounted to 0.86%. If the carbon dioxide is assumed to be due principally to uronic acid residues, the value for pentosan must be corrected. The total sawdust yielded 5.09% of furfural (equal to 8.86%, pentosan). The carbon dioxide content of 0.86% is equal to 3.44% uronic anhydride. Norris and Resch[15] found that the furfural resulting from galacturonic anhydride, on distillation with 12% hydrochloric acid, was only 43% of the theoretical, or 23.50% of the uronic anhydride. Using this figure, 0.81% of furfural was due to uronic anhydride. Apparently the difference, 4.28%, was the furfural due to pentosans. Accordingly the pentosan content was 7.33%, instead of 8.86%. Anderson[16] found 1.00% carbon dioxide in the wood of white spruce.

Inspection of the data for the five age zones showed the ash content to be constant within the sapwood and within the heartwood, but the values for the latter were approximately 50% higher than those of the sapwood. Other investigators[1–3] have found ash content higher in the sapwood in some instances and higher in the heartwood in others. The wood from older trees often is lower in per cent. ash than that from a younger tree of the same species.

The values for solubility in cold water, hot water, and 1% sodium hydroxide decreased from the outer to the inner sapwood, then rose sharply in the outer heartwood to their highest value and dropped slightly in the inner heartwood. Solubility in ether and alcohol–benzene had a constant value in the sapwood with an increase in the outer heartwood followed by a slight decrease in the inner heartwood.

Acetic acid values were constant within the sapwood and within the heartwood but were ap-

preciably higher in the former. This holds in all American conifers examined.[2,3] When the sapwood sawdust or the total sawdust was heated with absolute alcohol and *p*-toluenesulfonic acid in the Freudenberg method, a violet coloration first appeared. The reaction which caused this is unknown but the coloration suggests a possible method for distinguishing sapwood from heartwood in doubtful cases.

The methoxyl and pentosan values were practically constant in the four outer age zones, but both showed a sharp rise in the inner heartwood. This trend in the methoxyl content paralleled, to a certain extent, that of lignin, especially in regard to the final rise in the inner heartwood.

Nitrogen content was practically the same throughout the section but was slightly higher in the outer sapwood. One might expect this since most of the living cells were in this zone and conduction of nitrates occurred there also.

The lignin content showed appreciable increase from the periphery to the pith.

The cellulose content was nearly constant in the four outer zones but showed a considerable decrease in the inner heartwood. The pentosan in cellulose was irregular. Johnsen and Hovey[7] determined the cellulose in a balsam fir 10.5 inches (26.6 cm.) in diameter with 64 annual rings and found an increase from pith to sapwood, as follows: pith to 15th ring, 51.14%, 20th to 35th, 53.26% and sapwood, 54.21%.

Since in most determinations the values calculated for the total wood from the data of the individual age zones agreed very well with the values determined experimentally (compare last two rows, Table II), it was decided to calculate values for the sapwood and heartwood so that they might be compared with values found by Ritter and Fleck for other American conifers.[2,3] This was done from the data in Table I, Column 7.

In the American conifers they examined, Ritter and Fleck[2,3] found that the cold-water, hot-water, ether and alkali-soluble components were higher in the heartwood than in the sapwood and that, with the exception of lignin in white cedar, the cellulose and lignin contents were lower in the heartwood. White fir showed similar results for the extractives and cellulose but the lignin behaved like that of white cedar and was higher in the heartwood. Apparently, then, white cedar and white fir can be classed in a separate group from the others examined. Acetic acid was also higher in the sapwood of white fir as it was in all the woods they analyzed. In white fir both methoxyl and pentosan values were higher in the heartwood. Ritter and Fleck found fluctuations for these determinations. In general, the calculated sapwood and heartwood values agree with the data reported for American conifers.

TABLE III

CALCULATED VALUES FOR SAPWOOD AND HEARTWOOD

(% Oven-dry Weight)

Determination	Sapwood	Heartwood
Ash	0.38	0.63
Cold water	.53	1.99
Hot water	1.41	2.61
Ether	0.20	0.25
Alcohol–benzene	.94	1.67
1% NaOH	10.45	11.46
Determination	**Sapwood**	**Heartwood**
Acetic acid	1.70	1.31
Methoxyl	4.53	4.78
Pentosan	8.56	9.42
Nitrogen	0.06	0.06
Lignin	27.34	27.50
Cellulose	64.59	64.29

Comparison of our data for *Abies concolor* with those of Gäumann for *Abies pectinate*,[1] although different methods were used, showed the ash, lignin and solubility in ether to be higher in the heartwood in both cases. Gäumann found other extractives to be higher in the sapwood while the opposite was true in white fir. The values he found for pentosan and cellulose fluctuated throughout the year.

Summary

The effect of age on the chemical composition of white fir wood was studied. Values, calculated from the age zone data, for the composition of the sapwood and heartwood agree in general with the data reported by other investigators for American conifers.

Studies of the Pernicious Anemia Principle in Liver. III. The Isolation and Properties of a Substance with Primary Therapeutic Activity[1]

BY Y. SUBBAROW, BERNARD M. JACOBSON AND VILMA PROCHOWNICK

This communication is a detailed account and an extension of results previously reported in a preliminary form.[2]

It has already been found[3] that a therapeutically active extract of liver can be prepared by adsorption of Cohn's fraction G on norit, elution of the adsorbate by hot ethyl alcohol, and subsequent concentration of the elute by vacuum distillation (fraction B). The copious precipitate appearing on further concentration of the elute (fraction C) has been characterized as a complex purine.[4] The filtrate (fraction D) from 100 g. of fresh liver concentrated to 3 cc. is light brown in color, and contains 10 to 12 mg. of total nitrogen. This filtrate is the starting point of the preparation described below.

Experimental

After acidification of 150 cc. of the filtrate (derived from 5 kg. of liver) to *p*H 2 with hydrochloric acid, 16 g. of English fuller's earth was added, and the mixture was stirred mechanically for thirty minutes at room temperature. The precipitate was filtered off and washed once with 50 cc. of water. To the filtrate and washings were added 10 volumes of 95% ethyl alcohol and 10 volumes of ether, and the mixture was left in the cold room for twenty-four to thirty-six hours. The resulting precipitate was then filtered off. The precipitate (fraction H[5]) was obtained in a yield of 1 g. (20 mg. from 100 g. of liver) and contained 12 to 13% nitrogen.

One gram of this precipitate was dissolved in 50 cc. of water and the solution was brought to *p*H 3 with 10 *N* sulfuric acid. A crystalline precipitate immediately separated. This precipitate consisted mainly of calcium sulfate, and on the basis of spectroscopic examination contained traces of silver, copper, iron, aluminum and lead, all of the latter in a concentration of less than 0.01%, and probably derived from the fuller's earth. The filtrate of the calcium sulfate precipitate was then added to 40 cc. of water containing 1 g. of Reinecke salt[6] at 40°. After remaining in the cold room for twenty-four hours a crystalline precipitate formed which was filtered off and washed once with 50 cc. of ice-cold water. The precipitate was suspended in 300 cc. of 0.03 *N* sulfuric acid at 30–35°, and the Reinecke acid was removed by repeated extraction with 500 cc. of a mixture of equal volumes of amyl alcohol and ether. After several such extractions the color was entirely removed, and the solution was concentrated *in vacuo* to a volume of 25 cc. To this concentrate were added 10 volumes of acetone and 10 volumes of ether, and the mixture was kept in the cold room for forty-eight hours. A microcrystalline precipitate separated in a yield of 100 mg. (2 mg. from 100 g. of fresh liver). This precipitate is termed fraction I.

Fraction I was also prepared without the use of fuller's earth. To 1 liter of fraction D were added 7 liters of 95% ethyl alcohol and the mixture was kept at room temperature for five hours. The resulting precipitate, which contain none of fraction I, was filtered off. To the filtrate 3 liters of ethyl alcohol and 10 liters of ether were added, and the mixture kept in the cold room for forty-eight hours. The resulting precipitate, termed fraction E, was filtered off and dissolved in 500 cc. of water. To this was added 200 cc. of a 5% solution of rhodanilic acid in methyl alcohol. After forty-eight hours in the cold room a crystalline precipitate separated which was filtered off, and freed of rhodanilic acid by means of pyridine, with subsequent removal of the pyridine by ether, the method of regeneration described by Bergmann.[7] The regenerated rhodanilate solution was then precipitated by Reinecke salt as described above, and the subsequent procedure was followed. The yield of fraction I was approximately the same as that obtained by the previous method.

Properties of Fraction I.—The microcrystalline material, derived from either the crystalline rhodanilate or directly from the crystalline reineckate, is white and dissolves readily in water, forming a colorless solution. The sulfate is readily soluble in dilute alcohol, but is very little soluble in absolute alcohol. The sulfate can be precipitated from an aqueous solution acidified to *p*H 2.5 with sulfuric acid by the addition of acetone and ether. Repeated precipitation did not change the nitrogen content. The sulfate decomposes without melting above 290°. In 0.8% aqueous solution the sulfate has an optical activity $[\alpha]^{28}\text{D}$ −85.4 ±2°. *Anal.* Found: C, 41.56; H, 6.74; N, 13.13; S, 4.6. 3.4% of the 4.6% S is present as inorganic sulfate. The ash content of this sample was 1.6%. Spectroscopic examination disclosed that almost all of the ash consisted of chromium, evidently derived from the decomposition of the Reinecke salt. The amino nitrogen (Van Slyke[8]) was determined after interaction with nitrous acid at the end of

five minutes and at the end of sixty minutes, with the following results:

PER CENT. AMINO N FOUND

	5 min.	60 min.
Before hydrolysis	5	14.7
After hydrolysis for 6 hours in 2 *N* HCl	75	87

Under the usual conditions fraction I does not show a ninhydrin reaction, but after neutralization to *p*H 7 a slight reaction is observed. Fraction I reduces the Folin–Ciacalteau phenol reagent,[9] gives a positive orcin test, and a weak diazo reaction. The Sagakuchi, Millon, glyoxylic acid and biuret tests are negative.

Fraction I is readily precipitated by phosphotungstic acid and is partially precipitated by Hopkins' reagent ($HgSO_4$ in H_2SO_4). The reineckate can be recrystallized readily from hot water, but due to the decomposition products formed during the successive regenerations this salt is not suitable for further purification. A crystalline rufianate is readily obtained with the following composition: C, 46.5; H, 4.84; N, 4.23; S, 6.6. For further purification the rufianate is also not practicable due to the necessity of using large amounts of amyl alcohol in regeneration. Furthermore, if the rufianic acid is removed with barium the resulting barium rufianate precipitate adsorbs the fraction I.

An aqueous solution of fraction I, when exposed to ultraviolet light, exhibits an intense blue fluorescence. The absorption spectrum in the ultraviolet of an aqueous solution of fraction I (C 0.5 mg. per cc., L 1 cm.) as depicted in Fig. 1, shows an inflection between 2480 and 2560 Å.[10]

Therapeutic Activity.—That fraction H is therapeutically active is evidenced by satisfactory clinical and hematological improvement in four patients suffering from pernicious anemia, following the administration of the material by intramuscular injection. The therapeutic activity of fraction I has been tested similarly in two patients, with resulting moderate clinical and hematological improvement. The data are presented in Table I.

TABLE I

THE THERAPEUTIC ACTIVITY OF FRACTION H AND FRACTION I

Fraction no.	H	H	H	H	I	I
Patient no.	16	15	21	22	23	13
Total amount fraction administered, mg.	60	20	20	20	7.6	4
R. b. c. at beginning, millions per cu. mm.	1.05	1.28	1.15	0.88	2.41	1.40
R. b. c. at end, millions per cu. mm.	2.42	1.93	1.80	1.60	3.10	2.35
Reticulocytes at peak, %	31.0	24.4	30.2	24.6	6.6	12.0
Day of reticulocyte peak	6th	7th	5th	5th	4th	5th
Length of period, days	18	8	8	8	10	10

Since this paper has gone to press fraction I regenerated from the rufianate has been tested for its therapeutic activity on two patients. The resulting hematopoietic responses were similar to the responses to fraction I described in Table I.

It is to be noted that all of the experimental periods of therapeutic trial are of short duration, and are not adequate for an estimate of the capacity of fraction H and of fraction I to induce a complete clinical and hematological remission. It has already been reported[11] that the complete therapeutic activity of commercial liver extract probably depends upon its content of several chemically distinct substances. Fractions H and I, in the light of the present evidence, probably exert a primary or initiating therapeutic action, which is augmented by the addition of several other substances derived from crude liver extract. The evidence for this view, and the details of the therapeutic activities of fractions H and I, will be discussed in a forthcoming publication.

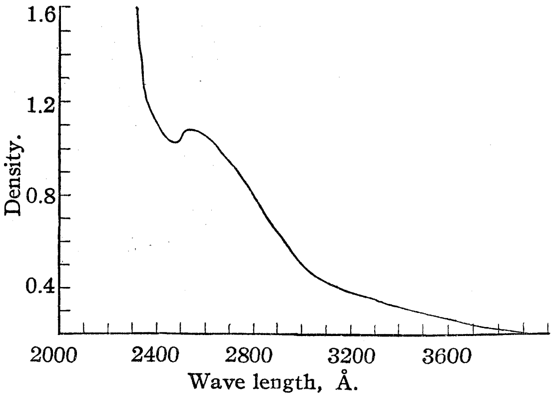

Fig. 1.

(10) For the determination of the absorption spectrum the authors are indebted to Prof. George R. Harrison of the Massachusetts Institute of Technology.

(11) Fiske, Subbarow and Jacobson, *J. Clin. Investigation*, **14**, 709 (1935).

There has recently been reported by Laland and Klem[12] the separation from liver of an amorphous, reddish-yellow material, in a yield of 0.35 mg. from 100 g. of fresh liver, with the following composition: C, 53.64; H, 6.85; N, 13.33; S, 0.74 (ash content 2.05%). The absorption spectrum in the ultraviolet showed two points of inflection, one between 2500 and 2650 Å. and another between 3450 and 3500 Å. The similarity between the nitrogen content and one point of inflection of the absorption spectrum of the material of Laland and Klem and fraction I is worthy of note. The material of Laland and Klem has been found to be therapeutically active, in doses of 0.7 mg., by Strandell, Poulsson and Schartum-Hansen.[13] Proof is still lacking that the chemically active material reported in this paper is a single pure chemical substance.

Summary

There is described the isolation from commercial liver extract of a microcrystalline white substance, as a sulfate, in a yield of 2 mg. from 100 g. of fresh liver, exhibiting intense blue fluorescence when exposed to ultraviolet light, and exerting therapeutic activity in pernicious anemia.

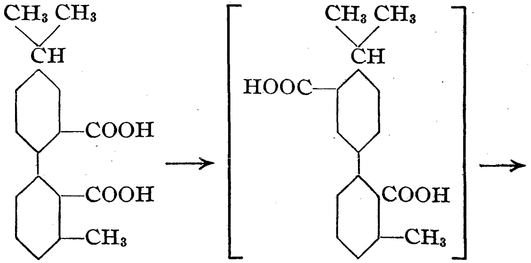
Investigations in the Retene Field. VII. Certain Fluorenones and Phenanthridones from Retenediphenic Acid

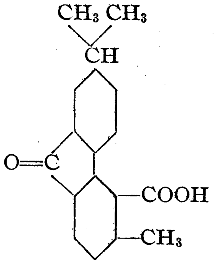
BY DAVID E. ADELSON[1] AND MARSTON TAYLOR BOGERT

In a previous publication[2] it was shown that the oxidation of retenequinone in glacial acetic acid solution with 30% hydrogen peroxide yielded retenediphenic acid. This paper is concerned with the preparation and proof of structure of some additional derivatives of retenediphenic acid and with the establishment of the configuration of compounds previously reported.[2]

When retenediphenic acid (I) was treated with 95% sulfuric acid, a rotation of one of the rings of the biphenyl nucleus took place and the hypothetical intermediate (II) thus formed lost a molecule of water in two ways to yield 6-methyl-2-isopropylfluorenone-5-carboxylic acid (III) and 1 - methyl - 7 - isopropylfluorenone - 5 - carboxylic acid (IV).

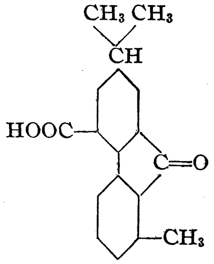


(I) (II)



(III)

and



(IV)

At 110° the principal product was the keto acid (III), while the isomeric acid (IV) was isolated when the reaction was carried out at room temperature. At 60° there resulted a mixture of acids which could not be separated by fractional crystallization; at 175° complete sulfonation took place. These keto acids, (III) and (IV), were characterized by conversion into the oximes, the methyl esters and the oximes of the latter.

At 110° the action of 95% sulfuric acid on the 3-methyl-4′-isopropyl-2′-carbomethoxybiphenyl-2-carboxylic acid (V) resulted in a mixture of the keto acids, (III) and (IV), and the methyl ester of (IV). This is similar to the experience of Underwood and Kochmann,[3] who studied the action of sulfuric acid on methyl acid diphenate. At room temperature, however, 95% sulfuric acid converted the acid ester (V) into the methyl ester

---

(1) Fritzsche Fellow in Organic Chemistry, Columbia University, 1935–1936.

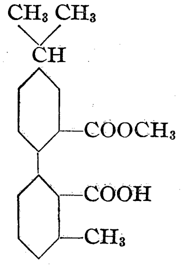
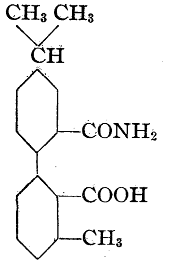
(3) Underwood and Kochmann, *ibid.*, **46**, 2074 (1924).

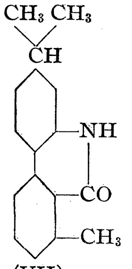
of (IV) in quantitative yield. The last reaction furnished the important link essential to the determination of the structures of the compounds reported in this and the previous paper.[2]



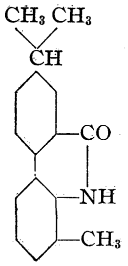
(V)



(VI)



(VII)



(VIII)

Concentrated ammonium hydroxide converted the acid methyl ester (V) into 6-methyl-5′-isopropyl-1′-diphenamic acid (VI) which yielded 8-methyl-2-isopropylphenanthridone (VII) when subjected to the Hofmann degradation. This phenanthridone (VII) was isomeric but not identical with the product obtained from the Beckmann rearrangement of 1-methyl-7-isopropylfluorenonoxime.[4] The previously reported phenanthridone is therefore 1-methyl-7-isopropylphenanthridone (VIII). Oxidation of (VII) yielded hemimellitic acid, thus indicating that the amide group in the amic acid (VI) and the ester group in the acid methyl ester (V) were in the same benzene nucleus as the isopropyl group. From this it followed that the action of 95% sulfuric acid on (V) at room temperature should yield the methyl ester of (IV) and that the acid (III), isomeric with (IV), should not yield retene ketone (1-methyl-7-isopropylfluorenone) upon decarboxylation, and such was actually found to be the case.

As a by-product in the action of 95% sulfuric acid on retenediphenic acid at 110°, there was formed a small amount of a neutral body. Its structure has not yet been determined.

Pyrolysis of retenediphenic acid yielded retene ketone.[5,6] This is analogous to the behavior of diphenic acid, which yielded fluorenone under similar treatment.[7,8] A better yield of retene ketone was obtained by dry distillation of retenediphenic anhydride.[2] Fluorenone has been obtained from diphenic anhydride in similar fashion.[8] The over-all yield of the ketone, based on retene, was 21%, whereas the older method of preparation[6] gave a yield of 13%.

So far as our experiments have gone, only one of the possible stereoisomers was encountered in these reactions.

Acknowledgments—We are indebted to Dr. Torsten Hasselstrom for preliminary work on the preparation of 6-methyl-2-isopropylfluorenone-5-carboxylic acid and for authentic samples of 1-methyl-7-isopropylphenanthridone and retene ketone.

Experimental

6 - Methyl - 2 - isopropylfluorenone - 5 - carboxylic Acid (III).—A solution of 10 g. of retenediphenic acid in 25 cc. of 95% sulfuric acid was maintained at 110–115° for twenty minutes, cooled and poured onto cracked ice. The yellow solid which this precipitated was dissolved in ether, and the solution washed with water and dried over anhydrous magnesium sulfate. Evaporation of the solvent yielded 9 g. of a mixture of keto acids, (III) and (IV). Because of the similarity of their solubilities in organic solvents, their separation proved very difficult. Fractional crystallization of the mixture from benzene gave 3 g. of the keto acid (III), which was then recrystallized from 90% formic acid, appearing as long, yellow needles, m. p. 156–156.5° (corr.).

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.11; H, 5.76. Found: C, 76.78; H, 5.86.

Upon dry distillation of this acid, carbon dioxide was evolved and there appeared in the distillate a neutral, yellow oil, which could not be obtained in the crystalline state even when seeded with a crystal of retene ketone.

When the combined benzene mother liquors from the above operations was evaporated to dryness and the residue boiled with 10% sodium carbonate solution, there remained a small amount of undissolved material. This neutral body, which was also insoluble in hot dilute caustic alkali, appeared as small, yellow leaflets from 95% ethanol, m. p. 194–195° (corr.). Its structure has not yet been determined. Upon acidification of the carbonate filtrate, the mixture of acids was reprecipitated. Attempts to isolate the isomeric acid (IV) from such a mixture were unsuccessful.

Methyl Ester.—The dry potassium salt (1 g.) of the keto acid (III) was boiled with 5 g. of dimethyl sulfate for fifteen minutes, cooled and the excess dimethyl sulfate destroyed by pouring the reaction mixture into water. The resulting suspension was extracted with ether, the ethereal solution washed with 10% sodium carbonate solution, water and

finally dried over anhydrous magnesium sulfate. Evaporation of the solvent, followed by recrystallization of the residual yellow solid (0.7 g.) from methanol, yielded tiny glistening flakes, m. p. 86.5–87.5° (corr.).

Anal. Calcd. for $C_{19}H_{18}O_3$: C, 77.51; H, 6.17. Found: C, 77.37; H, 5.91.

Oxime of the Methyl Ester.—A suspension of 0.6 g. of the above methyl ester, 1 g. of hydroxylamine hydrochloride and 1.5 g. of anhydrous barium carbonate in 20 cc. of absolute methanol was refluxed for eight hours, filtered and the filtrate diluted with water. This precipitated the oxime in nearly theoretical yield. Recrystallized from dilute ethanol, it appeared as short, pale yellow needles, m. p. 173–174° (corr.).

Anal. Calcd. for $C_{19}H_{19}O_3N$: C, 73.75; H, 6.20. Found: C, 73.86; H, 5.92.

The oxime of the free acid, prepared similarly, appeared as short, cream-colored needles from dilute ethanol which darkened slightly over 250° and melted with decomposition at 268–269° (corr.).

Anal. Calcd. for $C_{18}H_{17}O_3N$: C, 73.19; H, 5.81. Found: C, 73.19; H, 6.09.

1 - Methyl - 7 - isopropylfluorenone - 5 - carboxylic Acid (IV).—Retenediphenic acid (2.5 g.) was dissolved in 10 cc. of 95% sulfuric acid at room temperature and, after twenty-four hours, the clear solution was poured onto cracked ice. The yellow precipitate thus formed was filtered, washed with water and recrystallized from 90% formic acid, from which it appeared as broad, yellow leaflets, m. p. 200.5–201° (corr.); yield 1.0 g.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.11; H, 5.76. Found: C, 76.62; H, 5.94.

When retenediphenic acid was heated with 95% sulfuric acid at 60° for twenty minutes and the reaction mixture worked up as described for the above keto acid (III), a mixture of products resulted which could not be separated by fractional crystallization. At 175° complete sulfonation resulted even when heat was applied for only two minutes.

Methyl Ester.—This was prepared from the potassium salt of the keto acid (IV) in a manner similar to the synthesis described above for the isomeric methyl ester. Recrystallized from methanol, it appeared in tufts of short, bright yellow needles, m. p. 104–104.5° (corr.).

Anal. Calcd. for $C_{19}H_{18}O_3$: C, 77.51; H, 6.17. Found: C, 77.31; H, 6.27.

Two grams of the acid methyl ester (V) was dissolved in 8 cc. of 95% sulfuric acid at room temperature and, after a day, the crimson solution was poured into water, a yellow precipitate forming. This was dissolved in ether, the ethereal solution was washed with 10% sodium carbonate solution, water and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave the keto methyl ester in practically quantitative yield; recrystallized from methanol, it appeared as tufts of short, bright yellow needles, m. p. 104–104.5° (corr.). Mixed with a sample of the above methyl ester of m. p. 104–104.5° (corr.), it gave no depression.

Anal. Calcd. for $C_{19}H_{18}O_3$: C, 77.51; H, 6.17. Found: C, 77.34; H, 6.45.

The oxime of the methyl ester, prepared similarly to the isomeric oxime described above and crystallized from dilute ethanol, appeared as clusters of long, cream-colored needles, m. p. 151.5–152° (corr.).

Anal. Calcd. for $C_{19}H_{19}O_3N$: C, 73.75; H, 6.20. Found: C, 73.72; H, 6.52.

The oxime of the keto acid (IV), prepared similarly, crystallized from dilute ethanol in short, pale yellow needles which melted with decomposition at 249–250° (corr.).

Anal. Calcd. for $C_{18}H_{17}O_3N$: C, 73.19; H, 5.81. Found: C, 73.12; H, 5.78.

6 - Methyl - 5′ - isopropyl - 1′ - diphenamic Acid (VI).—The acid methyl ester (V) was dissolved in concentrated ammonium hydroxide and allowed to stand with occasional shaking for a week. Dilution of the solution followed by acidification yielded a white precipitate which appeared as colorless, hard prisms (yield 25%) from 95% ethanol, m. p. 197–198° (corr.). Mixed with an authentic specimen of the amic acid (VI) of m. p. 201–202° (corr.), it melted at 200–201° (corr.).

8-Methyl-2-isopropylphenanthridone (VII).—To a solution of 3.5 g. of the amic acid (VI) in 30 cc. of 10% potassium hydroxide, there was added slowly a solution of 3 g. of bromine in 30 cc. of 10% potassium hydroxide. The clear solution was cooled in an ice-bath for thirty minutes, heated at 60–65° for another thirty minutes, cooled, 1 g. of sodium bisulfite added and the resulting solution acidified with concentrated hydrochloric acid. The voluminous white precipitate was boiled with 50 cc. of 5% potassium hydroxide solution, filtered, washed with water, dried at 110°, and recrystallized from benzene, 95% ethanol and finally from benzene, from which it appeared as long, silky white needles, m. p. 230–231° (corr.). A mixture of this and an authentic specimen of 1-methyl-7-isopropylphenanthridone[4] (VIII) of m. p. 221–222.5° (corr.) melted at 187–188° (corr.).

Anal. Calcd. for $C_{17}H_{17}ON$: C, 81.23; H, 6.82. (Calcd. for the amino carboxylic acid, $C_{17}H_{19}O_2N$: C, 75.79; H, 7.12). Found: C, 81.17; H, 7.10.

Two grams of the above phenanthridone was dissolved in 7 cc. of 95% sulfuric acid and the solution poured into 150 cc. of water. The finely-divided suspension was made alkaline with 10% potassium hydroxide, diluted to a volume of 400 cc., 17 g. of potassium permanganate added and the mixture was stirred and refluxed for twenty hours. The solution was filtered, the colorless filtrate evaporated to a small volume, cooled, extracted with 350 cc. of ether and the latter dried with anhydrous magnesium sulfate. Evaporation of the ether yielded 0.7 g. of a white solid which appeared as white tablets from an ether–petroleum ether mixture. After drying at 110° it melted at 188–189° (corr.), with decomposition. Upon cooling, the fused material solidified and melted at 196–197° (corr.). The recorded melting points for hemimellitic acid and hemimellitic anhydride[9] are 190 and 196°, respectively. The acid gave an excellent fluorescein test on fusion with resorcinol and sulfuric acid. Upon treating an aqueous solution of the acid with a concentrated potassium chloride solution, there resulted tiny, glistening flakes which are characteristic of the mono-potassium salt of hemimellitic acid.[9]

[9] Graebe and Leonhardt, *Ann.*, **290**, 220 (1896).

Anal. Calcd. for $C_9H_6O_6$: C, 51.42; H, 2.88. Found: C, 51.36; H, 2.97.

Retene Ketone (1-Methyl-7-isopropylfluorenone).—Two grams of retenediphenic anhydride was dry distilled, yellow vapors coming over accompanied by carbon dioxide. The distillate soon solidified to a yellow, crystalline material; yield, 1.5 g. (90%). From 95% ethanol it appeared as long, flat, sulfur-yellow prisms, m. p. 89–90° (corr.). Mixed with an equal amount of an authentic specimen of retene ketone of m. p. 88–89° (corr.), it melted at 89–90° (corr.).

When retenediphenic acid or an intimate mixture of its anhydride and soda lime were distilled, retene ketone also resulted. In these cases, however, losses due to charring were appreciable and the yields lower.

Summary

1. Dehydration of retenediphenic acid with 95% sulfuric acid yields two isomeric methylisopropylfluorenone carboxylic acids.

2. These keto acids have been characterized by their oximes, methyl esters and the oximes of the latter.

3. Ammonia converts methyl acid retenediphenate into the previously reported retenediphenamic acid which undergoes the Hofmann degradation to yield 8-methyl-2-isopropylphenanthridone. Oxidation of the latter yields hemimellitic acid, thus establishing the structures of the compounds concerned.

4. Treatment of methyl acid retenediphenate with 95% sulfuric acid at room temperature yields the methyl ester of 1-methyl-7-isopropylfluorenone-5-carboxylic acid. The isomeric acid is therefore 6-methyl-2-isopropylfluorenone-5-carboxylic acid.

5. Pyrolysis of retenediphenic anhydride gives retene ketone in 90% yield.

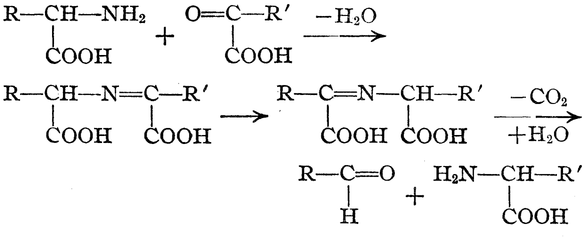
The Reaction between α-Ketonic Acids and α-Amino Acids

BY ROBERT M. HERBST

In a previous paper[1] it was shown that a reaction takes place between certain α-ketonic acids and α-amino acids. The first step in the reaction was assumed to be interaction between the carbonyl and the amino groups to form a Schiff base. The second step involved the migration of a hydrogen atom from the α-carbon of the amino acid to the α-carbon of the ketonic acid residue, and the third the elimination of carbon dioxide from the intermediate and the addition of water resulting in fission with the formation of an aldehyde and an amino acid.



$$\underset{\text{COOH}}{\text{R—CH}}\text{—NH}_2 + \text{O=}\underset{\text{COOH}}{\text{C}}\text{—R}' \xrightarrow{-\text{H}_2\text{O}}$$

$$\text{R—}\underset{\text{COOH}}{\text{CH}}\text{—N=}\underset{\text{COOH}}{\text{C}}\text{—R}' \longrightarrow \text{R—}\underset{\text{COOH}}{\text{C}}\text{=N—}\underset{\text{COOH}}{\text{CH}}\text{—R}' \xrightarrow[+\text{H}_2\text{O}]{-\text{CO}_2}$$

$$\text{R—}\underset{\text{H}}{\text{C}}\text{=O} + \text{H}_2\text{N—}\underset{\text{COOH}}{\text{CH}}\text{—R}'$$

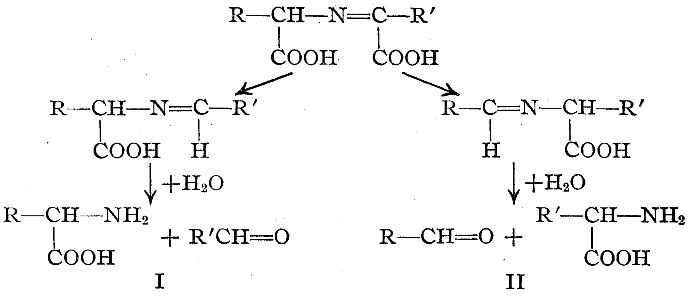
Certain results reported in the previous paper made it desirable to continue the investigation in order to gain greater insight into the mechanism of the reaction. In experiments with *l*-cystine and pyruvic acid acetaldehyde was always obtained in appreciable amounts. In the absence of any product, other than carbon dioxide, which could be attributed to the cystine molecule, it was concluded that the acetaldehyde was derived in some way from this source. This view has now been shown to be incorrect, for in the reaction between cystine and both phenylpyruvic and benzoylformic acids *no* acetaldehyde could be found. Moreover, small amounts of acetaldehyde have been isolated from the products of the reaction of pyruvic acid with *p*-methoxyphenylalanine, α-amino-*p*-methoxyphenylacetic acid, ethylcysteine, benzylcysteine and phenylcysteine, while with α-aminophenylacetic acid *no* acetaldehyde could be detected. These results point to pyruvic acid or some intermediate formed with the above amino acids as the principal source of acetaldehyde. The possibility remains that acetaldehyde could be formed by the secondary interaction of pyruvic acid with alanine formed during the primary reaction. In a separate experiment with this pair acetaldehyde was formed, but too slowly to account for its rapid formation in the reaction of pyruvic acid with cystine, S-phenylcysteine and S-benzylcysteine. The conclusion is therefore unescapable that the formation of acetaldehyde is largely a direct result of the primary reaction of pyruvic acid with the above amino acids.

---

(1) Herbst and Engel, *J. Biol. Chem.*, **107**, 505 (1934).

To determine the probable fate of the cystine structure, the reaction of several S-substituted cysteine derivatives with pyruvic acid was studied. Of these, ethylcysteine gave the clearest results since it was possible to demonstrate the formation of considerable quantities of ethylthioglycolic aldehyde as well as acetaldehyde. The analogous aldehydes from phenylcysteine and benzylcysteine, which were not found in the usual experiments, could be obtained only by continuous distillation of the volatile products from the reaction flask, and then only in small yield. In both cases considerable decomposition took place with the formation of thiophenol and diphenyl disulfide in the first, and of benzyl mercaptan in the second. No analogous aldehyde could be obtained from cystine even in distillation experiments.

The results outlined above make it desirable to formulate a more labile mechanism for the reaction than the rather static mechanism given above.[2] It is now suggested that decarboxylation takes place while the molecule is momentarily in an unbalanced state during the shift of the double bond. The nature of the substituents R and R′ will influence the extent of decarboxylation in the direction of either Scheme I or II.



$$\mathrm{R{-}\underset{COOH}{CH}{-}N{=}\underset{COOH}{C}{-}R'}$$

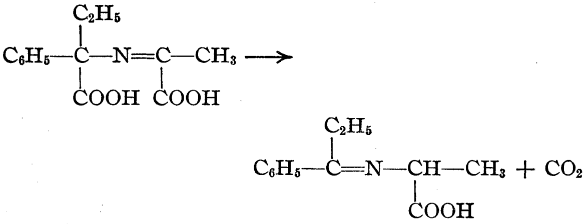
$$\mathrm{R{-}\underset{COOH}{CH}{-}N{=}\underset{H}{C}{-}R'} \xrightarrow{+H_2O} \mathrm{R{-}\underset{COOH}{CH}{-}NH_2 + R'CH{=}O} \quad \mathrm{I}$$

$$\mathrm{R{-}\underset{H}{C}{=}N{-}\underset{COOH}{CH}{-}R'} \xrightarrow{+H_2O} \mathrm{R{-}CH{=}O + R'{-}\underset{COOH}{CH}{-}NH_2} \quad \mathrm{II}$$

Such a mechanism would explain the observed formation of both aldehydes RCHO and R′CHO.

Schiff bases from α-phenyl-α-amino acids undoubtedly possess a strong tendency to form conjugated systems. Thus in the reaction of α-aminophenylacetic acid with pyruvic acid, the side chain double bond of the initial Schiff base is not conjugated with the benzene ring, and the tendency to form a conjugated system may explain the completeness of the reaction in the direction of Scheme II. When a methoxyl group is introduced in the para-position in aminophenylacetic acid, the tendency to form a conjugated system is possibly less strong, for the reaction proceeds partly in the direction of Scheme I.

Of particular interest are the results obtained in the reaction between α-amino-α-phenylbutyric acid and pyruvic acid, whereby propiophenone is produced in considerable quantity, together with mere traces of acetaldehyde. Here the tendency for the double bond to shift to the conjugated position is great, but this shift can occur only with simultaneous decarboxylation of the amino acid structure



$$\mathrm{C_6H_5{-}\overset{C_2H_5}{\underset{COOH}{C}}{-}N{=}\underset{COOH}{C}{-}CH_3 \longrightarrow C_6H_5{-}\overset{C_2H_5}{C}{=}N{-}\underset{COOH}{CH}{-}CH_3 + CO_2}$$

Contrary to a previous statement[1] it has now been found that α-aminoisobutyric acid also reacts (though very slowly) with pyruvic acid. In this case a minute amount of acetaldehyde is formed, but *no* acetone could be detected. Clarke, Gillespie and Weisshaus[3] have observed a similar difference in the action of formaldehyde in formic acid on this pair of amino acids.

Further support for the view that decarboxylation occurs exclusively during tautomeric shift is the almost complete absence of decarboxylation on treating alanine with benzoylformic acid. The Schiff base formed by this pair is conjugated, hence there is no tendency for the double bond to shift; practically no carbon dioxide is eliminated, and only a trace of benzaldehyde is formed. That this result probably is not due to failure of benzoylformic acid to form a Schiff base is shown by the fact that it reacts with α-amino-*p*-methoxyphenylacetic acid, cystine and ethylcysteine.

Experimental

The experiments were carried on in the apparatus previously employed,[1] modified to permit gravimetric estimation of carbon dioxide. The gas coming from the reaction flask was passed through a series of wash bottles containing, respectively, 5% sodium bisulfite, 2% potassium per-

---

[2] Ingold and his co-workers [*J. Chem. Soc.*, 1778 (1935)] in a study of methyleneazomethine (C=N—C) systems from a kinetic point of view have found no evidence in support of an intermediate between tautomeric forms of simple Schiff bases. However, none of the systems considered involved carboxyl groups on the carbon atoms adjacent to the nitrogen [*cf.* also, Baker, Nathan and Shoppee, *ibid.*, 1847 (1935), and Turcan, *Bull. soc. chim.*, [5] **3**, 283 (1936)].

[3] Clarke, Gillespie and Weisshaus, THIS JOURNAL, **55**, 4571 (1933).

manganate in 2.5% sulfuric acid, two bottles with concentrated sulfuric acid and a Geissler absorption bulb charged with 40% potassium hydroxide. Suitable blank runs showed that only carbon dioxide was absorbed by the potash bulbs. The gas capacity of the whole train when charged was about 100 cc. Carbon dioxide was estimated periodically by changing the Geissler bulbs and weighing them. This method of estimating carbon dioxide was quicker and more convenient than that previously employed, and seemed to give more accurate results.

Pyruvic acid alone in aqueous solution slowly gives off carbon dioxide under the conditions of the experiment. The values obtained during actual experiments have been corrected, therefore, by subtraction of a suitable blank value, on the assumption that the amino acid has no effect on the rate of carbon dioxide production from pyruvic acid as such.

The reactions of pyruvic acid with α-aminophenylacetic acid and with cystine were repeated in the modified apparatus for purpose of comparison. Both experiments were in all other respects duplicates of those previously reported.

The isolation of reaction products followed in general the methods previously employed. After completion of the reaction aldehydic products were isolated as derivatives with dimedon (dimethyldihydroresorcinol) or 2,4-dinitrophenylhydrazine. Derivatives already described in the literature were identified by their melting points and mixed melting points with authentic specimens; others were identified by elementary analysis.[4] Aldehydes of low molecular weight were found in the sodium bisulfite wash bottle; less volatile aldehydes were isolated from the reaction mixture. To estimate quantitatively the amount of volatile carbonyl derivatives taken up in the bisulfite trap, the excess and bound bisulfite were titrated with standard iodine solution, as in the estimation of acetaldehyde in lactic acid determinations.[5] No acetaldehyde or other volatile carbonyl derivative is formed from pyruvic acid alone under the experimental conditions, as determined by suitable blank experiments.

Amino acids were isolated from the reaction mixture as previously described (except as noted in specific instances), either as such or in the form of derivatives with phenyl isocyanate or benzenesulfonyl chloride. Identity was established by elementary analysis, or by melting point and mixed melting point, respectively.

Mercaptans were isolated from the ether soluble portion of the reaction mixtures by vacuum distillation after removal of the solvent. Identification as 2,4-dinitrophenyl derivatives[6] rested upon melting points controlled by admixture of authentic specimens.

Reactions with Pyruvic Acid

In general 10 mml. of amino acid and 40 mml. of pyruvic acid were employed, exceptions being the reaction with α-aminophenylacetic acid where 30 mml. of pyruvic acid was employed, and the reaction with cystine where 5 mml. of the amino acid was employed. The yields of carbon dioxide and duration of the reactions are indicated by the curves in Figs. 1 and 2.

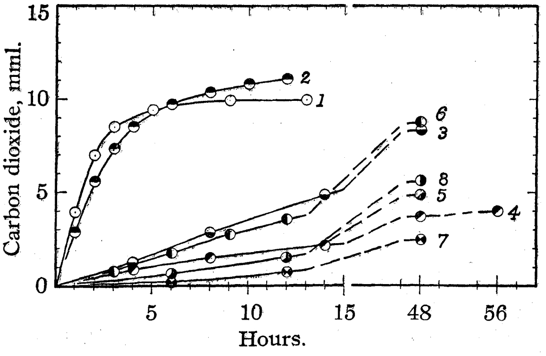


Fig. 1.—Rate of carbon dioxide evolution during reaction of pyruvic acid with: 1, α-aminophenylacetic acid; 2, α-amino-p-methoxyphenylacetic acid; 3, p-methoxyphenylalanine; 4, glutamic acid; 5, alanine; 6, leucine; 7, α-aminoisobutyric acid; 8, α-amino-α-phenylbutyric acid.

α-Aminophenylacetic Acid.—No acetaldehyde could be found. The yields of alanine (7.5 mml.) and benzaldehyde (7 mml.) were about the same as in earlier experiments.

Alanine.—Titration of the excess and bound sodium bisulfite in the trap indicated the presence of 4.4 mml. of an aldehyde, subsequently identified as acetaldehyde. Practically all of the alanine could be recovered in pure form.

Leucine.—Most of the isovaleric aldehyde was carried over into the bisulfite trap. Titration of an aliquot of the bisulfite solution indicated 12.2 mml. of aldehydes, however, since a permanent end-point in the titration was reached only after the solution began to smell strongly of isovaleric acid, much of the iodine was probably used to oxidize the aldehyde. Acetaldehyde could not be found. About 4 mml. of alanine was isolated.

α-Amino-p-methoxyphenylacetic Acid.—The high yield of carbon dioxide (11 mml.) may be explained by the formation of acetaldehyde according to Scheme I. Alanine was isolated in good yield, while anisaldehyde was obtained in 70–75% yield.

p-Methoxyphenylalanine.—Acetaldehyde was found in appreciable amounts. Alanine was isolated in small yield. p-Methoxyphenylacetaldehyde was obtained in the form of a condensation product with pyruvic acid, the lactone of α-keto-γ-hydroxy-δ-(p-methoxyphenyl)-valeric acid, which crystallized from the reaction mixture as it cooled, giving needles from hot water, m. p. 160°.[7]

[7] All melting points are corrected.

pyruvic acid 2,4-dinitrophenylhydrazone, m. p. 222°, could be isolated.

Glutamic Acid.—The amino acid mixture obtained by the usual procedure was treated with zinc oxide to remove glutamic acid, after which alanine could be isolated as the benzenesulfonyl derivative. No aldehydic products could be isolated.

α-Aminoisobutyric Acid.—The yield of carbon dioxide was 2.5 mml., as compared with only 0.3 mml. of aldehyde. The bisulfite solution was fractionated carefully after alkalinization with sodium bicarbonate, and the distillate caught in a trap immersed in a solid carbon dioxide–alcohol bath. Although the distillate smelled of acetaldehyde, not sufficient 2,4-dinitrophenylhydrazone for purification and identification could be obtained. As in earlier experiments the aminoisobutyric acid was recovered almost quantitatively.

α-Amino-α-phenylbutyric Acid.—From the reaction mixture 1.4 mml. of propiophenone and a small amount of alanine were isolated. The bisulfite solution contained 0.6 mml. of carbonyl compounds, of which 0.05 mml. could be identified as acetaldehyde.

Cystine.—The bisulfite trap yielded 1 mol. of acetaldehyde. The formation of 11 mml. of carbon dioxide, an excess of 1 mml. over that expected in accordance with Scheme II, together with the formation of acetaldehyde, indicates partial reaction in the sense of Scheme I. No hydrogen sulfide was formed during the reaction; the only sulfur-containing material found was a black resin from which no definite compound could be isolated.

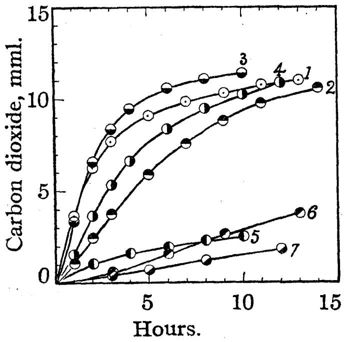

Fig. 2.—Rate of carbon dioxide evolution during the reaction of: 1, cystine with pyruvic acid; 2, S-ethylcysteine with pyruvic acid; 3, S-phenylcysteine with pyruvic acid; 4, S-benzylcysteine with pyruvic acid; 5, cystine with phenylpyruvic acid; 6, cystine with benzoylformic acid; 7, α-amino-*p*-methoxyphenylacetic acid with benzoylformic acid.

S-Ethylcysteine.—Acetaldehyde was found in the bisulfite trap together with a small amount of ethylthioglycolic aldehyde. Quantitative estimation of the aldehyde content of the trap was impossible because of secondary oxidations. Steam distillation of the reaction mixture yielded considerable quantities of an oil, the dimedon derivative (m. p. 93–94°) of which analyzed correctly as that of ethylthioglycolic aldehyde.

Anal. Calcd. for $C_{20}H_{30}O_4S$: C, 65.52; H, 8.26; S, 8.75. Found: C, 65.63; H, 8.17; S, 8.61.

Alanine was isolated in good yield. The odor of ethyl mercaptan was evident in the reaction mixture.

S-Phenylcysteine.—No aldehydic product, except acetaldehyde, of which there was 2.3 mml. in the bisulfite trap, could be found among the reaction products. Alanine was isolated in good yield. A large amount of brown oil, from which thiophenol and diphenyl disulfide were isolated, was formed during the reaction.

When the reaction was run with continuous distillation of the volatile products, instead of under reflux as was usually the case, phenylthioglycolic aldehyde was found in small amount in the distillate, and isolated as the dimedon derivative, m. p. 127–128°.

Anal. Calcd. for $C_{24}H_{30}O_4S$: C, 69.51; H, 7.30; S, 7.74. Found: C, 69.43; H, 7.34; S, 7.73.

In this case the reaction was run over a period of two to three hours, and the volume in the reaction flask was kept constant by the slow addition of water through a dropping funnel. A small amount of phenylthioglycolic aldehyde was prepared for purpose of comparison by boiling a solution of 5.5 g. of thiophenol with 7.6 g. of chloroacetal in absolute alcohol containing 1.15 g. of sodium for fifty hours, followed by hydrolysis with hydrochloric acid. The product, obtained in poor yields, was isolated as the dimedon derivative and proved to be identical with the substance obtained in the above reaction.

S-Benzylcysteine.—Acetaldehyde, 1.6 mml. by titration, was the only aldehydic product which could be isolated. Alanine was formed in good yield. A large amount of brown oil separated during the reaction, and upon careful examination yielded only a small quantity of benzyl mercaptan. By applying the technique of continuous distillation to this reaction it was possible to obtain a small amount of benzylthioglycolic aldehyde, dimedon derivative, m. p. 88–89°; and 2,4-dinitrophenylhydrazone, m. p. 156–157°.

Anal. Calcd. for $C_{25}H_{32}O_4S$: C, 70.04; H, 7.53; S, 7.49. Found: C, 70.23; H, 7.51; S, 7.69.

Anal. Calcd. for $C_{15}H_{14}N_4O_4S$: C, 51.99; H, 4.08; S, 9.26. Found: C, 51.98; H, 4.12; S, 9.28.[8]

Reaction with Phenylpyruvic Acid

Cystine.—During the reaction of cystine (2.5 mml.) with phenylpyruvic acid (10 mml.), 2.5 mml. of carbon dioxide was evolved in the course of ten hours (Fig. 2, Curve 5). The reaction was not continued over a longer period since phenylpyruvic acid gradually condenses with itself under the conditions of the experiment. No acetaldehyde nor other aldehydic products could be found among the products of the reaction. Some difficulty was encountered in separating the small amount of phenylalanine formed from traces of cystine. Analytically pure phenylalanine was obtained after decomposition of the cystine by boiling the amino acid mixture with a suspension of calcium hydroxide to which a few crystals of lead acetate had been added. After removal of the calcium and lead, phenylalanine separated upon concentrating the solution.

Reactions with Benzoylformic Acid

Usually 10 mml. of amino acid and 10 mml. of benzoylformic acid were employed in the reactions; in the case of cystine 5 mml. of the amino acid was employed. Except where specifically stated the duration of the reactions and yields of carbon dioxide are shown in Fig. 2.

Alanine.—After nine hours, only a trace of benzaldehyde (about 0.05 mml.) could be isolated, and the carbon

---

[8] Micro Dumas determinations on 2,4-dinitrophenylhydrazine or derivatives thereof are not reliable.

dioxide evolved was less than could be estimated (0.1–0.2 mml.).

α-Amino-*p*-methoxyphenylacetic Acid.—From the reaction mixture an aldehyde fraction consisting of benzaldehyde and anisaldehyde was isolated as a mixture of the 2,4-dinitrophenylhydrazones, m. p. 231–233°. The corresponding derivatives of benzaldehyde and anisaldehyde melt at 242–243° and 255°, respectively. The yield of hydrazones calculated as benzaldehyde was 0.5 mml. A methoxyl determination showed 3.5% OCH_3, indicating a mixture of 64% benzaldehyde and 36% anisaldehyde. The amino acid fraction (8.0 mml.) consisted chiefly of aminomethoxyphenylacetic acid (OCH_3, 15.64; N, 7.43).

Cystine.—No benzaldehyde nor hydrogen sulfide could be detected. From the reaction mixture about 0.5 mml. of α-aminophenylacetic acid was isolated after removal of the last traces of cystine by treatment with lime and lead acetate.

S-Ethylcysteine.—During twelve hours only 0.7 mml. of carbon dioxide was formed. From the bisulfite trap a small quantity of ethylthioglycolic aldehyde was isolated. Neither benzaldehyde nor acetaldehyde could be identified as reaction products.

Summary

The investigation of the reaction between α-amino acids and α-ketonic acids has been extended in such a manner as to demonstrate more clearly the mechanism involved. The first steps in the reaction appear to lead to the formation of a Schiff base with a carboxyl group on each of the carbon atoms adjacent to the central nitrogen atom. The double bond of the methyleneazomethine system has a tendency to shift (C—N=C $\longrightarrow$ C=N—C) with the simultaneous elimination of carbon dioxide from either carboxyl group, both processes being dependent upon the nature of the other carbon substituents. In the case of α-amino-α-phenylbutyric acid this tendency is so pronounced that it takes place in spite of the necessity of forcing the displacement of the carboxyl group. Two new Schiff bases are assumed to result. Of these, one hydrolyzes to give the original amino acid and the aldehyde formed by decarboxylation of the ketonic acid; the other decomposes to form a new amino acid, derived from the ketonic acid by amination and reduction, and the aldehyde resulting from the oxidative deamination and decarboxylation of the original amino acid.

Further Observations Concerning the Crystallization of Undercooled Liquids

BY WILLIAM T. RICHARDS, EDWARD C. KIRKPATRICK AND CARL E. HUTZ

Introduction

The belief that homogeneous crystallization[1] of metastable liquids could be described successfully in statistical terms originated with the Kinetic Theory of Heat. With the writings of de Coppet, Ostwald and Tammann, which are too well known to require summary here, this belief became increasingly articulate. Recently Volmer[2] and Stranski[3] have expressed it in terms of Fluctuation Theory, and theoretical aspects of homogeneous crystallization have now advanced as far as the imperfect state of the Kinetic Theory of Liquids permits. Experiment has failed to keep pace with this development. A few cases of homogeneous crystallization, notably those described by Tammann[4] in very viscous melts, where the linear crystallization velocity is extremely small, have been reported. In general, however, a considerable body of scattered experimental work has served only to confuse the issue by the introduction of heterogeneous effects. The mechanism of heterogeneous crystal nucleus formation presents, however, certain points of interest in its own right, although the language for its description is at present less unequivocal and aesthetic than that for homogeneous crystallization. When the immense practical importance of the problem of efficiently inducing crystallization in metastable liquids, affecting, as it does, most organic preparations and many technical processes, is recalled it will be clear that any investigation concerning crystallization which contributes to the present knowledge, however imperfectly its results may be formulated, deserves attention. The object of the present communication was initially to determine the homogeneous crystallization rates of a number of liquids. It was found necessary, however, to interpret the re-

---

(1) The term "homogeneous crystallization" will be used throughout to designate crystallization occurring in the free liquid, as opposed to "heterogeneous crystallization" which occurs at an interface.

(2) M. Volmer, *Z. Electrochem.*, **35**, 55 (1929).

(3) I. N. Stranski and R. Kaischew, *Z. physik. Chem.*, **B26**, 100, 317 (1934).

(4) G. Tammann, "Kristallisieren and Schmelzen," 1903.

sults in heterogeneous terms. This interpretation is incomplete in many respects but, since independent experiments from Germany have appeared during the progress of the investigation, it has been decided to report its present status, indicating in the discussion the directions in which future progress appears most probable. As an introduction a brief *résumé* of various heterogeneous effects which have been reported will be given. This review can, owing to the scattered and usually wholly independent investigations with which it deals, make no claim to completeness.

It was Tammann himself who first threw serious doubt upon the homogeneous mechanism, although he does not appear to have been willing to accept the full implications of his work. He reported that, with betol, quartz powder greatly increased the number of crystal nuclei and that powdered glass effectively prevented their formation.[5] Simultaneously Schaum reported that tubes of benzophenone showed a marked decrease in their tendency to crystallize with increasing number of meltings;[6] this phenomenon of "aging" will receive further attention below. Continuing his studies with Schoenbeck, Schaum then demonstrated that crystallization repeatedly occurred at the same spots, and that these spots could be deactivated with increased heating above the melting temperature.[6a] Similarly Jaffé showed that mechanical cleaning, such as intensive filtration, served to increase the range of temperature in which a solution could be maintained in a supersaturated condition,[7] and Füchtbauer extended these observations to undercooled liquids.[8] Both authors seem clearly to have recognized the heterogeneous character of the process of crystal nucleus formation, and Füchtbauer cites the effect of preheating noticed by Schaum and Schoenbeck, although apparently unconscious of earlier work on the subject. Young and Burke,[9] R. Marcelin,[10] Hinshelwood and Hartley[11] and Schaum and Riffert[12] independently not only of each other but of most previous work in the field, have described various aspects of the effect of preheating, and appear to agree that the crystallization center is situated on an interface of some sort. In apparent contradiction to this Orthmer[13] and Kornfeld[14] report a statistical distribution when the crystallization of a large number of samples was observed for long periods of time. Orthmer, however, admits the influence of foreign solids without attempting to account for it. It is believed that these various findings have been successfully explained by a communication from this Laboratory[15] in which it was demonstrated not only that the presence of overheatable nuclei was due to the presence of an interface but that, by the introduction of suitable solid adsorbents which had previously been infected with crystalline material, the number of crystal nuclei could be increased to almost any extent desired. A theory was given based upon the existence of two hypothetical modifications of the adsorbate which were called "crystalline"[16] and "liquid," respectively. Several consequences of the theory, especially its implication that crystal nuclei could be developed above the melting temperature, were confirmed experimentally. The subsequent publications of Biilmann and Klit[17] and Roginsky, Sena and Zeldowitsch[18] confirm this standpoint, and it does not at present appear to require modification.

Two questions remain unanswered by the work which has been summarized above. When the "crystalline adsorbate" has been destroyed by heating until all overheatable germs have disappeared, will crystallization take place in a homogeneous and consequently statistical manner? If not, is there a connection between the presence of adsorbents which contribute to the formation of overheatable germs and the process of crystallization, even when the overheatable germs themselves have been destroyed? It is believed that conclusive negative answers to both these questions may be inferred from the evidence presented below.

