$$\mathbf{F} = \mathbf{G} + \mathbf{R} = \frac{3\epsilon}{2\epsilon + 1}\,\mathbf{E} + \frac{2(\epsilon - 1)}{(2\epsilon + 1)a^3}\,\mathbf{m} \tag{12}$$

This equation formulates the conditions for equilibrium *in the environment of the molecule.* The condition for internal equilibrium of the molecule is given by our model

$$\mathbf{m} = \mu_0\mathbf{u} + \alpha\mathbf{F} \tag{4}$$

Accordingly, for a given instantaneous direction **u** of the "permanent dipole" axis the total electric moment of the molecule is given by the formula

$$\left(1 - \frac{2(\epsilon - 1)}{(2\epsilon + 1)}\frac{\alpha}{a^3}\right)\mathbf{m} = \mu_0\mathbf{u} + \frac{3\epsilon}{(2\epsilon + 1)}\,\alpha\mathbf{E} \tag{13}$$

When we introduce the "internal dielectric constant" n^2 according to Eq. 3, we obtain a convenient explicit formula as follows

$$\begin{aligned} \mathbf{m} &= \frac{(n^2 + 2)(2\epsilon + 1)}{3(2\epsilon + n^2)}\,\mu_0\,\mathbf{u} + \frac{\epsilon(n^2 - 1)}{(2\epsilon + n^2)}\,a^3\mathbf{E} \\ &= \mu\mathbf{u} + \frac{\epsilon(n^2 + 2)}{(2\epsilon + n^2)}\,\alpha\,\mathbf{E} \end{aligned} \tag{14}$$

In the same notation, the explicit formula for the internal field becomes

$$\mathbf{E} + \mathbf{I} = \mathbf{F} = \left(1 + \frac{n^2(\epsilon - 1)}{(2\epsilon + n^2)}\right)\mathbf{E} + \frac{2(\epsilon - 1)}{(2\epsilon + 1)}\frac{\mu}{a^3}\mathbf{u} \tag{15}$$

As regards the induced moment in the **E** direction, this formula does not differ greatly from that of Clausius and Mosotti, which is

$$\mathbf{I} = \mathbf{E}(\epsilon - 1)/3$$

while with $\mu = 0$, Eq. 15 gives

$$\mathbf{I} = \mathbf{E}n^2(\epsilon - 1)/(2\epsilon + n^2)$$

For a non-polar liquid we have $\epsilon = n^2$, and the two formulas are identical. In application to mixtures of non-polar liquids, Eq. 15 yields slightly higher values of ϵ.

Nevertheless, in applying the same formulas to polar liquids we shall presently derive results which are very different from those previously accepted. The problem before us is to compute the effective energy of interaction between the molecule and the field, and the consequent average orientation of the molecule.

For this purpose it is not admissible, as Debye did, to assume that the orienting force is proportional to the time average of $\mathbf{F}$. Since $\mathbf{F}$ depends on the orientation, we must compute the orienting force-couple for each individual direction of $\mathbf{u}$; the *work* involved in the process of orientation is then the potential of this orienting force.[4] The force-couple equals the vector product of $\mathbf{F}$ and $\mathbf{m}$. We can use either of the expressions for $\mathbf{F}$ given by Eqs. 12 and 15; the former represents a more instructive decomposition of the vector

$$\begin{gathered}\mathbf{F} = \mathbf{G} + \mathbf{R}\\ \mathbf{G} = \mathbf{E} \times 3\epsilon/(2\epsilon + 1)\\ a^3\mathbf{R} = \mathbf{m} \times 2(\epsilon - 1)(2\epsilon + 1)\end{gathered}$$

The force-couple equals

$$\mathbf{M} = \mathbf{F} \times \mathbf{m} = \mathbf{G} \times \mathbf{m} = (3\epsilon/(2\epsilon + 1))\,\mathbf{E} \times \mathbf{m} \qquad (16)$$

We observe that *the reaction-field* $\mathbf{R}$*, being parallel to the dipole* $\mathbf{m}$*, does not contribute to the orienting force-couple.* The calculation is easily completed with the aid of Eq. 14; this time only the part parallel to $\mathbf{u}$ matters, because $\mathbf{G} \times \mathbf{E}$ vanishes

$$\mathbf{M} = \mu\,\mathbf{G} \times \mathbf{u} = \mu^*\,\mathbf{E} \times \mathbf{u} \qquad (17)$$

Here, in accord with the notation of Eq. 7

$$\mu^* = \mu\,3\epsilon/(2\epsilon + 1) \qquad (18)$$

stands for the "external" characteristic moment of the molecule, while the actual electric moment μ will depend on the dielectric constant of the environment according to Eq. 14

$$\left.\begin{aligned}\mu &= \frac{(n^2 + 2)(2\epsilon + 1)}{3(2\epsilon + n^2)}\,\mu_0\\ \mu^* &= \frac{\epsilon(n^2 + 2)}{(2\epsilon + n^2)}\,\mu_0\end{aligned}\right. \qquad (19)$$

Dropping the vector notation, Eq. 17 may be written

$$M = \mu^*\,E \sin\theta$$

then the work of orientation, w, is given by

$$\left.\begin{aligned}\partial w/\partial\theta &= M;\\ w &= -\,\mu^*\,E\cos\theta\end{aligned}\right. \qquad (20)$$

This extremely simple result suggests the possibility of an equally simple derivation; for this purpose, it is convenient to invert the problem. Let us keep the orientation of the molecule fixed, and find out how the work of creating a field of a certain intensity E in a given direction depends on the angle θ between this direction and the dipole axis of the molecule. The most elementary derivation is obtained if we assume that the external field is due to a charge of the magnitude $-r_1^2E$ at some point (r_1, θ, φ) on a large sphere of radius r_1. In order to change the direction of the field at constant intensity, we move the charge to another point on the sphere. The work involved is given by the potential

$$\psi = \mu^* \cos\theta/\epsilon r^2$$

(*cf.* Eq. 6), of the field due to the molecule, and Eq. 20 obviously results. This alternative computation of w exhibits the reciprocal character of Eq. 11.

The mean orientation of the molecules in the field is given by Boltzmann's formula

$$\overline{\cos\theta} = \int \cos\theta\, e^{-w/kT} \sin\theta\, d\theta\, d\varphi \Bigg/ \int e^{-w/kT}$$
$$\mathit{sin}\,\theta\, d\theta\, d\varphi = L(\mu^*E/kT) = \coth(\mu^*E/kT) - (kT/\mu^*E) = (\mu^*E/3kT) - O(E^3)$$

Thus, for low field intensities E, we have[5]

$$\overline{\cos\theta} = \mu^*E/3kT \qquad (21)$$

and we can compute the polarization per unit volume from Eq. 14, as follows

$$\mathbf{P} = N\overline{\mathbf{m}} = N\left(\frac{\mu\mu^*}{3kT} + \frac{\epsilon(n^2 + 2)}{(2\epsilon + n^2)}\,\alpha\right)\mathbf{E} \qquad (22)$$

Dielectric Constants of Pure Polar Liquids

In computing the dielectric constant, we shall assume that the volume of the liquid equals the sum of the volumes of the molecules; accordingly

$$N \times 4\pi a^3/3 = 1 \qquad (23)$$

With the notation expressed by Eq. 3, we then obtain

$$4\pi N(n^2 + 2)\,\alpha = 4\pi N(n^2 - 1)a^3 = 3(n^2 - 1) \qquad (24)$$

Now the fundamental electrostatic formula

$$(\epsilon - 1)\,\mathbf{E} = 4\pi\mathbf{P} \qquad (25)$$

yields in combination with Eqs. 22 and 24 the following implicit formula for the dielectric constant

$$\epsilon - 1 = 4\pi N\,\frac{\mu\mu^*}{3kT} + \frac{3\epsilon(n^2 - 1)}{2\epsilon + n^2}$$

---

[4] In a polar medium, the field fluctuates with the rotation of the neighboring molecules. In such a case, the *average force* is the important quantity [(L. Onsager, *Chem. Rev.*, **13**, 73 (1933))]. An alternative procedure is to compute the work of charging a dipole in a given direction **u**.