Experimental

The experiments were conducted with a large number of tubes, usually about a hundred, which were immersed si-

multaneously in a constant temperature bath. They were then photographed on successive single frames of a 16-mm. motion picture camera at intervals of four minutes. A telechron motor, fitted with appropriate gears and contacts, provided that the bath should be stirred for three minutes and fifty seconds; the stirring was then discontinued and the illumination switched on, and, after ten seconds in which the agitation of the bath subsided, the picture automatically taken. The cycle then began anew. The apparatus was capable of functioning continuously for weeks without failure. The thermostat was a Dewar flask of about 20-liters capacity, and the tubes were held in this by a black Bakelite rack perforated to receive 100 tubes, each of which contained about 10 cc. of undercooled liquid. The photographic negative revealed clearly the difference between crystallized and uncrystallized material although it did not generally permit the location of the point at which crystallization began. Several other pertinent objects such as a clock, written information concerning the nature and conditions of the determination, etc., were also photographed. Thus, in the relatively small compass of a few feet of film, a complete record of the performances of each tube in a determination could be secured. A detailed record of this character would have been essential if statistical crystallization had been found; actually visual observation often provided sufficient evidence more conveniently.

Experiments were carried out with four substances. Salol, of the U. S. P. grade, was studied without attempt at purification. Several sources provided different samples of salol, but, in spite of minor variations in the melting point, the behavior of the various samples was uniform. Benzophenone, which had been twice distilled *in vacuo* with as little ebullition as possible, was also employed. Benzene, initially of the reagent grade, was shaken successively with sulfuric acid, dilute sodium hydroxide and water. It was then twice distilled from phosphoric anhydride. Purified carbon tetrachloride was also used, but since it was found to crystallize in too narrow a temperature range to permit differentiation in the behavior of individual samples, experiments with this substance will not be reported. The tubes were of Pyrex glass, and were steamed out for five minutes each by a jet of live steam, and dried at 110° by blowing in clean compressed air. They were evacuated and sealed after being filled with liquid. Ordinary cleanliness was maintained during their filling, but especial precautions to exclude dust were taken only in one case, which will receive individual mention below.

In reporting the experimental findings two alternatives are possible, neither of which is wholly satisfactory. Either detailed accounts of each of the various experiments may be given, or the general conclusions from a group of experiments may alone be stated. The first method would fill an immense amount of space with virtually unreadable material and, since the results are clearly not reproducible in detail, the space would largely be wasted. The second suppresses the facts and places too much emphasis on the judgment of the experimenters; details of importance may thus be lost by oversight. It has been decided to adopt the second alternative and to state the results in a series of conclusions, for which the experimental basis will be sketched only briefly. The reader is cautioned that few of these conclusions are wholly without exception; none, however, have been stated which do not represent an overwhelming majority of cases. A few specific experiments, which are not easily generalized in this way, will then be cited.

1. All samples of salol, benzophenone and benzene could be crystallized by immersing in a slush of solid carbon dioxide and acetone, and returning slowly to room temperature. (It will be apparent in the discussion why this seemingly obvious statement is included.)

2. Ten per cent. of the salol and benzophenone samples and 50% of the benzene samples could be activated by low temperature crystallization to produce crystals at relatively small undercoolings. For example 8 of 94 tubes containing benzophenone could be undercooled at −17° for twenty-four hours, and would remain apparently indefinitely at room temperature, without crystallization. After crystallization in a carbon dioxide–acetone mixture they could be heated to 100° and yet would crystallize within twenty-four hours at room temperature. A temperature of 140° was, however, sufficient to destroy this activity. Similar behavior with salol and benzene was found. Activity of this kind was destroyed with benzene, however, at about 25°, and, when present, manifested itself by permitting only two or three degrees of undercooling. This type of behavior is believed to depend on the presence or destruction of a "crystalline adsorbate."[15]

3. Crystallizations were conducted at various temperatures with each substance to determine a convenient temperature for a large number of identical determinations. Such a temperature was low enough to ensure the crystallization of at least half the tubes within forty-eight hours, and yet not so low that 15% of the tubes crystallized in the first hour. This permitted the establishment of a definite order of crystallization in the case of each substance. The temperatures were: salol −5°, benzophenone −17°, benzene −4°.

4. Repeated crystallizations at these temperatures showed, in agreement with the result which led Hinshelwood and Hartley[11] to postulate a heterogeneous mechanism, that initially the rate of

crystallization was three to ten times that reached after a few hours. A fairly constant rate was sometimes established after the first burst of activity, but it is believed that this is without significance.

5. Each sample behaved in an extremely individual and surprisingly consistent manner. For example, some six of the first ten to crystallize were almost always the same. Some 20% of the total number never crystallized at the temperature specified in the last sentence of (3) and these were also consistently the same samples. Among the intermediate cases the order of crystallization was surprisingly consistent throughout. It is believed, therefore, that a heterogeneous mechanism is responsible for crystallization in all three liquids at these temperatures.

6. No correlation could be found between the ability to form overheatable nuclei, as described in (2), and outstanding rapidity of crystallization at low temperatures. The lack of correlation between the two types of crystallization was, indeed, so striking that no doubt can remain that a different mechanism is involved in the two cases.

A few additional experiments also should be reported.

In the hope of eliminating dust, fifty tubes containing benzophenone which had been filled *in vacuo* in a mammoth all-glass apparatus from twice vacuum-distilled benzophenone were studied. Their behavior differed in no important respect from those filled in the air without special precautions.

The effect of the addition of washed powdered glass and cleaned active charcoal to salol and to benzophenone was also studied. Powdered glass served slightly to increase the tendency to crystallize, and active charcoal very greatly increased it in both cases. It should be added that these substances were added to samples which showed total inability to crystallize under ordinary conditions.

One experiment with benzene also should be cited. After 30% of the samples had crystallized at $-4°$ all tubes were placed in a bath at $+17°$ for twelve hours. On re-immersion in the bath at $-4°$ all thirty of the previous tubes plus fourteen more (44% of the total 100) had crystallized within five minutes. This appears to indicate a slow formation on the adsorbent even above the melting temperature of a form of adsorbate favorable to crystallization.

Discussion

The experiments outlined above lead inescapably to the conclusion that crystallization from undercooled liquids proceeds commonly by a heterogeneous, not by a homogeneous, mechanism. Although only three substances have been studied, two represent the unusual liquid which permits great undercooling, and one the typical symmetrical compound which can be undercooled only a few degrees. There can be little question, therefore, of the generality of the results. As a consequence it is necessary to limit the applicability of any theory describing homogeneous crystallization to very viscous liquids in which the crystal growth velocity is small enough to permit the spontaneous formation of a large number of nuclei before a few of them have grown to sizes which are comparable with the total volume of liquid. It is necessary furthermore to suppose that the "nucleation numbers" found by Tammann, which for thirty years have formed the ground-work for discussion of the subject, are not natural constants but represent only the properties of the particular combination of interfaces which happened to constitute the system which he was observing. Finally, it is indicated inescapably that investigations like the present one, where the crystallization of a large number of tubes is studied as a function of time in the hope of establishing a significant crystallization rate at a given temperature, do not give results which characterize the liquid.

It is, indeed, a questionable matter whether a liquid composed of highly unsymmetrical molecules unconfined by solid surfaces would be capable of forming the solid phase by thermal fluctuations within a reasonable time. In this connection a recent series of papers by Meyer and Pfaff[19] which greatly extend the work of Jaffé and Füchtbauer cannot receive too great attention. These investigators have shown that, by employing sintered glass filters passing particles of 1.5 μ or less, water which may be undercooled 33°, and benzophenone and salol which may be vitrified and returned to room temperature without crystallization, may be obtained. It is the stated belief of these writers that crystallization ordinarily occurs on minute dust particles of unspecified composition, and that removal of the dust precludes the possibility of crystallization.

---

(19) J. Meyer and W. Pfaff, *Z. anorg. allgem. Chem.*, **217**, 257 (1934); **222**, 382 (1935); **224**, 305 (1935). A recent paper on water by G. Tammann and A. Büchner, *ibid.*, **222**, 371 (1935), expresses agreement with this standpoint.

To this point of view the investigation reported above contributes the following additional facts. The crystallization centers vary greatly in activity. They are so few in number that two 10-cc. portions of a liquid poured into separate tubes, with an effort to have all conditions identical may comport themselves wholly differently. This is doubtless also the reason for the aging effects so often described. The low-temperature crystallization centers bear no direct relation to the type of adsorption which permits the formation of overheatable nuclei, although carbon appears to be active in both respects. Finally, it is necessary to suppose that the walls themselves can assist in the formation of crystal centers, since dust-free benzophenone, obtained by distillation *in vacuo,* showed no more uniformity than that prepared without special precautions. It should be mentioned in this connection that Meyer and his associates, who were especially concerned with obtaining great undercooling, flamed their glassware intensively before introducing the liquid, whereas we merely cleaned it as described above. This may be the reason why they found no nuclei due to the presence of the containing vessel.

Attempts to account for this behavior must at present be disagreeably speculative. The crystallization centers are so small and so few in number that they defy direct study. It is natural to speak of oriented adsorption of liquid molecules at the interface, but to do so is little more than to give a resounding name to ignorance. The picture outlined in this paragraph is therefore presented in the most humble and tentative spirit, and is included merely to show that one type of adsorptive force is sufficient to account both for the retention of the "crystalline adsorbate" and for the apparently wholly unrelated activity in forming the crystallization centers at low temperatures. Let us consider a wedge-shaped crevice on the surface of the adsorbent. The adsorption forces will be strongest at the bottom of this crevice and become progressively weaker as the surface is approached, as Polanyi[20] and others have shown. Let us further suppose that the adsorbate molecules are oriented in the crevice in much the same way that fatty acid molecules are oriented by glass;[21] this assumption can scarcely meet with objection. Finally let us assume, entirely *ad hoc,* that this orientation causes the adsorbate to resemble the crystal increasingly as the orientation increases; let us suppose, in other words, that the orientation provides the greater part of the surface work, work necessary for the destruction of molecular aggregates, etc., which together may be called the "activation energy of crystallization."[22] Now the conditions are such, in the type of investigation reported above, that the entire liquid will crystallize from a single nucleus in a time much shorter than that necessary for the nucleus to become active. The portion of the adsorbate which most rapidly can project crystals into the free liquid will then cause the crystallization of the entire liquid. The lower the temperature, in the range with which we are at present concerned, the greater the instability of the undercooled liquid and the less the orientation of the adsorbate necessary to produce crystallization. But it already has been inferred from experimental evidence that the rate of rearrangement in the adsorption space is extremely slow.[15] In terms of the present over-simplified picture this involves the rearrangement of molecules bound by powerful adsorptive forces in a crevice of molecular dimensions. It is in all probability, however, exactly these molecules which form the overheatable nuclei. This may be inferred both from the high temperatures necessary to destroy them, and from the fact that weeks must sometimes elapse before they manifest their presence. If all this is granted as plausible, it is not surprising that the strongly bound molecules cannot project crystals into the free liquid with the rapidity of their more loosely bound neighbors, even though the energy conditions may favor them.

The course for future investigations is clear. There is little to be gained at present in multiplying experiments of the type which are here recorded. Rather, a detailed study should be made of the various surfaces which most effectively contribute to the formation of crystallization centers. This should embrace not only a wide variety of substances, but also as great variations in surface configuration and particle size as possible. The information so accumulated should, on the one hand, permit the elimination of heterogeneous effects in crystallization and, on the other, contribute vitally to the important practical problem of securing the crystallization of difficultly crystallizable liquids.

Summary

It has been shown that salol, benzophenone and benzene crystallize spontaneously by a heterogeneous mechanism even in the absence of overheatable nuclei. The tendency to form overheatable nuclei and the spontaneous tendency to crystallize, appear to be entirely unrelated, since the former may be destroyed by heating without affecting the latter. A tentative mechanism is suggested whereby one type of absorptive force might result in both forms of activity. The study has been related to previous investigations on the subject.

Phase Equilibrium Relationships in the Binary System, Sodium Oxide–Boric Oxide, with Some Measurements of the Optical Properties of the Glasses

By G. W. Morey and H. E. Merwin

The literature contains a number of observations on some of the compounds in the system, $Na_2O–B_2O_3$, which will be referred to in connection with those compounds, but there has been no systematic study of the system as a whole, except that by Ponomareff,[1] the results of which are as near correct as would be expected from his experimental method.

Most of the information relating to the phase equilibrium relations in the system was obtained by the usual quenching method. In this method a small sample of the material, usually in the form either of a homogeneous glass, or the product obtained by crystallizing such a glass, is held at constant temperature long enough for equilibrium to be attained, then cooled quickly enough to freeze that equilibrium. The quenched charge is then examined with the petrographic microscope. If it originally contained crystals and has become all glass, the temperature of heat treatment was above the liquidus; if both crystals and glass, below the liquidus. The crystals may be positively identified by their optical properties, and thus assurance given as to the crystalline phase present. The quenching method is preferred by experienced workers whenever it can be applied, but in some cases crystallization takes place so rapidly that the melt cannot be quenched. In such cases recourse must be had to the method of heating curves, and it was necessary to study the metaborate in this manner. The heating-curve method can give good results with sodium diborate, when the necessary care is exercised, as was shown by Day and Allen;[2] and it has been applied by the present authors to sodium tetraborate with satisfactory results. With intermediate mixtures, however, the heating-curve method is of doubtful assistance.

Preparation and Analysis of Materials

The raw materials used were sodium carbonate, borax ($Na_2O{\cdot}2B_2O_3{\cdot}10H_2O$) and boric acid ($H_3BO_3$). The sodium carbonate was from a specially purified stock which contained less than 0.009% $Fe_2O_3 + Al_2O_3$. The borax and boric acid were from several sources, but were purified by recrystallization before using. The mixtures were made by adding sodium carbonate or boric oxide to fused $Na_2O{\cdot}2B_2O_3$, with careful mixing, and the composition was usually known from the synthesis having been carried on under controlled conditions.

The composition of some of the mixtures was established by analysis, using a novel method. It was found that when a mixture of $Na_2O + B_2O_3$ containing an excess of boric oxide over the ratio of 1:1 was evaporated on the steam-bath with hydrofluoric acid, it was changed quantitatively to sodium borofluoride, $NaBF_4$. The properties of this compound will be discussed by us in another place. For our present purpose, it is sufficient to say that it can be dried to constant weight at 110°, and that numerous checks made by converting it to sodium sulfate established its constancy of composition. It melts, with some decomposition, at 373°. The original weight can be restored by adding a little boric acid and again evaporating with hydrofluoric acid. For example, a sample of borax, prepared by recrystallization of a commercial preparation and dehydra-

---

(1) J. F. Ponomareff, *Z. anorg. allgem. Chem.*, **89**, 383 (1924); *J. Soc. Glass Techn.*, **11**, 39 (1927). The second reference apparently represents no new experimental work, contains several errors, *e. g.*, p. 43, where the compound $Na_2O{\cdot}7B_2O_3$ is claimed, probably a misprint for $Na_2O{\cdot}4B_2O_3$, and without justification claims the crystallization of B_2O_3, reproducing in support a picture of a crystal given in the earlier paper as $Na_2O{\cdot}4B_2O_3$.

TABLE I[a]

THE CHANGE OF BETA-SODIUM DIBORATE TO ALPHA-SODIUM DIBORATE

Run	Temp., °C.	Time	Results; remarks	Run	Temp., °C.	Time	Results; remarks
Original material beta-sodium diborate				Original material a mixture of alpha- and beta-sodium diborate			
1	720	40 m	Changed to alpha				
2	660	20 m	Changed to alpha				
3	640	20 m	Changed to alpha, but still cloudy				
4	600	20 m	Cloudy; partly changed to alpha				
7	580	30 m	Traces of beta remain				
6	590	30 m	Much beta remains				
5	575	30 m	Mostly beta; trace of alpha	8	575	36 hr	All alpha
12	525	6 da	All changed to alpha	9	525	16 hr	All alpha
				10	510	48 hr	Practically all alpha
16	500	7 da	Unaltered beta; no alpha	16	500	7 da	Trace of beta remains, but has different look. Indices seem to be lowered somewhat
14	475	9 da	Unaltered beta; no alpha	11	475	16 hr	Beta is partly changed to alpha
				15	450	3 da	All grains of beta seem to have remained beta, but many of them have a different appearance from the original beta. Transformation may have begun.
13	360	5 da	Remains beta				

[a] We are indebted to our colleague, Dr. Earl Ingerson, for carrying out these experiments.

tion, gave 30.77% Na_2O by the method of evaporation with hydrofluoric acid, to be compared with the theoretical value of 30.78%. A mixture made up by controlled synthesis, with a composition calculated to be 27.91% Na_2O, gave 27.88% by the method using hydrofluoric acid. Another mixture gave 29.80% Na_2O when decomposed by hydrofluoric acid and sulfuric acid, when the Na_2O was weighed as Na_2SO_4, and 29.82% when the Na_2O was weighed as $NaBF_4$.

Temperature measurements were made with platinum *vs.* platinum + 10% rhodium thermocouples, with the cold junction in ice. Electromotive forces were measured on a White potentiometer. The thermocouples were calibrated at the following points: zinc,[3] melting point 419.4°; NaCl,[4] melting point, 800.4°; gold,[3] melting point, 1062.6°, and used with a deviation curve, as described by Adams.[3]

Properties of the Compounds

The hygroscopicity, and the existence of more than one form, of some of the compounds has caused confusion as to the identity of the material on which some of the physical properties recorded in the literature have been determined. Because of this uncertainty we have made no comments on the discrepancy between the optical properties observed by us and by others. For the same reason we have not attempted to verify the x-ray patterns given by Cole, Scholes and Amberg,[5] or by Menzel.[6]

1. Sodium Orthoborate, $2Na_2O{\cdot}B_2O_3$.—This is the only new compound found in the present study. It is easily obtained by fusing borax with sodium hydroxide or sodium carbonate in the theoretical proportions. It is remarkable for its low melting point, 625°, and the fact that in small quantities it can be obtained as glass. The system Na_2O–B_2O_3 is thus in marked contrast to the system Na_2O–SiO_2,[7] in which the (incongruent) melting point of the ortho-compound is higher than that of the meta-compound, and the tendency toward crystallization increases regularly with content of Na_2O. Sodium orthoborate is very hygroscopic, and attacks the index liquid. It is biaxial, positive: $\gamma = 1.55_0$, $\beta = 1.52_0$, $\alpha = 1.50_0$.

The eutectic between sodium orthoborate and sodium metaborate is close to the composition of the orthoborate, but its exact composition was not determined. The liquids in this composition region contain about 1% carbon dioxide, but in spite of this the orthoborate melted fairly sharply, with the first sign of sintering not more than 5° below the melting point. Mixtures intermediate between the ortho- and metaborates yield thin liquids which crystallize readily, and the presence of a small amount of metaborate makes it impossible to cool the melt to yield a glass. No liquidus

determinations were made in this region, which is not indicated in Fig. 1.

2. **Sodium Metaborate,** $Na_2O·B_2O_3$.—A melting point for this composition was approximately determined by Burgess and Holt[8] as 930°. Van Klooster[9] found for the compound 966°, a value confirmed by Cole, Scholes and Amberg[5] (965 ±2°), and by us (966°). It crystallizes too readily to be obtained as glass. It is uniaxial, negative, $\omega = 1.568$, $\epsilon = 1.457$. It is very hygroscopic, and it slowly attacked the immersion liquid used for refractive index determination.

3. **Sodium Diborate,** $Na_2O·2B_2O_3$, **α-Form.**—This is the well-known "dehydrated borax," whose melting point was determined to be 742° by Day and Allen.[2] Other investigators have reported lower melting points. Ponomareff[1] found 732°, Cole, Taylor and Scholes,[5] 735 ± 5°, Menzel,[6] 738°. Burgess and Holt[8] found roughly 791°, but considered that this was not a true compound, but a eutectic mixture. This higher melting point is difficult to explain, but the lower ones are accounted for by the ease with which the compound takes up water from moist air. This is illustrated by the following observations, made to determine the suitability of the compound for the standardization of thermocouples.

A sample of borax was purified by recrystallization, dehydrated carefully, melted and crystallized, and the melting point of this product determined by the quenching method. It was found to melt sharply; at 741° it was not sintered, at 742° there was a very little sintering, while at 742.7° it was completely melted. The melting point is inferred to be 742.5°. The sample was then left in a screw-topped vial over the summer, when it showed a melting point of 736°. On remelting a part of the stock and recrystallizing, a melting point of 741.2° was obtained. A study of the rate of drying of some of the stock exposed over the summer showed a loss, from 10 g., at 115°, of 26 mg. in three hours, followed by 1.3 mg. in eighteen hours; subsequent heating at 300° gave an initial loss of 32.5 mg., in twenty-four hours, but on further heating the sample gained 2.1 mg. in weight. This was during a period of very humid weather, and it was found that during such weather not only would the crystalline material take up water at 300°, but the melt itself would take up water. For example, a 10-g. crystalline sample, dried at 700° (at which temperature the whole of the water was lost), on melting increased in weight 5.6 mg. The melt had been cooled quickly, so that it remained glassy; on heating to just below the melting point until it crystallized, a matter of about two hours, the crucible had returned to within 0.3 mg. of the previous weight. Quenching experiments gave a liquidus only slightly lower than the original material. There was some formation of glass at 736°, indicating a small range of melting. It is evident that during humid weather crystalline anhydrous sodium diborate will take up enough water to lower its melting point appreciably; that some water is taken up even at 300°; that the water can be entirely driven off from the crystalline compound at 700°; and that the just molten glass can take up some water. It is not a favorable material for the standardization of thermocouples.

Another sample of 4 g. on heating at 700° showed, in eighteen hours, a loss of 2.4 mg.; further twelve hours, no change in weight; twenty-two hours, loss of 0.5 mg. It is evident that the rate of evaporation from molten borax near its melting point is small. At 1200° in twenty-two hours the same sample lost 0.7215 g.; further heating for twenty hours showed a loss of 0.5235 g. The total loss was 1.2479 g., and analysis showed the composition to be 25.30% Na_2O. The original pure diborate contained 30.81% Na_2O, hence this indicates that more sodium oxide than boric oxide had evaporated, and calculation shows the average composition of the vapor to be 43% Na_2O. Experience has shown that while boric oxide passes into the vapor phase readily in the presence of water, anhydrous boric oxide, which can be obtained from the hydrous crystals only by prolonged heating at temperatures above 1200°, is not especially volatile even at 1200°.

The above discussion has referred to the form of crystalline sodium diborate ordinarily obtained, which should be called α-sodium diborate. The granular crystals have two or more good cleavages, and are biaxial, positive, $\alpha = 1.471$, $\beta = 1.493$, $\gamma = 1.528$.

Another form of crystalline sodium diborate is sometimes obtained when a borax glass is crystallized. We have obtained it in pure form only once, and it has occasionally been observed mixed with the α-form. That it is probably monotropic

is shown by the experiments of Table I. Above 600° it changes to the α-form in twenty minutes. At lower temperatures the change is slower, but is accelerated by the presence of the α-form. At low temperatures the change is very slow, or does not take place within a few days, but in no case was the transformation from the α-form to the β-form observed.

TABLE II

EXPERIMENTAL RESULTS IN THE SYSTEM Na_2O–B_2O_3

Weight fraction Na_2O	Weight fraction B_2O_3	Liquidus temp., °C.	Solid phases

[a] The weight fraction B_2O_3 in parentheses indicates that the Na_2O was determined by analysis, B_2O_3 by difference. The other compositions represent controlled syntheses.

[b] Determined by heating-curve method.

A careful search for an enantiotropic inversion was made from below 500° to the melting point, using a differential thermocouple and a neutral body. No indication of an inversion was obtained.

Beta-sodium diborate forms granular crystals, $\alpha = 1.50$, $\beta = 1.52$–3, $\gamma = 1.555$.

A third form of sodium diborate, γ-, was obtained under conditions which cannot be specified precisely. A stock of the crystalline material was prepared as usual by recrystallizing commercial borax, dehydrating, melting and crystallizing. This was to be used in making some other mixtures; and because the weather at the time was humid it was kept in a covered beaker on a hot plate, at about 300°. Some of this material was left for two and a half years, after which it was found to have the following optical properties: positive, with large axial angle, $\alpha = 1.526$, $\beta = 1.544$, $\gamma = 1.576$. It has one fair cleavage.

Analysis gave 30.84% Na_2O, which indicates that the composition had not changed. On heating at 700° for fifteen minutes the material was unaltered; but in four hours it contained both the α-form and unaltered material. Heated for fifteen minutes at 725° it was entirely changed to the ordinary form. In both cases in which alteration was observed there were indications that fusion had preceded recrystallization. Since the material remained largely in discrete grains, the fusion was probably local with immediate crystallization.

In one experiment sodium metaborate crystallized from a melt of the composition of sodium diborate.[10] There was, of course, much glass, but no other crystals. An attempt to determine the metastable liquidus of sodium metaborate at this composition failed, because of formation of sodium diborate.

4. Sodium Triborate, $Na_2O\cdot 3B_2O_3$.—Ponomareff gave 694° for the melting point of this compound, while Cole, Taylor and Scholes found 720 ± 5°. We have found that it has an incongruent melting point at 766°, decomposing at that temperature into crystals of sodium tetraborate and a liquid containing 76% B_2O_3. It is biaxial, negative, $\alpha = 1.453$, $\beta = 1.525$, $\gamma = 1.551$.

5. Sodium Tetraborate, $Na_2O\cdot 4B_2O_3$.—This compound was first obtained by Le Chatelier.[11] Burgess and Holt gave for it a melting point of 858°, and Cole, Taylor and Scholes gave 810 ± 5°; our determination is 816 ± 0.5°. The form which separates from the melt at high temperatures is biaxial, positive, $\alpha = 1.499$, $\beta = 1.525$, $\gamma = 1.582$. This same compound was usually obtained on crystallizing all mixtures containing

---

(10) H. Menzel, *Z. anorg. allgem. Chem.*, **224**, 1 (1935), claimed to have obtained two new allotropic forms of sodium diborate, which melted at 710 and 663°, respectively. One of these may have been the above β-sodium diborate, the other, sodium metaborate, but the information as to their properties is so meager that identification is not possible.

(11) H. Le Chatelier, *Bull. soc. chim.*, **21**, 34 (1899).

up to 99% B_2O_3; but in some cases a second form was obtained, which crystallized in thin blades, $\alpha = 1.52$, $\beta = 1.54$, $\gamma = 1.56$. It was at first thought that this might be a higher borate, but when a mixture containing 98% B_2O_3 was held for ten months at a little below 300°, boric oxide evaporated, leaving crystals which had these properties, together with a little glass. Analysis gave 14% Na_2O, 86% B_2O_3, near the composition of the tetraborate. On heating for two hours at 630° the crystals were unaltered, but the glass was more evident; at 685° the crystals were about one-half altered to the high-temperature form of the tetraborate; while in thirty minutes at 770° it was more than three-quarters glass, and the crystals were all the high form of the tetraborate. The most probable conclusion is that these two crystals are an allotropic form of the tetraborate. Thus the form appearing at low temperatures is either monotropic, or it is enantiotropic, with a slow rate of inversion.

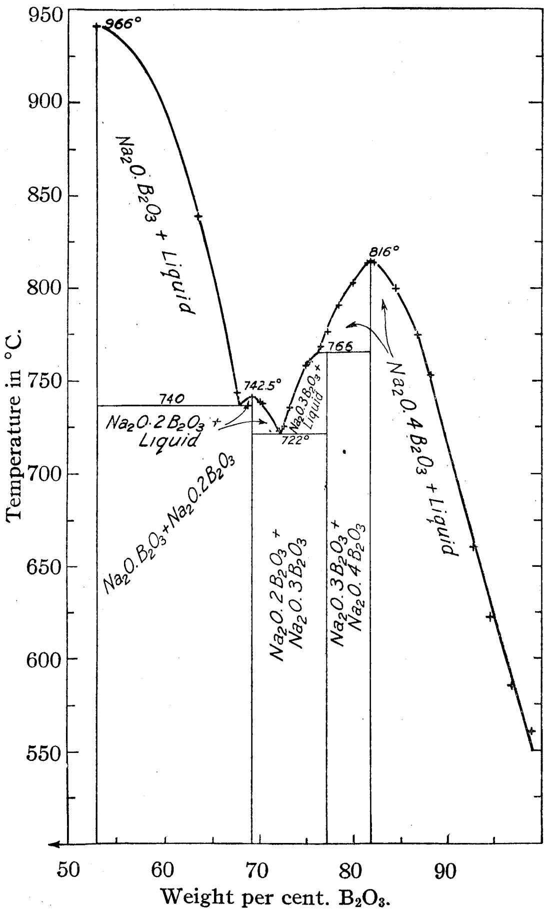

Fig. 1.—Phase equilibrium relations in the binary system, Na_2O–B_2O_3.

A careful search for an enantiotropic inversion was made from below 500° to the melting point, using a differential thermocouple and a neutral body. No indication of an inversion was obtained.

The Phase Equilibrium Diagram

The phase equilibrium relations between the various crystalline compounds and liquids are shown in Fig. 1, and the experimental results on which that figure is based are assembled in Table II.

The lowest melting compound is the orthoborate, and the eutectic between it and metaborate is close to the composition of the orthoborate. The liquid in this part of the diagram contains about 1% of carbon dioxide, but in spite of this the orthoborate melted fairly sharply, with the first sign of sintering not more than 5° below the melting point, so that its melting point is fairly accurate. Mixtures intermediate between ortho- and metaborate yield thin liquids which crystallize readily, and the presence of but a small amount of metaborate makes it impossible to cool the melt to form a glass.

The metaborate, $Na_2O \cdot B_2O_3$, has the highest melting point of any of the compounds, and it crystallizes so readily that it is not possible to obtain it as glass. The eutectic between it and sodium diborate is at 740° 68 weight per cent. B_2O_3. The melting point then rises to that of sodium diborate, 742.5°; then falls to the eutectic between diborate and triborate, at 722°, 72.3% B_2O_3. Sodium triborate melts incongruently at 766°, giving crystals of sodium tetraborate, $Na_2O \cdot 4B_2O_3$, and a liquid containing 76% B_2O_3. From this incongruent melting point the liquidus rises to the melting point of the tetraborate, at 816°. This compound remains the primary phase up to 99% B_2O_3, but below 700° a second sort of crystals, probably of the same composition, sometimes appears. In all the mixtures whose liquidus temperatures were determined, however, the crystalline phase which was present was the high-temperature form.

The phase equilibrium diagram shows the melting point curve of sodium tetraborate extending to within about 1% of the B_2O_3 side. Whether or not the lower part of this curve is metastable cannot be stated because boric oxide has not been crystallized from these melts. If the above curve is not metastable and the melting point of boric oxide and the eutectic between $Na_2O{\cdot}4B_2O_3$ and B_2O_3 lies at a temperature considerably lower than 500°, then the melting point curve must be nearly vertical at the eutectic. This is to be expected from thermodynamic considerations. As the liquid phase approaches one of the components in composition, while the crystalline phase contains a finite amount of the other component, the slope of the T–X curve must approach infinity.

All our attempts to crystallize boric oxide have failed. They include long heating of the anhydrous material at many temperatures. In one series of experiments, boric oxide glass was heated from a month to six weeks at a series of temperatures differing not more than 10°, and covering the range from 700 to 200°. In other experiments boric oxide glass was heated on a hot-plate, whose temperature ranged from 260 to 285°, for a year and a half. The material was in a covered crucible, and this in turn was in a covered glass dish. Under these conditions the glass took up some water during the humid summer months but no indication of crystallization was observed. It is elsewhere mentioned that under the same conditions a glass rich in boric oxide lost enough of this component to attain practically the composition of the crystalline tetraborate. It is probable that this loss in boric oxide was caused by the presence of moisture in the atmosphere. A glass containing 99% B_2O_3 grew beautifully formed crystals of $Na_2O{\cdot}4B_2O_3$ in three months at 525°; and, when heated for a year at a little below 300° in a sealed tube, crystals of the low-temperature form of $Na_2O{\cdot}4B_2O_3$ were formed. If these heatings had been below the melting point of boric oxide, certainly it might have been expected to crystallize, especially since the tetraborate did grow.

Other experiments include attempts to condense it from the vapor phase. In all work with anhydrous boric oxide emphasis must be placed on its extremely hygroscopic character. In making microscopical examination of the various products the material is usually crushed to a powder in an oil. In determining the properties of anhydrous boric oxide it is necessary to take the most extreme precautions to prevent the contamination by water, and that such contamination had not taken place should be proved. It was found that molecular distillation methods in which proper precautions were taken to exclude moisture gave only glassy boric oxide.

Other methods were tried. One was a prolonged pounding in a heated mortar, with exclusion of air, but this was a failure. Temperatures ranged from 80 to 250°, and at the highest temperature the glass was pounded into a cake, almost clear glass. Attempts were made to find "mineralizers" other than water. These included toluene, which was boiled for six weeks with the anhydrous glass, under a reflux condenser, provided with a guard tube, without result except for a slight film of boric acid. Other organic solvents were tried in bombs, usually at 200°, but no crystalline boric oxide could be found.

These experiments overlapped the temperature range in which Taylor and Cole believed they had crystallized boric oxide. The procedure described by them was tried several times, but crystalline boric oxide was not obtained. In our opinion, the crystallization of boric oxide is yet to be proved.

Refractive Dispersions of Glasses

The only Na_2O–B_2O_3 glasses for which refractive dispersions (C, D, F) are recorded[12] are B_2O_3 and $Na_2O{\cdot}2B_2O_3$. Three sets of these dispersions are fairly close to ones we have made. Errors of copying seem to appear in the other two, but values for n_D seem unaffected: for B_2O_3 1.463 +, and for "borax glass" 1.515+. Corresponding densities are 1.850 + and 2.370. The density of boric oxide glass is greatly affected by annealing.[13]

[13] Arnold Cousen and W. E. S. Turner [*J. Soc. Glass Tech.*, **12**, 169 (1928)] found for chilled droplets <1.81, which was raised to >1.84 by annealing. Very recent work by P. Wulff and S. K. Majumdar [*Z. physik. Chem.*, **31B**, 319 (1936)] records a range of 1.778–1.838 for d, and 1.4502–1.4633 for n_D. Further study is required to show the effect of annealing and of small content of water on the specific refraction.

The measurements of Table III were made on prisms, from a few grams of glass cooled in air from fusion. The boric oxide prisms were protected from filming by oil and cover glasses.

Summary

A study of the phase equilibrium relationships in the system Na_2O–B_2O_3 has shown the existence of the compounds: sodium orthoborate, $2Na_2O \cdot B_2O_3$, with a congruent melting point at 625°; sodium metaborate, $Na_2O \cdot B_2O_3$, with a congruent melting point at 966°; sodium diborate, $Na_2O \cdot 2B_2O_3$, with a congruent melting point at 742°; sodium triborate, $Na_2O \cdot 3B_2O_3$, with an incongruent melting point at 766°, 76 weight per cent. B_2O_3; and sodium tetraborate, $Na_2O \cdot 4B_2O_3$, with a congruent melting point at 816°. The orthoborate, which is a newly discovered compound, can be cooled to a glass, as can mixtures containing more boric oxide than the diborate. The metaborate and compositions near it crystallize too readily to be quenched to a glass. In addition to the forms stable at the liquidus, sodium diborate may occur in two, and the tetraborate in one, additional form which are probably monotropic. Attempts to prepare crystalline boric oxide were not successful, and doubt is expressed as to previous claims to its crystallization. Refractive dispersions were measured for boric oxide, sodium tetraborate and sodium diborate glasses.

Heat Content and Heat Capacity of Aqueous Sodium Chloride Solutions

BY T. F. YOUNG AND J. S. MACHIN

Computations of activity coefficients from cryoscopic and thermal data have been greatly limited by a lack of adequate measurements.[1] This investigation was undertaken primarily to supply the heats of dilution required for a reliable determination of relative activities of sodium chloride in aqueous solutions. Because electromotive force methods[2,3] have been employed extensively in thermodynamic investigations of that electrolyte, sodium chloride is especially suitable for a critical comparison of the cryoscopic and electrical methods of evaluating activity coefficients.

The calorimetric data presented are of further interest because they furnish information concerning the variation with composition of apparent and partial molal heat capacities, and consequently have an important bearing upon the validity of the Debye–Hückel theory.[4]

The advantages of the chord-area method for the precise evaluation of partial molal properties from heats of dilution have been discussed by Young and Vogel.[5] The procedure they employed depends upon the determination of the derivative, S, of the apparent molal heat content with respect to the square root of the molality, m. Each heat of dilution experiment furnishes one average value of S which may be represented on a derivative plot by the ordinate of a horizontal line (called a "chord") extending between limits representing the initial and final values of $\sqrt{m}$, *i. e.*, $\sqrt{m_1}$ and $\sqrt{m_2}$. A special procedure was suggested by Young and Vogel[5] (p. 3037) to facilitate the drawing of a derivative curve so as to balance appropriate areas accurately. That procedure depends upon the drawing of a preliminary S curve, and the evaluation (by successive approximations, if necessary) of S', the first derivative, and S'', the second derivative of S. The final S curve is drawn in accordance with a series of points which have been plotted a distance, $P_i - \overline{P}_i$, above the center of each chord, computed from the equation

$$P_i - \overline{P}_i = -S'' (\Delta\sqrt{m})^2/24 \qquad (1)$$

where P_i represents the ordinate of a point on the derivative curve above the center of the ith chord, and $\overline{P}_i$ is the ordinate of the chord. For an application of this method it was desirable to produce chords so short that the uncertainties in values of $P - \overline{P}$ would not be large in comparison with the probable errors in the experimentally determined values of $\overline{P}$. For experiments with concentrated solutions, a dilution vessel having a volume about 0.03 that of the final diluted solution was used; for experiments with relatively dilute solutions, a larger vessel having a volume about 0.085 that of the final diluted solution was employed.

Experimental Procedure

The apparatus and procedures were similar to those described by Young and Vogel. The more important changes are described below.

Instead of the thin glass containers used in the earlier work, two silver capsules were employed. The smaller one, of about 25-cc. capacity, was used for the dilution of the more concentrated solutions. It consisted of a pure silver tube which could be closed with two spun silver caps, each provided with two small tabs for the attachment of wires. The tube was supported by a glass rod to which it was held by clamps and screws of pure silver. The larger vessel, of about 75-cc. capacity, was constructed of silver sheet and "silver solder" (largely copper and silver). Its cross section was a flattened ellipse. Rounded shoulders at the top and bottom terminated in vertical necks whose cross sections were similar in shape to, but smaller than, that of the body of the vessel. These were closed by soldered silver caps, to which wires were attached. After each experiment with this capsule the residual solution was tested with ammonium sulfide. No trace of copper was ever detected.

The covers were sealed to the body of the capsules with paraffin. For work at low temperatures the paraffin was covered with petroleum jelly to prevent leaks through small cracks produced in the paraffin. A gentle pull on a rod projecting through the calorimeter cover and attached by wires to the caps, detached first one and then the other. When blank experiments (*i. e.*, experiments with water both inside and outside the capsules) were made, no heats of opening were perceptible. To avoid errors due to lagging of the temperature of the contents of the dilution vessel, the caps were not removed for a dilution experiment until the temperature variation within the calorimeter had been reduced to less than 0.03 microvolt per minute.

The calorimeter was equipped with three tantalum propellers mounted on a single shaft. The submerged portion of the shaft was a tantalum tube on which the propellers were mounted. It was cemented to an upper portion made of glass tubing. A small synchronous motor geared directly to the stirrer rotated it at 450 revolutions per minute.

The calorimeter heater was similar to that used by Young and Vogel. Its flattened case was of platinum sealed with gold. Its leads were encased in a long thin tube of platinum-iridium, which projected through one of the openings of the calorimeter top. The tube extended to the bottom of the calorimeter where it terminated in a short U-shaped portion sealed to the bottom of the vertical case. The heater current was controlled by a semi-automatic set of switches. A manually operated switch caused the seconds pendulum of a weight driven clock, upon its next passage through a pool of mercury, to actuate an automatic switch which closed the heater circuit. Another manual switch was then closed to provide a by-pass for the current while two of the three leads to the automatic switch were interchanged. After a selected interval the pendulum, operating the automatic switch as before, opened the circuit.

Following each dilution there were usually two heating periods of three minutes each, from which the heat required for a temperature change of one microvolt was determined. The average deviation of 104 measurements from 52 respective means is 0.024%.

For work near 12.5° the thermostat was cooled by water pumped from an ice-water mixture through the copper coils immersed in the thermostat fluid (either water or an alcohol-water mixture), and returned to the source. For the measurements near 0°, brine was pumped through the coils. Temperature regulation was maintained by electrical heating and a large mercury regulator.

Materials.—The objectives of this investigation require a knowledge of the variation of the derivative, S, with temperature. It was desirable, therefore, to determine S at each of the three temperatures for solutions of as nearly the same composition as possible. Consequently, large quantities of the solutions were prepared and in general, two dilutions of each were made at each temperature. (An accident caused the omission of one duplicate at 25°.) Since the ratio of the volume of the solution in the calorimeter to the volume of the diluting water varied slightly, the centers of the chords derived from each stock solution were not quite the same. Corrections for these differences were computed and applied, as described below, but were extremely small. In some ranges of composition, analytical errors may introduce large errors into the chords[5] (p. 3036). In general, the use of the same solutions at all three temperatures reduced the effects of such errors upon the determinations of the variations of S with temperature, since partial cancellation ensued.

All solutions were prepared from distilled water and C. P. sodium chloride. All but the two most dilute were analyzed by the residue method of Richards and Hall.[6] Those two were prepared by weight dilution from more concentrated solutions. The quantities of solution (usually about 0.8 liter) and water introduced into the calorimeter were determined with weight burets.

Results

The experimental data are in Table I: $\Delta\phi H$ represents the heat absorbed in fifteen degree calories per gram formula weight of sodium chloride, t is the temperature of the solution and diluting water just before mixing; and $\sqrt{m_1}$ and $\sqrt{m_2}$ are the square roots of the initial and final molalities, respectively. The numbers of significant figures in the $\sqrt{m}$ columns were determined by the necessity for a precise computation of the difference, $\sqrt{m_2} - \sqrt{m_1}$. Because the second solution was produced by the dilution of the first, the difference, $\sqrt{m_2} - \sqrt{m_1}$, was determined to more decimal places than either $\sqrt{m}$.

Since the measurements were not performed at exactly the selected temperatures, it was necessary to apply a small correction to each determination to obtain $\overline{P}$ for one of the three temperatures, 0, 12.5 and 25°. The procedure was facilitated by the facts that solutions of the same composition were diluted in each of these temperature regions

---

[6] Richards and Hall, THIS JOURNAL, **51**, 709 (1929).

and that the compositions of the respective solutions formed in each temperature range were nearly the same. For each dilution range, for example, the dilution of the 1.5742 molal solution ($\sqrt{m}$ = 1.2547) to solutions approximately 1.432 molal, the average value of the derivative $d\bar{P}/dt$ between 0 and 12.5 and the average value of $d\bar{P}/dt$ between 12.5 and 25° were computed from the data in column 4 of Table I. The two chords so obtained were plotted as ordinates with temperatures as abscissas and the $d\bar{P}/dt$ curve was drawn in accordance with the chord-area principle. From the straight line so obtained, a value of $d\bar{P}/dt$ was determined, for example, for the interval between 12.50 and 12.58°, the actual temperature of one of the observations. This value of the temperature coefficient multiplied by the difference, 12.50–12.58°, was added to the $\bar{P}$ observed at 12.58 to yield $\bar{P}$ at 12.50°. No correction at 25 or 12.5° amounted to more than two units and none at 0° to more than five units. Consequently the inaccuracy introduced by the treatment of $d\bar{P}/dt$ as a linear function of temperature is very small.

The $\bar{P}$ values are given in the last column of Table I, and are plotted as chords on Fig. 1, the curves of which represent the derivative $S = d(\phi H)/d\sqrt{m}$ as a function of $\sqrt{m}$. The results of duplicate experiments with concentrated solutions differed so little that they are not distinguishable on the plot. Individual chords are discernible however in the dilute solution region. Measurements of the heats of dilution at 0° of the most dilute solution represented in Table I are relatively inaccurate because the temperature changes produced were very small (equivalent to galvanometer deflections of about 2 mm.). Corresponding data for 12.5 and 25° have been omitted entirely because of the availability of the equations recently derived by Young and Groenier[7] from the data obtained by Gulbransen and Robinson[8] with their calorimeter designed specially for very small thermal effects. The circles represent values calculated for 25° from Young and Groenier's equation 8 and for 12.5° from the fol-

lowing equation which is the mean of their equations 10 and 11

$$S = 385 - 1591\sqrt{m} + 758\,m \qquad (2)$$

The accuracy of this equation is restricted, especially for relatively large molalities, by the excessive length of Gulbransen and Robinson's chords, and is further limited by the necessity for interpolation. Nevertheless, because of the superior precision of Gulbransen and Robinson's apparatus for the measurement of very small thermal effects, equation 2 was given greater weight in the drawing of the 12.5° curve near $\sqrt{m} = 0.44$ than was given to the data of Table I. If the small discrepancy apparent in this region be entirely due to errors in the observed galvanometer deflections produced by the dilution of the 0.204 molal solution ($\sqrt{m} = 0.452$), the mean error is less than 0.75 mm. In the same concentration range, the 25° data of the two investigations merge, somewhat fortuitously, with no significant discrepancy.

The final curves as shown in Fig. 1 were drawn with reference to *points* calculated, by means of equation 1, from values of S' and S'' determined from preliminary plots. The sizes of the dilution vessels had been so chosen that the average value of $P - \bar{P}$ was less than 0.04, and the largest was but 0.15, which is less than the precision of measurement. The experimental dilutions were nearly equivalent, therefore, to direct determination of the derivative, S.

For calculations involving a large scale reproduction of Fig. 1, the original data in Table I are not convenient. The dilution of the 1.5742 molal solution, for example, leads to values of S which correspond to six slightly different molalities. Each datum corresponds to a $\sqrt{m}$ which is the mean of $\sqrt{m_1}$ and $\sqrt{m_2}$ of the dilution experiment from which it was derived. Let X_j denote this mean $\sqrt{m}$ of the jth dilution. The mean of the six X_j values is 1.2257. For the small interval between each X_j and 1.2257, S' was determined from curves previously mentioned. This value of S', multiplied by $(1.2257 - X_j)$, was added to S previously computed for X_j. The sum is the derivative, S, which corresponds exactly to $\sqrt{m} = 1.2257$. All six experiments thus yielded derivatives for this same value of $\sqrt{m}$. The experiments had been so designed that all of the increments were insignificant: the largest was but 0.21.

Table II contains the resulting values of the derivative, S, corrected as described for temperature, curvature (by equation 1), and composition. These are not data read from smooth curves but

Table II is suitable for a test of the precision of the calorimetric measurements. The average fractional discrepancy between duplicate measurements of heats of dilution of solutions more concentrated than 0.6 molal is about 0.2%, *i. e.*, the average deviation from the mean is 0.1%. The discrepancies in the data for the three most dilute solutions, *i. e.*, those producing very small temperature changes, are better expressed in terms of either equivalent temperature differences or galvanometer deflections. The average deviation from the mean of those data is equivalent to a deflection of about 0.2 mm.

Discussion

Three general methods have been used to test the validity of the Debye–Hückel theory for infinitely dilute solutions. Experimentally determined activity coefficients, heats of dilution and heat capacities have been compared with theoretical predictions. Many uni-univalent electrolytes in aqueous solution have been shown to meet the first two tests. The activity coefficients of sodium chloride have been compared by Brown and MacInnes,[3] and the heats of dilution by Young and Groenier[7] with the theoretical equations for extremely great dilutions.

From precise determinations of ϕC, the apparent molal heat capacity, Randall and Rossini[9] have calculated limiting values of the derivative, $d(\phi C)/d\sqrt{m}$, as m approaches 0. Though the dielectric constant of water has not been determined with sufficient precision to permit an accurate theoretical calculation of the limiting slope, Randall and Rossini demonstrated that their estimates were of the "proper order of magnitude" and that they showed "about the right" variations with changes of valence type. Their estimates depended upon extrapolations based upon the assumption that ϕC is *approximately* a linear function of $\sqrt{m}$. In a subsequent examination of various published data for 19 uni-univalent electrolytes, Rossini[10] concluded that ϕC "can be represented within the accuracy of the best experimental data, as a linear function of $\sqrt{m}$, from the lowest measured concentration to about 2.5 molal." Employing strictly linear extrapolations, he derived new values of the limiting slopes which are very similar to those of Randall and Rossini. Gucker and Schminke[11] also investigated several electrolytes of the 1–1 valence type, and found linear relationships between ϕC and $\sqrt{m}$ to represent their very precise measurements throughout wide ranges of concentration. For three of their solutes they found the linear relationship valid over the whole range investigated, and by extrapolation estimated the respective limiting derivatives. The largest of their values is over three times the smallest. A similar variation exists in the limiting slopes tabulated by Rossini. Randall and Rossini did not investigate the electrolytes whose limiting slopes were found in the later investigations to be the smallest. Nevertheless, the largest limiting value in their table is 65% larger than the smallest. If these differences are significant, the data are in conflict with the Debye–Hückel theory, which demands that the limiting slopes be the same for all strong electrolytes of a given valence type. It is important, therefore, to investigate the validity of the linear relationship upon which the various extrapolations were based. Gucker[12] has pointed out the difficulty of obtaining the precision necessary for this purpose from direct heat capacity measurements. The heat of dilution data, however, may be used.

If, at each temperature between 12.5 and 25°, $d(\phi C)/d\sqrt{m}$ is independent of molality, the vertical distance between the two upper curves of Fig. 1 must be constant. In Fig. 2 the solid line exhibits the difference between the two smooth S curves divided by 12.5; it therefore represents for each molality, the average value of $d(\phi C)/d\sqrt{m}$ throughout the temperature range between 12.5 and 25°. The open circles show, for comparison, data calculated directly from values of P in Table II, and the filled circles denote cor-

responding data derived from Young and Groenier's equations. The dashed line represents the constant value 14.4 which Rossini found to be valid for the various sodium chloride data at, and somewhat below, 25°. The measurements reported here and represented by the open circles, are in themselves evidence of the failure of the linear relationship,[13] but the smallness of the thermal effects observed made corroboration desirable. This has now been supplied by the measurements of Gulbransen and Robinson which reveal similar evidence of the variation of $d(\phi C)/d\sqrt{m}$ with composition. The variation observed within the concentration range of either investigation alone might not seem conclusive, because it might be ascribed to experimental error. A single horizontal line drawn through both sets of points, however, would imply the existence of very large and improbable errors, and would be untenable. Manifestly, the derivative $d(\phi C)/d\sqrt{m}$ does vary with composition.

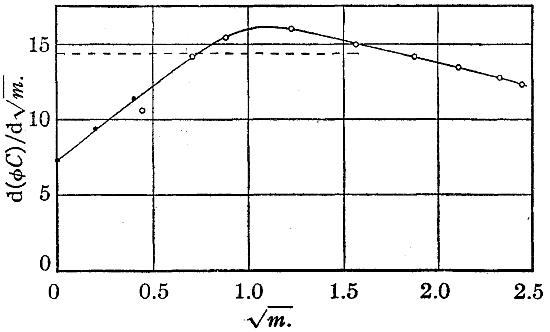

Fig. 2.

On Fig. 3 is plotted $\phi C - \phi C^\circ$ *vs.* $\sqrt{m}$. The dashed line represents Rossini's equation for temperatures between 18 and 25°; the solid line represents the integration of the solid curve of Fig. 2, *i. e.*, the average value of $\phi C - \phi C^\circ$ throughout the range between 12.5 and 25°. Because of the temperature difference the two curves should not correspond exactly. It is to be observed that their shapes are similar throughout the range between $\sqrt{m} = 0.2$ and $\sqrt{m} = 1.6$, *i. e.*, the range investigated experimentally by Randall and Rossini. Within this limited region the integrated (solid) curve is, in fact, approximately straight and its average slope does not differ greatly from that of the dashed line. Since there is some difference between the temperatures to which the two lines correspond, the agreement within the concentration range between $\sqrt{m} = 0.2$ and $\sqrt{m} = 1.6$ is quite satisfactory. There is, therefore, no conflict between Randall and Rossini's precise measurements[14] and the heats of dilution.

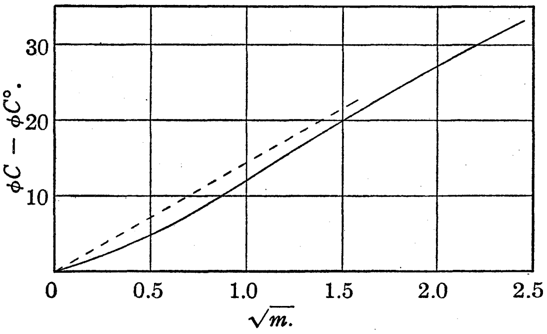

Fig. 3.

The slope of the ϕC *vs.* $\sqrt{m}$ curve for sodium chloride varies so rapidly near the origin that the limiting slope determined by linear extrapolation of apparent molal heat capacities is much larger (about twice as large) than the value derived from heats of dilution. Yet the heat capacity measurements for sodium chloride—especially those at 25°—are among the best in existence. The differences found between the limiting slopes of the various salts are, therefore, not significant and constitute no evidence of failure of the Debye–Hückel theory. That the theoretical limiting law is valid for sodium chloride at least is indicated by other data; the activity coefficients determined by Brown and MacInnes and the apparent molal heat content equations of Young and Groenier. More investigations of the latter type are desirable to supply further information concerning the variation with concentration of the heat capacities of electrolytic solutions.

These heat of dilution data have already been utilized[1] for a preliminary computation of activity coefficients from available freezing point tables. The computation revealed errors in older activity

---

(13) This was pointed out at the meeting of the American Chemical Society in March, 1933; *cf.* Young, ref. 1. The purpose of Rossini's investigation of existing heat capacity data was to collect and arrange them conveniently for various thermochemical calculations. He did not discuss the relation of his equations to the Debye–Hückel theory. The influence upon his calculations of the differences between the two curves of Fig. 2 (and the corresponding curves of Fig. 3) are small and probably quite negligible.

(14) It is interesting that three of the four actual measurements (not average values) corresponding to Randall and Rossini's two smallest concentrations indicate a curvature in the expected direction. The fourth measurement yields a point which is well below even the straight line drawn by Rossini. Randall and Rossini did actually put some curvature into the line drawn to represent their measurements, but the heat capacity data were not capable of determining the change of slope quantitatively. Indeed, Rossini later represented the same data by a linear equation.

coefficient calculations introduced by the use of inaccurate and inadequate thermal data. A subsequent communication will describe the application of these dilution measurements to some freezing point determinations recently made in this Laboratory.

Summary

Differential heats of dilution to be used with cryoscopic data for the evaluation of activity coefficients of sodium chloride in aqueous solution have been obtained (by the chord-area method) from appropriate calorimetric measurements at 0, 12.5 and 25°.

These dilution data have been combined with those of Gulbransen and Robinson (extrapolated to infinite dilution by the method of Young and Groenier) to demonstrate that the apparent molal heat capacity of sodium chloride in aqueous solution is not a linear function of the square root of the molality. Many of the discrepancies between various precise measurements of the heat capacities of electrolytes, and the limiting law derived from the Debye–Hückel theory arose from linear extrapolations. Others are probably due to extrapolations which are too nearly linear. The theory is in agreement with measurements of the heats of dilution of aqueous sodium chloride solutions.

The Normal Vapor Pressure of Crystalline Iodine[1]

BY LOUIS J. GILLESPIE AND LEWIS H. D. FRASER

The normal vapor pressure of iodine is the pressure of the pure vapor in equilibrium with pure solid or liquid iodine when this is subjected to the pressure only of the pure vapor. But few attempts have been made to measure it directly. Ramsay and Young[2] appear to have determined the pressure of air necessary to stop the sublimation of iodine at various temperatures from 58 to 113°. Haber and Kerschbaum[3] used a vibrating quartz fiber as manometer below 0 to $-48°$. They report some data by Naumann[4] from 19 to $-40°$. The precision of none of this work is within the theoretical uncertainties of the better indirect methods.

These uncertainties are due to the assumption, necessary in the indirect methods as ordinarily practiced, that iodine vapor behaves as an ideal gas—more particularly, that a mixture of iodine vapor and a permanent gas behaves as an ideal gas mixture. Gerry and Gillespie[5] showed how the uncertainties may be removed by applying thermodynamic corrections. They derived the corrections from the extensive data of Braune and Strassmann[6] and applied them to the precise indirect results of Baxter and co-workers.[7] They applied to these corrected results the rational equation of Giauque,[8] which has only one adjustable constant—the coefficient of the reciprocal temperature—and found the following equation to fit the corrected results very well

$$\log p = -3512.8/T - 2.013 \log T + 13.3740 \quad (1)$$

where p is the vapor pressure of the solid iodine in atmospheres, log is to the base 10 and $T = 273.1 + t°$.

The present paper deals with some direct measurements of the normal vapor pressure of solid iodine, of relatively high precision, made by means of a flexible metallic diaphragm to restrain the iodine vapor and devices for measuring precisely the low pressures of dry air on the opposite side of the diaphragm when the position of a pointer on the diaphragm, observed with a microscope, indicates a state of balance.

Apparatus

Corrosion experiments showed that platinum is not attacked by iodine, and gold becomes slightly tarnished, but the tarnish disappears on standing in air. These metals and glass were used to contain the iodine.

Figure 1 shows the diaphragm A, a disk of platinum-rhodium foil (4% Rh) 0.01 mm. thick with an effective diameter of 5.7 cm. It is mounted between two brass

rings B and B′. Through six holes in these rings screws pass into the block C. By tightening these screws the diaphragm is stretched over the curved surface of C like a drumhead and free from wrinkles. All brass surfaces against which iodine vapor may come are gold-plated. The tube D is of glass. It is ground well to the gold-plated conical hole in C, and the annular space at the bottom is tightly packed with gold dental moss and sealed with deKhotinsky cement, protected in turn with several coats of shellac.

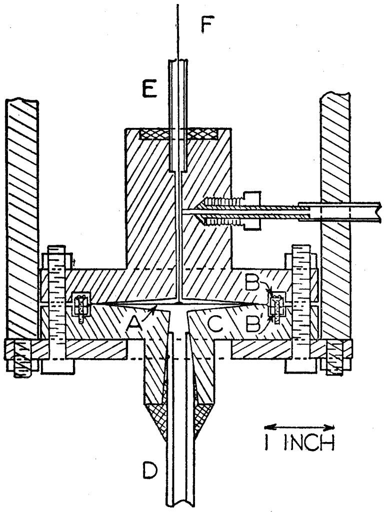

Fig. 1.—Diaphragm pressure balance.

The pointer F is a very light fiber of blue glass cemented to the diaphragm. The pointer and the tube E extend well up out of the thermostat. The top of the pointer is cut off square and is observed through the flattened wall of the top of the tube E through a microscope with the aid of a scale in the ocular.

The sensitivity of the diaphragm has been from 0.001 to 0.004 mm. of mercury pressure, depending on the initial stretch given the foil.

The portion of the apparatus shown in Fig. 1 is well immersed in the oil of the thermostat.

Figure 2 shows a manometer used by Professor F. G. Keyes in unpublished research and kindly lent to us. The arms A and B are 3.2 cm. in diameter. A vacuum is maintained over the mercury in B. The pointer P is operated by a 12.7-cm. dial D through a mercury-protected packing gland G. This can be tightened at any time by means of a special wrench. The periphery of the dial has 200 equal divisions; the thread of the screw is about 1 mm. in pitch, and the position of the screw can easily be estimated to 0.001 mm.

The manometer and the compression chamber C are in an air-bath. By means of the compression chamber the pressure of the dry air can be multiplied about 7 times before measurement with the manometer.

Experience showed that the zero reading of the dial (for equal pressures on both sides) varies with time, particularly because of necessary retightening of the packing. Hence in many cases it was preferred to find the pressure without the zero reading, by measuring in turn the dial reading for the original pressure and for the pressure after compression in the chamber C, and dividing the difference of the two dial readings by a number equal to the compression ratio diminished by unity. The pitch of the screw has been carefully calibrated by means of a good cathetometer with invar scale and found to be uniform. From the temperature of the air-bath and the value of gravity at Cambridge, pressures in international millimeters of mercury were calculated from the dial readings. These pressures are those of the dry air in the apparatus. When the vapor pressure of mercury is added we obtain the total pressure which balances the iodine pressure across the diaphragm.

A portion (not shown) of the tube D in Fig. 1 is bent to give elasticity and communicates through two special stopcocks either to a tube containing the supply of pure iodine or to the vacuum line, which includes condensing trap, gage and mercury and oil pumps. The stopcocks are operated under the oil of the thermostat but are protected by shields so that no oil can touch the plugs. By means of these cocks the tube D can be evacuated for a null-point determination of the diaphragm or connected with the iodine reservoir for a vapor pressure measurement. These cocks are lubricated with a mixture of meta- and pyrophosphoric acids obtained by heating two parts by weight of 85% ortho- with one part of metaphosphoric acid to various temperatures and for different lengths of time.[9] The mixtures used are very viscous and the cocks readily freeze if not turned frequently. The volume of the tubing D and its ratio to the volume of the system including the McLeod gage are known, so that any permanent gas present with the iodine after an experiment can be determined.

The pressure of the air used to balance the vapor pressure is steadied by means of a large bulb in the thermostat.

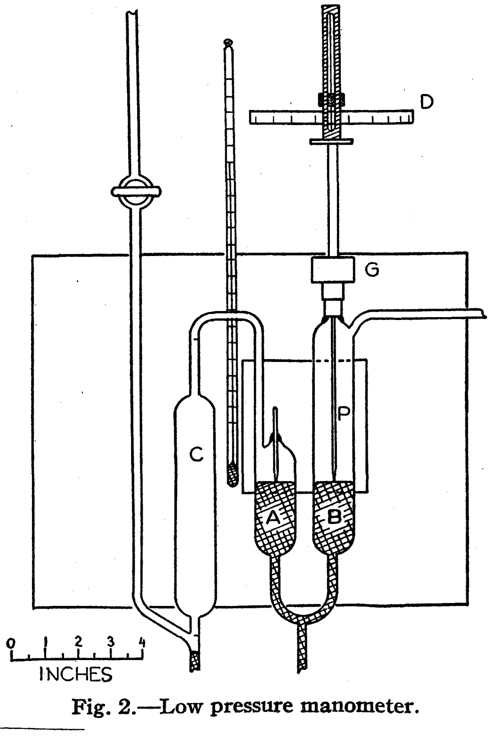

Fig. 2.—Low pressure manometer.

---

[9] Stephens, THIS JOURNAL, 52, 635 (1930).

The stirrer of the thermostat and its motor are hung on a separate support to avoid vibration.

The Experiments

The iodine used was purified and dried by subliming it *in vacuo* from a mixture of resublimed iodine, anhydrous potassium iodide and phosphorus pentoxide. Sublimation was between temperatures of about 45 and −78° and required about three days. The bulb containing the pure product was brought into communication with the rest of the apparatus by breaking a glass tip *in vacuo* by a solenoid arrangement.

Before admitting iodine vapor to the tube D of Fig. 1 for a measurement, it was necessary to find the reading of the pointer on the scale in the ocular of the microscope when equal pressures were on either side of the diaphragm. Zero pressure was chosen for this. The null-point of the diaphragm should not vary with the small pressures in question at constant temperature, because of the simple and symmetrical geometry of the strong metal apparatus.[10]

Iodine vapor was then admitted to the tube D from the reservoir, dry air being admitted to the air system on the other side of the diaphragm, and by use of a mercury injector the diaphragm was again brought to the null-point. When equilibrium had been reached the pressure of the dry air was measured as described above, and the vapor pressure of mercury at the temperature of the gage of Fig. 2 added to obtain the vapor pressure of iodine. After a series of such measurements the null-point was observed again and the results discarded if a significant change had occurred during the series.

No effort was spared to obtain the greatest precision of which the apparatus was capable. Thus twenty-four experiments involving over 500 settings of the dial were performed to determine the two compression ratios used in the multiplication of the pressure (about 7, in each case). The corrections for deviations from Boyle's law were negligible. Eighty-one vapor pressure measurements involving over 1600 settings of the dial were performed at four temperatures from 30 to 60°. Of these, 32 were discarded either because the null-point of the diaphragm had changed or because equilibrium seemed not to have arrived. At each temperature the exact value of the temperature varied slightly from run to run, and the mean reciprocal temperature was found for the mean value of the logarithm of the pressure. This calculation is slightly better than direct averaging of the pressure and temperature but gave practically the same results, because of the smallness of the temperature variation.

At the end of the experiments at 30 and 40° no partial pressure of permanent gas was found in the iodine chamber. When the pressures of permanent gas found at the end of the groups of experiments at 50 and 60° were divided by the time elapsed since the previous evacuation, the rates of air leakage appeared to be constant at each temperature, and from these rates corrections were applied to each result according to the time elapsed, Dalton's law being used for the small corrections. At 50° the correction was 0.3% of the final value of the presssure on the average, and reached about 1% in a single case. At 60° it was about 1% on the average and reached 3% toward the end of one series.

The results are shown in Table I. A thermodynamic check for consistency is given by calculating from each result the value of ΔE_0° in the following equation of Giauque

$$\Delta F^\circ = -RT \ln p_{\text{atm.}} = \Delta E_0^\circ + 429 + 4.0T \ln T - 61.186T \quad (2)$$

Table I

Vapor Pressure of Solid Iodine in Mm. and ΔE_0°

Temp., °C.	29.967	40.017	50.154	60.119
Pressure, mm.	0.46709	1.02614	2.21318	4.30723
ΔE_0°	15643.29	15645.56	15630.91	15644.50

The value of ΔE_0° at 50° is inconsistent with the others, pointing to too high a value of the vapor pressure (by about 0.045 mm.). At this temperature the same inorganic stopcock lubricant was used as for the two lowest temperatures, and it proved too fluid, finally failing altogether. We believe that this was associated with a perceptible vapor pressure of water which caused the high results. In any case, a stiffer batch of lubricant was prepared and used at 60°, and the results here are consistent with those at the lower temperatures. From the mean result for ΔE_0°, excluding the value for 50°, the latent heat of sublimation of iodine at 25° is found to be $\Delta H_{298.16} = 14880.8 \pm 0.8$ cal.$_{15}$ per gram mole. In the above calculations 273.16 was used for the ice point and 1.98690 cal.$_{15}$ for R.

The mean result for the coefficient of $1/T$ in the simple equation of Giauque for the vapor pressure is 3512.859, nearly the same as that in equation (1) above derived by Gerry and Gillespie. The following table affords a comparison between the observed vapor pressures and those calculated by equation (1) and by equation (1) but with the modified value of the coefficient (marked 0.859). All pressures are in international millimeters.

Table II

Observed and Calculated Vapor Pressures of Solid Iodine

Temperature, °C.	Observed	Calcd. Eq. 1	Calcd. 0.859
29.967	0.4671	0.4663	0.4661
40.017	1.0261	1.0284	1.0279
50.154	2.2132	2.1682	2.1673
60.119	4.3072	4.3107	4.3089

The agreement of the results with the calculated values is very good, with the exception of the data for 50°, which are excluded from all further

---

[10] Mr. Joseph E. Goossens found in this Laboratory that a glass diaphragm with a flattened working surface may change in null-point as the pressure is changed on both sides at constant temperature.

averages and calculations. The average percentage deviation from equation (1) is only 0.16, the greatest deviation being 0.0035 mm. and the greatest percentage deviation being 0.22. (The excluded value at 50 differs tenfold.)

The agreement of the data with equation (1) derived from the gas-stream data of Baxter and collaborators is noteworthy. The mean deviation (observed minus calculated) taken with respect to sign is only −0.044%. Now, in the reduction of these data by Gerry and Gillespie, the values of px_1 received corrections for non-ideality of the gas of 0.58, 0.51 and 0.37% at the temperatures 30, 40 and 60°, respectively, as may be found from their Table III. The agreement is therefore within the magnitude of the correction for failure of the ideal gas laws in the gas-stream method.[11]

The average percentage deviation of the results from the equation using the modified value of the coefficient of $1/T$ is 0.14%. The improvement (over 0.16) is not great. The use of a mean value (or of either) should afford very good vapor pressure values, probably from 0 to 100° or higher. Below 0° the equations do not agree well with the data of Haber and Kerschbaum and of Naumann—thus at −48.3° the observed pressure is only 72.7% of that calculated from equation (1) (or 72.3% of that calculated from the original equation of Giauque), and the true vapor pressure is in turn estimated by Haber and Kerschbaum to be about 12% lower than that observed (at room temperature), by reason of the Knudsen effect.[12]

The equations also disagree somewhat at 90° and above with the data of Ramsay and Young, the calculated values becoming progressively greater than the observed, the difference reaching 6.4% of the observed pressure at 113.8°.

These facts suggest that equation (1) is perhaps too simple in form for such a range of temperature as from −48 to 114°.

Nevertheless, the best values at present available for the normal vapor pressure of iodine are probably those calculable from equation (1) with the value 3512.830 for the coefficient of $-1/T$, which averages the results of Baxter and collaborators and the present work. Table III gives such values for even values of the temperature.

TABLE III

NORMAL VAPOR PRESSURE OF SOLID IODINE IN INTERNATIONAL MILLIMETERS OF MERCURY

t, °C.	0	10	20	25	30	40	50	60
p, mm.	0.0307	0.0814	0.201	0.309	0.467	1.027	2.144	4.276
t, °C.	70	80	90	100	110	114.15 (m. p.)		
p, mm.	8.175	15.04	26.73	45.97	76.76	94.18		

Summary

The normal vapor pressure of solid iodine has been measured directly by means of a flexible metallic diaphragm at 30, 40 and 60° with a precision of better than 0.004 mm. of mercury, or better than 0.22%. The results agree with the equation deduced by Gerry and Gillespie from the data of Baxter and collaborators, as corrected for failure of the ideal gas laws, within the magnitude of these corrections. A table is given of vapor pressures derived from a combination of the new data with the corrected older data, as embodied in the modified equation of Giauque

$$\log_{10} p_{\text{atm.}} = -3512.830/T - 2.013 \log T + 13.37400$$

The corresponding value of ΔH for the sublimation of iodine at 25° is 14880.7 cal_{15}/mole.

CAMBRIDGE, MASS. RECEIVED AUGUST 12, 1936

---

[11] Air was the inert gas in this case. The corrections depend in part on the nature of the inert gas.

[12] The calculated pressure at −48.3° is only 7.84×10^{-5} mm.; the observed, 5.7; the observed after Knudsen correction, 5.0×10^{-5} mm.

The System Dioxane and Water

BY FRANK HOVORKA, RALPH A. SCHAEFER AND DALE DREISBACH

Introduction

There has been a considerable interest shown in the use of symmetrical dioxane (1,4) after it was recommended by Anschütz and Broeker[1] as an excellent organic solvent for molecular weight determinations. The first important workers, Herz and Lorentz,[2] unfortunately overlooked the highly hygroscopic nature and the slow decomposition with time of dioxane. These two properties were later pointed out by Roth and Meyer[3] and consequently some of the results of Herz and Lorentz are in error because of the questionable purity of their dioxane.

Since dioxane is completely miscible with water it cannot only serve as a solvent for investigating the properties of the various solutes in it, but can also be used when it is desirable to know the properties of solutes in the mixed solvents, dioxane and water. Thus in view of the importance of dioxane in its various applications it was thought desirable to determine various physical properties not only in the pure state but also in its various mixtures with water over a wide range of temperatures.

Experimental

Materials.—The dioxane was purified by a modification of the Kraus and Vingee[4] method. Commercial dioxane was refluxed over sodium hydroxide and after distillation boiled for a long period over metallic sodium, fresh metal being added from time to time. It was then crystallized several times. The final product melted at 11.78 ± 0.01°.

The water used in this investigation was prepared by repeated crystallizations from selected pieces of ice.[5] The fifth crop proved very pure. The conductivity of the liquid from this ice was 0.95×10^{-6} mhos at 25°.

Procedure.—The apparatus was cleaned and dried and allowed to stand overnight in dry air. The different concentrations were prepared by weighing the desired amounts in small glass-stoppered bottles. Transfer of liquids and all the weighings were performed in an atmosphere of purified air. The dioxane was recrystallized each time before being used.

Temperatures in all cases were kept constant to 0.01° up to 40° and ±0.02° above 40°, and were referred to a thermometer calibrated by the Bureau of Standards.

Densities were determined by the dilatometer method. The dilatometer was calibrated with purified mercury. The working volume was 7.7 to 8.7 cc. and the total height 23.3 cm. The smallest volume capable of being read was 0.0001 cc., which corresponds to an accuracy of approximately one part in fifty thousand.

The capillary rise method was used for surface tension measurements as outlined by Richards and Coombs.[6] The large tube had a diameter of 3.8 cm. and the capillary tube a radius of 0.01815 cm. as determined by careful calibration with a mercury thread. The length of the thread was measured by means of a precision micrometer.

A static method similar to the one previously described by Hovorka and Dreisbach[7] was used for measuring the vapor pressure.

For the measurements of the three properties above a cathetometer with a reproducible accuracy of ±0.01 mm. was used. All of the determinations were carried out with the apparatus sealed off *in vacuo*.

The index of refraction was determined with an Abbé refractometer accurate to ±0.0001. Measurements were carried out at 25 ± 0.05° using sodium light as a source of illumination.

The freezing point curve was investigated with the usual Beckmann apparatus. The temperature was controlled by cooling ethyl alcohol with solid carbon dioxide in a gallon (4-liter) Dewar flask and was maintained three degrees lower than the freezing point of the solution under investigation. Precautions were taken to prevent moisture from entering the freezing point tube.

Experimental Results.—The experimental results are summarized in Tables I–VI and Figs. 1–3. The temperature is in degrees centigrade and vapor pressure in mm. of mercury. The vapor pressure data, Table III, are for round values of concentration obtained by graphical interpolation.

Discussion of Results

The results obtained deviate widely from the ideal solution laws as was to be expected, since dioxane is non-polar while water is a highly polar substance. A study of the experimental data shows a pronounced difference in internal pressures of the dioxane and water. Table IV of the partial molal volumes of the 25° isotherm shows this phenomenon exceedingly well. ($\overline{V} - V^0$ is the partial molal volume of each constituent, $\overline{V}$, less the molal volume of that constituent in the pure state, V^0.) From the curves in Fig. 1 we see that the maximum change in the partial molal

The partial pressure of water, Fig. 2, is abnormally high in this neighborhood, while dioxane follows the natural course for systems having a maximum vapor pressure. There is also a decided maximum in the density curve of this system. Geddes[8] reports a maximum in the viscosity of this system as well as an inflection point in the fluidity curve. The latter is "an unusual type of behavior." It is to be noted that this point of inflection may be due entirely to the densities given by Geddes. In the region between 0 and 5% water he gives two points which are decidedly higher than his values at 0 and 5%. No such high values were found in this work nor in that of Gillis and

(8) Geddes, THIS JOURNAL, 55, 4832 (1933).

Delaunois.[9] The density curve is quite normal in this region.

The refractive index does not possess a maximum but for both refractive index and surface tension the deviations from the ideal are very great.

The eutectic point at 0.152 mole fraction of dioxane and a temperature of −14.9° agrees well with that found by Gillis and Delaunois. However, these workers report a peculiar trend in the curve between 0.8 and 1.0 mole fraction dioxane. This has not been confirmed and the results obtained here are in excellent agreement with those found by Bell and Wolfenden.[10] Gillis and Delaunois in calling attention to this peculiar irregularity base their conclusions on one point only which may well be in error by 10%. Further, it is difficult to understand why they report two densities for their pure dioxane at 20°, namely, 1.0345 and 1.03215. The maximum deviation from the ideal linear freezing-point curve, Fig. 3, occurs at 0.37 mole fraction of dioxane corresponding to the maximum found in the density measurements.

Values for the vapor pressure of pure dioxane, Table III, are higher at low temperatures and lower at higher temperatures than the corresponding values given by Herz and Lorentz.[2] The vapor pressure may be expressed by means of the equation

$$\log_{10} P \text{ (mm.)} = -1933.8/T + 8.0588$$

with a maximum deviation of one per cent. over the temperature range 10 to 80°.

Dioxane itself is a very normal liquid. The Eötvös constant as calculated is 2.11 for the temperature range investigated. The parachor is 205.7, which agrees fairly well with the calculated value of 202.1. The molecular refraction according to the expression of Lorentz and Lorenz gives an experimental value of 21.678, which is in excellent agreement with the theoretical value of 21.690.

The authors wish to express their appreciation to Dr. J. O. Morrison, of Yale University, for furnishing the purified dioxane.

Summary

1. The density, surface tension and total vapor pressure of the dioxane–water system were investigated for the temperature range 10 to 80°.

2. The partial vapor pressure and the index of refraction for this system were determined at 25°.

3. The freezing point curve of the dioxane–water system was studied.

4. The dioxane–water system was discussed and the possible errors of other workers in the case of freezing points, density and fluidity were pointed out.

The Reaction of 2,3-Epoxybutane with the Grignard Reagent

BY D. L. COTTLE AND LEO S. POWELL

The rearrangement of certain ethylene oxides in Grignard reactions is well known. Among the simple alkyl or aryl substituted ethylene oxides, 2,3-epoxybutane,[1] 1,2-epoxy-2-methylpropane,[2] 1,2-epoxy-2-methylbutane,[3] 1,2-epoxy-2-phenylpropane,[4] and styrene oxide,[5] have been reported to rearrange in Grignard reactions to produce one alcohol, while 1,2-epoxypropane[6–8] and 1,2-epoxybutane[8] have been reported not to rearrange.

In order to explain the rearrangement of cyclohexene oxide in a methylmagnesium iodide reaction reported by Bedos, Bartlett and Berry[9] adopted the Blaise[10] structure for the primary intermediate.[11,12]

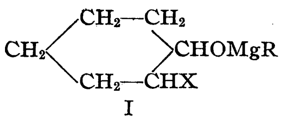
(9) Bartlett and Berry, THIS JOURNAL, **56**, 2683 (1934).

(10) Blaise, *Compt. rend.*, **134**, 552 (1902).

(11) This theory was criticized by Grignard [*Bull. soc. chim.*, [3] **29**, 944 (1903)] who preferred to depict the oxide ring as breaking at much higher temperatures. Boord and Summerbell readvanced the Blaise theory (Columbus, Ohio, meeting of The American Chemical Society, May, 1929) and Ribas and Tapia placed it on a more secure basis as a result of extensive experiments with ethylene oxide, epichlorohydrin and 3-methoxy-1,2-epoxypropane [*Anal. soc. españ. fís. quím.*, **30**, 778 (1932); **30**, 944 (1932)].

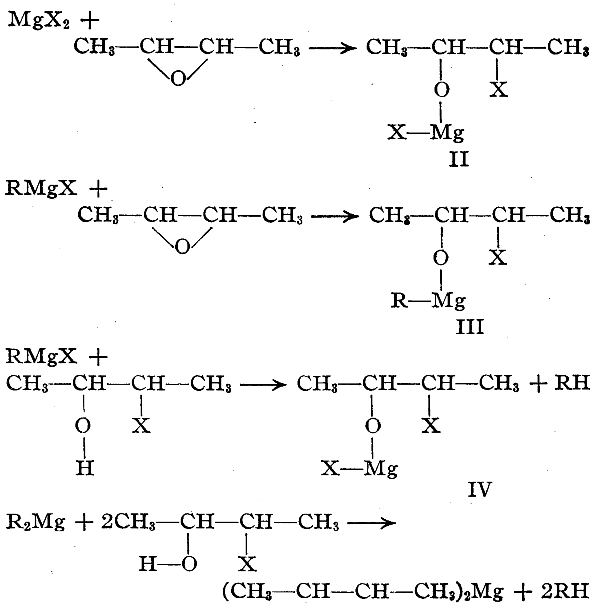
(12) Boord and Summerbell and Ribas and Tapia suggested as likewise possible the structures BrMgOCH$_2$CH$_2$Br and Mg(OCH$_2$CH$_2$Br)$_2$ for ethylene oxide intermediates.



I

These workers further assumed that I rearranged to cyclopentylformaldehyde instead of reacting through replacement of the halogen by the methyl group. These assumptions were based on experimental work by Bedos[13,14] who found that the alkoxide formed from cyclohexene chlorohydrin and ethylmagnesium bromide gave a 40% yield of cyclopentylformaldehyde when the ether was evaporated from its mixture with magnesium bromide. The oxide treated similarly with magnesium bromide etherate gave a 34% yield of aldehyde. These magnesium bromide reaction mixtures, both chlorohydrin and oxide, reacted vigorously with methylmagnesium iodide to form methylcyclopentylcarbinol.

If the reaction path outlined by Bartlett and Berry is applicable to 2,3-epoxybutane, 3-bromo-2-butanol should react with a Grignard reagent and yield a tertiary alcohol since Henry[1] obtained tertiary amyl alcohol when methylmagnesium bromide reacted with the oxide. The intermediates, II and III, would have structures similar or identical to IV and V.



$$MgX_2 + CH_3-\underset{\diagdown O \diagup}{CH-CH}-CH_3 \longrightarrow CH_3-\underset{\underset{X-Mg}{|}}{\underset{O}{|}}{CH}-\underset{X}{\underset{|}{CH}}-CH_3 \quad \text{II}$$

$$RMgX + CH_3-\underset{\diagdown O \diagup}{CH-CH}-CH_3 \longrightarrow CH_3-\underset{\underset{R-Mg}{|}}{\underset{O}{|}}{CH}-\underset{X}{\underset{|}{CH}}-CH_3 \quad \text{III}$$

$$RMgX + CH_3-\underset{\underset{H}{|}}{\underset{O}{|}}{CH}-\underset{X}{\underset{|}{CH}}-CH_3 \longrightarrow CH_3-\underset{\underset{X-Mg}{|}}{\underset{O}{|}}{CH}-\underset{X}{\underset{|}{CH}}-CH_3 + RH \quad \text{IV}$$

$$R_2Mg + 2CH_3-\underset{H-O}{\underset{|}{CH}}-\underset{X}{\underset{|}{CH}}-CH_3 \longrightarrow (CH_3-\underset{O}{\underset{|}{CH}}-\underset{X}{\underset{|}{CH}}-CH_3)_2Mg + 2RH \quad \text{V}$$

We found that 3-bromo-2-butanol reacted with the second mole of ethylmagnesium bromide without application of heat, and the end-products consisted of 2-butanone, postulated by Henry as an intermediate in the oxide reaction, and 3-methyl-3-pentanol. We were unable to isolate any 3-methyl-2-pentanol, which would have resulted from a replacement of the halogen by the alkyl group of the Grignard reagent. Thus, the explanation of Berry and Bartlett applies to 2,3-epoxybutane.

The Grignard reaction of this bromohydrin without application of heat undoubtedly is due to the secondary bromine atom. Ethylene bromohydrin is well known to require higher temperatures for reaction of the bromine atom.[15] The magnesium salt of 3-bromo-2-butanol, prepared from 2,3-epoxybutane and magnesium bromide in ether benzene solution decomposed practically quantitatively at slightly above room temperature. The product was 2-butanone. Rector[16] was able to prepare 3-bromo-2-butanol in 60% yield by this method by working at 0°.

Although the Blaise theory is satisfactory in predicting the behavior of 3-bromo-2-butanol the isolation by Henry, Fourneau and Tiffeneau and others of only one alcohol in the oxide reactions which involved rearrangements is not in satisfactory agreement with known experimental data. Ribas and Tapia[11] found in treating 2 moles of ethylene oxide with one of ethylmagnesium bromide in the cold that the magnesiumalkyl bond also reacted. Later, Bartlett and Berry[9] obtained no rearrangement in the reaction of cyclohexene oxide with diethylmagnesium or dimethylmagnesium. Ribas and Tapia obtained a 5% yield of *n*-butyl alcohol when ethylene oxide was reacted with ethylmagnesium bromide in a 1 to 1 ratio in the cold. This may be assumed to represent the percentage of reaction of C_2H_5Mg bond when in competition with a similar quantity of MgBr bond. Consequently, we considered it probable that small amounts of normal products

[13] Bedos, *Compt. rend.*, **189**, 255 (1929).

[14] Berry and Bartlett are confused in the history of this reaction for they credit Bedos with their explanation as well as with the experimental work. There is nothing in the reference[13] cited by Berry and Bartlett or in other articles by Bedos to indicate that he wished to advance the explanation credited to him. The statement by Berry and Bartlett[9] (p. 2684), "Bedos has further elucidated the mechanism of this rearrangement by showing that, as in the aliphatic series, the primary product of reaction between cyclohexene oxide and a Grignard reagent is the halohydrin derivative. . . .," is misleading in another respect inasmuch as in only one case, 1,2-epoxy-2-methylbutane, are there sufficient data in the literature to support a qualified explanation of an aliphatic ethylene oxide rearrangement. Moreover, no reference is given to the work of Ribas and Tapia of 1932 which is the only successful attempt to refute the unsatisfactory theory advanced by Grignard in 1903.

[15] Grignard, *Bull. soc. chim.*, [3] **34**, 918 (1905); Conant and Kirner, THIS JOURNAL, **46**, 240 (1924).

[16] Rector, Master of Science Thesis, Rutgers University, 1933.

in the rearrangements cited were overlooked by the early workers.

2,3-Epoxybutane was selected for investigation of this and related points for the following reasons: the recent description[17] of a source of pure 2-butene made its preparation in larger than usual quantities feasible; 3-bromo-2-butanol is the only bromohydrin that it can form; and the difference in boiling points of the possible alcohols produced by the Grignard reagent is greater than if a higher molecular weight oxide were used.

In the present work 2,3-epoxybutane was found to react with diethylmagnesium and dimethylmagnesium to yield secondary alcohols. These results are in complete agreement with the predictions of Bartlett and Berry[9] and have been reported by other investigators.[18] Secondary alcohols were also isolated in 2,3-epoxybutane reactions with ethylmagnesium chloride and bromide and methylmagnesium bromide. A trace of secondary alcohol probably was present in an ethylmagnesium iodide experiment. A tertiary alcohol also was produced in each of these reactions. That the formation of the secondary alcohol was due to a direct reaction of the alkylmagnesium bond with the oxide was demonstrated by the absence of the secondary alcohol in the 3-bromo-2-butanol reaction with ethylmagnesium bromide. The formation of appreciable yields of the tertiary alcohol (see Table I) without heating of the bromide and iodide reactions was predicted on the basis of the results obtained with 3-bromo-2-butanol.

TABLE I

Expt.	RMgX	Yield, % Secondary alcohol	Yield, % Tertiary alcohol
1	C_2H_5MgCl	27[a]	30[a]
2	C_2H_5MgBr	2	31
3	C_2H_5MgI	Trace	27
4	CH_3MgBr	7[a]	44[a]

[a] Based on refractive index of the mixture.

In view of the discovery by Brönsted and coworkers[19] that of the aqueous potassium halides, iodide adds faster than bromide and bromide faster than chloride to glycid and epichlorohydrin it is not surprising that of the three ethyl Grignard reagents, the iodide gave the least alkylmagnesium reaction. However, several factors need evaluation before a valid conclusion can be drawn.

The discovery by Schlenk and Schlenk[20] that the dioxane precipitate from a Grignard solution behaved like a Grignard reagent with esters and ketones caused us to treat 2,3-epoxybutane with the precipitate from an ethylmagnesium bromide solution. The precipitate contained a larger amount of magnesium halide bond compared with magnesiumalkyl than the original Grignard and a tertiary alcohol with very little if any of the secondary was expected. However, the precipitate was apparently too insoluble for reaction and dissociated to form soluble diethylmagnesium for only the secondary alcohol was formed.

In the reaction of 3-bromo-2-butanol there was obtained, besides 2-butanone, a small amount of liquid which boiled around 155–165°. From the boiling point, reduction of permanganate and the formation of a solid with semicarbazide solution this product contained an octenone. Pariselle and Simon[21] obtained a similar product in the reaction of isopropylmagnesium bromide with 2-butanone and analogous observations have been made by many other workers although generally with Grignard reagents with more complex alkyls than ethyl. In the present work similar material was obtained from the reaction of 2,3-epoxybutane with ethylmagnesium iodide and of 2-butanone with diethylmagnesium. In the latter reaction the yield of alcohol was only 8%.

Experimental

The Preparation of Crude 3-Bromo-2-butanol.—Bromine water was treated with 2-butene by the method given by Read and Williams[22] for ethylene bromohydrin. 2-Butene, generated by heating 4 moles of 2-butanol with 60% sulfuric acid,[17] was passed into the bottom of a well stirred, 5-liter, 3-necked flask which contained 4 liters of water. At the same time, air, regulated by a needle valve, carried bromine into the reaction vessel at such a rate as to give the solution a faint yellow color. The air and butene bubbles were broken up by Jena G-4 gas distribution tubes. In order to prevent the dibromide from extracting the butene and bromine from the water the flask was fitted with a siphon for the intermittent removal of the by-product.

At the end of the reaction the remaining dibromide was separated and the water layer saturated with salt and extracted with ether. After drying over sodium sulfate the ether was expelled on a water-bath. The residue, in 7 preparations, averaged 164 g. or 27% of the theoretical based on the 2-butanol used.

The Preparation of 2,3-Epoxybutane.—Crude 3-bromo-2-butanol (360 g.) was added drop by drop to a well-stirred solution of 450 g. of sodium hydroxide in 1050 cc. of water in a 2-liter, 3-necked flask heated on a water-bath. The oxide and some water distilled over at 50–60°. After drying over potassium carbonate it was fractionated with a 3-bulb Snyder column and gave a 75% yield of oxide, b. p. 55–59°, $n^{20}{}_{D}$ 1.3765, $d^{20}{}_{20}$ 0.8144.

The Preparation of Pure 3-Bromo-2-butanol.—The method of Thayer, Marvel and Hiers[23] for the preparation of ethylene bromohydrin was used. 2,3-Epoxybutane (66 g.) was added to 172 cc. of 48% hydrobromic acid kept at 0–2°. The yield was 123 g. or 88% of the theoretical of 3-bromo-2-butanol, b. p. 46–50° (8 mm.); $n^{20}{}_{D}$ 1.4780, $d^{20}{}_{20}$ 1.4500.

Anal. Calcd. for C_4H_9OBr: Br, 52.24. Found: Br, 52.2, 52.3.

This compound has been prepared previously.[24]

The Preparation of Reference Compounds.—In order to facilitate the identification of the various alcohols obtained in the experiments described below it was necessary to prepare some new urethans.

3-Methyl-3-pentanol was prepared from ethylmagnesium bromide and 2-butanone. The α-naphthyl urethan was prepared by heating 1 g. of the alcohol with 1.7 g. of α-naphthyl isocyanate for three hours. It melted at 83.5°.

Anal. Calcd. for $C_{17}H_{21}O_2N$: N, 5.17. Found: N, 5.05, 4.85.

The phenylurethan, similarly prepared, melted at 43.5°.

Anal. Calcd. for $C_{13}H_{19}O_2N$: N, 6.33. Found: N, 6.37, 6.32.

3-Methyl-2-pentanol was prepared from *s*-butylmagnesium bromide and acetaldehyde by an adaptation of the method for 3-methyl-2-butanol.[25]

The α-naphthylurethan melted at 72°.

Anal. Calcd. for $C_{17}H_{21}O_2N$: N, 5.17. Found: N, 5.21, 4.98.

3-Methyl-2-butanol was prepared according to the directions of Drake and Cooke.[25] The α-naphthylurethan melted at 108–109°.

Anal. Calcd. for $C_{16}H_{19}O_2N$: N, 5.45. Found: N, 5.39, 5.24.

The phenylurethan melted at 68°.

Anal. Calcd. for $C_{12}H_{17}O_2N$: N, 6.76. Found: N, 6.67, 6.87.

These derivatives and the α-naphthylurethan of 2-methyl-2-pentanol, described by Neuberg and Kansky,[26] were used in mixed melting point determinations with urethans prepared from the products of the experiments described below.

The Reaction of 3-Bromo-2-butanol with Ethylmagnesium Bromide.—The bromohydrin (0.65 mole), prepared from the oxide and hydrobromic acid, was added drop by drop to 480 cc. of an ice-cooled ether solution containing 1.3 moles of ethylmagnesium bromide. A precipitate gradually formed which filled half of the solution. Soon after removal of the ice-bath the reaction mixture refluxed violently for an hour. After standing overnight it was hydrolyzed, the ether extract dried over sodium sulfate and the ether removed on the water-bath. The residue was treated with 30% sodium hydroxide in order to remove unchanged bromohydrin. After extracting with ether and drying over potassium carbonate distillation was made through a 6-bulb Snyder column.

A portion of a 1.0-g. fraction boiling at 65–78° gave a semicarbazone which melted at 138–139°. A mixed melting point with an authentic semicarbazone of 2-butanone did not vary.

The fraction distilling at 121–122° weighed 17.4 g. which corresponds to a 26% yield of alcohol. It was identified as 2-methyl-2-pentanol. The 122–131° fraction weighed 0.9 g. and the material boiling from 131–136°, 0.6 g. The latter gave an α-naphthylurethan melting at 81.5°. A mixture with the α-naphthylurethan of 3-methyl-3-pentanol melted at 82.5°. When a mixture of equal quantities of 3-methyl-3-pentanol and 3-methyl-2-pentanol was reacted with α-naphthyl isocyanate no derivative melting above 52° could be obtained.

A residue of 1.0 cc. was investigated and is reported below.

The Reaction of 2,3-Epoxybutane with Magnesium Bromide.—One mole of oxide was added drop by drop to 1 mole of magnesium bromide, prepared in 300 cc. of ether by the method of Zelinsky[27] and diluted with 300 cc. of benzene. The original object of this experiment was the preparation of 3-bromo-2-butanol but cooling was inefficient and the hydrolysis product consisted of 16 g. of uninvestigated liquid which did not volatilize on the steam-bath. 2-Butanone was extracted from the ether and benzene distillate with sodium bisulfite and identified by the melting point of its semicarbazone and a mixed melting point determination. The oxide dissolved in ether and benzene did not give a precipitate with sodium bisulfite.

The Reaction of 2,3-Epoxybutane with Diethylmagnesium and Dimethylmagnesium.—The oxide was added drop by drop to the dialkylmagnesium in ether in an atmosphere of tank nitrogen using ordinary Grignard technique.

To 0.105 mole of dimethylmagnesium, prepared according to the method of Gilman and Schulze,[28] in 200 cc. of ether was added 0.20 mole of oxide. After addition of the oxide the reaction mixture was refluxed for a short time. A crude yield of 6.1 g. or 35% of the theoretical of alcohol identified as 3-methyl-2-butanol was obtained.

Diethylmagnesium, in 1 liter of ether (0.62 mole), was prepared from ethylmagnesium bromide by filtering off the dioxane precipitate. The oxide (0.62 mole) was added and the solution concentrated by distillation to 200 cc. of clear solution. On hydrolysis it gave a 50 g. or 79% yield of alcohol, b. p. 132–34°. In a similar experiment in which part of the alcohol was dehydrated during distillation, the alcohol was identified as 3-methyl-2-pentanol.

The Reaction of 2,3-Epoxybutane with the Grignard Reagents.—In each of the four experiments reported in Table I the ratio of Grignard reagent to solution was approximately 1 mole to 300 cc. The amount of the reagent

[27] Zelinsky, *Chem. Zentr.*, **74**, **II**, 277 (1903).

[28] Gilman and Schulze, THIS JOURNAL, **49**, 2329 (1927).

was determined by the titration method of Gilman and coworkers.[29] The oxide was added drop by drop to the reagent cooled in ice and the mixture allowed to come to room temperature. On warming up to room temperature a reaction set in which refluxed the ether violently for about an hour in each case. With the exception of the methylmagnesium bromide experiment, which stood overnight, the reaction mixtures were hydrolyzed at the end of this spontaneous reaction and worked up as described under the 3-bromo-2-butanol experiment.

The results were obtained with the following quantities of oxide and Grignard reagent: no. 1, 0.68 mole; no. 2, 0.30 mole; no. 3, 0.86 mole; no. 4, 1.0 mole. The yields of tertiary alcohol in expts. 2 and 3 were calculated on the basis of the product boiling at 121–122°. In expt. 2, the secondary alcohol boiled at 132–140°. The yields of secondary and tertiary alcohol in expts. 1 and 4 were determined from the refractive indices of the alcohol mixtures which were previously separated by distillation from low and high boiling substances. These mixtures then were fractionated until sufficient quantities of pure alcohols were obtained for the formation of a sharp melting α-naphthyl or phenylurethan. These derivatives were identified further by mixed melting point determinations with authentic samples. Experiment 3 produced 1 g. boiling at 131–140°, which gave an α-naphthylurethan melting at 56–66° after many recrystallizations. The experience with this material was similar to that recorded in the 3-bromo-2-butanol experiment for synthetic mixtures of the two possible alcohols. Experiment 3 also produced a residue of 4 g., the investigation of which is reported below.

The Reaction of 2,3-Epoxybutane with a Dioxane Precipitate from Ethylmagnesium Bromide.—The dioxane precipitate from a diethylmagnesium preparation by calculation contained 0.80 mole of active ethylmagnesium bromide. Enough ether was added to facilitate stirring and 0.80 mole of oxide added. At the end of nine to ten hours of refluxing the reaction mixture gave a negative Gilman and Schulze[30] test for R–Mg bond. The hydrolysis product was treated in the same manner as that in the 3-bromo-2-butanol experiment. Fractionation showed 0.6 g. boiling at 110–120°, 0.3 g. at 120–125°, 1.6 g. at 125–130° and 7.6 g. at 130–135°. The first two and last fractions gave sharp-melting α-naphthylurethans of 3-methyl-2-pentanol. The yield of alcohol based on the fractions boiling from 125–135° was 11% of the theoretical.

The Reaction of 2-Butanone with Diethylmagnesium.—2-Butanone (0.46 mole) was added to 0.195 mole of diethylmagnesium in 300 cc. of ether. The reaction mixture set to a gelatinous mass after standing overnight. At this time it gave a positive Gilman and Schulze color test. It was hydrolyzed and treated in the usual manner and 7.9 g. or a yield of 8% of 3-methyl-3-pentanol, b. p. 118–124°, and some unreacted ketone were obtained. There also was obtained 10.1 g. of some higher boiling material the investigation of which is reported below.

Examination of the Residues.—The major portion of the residues collected from the 3-bromo-2-butanol, ethylmagnesium iodide and diethylmagnesium experiments distilled at 155–165°. All three of these small fractions gave a test for unsaturation with potassium permanganate, evolved hydrogen bromide when treated with bromine in carbon tetrachloride and gave a small yield of crystals when treated with an excess of semicarbazide solution. After thorough washing with water, alcohol and chloroform, in all of which they were quite insoluble, they melted with decomposition at 250.5–251.5°, corr. The melting point varied with the rate of heating.

2-Butanone was treated with ethoxymagnesium bromide and the product, b. p. 170–173°, gave a good yield of crystals with semicarbazide solution which melted at the same temperature. This appears to be a new derivative of a 2-butanone condensation product.[31]

Anal. Calcd. for $C_9H_{17}N_3O$: N, 22.95. Found: N, 22.79, 22.76.

Mixtures of the latter with the crystals from the three residues mentioned above did not cause a change in melting point behavior.

Summary

1. The reaction of 3-bromo-2-butanol with ethylmagnesium bromide produced only the tertiary alcohol.

2. In complete agreement with the prediction of Berry and Bartlett, secondary alcohols were obtained from the reaction of 2,3-epoxybutane with diethylmagnesium and dimethylmagnesium.

3. The reaction of 2,3-epoxybutane with ethylmagnesium chloride and bromide and methylmagnesium bromide produced both secondary and tertiary alcohols. Henry obtained only the tertiary alcohol in the latter case.

4. The formation of tertiary alcohols in the Grignard reactions is interpreted as the result of a rearrangement of the halohydrin derivatives, *i. e.*, the Blaise intermediate, formed from the reaction of the magnesium halide bond with the oxide.

5. 2,3-Epoxybutane and magnesium bromide in ether and benzene solution produced 2-butanone. The same ketone was isolated in the reaction of 3-bromo-2-butanol with ethylmagnesium bromide.

6. 3-Bromo-2-butanol and 2,3-epoxybutane gave appreciable yields of alcohols when treated with Grignard reagents without the application of heat.

7. The reaction of 2,3-epoxybutane with ethylmagnesium iodide, of 2-butanone with diethylmagnesium and of 3-bromo-2-butanol with ethylmagnesium bromide produced, in addition to 3-methyl-3-pentanol, condensation products of 2-butanone.

The Isolation of 1,2-Diketones from the Ozonization of Disubstituted Acetylenes

BY THOMAS L. JACOBS

In a recent paper, Hurd and Christ[1] have discussed the course of the ozonization of acetylenes. They formulate the reaction as proceeding through a 1,2-diketone which is assumed to be oxidized by the hydrogen peroxide produced from the decomposition of the ozonide. From the six acetylenes ozonized, they isolated only acids in yields of 42–61%. The isolation of glyoxal in 81% yield from the ozonization of acetylene[2] is the only instance in which a 1,2-dicarbonyl compound actually has been obtained.

I have ozonized diphenylacetylene and benzylphenylacetylene[3] under carefully controlled conditions, and have isolated benzil and benzylphenyl diketone. At −78° the action of ozone on diphenylacetylene produced an unstable ozonide which decomposed to a black tar shortly after the solvent was removed. When the ozonization was carried out in petroleum ether at 5–15°, the product was a yellow oil which on hydrolysis gave benzoic acid in 65% and benzil in 5% yield. The unstable ozonide apparently produced the same yellow oil as an intermediate when treated with water. When benzylphenylacetylene ozonide, prepared at −30 to −40°, was decomposed with water, the sole products were a mixture of acids and tar. From the acid mixture were isolated benzoic acid in 60% and phenylacetic acid in 10% of the theoretical yield.

$$C_6H_5C{\equiv}CCH_2C_6H_5 \xrightarrow[H_2O]{O_3} C_6H_5COOH + C_6H_5CH_2COOH$$

When the product of ozonization was decomposed with neutral potassium iodide solution, benzylphenyl diketone was isolated in 25% yield. In addition, a small amount of acidic material and much tar were obtained. One attempt was also made to decompose the ozonide by distillation under reduced pressure. A mixture of acid and neutral material resulted, from which a low yield of a mixture of acids was obtained. The neutral portion was accidentally lost.

Ozone was never absorbed completely by any of the acetylenes investigated. The rate of absorption was nearly constant until one mole of ozone had been taken up for each mole of acetylene treated, and then began to fall off rapidly. In one experiment in which the ozonization was continued beyond this point, the initial absorption was 83% and dropped to 25%, but decreased only slowly from this point. The residual absorption probably represents attack of the benzene rings.

The isolation of 1,2-diketones does not prove that such compounds are always intermediates in the production of acids by the ozonization of acetylenes, but the brilliant yellow color of the oil which appears during the preparation or decomposition of the ozonides does suggest that this is the case. In this connection it should be noted that benzil is not attacked by ozone under the conditions of the experiments. The detailed mechanism postulated for the reaction by Hurd and Christ[1] assumes the formation of only monomolecular species, and this appears subject to some question. The amorphous character of the unstable product of ozonization at low temperatures indicates that it is probably polymeric.

An extension of the investigation has been temporarily interrupted, and a report of experiments already completed is made at this time in consideration of the publication of Hurd and Christ.[1]

Experimental

An ozonizer of the Henne[4] type yielding 6.5 to 8% of ozone when oxygen was supplied at 18 to 14 liters per hour was used. Ozone concentrations were determined by the

(4) Henne, THIS JOURNAL, **51**, 2676 (1929).

potassium iodide method of Smith.[5] The amount of ozone used was easily found by successive determinations on the oxygen stream first as it came from the ozonizer and second after it had passed through the solution of the acetylene. Dry oxygen was used. In experiments below 0°, the stream of ozonized oxygen was passed through a glass coil immersed in solid carbon dioxide–acetone before entering the reaction flask.

The Ozonization of Diphenylacetylene

Diphenylacetylene was prepared from benzil by the method of Schlenk, Bergmann and Rodloff[6] or by the action of alcoholic potassium hydroxide on stilbene dibromide.

The Isolation of Benzil.—A solution of 35.6 g. (0.2 mole) of diphenylacetylene in 350 cc. of purified petroleum ether was ozonized at 5–15°. The solvent was attacked almost as rapidly as the compound, but impurities thus introduced were volatile with steam. The ozonized solution, which contained a heavy, yellow, insoluble oil, was steam distilled, and the residue extracted with hot water. The oil remaining was dissolved in ether and extracted with 2% sodium hydroxide. The total benzoic acid obtained was 31.9 g. (65.5% yield). The ether solution gave 8.4 g. of neutral material from which 2.3 g. (5.5% yield) of benzil was obtained, m. p. 94–95°, mixed m. p. the same. The quinoxaline derivative was prepared, m. p. and mixed m. p. 124.5–125°. The residual neutral material was a mixture from which a very little more benzil was obtained by distillation.

Ozonization at −78°.—A solution of 5.2 g. of diphenylacetylene in 100 g. of methyl chloride was ozonized at −78°. The resulting mixture was opaque, and contained an amorphous white precipitate. The solvent was allowed to evaporate and the product was a pasty, yellowish, almost odorless mass, which after remaining at room temperature for about fifteen minutes decomposed suddenly with a considerable heat effect and the evolution of acrid white fumes. Benzoic acid was isolated in poor yield from the black tar remaining. The unstable ozonide was found to ignite with a puff and much liberation of carbon when heated on a platinum foil; it liberated iodine from neutral potassium iodide solution, reacted violently with concentrated sulfuric acid, and on heating in water was converted into a brilliant yellow oil, apparently the same as that obtained directly by ozonization at the higher temperature.

The Ozonization of Benzylphenylacetylene

All experiments with this compound were carried out in purified ethyl chloride at −30 to −40°.

Decomposition of the Ozonide with Potassium Iodide.—By ozonization of 5 g. (0.027 mole) of benzylphenylacetylene and evaporation of the solvent was obtained 5 cc. of a yellow oil containing considerable solid material. This product was decomposed by standing for fifteen hours with dilute, slightly acid potassium iodide solution; titration with thiosulfate (19.2 cc. of 0.4177 *N* required) gave the iodine liberated as 0.004 mole, equivalent to about one-seventh of the acetylene taken. The solution was extracted with ether and this extract washed with water and 10% sodium carbonate solution and dried over anhydrous potassium carbonate. Distillation gave 1.5 g. of a yellow oil, b. p. 161° (4 mm.). The product gave a quinoxaline derivative, m. p. 97–98°. Kohler and Barnes[7] report the boiling point of benzylphenyl diketone as 175° (8 mm.), and the melting point of the quinoxaline derivative as 97–98°. A mixed melting point of the quinoxaline derivative with that prepared by Kohler and Barnes showed no depression.

Decomposition of the Ozonide with Water.—The material from the ozonization of 19.2 g. (0.1 mole) of benzylphenylacetylene was extracted several times with hot water. Impure benzoic acid resulted on cooling and the acid was purified by crystallization from water. All aqueous residues were then extracted with ether in a continuous extractor for two hours. A total of 3.13 g. of mixed acids resulted; in order to effect a separation, the mixture was esterified in ether with diazomethane, and the mixture of esters distilled through a small, simplified Podbielniak-type column[8] (35 cm. long, 3 mm. internal diameter, containing a spiral of No. 28 platinum wire). This gave 0.94 g. of methyl benzoate, b. p. 72–73° (8 mm.), and 1.57 g. of methyl phenylacetate, b. p. 90–90.5° (8 mm.). Known methyl phenylacetate distilled through the same column at 89–90° (7.5 mm.). The recovery of pure, separated esters from the mixture of acids was 90%. The methyl phenylacetate from the ozonization had a refractive index of $n^{16}\text{D}$ 1.5102, compared with $n^{16}\text{D}$ 1.5100 for the sample prepared by standard methods (lit., $n^{16}\text{D}$ 1.5091). Both of these samples were converted to phenylacetamide by reaction with concentrated ammonium hydroxide. The melting point and mixed melting point was 159–160°. The total benzoic acid (including methyl benzoate) isolated from this ozonization was 7.3 g. (0.06 mole), a yield of 60%, assuming complete conversion of the acetylene to one mole of each acid. The phenylacetic acid recovered amounted to 0.01 mole (10% yield). The oily residue from the water extraction was not further examined.

Summary

From the decomposition of the products of ozonization of diphenylacetylene and benzylphenylacetylene, the corresponding 1,2-diketones have been isolated, as well as the expected acids.

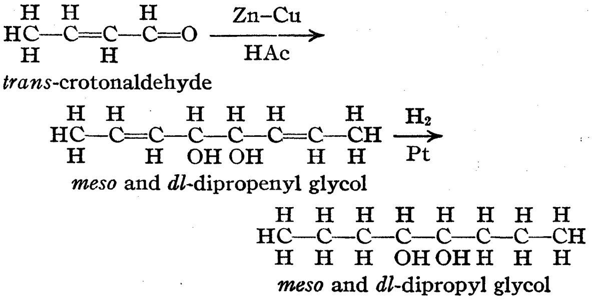
Investigations on the Stereoisomerism of Unsaturated Compounds. II. The Composition of Dipropenyl Glycol[1]

BY WILLIAM G. YOUNG, LEO LEVANAS AND ZENE JASAITIS

In continuing the study of methods of synthesis of pure isomers of the aliphatic polyene hydrocarbons of known configuration[2] it was important to know the composition of dipropenyl glycol. Since Kuhn and Rebel[3] reported that only one of the expected isomeric glycols was formed during the pinacolic reduction of aldehydes, we would expect that the reduction of *trans*-crotonaldehyde would produce only *dl*, *trans-trans*-dipropenyl glycol. However, if this were the case it would be difficult to explain the formation of two tetrabromides[4] or of two dimethylhexatrienes[5] from dipropenyl glycol. Since Kuhn and Rebel's method of oxidizing the dipropenyl glycol to racemic tartaric acid (by several steps) resulted in poor yields, they were not justified in concluding that only one stereoisomeric form was present in the original glycol. Accordingly, we reinvestigated the composition of dipropenyl glycol prepared by the pinacolic reduction of crotonaldehyde and reported[6] the formation and isolation of both *meso* and *dl*-dipropyl glycols from the catalytic reduction of dipropenyl glycol. The reactions involved were as follows



$$\underset{\text{H}}{\overset{\text{H}}{\text{HC}}}-\overset{\text{H}}{\text{C}}=\underset{\text{H}}{\text{C}}-\overset{\text{H}}{\text{C}}=\text{O}\xrightarrow[\text{HAc}]{\text{Zn–Cu}}$$

trans-crotonaldehyde

$$\underset{\text{H}}{\overset{\text{H}}{\text{HC}}}-\overset{\text{H}}{\text{C}}=\underset{\text{H}}{\overset{\text{H}}{\text{C}}}-\underset{\text{OH}}{\overset{\text{H}}{\text{C}}}-\underset{\text{OH}}{\overset{\text{H}}{\text{C}}}-\underset{\text{H}}{\text{C}}=\underset{\text{H}}{\overset{\text{H}}{\text{C}}}-\text{CH}\xrightarrow[\text{Pt}]{\text{H}_2}$$

meso and *dl*-dipropenyl glycol

$$\underset{\text{H}}{\overset{\text{H}}{\text{HC}}}-\underset{\text{H}}{\overset{\text{H}}{\text{C}}}-\underset{\text{H}}{\overset{\text{H}}{\text{C}}}-\underset{\text{OH}}{\overset{\text{H}}{\text{C}}}-\underset{\text{OH}}{\overset{\text{H}}{\text{C}}}-\underset{\text{H}}{\overset{\text{H}}{\text{C}}}-\underset{\text{H}}{\overset{\text{H}}{\text{C}}}-\text{CH}$$

meso and *dl*-dipropyl glycol

Contrary to the opinion expressed by Kuhn and Rebel,[3] several other investigators have clearly demonstrated that both *meso* and *dl* forms are produced by the pinacolic reduction of aldehydes. The duality of divinyl glycol has been established by separation into the *meso* and *dl* forms,[7] by hydrogenation to *meso* and *dl*-diethyl glycols[8] and by conversion into *dl*-mannitol[9] and allodulcitol.[10] The duality of dipropenyl glycol has also been conclusively established since our oral report[6] was made. Wiemann[11] treated the glycol with phenyl isocyanate and isolated a solid phenylurethan from which he recovered on hydrolysis *meso*-dipropenyl glycol, m. p. 48°. By catalytic reduction[12] of his dipropenyl glycol he obtained both the solid *meso*- and the liquid *dl*-dipropyl glycols which had been prepared from butyroin by Bouveault and Locquin[13] and identified by Veibel.[14]

Although the above-mentioned workers have established the fact that the pinacolic reduction of aldehydes gives both *meso*- and *dl*-glycols, they have not answered the important question which originally prompted the work on this subject. Kuhn and Rebel[3] had suggested that, from purely geometrical grounds, in such reactions there should be formed 25% each of the *d*- and *l*- and 50% of the *meso*-glycol. It is the purpose of this paper to show that in the case of the pinacolic reduction of crotonaldehyde, at least, the *meso*- and *dl*-glycols actually are formed in equal quan-

tities. This has been accomplished by determining the phase relationships existing between the *meso-* and *dl*-dipropyl glycols (Fig. 1) prepared from the dipropenyl glycol and by comparing the melting points of the bi-3,5-dinitrobenzoates prepared from the pure *meso-* and *dl*-dipropyl glycols and from various mixtures of these glycols (Table I). In this work the *dl*-dipropyl glycol, m. p. 28°, was obtained in a pure form for the first time.