[5] The given formula is not in general applicable to strong fields, *i. e.*, saturation; because its derivation involves the assumption of an isotropic environment.

which may be written more compactly

$$\frac{(2\epsilon + 1)(\epsilon - n^2)}{(2\epsilon + n^2)} = 4\pi N \frac{\mu\mu^*}{3kT} \qquad (26)$$

or in view of Eq. 18

$$3\epsilon(\epsilon - n^2)/(2\epsilon + n^2) = 4\pi N(\mu^*)^2/3kT \qquad (27)$$

Here, μ and μ^* still depend on ϵ according to Eq. 19. We obtain after elimination

$$(\epsilon - n^2)(2\epsilon + n^2)/\epsilon(n^2 + 2)^2 = 4\pi N\mu_0^2/9kT \qquad (28)$$

When ϵ is large, the left member is very nearly equal to

$$2\epsilon/(n^2 + 2)^2 \sim 4\pi N\mu_0^2/9kT \qquad (29)$$

One of the reasons for this simple limiting law is that μ and μ^* approach limits as ϵ increases. With the notation

$$\mu_\infty = \mu_0(n^2 + 2)/3 \qquad (30)$$

(*cf.* Eq. 19), we can write Eq. 28 in the alternative form

$$(2\epsilon + n^2)(\epsilon - n^2)/\epsilon = 4\pi N\mu_\infty^2/kT \qquad (31)$$

On the other hand, when only a small fraction of the electric susceptibility is due to orientation of the molecules, that is, whenever

$$\epsilon - n^2 \ll n^2$$

Eq. 27 agrees in the first approximation with the formula of Clausius and Mosotti. We readily derive from Eq. 27

$$\frac{\epsilon - 1}{\epsilon + 2} - \frac{n^2 - 1}{n^2 + 2} = \frac{3\epsilon(n^2 + 2)}{(2\epsilon + n^2)(\epsilon + 2)} \frac{4\pi N\mu_0^2}{9kT} = \frac{4\pi N\mu_0^2}{9kT} f(\epsilon, n^2) \qquad (32)$$

Fig. 1 indicates the range where the approximation of Clausius and Mosotti is good.

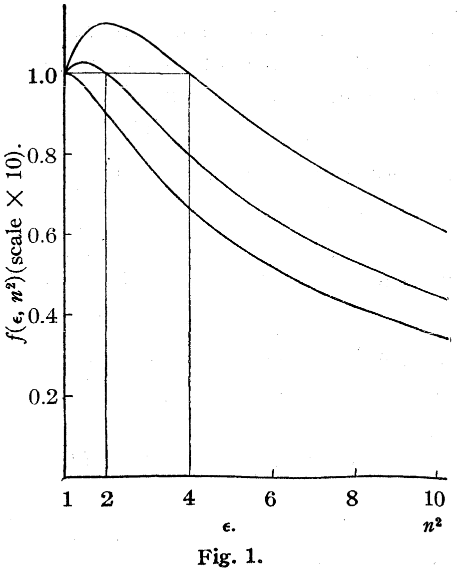

Fig. 1.

Dielectric Constants of Solutions

We shall consider a solution which contains in a unit volume $N_1, \ldots N_i, \ldots$ spherical molecules of different species, with radii $a_1, \ldots a_i, \ldots$, polarizabilities $\alpha_1, \ldots \alpha_i, \ldots$ and dipole moments $\mu_1, \ldots \mu_i, \ldots$, respectively. We introduce the individual refractive indices $n_1, \ldots n_i, \ldots$ by the relation

$$\alpha_i = a_i^3(n_i^2 - 1)/(n_i^2 + 2) \qquad (33)$$

and we shall denote the volume fractions by

$$\vartheta_i = N_i \times 4\pi a_i^3/3 \qquad (34)$$

The dipole moments will depend on the dielectric constant of the environment according to Eq. 19; the moments *in vacuo* will be denoted by μ_{0i}.

The fundamental electrostatic relation

$$(\epsilon - 1)\,\mathbf{E} = 4\pi\,\mathbf{P} \qquad (25)$$

yields in conjunction with Eqs. 22, 24 and 34

$$\epsilon - 1 = 4\pi \sum N_i \left(\frac{\epsilon(n_i^2 + 2)}{\epsilon + n_i^2}\alpha_i + \frac{\mu_i\mu_i^*}{3kT}\right) = \sum \vartheta_i \frac{3\epsilon(n_i^2 - 1)}{n_i^2 + 2\epsilon} + 4\pi \sum N_i \frac{\mu_i\mu_i^*}{3kT} \qquad (35)$$

Making use of the identity

$$3\epsilon(n_i^2 - 1) = (2\epsilon + n_i^2)(\epsilon - 1) - (2\epsilon + 1)(\epsilon - n_i^2)$$

we can rearrange Eq. 35 in the form

$$(1 - \Sigma\vartheta_i)(\epsilon - 1) + (2\epsilon + 1)\Sigma\vartheta_i(\epsilon - n_i^2)/(2\epsilon + n_i^2) = 4\pi\Sigma\, N_i\mu_i\mu_i^*/3kT \qquad (36)$$

Now if we assume that the entire space is occupied by the molecules

$$\Sigma\vartheta_i = 1 \qquad (37)$$

the first term in the member of Eq. 36 vanishes. Then in view of Eq. 18, Eq. 36 may be written

$$\Sigma\vartheta_i(\epsilon - n_i^2)3\epsilon/(2\epsilon + n_i^2) = 4\pi\Sigma\, N_i(\mu_i^*)^2/3kT \qquad (38)$$

which furnishes the generalization of Eq. 27 to the case of several molecular species. The right member of Eq. 38 depends on the dielectric constant according to Eq. 19:

$$\mu_i^* = \frac{\epsilon(n_i^2 + 2)}{(2\epsilon + n_i^2)}\mu_{0i} = \frac{2\epsilon}{(2\epsilon + n_i^2)}\mu^*_{\infty i} = \frac{3\epsilon}{(2\epsilon + n_i^2)}\mu_{\infty i} \qquad (39)$$

In the limit of high dielectric constants

$$\epsilon \gg n_i^2, (i = 1,2, \ldots)$$

Eq. 38 becomes

$$\epsilon = O(n^2) + 4\pi\Sigma N_i\mu_{i\infty}\mu^*_{i\infty}/3kT = O(n^2) + \sum \frac{(n_i^2 + 2)^2}{2} \frac{4\pi}{3} N_i \frac{\mu_{0i}^2}{3kT} \qquad (40)$$

We observe that in this limit, the dielectric constants of solutions are nearly additive.

The opposite extreme is a dilute solution of polar molecules in a non-polar medium. In the following, the index *m* will refer to the non-polar solvent, the index *s* to a polar solute present in small concentration, so that

$$\begin{aligned} \epsilon_m &= n_m^2 \gg \epsilon - \epsilon_m \\ \vartheta_m &\gg 1 - \vartheta_m = \vartheta_s \end{aligned} \qquad (41)$$

Neglecting terms of higher order in the concentration (N_s), we obtain for the dielectric constant of the solution

$$\epsilon = n^2 + \frac{4\pi(\mu^*)^2}{3kT} N_s \qquad (42)$$

here the "refractive index" of the solution differs from that of the solvent by the amount

$$n^2 - n_m^2 = \vartheta_s \frac{3n_m^2}{2n_m^2 + n_s^2} (n_s^2 - n_m^2) \qquad (43)$$

and the (external) dipole moment depends on the dielectric constant of the non-polar solvent according to Eq. 19

$$\mu^* = \frac{3n_m^2}{2n_m^2 + 1} \mu = \frac{n_m^2(n_s^2 + 2)}{2n_m^2 + n_s^2} \mu_0 \qquad (44)$$

For comparison, the Clausius-Mosotti formula yields (on our restrictive assumption of additive volumes)

$$\frac{\epsilon - 1}{\epsilon + 2} = \vartheta_m \frac{\epsilon_m - 1}{\epsilon_m + 2} + \vartheta_s \frac{n_s^2 - 1}{n_s^2 + 2} + \frac{4\pi}{3} N_s \frac{\mu_0^2}{3kT} \qquad (45)$$

and by neglecting terms of higher order we obtain the analogs of Eqs. 42 and 43

$$\epsilon = n^2 + 4\pi N_s((n_m^2 + 2)\,\mu_0/3)^2/3kT \qquad (46)$$

$$n^2 = n_m^2 + \vartheta_s \frac{(n_m^2 + 2)}{(n_s^2 + 2)} (n_s^2 - n_m^2) \qquad (47)$$