Experimental Part

The Preparation of Dipropenyl Glycol.—Several kilograms of dipropenyl glycol were prepared by the reduction of 200-g. portions of *trans*-crotonaldehyde[2] in a dilute solution of acetic acid according to Charon's method.[4] Special care was exercised to prepare an active zinc–copper couple[15] and to keep the temperature of the reaction mixture between −5 and −10° during the reduction. After the reaction mixture was filtered to remove the zinc–copper residue, it was extracted 7–8 times with 250-ml. portions of ether to assure the removal of the constituents which absorb bromine. It was also advantageous to neutralize the ether extract with potassium carbonate before removing the solvent. A fractional distillation of the product through a 90-cm. Claisen-head column filled with glass rings and equipped with a Hopkins condenser gave the two main fractions: crotyl alcohol, b. p. 117–120° (15% of theoretical), and dipropenyl glycol b. p. (9 mm.) 113.4–114.4° (67%). These yields are similar to those reported by Charon[4] but contrary to those reported by Kuhn and Rebel.[3]

Fractional Distillation of Dipropenyl Glycol.—Several distillations of dipropenyl glycol, b. p. (9 mm.) 113.4–114.4°, d^{20}_4 0.9744, through the fractionating column described above, failed to produce any evidence of separation into *meso-* and *dl*-isomers. The failure to separate the isomers by distillation is not surprising, since Van Romberg and Van Hasselt[7] have shown that in the case of the closely related *meso-* and *dl*-divinyl glycols the isomers possess the same boiling point.

Catalytic Hydrogenation of Dipropenyl Glycol and the Isolation of *meso-* and *dl*-Dipropyl Glycols.—Freshly distilled dipropenyl glycol (72 g.) was reduced with the aid of a platinum catalyst[16] in 200 ml. of 95% ethanol. The solvent was removed through a Hempel column and the mushy residue, m. p. 20–90°, was filtered. The solid portion after recrystallization from petroleum ether was found to be *meso*-dipropyl glycol, m. p. 123.5–124.5°.

Anal. Calcd. for $C_8H_{18}O_2$: C, 65.69; H, 12.42. Found: C, 65.67; H, 12.41.

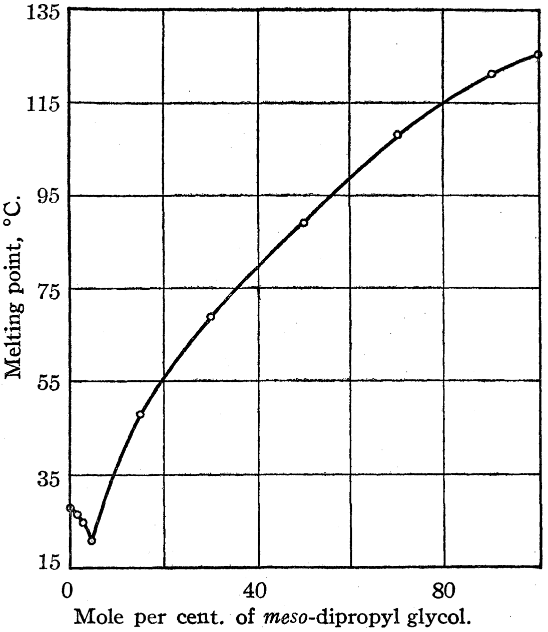

Fig. 1.—The melting point diagram of the system *meso-dl*-dipropyl glycols.

The filtrate was then fractionally distilled several times through the column described above. A fraction (1), b. p. (9.5 mm.) 110–111°, was obtained which was thought to be the pure *dl*-isomer. When a cooling curve was made the liquid supercooled easily due to its high viscosity but when seeded it solidified at 20.0–20.5°. The temperature remained constant for several hours when the bath temperature was held slightly above or below 20°, the only difference being in the quantity of crystals present in the mixture. However, when some of this fraction was converted into the bi-3,5-dinitrobenzoate, the product melted over a range indicating that the glycol fraction might not be a pure product, as suggested by the melting point. Consequently, a cooling curve was made using another fraction (3) which had some solid *meso*-glycol present even at 43°. As the mixture was cooled the quantity of solid increased until the temperature reached 15°. At this point a sudden evolution of heat occurred, the temperature rose to 20.0–20.5°, and the mixture solidified completely. The most likely explanation of this result is that 20.0–20.5° is the eutectic temperature for the system *dl-* and *meso*-dipropyl glycol. The *dl*-component failed to form when the eutectic temperature was reached, causing a metastable condition to exist, but as soon as some of the *dl*-component was formed an equilibrium was established immediately at the eutectic temperature. Fraction 1 was therefore subjected to several more fractional distillations until the main fraction had the same melting point after two consecutive distillations. This fraction was *dl*-dipropyl glycol, b. p. (9 mm.) 109.8–110°, m. p. 28°.

Anal. Calcd. for $C_8H_{18}O_2$: C, 65.67; H, 12.42. Found: C, 65.59; H, 12.43; $n^{24.5}_D$ 1.4419.

In a series of experiments the yield of *meso*-glycol was approximately 95% of that expected if the dipropenyl glycol contained equal quantities of *meso-* and *dl*-forms. The

(15) The zinc–copper couple was prepared by the method of Gladstone and Tribe, *J. Chem. Soc.*, **31**, 561 (1877), except that the copper sulfate solution was added to 80-mesh zinc in smaller portions and the reaction mixture was allowed to become decolorized completely before another portion was added. Although the yields of glycol decreased 10–15% if the sulfate solution were added in too large portions, nevertheless, we never obtained yields as low as those reported by Kuhn and Rebel.[3]

(16) Adams, Voorhees and Shriner, "Organic Syntheses," John Wiley and Sons, Inc., New York City, Vol. VIII, 1928, p. 92.

yield of *dl*-isomer was about 10% lower than the *meso*-form due to unavoidable losses during the many fractionations.

Analysis of Mixtures of the Dipropyl Glycols by Conversion into 3,5-Dinitrobenzoates.—In order to follow the degree of separation of the dipropyl glycols during the fractional distillation of large batches of material, it was desirable to have a convenient method of analysis. The preparation of the bi-3,5-dinitrobenzoates proved satisfactory for this purpose. It was found that 3,5-dinitrobenzoic acid, its acid chloride and the mono-ester of the glycols were all fairly soluble in a mixture of alcohol and nitrobenzene, while the di-esters of both glycols were insoluble. It was therefore possible to recrystallize the di-esters made from glycol mixtures without changing their composition. The crude esters were prepared from 0.3 g. of the glycol, 6 ml. of dry pyridine, and 1.2 g. of 3,5-dinitrobenzoyl chloride in the usual manner. The crude product thus obtained was dissolved in 4–5 ml. of warm nitrobenzene and then 40–50 ml. of alcohol was very slowly added to ensure the formation of crystals instead of oil. The product was finally filtered, washed with cold alcohol and dried in a vacuum desiccator; yield, 90–95% of theoretical based on the di-ester. Bi-3,5-dinitrobenzoate from *meso*-dipropyl glycol, m. p. 200.3–200.4°.

Anal. Calcd. for $C_{22}H_{22}O_{12}N_4$: C, 49.42; H, 4.15; N, 10.49; mol. wt., 530. Found: C, 49.40; H, 4.10; N, 10.69; mol. wt., 540 (in nitrobenzene). Bi-3,5-dinitrobenzoate from *dl*-dipropyl glycol, m. p. 125–125.3°. *Anal.* Found: C, 49.58; H, 4.21; N, 10.59; mol. wt. 538 (in nitrobenzene). The melting points of esters made from known mixtures and from the original mixture of dipropyl glycols are given in Table I. It will be seen that the eutectic mixture contains about 4.5% *meso*-glycol and the original mixture 50% *meso*-glycol.

The Melting Point Diagram for the System *meso-dl*-Dipropyl Glycol.—In view of the fact that distillation methods did not give a satisfactory estimate of the composition of the dipropyl glycol mixture obtained from the catalytic reduction of dipropenyl glycol, it was necessary to construct a melting point diagram for the system *meso-dl*-dipropyl glycol. The eutectic temperature for mixtures of *meso* and *dl*-dipropyl glycols was determined by the Beckmann method on ten different mixtures of glycols. The average value for these runs was 20.7 ± 0.5°. Due to the extreme viscosity of the glycol mixtures and since the Beckmann method is subject to more or less error,[17] the remaining data were obtained by the melting point method. Known mixtures of *dl*- and *meso*-dipropyl glycols were sealed in small tubes which were heated slowly in a water-bath under constant agitation. The temperature at which the last particle of solid disappeared was recorded as the melting point. The temperature of the bath was raised slowly (never faster than 1° in five to ten minutes) and all melting points were duplicated with at least two different tubes. In all mixtures richer in *meso* than the eutectic, the solid phase in equilibrium with the liquid was found to be the *meso*-isomer. The results are recorded in Fig. 1. The composition of the eutectic mixture was found to be about 5% *meso*- and 95% *dl*-dipropyl glycol. The composition of the crude glycol mixture obtained from the reduction of dipropenyl glycol proved to be 50% *meso* and 50% *dl* since the final melting point of this mixture was 90°. It may therefore be concluded that the pinacolic reduction of crotonaldehyde gives equal quantities of *meso*- and *dl*-dipropenyl glycol.

The authors are indebted to Mr. Harold Milner, of the Division of Plant Biology of the Carnegie Institution of Washington, for the micro-analysis of *meso*-dipropyl glycol and to Drs. G. Ross Robertson and J. B. Ramsey for their helpful suggestions.

Summary

Dipropenyl glycol obtained from the pinacolic reduction of crotonaldehyde has been found to contain equal quantities of the *meso*- and *dl*-glycols.

Pure *dl*-dipropyl glycol and the bi-3,5-dinitrobenzoates of both *meso*- and *dl*-dipropyl glycols have been prepared for the first time.

The melting point diagram of the system *meso-dl*-dipropyl glycol is given.

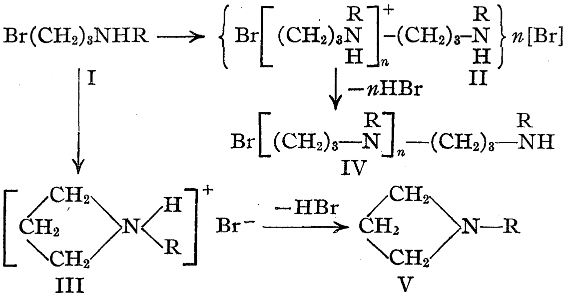
Ammonium Salts from Bromopropylamines. VI. Salts of Polymeric Tertiary Amines[1]

BY JOHN CHARLES COWAN AND C. S. MARVEL

Previous work in this Laboratory has shown that halogenated tertiary amines of the type $Br(CH_2)_nNR_2$ undergo self-condensation intermolecularly or intramolecularly to give polymeric or cyclic quaternary ammonium salts, depending on the numerical value of n and the nature of the R group. The work described in this communication was undertaken in order to learn whether linear polymeric or cyclic tertiary amines would be obtained by a similar self-condensation of halogenated secondary amines.

It should be noted that halogenated secondary amines may be expected to give far more complex products than were obtained from related halogenated tertiary amines. For, whereas the latter give stable quaternary ammonium salts, the former give tertiary amine salts which may react further with unchanged bromoamine. On the basis of our earlier work, bromopropylalkylamines (I) would be expected to condense intermolecularly to give long-chain polymeric compounds (II), or with certain R groups to form monomeric cyclic salts (III) containing a four-membered ring. In the presence of an excess of the bromoalkylamine, these products might be expected to undergo double decomposition reactions to yield the hydrobromide salt of the simple bromoamine and the free polymeric (IV) or cyclic (V) tertiary amine, which then would react further with the bromoalkylamine to give quaternary ammonium salts of very complex type.



Our experiments have shown that when a free bromoalkylamine of type I in which R is methyl, ethyl, n-propyl, n-butyl or isobutyl is allowed to stand at room temperature in concentrated solution, the polymerization reaction occurs fairly smoothly, and is accompanied by few side reactions. However, in dilute solution, the products become very complex, due to the occurrence of secondary reactions, the exact nature of which has not as yet been elucidated. This observation is in accordance with the views which Salomon[2] has recently expressed in connection with rates of reactions of primary amines containing a haloalkyl group.

The polymers which are formed by the intermolecular condensation reactions vary greatly in size, depending on the size of the R group. In Table I are given the calculated values for the number of monomeric units in and the molecular weights of the various polymeric tertiary amine salts which have been prepared. The values for the number of monomeric units ($n + 1$) in the polymers were calculated from the formula

$$\frac{n}{n+1} = \frac{\%\text{ ionic halogen}}{\%\text{ total halogen}}.$$

Since in a few cases the percentage of total halogen which we found in a polymer was lower than the theoretical value, we have used the theoretical value for total halogen in our calculations. It seems probable that any loss of halogen must be from the alkyl halide end-group, and not from the ionic fraction of the halogen.

TABLE I

MOLECULAR WEIGHTS OF POLYMERIC TERTIARY AMINE SALTS

$Br\{[(CH_2)_3NRH]_n{}^+(CH_2)_3NHR\}n[Br]^-$

R	$n + 1$	Approximate mol. wt.
CH_3	71–100	10800–15200
C_2H_5	22–23	3650–3820
n-C_3H_7	16–17	2880–3060
n-C_4H_9	20–21	3900–4100
i-C_4H_9	7–8	1350–1550

The polymeric salt from bromopropylmethylamine was treated with silver oxide to give the free base, which proved to be a viscous, semisolid, hygroscopic material. In 0.1 N solution, it gave a pH of approximately 9.3, indicating that it is a tertiary amine, and that it does not contain quaternary ammonium groups.

[a] Chlorine in the hydrochloride was determined in this case. The hydrochloride melted at 155–156°.

The bromoalkylamines were prepared from phenoxypropylalkylamines by cleavage with hydrobromic acid by the general methods which have been described previously[3] for related compounds.

Experimental Part

γ-Phenoxypropylalkylamines.—The phenoxypropylamines were prepared by adding four times the theoretical amount of an alcoholic solution of the appropriate primary amine to γ-phenoxypropyl bromide and allowing the solution to stand for about twenty-four hours until reaction was complete. The alcohol and excess amine were removed by distillation from a steam-bath, and the residue was treated with a 25% aqueous solution of sodium hydroxide. The phenoxypropylamine was collected in ether, the ether removed and the amine distilled under reduced pressure. For analysis, the amines were converted to the hydrobromides, and ionic halogen was determined by direct titration with silver nitrate. The amines thus prepared are described in Table II.

γ-Bromopropylalkylamine Hydrobromides.—The γ-phenoxypropylamines were cleaved with hot 48% hydrobromic acid solution by the procedure used in previous work.[3] The best results were obtained when these cleavage reactions were carried out in an oil-bath held at 137–142°. The distillate was tested with bromine water from time to time, and when no phenol was distilling, the reaction was complete. The reaction mixture was diluted with water and evaporated under reduced pressure. The residue was again dissolved in water and evaporated under reduced pressure to remove the excess hydrogen bromide. If the distillate at this point was not neutral to methyl orange, this process was repeated. The dry residue, free from excess hydrogen bromide, was dissolved in absolute alcohol (dried with magnesium methylate[4]) and treated with Norite until the filtered solution was pale amber or yellow. After removal of the Norite, a part of the alcohol was distilled off under reduced pressure and a large excess of dry ether was added to the remaining solution. In some cases, the bromoamine hydrobromides precipitated at once; in other cases, the salts came out on standing. For analysis the salts were recrystallized by taking up in alcohol and precipitating with ether until no change in melting point was observed on repeating the purification. Less highly purified salts were used for conversion into polymers. The properties of the bromoamine hydrobromides are listed in Table III.

[a] Bloc Maquenne.

Polymeric Tertiary Amine Salts.—Each of the free γ-bromopropylalkylamines in which the alkyl group was methyl, ethyl and n-propyl, respectively, was obtained by treating the crude hydrobromide with 50% sodium hydroxide solution and then distilling the free bromoamine from the reaction mixture under reduced pressure. The amines thus obtained contained some water, and they were allowed to polymerize without drying. The n-butyl and isobutyl derivatives polymerized very rapidly at the temperatures at which they distilled. Hence, in these cases the free amines were obtained by treating the salts with 25% sodium hydroxide solution at about 0°, and then extracting the amine with ether. About 15 cc. of 95% alcohol was added to the ether extract and then the solution was evaporated to 10–15 cc. Titration indicated that this gave 1.5–2 molal solutions of the bromoamine. On standing for two or three days, these bromoamines polymerized.

All of the polymeric amine salts were colorless to light amber, sticky, hygroscopic solids. The experiments are summarized in Table IV.

In dilute solution the products of polymerization were complex, and the nature of the physical properties precluded the possibility of crystallizing and separating the substances which were formed. A solution of 5 g. of γ-bromopropylethylamine was treated with an excess of cold (0°) 25% sodium hydroxide solution, and the free amine was taken up in ether and diluted to 145 cc. Titration with standard acid showed that this ether solution was 0.14 molar. This dilute solution was allowed to stand for three days at room temperature. Then the ether was removed and the residue dried over phosphorus pentoxide at 100° under reduced pressure. This crude mixture contained 51.66% bromine, but the bromide ion was only 45.45%. When this product was taken up in absolute alcohol and

precipitated with dry ether, the total bromine remained approximately constant at 51.96%, but the bromide ion fell to 43.38%. Further attempts to purify the mixture did not lead to any definite product.

A sample of the free polymeric tertiary amine was prepared from the polymeric salt obtained from γ-bromopropylmethylamine. The salt used in this experiment contained 50.3% bromine, and 49.07% bromide ion. A solution of 5 g. of this salt in water was treated with an excess of silver oxide, and then the solution was filtered. The filtrate was again treated with silver oxide to ensure complete removal of bromide ion. The mixture was centrifuged and the liquid filtered. The water was then removed under reduced pressure at room temperature (about 25°). The residue was an amber-colored, viscous, sticky, hygroscopic solid. This material still contained bromine which would react slowly with alcoholic silver nitrate. The water solution of the free polymer was tested with thymolphthalein, and showed a *p*H of about 9.3. This is slightly less basic than an aqueous solution of trimethylamine, showing that the polymer did not carry quaternary ammonium hydroxide groups. The polymeric amine could not be purified by reprecipitation, and the analysis was not especially significant.

Anal. Calcd. for $(C_4H_{10}N)_x$: N, 19.44. Found: N, 15.98.

Summary

γ-Bromopropylalkylamines in concentrated solution react intermolecularly to produce polymeric tertiary amine salts. The molecular weight of the linear polymeric salt is dependent on the alkyl group attached to the nitrogen atom, being about 10,000–15,200 when R is methyl, and falling to about 1350–1550 when R is isobutyl.

The Extraction of Europium from Monazite Residues and the Preparation of Pure Europium Compounds

BY HERBERT N. MCCOY

The method of separation of europium from other rare earths by reduction with zinc and precipitation as europous sulfate has been described in a preliminary note.[1] An account of further studies of some of the properties of europous salts is given in a later paper.[2]

The extraction of europium has now been carried out on a larger scale so that a more detailed description of the process of refinement can be given. In the earliest experiments, the starting material had been subjected to long-continued fractional crystallization as double magnesium nitrates in the presence of bismuth nitrate. It contained little besides samarium, europium and gadolinium. For this material, reduction in a Jones reductor two or three times repeated sufficed to give a pure product.[1]

When, later, material less rich in europium was used, it was found that modification of the process gave better recoveries of the desired element. Instead of running the rare earth solution through a reductor, it was found more expedient with low grade material to add zinc dust to the solution along with magnesium sulfate. It was also found that the addition of barium chloride as suggested by Selwood[3] for use in the electrolytic separation of europium was helpful in giving increased yields. The subsequent purification of the enriched europium concentrates so obtained was carried out in a large reductor as will be described later.

After europium had been extracted successfully from 12 to 15 lots of material varying in amounts from 20 g. to several kilograms and of varying degrees of richness, the separation of the europium

content of 386 kg. of rare earth oxalate was undertaken. This material was accumulated during several years as the residue from the technical production of La, Ce, Pr and Nd from Monazite sand from Travancore, India. The large scale operations were carried out in the works of the Lindsay Light and Chemical Co., Chicago.[4]

As the rare earths had been precipitated once as double sodium sulfates, the material doubtless contained but little ytterbium and lutecium, the compounds of which are easily soluble in a solution of sodium sulfate. The material had been freed from all but traces of cerium and thorium. Lanthanum, praseodymium and neodymium had been separated by systematic fractional crystallization of the double magnesium nitrates. The final mother liquors were precipitated with oxalic acid.

The material consisted essentially of the oxalates of Nd, Sa, Eu, Gd, Tb, Dy, Ho, Y and Er, in which the salts of Sa and Gd predominated. The europium oxalate content amounted to about 0.5%. Small amounts of thorium and lead were also present. The material was in the form of a light buff powder.

The 386 kg. of oxalates were boiled in an iron tank, fitted with a stirrer, with 210 kg. of caustic potash and about 1500 liters of water for about an hour, and filtered and washed in an iron suction filter. The hydroxides which resulted were dissolved in hydrochloric acid in a wooden tank to give 1070 liters of chloride solution of density 1.20. The solution settled clear, leaving but a very small residue which was discarded. It was but slightly acid to congo paper.

The chloride solution was reduced in 140-liter portions in a 210-liter stoneware jar, fitted with a cover and stirred vigorously by a 0.25 h. p. motor with stainless steel shaft and propeller.

In making a reduction there was added to the 140 liters of solution, 4 kg. of magnesium sulfate, 0.5 liter of glacial acetic acid and 0.65 kg. of zinc dust. The reduction began at once as was shown by the bleaching of litmus paper. To minimize reoxidation by air, the latter was displaced by a stream of carbon dioxide run into the jar. During the reduction, which required about five hours, a solution of 1 kg. of barium chloride in 20 liters of water was run in slowly. The reaction was judged to be finished when litmus was no longer bleached. The stirring was then stopped and the solution allowed to settle. The residue consisted largely of excess zinc, barium sulfate and europium sulfate, together with considerable rare earths. Usually the solution did not settle clear and had to be filtered. In such case the filter cake was returned to the jar. The reduction and filtration required the working time of one day.

To the whole of the residue left in the jar was added 140 liters of fresh rare-earth chloride solution, together with magnesium sulfate, acetic acid and zinc dust in amounts the same as for the first reduction and the process continuously repeated until, after eight runs, the whole of the solution had been worked up.

The accumulated residue was finally filtered and washed. It was a dark colored mass of high density. The wet cake weighed about 30 kg. It was returned to the jar in which it had been made, and covered with 170 liters of water, 1 kg. of sodium chlorate dissolved in a little water was added, followed by 15 liters of concentrated hydrochloric acid. A vigorous reaction took place as the remaining zinc dust dissolved. At the same time part of the europous sulfate was oxidized and passed into solution. The residue was now pure white. The solution settled clear overnight. The clear solution was drawn off and the rare earths precipitated by adding oxalic acid.[5]

The barium sulfate residue still contained much europous sulfate which was extracted by repeated treatments with hydrochloric acid and sodium chlorate in hot dilute solution. For 140 liters of water 14 liters of concentrated hydrochloric acid and 0.5 kg. of sodium chlorate were used. Each solution after it had settled was drawn off and treated with oxalic acid. A total of five extractions was made and 9 kg. of oxalic acid was used, giving 16 kg. of moist white oxalates.[6]

The oxalates so obtained were converted into hydroxides in a 175-liter glass-lined steam-jacketed kettle where they were boiled with 10 kg. of potassium hydroxide. The washed hydroxides after being dried weighed 7.2 kg. In all the large scale operations only technical grades of chemicals and ordinary water were used.

The dry hydroxides were now shipped to the laboratory for further treatment. They were still quite impure. An analysis[2] showed about 20% of the whole to be europium hydroxide. The remainder consisted of the same rare earths and other impurities as were contained in the original oxalates. The 7.2 kg. of hydroxides was dissolved in 7.5 liters of concentrated c. p. hydrochloric acid, diluted with water. The solution had a density of 1.27. It was filtered from a small residue. The chloride solution contained a small percentage of lead, which had to be removed in order to avoid trouble in the next operation. This was done by stirring with about 100 g. of amalgamated zinc. The europous salt first formed reacts with the lead chloride to give a black colloidal solution of metallic lead.

$$2EuCl_2 + PbCl_2 \longrightarrow 2EuCl_3 + Pb$$

The latter coagulates slowly, but after two days it could be filtered clear by the aid of filter-cel. The filtered solution contained but a trace of lead.

The solution was now ready for reduction. The reductor consisted of a 1-liter percolator holding 3.5 kg. of

[4] In this plant work I enjoyed the helpful and efficient coöperation of Mr. Mark W. Eichelberger, secretary and superintendent of the Company, to whom I wish to express my warmest thanks. Mr. Sterling Nails also assisted materially.

(5) Zinc can be precipitated as oxalate, but if the solution contains sufficient acid it does not come down nearly as readily as do rare-earth oxalates. By filtering promptly a separation may be made.

(6) The difficulty in extracting the europium is due to the fact that europic sulfate is the least soluble of the rare-earth sulfates [Jackson and Reinacker, *J. Chem. Soc.*, 1687 (1930)] and is much less soluble hot than cold. Hot water was used to facilitate oxidation.

amalgamated, C. P., 10-mesh zinc. The receiving vessel was a 4-liter wide-mouthed bottle. Into it was put a liter of a hot solution containing 400 g. of magnesium sulfate and 50 ml. of 6 *N* sulfuric acid. The exit tube of the reductor (with rubber tubing connector and screw clamp) reached nearly to the bottom of the receiving bottle. The bottle was closed with a cardboard cap having a hole for the tube. In this case no carbon dioxide or barium chloride was used.

It was found that a hot acidulated magnesium sulfate solution gave rise to the β-form of europous sulfate,[2] rather than the α-form. This is desirable as the former is less soluble and much denser than the latter. Two receiving bottles were used alternately.

The charge in a receiver was sufficient for 1.5 liters of rare earth solution of density 1.27. A precipitate of europous sulfate forms as the first drop of reduced solution enters the bottle. The rate of flow of solution is such that 1.5 liters are reduced in about forty minutes. The solution settles clear in about an hour longer. The precipitated europous sulfate is very dense and occupies but a small volume. While the first run is settling another 1.5-liter lot of chloride solution is run through the reductor into the alternate receiver charged with magnesium sulfate solution and sulfuric acid as before. The process was thus continued until the whole solution was converted into europous sulfate.

The accumulated filtrates from the process were saved to be again reworked for the small amount of europium they contained. The reduction of the europium by zinc is probably complete, $2EuCl_3 + Zn \longrightarrow 2EuCl_2 + ZnCl_2$, but apparently a small amount (about 1%) is reoxidized before it reacts to form sulfate. The amount is so small that it scarcely pays to try to prevent the re-oxidation.

The europous sulfate is filtered and the cream of wet sulfate poured into a boiling solution of sodium carbonate and sodium hydroxide. The amount of europous sulfate resulting from one run of 1.5 liters of rare earth solution—about 200 g. of moist filter cake—requires 80 g. of sodium carbonate, 15 g. of sodium hydroxide and 1.5 liters of water. It quickly turns light greenish-yellow when boiled due to change into europous carbonate. After ten minutes of boiling it is washed three times by decantation, filtered and washed free of sulfate with hot water. The carbonate is granular and very dense.

When it is dissolved in hydrochloric acid, a light yellow solution of the europous chloride is formed. Considerable other rare earths, as well as thorium, aluminum and perhaps other weak bases are present. If lead is present the solution will be dark and cloudy. Its purity may be 65 to 70%. It is now oxidized at the boiling point by 8 or 10 ml. of 6 *N* nitric acid.[7]

The nearly colorless oxidized solution is next freed from weak bases by neutralizing it (to congo paper) with basic magnesium carbonate, adding 10 g. of magnesium acetate, and boiling it for a few minutes. The rather heavy precipitate (42 g. wet, in one case) containing but a trace of europium is filtered out. To remove remaining rare earths, the crude europium trichloride is again run through the reductor, precipitated as europous sulfate with 160 g. of magnesium sulfate and 8 g. of sulfuric acid, the sulfate converted into carbonate, the latter dissolved in hydrochloric acid, and the whole process repeated several times. Re-oxidation of the europous chloride solution with nitric acid before running it through the reductor is unnecessary.

After the eighth precipitation as europium sulfate no further rare earths were recoverable from the filtrate, and the solution of europium trichloride resulting showed no absorption bands of other earths. It was again reduced and precipitated as sulfate. This was washed finally with methyl alcohol. The yield was 88 g. of dry europous sulfate. Upon analysis, a portion dried in the oven at 100° and titrated with 0.04 *N* permanganate[2] showed a purity of 99.7%.

Another lot, made from 1.5 liters of chloride solution of 20% purity, was treated similarly excepting but six precipitations as sulfate were made. The product, 104 g., titrated with standard permanganate, showed a purity of 96.6%. About a week's time is sufficient to prepare approximately 100 g. of pure europous sulfate from the 1.5 liters of chloride solution resulting from 0.5 kg. of crude hydroxide of 20% purity.

Summary

1. A process is described for the extraction of europium from rare earth residues from monazite by reduction of this element to the bivalent state with zinc and subsequent separation as insoluble europous sulfate.

2. Pure europium compounds have been prepared by several repetitions of these reactions.

The System Nickel Oxalate, Potassium Oxalate and Water at 30°

BY W. C. VOSBURGH, KATE ISRAEL AND OLIVE G. BIRCH

A complex oxalate with the formula $K_2Ni(C_2O_4)_2 \cdot 6H_2O$ was reported by Rammelsberg,[1] and an analogous sodium salt, $Na_2Ni(C_2O_4)_2 \cdot 8H_2O$, by Dodson,[2] but no satisfactory study of the system nickel oxalate, potassium oxalate and water by the phase rule method seems to have been made. Deakin, Scott and Steele[3] made some determinations of the solubility of nickel oxalate in potassium oxalate solutions. They found the approach to equilibrium very slow, and obtained evidence of the formation of solid solutions of nickel and potassium oxalates.

Experimental.—Nickel sulfate was treated to remove cobalt by the method used by Deakin, Scott and Steele.[3] Potassium oxalate was recrystallized. Nickel oxalate was prepared by adding a solution of nickel sulfate to a solution of oxalic acid at a slow rate with mechanical stirring. Samples of the complex salt were prepared by dissolving nickel oxalate in saturated potassium oxalate solutions at an elevated temperature, filtering and allowing to crystallize at room temperature.

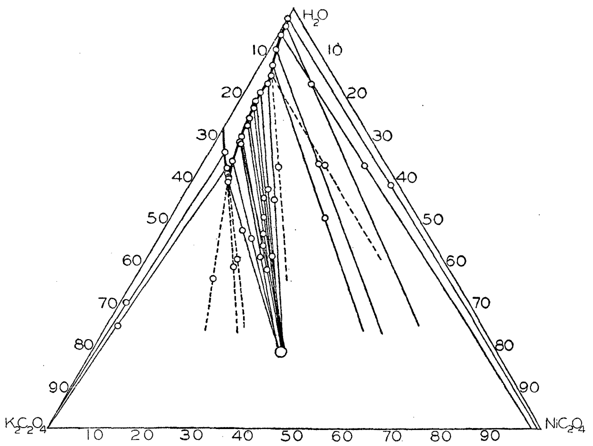

Fig. 1.—The system nickel oxalate, potassium oxalate and water at 30°. The large circle represents the theoretical composition of the compound $K_2Ni(C_2O_4)_2 \cdot 4H_2O$.

The experiments consisted in solubility determinations in which both the saturated solutions and wet solid phases were analyzed. The procedure was essentially as described in a previous paper[4] except as mentioned below. For solutions containing more than 12.4% of potassium oxalate, the samples were prepared as follows. A portion of either nickel oxalate or the complex salt was dissolved completely in a potassium oxalate solution by heating. The solution was allowed to cool in the Pyrex tube in which the sample was to be brought to equilibrium. In some of the experiments seeds were added. Seeding was found desirable, as otherwise erratic results were frequent. The excess complex salt was allowed to crystallize while the tube was rotated mechanically. The crystals were slow in forming, even after seeding. All samples were rotated for at least a week and some for much longer times. When the right solid phase was present, a week's rotation undoubtedly was sufficient, as the results were independent of the time of rotation.

For the more dilute potassium oxalate solutions (less than 12.4% potassium oxalate) the solid phase was nickel oxalate prepared either as described above or by slow addition of a nickel sulfate solution to a large excess of a potassium oxalate solution. Samples prepared by the second method were brought to equilibrium with solutions of about the same concentration as those from which they had been precipitated. The nickel oxalate was not dissolved completely and reprecipitated as in the more concentrated solutions.

The temperature was maintained at 30 ± 0.1° for at least a day previous to sampling, in either an oil-bath or an air-bath.

In the analysis of the samples,[5] the oxalate content was determined by titration with permanganate and the nickel content either by means of dimethylglyoxime or by cyanide titration.[6] Both methods for nickel were checked by the analysis of known samples to which potassium oxalate had been added. For some of the samples it was found necessary to evaporate to fumes with sulfuric acid to destroy the oxalate before titration with cyanide. The results are given in Table I and Fig. 1. In the fifth column of Table I the letter A represents solid solutions of nickel oxalate and potassium oxalate, B the complex salt, $K_2Ni(C_2O_4)_2 \cdot xH_2O$, and C potassium oxalate, possibly containing nickel oxalate in solid solution. In Fig. 1 the larger circle represents the theoretical composition of the compound $K_2Ni(C_2O_4)_2 \cdot 4H_2O$.

In the last column of Table I are given values for the percentage of water in the complex salt, calculated by algebraic extrapolation on the assumption of the formula $K_2Ni(C_2O_4)_2 \cdot xH_2O$. The theoretical value for $x = 4$ is 18.7% water and that for $x = 6$ is 25.7%. The results may be divided roughly into two groups, one indicating four and the other six molecules of water. In nearly all of the results that indicate six molecules, the percentage of nickel oxalate in solution is a little larger than that in comparable results indi-

cating four molecules. This suggests that the solid phases having the larger percentages of water were metastable and leads to the conclusion that the stable solid phase at 30° is the tetrahydrate. However, the variability in the calculated percentage of water could have been caused by a small variation in the ratio of nickel oxalate to potassium oxalate in the solid phase, and the conclusion as to the amount of water in the dry solid is uncertain.

In the experiments corresponding to the two tie-lines that approach the nickel oxalate corner of Fig. 1, the solid phase introduced was nickel oxalate prepared from nickel sulfate and oxalic acid. Since nickel oxalate is a hydrated salt, the direction of the lines indicates the presence of potassium oxalate in the solid phase, probably in solid solution. Other similar experiments gave similar results. The time allowed was insufficient for the establishment of equilibrium in the solid phases in these experiments.

Samples of nickel oxalate precipitated from potassium oxalate solutions were contaminated with potassium oxalate, the amount of contamination varying with the concentration of the solution. Portions of these precipitates were washed with water, dried at 110° and analyzed. The results are given in Table II.

TABLE II

COMPOSITION OF NICKEL OXALATE PRECIPITATED FROM POTASSIUM OXALATE SOLUTIONS

$K_2C_2O_4$, concn., %	[a]	3	5	7	10
Ni in ppt., %	31.83	29.37	26.74	23.44	20.26
C_2O_4 in ppt., %	46.67	47.88	49.20	50.80	51.50

[a] Precipitated from oxalic acid solution.

The conclusion of Deakin, Scott and Steele that solid solutions are formed of potassium oxalate in nickel oxalate is confirmed.

Summary

Solid solutions of nickel oxalate and potassium oxalate can exist in equilibrium at 30° with aqueous solutions containing less than 12.5% of potassium oxalate and saturated with the nickel salt. From 12.5% to saturation with potassium oxalate the stable solid phase is the complex salt $K_2Ni(C_2O_4)_2 \cdot xH_2O$ in which x is probably four.

Electrolysis of Methylmagnesium Iodide in *n*-Butyl Ether

BY WARD V. EVANS AND EDMUND FIELD

The electrolysis of the methyl Grignard reagents in ether solution has been studied[1] thoroughly for the three halides in ethyl ether using bright platinum electrodes. The products of the electrolyses in ethyl ether pointed definitely to the fact that the solvent played an important role. The ether appeared to be directly responsible for the ethylene, ethyl alcohol and isopropyl alcohol found, as a result of decomposition after the loss of a hydrogen to a free methyl radical to form methane. In order to bear this out and investigate further the mechanism involved, an electrolysis was carried out using *n*-butyl ether as the solvent.

It was also shown previously that the ratio between the methane and ethane formed depended on the current density independent of the concentration of the solution. This fact drew attention to the function of the surface of the electrode in the electrolysis. With this in view the effect of platinizing the anode where the gases evolved was determined by performing another electrolysis in ethyl ether.

Experimental

The apparatus and procedure were the same as that previously described. For the experiment with a platinized anode a platinized electrode of identical size and shape, dried by washing in anhydrous ether, was slipped over the anode.

On attempting the electrolysis of methylmagnesium iodide in butyl ether it was found necessary to introduce a new variable, that of temperature. At 40° polarization was so great that 110 volts would pass a sustained current of only 0.005 ampere. On raising the temperature to 90° polarization was still pronounced, a current of 0.2 ampere passing initially, dropping off to 0.05 ampere in one minute. The composition of the gases evolving at 90° was determined so as to enable an estimation of the effect of temperature to be made. The temperature was then raised to 143°, at which the solution refluxed gently. Polarization was almost completely absent and currents approaching 0.5 ampere could be maintained. A series of current densities was used at this temperature.

Methane and ethane predominated in the gases and small and erratic amounts of carbon dioxide were obtained just as in ethyl ether. Ethylene, formerly present, was absent; butane and butene-1 (the absence of butene-2 was not definitely proved) were new products, proved by a Podbielniak distillation of the 5 liters of gas collected during the run not used for Orsat analyses. The absence of ethyl ether vapor made the absorption analysis simple. The presence of the three saturated gases made it necessary to assume the amount of butane present before the simple combustion analysis could give the ratio of methane to ethane. The purely arbitrary assumption was made that butane was present to one-half the extent of the butene because this reduced the observed variations in the combustion values under apparently identical conditions to a minimum. The analyses are shown in Table I, where the arbitrary value for butane is given as well as the observed and corrected values for *n* in the formula C_nH_{2n+2}. The corrected value of *n*, representing the methane and ethane only, was used to calculate the fraction of methyls coupled, *Fc*, which is shown plotted as curve 1, Fig. 1.

The efficiency of the electrolysis was 43.3% based on the change in basic magnesium determined by titration. This is much lower than in ethyl ether. On the basis of the gas evolved using the corrected analysis for ethane and making use of the previously demonstrated[1] equivalency of methyls evolved to Grignard decomposed, the efficiency was 42%. The excellent agreement confirmed the assumptions made.

When the electrolysis was completed the solution was hydrolyzed in a nitrogen atmosphere and fractionally distilled through a 75-cm. vacuum jacketed spiral coil column; 2.6 cc. (0.043 equivalent per faraday) of butanol-1 was isolated (b. p. 116–116.5°, 3,5-dinitrobenzoate m. p. 63.5–64° and confirmed by a mixed melting point). A small amount of pentanol-2 was also found present, estimated at 0.2 cc. The presence of a secondary alcohol was first proved by the $ZnCl_2 \cdot HCl$ reagent; fractional crystallization of the dinitrobenzoate followed by means of mixed melting points with the known pentanol-2 deriva-

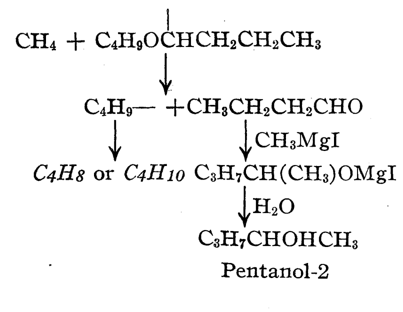
tive proved its presence. There was also found 5 cc. of high boiling liquid products.

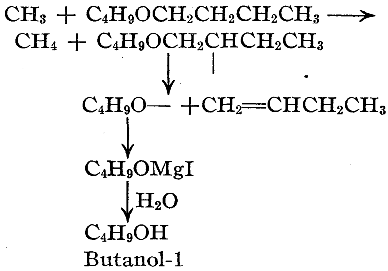
Decomposition of the Ether.—The products obtained were in excellent agreement with the mechanism proposed for the electrolysis in ethyl ether. Applied to the α- and β-hydrogens in butyl ether we have



$$\begin{array}{l} \mathrm{CH_3 + C_4H_9OCH_2CH_2CH_2CH_3 \longrightarrow} \\ \mathrm{CH_4 + C_4H_9O\overset{|}{C}HCH_2CH_2CH_3} \\ \qquad\qquad \downarrow \\ \mathrm{C_4H_9—\ + CH_3CH_2CH_2CHO} \\ \quad \downarrow \qquad\qquad \downarrow \mathrm{CH_3MgI} \\ C_4H_8 \text{ or } C_4H_{10} \ \mathrm{C_3H_7CH(CH_3)OMgI} \\ \qquad\qquad\qquad \downarrow \mathrm{H_2O} \\ \qquad\qquad \mathrm{C_3H_7CHOHCH_3} \end{array}$$

Pentanol-2

and



$$\begin{array}{l} \mathrm{CH_3 + C_4H_9OCH_2CH_2CH_2CH_3 \longrightarrow} \\ \mathrm{CH_4 + C_4H_9OCH_2\underset{|}{C}HCH_2CH_3} \\ \qquad\qquad \downarrow \\ \mathrm{C_4H_9O—\ + CH_2{=}CHCH_2CH_3} \\ \quad \downarrow \\ \mathrm{C_4H_9OMgI} \\ \quad \downarrow \mathrm{H_2O} \\ \mathrm{C_4H_9OH} \end{array}$$

Butanol-1

These two sets of reactions account for all the products identified and explain the absence of ethylene. There can be no question that the solvent furnishes the fourth hydrogen for the methane and that its subsequent decomposition is responsible for the secondary products formed.

The above mechanism applied to the other two kinds of hydrogen present in the ether molecule predicts products which were not found; this would seem to cast some doubt on the free radical mechanism and suggest another such as an ionic reaction. It is not necessary, however, to assume that these positions were not subject to attack, but merely that the intermediate radicals thus formed were stable enough to polymerize in some manner instead of breaking down, explaining the appreciable amount of high molecular weight liquid compounds obtained.

Fraction of Methyls Coupling.—The amount of coupling to form ethane was much lower in butyl ether than in ethyl ether, as is shown when curves I and II are compared with III and IV in Fig. 1. This indicates a greater rate of reaction of the butyl ether with the methyl radicals. Since this effect was obtained by changing both solvent and temperature, the individual effect of each remained to be determined. The two temperatures used showed that the coupling decreased as the temperature increased. An extrapolation down to the 40° used with ethyl ether by means of the Arrhenius equation gave a value for *Fc*, the fraction of methyls coupled, of 0.62; the observed value in ethyl ether at the same current density was 0.77. This may be interpreted to show that the loss of a hydrogen to a methyl radical takes place more readily in the case of butyl ether even at the same temperature. The slope of the line determined by the two points gave the low value of 1100 calories per mole for this reaction.

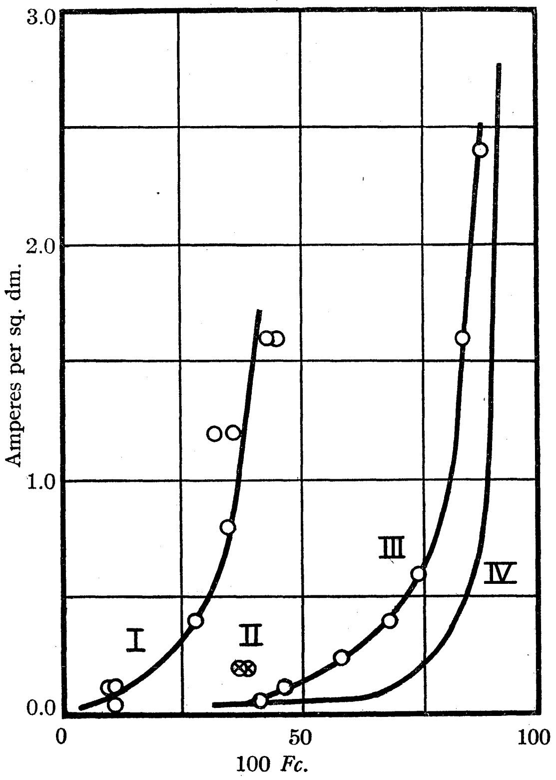


Fig. 1.—Effect of current density in electrolysis of methylmagnesium iodide: I, in butyl ether at 143°, bright electrodes; II, in butyl ether at 90°, bright electrodes; III, in ethyl ether, platinized anode; IV, in ethyl ether, bright electrodes.

Platinized Anode.—As was expected, the effect of platinizing the anode was a significant change in the methane–ethane ratio. The results are given in Table II. The perfect agreement between the first and eighth sample taken was good evidence that the platinized electrode was unchanged during the course of the electrolysis. One and one-half liters of gas was evolved before samples were taken in order to allow the electrode surface an opportunity to come to equilibrium.

The efficiency of electrolysis was entirely unaffected by platinizing the anode since an interpolation to the same concentration on our previously determined curve[1] also gives an efficiency of 76%. *Fc* showed the same dependence on current density as with bright electrodes, but is somewhat lower as may be seen in curves III and IV, Fig. 1. The platinizing seemed merely to cut down the apparent current density by exactly 5 in comparison with the bright electrode throughout the whole range studied. Evidently platinizing the anode served to increase its effective area by five so that the effective current density was decreased by that amount. Apparently the electrode merely provides an inert surface on which the reactions take place.

Summary

1. The theory that the solvent ether furnished the fourth hydrogen for the formation of the methane, with subsequent decomposition to give the secondary liquid and gaseous products found, was confirmed.

2. Butyl ether was more readily attacked by methyl radicals than was ethyl ether.

3. Increase in temperature favored the reaction with the solvent, increasing the proportion of methane.

4. The electrolysis efficiency was much less in butyl than in ethyl ether.

5. Platinizing the anode had no effect other than to increase the effective area by exactly five, with a resultant decrease in effective current density by that factor.

The Effect of Ortho Substitution on the Absorption of the OH Group of Phenol in the Infrared[1]

BY OLIVER R. WULF, URNER LIDDEL AND STERLING B. HENDRICKS

Infra-red absorption that is characteristic of the presence of NH and OH groups in organic molecules exhibits in general a dependence upon the character of the rest of the molecule, particularly upon that of neighboring groups.[2] In the present researches the spectra of such molecules are being measured quantitatively, giving the results as curves of the molal absorption coefficient against position in the spectrum. This dependence of the spectra upon the constitution of the rest of the molecule indicates that this type of measurement will be powerful as a means of studying molecular structure, when a satisfactory theory of this type of spectrum is developed. Among the compounds showing the influence of neighboring groups on NH or OH absorption, the ortho substituted derivatives of phenol are, in some respects, the simplest.

Certain groups, when substituted ortho to the phenolic OH, lead to the formation of a hydrogen bond.[3] In these cases it has been shown that the absorption normally characteristic of the presence of the OH group in the region 6500–7500 cm.$^{-1}$ is absent, and this has been developed as an empirical criterion for the presence of such hydrogen bonds. On the other hand, other groups, when substituted ortho to the phenolic OH, do not cause the OH absorption to disappear, but they frequently do alter it in an interesting way. These cases are important in that they give positive results, that is, they afford some absorption which may be studied quantitatively to investigate this dependence on neighboring groups in the molecule. In a previous paper[2] the simplest representative of this latter class of compound was *o*-chlorophenol. In the present paper results are given for a number of ortho substituted phenols.

It is the purpose of this research to present as broad a survey as possible of this general type of absorption in organic molecules rather than to undertake as yet a detailed study of a few. It seems wiser to adopt this attitude, leaving an intensive study of single compounds until the theory of the absorption is developed to a point that warrants this. However, under these conditions it is necessary to emphasize, as has already been done, that minor characteristics of the absorption curves, such as slight displacements or dissymmetries, should not be given credence until an exhaustive study of the particular compound is made. Similarly, failure to show any absorption at some particular point must not be construed as meaning that very weak absorption may not be present there.

Experimental Procedure

The experimental details have already been described.[2] The absorption is measured in dilute carbon tetrachloride solution usually of the order of 0.01 molal. In the case of each compound presented below, at least two separate records were taken using two different solutions.

Certain of the compounds used were purchased from the Eastman Kodak Company and others were synthesized by methods already outlined in the literature. In every case some of their properties were checked with those recorded in the literature. In a few cases where there was some question as to the purity of the product, as was true in the case of pyrogallol and pyrogallol dimethyl ether, the absorption was studied before and after recrystallization and where no noticeable alteration in the spectrum was effected, it was assumed that the observed spectrum was essentially due to the compound itself. It is important to emphasize that the presence of very small amounts of impurities is not of great consequence in this work. Insofar as they do not contain the group being studied (*i. e.*, OH or NH) their presence can practically be neglected, while if they do contain such a group, their effect is simply proportional to the amounts present. If present in small amount, their effect will be a small alteration of the absorption curve, and minor characteristics, found in any of these curves, must be checked by further experimental work before being given importance, because of the rather wide limits of experimental error in the quantitative determination of the absorption coefficients themselves.[2]

Since pyrogallol and 1,8-dihydroxynaphthalene are only slightly soluble at room temperature, they were run at 60° as well, in order to secure an adequate concentration of the substance and hence of the absorption. Since no definite effect of temperature was observed, the runs at room temperature and at 60° were used together in determining the final or average curve.

Results

The curves, given in Fig. 1, present the results

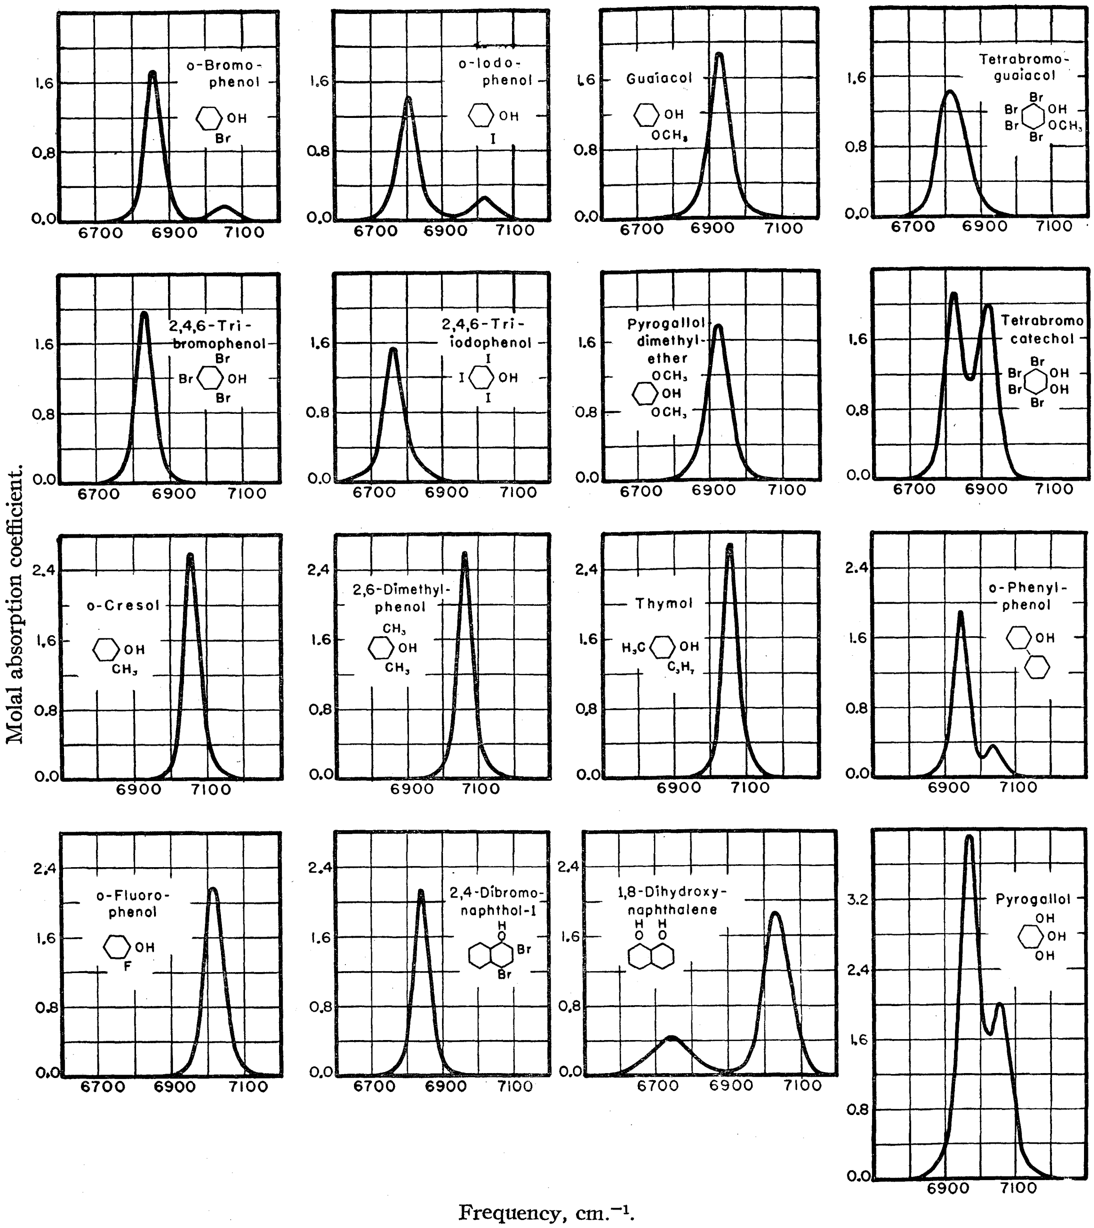

Fig. 1.—Molal absorption coefficients for some ortho substituted phenols.

in sufficient detail so that little further description need be given. In those cases where one of the ortho hydrogens of phenol remains, an absorption peak at approximately the phenol frequency is present. In most of the others this peak is missing, the evident exception being 2,6-dimethylphenol. In Table I the areas under the absorption curves are given, as was done in reference 2 where the areas for those compounds whose curves were published in that paper may be found.

A word must be said regarding the region 7100–7400 cm.$^{-1}$. Atmospheric water vapor absorption lies here, and makes observation difficult. Additional absorption of considerable strength would not be missed, and could be read though with less accuracy than that in other regions. It would, however, be possible to miss weak absorption, especially on days of high humidity, and therefore our curves must not be construed as indicating no absorption in this region. This applies to all results which we have published. Very weak absorption due to OH lies in this region. During an attempt to study in detail the effect of temperature upon the *o*-chlorophenol ab-

Tetrabromocatechol	290
Pyrogallol	440

sorption, two further weaker peaks to higher frequencies were discovered while working on a very cold and dry winter day and at high concentrations. The weakest of these is probably due to OH, while the other might be ascribed to either OH or CH. There is indication that weak absorption in this region occurs in several if not all of the present compounds. It is not practical to measure this, however, at the concentrations used in this work, and no effort has been made to indicate its presence in the absorption curves. Hence reiteration of the words at the beginning of this paragraph must be made here to avoid misunderstanding.

Discussion

In reference 2 a simple theoretical discussion of the characteristics of this type of spectra was given, in which possible causes for the appearance of more than one single peak after substitution, as well as for pronouncedly broadened peaks, were mentioned. It was suggested that the appearance of several frequencies (peaks) of absorption was due to a coupling of the OH or NH group with a near-by group of similar frequency. Pauling has suggested recently[4] that the complexity of the spectra is due rather to two or more types of OH or NH groups having different characteristic frequencies. He points out that, because of resonance with other structures besides those of the Kekulé type, the C–O bond in phenol possesses some double bond character, which tends to cause the OH group to lie in the plane of the ring. The OH group then can orient itself stably in two positions which in phenol, however, are equivalent. Though different from phenol, these two positions are also equivalent for a symmetrical ortho disubstituted phenol, but not for the unsymmetrical case and are thus different for mono-ortho substituted phenols. In general, the OH group in the two forms of such a molecule, called by Pauling *cis* and *trans* forms, will lead to different characteristic absorptions. Furthermore, the amounts of the two different forms of molecule, present in equilibrium with one another, evidently will depend upon the difference in free energy between the two forms. There is, however, no evident quantitative relation between the free energy difference of any one pair of *cis* and *trans* forms and the frequency difference of their absorptions.

This interpretation is the only specific description of this type of absorption which we now have. It will therefore be helpful to attempt to interpret the present results as far as possible in accordance with it, in order to see to what extent it accounts for the observations.

Attempting now to interpret the absorption curves in terms of this picture, *o*-bromo- and *o*-iodophenol show in a similar way as does *o*-chlorophenol[2] two distinct peaks, one (*trans* form) approximately at the normal phenol frequency. The other peak (*cis* form) lies to lower frequencies and by a progressively increasing amount in the order *o*-chloro-, *o*-bromo-, *o*-iodophenol, indicating a progressively increasing proton attraction in this order. The increasing polarizability of the ortho substituent is the most evident way of accounting for this, and the result indicates that the dipole moments in the ortho groups $C^{+} \text{---} {}^{-}X$, where X is the halogen, are relatively unimportant since the dipole moments for these groups are in the opposite order, thus that of C–Cl being considerably greater than that for C–I. This may seem reasonable from the circumstance that the dipole is oriented approximately at right angles to the direction toward the H atom. A rough measure of the increase in polarizability is given by the change in the molecular refractivities of the three monohalogen substituted benzenes, which are *o*-chloro 31.1, *o*-bromo 34.0 and *o*-iodo 39.2, respectively, for sodium D, these values being computed from data taken from the "International Critical Tables," Vol. VII, p. 34.

In the case of *o*-fluorophenol a single peak occurs but this peak is somewhat broad and has its maximum at about 7015 cm.$^{-1}$, an appreciably

---

[4] Pauling, THIS JOURNAL, **58**, 94 (1936).

lower frequency than that of the *trans* peak in the other three analogous ortho substituted phenols. The broadening is in accord with the hypothesis that the *o*-fluorophenol absorption is comprised of two frequencies as in the case of the other three compounds, one at about 7050 cm.$^{-1}$ and the other at 7015 cm.$^{-1}$ and that in this case they largely overlap one another.

In the symmetrical 2,4,6-trichloro-, tribromo- and triiodophenols but one peak appears, the *cis* peak, since the two positions of the OH group are now the same, and are *cis* in character. The peak in each case lies moreover at approximately the same position as the *cis* peak of the respective three mono-ortho substituted derivatives. Actually in all three cases the peak in the symmetrical tri-substituted compounds is slightly but definitely at a lower frequency than the *cis* peak of the respective ortho substituted compound. The difference, while rather small, appears to be real.

Where the ortho substituent is a group of atoms rather than a single atom, the situation is more complicated. In this case it is difficult to see what the combined effect of polarizability and of the several variously oriented dipoles within the group might be. However, several such compounds were measured and it is interesting to consider the character of the absorption which they afforded.

o-Cresol and thymol show only a single prominent peak at about the normal phenol frequency. In the case of *o*-cresol it is probable that proton repulsion would characterize the *cis* form because of the rather close proximity of the hydrogen of the hydroxyl group to the hydrogen atoms of the methyl group. The single peak could be interpreted either as due to equal amounts of *cis* and *trans* forms of practically the same frequency, analogous with phenol, or as due to the *trans* form alone, the *cis* form being of different frequency and of much greater free energy, hence not present in appreciable amounts. From the geometry of *o*-cresol the first alternative presumably is the more reasonable. While the situation in thymol is not so simple as in *o*-cresol, the absorption appears to be of the same type. But the choice between the two possible interpretations in the case of *o*-cresol is substantiated by the absorption of 2,6-dimethylphenol. Here both positions of the O–H group are *cis* positions, and still a single peak of roughly the phenol area and at approximately the phenol frequency appears.

Again, in *o*-hydroxybenzonitrile[5] the absorption consists of two peaks, a small one (*trans*) at approximately the normal phenol frequency and a larger one (*cis*) at a somewhat lower frequency, indicating a small proton attraction by the substituent group.

The spectrum of *o*-phenylphenol (2-hydroxydiphenyl) interpreted in terms of the same picture, also shows appreciable amounts of both *cis* and *trans* forms of the molecule present. This is of considerable interest since it suggests a conclusion as to the structure of the rest of the molecule. If the two rings were coplanar as they are crystalline diphenyl, the hydrogen atoms of the hydroxyl group would be in very close proximity to the near-by hydrogen of the substituted ring, even allowing severe distortion of the valence angles. The strong resultant repulsion would ensure the presence of only a *trans* form. Since both forms are found it is to be concluded from the picture that the two rings do not lie in the same plane, and indeed, from the geometry of the system, that they are considerably removed from such position even as they are in optically active diphenyl derivatives. With the two rings swung far out of a common plane the first carbon atom of the ortho substituted ring lies closest to the hydroxyl hydrogen, and if this near-by carbon atom exercises an appreciable proton attraction, this would lead to a *cis* form of lower energy than the *trans* form, and could give rise to the two peaks.

Especial interest attaches, moreover, to guaiacol. Proton attraction by the oxygen of the methoxy group might be expected, and this appears to be present. A comparison with the absorption of catechol helps to make the guaiacol absorption more understandable. As presented in reference 2, catechol shows two peaks of equal intensity, one at the normal phenol frequency, the other at a considerably lower frequency. Pauling has interpreted these as arising from a *cis* and a *trans* form within the same molecule, the hydrogen of one of the hydroxyl groups being in the *cis* position owing to the proton attraction of the neighboring oxygen, but the hydrogen attached to this second oxygen having only the *trans* position left to it, strong proton repulsion presumably preventing both hydroxyls turning toward one another. This second (*trans*) OH group is thus essentially the same as the OH

---

(5) Hendricks, Wulf, Hilbert and Liddel, THIS JOURNAL, **58**, 1991 (1936).

group of phenol. In guaiacol one of the two hydroxyl hydrogens of catechol is removed, leaving, however, the corresponding hydroxyl oxygen in its old position. This leaves for the remaining hydroxyl group the *cis* position as the position of lowest energy. The guaiacol peak (*cis*) lies at a slightly lower frequency than the *cis* peak of catechol.

Important in a closely similar way is the absorption of 3-nitrocatechol, the curve for which has already been published.[3] Its absorption is very nearly the same as that of guaiacol. In 3-nitrocatechol the hydrogen of the hydroxyl group nearest the NO_2 group engages in a hydrogen bond, removing the OH absorption of this hydroxyl group. The remaining OH group shows the *cis* form absorption just as does guaiacol.

It appears, however, that in guaiacol and 3-nitrocatechol the difference in free energy between the *cis* and *trans* forms of the available OH group is greater than it is for instance in *o*-chlorophenol, *o*-hydroxybenzonitrile or even *o*-iodophenol, since no absorption due to a *trans* form can be seen. This is a necessary conclusion of the stereochemical interpretation *unless* the absorption coefficients for the two forms are greatly different from one another, in contrast to what is presumed to be true in the case of catechol. It has already been shown[2] that the absorption coefficient can be somewhat altered by the presence of another neighboring group.

In guaiacol the O–C of the methoxy group must be thought of as in the *trans* position, and this leaves an appreciable dipole moment (the O–C moment) so oriented as to give a resultant proton attraction. This might account for the deeper energy minimum in which the *cis* OH of guaiacol seems to lie as compared with the OH of *o*-iodophenol. Furthermore, it seems necessary to conclude that this greater free energy difference does not necessarily mean a greater shift in the absorption frequency for here the guaiacol peak is at a considerably higher frequency than is, for example, the peak of the cis form of *o*-iodophenol. It would appear that this could be the case. The form of the potential curve in which the vibrating hydroxyl swings will be different where simply the polarization of a near-by atom, such as the iodine atom, is concerned than it will where, as in guaiacol, the permanent dipole moment of another group, here the O–C moment, is so oriented as to exert attraction for the proton of the hydroxyl group. In this respect 3-nitrocatechol is similar except that here the active *cis* OH faces an OH locked in a hydrogen bond with the oxygen atom of the NO_2 group.

Pyrogallol shows a particularly interesting absorption. It is clear that, from the explanation suggested by Pauling for catechol, one would expect in pyrogallol a molecule possessing two *cis* OH groups and one *trans* group. In other words the third OH group when added to catechol finds the *cis* position available for it just as the *cis* position was available to the second group when added to phenol. The absorption of pyrogallol shows two peaks, one (*trans*) at approximately the normal phenol frequency and possessing an area approximately equal to phenol. The other peak (*cis*) is at lower frequencies and not far from the position of the *cis* peak of catechol. The area of this latter peak, moreover, is roughly twice that of phenol, and thus the absorption of this molecule is in rather striking accord with what might be expected, using Pauling's interpretation as a guide.

It is also interesting to compare the absorption of 1,8-dihydroxynaphthalene with that of catechol. It will be recalled that in catechol the configuration in which both OH groups were in *trans* positions appeared to occur in too small amounts to be noticeable, the two peaks possessing about the same area. That is, the catechol molecules were interpreted as being essentially all of one sort, this possessing one *cis* and one *trans* OH group. As mentioned above, this conclusion contained the assumption that the absorption coefficients of the two groups were the same. In 1,8-dihydroxynaphthalene the two OH groups are even closer together than in catechol, and the configuration in which the two groups turn toward one another is even more improbable than in catechol. The configuration possessing one *cis* and one *trans* group would certainly seem to be a possible one, and two peaks are indeed observed. However, while the total area is approximately that of two phenol-like OH groups, the area of the *cis* peak is considerably smaller than that of the *trans* peak. This would indicate that the configuration possessing two *trans* groups is also present in considerable amount, that is, that the difference in free energy between the *cis*–*trans* and *trans*–*trans* configuration is less than the corresponding free energy difference in catechol. It does not, however, seem probable that the hydrogen atom of the *cis*-hydroxyl group is sufficiently close to the oxygen atom of the adjacent group that repulsion offsets somewhat the proton attraction of this atom. Furthermore, the shift of the *cis* peak to lower frequencies is greater than that in catechol. It may be that here the absorption coefficients of the *cis* and *trans* forms are considerably different. If this is not the case, we are again confronted with the circumstance that a relatively large displacement of the *cis* peak from the normal phenol frequency does not necessarily mean a correspondingly large free energy difference between the *cis* and *trans* forms.

A further interesting opportunity to test the interpretation suggested by Pauling is to be had in some of the derivatives of the above mentioned compounds. In pyrogallol dimethyl ether the remaining hydroxyl group of pyrogallol would have only the *cis* position available to it, this *cis* position being similar to the *cis* position in guaiacol. The absorption does, indeed, consist of a single peak of approximately the area of a single OH group and at approximately the position of the guaiacol peak.

In tetrabromoguaiacol the position of the hydroxyl group which occurs in guaiacol itself (*cis*) presumably is not greatly changed, but in the position turned away from the oxygen atom of the O–CH_3 group, which position is essentially absent in guaiacol, the OH group finds a bromine atom adjacent in tetrabromoguaiacol. One would in first approximation expect proton attraction by the bromine atom similar to that in *o*-bromophenol and a *cis* peak at about the same position. The positions of the guaiacol peak and of the *cis* peak of *o*-bromophenol (or 2,4,6-tribromophenol) are not far removed from one another, and the broad peak observed for this compound may be interpreted as two overlapping peaks of approximately this frequency separation. It seems apparent, however, that, if this is the case, both peaks have been shifted somewhat to lower frequencies, recalling the observation that the *cis* peak in the monohalogen ortho substituted phenols seems to shift slightly to lower frequencies in the respective 2,4,6-trisubstituted phenols where both ortho positions are occupied by the halogen.

In 2,4-dibromonaphthol-1 the *cis* position of the OH group would be expected to be similar to the *cis* position of *o*-bromophenol, but in the *trans* position the adjacent hydrogen atom is considerably closer than in *o*-bromophenol, presumably leading to stronger proton repulsion. This would be expected to reduce the fraction of the molecules in the *trans* position, and indeed the *trans* peak is not observed, a single peak (*cis*) showing at approximately the position of the *cis* peak of *o*-bromophenol.

Finally in tetrabromocatechol the *cis* position of catechol should be present with roughly the same character, in first approximation, as in catechol itself, but the *trans* position no longer has a hydrogen atom adjacent, but a bromine atom, which exercises proton attraction, and which should lead to a *cis* peak at roughly the position of the *cis* peak of *o*-bromophenol. Two peaks are observed, but here again, as seemed probable also in tetrabromoguaiacol, the two peaks are shifted to somewhat lower frequencies than those occurring in the respective mono-ortho substituted compound, a characteristic apparently frequently to be found in phenols in which both ortho positions are occupied by a group exercising proton attraction. Moreover, it is to be noticed that here the configuration in which the two OH groups are turned away from one another would not be expected to possess as much excess free energy over the configuration one *cis*–one *trans* as was the case in catechol because of the attraction here exercised by the bromine atom. A similar remark applies of course to tetrabromoguaiacol as well. In other words, keeping in mind the suggested interpretation of the absorption of catechol, there seems to be no reason why the two peaks in these two compounds should be expected to possess the same area, and it may be that the small apparent difference in area of tetrabromocatechol is to be explained in this way. Finally, it is interesting to note that in both tetrabromocatechol and tetrabromoguaiacol, one quite definite prediction could be made beforehand on the basis of Pauling's interpretation, namely, that neither of these should possess characteristic OH absorption at the position of the normal phenol peak.

Thus the spectra of these compounds appear to possess characteristics which are rather strikingly in accord with Pauling's interpretation. At the same time they raise points which are not clear and which await further elucidation.

The authors are much indebted to Professor Linus Pauling for discussion of this type of spectra and for helpful advice as to its interpretation.

Summary

The absorption, characteristic of the presence of the OH group and in the region of its first vibrational overtone, has been measured quantitatively for certain ortho substituted phenols and the results have been presented as curves of the molal absorption coefficient against position in the spectrum.

The results have been discussed in the light of Pauling's recent interpretation of this type of spectra. For the most part the correspondence is remarkably close.

The Heat of Fusion and Vapor Pressure of Stannic Iodide

BY GEORGE R. NEGISHI

The investigations of Hildebrand and coworkers[1] in this Laboratory during recent years upon the subject of intermolecular forces and solubility have included a study of tetrahalides as examples of molecules having widely differing volumes and intermolecular fields but with a common highly symmetrical structure. Stannic iodide is one of the substances concerning which a considerable body of solubility data has been accumulated; however, its evaluation has been unsatisfactory on account of lack of accurate knowledge of its heat of fusion and vaporization. The work herein described has been carried out in order to fill this gap.

Preparation and Purification of Stannic Iodide.—This compound was prepared and purified by the method described by Dorfman and Hildebrand,[1] followed by two fractional distillations under high vacuum (10^{-5} mm.). The purity of the final product was undoubtedly high, as indicated by sharp breaks in the cooling curve, and by the absence of premelting in the heat of fusion determinations.

The Melting Point.—The sample was distilled under high vacuum into a Pyrex tube, in the center of which extended a narrow Pyrex tube almost to the bottom. The temperature of the freezing mixture was measured by means of an alumel–chromel thermocouple inserted into the central narrow tube. The couple was calibrated against the melting points of water and tin, the boiling point of water and the transition point of sodium sulfate decahydrate. The thermoelectric current was measured by means of a Leeds and Northrup Student Type potentiometer. A change in temperature of 0.1° could be detected. The sample was heated in a copper cylinder 20 cm. high, 5 cm. in diameter and 9 mm. thick, provided with a heating coil and thermally insulated with Sil-o-cel. The temperature was regulated by means of a rheostat. During the measurements the temperature of the furnace was lowered rather rapidly to the freezing point of the stannic iodide, after that at about 0.05° per minute. The apparatus was shaken continuously on a rocker except when the readings were taken. The melting point was determined from the "break" in the cooling curve. The plot of the curve is shown in Fig. 1. The melting point thus determined was 144.5°. This value is to be compared with the values of 143.5,[1] 145.3[2] and 146.2°,[3] from other sources.

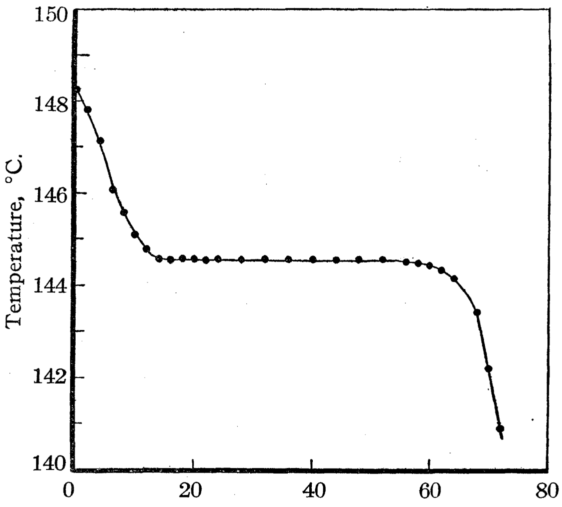

Fig. 1.

The vapor pressure was determined by means of a glass click gage as described by Smith and Taylor.[4] The click constant was determined at the pressures and temperatures of the actual runs. The constant increased with both increasing pressure and temperature up to a point where a permanent change set in. The "click-in" constant was found to be more reliable than that of "click-out," so only the former was calibrated. The space above the click gage (the manometer side) was evacuated to 10^{-2} mm. before each "click-in" was made. This was not necessary at lower temperatures, but above 200° it was essential.

[4] D. F. Smith and N. W. Taylor, THIS JOURNAL, **46**, 1393 (1924).

The click gage used seemed to have experienced fatigue above 200°.

A tube containing the sample was broken off in an atmosphere of nitrogen, inside of a box dried with phosphorus pentoxide, and some of the solid was transferred to the apparatus. After evacuating it down to 10^{-5} mm. the side pieces were sealed off. The lower half of the apparatus was wrapped in a thin copper sheet. The apparatus up to 3.8 cm. from the stopcock was then placed in a furnace, which was similar to the one described above except that the height of the copper cylinder was 35.5 cm. The temperature of the sample was measured with a mercury thermometer inserted in the cylinder next to the bulb of the apparatus. All the thermometers used were calibrated against the Bureau of Standards calibrated mercury thermometers. The mercury columns in the manometer were read by means of a cathetometer which was graduated to 0.1 mm. The readings were reduced to 0°.

The temperature was kept within ± 0.05° for at least thirty minutes before runs were made. Usually it required from one and one-half to two hours to complete a series of three to five runs at a given temperature. Two complete sets of determinations were made over the range of temperature, one ascending, the other descending. The readings agreed within 0.1 mm. in most cases.

The results of the measurements are shown in Table I.

TABLE I

VAPOR PRESSURE OF STANNIC IODIDE FROM 160 TO 250°

Temp., °C.	Obsd. P, mm.	Calcd.
160.22	6.00	6.04
170.07	8.76	8.62
185.35	14.25	14.38
200.86	23.52	23.53
225.75	48.52	48.52
250.35	93.59	92.33

The last column of the table is calculated from the equation

$$\log P_{\text{mm.}} = 7.6571 - \frac{2971.36}{T} - \frac{3689.1}{T^2} \qquad (1)$$

empirically derived from the experimental data. The influence of the term in $1/T^2$ is very small. The extrapolated value of the boiling point is found to be 348° in comparison with 340°[5] and 346°[2] found elsewhere. The last two values are of unknown reliability since no experimental details are given and no special precautions to exclude oxygen and water vapor are mentioned, although stannic iodide decomposes readily in the presence of even slight amounts of oxygen or water vapor in the neighborhood of its boiling point. In our case, although the vapor pressure measurements made within the temperature range are reliable, the extrapolation beyond the range was so large that the uncertainty in the value of the boiling point might be appreciable. The heat of vaporization, calculated from equation 1, is 13,700 cal. per mole at 25° and 13,650 at the boiling point.

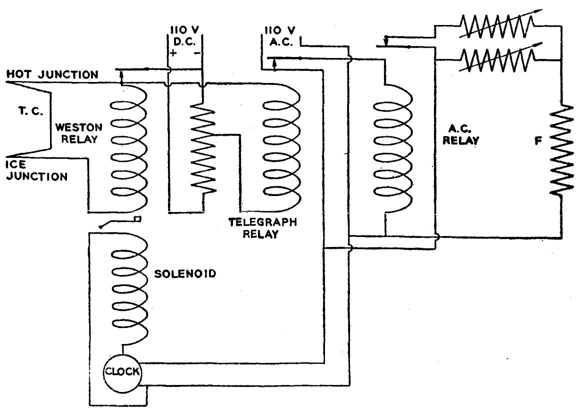

Fig. 2.—Temperature regulation circuit.

The heat of fusion was determined by the method of mixtures. The furnace was made of a heat-insulated solid copper block 12 cm. in diameter and 33 cm. long. In the center of the block to two-thirds of the way up from the bottom, was drilled a 1.5-cm. hole, which was 1 mm. larger than the diameter of the tube containing the sample. The tube was supported in the furnace by the wire inserted at the side of the block. Two holes of small diameter were drilled down from the top, one of them as closely as possible to the central bore. A No. 20 chromel–alumel calibrated thermocouple cased in a 5-mm. thin Pyrex tubing was inserted into this in order to measure the temperature of the furnace. A similar thermocouple for regulating the temperature of the furnace was inserted into the other. The block was heated electrically. The central bore was extended 3 cm. beyond the bottom with a monel tube of the same bore closed with a brass cap.

The calorimeter was made of a half-pint (210-cc.) silvered Dewar flask with a tightly fitting copper cover consisting of two copper sheets at 1 cm. apart. A "basket" of copper gauze was suspended from the cover near the bottom of the flask to catch the tube of stannic iodide as it dropped in from the furnace above. The heat capacity of the calorimeter was determined by the aid of a copper rod weighing 55 g. The rise in the temperature of the water was measured with a 6-junction (No. 32 copper–No. 26 advance) thermocouple whose junctions were cased in a thin 6-mm. Pyrex tube filled with pure naphthalene. The thermocouple was calibrated against the melting point of ice and the transition point of sodium sulfate decahydrate. The heat content of the Pyrex tubing used was determined at several temperatures.

The temperature of the furnace was regulated with a regulator built by Mr. Abrams of this Department. A diagram of it is shown in Fig. 2, which is self-explanatory except, perhaps, for the clock. This was so connected that it made a contact with the magnetic hammer every minute, which tapped the Weston relay in order to keep the fine wire of the relay from "sticking" to the contact. By means of this regulator, the temperature of the furnace was kept within ± 0.05° without any difficulty.

---

(5) "Int. Crit. Tables," Vol. I, 1926, p. 163.

Measurements.—The tube containing the distilled sample of stannic iodide was heated in the furnace at a given temperature (within ± 0.05°) for at least one and one-half hours before it was dropped into the calorimeter, which contained a measured quantity of water at approximately the thermostat temperature, 25 ± 0.02°. The calorimeter was placed in the water thermostat; part of the copper cover was immersed in the water of the thermostat in order to keep its temperature uniform. The stirrer was then connected to the motor and the thermocouple was inserted into the calorimeter. The temperatures of both the water in the calorimeter and the furnace were read on the Leeds and Northrup type K_2 potentiometer, which was graduated to 0.5 microvolt, and it could be estimated easily to 0.1 microvolt. The potentiometer was connected to a sensitive galvanometer. With this set-up temperature changes of 0.001° in the calorimeter and of 0.01° in the furnace could be detected. Readings were made every two minutes until the rate of the change in the temperature of the water became uniform, then the sample tube was dropped into the calorimeter. About one minute elapsed between the time the stirrer was stopped and started again. The temperature change was recorded every two minutes until a uniform cooling rate was obtained. A complete run required from twenty-five to thirty-five minutes. The rate of heating due to stirring was on the average 0.001° per minute, and the rate of cooling was from 0.001 to 0.0012° per minute. The total temperature change in the calorimeter was from 0.6 to 2°.

Results and Discussion.—The value of the total heat capacity of the calorimeters used including 325 cc. of water, was approximately 340 cal., with the largest deviation amounting to 1.6 cal. for the first calorimeter and 0.15 cal. for the second. The specific heat of the Pyrex glass used could be expressed within ±0.1% from the measured values by $C_p = 0.1141 + 0.000253 23T$. The total heat of the copper rod used was derived from its specific heat equation

$$C_p = 0.09202 + 0.0000136T - \frac{452}{T}$$

determined empirically by Bronson, Chisholm, and Dockerty[6] from the results of their measurements.

The heat content of the solid with a mean deviation of ±20 cal. in the temperature interval between 25 and 144.5° is given by

$$C_p = 19.4 + 0.036T$$

where C_p is the molal heat capacity of the solid. The average deviation of the measured values from this equation is ±0.8% with the maximum deviation 1.5%. The curve for the total heat content of the liquid is a straight line, giving 40.1 ± 0.5 cal. per mole for the molal heat capacity in the range of temperature from 144.5 to 170°. We get 4600 ± 20 cal. for the molal heat of fusion. Hildebrand[7] estimated the value of ΔH_m from the entropy of fusion of other tetrahalides (chlorides and bromides) of the fourth group and from the solubility of stannic iodide in carbon disulfide, and obtained the value 3850 cal. per mole. This value is, of course, only an approximation and it is likely to be too small. If the melting and boiling points, the entropy of fusion and other physical properties of the halogens (except fluorine) are plotted, it is seen that changes from bromine to iodine are always greater than those from chlorine to bromine. A similar state of affairs results when the melting and boiling points of the tetrahalides of the fourth group are plotted. This indicates that the intermolecular forces are determined to a large extent by those halogen atoms surrounding the central atom and independent of it.[8] Moreover, these curves are roughly parallel to those of the halogens, but not coincident with them. This is to be expected from the fact that the molecular size and bond energies of these tetrahalides have some effect on their intermolecular forces and orientations in the liquid state.[9] Since the entropy of fusion of iodine is much greater than those of bromine and chlorine, we may assume that the entropy of fusion of stannic iodide should be greater than those of tetrachlorides and bromides.

If intermolecular forces of tetrahalides are determined largely by the halogen atoms surrounding the central atom, we should expect the solubility of stannic iodide in iodine and also that of iodine in stannic iodide[10] to obey closely the ideal law. This corresponds to the facts. The slope of the former solubility curve gives ΔH_m approximately equal to 4250. This value is lower than ours, but it is within their experimental accuracy.

Parks and Dodd[11] obtained $\Delta H_m = 4110$ cal. per mole from their rough experimental measurements employing also the method of mixtures. However, they have stated that there was a considerable amount of premelting near the melting point of the solid and so their results were not very reliable. We shall, therefore, take $\Delta H_m = 4600$ as the heat of fusion of stannic iodide at its melting point.

Summary

The melting point of stannic iodide has been determined by the cooling method, and the value obtained was 144.5 ± 0.1°.

The vapor pressure of stannic iodide from its melting point to 250° has been determined by means of a glass click gage. The molal heat of vaporization calculated from the vapor pressure is 13,750 ± 50 cal. per mole at 25° and varies but little with temperature.

The heat of fusion of stannic iodide was found to be 4600 ± 20 cal. per mole at the melting point. The molal heat capacity of the solid can be expressed within 0.8% of the measured values in the temperature range 25° to the melting point by C_p 19.4 + 0.036T, while that of the liquid, from the melting point to 170° is 40.1 ± 0.5 cal. per mole.

The Ultraviolet Absorption Spectra of Substituted Biphenyls[1]

BY LUCY W. PICKETT, GERTRUDE F. WALTER AND HELEN FRANCE

Investigations by Adams and others[2] have shown that those unsymmetrical derivatives of biphenyl which have substituents above a certain limiting size in the positions adjacent to the bond joining the two benzene nuclei may be resolved into stereoisomers. This phenomenon is explained as a result of the restriction of the rotation of the two benzene rings by the interference of the substituting groups. Some absorption spectra measurements made in a study of the physical properties of biphenyl derivatives showed unexpected differences in absorption which led to further investigation.

Methyl and chloro derivatives of biphenyl were chosen for the comparison because these groups do not show selective absorption in the region under investigation and are known to introduce comparatively slight modifications in the spectrum of benzene. Furthermore, these groups are sufficiently large to restrict the rotation of the benzene nuclei when they are in the 2,2′,6,6′-positions. The spectroscopic study was made with the simplest compounds available which had the above characteristics.

Experimental

Preparation of Compounds.—After purification the compounds were in each case crystallized from the optically pure solvent used in the measurements. After the absorption spectrum had been photographed, the material from which the sample was taken was further distilled or crystallized and photographs again taken. The second results agreed with the first in all cases except one as noted below in the discussion of the source and treatment of individual substances.

Biphenyl, m. p. 69–69.5°, obtained from Eastman Kodak Co., was purified by vacuum distillation and repeated crystallization from alcohol.

3,3′-Bitolyl,[3] b. p. 154° at 14 mm., was prepared by the condensation of *p*-iodotoluene with activated copper bronze and purified by two vacuum distillations. Although the product boiled constantly, a photograph taken at this time indicated slightly different absorption from that which was obtained from material distilled a third time. A fourth distillation yielded material identical with the latter.

4,4′-Bitolyl, m. p. 119.5–120°, was prepared by the condensation of *p*-bromotoluene and purified by vacuum distillation and crystallization from alcohol.

Bimesityl, m. p. 100–100.5°, was prepared from bromomesitylene by the method described by Moyer and Adams[4] and crystallized repeatedly from alcohol.

4,4′-Dichlorobiphenyl, m. p. 146.5–147°, was obtained from Eastman Kodak Co. and purified by recrystallization from alcohol.

2,4,6,2′,4′,6′-Hexachlorobiphenyl, m. p. 111.5–112°, was prepared from trichloroiodobenzene by condensation with copper bronze and recrystallized from alcohol. The trichloroiodobenzene was obtained from diazotization of trichloroaniline.

***o*-, *m*- and *p*-diphenylbenzenes,** m. p. 58, 87, 211.5°, were obtained from Eastman Kodak Co., and recrystallized repeatedly from benzene and alcohol.

Mesitylene, b. p. 66.4° at 24.5 mm., was obtained from Eastman Kodak Co., and vacuum distilled.

Absorption Spectra Measurements.—The absorption measurements were made with a Hilger quartz spectro-

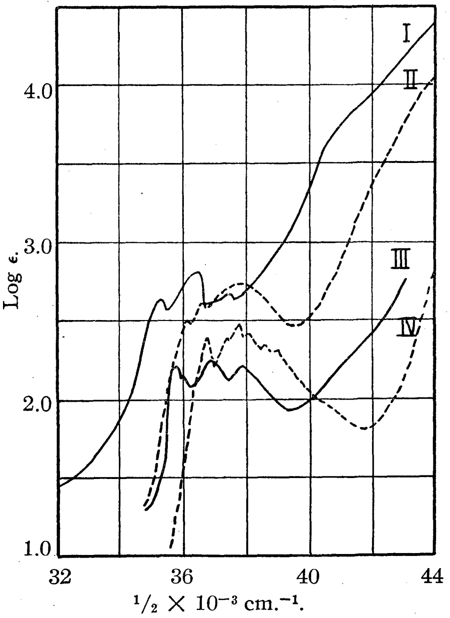
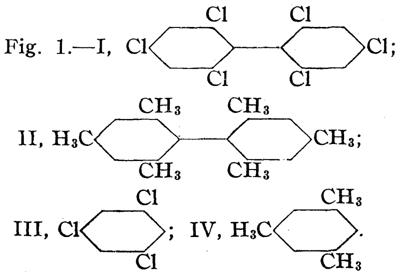
graph (E-2) using a comparison method which has been described.[5] The source of light for most of the measurements was a condensed copper spark. In order to detect the presence of weak bands in the region of the band maxima the continuous light from a discharge through hydrogen was used for a series of closely spaced exposures made through slightly varying thicknesses of solution for each compound. Both ethyl alcohol and hexane were used as solvents and it was found that the curves obtained in the two solvents agreed closely except for very slight shifts toward the visible for the alcohol solutions. The absorption curves presented show the logarithm of the molecular extinction coefficient plotted against the wave number. Each curve represents over sixty experimental points which are not shown because they are so closely spaced.

Photographs of the solid biphenyl were made by mounting a very thin uniform crystal on a fluorite plate placed before the slit of the spectrograph normal to the light beam. The thickness was calculated from the interference color between crossed nicol prisms using the refractive indices determined by Hendricks and Jefferson.[6]





Discussion of Results

The absorption curves of 2,4,6,2′,4′,6′-hexachlorobiphenyl and bimesityl in alcohol solution are shown in Fig. 1. Each has a group of three absorption bands whose positions are as follows

Compound	Band maxima (1/λ cm.$^{-1}$)		
Bimesityl	36070	36480	37800
Hexachlorobiphenyl	35260	36350	37360

The position of the bands is practically the same in hexane and alcohol solutions, the difference being less than the error of measurement. It was especially noticeable in the chlorine compound that the bands had very sharp edges on the short wave length side.

For comparison are shown the absorption curves of the corresponding benzene derivatives, 1,3,5-trichlorobenzene and mesitylene as measured by Conrad-Billroth[7] and Wolf and Strasser.[8] The curve of the second compound is continued into the shorter wave region from data obtained in this Laboratory. It will be noticed that the band maxima of the most intense bands in the benzene derivative correspond to similar ones in the biphenyl compound which are displaced toward the visible. This shift is small and fairly constant (340, 350, 300 cm.$^{-1}$) for the chloro compounds but larger for those with methyl groups so that the second band of bimesityl almost coincides in frequency with the first band of mesitylene. The extinction coefficient of the band maxima of the biphenyl derivative is two or three times that of the corresponding benzene indicating that the absorption is nearly additive for the two benzene rings.

A similar comparison would be expected between monosubstituted derivatives of benzene and disubstituted derivatives of biphenyl but Fig. 2 shows that the curves for 3,3′- or 4,4′-bitolyl and 4,4′-dichlorobiphenyl in alcohol solution differ markedly from those of toluene[9] and monochlorobenzene.[10] In each case the narrow band structure is lost completely and the intensity increase is of the order of 100-fold. A difference of this kind is known to exist between benzene and biphenyl[11] and a recent article[12] by Seshan notes that the loss of banded structure is characteristic of the absorption of terphenyl and *s*-triphenylbenzene as well.

A study of the *o*-, *m*- and *p*-diphenylbenzenes in hexane solution with biphenyl included for com-

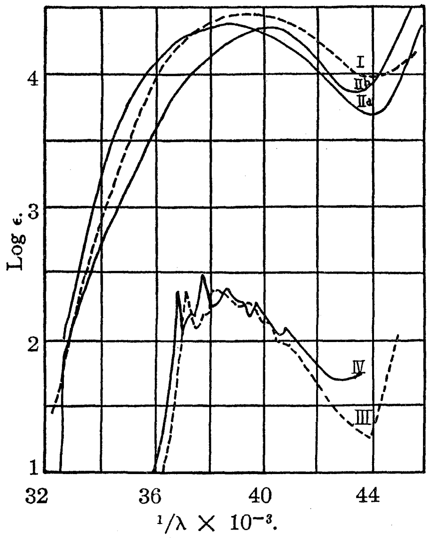

Fig. 2.—

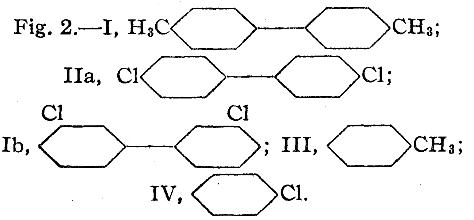

parison is illustrated in Fig. 3. The absorption band of the meta compound is similar in position to that of biphenyl but of greater intensity while that of the para compound is displaced toward the visible and still slightly higher. In the ortho compound there is a second rise in absorption overlapping the band so that the minimum is not developed but the band which corresponds to those of the other isomers is of lower intensity.

In a study of several complete series of halogenated and methylated benzenes, Conrad-Billroth[7,13] has shown that the number and position of substituting groups causes some modification in the position and intensity of the absorption bands and has called attention to the para effect, namely, a heightened intensity exhibited by para compounds. The variation among biphenyl, dichlorobiphenyl and the bitolyls is of this order and is probably due to a similar cause. The magnitude of the intensity difference noted in the present paper is thought to require a different explanation.

An attempt at such explanation is hardly justified at present. The evidence shows that a molecule such as bimesityl absorbs light as two mesitylene molecules while bitolyl has a greatly increased probability of absorption compared to two toluene molecules. If the increased intensity of absorption directly results from the free rotation of the molecule, solid biphenyl should show less intense absorption than in solution. Measurements of single crystals showed that the absorption curve of solid biphenyl was shifted toward the visible by about 550 cm.$^{-1}$ from that of the solution and although the measurements did not extend to the top of the band there was no evidence of decrease in intensity of absorption. It is possible that the increased absorption may be dependent on the planar form of the molecule[14] since the most stable position for biphenyl in solution is probably planar, a form which the 2,2′,6,6′-derivatives cannot assume because of the interference of substituting groups. Similarly, *o*-diphenylbenzene is less likely to be planar than the *m*- or *p*-isomers. Regardless of explanation, these results suggest a possible means of distinguishing compounds of restricted rotation.

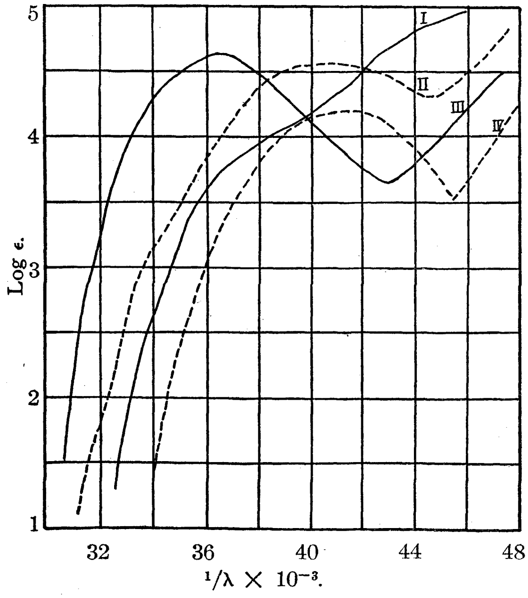

Fig. 3.—I, *o*-Diphenylbenzene; II, *m*-diphenylbenzene; III, *p*-diphenylbenzene; IV, biphenyl.

The effect of substitution of chloro and methyl groups on the wave length of the band maxima is just that which would be predicted from the results of a study of benzene derivatives.[13] The band is displaced toward the visible in all cases. This shift is greater for the chloro than the methyl derivatives, greater for the para than the meta compound, and approximately twice as great for the hexasubstituted as for the disubstituted compounds.

Summary

Absorption curves showing molecular extinction coefficients in the region 32–46,000 cm.$^{-1}$ are given for five methyl and chloro derivatives of biphenyl and three diphenylbenzenes.

The compounds with restricted rotation differ markedly in the intensity and structure of the absorption band from those capable of free rotation.

An X-Ray Study of Substituted Biphenyls

BY LUCY W. PICKETT

The explanation advanced for the stereoisomerism observed in certain unsymmetrical derivatives of biphenyl[1] is that the rotation of the benzene rings is restricted by the interference of sufficiently large groups in the 2,2′,6,6′-positions. The crystal structure of biphenyl derivatives with restricted rotation is thus of interest in confirming this explanation but so far no derivatives of this type have been solved completely. Magnetic measurements have been published recently[2] which may offer a clue to the orientation of the molecules and it thus seems advisable to make available the x-ray findings on substances of this type. The results of a continued investigation of some derivatives of biphenyl which were described in an earlier paper by Clark and Pickett[3] are here presented together with measurements on two similar compounds, racemic 3,3′-diaminobimesityl and quaterphenyl.

Experimental

Well-known experimental methods using single crystals and the Kα radiation of copper were employed. Rotation and Weissenberg photographs were used in the interpretation, and measurements of the relative intensity of reflections were made with the integrating photometer designed by Robinson.[4] Since the measurements made in this way are relative, the structure factors given in the paper include arbitrary constants. The preparation and melting points of the compounds are described in an earlier paper.[5] The optical observations were made with a Leitz petrographic microscope (GM).

The results of the unit cell and space group determinations are summarized in Table I while those results which present especial points of interest are considered individually in the following discussion. Most of the data in the table are like those presented in the earlier paper[3] but are included for convenient reference.

Bimesityl is reported in Groth[6] as monoclinic prismatic, exhibiting the forms (001), (100) and (110). A goniometric examination confirmed the angular measurements within the limits of experimental error and together with the x-ray data showed that the form designated as (110) was rather (012) (the *a*- and *c*-axes have been renamed to correspond with the usage for other biphenyls).

An optical examination of the tablets with extended (001) faces which are formed by crystallization from an alcohol–water mixture showed parallel extinction and positive elongation. The typical interference figure obtained shows one optic axis emerging at the edge of the field but by rotating the crystal on the *b*-axis an acute bisectrix figure was obtained which showed that the crystal is biaxial negative with small optic angle. The optic axes are in the (010) plane of this monoclinic crystal with the X-direction approximately 36° from the *c*-axis in the obtuse angle β.

Analysis of the x-ray photographs showed that the most probable space group is C_{2h}^5 or C_{2h}^4 depending on the questionable existence of a very weak (030) reflection. The conclusion is therefore that the *b* spacing is either exactly or practically halved. The intensities of the reflections

[a] The space group assignments differ from those in the early paper by Clark and Pickett,[3] *cf.* discussion. [b] This space group is the second alternative suggested by Clark.[3]

from a large number of planes have been measured and structure factors calculated therefrom. Attempts have been made to locate the positions of the individual atoms but the results thus far have been negative. Trial and error analyses show that the length of the molecule is not parallel to the *c*-axis although the unit cell dimensions indicate that the length is more or less parallel to this direction. One-dimensional Fourier projections of the density of the scattering matter along the normal to the (001) plane were made using all possible combinations of signs of terms but none of the contour maps obtained suggested the form of the molecule, probably because the projections so obtained were confused composites of more than one molecule.

***l*-3,3′-Diaminobimesityl** was prepared by Moyer and Adams.[7] Not only in unit cell dimensions but in the intensity of reflections from corresponding planes does this compound show a striking resemblance to bimesityl. It was first observed that like bimesityl the (*h0l*) and (0*k*0) planes where *l* and *k* are odd were missing but with long exposures, faint (101) and (010) reflections were unmistakably found. Since no other spacings were consistently halved, the space group C_2^1 was indicated with the molecules occupying two sets of equivalent positions, a possibility suggested by Dr. Huggins.[3] The evidence of the similar intensities shows that the molecules of the two compounds, bimesityl and *l*-3,3′-diaminobimesityl, must have very similar spatial arrangements. The two are alike in chemical structure except for the substitution of two hydrogen atoms by amino groups in the second. This suggests that whereas the second molecule of bimesityl in the unit cell may be derived from the first by reflection and a translation of one-half, corresponding molecules of the optically active compound would bear the same relation if the $\mathrm{NH_2}$ groups could be ignored, thus simulating the C_{2h}^5 symmetry. The presence of the asymmetrically placed amino groups makes reflection of the entire molecule impossible and lower real symmetry exists.

Racemic 3,3′-diaminobimesityl also prepared by Moyer and Adams[7] yields ambiguous results. Recrystallized from alcohol on a microscope slide, it forms square or rectangular tablets with parallel extinction and positive elongation from which acute bisectrix interference figures are obtained which indicate that the crystal is biaxially nega-

---

[7] Moyer and Adams, THIS JOURNAL, **51**, 630 (1929).

tive. A Laue photograph with the x-ray beam parallel to the *a*-axis showed the two-fold symmetry. However Weissenberg photographs about perpendicular *a*- and *b*-axes appeared identical. It is possible that some type of twinning might give rise to these anomalous results.

2,4,6,2′,4′,6′-Hexachlorobiphenyl crystallizes from alcohol to form crystals with (001), (101), (111), (100) and (011) faces. Since no measurements of its crystal form have been reported,[8] goniometric measurements were made on six crystals which showed good reflections and the angular measurements recorded in Table II.

Angular Measurements of Hexachlorobiphenyl

Angle	No. of measurements	Range	Mean observed	Average deviation	Calculated value
(100):(001)	16	91°41′–91°56′	91°49′	4′	
(101):(111)	14	56°01′–56°11′	56°08′	3′	
(001):(101)	6	52°25′–52°33′	52°30′	2′	
(101):(100)	5	35°37′–35°46′	35°41′	4′	35°41′
(001):(011)	4	68°34′–68°47′	68°40′	4′	68°36′
(100):(011)	2	90°00′–90°34′	90°17′	17′	90°16′
(100):(111)	3	62°57′–63°11′	63°03′	5′	63°05′

These showed that the crystal is monoclinic prismatic with an angle β of 91°49′ and an axial ratio 1.8785:1:2.554. Extinction is unsymmetrical in the principal views. An acute bisectrix figure may be seen from the (101) face, which shows that the crystal is negative with a small optic angle. Examination of the x-ray photographs showed that of the planes with indices up to and including $h = 6$, $k = 3$, $l = 7$, those which may be classified as (hkl) where $k + l$ is odd and ($h0l$) where h or l is odd are missing. This led to the assignment of space group C_{2h}^6 instead of that reported in the earlier paper.

Quaterphenyl,[9] m. p. 310°, was kindly supplied by Dr. Robertson. It is very difficultly soluble and was finally crystallized in tiny flakes with (001) faces from monobromobenzene. Optical examination showed that the crystal is biaxially positive with the direction of vibration of the slow ray that which was later known to be the long axis of the molecule. The unit cell whose dimensions are shown in Table I is similar to those of biphenyl[3,10] or terphenyl[11] differing only in the length of the *c*-axis. Hertel and Romer[12] have reported the unit cell dimensions and space group of quaterphenyl.

The extremely small size of the crystal made it difficult to obtain reflections of measurable intensity from more than a small number of planes. Relative intensity values, measured photometrically are listed in Table III together with visual estimates of intensity of those reflections not suitable for measurement.

Table III

Observed and Calculated Intensities of Reflections from Quaterphenyl

Plane *hkl*	2 sin θ	Observed intensity Visual	Observed intensity Measured	Calcd. intensity $\theta = 34°$ $\phi = 12°$

The position of the individual molecules in the unit cell was found through the assumption that their orientations are similar to biphenyl and terphenyl with a probable slighter tilt to the *c*-axis. After some trial and error experimentation, planar molecules with a carbon–carbon distance of 1.42

---

[8] A private communication from Dr. Wherry which stated that the crystal was monoclinic with β = about 92° agrees with the present finding.

[9] This report was presented at a meeting of the American Chemical Society in September, 1933.

[12] Hertel and Römer, *ibid.*, **B23**, 226 (1933).

Å. in the ring and 1.48 Å. between rings were postulated, with centers of symmetry at the coördinates (000) and (1/2,1/2,0) and rotated 34° (θ) about the c-axis and 12° (ϕ) about the b-axis from an original position in the (100) plane with length parallel to the c-axis. The intensity of reflections from such a structure agreed well with the experimental values as shown in Table III. The lack of agreement in the lower orders of the (001) planes is not significant as the factors used in the calculation are uncertain in this region.

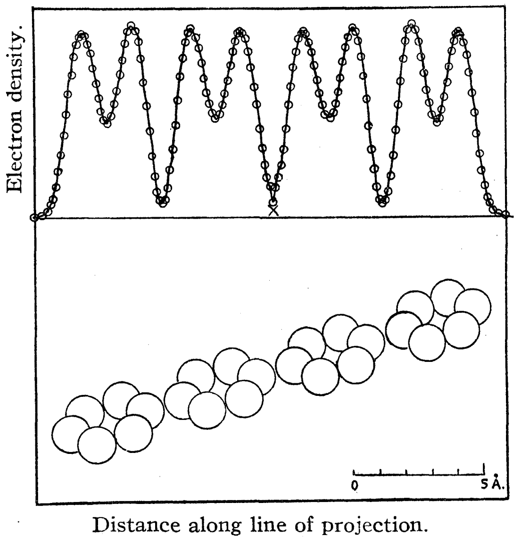

Fig. 1.—The projection of the electron density of quaterphenyl upon the line normal to the (001) plane is shown together with a diagrammatic representation of carbon atoms in an arrangement consistent with the projection. X is center of symmetry.

A one-dimensional projection of the electron density of the scattering matter in the crystal was made upon the normal to the (001) face. Relative F values were calculated from the measured intensities (I) of the first ten orders of the (001) planes according to the formula, $F = \left(I/1 + \frac{\cos^2 2\theta}{\sin 2\theta}\right)^{1/2}$ using the signs determined in the trial and error analysis described above. The electron density was found at points approximately 0.1 Å. apart (the unit cell length being divided into 180 parts), along the direction chosen for the projection, from the summation, $d = \Sigma F_{(001)} \cos 2\pi lz/c$. The values so obtained are plotted in Fig. 1 together with a molecular model which is consistent with the projection. The two molecules in the unit cell project as a single molecule since the atoms have like z-coördinates. Each peak apparently represents three unresolved atoms of carbon in each molecule.

From this experimental curve it is evident that the four benzene rings are extended coaxially while the equal width of peak suggests that the rings are coplanar. The length of projection of a single ring corresponds to that of a molecule with 1.42 Å. between the carbon atoms of the same ring and 1.48 Å. between those of adjacent rings if this molecule is placed at a tilt of 17.3° from the normal to the (001) face or 11.5° from the c-axis.

The above evidence does not exclude the possibility of a shorter molecule at a lesser tilt. For this reason, comparisons of observed and calculated structure factors were made for slightly differing structures (*e. g.*, for molecules with a distance between rings of 1.42 Å. and a tilt of 8.5°), using those planes which are accurately measurable and especially sensitive to change in length of the molecule, namely, (008), (009), $(20\bar{7})$ $(20\bar{8})$. The model described above with $\theta = 34°$, $\phi = 11.5°$, C–C = 1.48 Å. showed the best agreement with the experimental data. The structure factors of the above mentioned planes are insensitive to small changes in θ.

Krishnan and Banerjee[2] from measurements of magnetic susceptibilities independently reached the conclusion that the orientation of the quaterphenyl molecule was ±32° from the plane of symmetry and 17.1° from the normal to the (001) plane, results in close agreement with these.

The structure factors have been recalculated recently using the atomic f values for carbon in anthracene published by Robertson[13] and a carbon–carbon distance of 1.41 Å. which has been generally accepted for the aromatic carbon atom. Since there is less evidence for the distance 1.48 as existing between benzene rings these calculations were designed as a test of this distance. A comparison of structure factors for molecular models with $\theta = 32°$, $\phi = 11.3°$, a carbon–carbon distance in the ring of 1.41 Å. and the two alternatives 1.41 and 1.48 between rings is shown in Table IV with the experimental values. The results show conclusively that if the orientation of the molecule found from the magnetic susceptibility results and indicated independently by the x-ray work is correct, the distance between rings must be 1.48 rather than 1.41 Å. This is in accord with results of analyses of biphenyl[10] and terphenyl.[11]

[13] Robertson, *Proc. Roy. Soc.* (London), **A150**, 106 (1935).

TABLE IV

hkl	*F*, exptl.	*F*, calcd. C–C = 1.48	*F*, calcd. C–C = 1.41
008	49.5	49.3	37.4
009	53.0	53.1	65.0
$20\bar{7}$	40.5	38.1	27.3
$20\bar{8}$	63.6	66.0	75.3

Probable positions for the 48 carbon atoms in the unit cell are x,y,z; $\bar{x},\bar{y},\bar{z}$; $^1/_2 + x$, $^1/_2 - y,z$; $^1/_2 - x$, $^1/_2 + y,\bar{z}$; the values of x,y,z for the twelve carbon atoms in the half molecule are as follows

Atom	*x*	*y*	*z*
1	−0.018	0	0.040
2	+ .043	+0.186	.089
3	+ .009	+ .186	.165

9	− .096	+ .186	.398
10	− .192	0	.425
11	− .254	− .186	.376
12	− .220	− .186	.300

The writer wishes to acknowledge with appreciation the grant of the European Fellowship from the American Association of University Women which made possible the work; and to express to Sir William Bragg and the Managers of the Royal Institution her thanks for the privilege of making the measurements in the Davy Faraday Laboratory, and to Dr. K. Lonsdale for her helpful interest in the work.

Summary

Additional experimental data concerning the crystal structures of five biphenyl derivatives are presented.

The unit cell of quaterphenyl has the dimensions $a = 8.05$ Å., $b = 5.55$ Å., $c = 17.81$ Å., $\beta =$ approximately 95.8° and contains two centrosymmetrical molecules. Trial and error analyses together with a one-dimensional Fourier projection indicate that the molecules are oriented at an angle of 17.3° to the normal to the (001) plane in the acute angle β and that the carbon–carbon distance between benzene rings is 1.48 Å.

Ultraviolet Absorption and Rotatory Dispersion of 3-Methylcyclohexanone[1]

BY H. S. FRENCH AND M. NAPS

The rotatory dispersion within an absorption band has thus far been recorded for only a limited number of compounds. We have been especially interested in such work on compounds containing the carbonyl group. It has been proved conclusively for several of these carbonyl compounds, especially camphor,[2] camphor-β-sulfonic acid,[3] and carvomenthone,[4] that the zero molecular rotation (and also the maximum of circular dichroism) occurs at a wave length greater by 60 to 110 Å. than the wave length of the maximum for the carbonyl absorption band. At least a slight shift in this direction may be noted in almost all the carbonyl compounds[5] thus far reported upon, although it is not so marked in the simpler ketones. This shift has been interpreted by some investigators[2,6] to mean an induced dissymmetry of the chromophore and a difference between the two carbon–oxygen valences. The use of rotatory dispersion curves in these cases shows therefore the non-homogeneity of an absorption band, or the fact that it is actually made up of two overlapping bands.

The present study was undertaken in order to collect further evidence concerning the carbonyl group by the use of a different cyclic ketone, 3-methylcyclohexanone,[7] simpler in structure than most of the carbonyl compounds previously used.

Previous determinations of the absorption spectrum of 3-methylcyclohexanone[8] were done

either by the older Hartley–Baly method, or in solvents other than cyclohexane. Previous determinations of its rotatory power[9] have been carried out only for a limited number of wave lengths in the visible region of the spectrum. There have been no previous determinations of its rotatory dispersion in the ultraviolet.

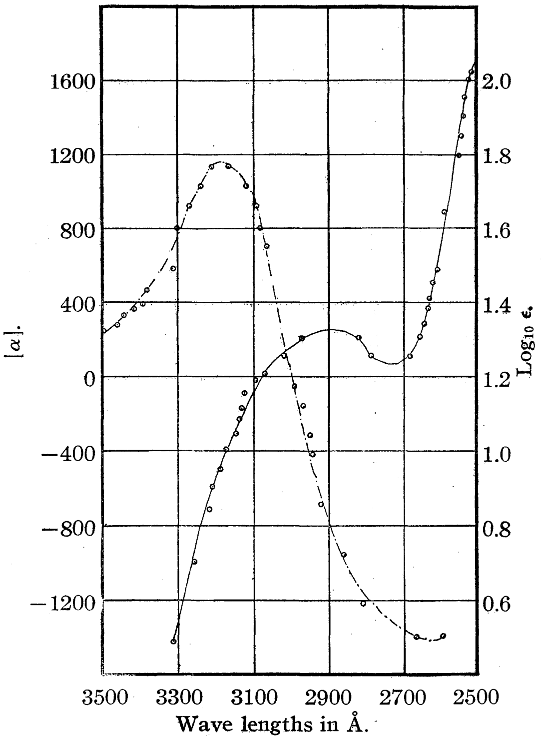

Fig. 1.—3-Methylcyclohexanone in cyclohexane: absorption spectrum, ————; rotatory dispersion, —·—·—·

The method for obtaining the absorption spectrum data has already been described in a communication from this Laboratory.[10] The rotatory dispersion data were obtained by the same method used in a previous publication.[3] The ultraviolet polarimeter was a new instrument, but was made by Hilger according to Lowry's specifications, and no new method was involved.

The 3-methylcyclohexanone is readily obtained in its optically active form by the hydrolysis of naturally-occurring optically active pulegone, and it is easily purified through its bisulfite addition compound.[11] The cyclohexane solvent used in both determinations was purified by the usual method.[12]

The results are shown in Tables I and II and in the curves.

(b)	3393	370.7	(e)	2667	−1401.0
(b)	3380	456.8	(e)	2598	

As expected, the positive and negative maxima of rotation occur approximately at the wave lengths corresponding to the half-width of the absorption band. The zero rotation is at 2970 Å., while the maximum of absorption is at 2890 Å. ($\log_{10} \epsilon = 1.34$). The zero rotation is thus displaced 80 Å. toward the red end of the spectrum.

There is therefore by this study added one more bit of evidence for the induced dissymmetry of the carbonyl group, and for the non-homogeneous nature of its absorption band.

Work is being continued along the same lines in this Laboratory on other cyclic ketones, and on similar compounds involving doubly-bound oxygen.

Summary

Tables and curves are given for the ultraviolet absorption and rotatory dispersion of 3-methylcyclohexanone in cyclohexane solution. These afford further evidence for the non-homogeneous nature of the carbonyl absorption band, and for the induced dissymmetry of the carbonyl group.