These formulas are seen to agree with Eqs. 42–44 in two cases: when $n_m = 1$ and when $n_m = n_s$. For values of n_m between these limits, Eqs. 42–44 predict larger increments of the "refractive index" and of the dielectric constant than does the classical theory. On the other hand, for $n_m > n_s$, the new formulas predict a *smaller decrement* of the refractive index, n, and a *smaller increment* of $\epsilon - n^2$, the susceptibility due to orientation. The quantitative relations between the two theories can be summarized as follows

$$\begin{aligned} &(n^2 - n_m^2)_{\text{new}}/(n^2 - n_m^2)_{\text{old}} = f \\ &(\epsilon - n^2)_{\text{new}}/(\epsilon - n^2)_{\text{old}} = f^2 = (\mu_{\text{app}}/\mu_0)^2 \\ &f = f(\epsilon_m, n_s^2) = 3\epsilon_m(n_s^2 + 2)/(2\epsilon_m + n_s^2)(\epsilon_m + 2) \end{aligned} \qquad (48)$$

Here, $\mu_{\text{app.}}$ denotes the "electric moment" computed by means of the classical formula, Eq. 1, from the dielectric constant of a solution which conforms to the present theory. The function $f(\epsilon, n^2)$ is represented in Fig. 1. Some of its important properties are

$$\begin{aligned} f(\epsilon, n^2) - 1 &= 2(\epsilon - n^2)(\epsilon - 1)/(2\epsilon + n^2)(\epsilon + 2) \\ f(1, n^2) &= f(n^2, n^2) = 1 \\ f(\epsilon, n^2) &\leqq f(n, n^2) = 1 + 2((n - 1)/(n + 2))^2 \\ f(\epsilon, n^2) &= f((n^2/\epsilon), n^2) \end{aligned} \qquad (49)$$

Discussion

The present development of the theory is by no means complete. One open question is the proper choice of the molecular "radius" *a*. The assumption that the molecules fill the whole volume of the liquid (Eqs. 23, 37), is a makeshift; and its application to the extreme case of a gas would be quite absurd. Assuming that our molecular model is adequate, it would appear better to find a suitable basis for the determination of constant "*a*." Then in order to allow for changes of volume due to thermal expansion or other causes it would only be necessary to consider the "void" as a constituent of a mixture. This point of view is in perfect accord with our Eq. 36, where the "void," of dielectric constant unity, enters quite symmetrically with the other constituents. Nevertheless, it appears that the development of the theory along these lines will involve careful consideration of molecular arrangements, and probably some arbitrary exercise of judgment.

Similar questions would arise in a generalization of the present theory to molecules of shapes other than spherical, in which case the ratios μ/μ_0, μ^*/μ_0 and μ^*/μ will be greater the shorter the dipole axis compared to other dimensions of the molecule. As far as dilute solutions in non-polar solvents are concerned, it is only necessary to compute the ratio μ^*/μ_0 as a function of ϵ_m; then μ^* determines the increment of the dielectric constant according to Eq. 38. On the other hand, for an imaginary polar liquid of refractive index unity the electric susceptibility must be proportional to the product $\mu\mu^*$, rather than to $(\mu^*)^2$. Fortunately, the difference between the two results is not in general very large. The paradox which it represents is capable of solution, but only by taking into account the reciprocity of neighborhood relations between non-spherical molecules!

The computation of the molecular radius (a) from the total volume of the liquid should lead to an underestimate of the dielectric constant for the given molecular model. The error ought not to be very large, except when a liquid is considered close to its critical point. The assumption of spherical molecules can cause positive or negative errors, perhaps about equally often. With this in mind we should inquire whether the present theory can furnish a reasonably good description for the *average* dielectric behavior of polar liquids and their solutions.

As regards the former, we have available Wyman's analysis[3] of an extensive material which he has compiled without apparent prejudice and without any knowledge of the theory to be tested. Wyman has summarized his conclusions in the formula

$$p = (\epsilon + 1)/A$$

where p measures the total "polarization" per unit volume, in our notation

$$p = \frac{4\pi}{3} \sum N\left(\alpha + \frac{\mu_0^2}{3kT}\right)$$

The value of the factor A is derived from measurements of ϵ together with measurements of μ_0 in the vapor in non-polar solvents. For a great number of liquids Wyman finds $A \sim 8.5$, with a certain spread given by the limits $A = 6.2$ and 11.

Wyman's formula is practically the same as our Eq. 29

$$\epsilon/A = 2\epsilon/(n^2 + 2)^2 \sim 4\pi N\mu_0^2/9kT \qquad (29)$$

We obtain $A = (n^2 + 2)^2/2$, and Wyman's typical value $A = 8.5$ corresponds to a refractive index

$$n = 1.46$$

which is very reasonable indeed. The range

$$6.2 < A < 11$$

corresponds to

$$1.275 < n < 1.64$$

A comparison with individual refractive indices has not been attempted; it would hardly be significant without allowance for molecular shape. Incidentally, our "refractive index" should include the "atomic polarization" due to elastic displacement of the atomic nuclei by the electric field.

According to Wyman's analysis, one group of liquid dielectrics deviates very markedly from the rest, in that they exhibit much larger dielectric constants than they ought to have. This group includes water, alcohols and ammonia; on the whole, it coincides with the liquids which on the basis of unusual thermodynamic behavior have long been considered as "associated."

There is good cause for the view that we are dealing here with a type of molecular interaction which does not admit of adequate description in terms of permanent and induced dipoles. A promising scheme for coördination of the phenomena is the "proton bond" theory,[6] which has recently been given considerable attention by Hildebrand[7] and by Pauling.[8]

If the dielectric behavior of the substances in question is to be explained along these lines, then an important part of the present theory may still be applicable. As a starting point, Eq. 26 can hardly be far from the truth; its derivation is almost phenomenological. Moreover, it is not likely that in a liquid like water, the ratio μ^*/μ will differ much from its normal value of 3/2; in order to account for the large anomalies in question, it would have to equal 3. Thus we are led to abandon Eq. 19, and that involves only a quite reasonable addition to the basic hypothesis of the proton bond theory: *The formation of a "hydrogen bond" increases the electric moment of the group which carries the hydrogen.*

On the basis of this general picture, we can estimate that a water molecule in the liquid has a dipole moment of the order $\mu \sim 3 \times 10^{-18}$ e. s. u., with $\mu^*/\mu \sim 3/2$. The increment from $\mu_0 = 1.8 \times 10^{-18}$ in the vapor could hardly be accounted for by ordinary homogeneous induction. The properties of water as a solvent for electrolytes appear to harmonize well with our assumption of a large electric moment.

This explanation for the anomaly of "proton bond" liquids differs from the "association theory" in the assumption of a large ratio μ/μ_0, while the "association theory" would call for an anomalous ratio μ^*/μ.

For dilute solutions of polar substances in nonpolar solvents, the present theory expects in accordance with experience that the "apparent" dipole moments computed on the basis of the Clausius–Mosotti equation should not in general differ much from those found in vapors of the same substances.

An important theoretical advance is the reconciliation of this empirical rule with the expectation of increased dipole moments in solutions; in our picture $\mu_{\text{app.}}$ is only a fictitious quantity with a complicated meaning.

According to Eq. 18, the apparent electric moments of a given molecule should be somewhat dependent on the solvent, so as to decrease with increasing dielectric constant of the environment. The researches of H. Mueller[2,9] have shown that

---

(9) H. Mueller, *Physik. Z.*, **35**, 346 (1934).

in spite of occasional irregularities, a general effect of this type exists. The effect is of the expected order of magnitude. Mueller's results[9] for the temperature dependence of $\mu_{\text{app.}}$ in solutions support the view that the "radius" a should be treated as a molecular constant. It is worth pointing out that the present theory gives a precise interpretation for the dielectric constants of dilute solutions: except for the susceptibility due to elastic polarization (refractive index), the increment of the dielectric constant is a measure for $(\mu^*)^2$, as given by our Eq. 42. We should also mention that the recent calculations by R. M. Fuoss[10] of the dielectric properties and of molecular interaction of salt molecules in non-polar solvents are in accord with the present theory, if only his electric moments, which he denotes by μ, are identified with our "external" electric moments μ^*.

As regards the electrostatic interaction of polar molecules in dilute solutions, Fuoss' computations are carried to a higher degree of approximation. A comparison with his results shows that in cases of extremely strong molecular interaction, the predictions of the present, simpler theory are subject to considerable modification. This disagreement should be taken as a warning against uncritical application of the present theory, which purports to be no more than a first approach to the complete description of dielectrics.

In our computations, the neighborhood of a molecule is considered as a continuum, thus neglecting its actual discrete structure. Moreover, the polarization of the neighboring liquid by a given molecule was considered as proportional to the field, while actually this relation might be modified by compression and by some sort of dielectric saturation. In spite of these shortcomings, the theory apparently accounts for a considerable field of experience, and there is some indication that an outstanding class of discrepancies are due to the physical assumptions involved in the conventional molecular model, and not to the mathematical approximations.