The Oxidation–Reduction Potentials of Derivatives of Thioindigo. I. Thioindigo Tetrasulfonate

BY PAUL W. PREISLER AND LOUIS H. HEMPELMANN

Until the mathematical formulation of the potential changes of the two-step oxidation–reduction process, involving one electron per step, by Michaelis[1] and by Elema,[2] resulting from their work upon the natural pigment pyocyanine, the potentials of all organic oxidation–reduction systems previously measured, which required two electrons per molecule for reduction, were considered to be one-step processes involving a pair of electrons.

Sullivan, Cohen and Clark,[3] who originally investigated systems of indigo sulfonate–leuco indigo sulfonate, considered these to be of the one-step two-electron class. Preisler and Shaffer[4] found that in the *p*H range of 10 to 12, red intermediate colors were formed, between the blue colors of the oxidants of indigo sulfonates and the yellow colors of the fully reduced reductants, when the oxidants were reduced by gradual addition of sodium hydrosulfite. A determination of the oxidation–reduction potentials in alkaline buffers revealed that these systems exhibited the characteristics of a two-step process.

An investigation of the potentials of simple and substituted sulfonates of the closely related thioindigo[5] is being conducted, to ascertain whether these exhibit the two-step oxidation–reduction process, to obtain further information on the nature of intermediary reduction products, and to study the effects of substitution on the potentials.

Since the initiation of this work, Remick[6] has reported on the potentials of thioindigo disulfonate and its reduction product and has concluded that his results with this compound show "... that the dye underwent a dimolecular reduction, involving but one electron per molecule of dye. The experimental data conform with the following mathematical formulation and establish this as the first system observed to undergo a thermodynamically reversible, dimolecular, oxidation–reduction reaction. No evidence of a second step was found." His mathematical formulation is developed on the assumption that this type of chemical reaction occurs.

This unusual interpretation of the thioindigo–leuco thioindigo system prompts the presentation at this time of results of work on the potentials of thioindigo tetrasulfonate, a representative derivative, which have been found to follow the same general mathematical formulations to which other previously studied organic systems seem to conform.

The potentials of the thioindigo tetrasulfonate–leuco thioindigo tetrasulfonate mixtures in acidic buffers of *p*H below 3 give typical curves approaching in shape those of a one-step two-valent process and in buffers of *p*H above 10.5 give curves showing transition into the shapes characteristic of the two-step process. In the *p*H range below 3, the E'_0–*p*H curve of the system oxidant–semiquinone lies in a region of more negative potential, and the E'_0–*p*H curve of the system semiquinone–reductant in a region of more positive potential, than that of the resultant oxidant–reductant curve; in the *p*H range above 10.5 the relative

positions are reversed. The much deeper red colors of the partly reduced solutions in buffers above *p*H 10.5 offer additional evidence of semiquinone formation.

Experimental

Thioindigo tetrasulfonate may be prepared as a well-crystallized tetrapotassium salt by the following method. Suspend 10 g. of powdered thioindigo[7] (Rowe: Colour Index No. 1207) in 100 cc. of metallic-salt-free 30% excess sulfur trioxide, fuming sulfuric acid, in a long-necked flask lightly stoppered with a glass bulb. Heat for four hours or longer in a suitable bath at 145–150° under a hood since sulfur trioxide fumes are evolved copiously. Cool, pour the mixture into 1 liter of water and filter. Add small portions of 50% filtered potassium carbonate solution until but little carbon dioxide is evolved on addition and the mixture is still slightly acid to congo red. Filter off the light red precipitate and wash with a filtered 5% KAc–0.3% HAc solution to remove sulfate. Dissolve the precipitate in 1 liter of water, heat to boiling, add 100 cc. of a filtered 50% KAc–3% HAc solution and allow to cool slowly. Filter off the crystalline red salt and wash at least ten times with filtered 5% KAc–0.3% HAc solution and then at least ten times with 95% alcohol followed by some absolute alcohol; yield about 80%.

Analyses of material prepared by this method were made for sulfur and potassium: sulfur by fusion with sodium dioxide, potassium perchlorate and benzoic acid, in a Burgess–Parr bomb, precipitating as barium sulfate, igniting and weighing; for potassium by ashing to potassium sulfate and weighing. Samples were dried for five hours at 200° or at 135° and 5 mm. The moisture of different preparations varied from 6 to 9%.

Potassium: found, 20.03, 19.97, 20.01, average 20.00%; calcd., 20.34%. Sulfur: found, 24.66, 24.68, average 24.67%; calcd., 25.02%. Sulfur–potassium atomic ratio, 1.505, corresponding to 6.02 S to 4.00 K, calcd. 6 to 4. The slightly low values for potassium and sulfur are perhaps due to incomplete drying. Some of the moisture in the original sample is probably in the combined state, since the sample becomes much darker red on heating. The position of the KSO_3-groups was not determined but by analogy to indigo they are considered to be in the 5,5′,7,7′-positions.

The potentials of two platinum electrodes, immersed in the buffered solution of the thioindigo tetrasulfonate and its reduction products, were measured by a potentiometer system against a saturated calomel cell connected to the solution by a 5% agar–saturated potassium chloride bridge. Electrodes usually agreed to within 0.0002 volt. The calomel cell was standardized against a hydrogen electrode in 0.05 *M* acid potassium phthalate. The *p*H values of the buffers were determined by a hydrogen electrode.

The mixture of oxidant and its reduction products was made by titrating the deoxygenated, buffered, oxidant solution with a reducing agent similarly prepared. The volume at the beginning of the titration was 55 cc. and about 10 to 15 cc. was added. The E_0' values and slopes were determined graphically; the table summarizes the results.

POTENTIALS OF MIXTURES OF EQUIVALENT AMOUNTS OF OXIDANTS AND REDUCTANTS IN BUFFERS AT VARIOUS *p*H

*p*H	E_0' ox–red volt	$(E^1/_4 - E^3/_4)/2$	E_0' ox–semi	E_0' semi–red	Type buffer
0.04	0.408	(Between			HCl
.78	.362	0.014–0.015)			HCl
1.09	.345				HCl
1.48	.323				Citrate
2.05	.290				Citrate
2.97	.236				Citrate
3.56	.200				Citrate
4.00	.177				Citrate
4.46	.162				Citrate
4.73	.147				Citrate

11.18	−.059	.036	− .029	− .089	Phosphate

The buffers were 0.05 to 0.10 *M* in buffering ion and the reactants about 0.0005 *M;* no correction was made for the *p*H changes accompanying the reduction. An equivalent amount of sodium hydroxide was added to the titanium trichloride titrating solutions to compensate for the excess hydrochloric acid (7.493 *N*) in the commercial titanium trichloride (1.29 *M*) preparations. Titanium trichloride was used as reducing agent in buffers from *p*H 0.04 through 4.73; sodium hydrosulfite in the more alkaline buffers.

Commercial tank nitrogen, deoxygenated by passing over heated copper, was used to deoxygenate and stir the solutions. Temperature variations were less than 0.1° and the bath was maintained at 30.0°.

The number of equivalents involved in the complete reduction of indigo tetrasulfonate was determined by comparing the quantity of standard titanium trichloride solution required to reduce a known quantity with that required by a standard ferric chloride solution: 0.404 g. of thioindigo tetrasulfonate containing 5.6% moisture, was made up to 100.00 cc. Of this solution, 5.00 cc. was added to 50.00 cc. of hydrochloric acid, the final *p*H of this mixture being 0.78. At this *p*H, the potential mixture curve most closely resembled a two-electron shape curve, as given by $E_h = E_0' - (RT/nF) \log_e [(\text{Red})/(\text{Ox})]$, the E_0' values calculated from experimental measurements, taken at 1-cc. intervals, were within 0.001 volt of the theoretical E_0' for all mixtures containing from 6.3 to 94.9% of reductant. This solution required for complete reduction to a pale yellow solution, 15.8 cc. of a titanium trichloride solution in similar buffer. Five cc. of a 0.0101 *N* ferric chloride solution added to 50.00 cc. of about 1 *N* hydrochloric acid with titrated titanium trichloride of the same strength as used in the indigo tetrasulfonate determination required 15.6 cc., both end-points being determined graphically. Calculation shows that within the limits of

---

[7] Obtained through the courtesy of the Society of Chemical Industry in Basle.

experimental error, two equivalents of reducing agent per mole of indigo tetrasulfonate were used. Similar relationships hold at all other pH values studied. The data of Knecht and Hibbert[8] on the use of titanium trichloride for determination of thioindigo led to the same conclusion.

The initial concentration of the oxidant was changed by adding 35 cc. of the above solution of hydrochloric acid of proper strength to make final pH of 0.78 and diluted to 55.00 cc. and then titrated with a titanium trichloride solution of seven times the concentration of the previously used solution. The E_0' of this titration was within 0.001 volt of the E_0' of the above titration. The maximum calculated pH change would correspond to about 0.002 volt. Concentration apparently has but little effect on potential in this pH region. All other titrations were made at about 0.0005 M initial oxidant concentration. The effect of concentration changes in the region of apparent semiquinone formation was not studied because of certain decompositions of the materials in the alkaline buffers, which would make the results questionable. The occurrence of semiquinones, rather than meriquinones, is not absolutely established but the results fit the general theoretical considerations and are analogous to those with indigo sulfonates where semiquinone formation seems the most likely explanation.

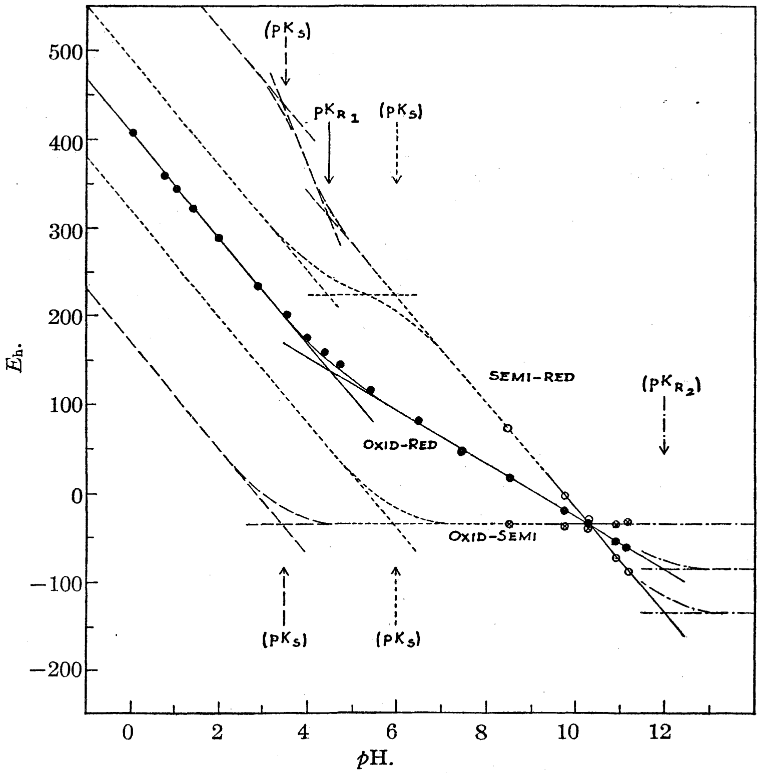

Fig. 1.

Discussion

The relationships existing between the two component oxidation–reduction systems and their resultant can be more easily recognized by a study of the graph showing the corresponding curves of E_0' against pH.

The change in slope of the resultant oxidant–reductant E_0'–pH curve at pH 4.5 indicates an ionization in the reductant; a color change to deeper yellow accompanies the ion formation. The experimental points from pH 8.5 to 11.2 set the slopes of the two primary E_0'-pH curves in this region. The pK of the semiquinone may be either lower or higher than this first pK at 4.5 of the reductant: if lower, the slopes of the semiquinone–reductant E_0'–pH curve (shown by the long-dash line), as it extends into more acid regions from pH 8.5, will change from 0.06 to 0.12 at the pK of the reductant and then to 0.06 again at the pK of the semiquinone; and, if higher, it will change (shown by the short-dash line), from 0.06 to 0.00 at the pK of the semiquinone and from 0.00 to 0.06 at the pK of the reductant. The slope of the oxidant–semiquinone E_0'–pH curve is 0.00 at pH 8.5 or higher pH and will change to a slope of 0.06 at the pK of the semiquinone. The relative positions of the pK values will determine which order of slopes will prevail, the curves drawn are for illustration of the effect only and do not represent accurate location.

An exact estimation of the pK of the semiquinone cannot be made with the data at hand: the instability of the potentials and the momentary deepening of the red color on addition of reducing agent in buffers about pH 5 suggests that a different ionic species of the semiquinone with somewhat slower reaction rate is perhaps present in this region, although its relative position to the first pK of the reductant is indeterminate. This would suggest that the pK of semiquinone is higher than the pK of reductant and that the system is of the type indicated by the short-dash lines.

The decomposition of materials in buffers of pH greater than 11.5 prevents the estimation of the second pK of the reductant. At higher pH than this pK, all E_0'–pH slopes would be 0.00 (shown by short-dash long-dash line).

The above interpretation seems consistent with the results obtained and follows the general theory

---

[8] E. Knecht and E. Hibbert, *Ber.*, **40**, 3821 (1907).

which apparently holds for other readily reversible electromotively active organic oxidation–reduction systems. Preliminary experiments with certain other substituted thioindigo sulfonates indicate that these also exhibit semiquinone formation.

The formulation by Remick for the thioindigo disulfonate–leuco thioindigo disulfonate system was developed by considering that the reduction of two molecules of oxidant involving two electrons, one for each molecule, resulted in the formation of one molecule of reductant. This interpretation cannot be applied to the data presented for the tetrasulfonate, which show that one molecule of oxidant requires two reducing equivalents for conversion into one molecule of reductant. The introduction of the additional two sulfonic acid groups probably would not change the fundamental character of the reduction process of the thioindigo nucleus. The oxidation–reduction process for the several homologous indigo sulfonates has been found to be of the same type.

A comparison of the constants of indigo tetrasulfonate ($E_0 = 0.365$ volt and $pK_{R1} = 6.9$) and thioindigo tetrasulfonate ($E_0 = 0.409$ volt and $pK_{R1} = 4.5$) reveals that the substitution of S for N into the two heterocyclic organic nuclei would increase the E_0 value and the acidic dissociation of the reductant.

The instability of the oxidant or its reduction products and the semiquinone formation make thioindigo tetrasulfonate unsuitable for use as an oxidation–reduction potential indicator, except in acid pH regions below about pH 2.5.

Summary

The tetrapotassium salt of thioindigo tetrasulfonate has been prepared after direct sulfonation of thioindigo with fuming sulfuric acid. The oxidation–reduction potentials of the system thioindigo tetrasulfonate–leuco thioindigo tetrasulfonate have been determined for the pH range 0.0 to 11.5. The orange-red oxidant is converted into the yellow reductant by a reaction involving two reduction equivalents per molecule. The constants of the system established are $E_0 = 0.409$ volt and the first pK of the reductant is 4.5. Formation of a deeper red semiquinone was noted in the pH region from 8.5 to 11.5. Except in acid solution of pH less than 2.5, the material is not particularly suitable as an oxidation–reduction indicator.

The Preparation of Some Organic Mercurials from Diazonium Borofluorides

BY MELVIN F. W. DUNKER,[1] EDGAR B. STARKEY AND GLENN L. JENKINS

Of the many methods of making aromatic mercury compounds, only two have made use of the diazonium salts. McClure and Lowy[2] noticed that on reducing electrolytically a diazonium solution using mercury electrodes, a small amount of mercurial was formed. They were also successful in preparing the corresponding mercury derivatives by stirring the diazonium solution with finely divided mercury produced mechanically. Nesmejanow[3] has succeeded in preparing the mercury derivatives of nuclei containing no group or groups such as alkyl, halogen, hydroxyl, etc., by treating the diazonium chloride–mercuric chloride double salt with precipitated copper powder; but when the nuclei contained groups such as carboxyl, nitro, sulfonic acid, etc.,[4] temperatures ranging from −10 to −70° were necessary.

Using more stable diazonium compounds such as the diazonium borofluorides of Balz and Schiemann,[5] and by producing very finely divided mercury by reduction with stannous chloride directly in the reaction mixture, it was found that some aromatic mercurials could be prepared in better yields. The replacement of the diazonium group with mercury was carried out at room temperature. In the course of the preparation of the necessary diazonium borofluorides, better yields were obtained by diazotizing in borofluoric acid.

The probable equations are illustrated by the following

Experimental

Diazonium Borofluorides.—The preparation of phenyl diazonium borofluoride illustrates the improved method referred to above.

To a mixture of 21.6 g. of aniline in 115 cc. of 50% fluoboric acid cooled in an ice-bath and stirred vigorously was added slowly a solution of 18 g. of sodium nitrite in 36 cc. of water. The diazonium compound was collected on a Büchner funnel, washed once with fluoboric acid, twice with alcohol and then thoroughly with ether. The yield was 90 to 97% of the theoretical amount as compared to 63% reported by Balz and Schiemann.[5] The yields of the other diazonium borofluorides are given in the table.

Phenylmercuric Chloride.—To a rapidly stirred suspension of 12.7 g. of $SnCl_2 \cdot 2H_2O$ and 7.0 g. of mercuric chloride in 50 cc. of acetone and 25 cc. of water was slowly added a solution of 5.0 g. of $C_6H_5N_2BF_4$ and 10.5 g. of mercuric chloride in 200 cc. of acetone. When the effervescence had ceased, the mixture was refluxed for about ten minutes and filtered hot, washing the residue with small portions of hot acetone. On standing, 5.25 g. of phenylmercuric chloride crystallized out, representing 60% of the theoretical based on aniline as compared to 51% obtained by Nesmejanow[3] and 70% obtained by the same author[4] at −70°. When the above reaction was carried out at 0 to 5°, a yield of 16% was obtained.

***p*-Chloromercuri-benzenesulfonic Acid, *o*-Chloromercuri-benzoic Acid, *p*-Chloromercuri-benzoic Acid.**—These compounds were prepared in the same manner, except that the diazonium borofluorides and mercuric chloride were added as a suspension rather than a solution, the volume of the solvent being reduced from about 300 to 100 cc. or less. The mercurial was extracted from the mixture with ammonium hydroxide and then converted to the free acid.

5-Chloromercuri-salicylic Acid.—In this case no appreciable yield was obtained using stannous chloride. To a suspension of 0.04 mole of precipitated copper powder and 0.016 mole of mercuric chloride in 150 cc. of water was added a dry mixture of 0.016 mole of the diazonium compound and 0.016 mole of mercuric chloride. The solid was filtered out and extracted with 10% sodium hydroxide. The sodium hydroxide solution was decolorized with charcoal and precipitated with hydrochloric acid. The mercurial was crystallized from acetone and then from alcohol.

In an attempt to prepare 2-chloromercuri-*p*-phenolsulfonic acid by the above method, the product obtained as indicated by analysis seemed to be 2,6-dichloromercuri-*p*-phenolsulfonic acid. Rupp and Herrmann[6] reported the mono-mercury compound to be unstable, changing to the di-mercury compound on crystallization from water.

***p*-Chloromercuri-diphenyl.**—Five grams of *p*-diphenyldiazonium borofluoride and 5 g. of mercuric chloride were mixed with 50 cc. of glacial acetic acid and added slowly to 5 g. of mercuric chloride and 8 g. of $SnCl_2 \cdot 2H_2O$ in 50 cc. of acetone. The mixture was stirred for two hours and filtered. On standing in a refrigerator, the filtrate deposited shiny white plates. The mercurial was crystallized from acetone. The crystals melted at 329° with decomposition. When copper powder was used, no mercurial was obtained. If the reaction mixture was cooled strongly, the decomposition was very slow. It is believed that this is the first report of the preparation of this compound.

Further applications of this method of synthesis of mercurials are being studied.

TABLE I

Aryl radical	Yield of diazonium compd., %	Chloromercuri compds. % yield based on amine	% Hg Calcd.	% Hg[a] Found
Phenyl	90–97	60	64.1	64.5

[a] The mercury analyses were made by the method of Tabern and Shelberg, *Ind. Eng. Chem., Anal. Ed.*, **4**, 401 (1932).

Summary

1. Several aryl mercurials have been prepared by replacing the diazonium borofluoride group using freshly reduced mercury.

2. A new compound, *p*-chloromercuri-diphenyl has been prepared.

3. An improved method for the preparation of diazonium borofluorides is reported.

The Reaction of Potassium Amide in Liquid Ammonia with Diarylbromoethenes

By George H. Coleman, William H. Holst and Roy D. Maxwell

The behavior of certain diarylchloroethenes and ethanes with potassium amide in liquid ammonia has been reported in a previous paper.[1] These compounds are not affected by boiling alcoholic potassium hydroxide but are very rapidly changed with the loss of hydrochloric acid by potassium amide in liquid ammonia to the corresponding tolanes. To illustrate, 1,1-di-*p*-tolyl-2-chloroethene forms *p,p'*-dimethyltolane. A series of such para substituted compounds was studied and as anticipated only symmetrical tolanes were obtained.

The present paper is a report of work with diarylbromoethenes having substituents in the ortho and in the meta positions of the aryl radicals. The bromoethenes were used since they could be prepared more easily than the corresponding chlorine compounds. In order to determine whether bromoethenes would undergo the rearrangement with potassium amide as readily as chloroethenes, the reaction was first tried with 1,1-diphenyl-2-bromoethene and 1,1-di-*p*-tolyl-2-bromoethene. Good yields of tolanes were formed.

The following ortho and meta substituted bromoethenes were used: 1,1-di-*o*-tolyl-2-bromoethene; 1,1-di-*o*-methoxyphenyl-2-bromoethene; 1,1-di-*m*-tolyl-2-bromoethene; and 1,1-di-*m*-methoxyphenyl-2-bromoethene. In each case the corresponding symmetrical tolane was obtained.

With respect to the mechanism of the reaction the question of whether a proton or the halide ion is first removed from the molecule was considered. The loss of a proton due to the presence of a base (in this case the amide ion, NH_2^-) has been proposed as the initial step in several related reactions.[2] However, the mechanism given by Whitmore and Fleming[3] for the formation of trimethylethylene and *t*-amyl acetate in the reaction of neopentyl iodide with silver acetate in acetic acid seems more applicable to the present case. According to this mechanism the diarylbromoethene first loses the halide ion leaving a carbon atom with a sextet of electrons. This carbon attracts a pair of electrons from the next carbon atom, the aryl group held by the shifting electron pair moving with it. The system thus formed is still electronically deficient. This deficiency is satisfied by the shift of an electron pair to form a triple bond and liberate a proton, thus forming a tolane.

If the loss of a proton is assumed as the first step the formation of a tolane can also be explained by a somewhat similar mechanism. However Buttenberg[4] obtained a mixture of diphenylvinyl ethyl ether and tolane when 1,1-diphenyl-2-chloroethene was heated with sodium ethylate at about 200°. The formation of diphenylvinyl ethyl ether is not readily explained if the removal of a proton is assumed as the first step. In the present work with potassium amide no amine was found in the reaction product but this would not necessarily exclude the mechanism proposed.

In the work with diarylchloroethenes[1] it had been observed that the yields of tolanes were 90% or above for all the compounds used except those containing the *p*-ethylphenyl, *p*-*n*-propylphenyl and *p*-*n*-butylphenyl groups. From these compounds liquid mixtures were formed containing not more than 60% of the pure tolanes. In seeking the cause for this difference the purity of the starting material was considered. Since these diarylchloroethenes were liquids the purity could not be as easily determined as with solids. Therefore several diaryldibromoethanes and diaryldichloroethanes, all of which were solids were prepared, carefully purified and treated with potassium amide in liquid ammonia. The compounds used were: 1,1-diphenyl-2,2-dibromoethane, 1,1-diphenyl-2,2-dichloroethane, 1,1-di-*p*-tolyl-2,2-dibromoethane, 1,1-di-*p*-tolyl-2,2-dichloroethane, 1,1-di-*p*-ethylphenyl-2,2-dibromoethane and 1,1-di-*p*-ethylphenyl-2,2-dichloroethane. From the phenyl and *p*-tolyl compounds the yields of tolanes were about 90–95% of the theoretical. With the *p*-ethylphenyl compounds the products were again oily mixtures from which yields of only 50–70% of pure tolanes could be separated.

o,o'-Dimethyltolane	138–142	0.75	n^{20}_D 1.6228	

The structures of the tolanes were proved by two methods. One was the synthesis of the corresponding stilbene from monochloroacetal and Grignard reagents and the conversion of the stilbene to the symmetrical dibromoethane from which the tolane was formed by treatment with alcoholic potassium hydroxide. The other method was the reduction of the tolanes to bibenzyls with boiling absolute alcohol and sodium.[5] This method was also used to prove more conclusively the structures of some of the tolanes reported in the previous paper.[1]

Experimental Part[6]

Diarylbromoethenes.—The bromoethenes were prepared by treating the corresponding unsymmetrical diarylethenes with bromine by a modification of the method used by Hepp.[7] The dibromo compounds formed by the addition of bromine were unstable and lost hydrogen bromine either during the reaction or the subsequent heating.

The unsymmetrical diarylethenes were prepared by treating the methyldiarylcarbinols with phosphorus pentachloride or thionyl chloride to form the methyldiarylchloromethanes followed by subsequent splitting out of hydrochloric acid by treatment with alcoholic potassium hydroxide or pyridine. The methyldiarylcarbinols were prepared by the method of Allen and Converse.[8]

The general procedure used in preparing the diarylbromoethenes is illustrated by the following preparation of 1,1-di-*o*-tolyl-2-bromoethene. Fourteen and one-half grams of di-*o*-tolylmethylcarbinol was dissolved in 100 cc. of carbon tetrachloride. After cooling the mixture to 0°, 7.6 g. of thionyl chloride was slowly added with occasional shaking. After addition, the reaction was allowed to proceed at room temperature for four hours. Fifteen grams of pyridine was added and the mixture was allowed to stand overnight. A solid, pyridine hydrochloride, formed and was filtered off, after which the solution was washed with water to remove excess pyridine and then dried with calcium chloride. After separating from the calcium chloride 11 g. of bromine was added and the mixture allowed to stand one hour with occasional shaking. A little cyclohexene was added to remove the excess bromine and the solvent evaporated under reduced pressure. Thirteen grams of crude liquid remained. Upon distillation under reduced pressure, two fractions were obtained: Fraction (1) 1.9 g. boiling below 120° (1.5 mm.). Fraction (2) 10.9 g. boiling at 140–155° (1.5 mm.) (90% at 150–155°).

Anal. of Fraction (2). Calcd. for $C_{16}H_{15}Br$: Br, 27.87. Found: Br, 28.01.

The physical properties and analyses of the bromoethenes not previously recorded are given in Table I.

Tolanes.—The general procedure used in carrying out the reaction of potassium amide with bromoethenes was essentially the same as that reported by Coleman and Maxwell[1] with chloroethenes. The following preparation of *m,m'*-dimethyltolane will illustrate. Two grams of metallic potassium was dissolved in 350 cc. of liquid ammonia contained in a Dewar flask. The potassium was converted to the amide and 5 g. of 1,1-di-*m*-tolyl-2-bromoethene dissolved in ether was slowly added. After evaporation of the ammonia, the product was extracted with ether and the ethereal solution washed and dried. The solvent was evaporated under reduced pressure and 3.4 g. (91%) of crude solid, melting at 68–70°, remained. Upon recrystallization from 95% alcohol, 3.2 g. (89%) of pure *m,m'*-dimethyltolane melting at 73.5–74° was obtained. The tolanes prepared are given in Table I.

Stilbenes.—The preparation of the symmetrically substituted stilbenes was carried out by the method described by Späth.[9] *o,o'*-Dimethylstilbene and *m,m'*-dimethylstilbene were both obtained in this manner.

Bromination of Stilbenes.—The procedure followed is illustrated by the following preparation of 1,2-di-*o*-tolyl-1,2-dibromoethane. One gram of *o,o'*-dimethylstilbene was dissolved in 10 cc. of dry carbon tetrachloride. To this solution 0.8 g. of bromine in 10 cc. of carbon tetrachloride was added. A white crystalline solid melting at 171–172° was obtained; yield 1.6 g. The two *sym*-diaryldibromoethanes prepared are given in Table I.

Tolanes from *sym*-Diaryldibromoethanes.—One gram of 1,2-di-*m*-tolyl-1,2-dibromoethane was refluxed with alcoholic potassium hydroxide for three hours. The solution was decanted from the potassium bromide and 50 cc. of ether added. This solution was washed with water, sepa-

rated and dried. The solvent was evaporated under reduced pressure. One-half gram of the crude tolane melting at 66–68° was obtained. Upon recrystallization from 95% alcohol, 0.48 g. of pure *m,m'*-dimethyltolane melting at 73.5–74° was obtained. A mixed melting point with *m,m'*-dimethyltolane prepared from 1,1-di-*m*-tolyl-2-bromoethene showed no depression.

The same procedure was used with 1,2-di-*o*-tolyl-1,2-dibromoethane. *o,o'*-Dimethyltolane was obtained, n^{20}_D 1.6214. The index of refraction of the tolane prepared from 1,1-di-*o*-tolyl-2-bromoethene was n^{20}_D 1.6228.

Bibenzyls.—All tolanes were reduced by the following method which is a modification of the one described by Aronstein and Holleman.[5] One gram of tolane was dissolved in 15 cc. of absolute alcohol. The solution was heated to boiling and immediately poured, with caution, into a flask containing 1.5 g. of metallic sodium, cut in small pieces and freed from oxide and ligroin. The flask was then attached to a reflux condenser and the mixture refluxed until all the sodium was dissolved.

The mixture was cooled and 60 cc. of distilled water was added to decompose the sodium ethylate after which the entire solution was extracted with 100 cc. of ether. The ethereal solution was dried, filtered and the solvent evaporated under reduced pressure. One and one-tenth grams of crude bibenzyl melting at 49–51° remained. One gram of pure bibenzyl melting at 51.5–52.5° was obtained upon recrystallization from 95% alcohol. A mixed melting point with pure bibenzyl showed no depression. The bibenzyls prepared by this procedure are given in Table II.

unsym-**Diaryldichloroethanes.**—The following unsymmetrical diaryldichloroethanes were prepared from dichloroacetal and aromatic hydrocarbons by the methods described by Buttenberg[4] and by Wiechell:[10] 1,1-diphenyl-2,2-dichloroethane, 1,1-di-*p*-tolyl-2,2-dichloroethane and 1,1-di-*p*-ethylphenyl-2,2-dichloroethane.

unsym-**Diaryldibromoethanes.**—Three unsymmetrical diaryldibromoethanes corresponding to the chloroethanes were prepared from dibromoacetal and aromatic hydrocarbons. The following procedure for the preparation of 1,1-di-*p*-tolyl-2,2-dibromoethane is typical.

Twenty-five grams of dibromoacetal[11] was dissolved in 20 g. of toluene in a 500-cc. Erlenmeyer flask. This mixture was cooled to 5–8° and 75 cc. of concd. sulfuric acid added with stirring at such a rate that the temperature did not rise above 50°. The mixture was stirred for one hour after addition of the acid. It was then poured into 600 cc. of ice and water, whereupon a solid separated; 16.8 g. (50%) melting at 93–96° was obtained. After recrystallization from 95% alcohol the melting point was 95.5–96.5°.

Tolanes from Diaryldibromoethanes and Diaryldichloroethanes.—The reactions of these compounds with potassium amide were carried out in essentially the manner described for the ethenes except that the relative amount of potassium amide was doubled. The results for the six compounds used are listed in Table III. The products were identified by mixed melting points with authentic samples.

TABLE III

DIARYLDICHLOROETHANES AND DIARYLDIBROMOETHANES WITH POTASSIUM AMIDE IN LIQUID AMMONIA

Substance	M. p., °C.	Yield of tolanes, %
1,1-Diphenyl-2,2-dibromoethane	79.5–80.5	95
1,1-Diphenyl-2,2-dichloroethane	74–75	91
1,1-Di-*p*-tolyl-2,2-dibromoethane	95.5–96	92
1,1-Di-*p*-tolyl-2,2-dichloroethane	80–80.5	86
1,1-Di-*p*-ethylphenyl-2,2-dibromoethane	79–79.5	73
1,1-Di-*p*-ethylphenyl-2,2-dichloroethane	56–56.5	52

Summary

1. The action of potassium amide in liquid ammonia on 1,1-diaryl-2-bromoethenes causes the loss of a molecule of hydrogen bromide and the rearrangement of the molecule to form substituted tolanes.

2. A mechanism for the reaction is suggested. A given substituent in the phenyl group of the ethene is found in the same position relative to the point of attachment of the phenyl radical in the corresponding tolane.

Reduction of Acetobromoarabinose by Zinc and Acetic Acid[1]

BY GEORGE E. FELTON

The reaction of a suspension of zinc dust in acetic acid on an acetobromo sugar was carried out first by Emil Fischer.[2] The object of his experiment was to replace the bromine atom of the acetobromoglucose by hydrogen to obtain thereby an acetylated anhydrosorbitol derivative, tetraacetyl styracitol. As is now well known the product sought was not obtained by this method. However, a good yield of an unsaturated acetylated glucose derivative, named triacetyl glucal, was secured. The glucal and similar derivatives of other hexoses, pentoses and disaccharides have since proved of great value in the synthesis of new compounds, so that the discovery of this reaction is now considered a very fortunate occurrence in carbohydrate chemistry.

As a step in the preparation of *l*-arabinal, to be used for degradation to *l*-erythrose by means of ozone splitting[3] acetobromoarabinose was reduced numerous times by means of zinc and acetic acid. The yields obtained by Austin and Humoller[4] with zinc containing 5% of a copper–zinc couple were practically exactly duplicated by using a few drops of chloroplatinic acid for each preparation as had been suggested by Bergmann, Schotte and Rennert[5] in the preparation of rhamnal.

Gehrke and Aichner[6] reported that the products of the zinc and acetic acid reduction of acetobromoarabinose were a low boiling compound of watery consistency, diacetylarabinal and a higher boiling very viscous compound, triacetylarabinose. The triacetylarabinose was identified by acetylating to give a known tetraacetate. Besides the two reported compounds a third product has now been obtained. This product remained in the distilling flask after the diacetylarabinal and triacetylarabinose had been driven off as much as possible. The new compound was secured in crystalline form by taking up the residue in hot alcohol and allowing the solution to cool. If a large amount of sirup remained in the flask, the alcohol solution had to be seeded to effect a separation of the crystalline compound.

The properties of this new compound were as unexpected as those of the first glucal preparation. The derivative contained no halogen, unsaturated linkages, or free reducing groups detectable by boiling Fehling's solution. From benzene it was obtained in the form of needles melting at 167–169°, whereas from absolute alcohol it appeared as diamond-shaped plates melting at 184.5–185.5°. Each form was readily converted into the other and neither contained any solvent of crystallization. The compound was obtained from 95% alcohol occasionally in the lower melting form but most often in the higher.

After acid hydrolysis the compound reduced Fehling's solution, thereby suggesting a glycosidic linkage. The freezing point lowering in benzene showed a molecular weight of about 390. Four acetyl groups were found by alkaline hydrolysis. Carbon and hydrogen analyses agreed most closely with the values calculated for a tetraacetyl desoxypentose disaccharide.

The acetyl groups were removed by barium hydroxide hydrolysis and the acetyl free sugar obtained in crystalline form. It possessed an unsharp decomposition point of about 177–180°. The acetyl free product did not reduce Fehling's solution until after acid hydrolysis. The carbon and hydrogen analysis agreed with the values calculated for a desoxypentose disaccharide.

Attempts to prepare a benzylphenylhydrazone, after hydrolyzing by refluxing with dilute hydrochloric acid, failed to yield a crystalline derivative. This negative result may have been due to decomposition of the simple sugar formed by the hydrolysis.

Experimental

Reduction of Acetobromo-*l*-arabinose.—The reduction of acetobromoarabinose was carried out according to the procedure of Levene and Mori[7] for the preparation of diacetylxylal. The diacetylarabinal and triacetylarabinose formed from 90 g. of acetobromoarabinose were distilled

off in a vacuum as completely as possible without heating the bath to over 150°. The residue remaining in the distilling flask was dissolved in 10 cc. of warm 95% alcohol. This solution was allowed to stand at room temperature until crystallization of the new compound reached completion. Cooling to 0° would precipitate sirupy reducing compounds which had not been removed by the distillation. The crystallization at room temperature was very satisfactory although low yields of the non-reducing compound necessitated the use of seed crystals. The solid product was then filtered and purified by recrystallization from a small amount of absolute alcohol. One recrystallization served to free the product from reducing materials and further recrystallizations caused no more change in its physical constants. The crystals were diamond-shaped plates and melted at 184.5–185.5°; $[\alpha]^{23}\mathrm{D}$ +69.2° (0.1705 g. in 9.98 cc. of chloroform in a 1.1-dm. tube rotated 1.30° to the right). Recrystallized from benzene the compound formed needles which melted at 167–169°; $[\alpha]^{23}\mathrm{D}$ +69.5° (0.1774 g. in 9.98 cc. of chloroform in a 1.1-dm. tube rotated 1.36° to the right). Neither crystalline form lost any weight on drying over phosphorus pentoxide at 78° in a vacuum.

The new compound was secured in yields of from 0.1 to 1 g. for each 90 g. of acetobromoarabinose reduced. The yields of diacetylarabinal and triacetylarabinose were 34 g. and 8 g., respectively.

The compound was easily soluble in chloroform, warm alcohol, ethyl acetate and acetic acid, slowly soluble in benzene, insoluble in cold alcohol and ether and very insoluble in water.

The non-reducing material gave a molecular weight of 390 (0.5706 g. in 80.5 g. benzene gave a freezing point lowering of 0.094°). A tetraacetyl desoxypentose disaccharide would have a molecular weight of 418.

Anal. Calcd. for $C_{18}H_{26}O_{11}$ (418): C, 51.65; H, 6.26; CH_3CO, 41.1. Found: C, 51.44; H, 6.25; CH_3CO, 40.7.

Desoxypentose Disaccharide.—Three-tenths gram of tetraacetyl desoxypentose disaccharide was deacetylated by dissolving in 25 cc. of water containing 1 g. of barium hydroxide. The solution was freed of excess barium hydroxide by carbon dioxide. The barium carbonate was removed by filtration and the water evaporated off under reduced pressure. The residue, which still contained inorganic salts, was extracted several times with warm absolute alcohol and the alcohol was removed by a vacuum distillation. The residue remaining in the distilling flask was extracted with a small amount of water to free the preparation from any compound which had not been deacetylated. The water solution was evaporated slowly in a vacuum desiccator over phosphorus pentoxide. After the water had been removed the compound solidified. The yield was 0.16 g. or 90%. After recrystallization from isopropyl alcohol and ether the desoxypentose disaccharide melted at 177–180°. The melting point was not sharp and there was a great deal of decomposition.

Anal. Calcd. for $C_{10}H_{18}O_7$ (250): C, 48.00; H, 7.25. Found: C, 47.80; H. 6.81.

Acknowledgment—The author wishes to express his appreciation to Dr. R. M. Hixon and Dr. W. Freudenberg for their advice and suggestions and to Dr. I. B. Johns for the micro-analyses.

Summary

The reduction of acetobromoarabinose was found to yield a non-reducing compound which had not been previously reported. The analysis of the new compound showed it to be a tetraacetyl desoxypentose disaccharide. The free disaccharide was also prepared in crystalline form.

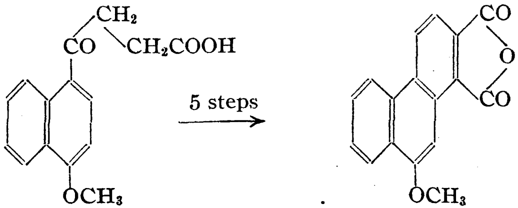
The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. IV. Hydroxylated Compounds

BY L. F. FIESER AND E. B. HERSHBERG

This work was undertaken with the idea that the introduction of hydroxyl or methoxyl groups into the phenanthrene dicarboxylic anhydrides[1] and the hexa- or octahydrophenanthrene dicarboxylic anhydrides[2] previously described might afford substances of oestrogenic activity, the presence of hydroxyl and carbonyl groups in different parts of the molecule establishing at least a superficial resemblance to oestrone. One such compound was prepared from the condensation product of succinic anhydride and α-methoxynaphthalene, I, by reduction, esterification, condensation with ethyl oxalate, cyclization and dehydrogenation, giving 9-methoxyphenanthrene-1,2-dicarboxylic anhydride, II.



I II

An anhydride of a second type was obtained

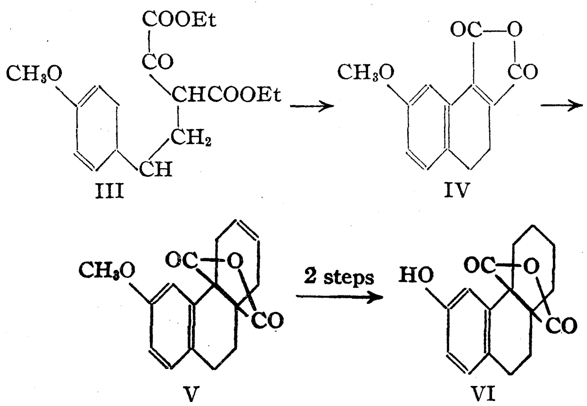
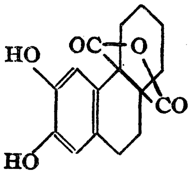
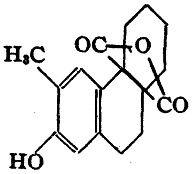
from γ-(4-methoxyphenyl)-butyric acid, readily prepared from anisole and succinic anhydride, through the oxalyl derivative III, the unsaturated anhydride IV, and the butadiene addition product V. After saturation of the active double bond this was demethylated satisfactorily, giving VI.



The 6,7-dihydroxyoctahydrophenanthrene-11,12-dicarboxylic anhydride VII was prepared similarly starting with veratrole, while VIII was obtained from Martin's γ-(3-methyl-4-methoxyphenyl)-butyric acid.[3] The only noteworthy observation to be recorded in connection with the syntheses is that in the Bougault cyclization of oxalyl derivatives such as III, or that from I, with sulfuric acid the unsaturated anhydride is often accompanied by a considerable amount of the corresponding aromatic anhydride. Since this has not been observed in other cases it appears that methoxyl groups render the dihydro derivatives particularly susceptible to the dehydrogenating action of sulfuric acid. By using acid just strong enough to effect the cyclization, the aromatization in some cases can be prevented or at least minimized. It should be noted that by heating the unsaturated compounds or the crude mixtures with sulfur, naphthalene derivatives of use in general synthetic work can be obtained easily in good yield. The 6-methoxy-, 7-methoxy- and 6-methoxy-7-methyl derivatives of 1,2-naphthalic anhydride (naphthalene-1,2-dicarboxylic anhydride) are described in this paper.



VII



VIII

In the first paper of this series[1] we cited a preliminary report from Dr. G. Pincus regarding the physiological activity of phenanthrene-1,2-dicarboxylic anhydride and its 3,4-dihydro derivative. The statements unfortunately were incomplete and misleading, as it was implied that the standard technique of bio-assay had been employed. Actually the anhydrides have given only negative results when injected subcutaneously into either spayed mice or immature rats even in large dosages. The reported cornifications were observed following the intraperitoneal injection into spayed mice of two 0.1-cc. doses of a solution of the material in sesame oil made twelve hours apart, and the appearance of a single cornified smear in any individual in six days was considered positive. In later experiments Pincus and Werthessen[4] abandoned the first technique as unreliable and developed a second special test method, also based on intraperitoneal injections, which seems to have promise as a preliminary guide. They report that in this more rigid test phenanthrene-1,2-dicarboxylic anhydride and its dihydro compound are inactive in relatively large dosages but that the compounds II, VI, VII and VIII described in the present paper give positive results and seem to be comparable with 1-keto-1,2,3,4-tetrahydrophenanthrene in oestrogenic activity, as judged by the special test. According to their ratings the dihydroxy compound VIII is the most active substance of the group and is more potent than ketotetrahydrophenanthrene.

Experimental Part[5]

Condensation of Phenol Ethers with Succinic Anhydride.—The Friedel and Crafts reactions of anisole and veratrole with succinic anhydride have been conducted in carbon bisulfide[6] or benzene[7] solution (no yields given) and, apparently with better results, using nitrobenzene[8,9] or tetrachloroethane.[10] After many trials in this Laboratory with these and other ethers, we found the following procedure very satisfactory and convenient: 0.4 mole of anisole (or veratrole) is dissolved with 0.42 mole of succinic anhydride in 400 cc. of tetrachloroethane and 100 cc. of nitrobenzene. The stirred solution is cooled to 0–5° (thermometer in liquid) and 0.84 mole of aluminum chloride ($AlCl_3$) is added gradually, keeping the temperature at 0–5°. At the end of the addition (one to two hours) a clear solution usually is obtained and it is allowed to stand

at 0–5° (packed in ice in the cold room) for three days, during which time a complex sometimes separates. After adding ice and hydrochloric acid and removing the solvent with steam, the product is either allowed to crystallize directly or it is dissolved in soda solution, the solution is clarified with Norite and acidified. The keto acid is obtained in a colorless or nearly colorless condition quite satisfactory for further use. In this way β-(4-methoxybenzoyl)-propionic acid was obtained as colorless needles, m. p. 146–147°, in 85% yield. The results were duplicated by W. P. Campbell and by H. L. Holmes, the latter using as much as 173 g. of anisole in one experiment. By the same procedure β-(3,4-dimethoxybenzoyl)-propionic acid, m. p. 157–159°, was obtained in 67% yield, and H. L. Holmes obtained the same yield using 341 g. of veratrole. In other experiments with veratrole it was found that when using the tetrachloroethane–nitrobenzene mixture the yield dropped to 40% or less when the amount of aluminum chloride was changed from two equivalents to either one or three equivalents, and that the yield was also decreased by conducting the reaction at room temperature (43%, m. p. 152–154°). Following the procedure of Haworth and Mavin,[8] using nitrobenzene alone and operating at room temperature, we obtained material somewhat inferior (brown, m. p. 150–155°) to that above in slightly better yield (73%). Using carbon bisulfide[6] the yield was low (46%) and product of poor quality.

β-(4-Methoxy-1-naphthoyl)-propionic[11] acid was prepared by the above procedure but using tetrachloroethane alone as the solvent, the yield of material melting at 170–172° being 98%; the recrystallized acid melted at 171–172°.

Clemmensen Reduction.—A report has already been made[3] of the yields obtained by Martin's modified method of reduction in the preparation of γ-(4-methoxyphenyl)-butyric acid (ethyl ester, b. p. 177–178°, 15.5 mm.), γ-(3,4-dimethoxyphenyl)-butyric acid (ethyl ester, b. p. 186–189°, 8.5 mm.) and **γ-(4-methoxy-1-naphthyl)-butyric acid** (ethyl ester, b. p. 239–242°, 16 mm.). Crystallized from alcohol and from benzene–ligroin, γ-(4-methoxy-1-naphthyl)-butyric acid formed small colorless plates, m. p. 129–130°.

Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.74; H, 6.59. Found: C, 73.92; H, 6.18.

γ-(3-Methoxy-4-methylphenyl)-butyric acid (ethyl ester, b. p. 171–173°, 11 mm.) was prepared from β-(*p*-toluyl)-propionic acid (230 g.) according to Martin,[3] the yields throughout being essentially as reported.

Conversion of the γ-Arylbutyric Esters into Cyclic Unsaturated Anhydrides.—The condensations of the esters with ethyl oxalate were carried out with the use of potassium ethylate, although in subsequent experiments in this Laboratory it was found that sodium ethylate is satisfactory with at least some of the methoxy compounds (H. L. Holmes). In the standard procedure 0.104 mole of potassium, cleaned by boiling with purified dioxane, was powdered under toluene in a nitrogen atmosphere and treated in ether suspension under reflux with 0.104 mole of absolute ethyl alcohol. At the end of the reaction 0.15 mole of ethyl oxalate was added and the resulting clear solution was treated with 0.1 mole of the γ-arylbutyric ester in absolute ether. In all 300–350 cc. of ether was used. The solution usually was refluxed for eight to ten hours to complete the reaction, and the potassium derivative of the product often separated during this time in a solid condition or as an oil. In this case the salt was separated by filtration or decantation, washed with dry ether, and decomposed with ice-cold 60% sulfuric acid in the presence of ether, the oxalyl derivative being recovered by extracting with ether and flashing off the solvent at the water pump. Any material remaining in the mother liquor was similarly recovered and worked separately. Some experimentation was necessary in each case to determine the strength of sulfuric acid most suitable for effecting the cyclization of the oxalyl derivative, and the specific data are noted below. Unlike the unsubstituted unsaturated anhydrides, the methoxylated compounds have a tendency to undergo partial dehydrogenation under the influence of the sulfuric acid and the aromatic anhydrides are often present in the crude reaction products.

7 - Methoxy - 3,4 - dihydronaphthalene - 1,2 - dicarboxylic Anhydride.—The potassium salt of the oxalyl derivative separated nearly completely as a solid, and 24.5 g. of the salt was added in small portions to 75 cc. of 60% sulfuric acid, stirred mechanically and cooled in an ice–salt bath. The resulting oily suspension was heated for fifteen minutes on the steam-bath, cooled, treated with 150 cc. of 80% sulfuric acid and heated fifteen minutes longer, when the oil had changed to a yellow solid. On pouring the mixture into water, collecting and washing the product, 13.6 g. (77% yield from the butyric ester) of good anhydride was obtained. The material from the ether mother liquor yielded 0.8 g. of less pure anhydride. After repeated crystallization from benzene–ligroin (readily soluble in benzene) the compound was obtained as bright yellow, heavy prismatic needles, m. p. 164.5–165°.

Anal. Calcd. for $C_{13}H_{10}O_4$: C, 67.79; H, 4.39. Found: C, 67.93; H, 3.97.

In one experiment cyclization of the oxalyl derivative with concentrated sulfuric acid at 20° was tried. The material was largely sulfonated and the water-insoluble product was found to contain a considerable amount of the aromatic anhydride (see Table I), which was obtained pure after five crystallizations from benzene.

6,7 - Dimethoxy - 3,4 - dihydronaphthalene - 1,2-dicarboxylic Anhydride.—The potassium salt separated as an oil and this was washed and converted into the free oxalyl derivative which, for cyclization, was heated for twenty minutes on the steam-bath with 70% sulfuric acid. The product separated as a bright red, crystalline solid and was washed with 60% acid and with water; yield crude (m. p. 180–186°) 56%. The anhydride is moderately soluble in benzene and gives a pure yellow solution; the recrystallized material forms bright red needles from this solvent, m. p. 192.5–193.

Anal. Calcd. for $C_{14}H_{12}O_5$: C, 64.59; H, 4.65. Found: C, 64.79; H, 4.67.

When the ester condensation was interrupted after three and one-half hours, the anhydride obtained from the cyclization of the potassium salt which separated corresponded

---

[11] Ruzicka and Waldmann, *Helv. Chim. Acta*, **15**, 907 (1932).

to a 43% yield. Treatment of the material from the ether mother liquor with 70% sulfuric acid gave 6,7-dimethoxy-1-tetralone,[8] m. p. 99.5–100° (purified) in 34% yield. This undoubtedly came from unreacted anisylbutyric ester.

6-Methoxy-7-methyl-3,4-dihydronaphthalene-1,2-dicarboxylic Acid.—In the ester condensation the red-orange ethereal solution deposited no salt and the crude oxalyl compound was obtained by adding cold dilute sulfuric acid and extracting with ether. For cyclization the oil was heated with 78% sulfuric acid at 70–80° for thirty minutes, giving very nearly pure anhydride in 82% yield. After two crystallizations from benzene (moderately soluble) the substance melted constantly at 189.8–190.3° and formed thin, yellow diamond-shaped plates. The cyclization was also accomplished by heating nearly to boiling for a few minutes with a solution of zinc chloride in glacial phosphoric acid.

Anal. Calcd. for $C_{14}H_{12}O_4$: C, 68.82; H, 4.96. Found: C, 69.07; H, 5.17.

6-Methoxy-3,4-dihydronaphthalene-1,2-dicarboxylic Anhydride.—The oxalyl derivative prepared from ethyl γ-(*m*-methoxyphenyl)-butyrate[3] on cyclization with 75% sulfuric acid at 80° for fifteen minutes gave a mixture of the unsaturated and aromatic anhydrides. A fairly sharp separation was accomplished with ether, in which the dihydro compound alone dissolves easily. The aromatic anhydride, described in Table I, was identified by comparison with a sample obtained by sulfur dehydrogenation of the dihydro derivative. The latter, purified by repeated crystallization from benzene–ligroin, formed yellow needles, m. p. 164–165°.

Anal. Calcd. for $C_{13}H_{10}O_4$: C, 67.79; H, 4.39. Found: C, 67.83; H, 4.49.

9-Methoxy-3,4-dihydrophenanthrene-1,2-dicarboxylic Anhydride.—The potassium derivative of the oxalyl ester largely separated as a solid after two hours of refluxing, and after standing for six hours longer the salt was collected, washed and decomposed with cold acid. The crude product, a pale yellow oil, was stirred with 84% sulfuric acid on the steam-bath for fifteen minutes, when conversion to an orange solid was complete. Washed with 84% acid and with water, this melted in the range 185–205° and proved to be a mixture of the unsaturated and the aromatic anhydrides. The latter is the less soluble of the two and was obtained pure after repeated crystallization from benzene (Table I); the former was isolated by fractional crystallization from glacial acetic acid (readily soluble). It forms reddish orange needles, m. p. 194–197°, which separate in a brilliant condition but become opaque on drying.

Anal. Calcd. for $C_{17}H_{12}O_4$: C, 72.83; H, 4.32. Found: C, 73.07; H, 4.42.

Aromatic Anhydrides.—The substances isolated as by-products in the cyclization experiments are listed in Table I. They can be obtained also by heating the unsaturated anhydrides with the calculated amount of sulfur in a bath at 240–250° for fifteen to twenty minutes, followed by distillation at diminished pressure and crystallization. Benzene was found to be a good solvent in each case.

Diels–Alder Reaction.—The addition products listed in Table II were prepared as follows (or with double the quantities). About 25 g. of fresh butadiene was distilled into a mixture of 10 g. of the appropriate unsaturated anhydride and 15 cc. of dioxane contained in a Pyrex tube and cooled in a bath of solid carbon dioxide with the eutectic mixture of chloroform and carbon tetrachloride (equal parts), and the tube was sealed and heated at 160–180° for thirteen to fifteen hours. After opening the tube in the same cooling mixture the excess butadiene was evaporated by gentle warming and the product was obtained as a clean solid free from polymer by distillation in high vacuum in 75–85% yield. This material invariably contained a small amount of a colored impurity having the properties of the aromatic anhydride corresponding to the starting material and evidently arising by a dehydrogenation or disproportionation in the course of the reaction. This is considerably less soluble in benzene–ligroin than the addition product and can be eliminated by crystallization, but a more convenient method is based upon the greater resistance of the addition product to hydrolysis. The crude material is crystallized once from a concentrated benzene–ligroin solution and shaken with warm dilute aqueous-alcoholic alkali until the yellow or orange material has been hydrolyzed and dissolved and the largely unattacked addition product is left in a completely colorless condition. Crystallization from benzene–ligroin then gives pure material.

The 6-methyl-7-methoxy derivative was converted into the dipotassium salt of the corresponding acid by re-

6-Methyl-7-methoxy-	Needles	149.5–150	71.95	71.78	6.73	6.81

fluxing with 4 *N* potassium hydroxide until dissolved and adding stronger alkali, and the dry salt (iridescent leaflets) was heated slowly in a bath from 350 to 420°, applying suction. The small amount of yellow oil which distilled was heated with selenium at 300° and the extracted product, **2-methoxy-3-methylphenanthrene,** after sublimation and crystallization from methyl alcohol, melted at 132–132.5°.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.49; H, 6.31. Found: C, 86.55; H, 6.54.

The picrate formed orange needles, m. p. 142.5–143°, from benzene–ligroin.

Anal. Calcd. for $C_{22}H_{17}O_8N_3$: N, 9.31. Found: N, 9.25.

2,3 - Dimethyl - 6 - methoxy - 1,4,11,12,13,14 - hexahydrochrysene-13,14-dicarboxylic anhydride, obtained by heating the corresponding unsaturated anhydride with 2,3-dimethylbutadiene at 100° for two days, formed colorless prisms, m. p. 181–182°, from benzene–ligroin.

Anal. Calcd. for $C_{23}H_{22}O_4$: C, 76.48; H, 6.13. Found: C, 76.48; H, 6.13.

Octahydrophenanthrene Anhydrides.—The three addition products listed in Table II were converted into the saturated compounds of Table III by hydrogenation in glacial acetic acid solution in the presence of Adams catalyst at atmospheric pressure. The absorption of gas was complete in five to ten minutes (3-g. samples) and the products were obtained in nearly quantitative yield. Benzene–ligroin was used for recrystallization.

Dimethyl 6,7-dimethoxy-1,2,3,4,9,10,11,12-octahydrophenanthrene-11,12-dicarboxylate, obtained by converting the anhydride into the free acid and esterifying with diazomethane, formed colorless microcrystals, m. p. 134.5–135.5°.

Anal. Calcd. for $C_{20}H_{26}O_6$: C, 66.26; H, 7.24. Found: C, 66.32; H, 7.56.

Demethylation.—The ethers of Table III were demethylated by refluxing 1 g. of the material with 10 cc. each of glacial acetic acid and 48% hydrobromic acid for three to five hours. On dilution with water the product separated as an oil which became crystalline after standing for several hours; average yield 80%.

6 - Hydroxy - 1,2,3,4,9,10,11,12 - octahydrophenanthrene-11,12-dicarboxylic anhydride crystallized from benzene as colorless prismatic needles, m. p. 160–160.5°.

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.56; H, 5.92. Found: C, 70.69; H, 5.66.

6,7 - Dihydroxy - 1,2,3,4,9,10,11,12 - octahydrophenanthrene-11,12-dicarboxylic anhydride formed small round crystal clusters, m. p. 147.5–148.5°, from benzene. It is very soluble in alcohol, moderately soluble in hot benzene, slightly soluble in hot water.

Anal. Calcd. for $C_{16}H_{16}O_5$: C, 66.64; H, 5.59. Found: C, 66.69; H, 5.58.

The diacetyl derivative, prepared with the use of acetic anhydride and sodium acetate, formed colorless iridescent plates from alcohol, m. p. 151.5–152°.

Anal. Calcd. for $C_{20}H_{20}O_7$: C, 64.48; H, 5.43. Found: C, 64.63; H, 5.55.

The dibenzoyl derivative was prepared by boiling the substance in pyridine solution with benzoyl chloride for five minutes, adding water, and treating the precipitated oil with alkali, when it at once solidified. Crystallized from alcohol, it formed clusters of short needles, m. p. 175–175.5°.

Anal. Calcd. for $C_{30}H_{24}O_7$: C, 72.55; H, 4.88. Found: C, 72.65; H, 4.93.

6 - Methyl - 7 - methoxy - 1,2,3,4,9,10,11,12 - octahydrophenanthrene-11,12-dicarboxylic anhydride formed colorless microcrystals from benzene–ligroin, m. p. 134.5–135.5°.

Anal. Calcd. for $C_{17}H_{18}O_4$: C, 71.30; H, 6.33. Found: C, 71.30; H, 6.33.

Summary

Hydroxyl or methoxyl derivatives of phenanthrene-1,2-dicarboxylic anhydride and of octahydrophenanthrene-11,12-dicarboxylic anhydride which are of interest in the study of oestrogenic activity are described in this paper.

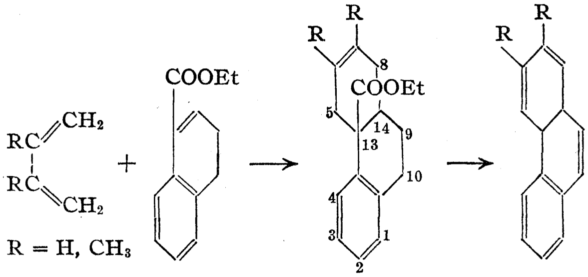
The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. V. The Addition of Dienes to Cyclic α,β-Unsaturated Esters

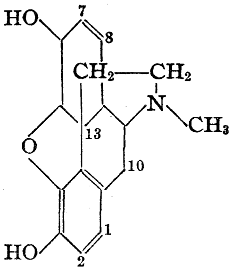
BY L. F. FIESER AND H. L. HOLMES

Having found that derivatives of maleic anhydride in which the active ethylenic linkage is incorporated in an alicyclic ring are capable of entering into the Diels–Alder reaction with dienes,[1] the possibility of effecting a similar addition in the case of cyclic α,β-unsaturated esters has been investigated in the hope that this might provide a route to hydrophenanthrene derivatives of a type hitherto inaccessible by synthesis. The reaction was tried first with ethyl Δ^1-dihydro-1-naphthoate (I) prepared by reducing α-naphthoic acid with sodium amalgam and rearranging the labile Δ^2-dihydro derivative with alkali according to v. Baeyer and Schoder,[2] followed by Fischer esterification.[3] With both butadiene and 2,3-dimethylbutadiene addition to the double bond of the ester was found to occur slowly, giving hexahydrophenanthrene carboxylic esters of the type II. The reactions did not proceed as well as in the case of Δ^1-dihydronaphthalene-1,2-dicarboxylic anhydride[1] and the conversion invariably was far from complete, but the pure esters (II) were obtained in 21–27% yield by heating the components at 100° for eight days or at 150° for forty-one hours. The addition products, one of which was obtained as a liquid and the other as a low-melting solid, are easily separated from the starting material by taking advantage of the great resistance to hydrolysis of the tertiary ester group. By refluxing a mixture of I and II with 10% potassium hydroxide the unsaturated ester can be completely hydrolyzed without appreciably affecting the addition product. The corresponding acids were obtained as crystalline solids by saponification of the esters with sodium ethylate at 180°. The substances have not yet been investigated in sufficient quantity to determine whether more than one *dl*-mixture is present. That the addition products have the expected structures was established by their conversion on dehydrogenation with selenium, either as the esters or as the free acids, into phenanthrene and 2,3-dimethylphenanthrene.[1,4]

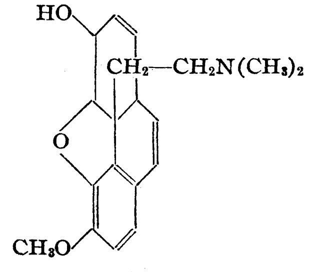


I II III

These observations are of particular interest in connection with the morphine problem. In the Gulland–Robinson formula (IV) for this alkaloid the ethanamine chain is assumed to be attached to the phenanthrene skeleton at a position (C_{13}) corresponding to that occupied by the carbonyl group of the synthetic compounds described above. The location of this end of the C–C–N chain, however, is the one point regarding the structure which still remains to be unambiguously established. The present synthesis makes available for the first time substances of known structure having a carbon substituent at the position which is indicated as being the most likely point of attachment of the ethanamine chain, and it offers promise of providing a route to compounds which may be obtainable from morphine, for example by the further degradation of α-methylmorphimethine, V.



IV



V

In order to approach sufficiently closely to the morphine type of structure it seemed essential to develop a flexible method of procuring substituted dihydro-α-naphthoic esters suitable for the preparation of hydrophenanthrene carboxylic

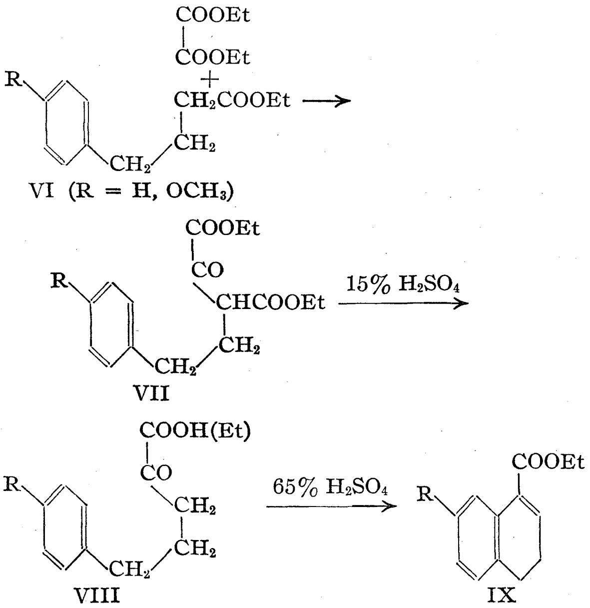
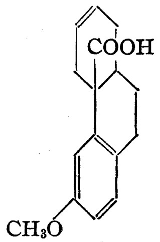
acids carrying a hydroxyl or methoxyl group in the 3-position (morphine numbering, see formula II), and possibly also in the 4-position. The method used by v. Baeyer and Schoder[2] in the case of the parent compound would require difficultly accessible or unknown aromatic acids as starting materials, if indeed it is applicable to such substances, and we turned to synthesis. α-Oxalyl-γ-phenylbutyric esters of the type VII are readily obtainable by the ester condensation from the γ-phenylbutyric esters easily prepared from benzene or anisole and succinic anhydride, and after some trial it was found that hydrolysis and decarboxylation can be accomplished by boiling the esters for fifteen to eighteen hours with 15% sulfuric acid. α-Keto-δ-phenylvaleric acid (VIII) and its *p*-methoxy derivative were obtained in this way in over-all yield from VI of about 70%. Cyclization to the dihydro-α-naphthoic ester (IX) was brought about by warming the keto esters (VIII) with 65% sulfuric acid for one to two hours on the steam-bath, and the yields again were good. The Δ^1-dihydro-1-naphthoic acid obtained by this synthesis was fully identified by comparison with the product prepared by the previous method.[2] The 7-methoxy-Δ^1-dihydro-1-naphthoic acid yielded on dehydrogenation with sulfur an acid having the properties recorded for 7-methoxy-1-naphthoic acid.[5] Contrary to the experience of Darzens[6] in an analogous case, no decarboxylation occurred in the course of the dehydrogenation of the above acid or of 7-methoxy-1,2,3,4-tetrahydro-1-naphthoic acid. The synthesis provides a convenient route to aromatic acids of the type indicated as well as to their dihydro derivatives, and further applications are being investigated.



Butadiene was successfully added, if in low yield, to ethyl 7-methoxy-Δ^1-dihydro-1-naphthoate, affording after hydrolysis 3-methoxy-5,8,9,-10,13,14-hexahydrophenanthrene-13-carboxylic acid (X). With the introduction of a methoxyl group in the position occupied by a similar group in the case of codeine, a part of the proposed program has been realized. A start has been made in the direction of introducing a second methoxyl group at C$_4$ by the synthesis of 5-bromo-7,8-dimethoxy-3,4-dihydro-1-naphthoic acid, but a report of this work will be deferred to a later publication. In addition to the proposed inquiry regarding the structure of morphine it is planned to investigate the use of acids such as X as starting materials for the synthesis of basic substances of possible morphine-like actions.



X

Experimental Part[7]

Synthesis of Δ^1-Dihydro-α-naphthoic Acids

α-Keto-δ-phenylvaleric Acid.—One hundred grams of ethyl γ-phenylbutyrate was condensed with ethyl oxalate in the presence of sodium ethylate according to the procedure previously outlined[1] and the crude α-oxalyl-γ-phenylbutyric ester, after removal of the solvent ether and the excess diethyl oxalate by vacuum distillation, was refluxed vigorously with 700 cc. of 15% sulfuric acid for fifteen hours, when the at first steady evolution of carbon dioxide had practically ceased. The keto acid appeared as a viscous brown oil. This was taken up in ether, washed with water, and the acid was extracted with 200 cc. of 10% sodium hydroxide solution. The alkaline extract was clarified with Norite and acidified, and the light yellow oil was taken up in ether and dried. Evaporation of the solvent left an oil which failed to solidify, and this was consequently esterified with ethyl alcohol and hydrogen chloride. The ethyl ester distilled at 165–170° (12 mm.); yield 72 g. (62.5%). On redistillation the chief fraction boiled at 164° (13 mm.), and 5 g. of the purified ester was saponified by refluxing for one hour with 25 cc. of 20% alkali. The solution was clarified and acidified, and after thorough cooling the keto acid solidified; yield 4.3 g. (98%). The substance crystallized from hexane in the form of colorless blades, m. p. 68–69.5°. It is very soluble in alcohol or benzene in the cold and moder-

(7) All melting points are corrected.

ately soluble in boiling hexane. A sodium salt crystallizing in plates separates from an aqueous solution containing a moderate excess of sodium carbonate.

Anal. Calcd. for $C_{11}H_{12}O_3$: C, 68.75; H, 6.25. Found: C, 68.56; H, 6.25.

Δ^1-Dihydro-α-naphthoic Acid.—For cyclization 72 g. of ethyl α-keto-δ-phenylvalerate was stirred mechanically with 450 cc. of 65% sulfuric acid and heated for two hours on the steam-bath. The material did not dissolve and changed little in appearance in the course of the reaction. The mixture was cooled and poured onto 1 kg. of ice, and the light green oil was extracted with ether and the solution washed with water. The ethereal extract was mixed with 500 cc. of 5% sodium hydroxide and after boiling off the ether the mixture was refluxed for two hours to hydrolyze some ester present and the solution was clarified with Norite, cooled and acidified. The product separated as a solid (56.5 g.) which was obtained in a nearly pure condition by crystallization from hexane; yield 48.5 g. (85%). After several recrystallizations the acid melted constantly at 120–121°.

Anal. Calcd. for $C_{11}H_{10}O_2$: C, 69.86; H, 6.72. Found: C, 69.71; H, 7.07.

A sample of the unsaturated acid prepared according to v. Baeyer and Schoder[2] and crystallized from ethyl acetate and from hexane melted at the same temperature as the synthetic substance and did not depress its melting point. The observations are in agreement with the statement of v. Auwers and Möller[8] that the acid melts at 121° rather than 125°.[2]

The ethyl ester was prepared according to Rabe[3] in 91% yield, b. p. 170–172° (19 mm.), n^{25}D 1.5561. Dehydrogenation of the unsaturated acid (1 g.) with sulfur (0.19 g.) at 230–240° gave after vacuum distillation 0.93 g. of light yellow α-naphthoic acid which on crystallization was obtained colorless, m. p. 161.4–161.6°.

α-Keto-δ-(4-methoxyphenyl)-valeric Acid.—Ethyl γ-(4-methoxyphenyl)-butyrate (90 g.) was condensed with ethyl oxalate (90 g.) using the ethylate from 9.88 g. of sodium (twenty hours of refluxing) and following the procedure[1] for the parent compound. After removing the ether from the reaction product the crude oxalyl derivative was refluxed vigorously with 800 cc. of 15% sulfuric acid for eighteen to twenty-four hours. The oily layer was taken into ether and dried, and on removing the solvent the keto acid was obtained as a solid; yield, after one crystallization, 72.2 g. (80%). The acid is sparingly soluble in hexane and crystallizes as thin colorless plates. The melting point is like that of camphor;[9] the substance begins to liquefy at about 65° and the last crystal skeleton disappears at 74°. Addition of sodium chloride to the sodium carbonate solution causes the separation of characteristic hair-fine needles of the sodium salt.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.87; H, 6.35; neut. eq., 222. Found: C, 64.70; H, 6.46; neut. eq., 219.

The ethyl ester was prepared by esterification with absolute alcohol and hydrogen chloride, washed and dried in ether with magnesium sulfate, and distilled; b. p. 190–192° (10 mm.), n^{20}D 1.5080, yield 92%. In another experiment 150 g. of ethyl γ-(4-methoxyphenyl)-butyrate, run in two portions, gave 169 g. (72%) of the keto ester.

7-Methoxy-Δ^1-dihydro-1-naphthoic Acid.—A mixture of 25 g. of ethyl α-keto-δ-(4-methoxyphenyl)-valerate and 200 cc. of 65% sulfuric acid was stirred vigorously on the steam-bath (75–80°) for one hour and then poured onto ice. The oily product, which appeared to be partially hydrolyzed ester, was taken into ether and, after removal of solvent, refluxed for two hours with 100 cc. of 9% sodium hydroxide, and the alkaline solution was clarified with Norite and acidified. The acid separated as an oil which soon solidified (19.8 g.). On crystallization from water, in which the substance is moderately soluble, 14 g. (68.5%) of pure material was obtained as colorless plates, m. p. 116–117°. It also crystallizes well from hexane (sparingly soluble) in plates; it is very soluble in benzene in the cold.

Anal. Calcd. for $C_{12}H_{12}O_3$: C, 70.54; H, 5.94. Found: C, 70.09; H, 5.96.

The ethyl ester was obtained by Fischer esterification in 85% yield, b. p. 186–187° (9 mm.).

7-Methoxy-1-naphthoic Acid.—7-Methoxy-Δ^1-dihydro-1-naphthoic acid (0.6 g.) was heated with 0.1 g. of sulfur at 230–240° for one-half hour and the product distilled at 9 mm. and crystallized from hexane, yielding 0.5 g. of yellow needles. After further recrystallization the substance was obtained as long, slender, colorless needles, m. p. 169–170° (lit. 167–168°, uncorr.).[5] Demethylation with hydrobromic and acetic acids and crystallization from water gave 7-hydroxy-1-naphthoic acid, m. p. 255–256° (lit. 253–254°, uncorr.[10]).

7-Methoxy-1,2,3,4-tetrahydro-1-naphthoic acid, prepared by hydrogenation with Adams catalyst, crystallized from dilute alcohol as colorless prisms, m. p. 137.5–138.5°.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.86; H, 6.72. Found: C, 69.75; H, 6.96.

Like the dihydro derivative, the tetrahydro compound gave 7-methoxy-1-naphthoic acid on dehydrogenation with sulfur. In neither case was any β-naphthol methyl ether detected in the mother liquors.

Diels–Alder Reaction

5, 8, 9, 10, 13, 14 - Hexahydrophenanthrene - 13 - carboxylic Acid.—A mixture of 11 g. of ethyl Δ^1-dihydro-1-naphthoate and 10 g. of butadiene was heated in a sealed tube at 150° for forty-one hours. After evaporating the butadiene still present the liquid material was distilled from the polymer, the boiling range being 155–214° at 8 mm. (7 g.). This was refluxed for four hours with 30 cc. of 10% potassium hydroxide and the unsaponified oil remaining was washed and dried in ether and distilled. **The ethyl ester** was obtained after redistillation as a viscous oil, b. p. 164–166° (5 mm.), yield 3 g. (21%).

Anal. Calcd. for $C_{17}H_{20}O_2$: C, 79.99; H, 7.99. Found: C, 79.40; H, 7.89.

For saponification 0.48 g. of the ester was heated with a solution prepared from 2 g. of sodium and 30 cc. of absolute alcohol at 170° for eighteen hours. On diluting the alkaline solution and acidifying, the acid separated as a solid (0.4 g.). Crystallized from dilute methyl alcohol it

formed rectangular microprisms, m. p. 137–138°. Further crystallization from hexane, in which the acid is readily soluble, gave compact clusters of microprisms, m. p. 141.5–142.5° with some previous softening. An extensive fractionation was not undertaken.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.97; H, 7.02. Found: C, 79.37; H, 7.40.

On dehydrogenation with selenium at 300° for twenty-one hours the once crystallized acid (0.55 g.) yielded a hydrocarbon (0.21 g.) which after crystallization melted at 96–97° and was identified as phenanthrene by mixed melting point.

6, 7 - Dimethyl - 5, 8, 9, 10, 13, 14 - hexahydrophenanthrene-13-carboxylic Acid.—The ethyl ester was prepared as above from 15 g. of the unsaturated ester and 18 cc. of 2,3-dimethylbutadiene, heating being continued for eight days at 100°. After treatment with 10% potassium hydroxide the ethyl ester was distilled as a liquid which solidified; b. p. 166° (4 mm.), m. p. 49.5–50°, yield 5.7 g. (27%).

Anal. Calcd. for $C_{19}H_{24}O_2$: C, 80.23; H, 8.51. Found: C, 79.61; H, 8.84.

The free acid, prepared as above (85% yield), crystallized from very dilute alcohol as small, colorless prisms, m. p. 162–163°. Recrystallization from hexane (readily soluble) gave small, hard, crystalline clusters, m. p. 168–169° with some previous softening.

Anal. Calcd. for $C_{17}H_{20}O_2$: C, 79.70; H, 7.81. Found: C, 80.17; H, 7.87.

On dehydrogenation with selenium for thirty-six hours, 1.7 g. of the crude acid yielded 0.7 g. of purified crystals melting at 78–78.5° and identified by mixed melting point determination as 2,3-dimethylphenanthrene.[1]

3 - Methoxy - 5, 8, 9, 10, 13, 14 - hexahydrophenanthrene-13-carboxylic Acid (X).—A mixture of 20 g. of ethyl 7-methoxy-Δ^1-dihydro-1-naphthoate and 15 g. of butadiene was heated for twenty-one hours at 220–245°. The crude ester mixture (18.6 g.) was refluxed with 70 cc. of 20% alkali for four hours and the residual oil was dried and distilled, b. p. 202–204° (14 mm.); yield 3.3 g. (13%). On saponification of the ethyl ester with sodium ethylate as above the free acid was obtained from dilute alcohol as colorless microprisms, m. p. 139.5–141° with previous softening.

Anal. Calcd. for $C_{16}H_{18}O_3$: C, 74.41; H, 7.03. Found: C, 74.03; H, 7.01.

Summary

Hydrophenanthrene derivatives having a carboxyl group at the 13-(or 12-) position can be obtained by the addition of dienes to Δ^1-dihydro-1-naphthoic esters. A convenient synthesis of the unsaturated esters consists in the acid hydrolysis of α-oxalyl-γ-arylbutyric esters to α-keto-δ-arylbutyric acids and cyclization of the keto esters with sulfuric acid. These methods afford a new approach to substances having some features of the morphine structure.

The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. VI. 1',3'-Diketocyclopentenophenanthrenes

BY L. F. FIESER, M. FIESER AND E. B. HERSHBERG

Having found a convenient method of preparing phenanthrene-1,2-dicarboxylic anhydride by synthesis,[1] it was of interest to undertake the conversion of the substance into a compound having the 1,2-cyclopenteno ring system. The anhydride was converted into the dimethyl ester I either by the Fischer esterification of the corresponding acid, obtained through the dipotassium salt, or by the direct action of methyl alcoholic hydrogen chloride. On condensation with ethyl acetate in the presence of sodium I yielded a diketo ester II which was hydrolyzed to 1',3'-diketo-1,2-cyclopentenophenanthrene, III (or the enolic form). The pure diketone was obtained in 76% yield. Employing anhydrides prepared from intermediates already described,[1,2] the isomeric diketone IV and the dimethylene (ace-) derivative V were synthetized in good yield.

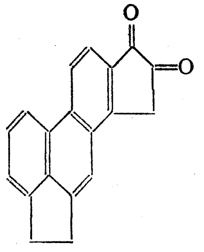
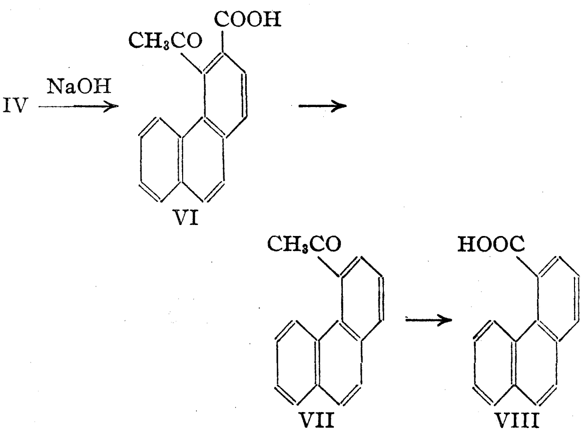
IV



V

The isomeric phenanthrindanediones III and IV dissolve in dilute alkali even in the cold to give red solutions. On refluxing for several hours the color fades and acetylphenanthroic acids are formed in good yield. The substance obtained from the 3,4-isomer IV proved to be a single individual of the structure VI, for on decarboxylation with copper carbonate and quinoline it yielded the hitherto unknown 4-acetylphenanthrene (VII).



The structure of the latter compound follows from the non-identity with the 3-isomer and from the fact that on hypochlorite oxidation it yields a substance having the properties of the known 4-phenanthroic acid.[3] The material resulting from the cleavage of the diketo-1,2-cyclopentenophenanthrene had the composition and properties of a mixture of the two possible acetylphenanthroic acids and evidently there is no great preference for cleavage at one or the other ketonic group. The contrasting behavior of the isomer IV is interpreted as being due to the protection of the carbonyl group in the hindered 4-position, and this constitutes another example of the blocking effect of the neighboring aromatic ring.[4]

In the special test for oestrogenic activity developed by Pincus and Werthessen[5] 1',3'-diketo-1,2-cyclopentenophenanthrene appears to be comparable in potency with 1-keto-1,2,3,4-tetrahydrophenanthrene, while the isomer IV is entirely inactive.

Experimental Part[6]

Phenanthrene-3,4-dicarboxylic anhydride was obtained in 90% yield by heating the dihydro compound[1] with the calculated amount of sulfur in a bath at 320–330° and distilling the product when the evolution of gas was complete. The anhydride is sparingly soluble in glacial acetic acid, fairly readily soluble in xylene, and it crystallizes from the latter solvent as fine, lemon yellow needles, m. p. 253.5–254°.

Anal. Calcd. for $C_{16}H_8O_3$: C, 77.39; H, 3.25. Found: C, 77.37; H, 3.19.

8,9-Acephenanthrene-1,2-dicarboxylic anhydride, prepared similarly in equally good yield, formed fine orange-yellow needles, m. p. 297–298°, uncorr., from dioxane (moderately soluble).

Anal. Calcd. for $C_{18}H_{10}O_3$: C, 78.82; H, 3.68. Found: C, 78.62; H, 3.97.

Dimethyl phenanthrene-1,2-dicarboxylate was at first prepared through the dipotassium salt, which was obtained by refluxing the anhydride (1 g.) with a solution of potassium hydroxide (7 g.) in water (20 cc.) and methyl alcohol (10 cc.) for one-half hour and adding saturated potassium chloride solution. The crystalline salt (1.3 g.) which separated on cooling was added to methyl alcohol saturated with hydrogen chloride, and after two days at room temperature the mixture was refluxed for five hours. On dilution with water the ester separated as a pale yellow solid. On crystallization from methyl alcohol two forms were obtained, the less soluble substances appearing as pale yellow needles, m. p. 131.8–132.2°, and the material from the mother liquor forming colorless, pearly plates, m. p. 132.5–133°. No depression was observed on mixing the samples, and on hydrolysis both yielded, after dehydration of the acid on heating, the original anhydride. A better method of preparation consists in refluxing the anhydride (2 g.) with methyl alcohol saturated with hydrogen chloride for about twenty hours. The anhydride slowly dissolved and the solution after being concentrated and cooled deposited the yellow needle-form of the ester (2.1 g.).

Anal. Calcd. for $C_{18}H_{14}O_4$: C, 73.44; H, 4.79. Found: (yellow needles) C, 73.10; H, 4.43; (colorless plates) C, 73.87; H, 5.07.

The 3,4-dihydro derivative, obtained in good yield through the dipotassium salt of the unsaturated acid, crystallized from methyl alcohol as colorless needles or plates, both melting at 109.8–110°.

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.95; H, 5.45. Found: C, 72.75; H, 5.58.

Dimethyl phenanthrene-3,4-dicarboxylate was best prepared directly from the anhydride by boiling with methyl

[6] The melting points are corrected except as noted, using the precision apparatus of Hershberg, *Ind. Eng. Chem., Anal. Ed.*, **8**, 312 (1936), and employing 0.1° Anschütz thermometers (total immersion) calibrated with a thermometer with the Bureau of Standards certificate. Analyses by Mrs. G. M. Wellwood.

alcohol and hydrogen chloride; yield quantitative. It formed large, transparent prisms, m. p. 114.5–114.8°, from ether–petroleum ether. The substance is very soluble in alcohol or glacial acetic acid.

Anal. Calcd. for $C_{18}H_{14}O_4$: C, 73.45; H, 4.80. Found: C, 73.34; H, 4.80.

The ester was also obtained by esterification of the free acid with diazomethane, and the samples were identical. **Phenanthrene-3,4-dicarboxylic acid** was prepared by hydrolyzing the anhydride with boiling alkali and carefully neutralizing the filtered solution with acetic acid. Very faintly yellow, glistening plates of a monohydrate were deposited on cooling.

Anal. Calcd. for $C_{16}H_{10}O_4 \cdot H_2O$: C, 67.59; H, 4.26. Found: C, 67.50; H, 4.40.

Dimethyl 8,9-acephenanthrene-1,2-dicarboxylate, prepared from the anhydride, alcohol and hydrogen chloride (thirty-six hours), separated as fine, faintly yellow needles from glacial acetic acid, m. p. 170.6–171°.

Anal. Calcd. for $C_{20}H_{16}O_4$: C, 74.98; H, 5.04. Found: C, 74.68; H, 5.10.

1′,3′-Diketo-1,2-cyclopentenophenanthrene (III).—Dimethyl phenanthrene-1,2-dicarboxylate (4.85 g.) was dissolved in 50 cc. of ethyl acetate and 2 g. of fine sodium shavings was added. After refluxing for two hours on the steam-bath 25 cc. more ethyl acetate and 1 g. of sodium were added. This was repeated two hours later and the reaction was stopped after refluxing for six hours. The mixture was pasty with the precipitated sodium derivative of the diketo ester and this was collected after cooling and washed with dry ether. The salt was then decomposed by boiling with 200 cc. of 95% alcohol and 5 cc. of concentrated hydrochloric acid for about ten minutes, during which time carbon dioxide was evolved and the heavy sodium salt partly dissolved and was eventually all transformed to a bulky, light yellow solid. After cooling, the precipitated diketone was collected and washed well with water and then with alcohol. After crystallization by dissolving the substance in 75 cc. of dioxane and adding 50 cc. of 95% alcohol to the hot solution, there was obtained 3.1 g. (76% yield) of the pure diketone. Smaller runs gave yields up to 85%.

The diketone crystallizes well from the above mixture or from benzene and forms short, light yellow needles melting at 240.5–241.5°, dec., when heated in a Pyrex capillary. In a soft glass capillary the sample does not melt but gradually decomposes in the range 240–245°. It dissolves slowly in dilute alkali in the cold, easily on warming, to a cherry red solution. If acidified at once the solution deposits the unchanged material.

Anal. Calcd. for $C_{17}H_{10}O_2$: C, 82.93; H, 4.11. Found: C, 82.75; H, 4.08.

1′,3′-Diketo-3,4-cyclopentenophenanthrene (IV).—The condensation of the appropriate ester (3 g.) was conducted as above except that in these (earlier) experiments only one addition of fresh sodium and ethyl acetate was made. The orange diketo ester salt (5 g.) was rubbed to a paste with 15 cc. of alcohol and 5 cc. of a solution of 10 cc. of concentrated hydrochloric acid in 50 cc. of water was added with stirring. The salt dissolved in the cold to a clear yellow solution and on gentle boiling carbon dioxide was evolved and the diketone separated as light yellow needles in a very pure condition; yield 1.26 g. (50%). The substance is moderately soluble in benzene and readily soluble in glacial acetic acid; it crystallizes from these solvents as light yellow needles, m. p. 201.4–202°. The solubility is greater than that of the isomer and the other properties are as above.

Anal. Calcd. for $C_{17}H_{10}O_2$: C, 82.93; H, 4.11. Found: C, 82.92; H, 4.26.

A monosemicarbazone was deposited from a solution of the components in glacial acetic acid on short boiling. The substance separated as small, pale yellow plates, dec. 300–305°, in a condition suitable for analysis. It is very sparingly soluble in the usual solvents.

Anal. Calcd. for $C_{18}H_{13}O_2N_3$: N, 13.87; Found: N, 13.58.

1′,3′-Diketo-1,2-cyclopenteno-8,9-acephenanthrene (V) was obtained by the procedure described immediately above in 65% yield. The substance is very sparingly soluble in the usual solvents and moderately soluble in tetrachloroethane, from which it crystallizes as fine, bright yellow needles melting at 338–340°, dec., uncorr.

Anal. Calcd. for $C_{19}H_{12}O_2$: C, 83.80; H, 4.45. Found: C, 82.68, 82.76; H, 4.37, 4.41.

4-Acetyl-3-phenanthroic Acid.—The red solution of 1 g. of the diketone IV in 50 cc. of 1 *N* sodium hydroxide turned pale brown after refluxing for six hours. The material which precipitated on acidification was dried and crystallized from benzene–ligroin giving pale yellow crystals melting at 201–202°; yield 0.9 g. (84%). After two recrystallizations from benzene the keto acid was obtained as clusters of colorless, prismatic needles, m. p. 201.5–202.5°.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.24; H, 4.58. Found: C, 77.29; H, 4.81.

4-Acetylphenanthrene.—As attempted decarboxylation of the keto acid without solvent was unpromising, a solution of 0.48 g. of the substance in 3 cc. of quinoline was treated with about 50 mg. of basic copper carbonate and heated at 240–260° for forty-five minutes, most of the carbon dioxide being eliminated in about fifteen minutes. The quinoline solution was diluted with ether, filtered, and extracted with dilute mineral acid to remove the quinoline and with dilute alkali to remove any unchanged acid. After distillation of the ether the residue was distilled at 2 mm., giving a light yellow oil which readily solidified on cooling. After crystallization from ligroin or petroleum ether, in which the substance is moderately soluble, there was obtained 0.27 g. (68% yield) of ketone, m. p. 88.5–90.5°. After two recrystallizations it formed large clusters of heavy colorless plates, m. p. 89.8–90.3°.

Anal. Calcd. for $C_{16}H_{12}O$: C, 87.23; H, 5.50. Found: C, 87.19; H, 5.01.

A solution of the acetyl compound and phenylhydrazine after being boiled for a few minutes and diluted with water yielded only the unchanged ketone.

The picrate forms easily using methyl alcohol as the solvent. It crystallizes as long, slender, yellow needles melting at 129.5–130.5°.

Anal. Calcd. for $C_{16}H_{12}O \cdot C_6H_3O_7N_3$: N, 9.35. Found: N, 9.33.

For conversion to **4-phenanthroic acid**, 0.1 g. of 4-acetylphenanthrene was boiled for one and one-half hours with a sodium hypochlorite solution prepared from 1 g. of the commercial calcium salt (H. T. H.). After cooling, filtering and destroying the excess reagent, the product was precipitated by acidification and crystallized from dilute alcohol. It formed glistening, colorless plates, and after thorough drying at 130° to remove solvent, the acid melted at 171.5–173°. Kruber[3] reports the value 170–171°, uncorr.

Cleavage of 1′,3′-Diketo-1,2-cyclopentenophenanthrene.—After refluxing a solution of the diketone (1.2 g.) in 1 *N* sodium hydroxide for ten hours the light brown solution was filtered from a small amount of purple material and acidified. The acidic product which precipitated was crystallized from benzene, giving 0.96 g. of material. After a second crystallization the substance, m. p. 190–193°, had approximately the composition of a mixture of acetylphenanthroic acids.

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.24; H, 4.58. Found: C, 77.63, 77.40; H, 5.22, 5.36.

In further recrystallizations the melting point of the less soluble portion rose to about 216°, but an assuredly homogeneous product was not obtained.

Summary

The condensation of the 1,2- and 3,4-dicarboxylic esters of phenanthrene with ethyl acetate proceeds smoothly, affording diketocyclopentenophenanthrenes of interest in the study of oestrogenic activity. The alkaline cleavage of the 1,2-derivative proceeds in both possible directions, whereas with the 3,4-diketone steric hindrance at the 4-position is so pronounced that the reaction affords pure 4-acetyl-3-phenanthroic acid. This on decarboxylation yields the new 4-acetylphenanthrene.

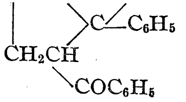
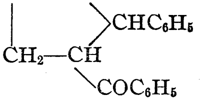
The Rearrangement of 1-Phenyl-5-benzoylcyclopentene Oxide

BY S. H. BABCOCK, JR., AND REYNOLD C. FUSON

The chief product in the reduction of 1,4-dibromo-1,4-dibenzoylbutane with zinc dust and sodium iodide has been shown to be 1-phenyl-5-benzoylcyclopentene oxide (I).[1] The oxide was accompanied by an isomer which appeared to be derived from it by rearrangement. This isomer was obtained also (1) by the action of alcoholic hydrogen chloride on the oxide; (2) by treatment of a solution of the oxide in glacial acetic acid with ozone; and (3) together with I by the action of perbenzoic acid on 1-phenyl-5-benzoylcyclopentene. It has now been shown that the oxide readily undergoes rearrangement when dissolved in hot glacial acetic acid, and that the rearrangement product is identical with that reported by Fuson and Farlow. The compound has proved to be 2-phenyl-3-benzoylcyclopentanone (II).

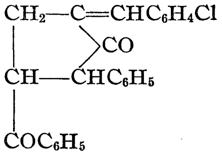


I

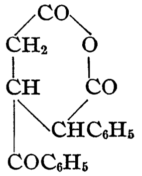


II

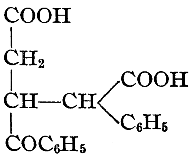
The structure of this compound has been established by a degradation process leading to the formation of α-phenyl-β-benzoylglutaric acid (V). The ketone condensed readily with *p*-chlorobenzaldehyde to give a chlorobenzal derivative (III).



III



IV



V

When treated with ozone this compound gave *p*-chlorobenzaldehyde, *p*-chlorobenzoic acid and an anhydride (IV) corresponding to that of α-phenyl-β-benzoylglutaric acid (V). By hydrolysis of the anhydride the acid was obtained in the two forms required by theory. One of these melted at 176–177°, and, when heated in the presence of alkali, isomerized to the other, which melted at 135–136°.

Mention should be made of the fact that under certain conditions the rearrangement of the oxide

---

[1] Fuson and Farlow, THIS JOURNAL, **56**, 1593 (1934).

to the cyclopentanone could be interrupted at an intermediate state. The intermediate compound has not been investigated fully, but it appears likely that it is the theoretically possible geometrical isomer of II.

Experimental

1-Phenyl-5-benzoylcyclopentene Oxide.—The general procedure of Conant and Lutz,[2] and Fuson and Farlow[3] was followed. It was found, however, that the reactants could be used in more nearly equivalent quantities—a modification which increased the yield of oxide by rendering its purification less troublesome. From 200 g. of 1,4-dibromo-1,4-dibenzoylbutane, 40 g. of zinc dust and 186 g. of hydrated sodium iodide was obtained 44 g. of the pure oxide.

Rearrangement of 1-Phenyl-5-benzoylcyclopentene Oxide

(a) **By the Action of Hydrogen Chloride in Alcohol.**—One gram of the oxide was shaken for ten minutes with 25 cc. of absolute alcohol saturated with dry hydrogen chloride. The mixture was then quickly filtered and poured onto 100 g. of cracked ice. The product, after crystallization from methanol, melted at 159–159.5° (corr.) and, when mixed with the sample prepared by Fuson and Farlow, showed no lowering of the melting point.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.8; H, 6.1; mol. wt., 264. Found: C, 81.7; H, 6.2; mol. wt. (Rast), 260, 270.

(b) **By Heating with Glacial Acetic Acid.**—A solution of 1 g. of the oxide in 25 cc. of glacial acetic acid was heated in such a manner that at the end of two minutes the temperature had reached 100°. It was then poured onto 50 g. of ice. After repeated recrystallization from methanol the product melted at 123.5–124.5°.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.8; H, 6.1. Found: C, 81.8; H, 6.4.

This method of treatment usually gave a product melting at 116–119° which was very difficult to purify. This substance was dissolved in boiling glacial acetic acid, and the solution was then diluted with hot water until a slight cloudiness was noted. This was discharged by heating, and the solution was allowed to cool. The product softened at 110–113°, and melted at 152–154°. This compound, when subjected to a second treatment similar to that just described, melted at 153–155°. A mixture of this with the oxide melted at 154–157°.

That the substance melting at 116–119° was an intermediate in the conversion of the oxide to the cyclopentanone was further supported by the fact that a hot, slightly alkaline solution of alcohol converted it into the pure cyclopentanone.

Reactions of 2-Phenyl-3-benzoylcyclopentanone

(a) **With Alcoholic Hydrogen Bromide.**—Treatment with this reagent for four days at 0° produced no change.

(b) **With Bromine.**—Bromination in chloroform solution gave a product which crystallized from alcohol in the form of yellow-orange needles melting at 136.5–137.5°.

Anal. Calcd. for $C_{18}H_{14}O_2Br_2$: C, 51.0; H, 3.3. Found: C, 51.4; H, 3.0.

Attempts to dehalogenate the dibromide by treatment with pyridine, zinc dust or sodium iodide all failed to give products which could be characterized.

(c) **With *p*-Chlorobenzaldehyde.**—One-half gram of the ketone and 0.5 g. of the aldehyde gave 1 g. of a solid which, after two recrystallizations from benzene and high-boiling petroleum ether, melted at 207–207.5°.

Anal. Calcd. for $C_{25}H_{19}OCl$: C, 77.6; H, 5.0. Found: C, 77.5; H, 4.9.

Ozonization of 8 g. of the *p*-chlorobenzal derivative gave a mixture of *p*-chlorobenzaldehyde, *p*-chlorobenzoic acid and 5.5 g. of **α-phenyl-β-benzoylglutaric anhydride.** The anhydride crystallized from benzene in needles melting at 183–184°.

Anal. Calcd. for $C_{18}H_{14}O_4$: C, 73.4; H, 4.8. Found: C, 73.3; H, 5.1.

The anhydride was dissolved in a 10% sodium hydroxide solution and the solution was filtered and acidified. The free **α-phenyl-β-benzoylglutaric acid,** after recrystallization from a mixture of ethyl acetate and petroleum ether, melted at 176–177°.

Anal. Calcd. for $C_{18}H_{16}O_5$: C, 69.3; H, 5.1; neut. equiv., 156. Found: C, 69.0; H, 5.3; neut. equiv., 156.

Concentration of the mother liquors yielded an isomeric acid melting at 135–136° (from benzene).

Anal. Calcd. for $C_{18}H_{16}O_5$: C, 69.3; H, 5.1; neut. equiv., 156. Found: C, 69.3; H, 5.4; neut. equiv., 155, 159.

The acid melting at 176–177° was heated for six hours with a 6% solution of alcoholic potassium hydroxide. Acidification of the resulting mixture gave the isomeric acid (melting at 135–136°).

Summary

It has been shown that 1-phenyl-5-benzoylcyclopentene oxide (I) rearranges to 2-phenyl-3-benzoylcyclopentanone (II) when treated with alcoholic hydrogen chloride.

The structure of the rearrangement product has been established by a degradation process leading to the formation of α-phenyl-β-benzoylglutaric acid which has been obtained in the two forms predicted by theory.

Bisulfite Compounds of Azo Dyes. V. Bisulfite Reaction of Azo Dyes Containing Two Auxochromes

BY NIKOLAI N. WOROSHTZOW AND ANATOLE S. TSHERKASSKI

While investigating the reaction of azo dyes with sodium bisulfite, it was determined in 1911 that the presence of a naphthalene component containing an amino or hydroxy group is necessary for the formation of bisulfite compounds.[1] On treatment with bisulfite, aminoazo dyes hydrolyze, giving off ammonia, and are converted to hydroxyazo dyes which form bisulfite compounds. In refuting the hypothesis of Spiegel, accepted at that time, according to which sodium bisulfite adds on to the azo group, giving the salt of hydrazo-N-sulfonic acid of the type $RN(SO_3Na)$-NHR', in 1915 the inadequacy of this theory was proved by a number of facts.[2] Of these, we consider the following most significant.

(1) The analogous physical and chemical properties of bisulfite compounds of dyes obtained by treating azo dyes with bisulfite and compounds obtained by coupling diazotized bisulfite compounds of aminonaphthols with benzene azo components (*e. g.*, phenol).

(2) The diazo dye obtained from α-naphthol and two molecules of diazotized aniline, $HOC_{10}H_5$-$(N{=}NPh)_2$, gives bisulfite compounds with only one molecule of sodium bisulfite, not with two as it should according to Spiegel, given two azo groups.

(3) All bisulfite compounds of azo dyes are colored—yellow, orange, red—while hydrazo compounds are colorless.

These and other considerations, developed in detail in former investigations, led us to the conclusion that the reactivity of azo dyes of the naphthalene series toward bisulfite is caused not by the azo group but by the auxochrome (NH_2 or OH) group in the naphthalene component of the dye and that the azo group of the dye plays a secondary role in this reaction, similar to that of the sulfo group in sulfonic acids of naphthols or naphthylamines, aiding or hindering the reaction according to the relative positions of the groups N=N and the reactive group OH or NH_2.

In a further work with S. W. Bogdanow, we succeeded in broadening this analogy to cover the bisulfite reaction of nitrosonaphthols.[3]

The analogous behavior of naphtholsulfonic acids and naphthol azo dyes in the bisulfite reaction was confirmed by physico-chemical investigation of the bisulfite compound of 2-naphthol-1-sulfonic acid.[4]

In the products of the reaction between bisulfite and naphtholsulfonic acids, nitrosonaphthols, or naphthol azo dyes, we find in all cases addition compounds of one molecule of bisulfite and one molecule of the original naphthol derivative. Here we definitely disagree with Bucherer who, on the basis of one incomplete analysis of the bisulfite compound of aminonaphthol, considers these compounds to be salts of acid esters of sulfurous acid and regards the reactivity of azo dyes with bisulfite from the point of view of Spiegel.[5]

Below we consider in greater detail the proof of the structure of the bisulfite compounds. Already in 1915, on the basis of the above-emphasized importance of the hydroxyl group in the reaction of the azonaphthol dye with bisulfite, it was suggested that dyes with one azo group and two hydroxyl groups can give compounds with bisulfite, containing two molecules of bisulfite and one molecule of dye.

This view has lately been disputed by A. King, an investigator who has contributed much interesting material in the field of bisulfite compounds of azo dyes.

King obtained the bisulfite compound of a dye obtained from diazotized 1,2-aminonaphthol-4-sulfonic acid and β-naphthol (I)

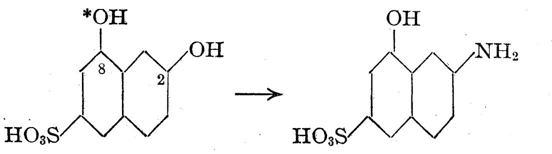
[5] H. T. Bucherer, *J. prakt. Chem.*, [2] **69**, 49 (1904); H. T. Bucherer and M. Schmidt, *ibid.*, [2] **79**, 385 (1909); Bucherer and E. F. Sonnenborg, *ibid.*, **81**, 8 (1910); Bucherer and W. Zimmermann, *ibid.*, **103**, 285 (1921).

and found only one bisulfite group although the dye contains two hydroxyl groups.[6]

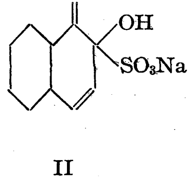
However, we do not see in King's experiment a refutation of our point of view, since the structure of this compound (I) has one peculiarity which allows us to foretell the inactivity of one of the hydroxyls, namely, the one present in the sulfonated nucleus.

It has long been known, from the work of Bucherer, that sulfo groups in the meta position to amino or hydroxyl groups in the naphthalene ring influence the bisulfite reaction unfavorably. It is possible, for example, using the ammonium salt of sulfurous acid, to exchange only one OH group for an amino group in 2,8-dihydroxynaphthol-6-sulfonic acid. Thus not diamino-

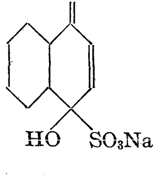


naphthalenesulfonic acid but aminonaphtholsulfonic acid is obtained, for the OH group in the 8-position marked by the star is paralyzed by the sulfo group in the meta position. Therefore we do not consider King's experiments final and have again taken up this work, formerly abandoned for various reasons, on the reactivity of monoazo dyes with two free auxochrome groups.

Before passing to a description of our experiments, we will attempt to give a short summary of the present state of the question of the structure of bisulfite compounds of azo dyes. Naphtholazo dyes give bisulfite compounds with the formula $HOC_{10}H_6N{=}NR\cdot NaHSO_3$. It is simplest to consider them according to the scheme corresponding to the quinoid (hydrazone) formula of azo dyes or the keto formula of naphthols, *e. g.*,

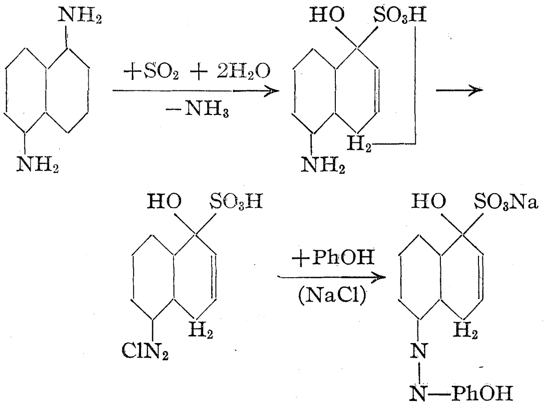


II



IIa

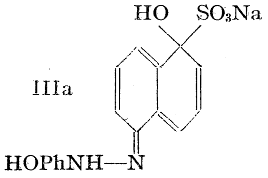
Here we employ the structure  $C\genfrac{}{}{0pt}{}{OH}{SO_3Na}$ and not the formerly used  $C\genfrac{}{}{0pt}{}{OH}{OSO_2Na}$, as better answering the facts on the basis of the proof of the structure of carbonyl bisulfite compounds by Raschig.[7] But earlier we saw that bisulfite compounds of azo dyes can be formed which do not differ in physico-chemical properties from the abovementioned compounds formed by introducing a bisulfite group into the diazo component before coupling, *e. g.*,

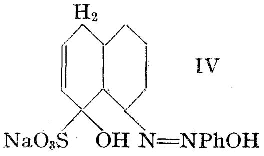


III

The compound III may be considered in its hydrazone form (IIIa) corresponding to ananaphthoquinone

IIIa

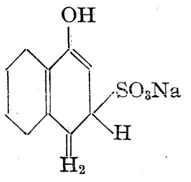




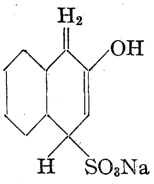
IV

But such a transformation cannot be allowed for the analogous 1,8-aminonaphthol derivative, *e. g.*, (IV) where the quinone-hydrazone structure is excluded by the impossibility of the existence of 1,8-naphthoquinone. Later investigation of the bisulfite reaction of nitroso-β-naphthol led S. W. Bogdanow to suggest another form for the structure of naphthol bisulfite compounds and hence for bisulfite compounds of azo dyes.[8]

Bogdanow considers these compounds of α- or β-naphthol to have the structures V and VI.



V



VI

In favor of this view we note the unfavorable influence of the sulfo group in the meta-position

---

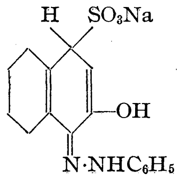
[6] A. King, *J. Chem. Soc.*, 1271 (1932).

[7] F. Raschig, *Ber.*, **59**, 859 (1926).

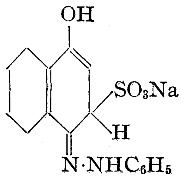
[8] S. W. Bogdanow, *J. Gen. Chem.* (*U. S. S. R.*), **64**, 9 (1932).

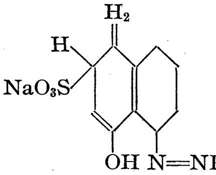
to the OH on the formation of bisulfite compounds, which can be explained by the comparative ease with which the sulfo group enters the 4-position in reduction reactions of bisulfite β-naphthol derivatives, *e. g.*, in the conversion of the bisulfite compound of nitroso-β-naphthol to 1,2-aminonaphthol-4-sulfonic acid.[9] According to Bogdanow the structures of the compounds II, IIa and IV are

VII



VIIa

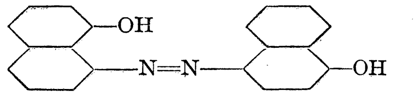




VIII

Thus, from the reactivity of the naphthalene component of azo dyes, with an OH group, we may consider permissible in various cases two different structural forms of bisulfite compounds of azo dyes—the hydrazone form in the quinoloid bisulfite (II, IIa) and hydroxyquinoidosulfonic acid (VII, VIIa) variants and the azoid form in the keto bisulfite (IV) and dihydronaphtholsulfonic acid (VIII) variants. A final choice of variants or determination of their stability under various conditions remains to be decided by further investigation.

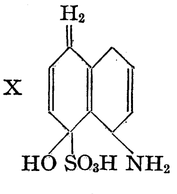
We set ourselves the task of studying the behavior of dyes with the structure IX in the bisulfite reaction. We shall also study mono-



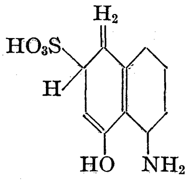
IX

bisulfite azo dyes obtained from the diazotized compounds of X or Xa and α-naphthol or α-

X

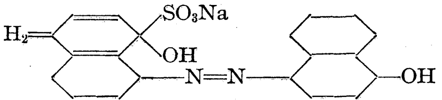


respectively



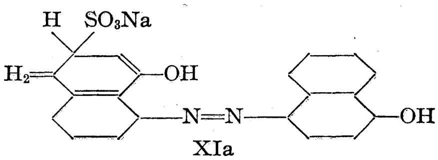
Xa

naphthylamine. The bisulfite compound of 1,8-aminonaphthol (X or Xa) was obtained by one of the authors in 1915 from 1,8-naphthylenediamine by Bucherer's method and its composition determined by analysis. Thus dyes which are derivatives of this bisulfite compound have the structure



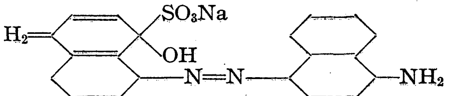
resp.

XI



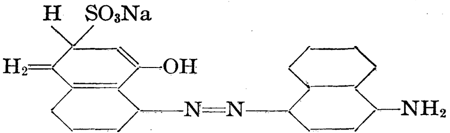
XIa

and



resp.

XII



XIIa

The diazotization of compound X takes place smoothly and quickly and requires no especially low temperatures since the diazo compound is stable. Coupling with α-naphthylamine to give the dye XII is carried out in an acid medium. An azo compound containing a bisulfite group (XII) is precipitated. On recrystallization, irregular reddish-violet needles are obtained. Coupling with α-naphthol to give the dye XI required a search for the proper medium since an alkaline soda medium affects the stability of the bisulfite radical. In an acid medium, coupling takes place very slowly. The best medium proved to be acetic acid to which a large quantity of sodium acetate was added. On recrystallization from alcohol, the orange-red dye XI precipitates in the form of fine, irregular needles. Both coupling products were treated with a 35% solution of bisulfite.

The aminoazo dye, XII, dissolves even in the cold in three to four times the theoretical amount of bisulfite solution, giving a yellow solution from which the new compound settles out in yellow crystals.

The hydroxyazo dye XI reacts only upon warming. In this case yellow crystals settle out more quickly.

---

[9] Schmidt, *J. prakt. Chem.*, [2] **44**, 513 (1891); M. Boeniger, *Ber.*, **27**, 23, 3050 (1894).

The mother liquor obtained from the product prepared from the aminoazo dye contains an amount of ammonia corresponding to one molecule of ammonia for each molecule of aminoazo body.

The mother liquor from the product prepared from the hydroxyazo dyes does not contain ammonia. Therefore, the reaction of aminoazo dyes is accompanied by hydrolysis of the amino group in naphthalene dyes, in this case under extraordinarily mild conditions.

The compounds obtained from both dyes proved to be identical in composition and properties. The substance crystallizes in yellow, well-formed needles. It is soluble in water and alcohol.

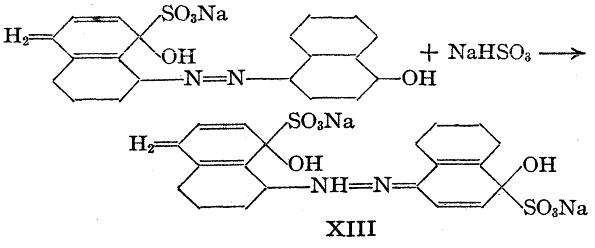
On diluting and warming the aqueous solution to 70°, the substance darkens and decomposes, giving off bisulfite. It is stable toward acids. Alkaline carbonate solutions decompose it, splitting off sulfur in the form of $SO_3^{=}$ ions, and a red substance is formed which crystallizes out when an excess of alkali carbonate is added. On heating the soda solution, the sulfur is completely split off as $SO_3^{=}$ ions, and a violet solution of a dye containing no sulfur is obtained. On treatment with caustic solutions, the substance decomposes rapidly, splitting off sulfurous acid. On heating with an excess of alkali or alkaline carbonates above 100°, a reddish-brown tarry mass is obtained.

The composition of the yellow bisulfite compound of both XI and XII is $HOC_{10}H_6N{=}NC_{10}H_6OH \cdot 2NaHSO_3$.

Thus the substance is an addition product of two molecules of bisulfite and one molecule of the dihydroxy dye.