Summary

1. The dipole theory of dielectrics, as originally developed with the aid of Mosotti's formula for the "internal field," leads to the expectation of electrical Curie points, with attendant instability for liquids of high dielectric constants. This prediction is not verified by experience.

2. The field which acts upon a molecule in a polarized dielectric may be decomposed into a *cavity field* **G**, given by the shape of the molecule and proportional to the external field intensity, and a *reaction field* **R**, which is proportional to the total electric moment, and depends on the instantaneous orientation of the molecule.

3. The mean orientation of a molecule is determined by the orienting force-couple exerted by the cavity field **G** upon the electric moment of the molecule. The earlier naïve application of the Mosotti formula is equivalent to the assumption that the effective orienting field equals the average of $(\mathbf{G} + \mathbf{R})$, and incorrect because **R** never exerts a torque upon the molecule.

4. Since all real molecules are electrically deformable, the reaction field **R** will cause an enhancement of the electric moment of any molecule immersed in a dielectric. The induced moment due to the cavity field **G** will be similarly enhanced by the corresponding component of **R**.

5. The electric moment μ of a spherical molecule is computed as a function of the dielectric constant ϵ of the environment. In addition, it is convenient to consider an "external" electric moment μ^*, which determines the interaction of the molecule with all distant charges and long range fields in the dielectric. For spherical molecules, the ratio μ^*/μ increases from unity to 3/2 as the dielectric constant of the environment increases from 1 to ∞. Both μ and μ^* approach limits, which depend on the deformability of the molecule, for $\epsilon \longrightarrow \infty$. Accordingly, no Curie point is expected.

6. For simplicity, the computations are restricted to spherical molecules. The resulting formulas for the dielectric constants of pure polar liquids are similar to those proposed on empirical grounds by Wyman. For solutions of polar molecules in non-polar liquids the predictions of the earlier theory are largely upheld, but with certain minor modifications which are in qualitative agreement with the experiments of Horst Mueller.

The Separation and Determination of Tungsten and Molybdenum

BY HERMAN YAGODA[1] AND HAROLD A. FALES

The precise analysis of materials containing tungsten and molybdenum is complicated by the fact that in separating tungstic acid the precipitate is always contaminated by appreciable quantities of molybdenum,[2] and that in the formation of molybdenum sulfide, a considerable amount of tungsten is precipitated with it. The problem of the separation of molybdenum, both from tungsten and the other metals, is further complicated in that molybdenum sulfide is seldom precipitated quantitatively in one operation, its complete removal demanding two or more repetitions of the treatment with hydrogen sulfide.

A bibliography of the literature on the methods of analysis for tungsten and molybdenum up to the year 1923 is available in the bulletin by Moore.[3] Since that time, new methods for the determination of these elements have appeared making use of organic precipitants, but none of the reagents is suitable for separating the two metals. Among the organic compounds proposed for these determinations are, 8-hydroxyquinoline[4] which forms stable compounds having the composition, $WO_2(C_9H_6ON)_2$[5] and $MoO_2(C_9H_6ON)_2$[6]; and α-benzoin oxime which is serviceable for the direct determination of molybdenum in steels.[7]

The methods for the separation of tungsten and molybdenum come under two general headings. In the first grouping, one of the constituents of the mixture is removed by extraction with a suitable solvent. In this class come the methods of Ruegenberg and Smith,[8] who employed concentrated sulfuric acid to separate the molybdenum from a mixture of hydrated tungstic and molybdic acids; also, the procedure of Merrill,[9] who effected a like separation through the use of selenium oxychloride as the solvent. Under the second classification come precipitation reactions, the mechanism of which, in general, lends itself to more exact separations than are possible by extraction methods. Unfortunately, the properties of the two ions in question are very similar, so that with the exception of the sulfides, salts of the two elements have not been discovered that have a sufficient difference in solubility to effect a quantitative separation of one metal from the other.

The disadvantage of the separation by means of hydrogen sulfide is that the precipitation of molybdenum sulfide is usually incomplete owing to the reduction of part of the molybdenum by the reagent to lower valency states in which the ions can no longer form insoluble sulfides.[2] A further inconvenience of the method is that the subsequent removal of the large quantities of tartaric acid, whose presence is essential for a sharp separation of the two elements, is a very difficult and time consuming operation.

The present investigations were initiated in order to circumvent the described difficulties in the quantitative precipitation of pure molybdenum sulfide. Examination of the law of mass action for the reaction between the hexavalent molybdenum ion and the hydrogen sulfide in an acid medium, reveals that the complete precipitation of the molybdenum sulfide is favored by a low hydrogen-ion concentration and a high concentration of hydrosulfide ion

$$Mo^{6+} + 3HS^- \rightleftharpoons MoS_3 + 3H^+ \qquad (1)$$

$$[Mo^{6+}] = [MoS_3][H^+]^3/k[HS^-]^3 \qquad (2)$$

The hydrogen-ion concentration can be reduced only over a narrow range as, in alkaline media, soluble sulfomolybdates are formed. The concentration of hydrogen sulfide can be increased by conducting the precipitation in a pressure bottle at an elevated temperature. The efficiency of this procedure is doubtful, for the pressure effect is probably nullified by the increased reducing action of the reagent at elevated temperatures.[10]

It occurred to the writers that another means of increasing the concentration of the hydrogen

sulfide in the system is to take advantage of the increased solubility of the gas in water at low temperatures. At 0° the solubility of hydrogen sulfide is 7.1 g. per liter, which is more than twice that at 25°.[11] As the concentration of the hydrosulfide ion enters as a cube in equation 2, doubling the concentration of the hydrogen sulfide tends to make an eight-fold effect in diminishing the molybdenum-ion concentration. Also, as the reaction is conducted at a low temperature, the reducing action of the reagent is considerably diminished, a factor which favors the quantitative separation of the sulfide. Experimental investigations revealed that this method was eminently suitable for the separation of molybdenum from tungsten.

Purification of Standards

$Na_2WO_4 \cdot 2H_2O$.—The purification of sodium tungstate was effected by following the procedure developed by Folin.[12] The final product was tested for traces of molybdenum by means of potassium ethyl xanthate.[13] By applying the spot test technique, described by Feigl[14] to solutions of the purified salt to which were added known quantities of sodium molybdate, it was found that the red coloration characteristic of the element was discernible in a mixture containing 0.005% of sodium molybdate. As the solution of the purified salt did not give any visible reaction, the sodium tungstate employed in these investigations probably contained not more than 0.005% of sodium molybdate. Analysis of the product for water of crystallization[15] and tungstic oxide[16] showed that the salt contained 10.91 ± 0.02% water and 70.27 ± 0.02% WO_3, which compares favorably with the theoretical amounts 10.92 and 70.30%, respectively.

$Na_2MoO_4 \cdot 2H_2O$.—This salt was purified by dissolving 50 g. of the best obtainable sodium molybdate in 300 cc. of water; to the solution was added 600 cc. of 95% alcohol. A small crop of crystals separated at this point, these were filtered off after a period of one hour and discarded. The clear filtrate was again treated with 600 cc. of alcohol, the small crystals of sodium molybdate were filtered, washed with 100 cc. of 95% alcohol and permitted to dry at room temperature. The product, weighing 25 g., consists of small pearly-lustered crystals that are completely water soluble.

There is no chemical test for tungsten sufficiently delicate to establish the presence of traces of the element as an impurity in sodium molybdate. Spectrographic examination of the purified salt showed a very faint line in the position where the most persistent line of the arc spectrum of tungsten is located. But, as the other characteristic lines of the optical spectrum of tungsten were not recorded on the plate, appreciable amounts of the element probably are not present in the sample. This is further evident from the chemical analysis in which it was found that the salt contained 14.91 ± 0.01% water[15] and 59.49 ± 0.02% MoO_3,[17] the values closely agreeing with the calculated percentages, 14.89 and 59.50, respectively.

Preparation of Reagents

0° Hydrogen Sulfide Water.—This solution can be prepared by bubbling a stream of the purified gas through a column of water that has been chilled in an ice-bath to 0°. Several methods for preparing this solution were investigated with the object of obtaining rapid saturation and economy in the use of the gas. It was found most convenient to pass the gas through a porous sphere of "Aloxite."[18] This produces an ascending stream of numerous minute bubbles that are almost entirely absorbed by the column of water before they reach the surface. The standard 61 cm. (2-ft.) Kipp gas generators do not supply sufficient pressure to overcome the internal resistance of the porous sphere and the hydrostatic pressure of the column of water above it. The pressure can be augmented easily by compressing the air in the head of the Kipp with the help of an atomizer bulb. Small tanks of liquid hydrogen sulfide, substituted for the Kipp generator, serve the purpose admirably well.

The length of time required to reach the saturation point depends upon the volume of water, its initial temperature and the rate of influx of the gas. The relative rate of absorption, under constant gas pressure, by a column of water at the freezing point is recorded in Table I.

TABLE I

RATE OF ABSORPTION OF HYDROGEN SULFIDE

Volume of water at 0°, 750 cc. Diameter of "Aloxite" sphere, 25 mm. Influx of gas, 150 bubbles per min., as counted in the wash bottle having a conducting tube of 4 mm. inside bore.

Time, min.	10	20	30	45	60	120
G. H_2S/l. sol.[19]	0.863	2.12	3.53	5.21	6.12	6.59
Molarity	0.0253	0.062	0.104	0.153	0.180	0.193

The point of near saturation can be ascertained visually when it is noted that large bubbles reach the surface of the solution. In one experiment on the absorption of hydrogen sulfide, the undissolved gas was collected, dried over calcium chloride, and its weight ascertained by measuring the increase in weight of a U-tube filled with sodium hy-

[15] The water content was determined by drying 1-g. samples of the salt at 120° for several hours in a platinum crucible. To make sure of the complete removal of the water, the anhydrous salt was heated to the point of fusion.

[16] The tungstic oxide was determined by the standard cinchonine-hydrochloric acid method.

[17] The molybdic oxide content was determined by precipitating and weighing lead molybdate.

[18] These aerator stones are manufactured by the Carborundum Company, Niagara Falls.

[19] The concentration of the hydrogen sulfide was determined by transferring a 10-cc. sample to a solution of lead acetate and weighing the resultant lead sulfide.

droxide pellets connected to the train. It was found that in the process of saturating 750 cc. of water only 0.42% of the total hydrogen sulfide escaped absorption.

Formic Acid.—The acid employed in these investigations was a standard product of analyzed purity, of 85–90% strength. Analysis of the material showed that its concentration was 23.7 molar. Dilute 2 *M* formic acid was prepared by diluting 80 cc. of the concentrated acid to one liter.

Ammonium Formate.—A 50% solution of the salt was prepared by dissolving 250 g. of the J. T. Baker Chemical Co. analyzed product in 150 cc. of water, warming the mixture until the crystals dissolved, filtering and diluting to 500 cc. The solution should have a *p*H of 6.7 using bromo cresol purple as the indicator.

Tartaric Acid.—A 50% solution of the acid was prepared from an analyzed grade product. After the procedure for the separation of the two metals was developed, it was found more convenient to use a 30% solution of the acid.

Quantitative Precipitation of Molybdenum Sulfide

Molybdenum sulfide can be precipitated from solutions acidified with hydrochloric, sulfuric or formic acid. If the filtrate is to be reserved for the analysis of tungsten, it is desirable that the acidifying agent be readily volatile. Complete precipitation in hydrochloric acid media is a difficult matter[2]; it was therefore decided to investigate the claims of Sterba-Böhm[20] concerning the precipitation of molybdenum sulfide in solutions acidified with formic acid, who concludes that the sulfide can be precipitated completely over a range of acidity varying from 5–20% of the acid. To check this, six samples of sodium molybdate were each dissolved in 125 cc. of 10% formic acid and the solutions were saturated at room temperature with hydrogen sulfide. On examination of the filtrates, all were found to contain minute amounts of molybdenum, averaging 0.10 ± 0.03 mg. of the metal.[21]

A series of analyses was then made using hydrogen sulfide water saturated at 0° as the precipitant. The sodium molybdate was dissolved in 10 cc. of water, 100 cc. of the hydrogen sulfide reagent was added to each sample and the solutions were acidified with measured volumes of 24 *M* formic acid. The mixtures were heated on a hot-plate; when the temperature reached 36° the molybdenum sulfide coagulated, and settled to the bottom of the beakers in the form of bulky deep black precipitates. After digestion for thirty minutes at 40–50° the sulfides were filtered and washed with 5% formic acid. All the filtrates were colorless and perfectly clear[22] and on analysis were found to contain only traces of molybdenum. The results from twelve experiments showed that on the average only 0.04 to 0.01 mg. of the metal failed to be precipitated by following this procedure. This loss is entirely negligible in the gravimetric determination of the element.

Determination of Molybdenum as Molybdic Oxide

After the molybdenum is separated as the sulfide, it is convenient to convert the molybdic sulfide to molybdic oxide and weigh the element in that form. The early investigators of this process[3] concluded that it was difficult to roast the sulfide to the oxide owing to the volatile nature of molybdic oxide. Recent work by Brinton,[23] Hartmann[24] and Knowles[7] proves that the moist sulfide can be converted to the oxide, at temperatures below 600°, without any appreciable loss; and that the process is quite rapid at temperatures above 500°. As the temperatures must be carefully controlled, it is best to ignite the molybdenum sulfide in an electric furnace. The simple heating unit described in Fig. 1, which can be readily assembled from standard laboratory stock, proved to be very useful in executing this process.

The improvised furnace reaches thermal equilibrium in about thirty minutes. With two 660-watt conical heating coils connected in series and insulated as shown in the diagram, the surfaces of the nickel crucibles reach a maximum temperature of 550°. At this temperature the furnace draws a current of 2.75 amp. at 120 volts. By removing part of the wiring from the heating coils, the temperature reaches 750° and the unit can then be employed for igniting precipitates of tungstic acid to the oxide. It is recommended that the crucible containing the precipitate be protected by a nickel crucible, as shown in the figure, in order to prevent its being scratched by the rough walls of the cone shaped heater.

During the progress of the work on the quantitative conversion of molybdenum sulfide to oxide, it was found

that the most concordant results were obtained when the sulfide was filtered through Gooch or porous bottom porcelain crucibles. Under these conditions the sulfide is deposited in a layer that is quite uniform in depth, and this promotes rapid conversion to the oxide. It was also noted that during the roasting process there was at times mechanical loss of oxide due to the sputtering of the burning sulfur. It is possible to avoid this loss and make the oxidation process quiescent by mixing the precipitate with a small amount of ashless filter paper fibers before conducting the filtration. In general, it takes fifteen to twenty minutes to convert 150 mg. of molybdic sulfide to the oxide. It was found by experiment that a sample of the oxide weighing 120 mg. could be heated for one hour at 550° without any detectable loss in weight. When the temperature was increased to 750°, 0.0036 g. was volatilized during a period of thirty minutes.

The results recorded in Table II show that the oxidation process is suitable for the quantitative determination of molybdenum. The sulfide was precipitated from solutions containing weighed samples of sodium molybdate, by the method previously described, using 100 cc. of the hydrogen sulfide reagent and 10 cc. of 24 *M* formic acid as the acidifying agent.

If facilities are lacking for igniting the sulfide by the described method, then it is preferable to determine the element by precipitating and weighing lead molybdate.[25] Solution of molybdenum sulfide can be effected by the action of nitric acid and bromine,[26] or a mixture of ammonium hydroxide and hydrogen peroxide.[27] These solvents oxidize the sulfide, producing appreciable amounts of sulfuric acid, so that it is necessary to separate the lead molybdate in the presence of ammonium acetate in order to prevent the precipitation of lead sulfate.[2] The recent work by McCay[28] shows that molybdates can be precipitated quantitatively by silver nitrate and the molybdenum determined by weighing the silver molybdate. The presence of sulfate ion does not interfere with this reaction and the method should prove useful under the present circumstances.

The Precipitation of Molybdenum Sulfide in the Presence of Tungsten

When a solution of sodium tungstate is treated with hydrogen sulfide and then acidified with dilute acid, no insoluble sulfide is formed. However, when molybdenum sulfide separates from a solution containing both metals it carries down with it part of the tungsten. The degree of contamination varies with the amount of molybdic sulfide formed, the concentration of tungsten in the solution and with the acidity of the medium. Koppel[29] claims that in the presence of formic acid the molybdenum sulfide separates free from tungsten; the writers have not been able to duplicate these results.