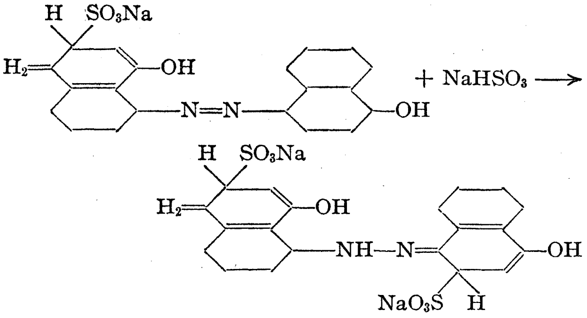
In favor of this theory we cite the yellow color of the new compound compared to the red color of the original monobisulfite compound and the increased solubility in water.

The formation of the dibisulfite compound according to the first variant may be represented as



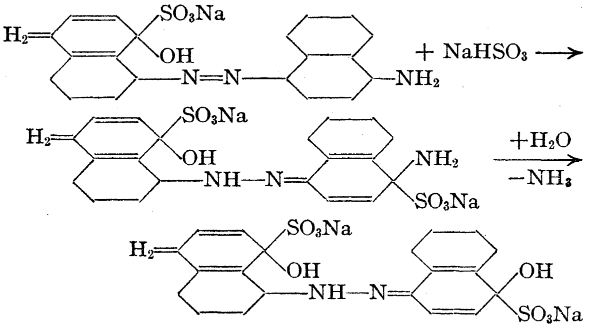
XIII

or according to the second variant (Bogdanow)



XIIIa

In the reaction between bisulfite and the aminoazo dye, according to the above scheme, in which the dibisulfite compound is formed, hydrolysis of the amino group either precedes or accompanies the reaction, for example (according to the first variant)



The possibility of obtaining from compounds XIII and XIIIa first the monobisulfite compound and then the dihydroxyazo compound, free of sulfur, by stepwise hydrolysis with alkaline reagents, is in agreement with this theory of the structure of XIII and XIIIa.

On treating the water solution of the yellow dibisulfite compounds with a soda solution at a temperature not greater than 40°, the solution turns red. On adding a large excess of saturated soda solution, orange-red, irregular needle-like crystals settle out. These proved to be the monobisulfite compound of the dihydroxyazo dye. Its properties did not differ from the above-mentioned original dye (XI). Evidently the molecule of bisulfite combining with the α-naphthol nucleus is less stable than that combined with 1,8-aminonaphthol.

If the product obtained by partial hydrolysis of the dibisulfite compound is treated with bisulfite, the yellow crystalline dibisulfite compound is obtained again.

When bisulfite is split off completely from the dibisulfite compound (or the monobisulfite compound XI) by treatment with an aqueous solution of soda above 70° or sodium hydroxide solution in the cold, the solution turns violet. On addition of excess concentrated sodium hydroxide solution, the monosodium compound of the dihydroxyazo dye, $NaOC_{10}H_6N_2C_{10}H_6OH$, settles out in beautiful violet needles.

It is interesting to note that it was not possible to recrystallize either the free dye or its sodium compound in sufficiently large quantities from organic solvents. As might be expected, the products obtainedf rom the dibisulfite compounds of both the aminoazo and oxyazo dyes proved to be identical.

When the sodium compound of the dihydroxyazo dye is treated with an alcoholic water solution of bisulfite, a mixture of the same yellow dibisulfite compound described above and the monobisulfite compound is obtained. At the same time reduction processes take place which greatly lower the yield of bisulfite compound. The products of reduction were not further investigated. The presence of ammonia and an aminohydroxy compound in the reaction mixture was confirmed.

On longer treatment of the dihydroxyazo dye with bisulfite, no bisulfite compound at all could be isolated because reduction processes dominate.

Experimental

The original product, the bisulfite compound of 1,8-aminonaphthol (X) was prepared as described in our second communication by treating 1,8-naphthylenediamine with bisulfite.

(1) **Aminoazo Dye (XII) (Monobisulfite Compound).**—Two grams of compound X was dissolved in 70 cc. of water at 70°. After filtering off the insoluble residue, the hot solution was cooled. Two cc. of hydrochloric acid (sp. gr. 1.19) was then added and the mixture treated with 3.6 cc. of a 16% solution of sodium nitrite. The solution of the diazo compound is brownish-red in color.

An alcoholic solution of 1.2 g. of α-naphthylamine was prepared separately and added with rapid stirring to the solution of the diazo compound at a temperature not exceeding 12°. Stirring was continued for three hours longer. The reddish-purple dye formed on coupling settles out completely on standing at 0°. The precipitate is filtered, washed free of excess chlorine ions with water and the paste treated with bisulfite (according to 4).

The dye dissolves poorly in water and rather well in alcohol. It is difficult to crystallize it from alcohol. Only 50 mg. of reddish-violet, irregular needles was obtained from alcohol. On treatment with sodium hydroxide solution, part of the precipitate dissolves, giving a reddish-violet color. On heating it dissolves completely in the alkaline solution.

Cold soda solution has no effect in the cold. On heating, a reddish-violet solution is formed.

The dye undergoes no change on treatment with hydrochloric acid.

(2) **Hydroxyazo Dye (XI) (Monobisulfite Compound).**—To the solution of diazo compound prepared in (1) from 2 g. of compound X a solution of sodium acetate was added to neutralize the hydrochloric acid. The solution was tested with congo red. Five cc. of acetic acid (80%) and 8 g. of crystalline sodium acetate were then added. A solution of 1.4 g. of α-naphthol in 12 cc. of water containing 0.4 g. of sodium hydroxide was added gradually, and an orange-red solution was formed. A crystalline dye settles out of the solution almost quantitatively on allowing to stand in the cold (−5°) for twenty-four hours and adding 10 g. of solid sodium chloride. The precipitate was filtered, washed with small portions of ice water and the paste treated with bisulfite. If coupling with α-naphthol is carried out in acetic acid solution without adding sodium acetate (or adding only a small amount of sodium acetate), the reaction is slowed up considerably and will go to an end on addition of an excess of α-naphthol. About four times the theoretical quantity of α-naphthol is required. However, the yield is small, and the product is contaminated by α-naphthol. On coupling with α-naphthol in sodium bicarbonate solution, the same results are obtained.

The dye dissolves fairly well in water, giving an orange-red solution. It dissolves readily in hot and cold alcohol. It does not crystallize well from alcohol. Only 30 mg. of pure substance was obtained in the form of fine, needle-like, reddish-orange crystals.

The dye does not dissolve in cold soda solution but gives a violet solution on heating. A deep violet solution is obtained on dissolving the dye in cold or hot sodium hydroxide solution.

On heating above 75°, the neutral aqueous solution darkens and becomes orange-brown in color. The dye is unchanged by hydrochloric acid.

Determination of sulfur in the bisulfite group of the dye is carried out in all cases in the following manner. A sample, weighed exactly, is dissolved in a definite volume of water so as to obtain a very dilute solution (0.005–0.01%) since at higher concentrations the violet color of the solutions makes it difficult to titrate with starch. A definite volume is treated with excess sodium hydroxide solution and heated for half an hour to 75°.

The sodium sulfite formed is titrated iodometrically. The solution containing the sulfite is added from a buret to a 0.01 *N* solution of iodine acidified with hydrochloric acid to disappearance of the blue color.

Anal. Calcd. for $C_{20}H_{15}N_2SO_4Na$: S, 7.65. Found: S, 7.24.

(3) **Dihydroxyazo Dye (IX) (1,5′-Dihydroxy-4,4′-azonaphthalene).**—Ten cc. of a solution of the diazo compound obtained according to (1) from 2 g. of compound X, was treated with an excess of alkali (5 cc. of a 30% sodium hydroxide solution). The solution turned deep red. The theoretical quantity of α-naphthol (1.2 g. of α-naphthol +0.34 g. of NaOH +10 cc. of water) was added gradually to the solution. Coupling takes place rapidly. However, the dye does not settle out quantitatively even after standing for twenty-four hours in the cold. When the mixture is treated with excess hydro-

chloric acid, the dye settles out quantitatively in the form of a reddish-violet powder, which gives with concd. sulfuric acid a bluish-green solution.

(4) **Dibisulfite Compound of the Dihydroxyazo Dye (XIII).** (a) **Preparation from the Aminoazo Dye (XII).**—A paste of the dye (prepared as in (1)) was shaken with 10 cc. of 35% sodium bisulfite solution at room temperature. The dye gradually goes into solution, and the color, which is orange-brown at first, turns orange-yellow. After eight to ten hours the dye is dissolved completely. On further standing, light yellow crystals of the dibisulfite compound settle out. When tests taken from the reaction mixture were observed under the microscope, the gradual disappearance of the reddish-violet crystals of monobisulfite compound and the precipitation of the yellow needles of dibisulfite compound could be followed. After three to four days the precipitation of the product is complete and the solution turns yellow. The crystals were filtered off, washed with small quantities of ice water and dried at room temperature over sulfuric acid in a desiccator. On drying with exposure to air above 40–50°, the product turns brown. When alkali is added to the mother liquor, ammonia is liberated.

The dibisulfite compound cannot be precipitated from the mother liquor by addition of sodium chloride. After half the water had been distilled off *in vacuo*, a mixture of crystals of sodium bisulfite and dibisulfite compounds settled out. When all the water had been distilled off at 35°, the residue was extracted with absolute alcohol to which 2 cc. of glacial acetic acid had been added. After filtering off the mineral salts, three-fourths of the alcohol was distilled off. On standing in the cold, orange-yellow crystals settled out of the remaining solution. These crystals were darker than those obtained in the first crop.

Quantitative Determination of the Ammonia Obtained by Hydrolysis of the Aminoazo Dye (XII) with Bisulfite.—A small quantity of thoroughly washed dye paste was dried to constant weight at 40° and a sample of the dry substance (0.5240 g.) mixed with 5 cc. of 35% sodium bisulfite solution and allowed to stand overnight. After twenty-four hours the mixture was treated with a large excess of sodium hydroxide solution and heated to boiling, the ammonia liberated being absorbed in 75 cc. of 0.04 *N* hydrochloric acid solution. The excess hydrochloric acid was titrated with 0.1 *N* sodium hydroxide solution. Calcd. for $C_{20}H_{14}N_2(SO_3Na)NH_2$: NH_3, 4.2. Found: NH_3, 3.9.

Iodometric Determination of Sulfur (see above).—Calcd. for $C_{20}H_{16}N_2S_2O_8Na_2$: S, 12.26. Found: S, 11.15.

(b) **Preparation from Hydroxyazo Dye (XI).**—To a paste of the dye (obtained from 2 g. of the bisulfite compound of 1,8-aminonaphthol according to (2)) was added 10 cc. of 35% sodium bisulfite solution and the mixture refluxed on a water-bath at 70°. After three hours the precipitate gradually dissolved.

After heating for twenty-four hours, the red crystals of the monobisulfite compound in the mixture disappeared, and their place was taken by pale-yellow crystals of the dibisulfite compound. The course of the reaction was followed under the microscope by observing test samples taken every hour.

The yellow crystals were filtered off, washed with a small quantity of ice-water, and dried at room temperature in a desiccator. On standing, a small quantity of yellow crystals settled out of the mother liquor. No ammonia was liberated on warming the mother liquor with alkali.

The dibisulfite compounds obtained according to (a) and (b) are absolutely identical. The compound is readily soluble in water, giving a yellow solution. It is readily soluble in alcohol. Its solubility in hot and cold alcohol is almost the same. It is difficult to recrystallize the compound from alcohol but it crystallizes from water in long pale yellow needles. The product was purified by recrystallization from small portions of alcohol. On cooling, only 60 mg. of pure substance was obtained.

Long boiling with alcohol or concentration of the alcohol solution of the product by distillation even *in vacuo* causes the product to darken and lose its crystalline form.

On heating with soda or sodium hydroxide solution, a violet solution is obtained. A solution of the dibisulfite compound does not change color on treatment with hydrochloric acid in the cold; on heating it reddens noticeably.

On heating 0.5–2% water solutions of the dibisulfite compound to 65°, the solutions redden.

Iodometric Determination of Sulfur.—Calcd. for $C_{20}H_{16}N_2S_2O_8Na_2$: S, 12.26. Found: S, 11.40.

(c) **Preparation from 1,5′-Dihydroxy-4,4′-azonaphthalene (IX).**—A paste of the dye obtained according to (3) undergoes no change when treated with bisulfite solution in the cold. On long heating at 70–95° the solution turns orange-brown, and the product is converted to a tarry mass. The reaction with sodium hydroxide indicates the presence of only traces of bisulfite compound. Ammonia was found in the reaction mixture. A solution of ferric chloride gives a dirty blue color with the reaction mixture.

Better results were obtained when four times the required amount of sodium bisulfite in alcoholic water solution (ratio of alcohol to water 3:2) was used and the mixture heated to 70° at a pressure of 100–120 mm.

After ten hours most of the dye had dissolved, giving a brown solution. Part remained in the form of black, tarry lumps. After filtering the cooled solution and allowing it to stand for twenty-four hours, a large quantity of orange-yellow crystalline bisulfite compound settled out. The course of the reaction was controlled by observing test samples of the reaction mixture under the microscope. The product was collected and dried as described above. It consisted of a mixture of mono and dibisulfite compounds.

(5) **Hydrolysis of the Dibisulfite Compound of 1,5′-Dihydroxy-4,4′-azonaphthalene.** (a) **Partial Hydrolysis.**—Two grams of dibisulfite compound prepared according to 4a and 4b was dissolved in 25 cc. of water, treated with 30 cc. of saturated soda solution in the cold and heated to 40°. The solution turns orange-red. After ten to fifteen minutes no further precipitation takes place. Sodium chloride and soda precipitate no more crystals from the filtrate. The crystalline precipitate is washed with ice water and dried as above.

The compound does not differ from the one described in (2) in crystalline form, solubility in water and alcohol, behavior toward alkalies and acids, behavior of its solutions on heating.

Iodometric Determination of Sulfur.—Calcd. for $C_{20}H_{15}N_2SO_8Na$: S, 7.65. Found: S, 7.31.

Two grams of the monobisulfite compound was treated with 10 cc. of 35% sodium bisulfite compound at 70°. After twenty-four hours the product dissolved completely. Yellow needles in all respects similar to those obtained in (4) settled out of the solution.

When treated with bisulfite in the cold, the monobisulfite compound is not converted to the dibisulfite compound even after forty-eight hours.

(b) **Complete Hydrolysis.**—The same results are obtained from hydrolysis of both the monobisulfite and dibisulfite compounds of 1,5′-dihydroxy-4,4′-azonaphthalene (XI).

One gram of the bisulfite compound was treated with 10 cc. of 25% sodium hydroxide solution. Very fine violet needles settled out in the cold, and on heating with excess sodium hydroxide, a violet solution was obtained. On cooling this solution, large violet needles with a metallic luster settled out. The product was recrystallized from hot alkali solution, washed with water to neutral reaction, and dried at 100°. According to the analysis, the product is the monosodium salt of the dihydroxyazo dye.

Analysis of the products obtained from the dibisulfite (1) and monobisulfite (2) compounds of the dihydroxyazonaphthalene: (1) Calcd. for $C_{20}H_{13}N_2O_2Na$: Na, 6.84; N, 8.5. Found: Na, 6.95; N, 8.3. (2) Calcd. for $C_{20}H_{13}N_2O_2Na$: Na, 6.84. Found: Na, 7.04.

On treating the hot (80°) alkaline solution of the dye with excess hydrochloric acid, all of the dye settles out in the form of reddish-violet powder which is absolutely identical with the product obtained in (3). The precipitate is washed thoroughly with water and dried at 100°.

The monosodium compound of the dye is insoluble in both hot and cold water, readily soluble in alcohol, ether, ethyl acetate and chloroform. It dissolves with difficulty in cold, better in hot benzene, toluene, nitrobenzene and glacial acetic acid. It is insoluble in cold alkalies but dissolves completely in hot alkalies. It is insoluble in both hot and cold soda solution.

The free dihydroxyazo dye behaves like the sodium compound toward solvents.

Summary

1. It has been shown, contrary to the statement of A. King, that it is possible to obtain addition products containing two molecules of bisulfite from monoazo dyes with two auxochromes. This proves the dominant importance of the auxochrome group (and the nucleus containing it) in the reaction of naphthaleneazo dyes with bisulfite and disproves Spiegel's theory.

2. The dibisulfite compound of the dye prepared from diazotized 1,8-aminonaphthol and α-naphthol may be obtained easily from the monobisulfite compound. Due to side reactions, a pure product cannot be obtained from the dye which contains no bisulfite group.

3. The formation of the dibisulfite compound from the monobisulfite compound of the α-naphthylamine dye is accompanied by hydrolysis of the amino group and the transition of the organic nucleus to the dihydroxy dye.

4. On hydrolysis of the dibisulfite compound of the dye in alkaline solution, stepwise decomposition takes place. First one molecule of bisulfite splits off, giving the monobisulfite compound. Then the second molecule splits off, forming the free dye.

5. The formation of bisulfite compounds corresponding to both the azoid and hydrazone forms is possible.

Preparation and Properties of Xyloseen-(1,2) Tribenzoate

BY RANDOLPH T. MAJOR AND ELMER W. COOK

In the course of the investigation of various new syntheses of ascorbic acid an attempt was made to prepare xyloseen-(1,2) triacetate. Only a gum was obtained. The preparation of xyloseen-(1,2) tribenzoate was then undertaken in the hope that it might crystallize. This proved to be the case. Xyloseen-(1,2) tribenzoate was prepared by a procedure similar to that described by Maurer and Petsch[1] for the preparation of glucoseen tetrabenzoate.

Experimental

***d*-Xylose Tetrabenzoate.**—*d*-Xylose (50 g.) was added gradually to a mixture consisting of 190 cc. of benzoyl chloride, 200 cc. of anhydrous pyridine and 380 cc. of anhydrous chloroform, cooled in an ice-bath. The xylose soon dissolved and the solution was allowed to stand for twenty-four hours. Chloroform (600 cc.) was then added and the solution was washed successively with cold dilute sulfuric acid, sodium bicarbonate and water. After drying over calcium chloride the chloroform was removed by evaporation *in vacuo*. The crystalline residue of α-*d*-xylose tetrabenzoate was recrystallized from dioxane with the addition of methanol. It was also recrystallized either

---

(1) Maurer and Petsch, *Ber.*, **66**, 998 (1933).

from absolute alcohol containing 10% pyridine or from benzene with the addition of petroleum ether; yield, 90%. The product was quite insoluble in water or petroleum ether and only slightly soluble in warm methanol. It was soluble in chloroform, dioxane and benzene; m. p. 115–116°; $[\alpha]^{20}D$ +115° in dry chloroform, $c = 2$.

Anal. Calcd. for $C_{33}H_{26}O_9$: C, 69.94; H, 4.63. Found: C, 70.15; H, 4.74.

***l*-Xylose Tetrabenzoate.**—α-*l*-Xylose tetrabenzoate was obtained in a similar manner; m. p. 115–116° and with the same rotation, but of opposite sign. However, on one occasion when crystallizing the reaction product from absolute alcohol containing 10% pyridine, the β-isomer was obtained; yield 29%; m. p. 173–174°; $[\alpha]^{20}D$ +44.5°, in dry chloroform, $c = 2$.

Anal. Calcd. for $C_{33}H_{26}O_9$: C, 69.94; H, 4.63. Found: C, 69.91; H, 4.64.

Benzobromo-*d*-xylose.—α-*d*-Xylose tetrabenzoate (25 g.) was dissolved in a mixture of anhydrous dioxane and chloroform. A saturated solution of hydrogen bromide in glacial acetic acid (50 cc.) was added and the whole allowed to stand for twenty-four hours. By this time benzobromo-*d*-xylose had precipitated. The mixture was cooled, filtered and washed with petroleum ether. The product was recrystallized from benzene by the addition of petroleum ether; yield 60%; m. p. 134–135°; $[\alpha]^{20}D$ +117°, in dry chloroform, $c = 2$.

Anal. Calcd. for $C_{26}H_{21}O_7Br$: C, 59.42; H, 4.03; Br, 15.22. Found: C, 59.62; H, 4.22; Br, 15.08.

The benzobromo-*d*-xylose was soluble in dioxane, chloroform, acetone and fairly soluble in methanol. It was insoluble in water, and only slightly soluble in petroleum ether.

Benzobromo-*l*-xylose.—Both α-*l*-xylose tetrabenzoate of m. p. 115–116° and β-*l*-xylose tetrabenzoate of m. p. 173–174° gave the same benzobromo-*l*-xylose of m. p. 134–135° and $[\alpha]^{20}D$ −116° in dry chloroform, $c = 2$.

***d*-Xylose Tribenzoate.**—Benzobromo-*d*-xylose (20 g.) was dissolved in 50 cc. of acetone and 0.8 cc. of water was added. The solution was cooled in an ice-bath and 12 g. of silver carbonate was added. After short stirring effervescence stopped. The mixture was then shaken an hour at room temperature. The insoluble silver salts were filtered and the filtrate evaporated *in vacuo* until a crystalline residue was left. The product was recrystallized from anhydrous benzene; yield, 98%; m. p. 188–189° (Pyrex capillary tube); $[\alpha]^{20}D$ +39.5°, in dry chloroform, $c = 2$.

Anal. Calcd. for $C_{26}H_{22}O_8$: C, 67.51; H, 4.80. Found: C, 67.54, 67.62; H, 4.85, 5.02.

Xyloseen-(1,2) Tribenzoate.—Benzobromo-*d*-xylose (20 g.) and anhydrous diethylamine (8.7 cc.) were dissolved in anhydrous benzene contained in a tightly capped bottle. The solution was heated at 55° for three hours, at the end of which time about 75% of the theoretical amount of diethylamine hydrobromide had precipitated. After cooling 150 cc. benzene was added and the mixture filtered. The filtrate was washed with iced dilute sulfuric acid and twice with ice water. The benzene extract was dried over calcium chloride and evaporated *in vacuo* to a gum. The gum was dissolved in 50 cc. of warm absolute ethanol and petroleum ether added to a faint turbidity. Upon allowing this to stand two to three days in an ice box, xyloseen-(1,2) tribenzoate precipitated. It was recrystallized from absolute ethanol; yield, 11%; m. p. 126–128°; $[\alpha]^{20}D$ −280°, in dry chloroform, $c = 0.5$.

Anal. Calcd. for $C_{26}H_{20}O_7$: C, 70.24; H, 4.54. Found: C, 70.34, 70.15; H, 4.80, 4.71.

Similarly *l*-xyloseen-(1,2) tribenzoate of the same melting point, and optical rotation, $[\alpha]^{20}D$ +280°, in dry chloroform; $c = 2$ was prepared.

Xyloseen-(1,2) Tribenzoate Dichloride.—*l*-Xyloseen-(1,2) tribenzoate (2.5 g.) was dissolved in 200 cc. of anhydrous benzene and chlorine was passed in until a permanent greenish-yellow color remained. After evaporating the solution *in vacuo* the gummy residue was crystallized from absolute ethanol. The 1-xyloseen-(1,2) tribenzoate dichloride was recrystallized from anhydrous benzene with the addition of petroleum ether; yield, 17%; m. p. 178–180°; $[\alpha]^{20}D$ +110°, in dry chloroform, $c = 1.5$.

Anal. Calcd. for $C_{26}H_{20}O_7Cl_2$: C, 60.57; H, 3.91; Cl, 13.77. Found: C, 60.70; H, 4.07; Cl, 13.26.

Summary

1. Dextro and levo xylose tetrabenzoate have been synthesized. The α form of the former has been isolated and both the α and β forms of the latter were made.
2. Benzobromo-*d*- and *l*-xylose have been made.
3. *d*-Xylose tribenzoate has been made from *d*-benzobromo-*d*-xylose.
4. Dextro and levo xyloseen-(1,2) tribenzoate have been synthesized.
5. *l*-Xyloseen-(1,2) tribenzoate dichloride was made by the addition of chlorine to *l*-xyloseen-(1,2) tribenzoate.

NOTES

Polymorphism of Acetaldehyde 2,4-Dinitrophenylhydrazone

By W. M. D. Bryant

In two earlier papers the writer reported the melting point and optical crystallographic constants of acetaldehyde 2,4-dinitrophenylhydrazone.[1] It was shown in the second paper that this derivative exists in at least two distinct crystalline modifications designated as stable and metastable, respectively. Shortly afterward Ingold, Pritchard and Smith[2] reported two crystalline modifications and commented on their possible identity with the above polymorphs. Their "metastable" modification, however, melted at 146°, while only one melting point (168.5°) was obtained from both of the writer's products. Campbell has recently stated[3] that only one modification exists and that the writer's metastable modification was merely contaminated material. This statement is completely at variance with the writer's previous work and with experiments to be reported below. Further, Campbell has incorrectly quoted this modification as melting at 147° instead of 168.5°. He suggests crotonaldehyde 2,4-dinitrophenylhydrazone as a possible contaminant.

Extending the work reported earlier, it has been possible to duplicate the preparation of the low melting material obtained by Ingold, Campbell, and also by Purgotti.[4] This material recrystallized once from benzene is optically indistinguishable from the stable modification as judged by refractive indices, optic axial angle and the highly characteristic inclined dispersion, but is quite distinct from the writer's metastable form. The material melts fairly sharply at 147° and the melting point is not noticeably depressed on mixing with some of the higher melting stable material. No similar product was obtained on mixing a small amount of crotonaldehyde derivat
(m. p. 199.6°) with some of the stable mod
tion.

While it is not proposed that the low
material is necessarily pure, it appears lik

the contaminant is of a catalytic sort (perhaps a trace of sulfuric acid) and that the low melting point is due to an inhibition of the transition from the stable to the metastable form rather than contamination by another "hydrazone." The fact that the stable and metastable forms previously reported both melted at 168.5° suggests that the transition ordinarily occurs in the solid state prior to fusion in the case of the pure stable modification and that the observed melting point is in both cases really that of the metastable form. It may well be that 147° approximates the melting point of the unchanged stable form. According to this reasoning the two products described by Ingold and by Campbell would both be the stable variety, with the difference that the low melting samples may contain a trace of negative catalytic material.

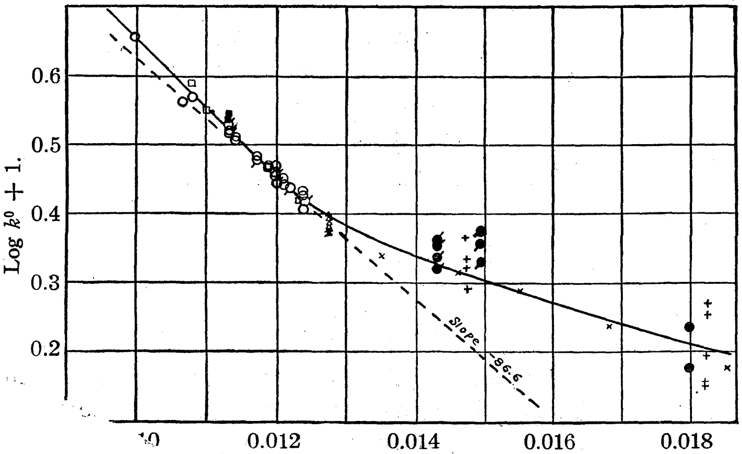
(3) Campbell, *Analyst*, **61**, 391 (1936).

(4) Purgotti, *Gazz. chim. ital.*, **24**, 569 (1894).

In testing the theory, La Mer and Kamner have used rate constants over the range $\mu = 0.002–0.05$. In most of their experiments in solvents of dielectric constant less than water, the primary salt effect is larger than the effect of decreasing the dielectric constant and as a consequence the experimental rates are higher in the mixed solvents than in water. It must be emphasized that the k^0s in equation (1) from Scatchard's theory are rate constants at zero ionic strength. We have calculated k^0 values from the data of the above investigators[1-3] by the well-known relation

$$\log k/k^0 = \frac{\epsilon^2 \mathbf{Z}_A \mathbf{Z}_B}{2.3D''k''T} \frac{\kappa}{1 + \kappa a} \qquad (2)$$

using Straup and Cohn's value, $a = 5.6$ Å. The rate constants at zero ionic strength (k^0) show a uniform decrease with decrease in dielectric constant. In the figure, we have plotted log k^0



Ac⁻ at 25°: Kappanna— + $C_2H_5OH-H_2O$, ●, Kamner— ▲, H_2O; ■, urea-H_2O, ●, glycerol- nd Cohn—△, H_2O, ○, glycine-H_2O, ○-, α-], urea-H_2O × $C_2H_5OH-H_2O$.

se in
),

points to the inadequacy of equation (2) for extrapolating to zero ionic strength. The "theoretical" slope using $a = 5.6$ Å. in equation (1) is shown in the figure.

In mixed solvents of dielectric constant greater than water there is good agreement with the theory. The somewhat steeper experimental slope may be attributed to the "salting in" of the highly polar non-aqueous constituents of the solvent. In solvents of dielectric constant less than water, the rate decreases less rapidly with decrease in dielectric constant than required by the approximate equation (1). This deviation might be expected for a variety of reasons. It may be due to a "salting out" of the non-aqueous solvent so that the effective dielectric constant about the reacting ions is less than the dielectric constant according to solvent composition.[5] Since k^0 values are calculated from experimental values at finite ionic strengths, the influence of salting out will be to give calculated values which are higher than the true k^0. Scatchard[4] has already pointed out the limitations imposed upon equation (2) through the neglect of "higher terms" in its derivation. Due to these limitations, equation (2) becomes less adequate for calculating k^0 from an experimental k at constant dielectric constant as the dielectric constant of the solvent is decreased. Due to each of these causes, one would expect the true k^0 to be lower than any calculated by equation (2). This conclusion is supported by our calculations, especially those using Kappanna's data which cover a considerable range of ionic strength. Almost invariably, the lowest k^0 (calculated) is obtained from the experimental k at lowest ionic strength.

The difference in rate constants found by Straup and Cohn in isodielectric solvents is of the same order of magnitude as found by Warner and War-
ck[5] for the conversion of ammonium cyanate
urea in isodielectric mixtures of water and
alcohols. These differences might be
d whether the deviations for the simple
s were due to salting in and salting out or
nadequacy of equation (2). In addition
factors already discussed, one might at-

rner and Warrick, THIS JOURNAL, **57**, 1491 (1935).

tempt to attribute deviations to a change in "a" with solvent or to ion associations which might change the factor $\mathfrak{z}_A\mathfrak{z}_B$ from 2 to 1. Considering all of the limitations imposed in obtaining equations (1) and (2) from the theory, one must conclude that the agreement is as good as could reasonably be expected.

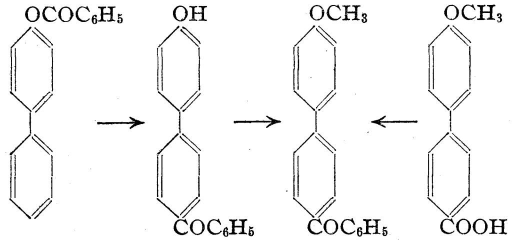
The Fries Rearrangement of 4-Benzoyloxydiphenyl

BY L. F. FIESER AND CHARLES K. BRADSHER

Having recently reported that the Fries rearrangement of 4-acetoxydiphenyl yields a mixture of 4-hydroxy-3-acetyldiphenyl and 4-hydroxy-4′-acetyldiphenyl,[1] we were interested to note that, in a paper published prior to ours but after the completion of our work, Hey and Jackson[2] obtained only 4-hydroxy-3-benzoyldiphenyl on heating 4-benzoyloxydiphenyl with aluminum chloride in tetrachloroethane solution at 140° and found no evidence of the heteronuclear migration of the benzoyl group. No trace of the alkali-soluble product, m. p. 193–195°, claimed by Blicke and Weinkauff[3] to be produced under identical conditions was observed. The latter investigators had assigned to their product, albeit without satisfactory evidence, the structure of 4-hydroxy-4′-benzoyldiphenyl and had regarded this as a case of heteronuclear rearrangement.

In view of the discrepancy in these two reports and the divergence of our results with the acetate from those of Hey and Jackson with the benzoate, we investigated the rearrangement of the latter ester under conditions similar to those employed with the former.[1] The reagents were brought together in the presence of carbon bisulfide, the solvent was distilled, and the residue heated at 160°. From the resulting mixture a substance identified as 4-hydroxy-4′-benzoyldiphenyl (II), m. p. 194–195° when pure, was isolated in 22% yield. As in other cases, the 4′-derivative is easily separated by virtue of its relatively low solubility. The structure of the substance was established by conversion to the methyl ether (III), which was compared with a sample synthesized by the condensation of the chloride of 4-methoxy-4′-carboxydiphenyl[1] (IV) with benzene. The two samples were found to be identical. The same substance resulted from the Friedel and Crafts reaction of 4-methoxydiphenyl with benzoyl chloride, as stated by Blicke and Weinkauff and by Hey and Jackson, but our results differed from those of the previous investigators in that we isolated not only the 4′-benzoyl derivative (37% yield) but also 4-methoxy-3-benzoyldiphenyl (39% yield).



I II III IV

We are in agreement with both pairs of investigators regarding the properties of the various compounds, and the differences in the results appear to be due to variations in the conditions of the reactions and the methods of separating the products. We are inclined to believe that the conditions for the Fries rearrangement specified by Blicke and Weinkauff are not very satisfactory, for although these workers undoubtedly obtained 4-hydroxy-4′-benzoyldiphenyl, we were no more able to duplicate their results, at least in one small-scale experiment, than were Hey and Jackson.

That under slightly different conditions the benzoyl group migrates to an appreciable and unmistakable extent to the 4′-position is consistent with the findings regarding the acetyl migration.[1] We do not, however, regard these examples of heteronuclear migration as having any great theoretical significance, for the evidence available indicates that the Fries reaction is not a true rearrangement but an intermolecular acylation.[4]

Experimental Part

Fries Rearrangement.—4-Benzoyloxydiphenyl (5 g.) was mixed thoroughly with finely powdered aluminum chloride (4.7 g.) and carbon bisulfide (25 cc.) and the solvent was removed by distillation from the steam-bath. The residue was heated for thirty minutes in an oil-bath maintained at 160°, and after cooling and adding ice and

dilute hydrochloric acid the product was taken up in ether. The ethereal solution was washed with dilute acid and with water and extracted with 2.5% sodium hydroxide, and on acidifying the alkaline extract there was obtained 4 g. of grayish material. On two crystallizations from benzene this afforded nearly pure **4-methoxy-4'-benzoyldiphenyl**, m. p. 193–195°, yield 1.1 g. (22%). A small amount of a highly colored impurity was removed on reprecipitation from an alkaline solution, and further crystallization from benzene gave round, faintly yellow crystal-clusters, m. p. 194–195°.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.18; H, 5.14. Found: C, 83.42; H, 5.14.

No pure products were isolated from the mother liquor. On conducting the rearrangement according to Blicke and Weinkauff[3] the alkali-soluble product amounted to only about 2% of the ester used and it consisted largely of 4-hydroxydiphenyl.

The acetate formed colorless plates, m. p. 127–128°, from methyl alcohol.

Anal. Calcd. for $C_{21}H_{16}O_3$: C, 79.72; H, 5.09. Found: C, 80.00; H, 5.39.

The methyl ether, prepared with the use of dimethyl sulfate and alkali, crystallized from benzene as colorless needles, m. p. 165–166°. It was identified by comparison with the samples described below.

Friedel and Crafts Reaction.—A solution of 10 g. of 4-methoxydiphenyl and 6.9 cc. of benzoyl chloride in 130 cc. of tetrachloroethane was cooled to −10° and 8 g. of aluminum chloride was added all at once. The mixture was stirred mechanically and allowed to come to room temperature. After eighteen hours ice and acid were added, the solvent was removed with steam, and the moist product was taken up in benzene. On concentrating the solution to a volume of 50 cc. and cooling, 5.8 g. of nearly pure **4-methoxy-4'-benzoyldiphenyl**, m. p. 165–167°, crystallized. The mother liquor was concentrated to a volume of 25 cc. and treated with petroleum ether. The material which separated on one crystallization from methyl alcohol gave 6.1 g. of a product melting at 91–92° (flat needles). This substance is insoluble in alkali and depresses the melting point of 4-methoxydiphenyl; it is undoubtedly 4-methoxy-3-benzoyldiphenyl, which Hey and Jackson[2] prepared by a synthesis establishing the structure and for which they report the melting point 93°.

Synthesis of 4-Methoxy-4'-benzoyldiphenyl.—A solution of 0.5 g. of 4-methoxy-4'-carboxydiphenyl[1] in 10 cc. of thionyl chloride was refluxed gently for one hour and the excess reagent was removed at reduced pressure. The residue was dissolved in 25 cc. of thiophene-free benzene, 0.3 g. of aluminum chloride was added and the mixture was refluxed for one hour. The reaction product, recovered in the usual way, crystallized from alcohol or benzene as colorless needles, m. p. 165–166°. Mixed melting point determinations of this 4-methoxy-4'-benzoyldiphenyl with both of the samples obtained above indicated the identity of all three preparations.

A New Synthesis of Morpholine

BY BURT L. HAMPTON AND C. B. POLLARD

Morpholine was first prepared by L. Knorr[1] by heating diethanolamine and an excess of concentrated hydrochloric acid in a sealed tube and then refluxing the reaction mass with potassium hydroxide. Because of low yields Knorr abandoned this method for the sulfuric acid method.[2] In both cases he failed to state his yields. However, Jones and Burns[3] have shown that morpholine is formed in about a 10% yield by the action of sulfuric acid on diethanolamine following the directions of Knorr. Therefore the yield using hydrochloric acid and potassium hydroxide must have been considerably lower. The only other methods for the preparation of morpholine are indirect ones and need not be reviewed here.

In his first preparation Knorr assumed the chlorohydrin of diethanolamine to be formed. Ring closure with loss of hydrogen chloride was then effected by refluxing in potassium hydroxide solution. He based this assumption on the fact that he was able to isolate the chlorohydrin of N-phenyldiethanolamine in a similar reaction; however, he was unable to isolate the chlorohydrin of diethanolamine because of its similarity in properties to the parent substance.

We have shown in this investigation that the chlorohydrin does not necessarily have to be formed and that no dehydrating agent other than that of heat on the hydrochloride is necessary for the formation of morpholine from diethanolamine. This was surprising in view of the work of Knorr.

Preparation.—Diethanolamine (2 moles) is placed in a round-bottomed flask fitted with a thermometer and an air-cooled condenser. Concentrated hydrochloric acid is added slowly until the solution is acid to litmus. The solution is then heated rapidly until the water is driven off, and the temperature of the solution is kept at 200–210° for fifteen hours. The reaction mass is now allowed to cool, an excess of calcium oxide is added, and the mixture subjected to dry distillation. The resulting liquid is dried over solid sodium hydroxide and refluxed over metallic sodium for thirty minutes; it is then subjected to fractionation. The entire product boils at from 126–129° and is practically anhydrous. The yield is around 48%. This procedure offers a rapid

method for the preparation of morpholine and obviates many steps necessary in other methods.

If instead of subjecting the mixture to dry distillation concentrated sodium hydroxide is added and the solution distilled with steam into hydrochloric acid, a yield of 65% of the hydrochloride of morpholine is obtained. This, when distilled over calcium oxide, gives about 45% of morpholine (based on diethanolamine).

If to the original reaction mass cold sodium hydroxide is added, and the resulting amine layer is extracted with ether, pure morpholine is obtained.

The picrate melts at 145–147°. Knorr gives the melting point of the picrate as 145–147°. N-(2-Chlorocinchoninyl)-morpholine was used for the analysis.

Alkylation of Aromatics with Olefins in the Presence of Boron Fluoride[1]

BY V. N. IPATIEFF AND A. V. GROSSE

In the course of our investigations on hydrocarbon reactions in the presence of metallic halides[2] the alkylation of aromatic hydrocarbons with olefins in the presence of boron fluoride was also accomplished. This fact is interesting in connection with recent similar work of Nieuwland[3] in which the addition of acids, especially sulfuric acid, was considered to play an important part in these condensations.

As has been recently shown in our laboratories[4] the sulfuric acid *per se* is an excellent alkylating catalyst under the conditions used by Nieuwland and the presence of boron fluoride is not necessary. On the other hand, boron fluoride *without acids* is *also* an alkylating catalyst.[5]

The alkylation of aromatic hydrocarbons with olefins, including ethylene,[6] takes place in the presence of boron fluoride in a *nickel-lined*[7] autoclave at room temperature and also at temperatures up to 250°.

In one particular experiment 250 cc. (219 g.) of benzene was treated in a rotating nickel-lined bomb with ethylene in the presence of 18.5 g. of boron fluoride and 2.0 g. of water for eight hours at 20–25°. The initial ethylene pressure was 20 atmospheres, which dropped readily to 10 atmospheres when fresh ethylene was pressed in. In all five refillings were made and 22 g. of ethylene was absorbed.

The reaction product, after washing and drying, was separated into the following fractions:

Charge, 250.0 cc.

Fraction	Boiling points at 760 mm., °C	Volume in cc.	% of total product	$n^{20.0}D$	Remarks: (All fractions water white and stable to $KMnO_4$ solution)
1	80 ± 1.5	180.0	72.0	1.5002	Pure benzene, solidifies in ice
2	81.5–135	1.0	0.4	1.4985	
3	136 ± 1	52.0	21.0	1.4960	Monoethyl benzene; $d^{20.0}_4$0.8674
4	137–182	3.5	1.5	1.4958	
5	183 ± 1	7.5	3.0	1.4974	Diethylbenzenes
Bottoms	>184	4.0	1.6	1.5032	
Losses		2.0	0.8		
Total		250.0	100		

As can be seen from these results over 25% of the benzene was alkylated to monoethyl-, diethyl and higher alkylbenzenes. The constants of our monoethylbenzene (see table) are in complete agreement with the values given in the literature (see "I. C. Tables," boil. point at 760 mm. 136°, $n^{20}D$ 1.4959, $d^{20.0}_4$ 0.8669). As a further check oxidation with boiling potassium permanganate solution gave only *benzoic acid*, melting at 122.0°, proving the absence of xylenes.

Thermal Type Silver–Silver Chloride Electrodes

BY C. K. RULE AND VICTOR K. LA MER

In connection with an investigation of the temperature coefficients of the e. m. f. of quinhydrone-silver chloride cells in deuterium oxide, we have tested the reliability of silver–silver chloride electrodes made by a thermal method analogous to that recommended by Owen[1] and by Keston,[2] respectively, for the corresponding iodide and bromide electrodes. An electrode formed from a coil of platinum wire sealed into a tube of Jena normal glass was covered with a paste composed of seven parts of silver oxide and one part of silver chlorate and heated to decomposition in an electric furnace. No appreciable differences were observed when the percentage of silver chlorate was varied between 8 and 15.

Twelve electrodes immersed in 0.01 M hydrochloric acid solution exhibited ±0.02 mv. as the average deviation from the mean. After standing for six weeks this value increased to not more than ±0.04 mv. Freshly made electrodes agreed with the old within this limit.

A comparison of the "thermal" type electrodes with those made by decomposing a paste of silver oxide by heat and then electrolyzing for five hours in 0.2 M hydrochloric acid solution at 1.8 milliamperes per electrode showed that the electrolytic type tended to drift and were on the average about 0.04 mv. more positive.

The Heat of Fusion of Stannic Iodide

BY SAMUEL S. TODD AND GEORGE S. PARKS

The changes in heat content of stannic iodide were measured by us in 1928 for the temperature intervals between 27 and 80, 120, 155 and 171°, respectively. A method of mixtures was used with a water calorimeter, the details of the apparatus and experimental procedure being given in a previous paper by Parks and Todd.[1] The sample of stannic iodide studied had been kindly prepared for us by Professor J. H. Hildebrand.

Although the error in the calorimetric measurements themselves was within 1%, considerable uncertainty as to the premelting effect in the crystalline material precluded at that time a reliable calculation of the heat of fusion of stannic iodide from our heat content data. Recently, however, Negishi[2] has obtained accurate information concerning the heat capacities of solid and liquid stannic iodide over a range of temperatures. Using his data and taking the melting point as 144°, we have now calculated the following fusion values from our four determinations pertaining to the 27–155° range: 7.23, 7.19, 7.24 and 7.25 cal. per gram. The mean heat of fusion is 7.23 (±0.14) cal. per gram or 4530 cal. per mole.

NEW BOOKS

Physical Aspects of Organic Chemistry. By WILLIAM A. WATERS, M.A., Ph.D. (Cantab.), University of Durham. Introduction by Professor T. Martin Lowry, George Routledge and Sons, Ltd., Broadway House. 68–74 Carter Lane, London E.C., England, 1935. xv + 501 pp. 14 × 22 cm. Price, 25s.

The title of this book does not indicate very clearly the nature of its contents. Actually it is largely concerned with current electronic ideas of valence and their application to organic chemistry, especially to details of reaction mechanism. The chapter headings are: Chemical Affinity, Physical Theories of Molecular Structure, Valency, Electrical Dipoles, Chemical Reactivity, Unsaturation, Free Radicals and Their Non-ionic Reactions, Ionization and Ionic Reactions, Acidity, The Reactivity of Halogen Compounds, General Polarity, Hydrolysis and Esterification, Ionotropic Change, Molecular Rearrangement, Conjugation, Aromatic Compounds—I, Aromatic Compounds—II.

But this list does not furnish an adequate indication of the range of topics dealt with. Many of these subjects are exceedingly broad, have a lengthy and complicated history and even today have not reached any state of agreed opinion. One is therefore especially impressed with the skill of presentation. The author states in his preface: "The historical aspect of a rapidly developing subject has been kept continually in view, with the intention of giving a general outline of theoretical organic chemistry rather than one *ad hoc* point of view." In general, he succeeds admirably in this aim. Any final interpretations are usually those of the English schools, whose recent writings on electronic mechanisms have been so extensive and ingenious, though sometimes obscure and not always in mutual agreement. Here the obscurity is resolved or avoided, conflicting viewpoints are judiciously weighed, and the attempt to interpret is seldom pushed to such a degree of detail that it ceases to be profitable or becomes devoid of plausibility.

No book is perfect, and this one errs perhaps in a tendency toward excessive conciseness. Thus the discussion of atomic structure is probably too brief to inform anyone not already informed.

In so extensive an effort it is natural also to find some errors in apportioning or assigning credit. For example, the Diels–Alder reaction, which is neatly, if rather sketchily, summarized in about two pages was not first discovered by Diels and Alder in 1928, but by v. Euler and Josephson in 1920. Incidentally also, this reaction is not diagnostic of conjugated systems, since even apart from side reactions consisting of complex polymerization it sometimes fails.

Again it seems scarcely correct to state that what are here called stable mixed double bonds were first suggested by Lowry in 1922. It is no doubt true that he first called attention to some special implications of this type of structure. But the arithmetical existence of a charge on atoms having unconventional valences could hardly escape the attention of anyone making the count of electrons necessary to write the structure. Besides, Langmuir[1] had already in 1921 presented a generalized formula for the calculation of such residual charges.

No one will, however, deny that Professor Lowry has made important innovations in the application of electronic ideas to chemical structures and reactions. Moreover, he laid the foundation for this book, completed by Dr. Waters, which is the first clear and comprehensive summary in its field.

(1) Langmuir, *Science*, **54**, 62 (1921). In his original paper [*Trans. Faraday Soc.*, **18**, 285 (1923)] Lowry says "It is difficult to believe that Langmuir can have overlooked the fact ... that the nitrogen atom is positively charged ... but I cannot find in any of Langmuir's papers a clear recognition of the phenomenon of intramolecular ionization." Apparently then he had not noted the paper cited above.

W. H. Carothers

Die Bierhefe als Heil-, Nähr- und Futtermittel. (Beer Yeast as a Medicinal Agent, Food and Feeding Stuff.) By Dr. Julius Schülein, Munich. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1935. viii + 194 pp. 29 figs. 15 × 22.5 cm. Price, RM. 9; bound, RM. 10.

The author has brought together a large amount of widely scattered material dealing with the use of yeast as a food and as a medicinal agent. Much of this information has heretofore not been assembled. He has attempted to give a general view of the subject, and discusses the state of research in connection with this field. The subjects discussed are vitamins, the use of yeast as a therapeutic agent, the use of yeast and yeast extracts in human nutrition and as a food for animals. The work on vitamins is fairly comprehensive, but some of the conclusions are based on vitamin researches carried on a number of years ago, and consequently certain statements should be interpreted with this fact in mind. This also applies to some of the statements concerning yeast. The term yeast is used indiscriminately. It is not always clear whether he refers to baker's yeast or beer yeast.

The data given on page nine require correction. In paragraph three it is stated that McCollum designated the antirachitic vitamin as vitamin D in 1922, whereas in the tabulation following paragraph four the date is given as 1925. In a number of instances it is believed the author has been too brief, consequently the reader does not obtain a clear conception of the papers cited and of the subject under discussion.

The author discusses the value of vitamin B for the pregnant mother and for the child. He also discusses the vitamin B/2 complex. Whether or not vitamins A, C and D are present in yeast is taken up in considerable detail. Mineral salts, glutathione, amino acids, enzymes, hormones and choline are discussed. The therapeutic use of yeast is given considerable attention.

In describing the production of vitamin D milk by the yeast feeding method the type of yeast employed for irradiation is not given. Statements in regard to the quality of the mineral yeast and top yeast grown on molasses to which mineral salts are added, should be modified as they do not apply to modern conditions.

The author reviews some of the most valuable work pertaining to the use of yeast in animal nutrition, and the preparation of yeast extracts rich in vitamin B. Fortification of diets deficient in certain vitamins by means of yeast is also discussed.

It is believed that this work will stimulate research in the fields which the author has reviewed. 436 references are given. A complete author and subject index is included.

C. N. Frey
G. W. Kirby

Le Mêtabolisme de L'Azote, Physiologie des Substances Protèiques. I. Aliments, Digestion, Absorption, Enzymes Digestif. No. XX, Les Problèmes Biologiques. (Nitrogen Metabolism. Physiology of Protein Materials.) By Émile F. Terroine. Published by Les Presses Universitaires de France, 49 Boulevard Saint-Michel, Paris. Price, 80 francs.

This is the second book by the author on nitrogen metabolism. The first dealt with the excretion of nitrogen and the protein requirements of animals. The object of the book under review is to consider the physiological phases of the utilization of nitrogen and the changes that take place in nitrogenous substances from the time of ingestion through their utilization. The subject is discussed under four headings: (a) Protein foods and their digestibility; (b) The nature of nitrogenous substances absorbed by the body; (c) The processes of digestion and absorption; (d) The factors in digestion (enzymes), their respective roles, and conditions necessary for their activity.

The first part of the work discusses protein foods in general, followed by the consideration of digestibility, the effects of various factors, physical, chemical and physiological, on the digestion of proteins, and a table of digestion coefficients.

The second part takes up the question of absorption of unmodified protein, a short discussion of food sensitization, and the absorption of the intermediate and final products of protein degradation, including evidence for the presence of these products in the blood.

The third part of the book is devoted to the processes of digestion and absorption in the various parts of the alimentary tract with particular attention to the extent of digestion and absorption and the interrelationship of the processes in one portion of the digestive tract to those in another.

The last section of the book is concerned with enzymatic processes, the role of the gastric, pancreatic and intestinal juices, and the enzymes responsible for digestion, and their mode of action.

The style of the book is monographic. The author has gathered a wealth of material and presented it critically from a functional and dynamic point of view. The subjects are discussed by topics and often through the use of the question and answer method to focus the attention of the reader on a specific point.

PAUL E. HOWE

Röntgens Briefe an Zehnder. (Röntgen's Letters to Zehnder.) Edited by LUDWIG ZEHNDER. Rascher et Cie., Verlag, Limmatquai 50, Zürich 1, Switzerland, 1935. 198 pp. Illustrated. 16 × 23 cm. Price, Swiss fr. 5; bound, 7.50.

This is a collection of the more important and interesting letters written by W. C. Röntgen to Ludwig Zehnder. The first letter was written in 1887 shortly after the two men had become acquainted during a summer vacation at Pontresina. In this letter Professor Röntgen offered Dr. Zehnder a position as Assistant and Demonstrator in his Laboratory at the Realgymnasium in Mainz. Zehnder was only slightly Röntgen's junior and they became close friends, this friendship being terminated only by Röntgen's death in 1922.

The letters referring to Röntgen's epoch-making discovery of x-rays are of course of particular interest, but all of the letters are valuable in disclosing the vigorous, earnest and high-minded personality of Röntgen. Some of the important letters are reproduced in facsimile and Zehnder has interspersed a sufficient account of the circumstances, together with a few of his own letters, so that the subject matter of Röntgen's letters can be adequately appreciated.

This indirect biography of Röntgen is eminently satisfactory and the only item that leaves one dissatisfied is the inexplicable action of his executors, as reported by Dr. Zehnder, in destroying, apparently on their own initiative, all documents bearing on Röntgen's discovery of x-rays, including the letters of Zehnder to Röntgen during the period of 1889–1902.

Incidentally, this collection of letters depicts an almost ideal friendship between these two men and reflects the admirable though quite different personalities of each of them.

ARTHUR B. LAMB

Atomspektren und Atomstruktur. Eine Einführung für Chemiker, Physiker und Physikochemiker. (Atomic Spectra and Atomic Structure. An Introduction for Chemists, Physicists and Physical Chemists.) By Dr. GERHARD HERZBERG, Lecturer in Physics at the Technical Institute, Darmstadt. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1936. xvi + 188 pp. 79 figs. 15.5 × 22.5 cm. Price, RM. 13; bound, RM. 14.

This is the first of two monographs by the author on atomic and molecular spectra. The second, on molecular spectra, is in preparation.

As the title suggests, the book is intended primarily to serve as an introduction to atomic spectroscopy for those who wish to obtain a working knowledge of the subject which has, more than any other, thrown light on the extranuclear structure of atoms. No attempt is made to give a rigorous presentation of the theory of atomic spectra. Only an elementary physical description of the fundamental principles of the quantum mechanics is set forth, but brief descriptions of this method of treating certain problems, including the hydrogen spectrum, the Zeeman effect and the Pauli exclusion principle are given. The vector model is used in treating the main body of spectroscopic phenomena and the building of the periodic system of the elements. The last chapter gives an application of atomic theory in its discussion of valency and collision processes.

The author takes pains to explain clearly the fundamental spectroscopic terms and concepts. A feature of the book is the large number of term diagrams which are a great aid in visualizing spectroscopic phenomena.

ROBERT B. KING

Annual Tables of Constants and Numerical Data, Chemical Physical, Biological and Technological. Published under the patronage of the International Union of Chemistry. N. THON, Editor-in-Chief. The McGraw-Hill Book Company, Inc., 330 West 42nd Street, New York, N. Y., 1936. 23 × 28.5 cm. Advance Reprints from Vol. XI. "Numerical Data on Rotatory Power," 1931–1934, by E. Darmois. 68 pp. $2.00. "Numerical Data on Radioactivity, etc.," 1931–1936, by I. Joliot-Curie, B. Grinberg and R.-J. Walen. 57 pp. $2.00. "Numerical Data on the Raman Effect, etc.," 1931–1934, by M. Magat. 112 pp. $3.00.

The Committee of Annual Tables, recently appointed by the International Union of Chemistry, announces that owing to the fact that Annual Tables has lagged behind its schedule of publication since Volume X (1930), the data for 1931 to 1936 are to be published in a more condensed form and more critically edited, in a series of fascicules by subjects, partly separately for 1931–1934 and 1935–1936, and partly for the wholly period 1931–1936. The full set of these fascicules will constitute Volumes XI and XII of Annual Tables. It is planned to complete this program in 1937, whereby the numerical material published by Annual Tables will then be brought strictly up to date.

In addition, an Index Volume by Substances for the Volumes VI–X (1923–1930), like the one published for the Volumes I–V (1910–1922), is to appear toward the end of

1936. A similar Index Volume will be prepared for the Volumes XI and XII, to be published in 1937.

The present three fascicules represent preprints from Volume XI. The section on Transmutations, in the fascicule by Joliot-Curie, giving a systematic, complete and critical account of the numerical data relative to nuclear reactions and artificial radioactive disintegrations, is particularly timely and noteworthy. The compilation of data on Rotatory Power, by Darmois, will be of great value to students of stereochemistry; while the compilation of data on the Raman Effect, by Magat, cannot fail to interest keenly those workers seeking a deeper knowledge of the structure of chemical compounds.

ARTHUR B. LAMB

Catalytic Reactions at High Pressures and Temperatures. By VLADIMIR N. IPATIEFF, Professor, Northwestern University, and Director of Chemical Research, Universal Oil Products Company. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1936. xxii + 786 pp. 56 figs. 14.5 × 22.5 cm. Price, $7.50.

This book makes no pretense, except possibly in its title, of being a comprehensive survey of catalytic reactions at high pressures and temperatures. It is primarily a collection and review of the author's own researches in the field of catalysis. The author prepared this book because, as he expresses it: "Much of my published work is inaccessible"; a circumstance which probably explains why he has sometimes failed to receive the recognition which he so frequently in this book feels to be his due.