Table III is a compilation of analyses of sodium tungstate and molybdate in which the sulfide was separated from solutions containing different concentrations of formic acid. Experiments 2 and 3 correspond to the conditions recommended by Koppel for the separation of the two elements. The results obtained show that the molybdenum sulfide carries down with it large quantities of tungsten, the degree of contamination increasing with the acidity of the solution.

The next matter investigated was whether the results obtained in dilute formic acid media could be improved upon by decreasing the hydrogen-ion concentration of the solution by means of the buffer action of ammonium formate. Under these conditions it was found that a brown colored variety of molybdenum sulfide separated from the solution in a finely divided granular form. After digesting the mixture at 50–60° for one hour the brown sulfide darkens in color, and is then capable of being filtered and washed without encountering any difficulties.

The precipitation of molybdenum sulfide was studied in buffered systems over a range of *p*H from 5.0 to 3.0. As the *p*H increased, the sulfide precipitated in purer form, and it was found that tungsten did not co-precipitate when the *p*H of the solution exceeded 4.5. Under these conditions, however, the hydrogen-ion concentration of the solution is not sufficient to decompose all of the soluble sulfomolybdate, with the result that part of the molybdenum remains unprecipitated. The data obtained from these experiments are summarized in Table IV.

A further attempt was made to render the above processes quantitative by precipitating the molybdenum sulfide in two stages, the idea being to precipitate the bulk of the sulfide in a pure form at a *p*H of 5.0, and then to complete the precipitation by a secondary addition of formic acid. Since the quantity of tungsten that coprecipitates is proportionate to the amount of molybdenum sulfide formed, the mechanism suggested that only a negligibly small amount of the metal would be carried down during the formation of the residual molybdic sulfide upon further acidification.

The experimental data assembled in Table V were obtained by dissolving the weighed salts in 10 cc. of water, 10 cc. of 50% ammonium formate and 100 cc. of hydrogen sulfide water saturated at 0°. Precipitation was initiated in solutions 1–5 by the addition of 5 cc. of 2 *M* formic acid and digesting the mixtures at 60° for one hour. The decomposition of the sulfomolybdate was completed by the further addition of 10 cc. of 2 *M* formic acid. The treatment given to samples 6 and 7 differed from that received from the others only in that the dilute and concentrated formic acids were added at approximately the same time. Comparison of the results obtained in experiments 4 and 5 with those from 6 and 7 shows that though the two-stage decomposition of the ammonium sulfo-

molybdate produces a less contaminated sulfide than that precipitated from a solution whose *p*H is adjusted to 3.0 from the very beginning of the reaction, the mechanism is not able to produce a quantitative separation of the two elements.

Since molybdenum sulfide can be precipitated free from tungsten in solutions containing tartaric acid,[31] experiments were made to determine whether the amount of tartaric acid required for the quantitative separation of the two metals could be diminished by conducting the reaction in solutions buffered by ammonium formate.

Weighed samples of sodium molybdate, of approximately the same mass, were dissolved in 10 cc. of a standardized solution of sodium tungstate containing 4 g. of $Na_2WO_4 \cdot 2H_2O$ per 100 cc. To these solutions were added varying volumes of 50% tartaric acid and 50% ammonium formate, 100 cc. of hydrogen sulfide reagent and 10 cc. of 24 *M* formic acid. The mixtures were kept at 60° for ninety minutes, a small quantity of filter paper pulp was added, the precipitates were permitted to settle, and then filtered through porous bottom porcelain crucibles. The sulfides were washed with five 10-cc. portions of a solution consisting of 5 cc. of 50% ammonium formate, 5 cc. of 24 *M* formic acid and 100 cc. of water; then ignited to oxides at 550° and weighed. The difference between the weights of the recovered oxides and the theoretical weight of molybdic oxide equivalent to the sodium molybdate put into the solution is a measure of the amount of tungstic oxide carried down by the molybdenum sulfide. The degree of co-precipitation can also be judged from the color of the resultant oxide. Pure molybdic oxide is white, and when it is contaminated, it is colored yellow by the tungstic oxide. The yellow coloration becomes quite pronounced when the impure oxide contains more than 4% of tungsten.

The results obtained from these experiments, recorded graphically in Fig. 2 show that in the absence of ammonium formate the molybdenum sulfide carries down with it appreciable amounts of tungsten even though the solution contains a high concentration of tartaric acid. The sulfide that separates under these conditions is black and non-crystalline, and filters and washes with great difficulty. Hence, part of the error observed in experiments 1–8 may be due to the presence of sulfotungstate in the incompletely washed precipitate, as is also indicated by the erratic disposition of the points in curve A of Fig. 2. In solutions buffered with ammonium formate, the tartaric acid is more effective in producing a complete separation

---

[30] The *p*H values of the solutions were estimated by the use of suitable indicators and standard buffer mixtures. Because of the bleaching action of the hydrogen sulfide, the measurements had to be made on independent systems in which an equal volume of water was substituted for the 100 cc. of the hydrogen sulfide reagent.

[31] Heinrich Rose, "Ausführliches Handbuch der analytischen Chemie," Vol. I, Part 2 (1851), pp. 356–357.

of the molybdenum sulfide from the tungsten, as can be seen by comparing the curves in Fig. 2.

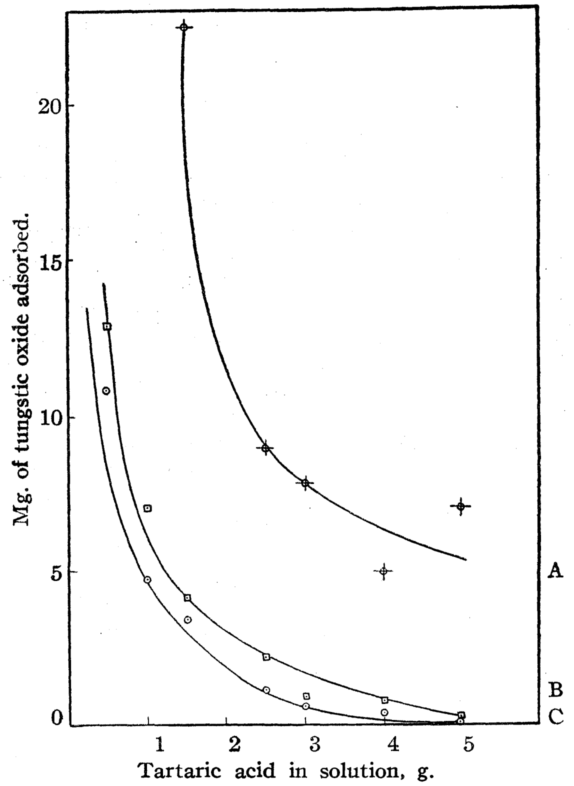

Fig. 2.—Contamination of MoS_3 by tungsten: ⊕, ammonium formate absent; ⊡, 2.5 g. of ammonium formate; ⊙, 5.0 g. of ammonium formate.

On the basis of the evidence presented in Table V and Fig. 2 the following procedure was developed for the separation and determination of molybdenum in the presence of tungsten.

Procedure A.—Dissolve the two salts in 10–15 cc. of water in a 250-cc. Erlenmeyer flask, add 10 cc. of 50% ammonium formate, 10 cc. of 30% tartaric acid, 100 cc. of hydrogen sulfide water saturated at 0° and 10 cc. of 2 *M* formic acid.[32] Heat the mixture on a water-bath to 60° and maintain the temperature for one hour. At the end of the digestion, add a small quantity of filter paper pulp, suspended in about 10 cc. of water, and complete the precipitation of the molybdenum sulfide by adding 10 cc. of 24 *M* formic acid. Keep the mixture in the water-bath for a period of thirty minutes, allow the precipitate to settle, and filter through a porous bottom or a Gooch crucible which has been heated to about 500°. Wash the precipitate with five 10-cc. portions of a solution made by diluting 5 cc. of 50% ammonium formate and 5 cc. of 24 *M* formic acid with 100 cc. of water. Ignite the precipitate in the oven described in Fig. 1 for twenty to thirty minutes until conversion to the oxide is complete; cool and weigh. Reheat the crucible over fifteen-minute intervals until it attains constant weight. Usually the conversion is complete at the end of the first ignition.

The results obtained following this procedure are recorded in Table VI. The small differences between the calculated and the observed values, together with the white color of the oxides, indicates that a fairly sharp separation of the two elements has been effected.

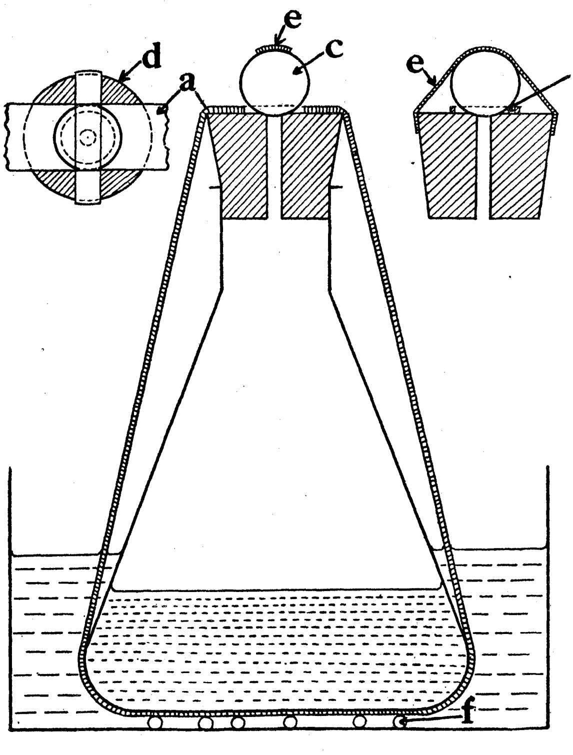

Fig. 3.—Safety pressure flask: a, large endless rubber band 1.4 mm. thick, 1.6 mm. wide and 25 cm. peripheral length at rest; b, 1.3 cm. diam. hole in rubber band; c, 1.6 cm. diam. sphere of glass or "marble"; d, semi-hard rubber stopper with 3-mm. hole in center; e, rubber band 6.4 mm. wide and 0.8 mm. thick; f, glass beads.

During the progress of this work recourse was made to the precipitation of molybdenum sulfide in pressure bottles. Difficulty was encountered in transferring the precipitate quantitatively from the pressure bottle of usual design owing to its narrow mouth and the dangling of the capping device when pouring the contents. Efforts were therefore made to convert Erlenmeyer flasks into pressure

---

[32] At this point the solution has a *p*H of 3.9; after the addition of the concentrated formic acid the *p*H drops to 2.9. Crystals of ammonium hydrogen tartrate may separate on the addition of the cold hydrogen sulfide solution, but these redissolve during the subsequent warming of the mixture.

bottles by closing the neck with a rubber stopper, the latter being kept in place by stretching rubber bands around it and the base of the flask. On warming the hydrogen sulfide mixture to 60°, the pressure developed by the liberated gases usually popped the stopper and on two occasions broke the bottom out of the flask.

To prevent such accidents, the safety pressure flask illustrated in Fig. 3 was designed. When the pressure inside the flask becomes sufficiently high, the sphere covering the opening in the stopper loosens and permits some of the gas to escape until the restoring force of the rubber band that keeps it in position is sufficient to balance the internal pressure. The equilibrium pressure varies with the tension in the band supporting the sphere. By closing a suction flask with these valves, maximum pressures above atmospheric of 46–80 cm. of mercury were recorded on a manometer attached to the side-arm.

The construction of the stoppering device is apparent from the figure. The accessory rubber bands are secured to the stopper by means of rubber cement. The band holding the sphere in place is best made by cutting the necessary length from a piece of 6-mm. rubber tubing. The semi-circular cross section of the tubing hugs the surface of the sphere and prevents side slippage.

1.5	.0501	.5022	.0296	.0298	− .0002

The results obtained by conducting the precipitation of the molybdenum sulfide in the safety pressure flasks, recorded in Table VII, show that the negative errors in the determination of molybdenum are slightly decreased. In general, little advantage is gained by conducting the precipitation under pressure. The use of the pressure flasks is recommended when the sample of tungsten contains only small amounts of molybdenum, or in the absence of adequate ventilation, to minimize the odor of the gas in the laboratory during the long digestion period.

The Determination of Tungsten

The filtrate and washings resulting from the separation of the molybdenum sulfide contains the tungsten in solution combined as a tartaro complex, together with the excess hydrogen sulfide, ammonium formate and formic acid. Evaporating the solution down to near dryness effects the removal of the hydrogen sulfide, formic acid and part of the ammonium formate. Treatment of the residue with 12 *M* hydrochloric acid and cinchonine precipitates after prolonged boiling the greater part of the tungstic acid in the form of a hard crystalline mass that adheres tenaciously to the surface of the beaker. The yield is not quantitative, as shown by the figures below.

$Na_2WO_4\cdot 2H_2O$	Tungstic oxide		
	Recov.	Calcd.	Diff.
0.2033	0.1385	0.1429	−0.0044
.1013	.0488	.0712	− .0224

Procedure B.—Treatment of the concentrated filtrate with 25 cc. of 16 *M* nitric acid produces a much better recovery of the tungsten. The acid facilitates the completion of the reaction by the removal of the ammonium salts, the presence of which retards the precipitation of tungstic acid,[2] (pp. 119 and 552), and also in that the simultaneous evolution of gases during the decomposition prevents the precipitate from adhering to the walls of the vessel. When the removal of the ammonium salts is completed the mixture is diluted with 100 cc. of water and 5 cc. of cinchonine reagent,[34] digested on a hot-plate for two hours and then filtered through an ashless filter paper. The precipitate is washed, ignited at 750° and the tungstic oxide weighed. The results obtained by following this procedure are not strictly quantitative except when only a small quantity of tartaric acid is present. For a given amount of tartaric acid the amount of tungsten remaining unprecipitated is remarkably constant, and by applying the necessary correction factor, the method is recommended for rapid routine analyses.

necessitates the removal of the greater part of the tartaric acid contained in it. Treatment with oxidizing acids is not recommended, as the process requires many repetitions in order to complete the destruction of the organic matter, and is subject to loss of material due to spattering.

During the later stages of the evaporation of the filtrate, ammonium hydrogen tartrate crystallizes from the solution. The greater part of the organic matter can be removed by taking advantage of the small solubility of this salt in mixtures of alcohol and water.

The solubility of ammonium hydrogen tartrate in water–alcohol systems was approximated by evaporating measured volumes of the saturated solutions and weighing the dry residues. From the solubility data in Table IX it can be seen that by evaporating the filtrate down to a volume of about 25 cc. and adding 50 cc. of alcohol to the concentrate, only about 120 mg. of tartaric acid will remain in solution. This small amount of tartrate no longer interferes with the quantitative separation of tungstic acid, as is demonstrated by the preceding experiments in Table VIII. After being washed with 50% alcohol, the crystals still occlude small quantities of tungsten. This is readily recovered by charring the filter paper containing the ammonium hydrogen tartrate in a platinum crucible containing about 500 mg. of sodium carbonate[2] (p. 61), extracting the residue with water, filtering off any carbonaceous matter, and adding the filtrate to the solution containing the bulk of the tungsten. The resultant solution is evaporated to a small volume to effect the removal of the alcohol, and the tungstic acid is precipitated by the addition of 25 cc. of 16 *M* nitric acid. From this point the precipitate is treated as described in procedure B.

In the table above are recorded the results of several analyses of mixtures of sodium tungstate and molybdate, arrived at by following procedure A for the separation of the sulfides in the presence of ammonium formate, tartaric and formic acids. The close agreement between the recovered and theoretical weights of the oxides shows that the method is satisfactory for the separation of the two metals in the absence of interfering elements. The application of these methods to the analysis of steels and minerals containing tungsten and molybdenum is in the process of investigation.

Acknowledgment.—The writer wishes to express his gratitude to the J. T. Baker Chemical Company whose grant of the 1935–36 Eastern Research Fellowship made these studies possible.

Summary

A new technique is described for precipitating metallic sulfides, using a saturated solution of hydrogen sulfide in water at 0° as the reagent. Molybdenum sulfide can be precipitated quantitatively in formic acid media by initiating the reaction at a low temperature and maintaining a high concentration of hydrogen sulfide in the solution. A quantitative separation of the sulfide in the presence of tungsten can be effected in a solution whose *p*H is adjusted to 2.9 by a buffer mixture consisting of ammonium formate, tartaric and formic acids. The article contains descriptions of a simple electric furnace for igniting precipitates at a constant temperature, and of an improved pressure bottle.

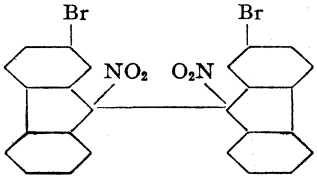
NOTES

2-Bromo-9-Nitrofluorene and 1,1-Dinitro-3,3'-dibromo-bifluorenyl

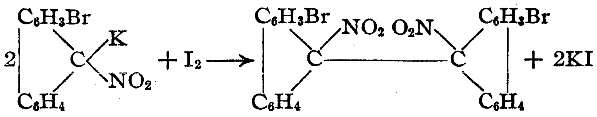
By C. Dale[1] and R. L. Shriner

Recently a compound melting at 170° was described as being 2-bromo-9-nitrofluorene.[2] It is very unusual for a normal nitro compound to melt higher than its aci-form (m. p. 132°). Moreover, the compound decomposes on heating and liberates oxides of nitrogen and forms 2-bromofluorenone. The alkali insolubility of the compound and failure to form a salt of the aci-form, even with potassium methoxide, indicate that it is probably the bimolecular oxidation product with the structure (I) analogous to the product obtained by Nenitzescu[3] in his study of aci-9-nitrofluorene.



I

A reëxamination of this compound has shown that it may be obtained in small amounts by boiling an alcoholic solution of the aci-form, or in good yields by treating the potassium salt of 2-bromo-9-nitrofluorene with one mole of iodine. The product of this reaction is a yellow powder which shrinks and decomposes over a considerable range of temperature (130–140°). By careful fractionation from methyl acetate, colorless crystals of the compound were obtained. They melted at 172.5° (175° corr.).



$$2\,(C_6H_3Br)(C_6H_4)C(K)NO_2 + I_2 \longrightarrow (C_6H_3Br)(C_6H_4)C(NO_2)-C(NO_2)(C_6H_3Br)(C_6H_4) + 2KI$$

The analyses for bromine and nitrogen previously given[2] are correct, but, of course, would check very closely the theoretical values for either the monomolecular or bimolecular structure. A combustion gave the following results: Calcd. for $C_{13}H_8O_2NBr$: C, 53.81; H, 2.76. Calcd. for $C_{26}H_{14}O_4N_2Br_2$: C, 54.00; H, 2.42. Found: C, 54.04; H, 2.51.

The molecular weight was determined by the micro boiling point method, using acetone and benzene as solvents. In acetone a molecular weight of 593 was obtained, and in benzene a value of 554 resulted. The calculated value for I, $C_{26}H_{14}O_4N_2Br_2$, is 578, whereas the molecular weight of $C_{13}H_8BrNO_2$ is 290. It is evident that the compound is the bimolecular oxidation product with the structure I.

p-Phenylphenacyl Esters of Organic Acids

By T. Leonard Kelly and Eugene A. Morisani

During the course of a research the following *p*-phenylphenacyl esters were prepared which do not appear in the literature. Since the melting points of these may be an aid in the identification of acids they are of value.

They were prepared according to the method of Drake and co-workers[1] and were recrystallized to constant melting point. All melting points are

COMMUNICATIONS TO THE EDITOR

SYNTHETIC SUBSTRATES FOR PROTEIN-DIGESTING ENZYMES

Sir:

Knowledge regarding the specificity of those enzymes which hydrolyze intact proteins (peptic, tryptic and catheptic proteinases) is meager. In general it is assumed that these enzymes react exclusively on high molecular substrates.

Recently it has been possible to study the specificity of proteinases with the aid of synthetic substrates. Such substrates have been found in this Laboratory for the catheptic enzymes, papain, liver-cathepsin and bromelin. The authors have now observed the splitting of α-hippuryl-lysine-amide by tryptic proteinase.

α-Hippuryl-ε-carbobenzoxy-lysine methyl ester was converted into α-hippuryl-ε-carbobenzoxy-lysine amide, m. p. 212°, with the aid of methanolic ammonia. *Anal.* Calcd. for $C_{23}H_{28}N_4O_5$: C, 62.7; H, 6.4; N, 12.7. Found: C, 62.6; H, 6.7; N, 12.8. This amide was hydrogenated catalytically, yielding α-hippuryl-lysine-amide which was isolated as the strongly hygroscopic hydrochloride, m. p. 248°. *Anal.* Calcd. for $C_{15}H_{23}N_4O_3Cl$: C, 52.5; H, 6.8; N, 16.3. Found: C, 52.0; H, 7.0; N, 15.9.

The tryptic proteinase was prepared according to E. Waldschmidt-Leitz and A. Purr [*Ber.*, **62**, 2217 (1929)]. The preparation contained no dipeptidase, aminopeptidase, and no carboxypeptidase; however, protaminase probably was present (Table I).

TABLE I

ENZYMIC HYDROLYSIS OF α-HIPPURYL-LYSINE-AMIDE AT 40°

(Titration of liberated carboxyl groups)

Enzyme	Time, hrs.	Hydrolysis in % of one peptide bond
Tryptic proteinase, *p*H 8.8	22	123
	72	200
Tryptic proteinase, *p*H 8.8	18	121
	42	175
HCN-Papain, *p*H 5.0	5	58
	24	80
	49	85

In contrast to HCN-papain, which splits only one peptide bond, tryptic proteinase splits two. After a complete splitting, hippuric acid was isolated from the digest (over 70% of the theoretical amount). Therefore, the splitting also must have liberated lysine and ammonia. That the free ε-amino group is an essential condition for the enzymic hydrolysis is shown by the fact that the above mentioned α-hippuryl-ε-carbobenzoxy-lysine amide is not hydrolyzed under the conditions of our experiments. The hydrolysis of our substrate by tryptic proteinase is remarkable since tryptic proteinase is supposed to react exclusively on anionic substrates.

It is intended to continue this research by studying the action of pure tryptic proteinases.

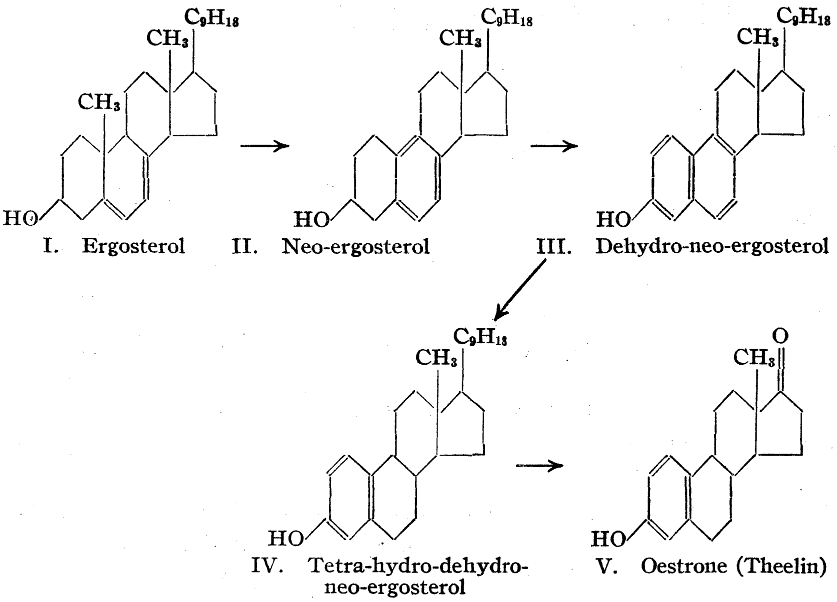
STEROLS. VI. SYNTHETIC PREPARATION OF OESTRONE (THEELIN)

Sir:

The evidence for the accepted structure of oestrone has recently been reviewed [L. F. Fieser, "Chemistry of Natural Products Related to Phenanthrene," A. C. S. Monograph Series, No. 70]. We have been able to prepare a well crystallized compound from ergosterol which by analysis, derivatives and mixed melting points, is identical with oestrone isolated from pregnancy urine. It has been previously shown that ergosterol may be converted into 3-hydroxy-nor-allo-cholanic acid [Chuang, *Ann.*, **500**, 270 (1933); Fernholz and Chakravarty, *Ber.*, **67,** 2021 (1934)] which is also obtainable from dihydro-cholesterol. This acid can give rise to isoandrosterone which differs from androsterone only in configuration of the hydroxyl group in the 3-position. Therefore, with the preparation of oestrone from ergosterol, a complete connection between the hormones, male and female, has been established.



I. Ergosterol II. Neo-ergosterol III. Dehydro-neo-ergosterol

IV. Tetra-hydro-dehydro-neo-ergosterol V. Oestrone (Theelin)

In the present work, dehydro-neo-ergosterol, III, was prepared from ergosterol by the method of Windaus [Windaus and Borgeaud, *Ann.*, **520,** 235, 460 (1928)], Inhoffen [Inhoffen, *ibid.*, **497,** 130 (1932)], and Honigmann [Honigmann, *ibid.*, **511,** 292 (1934)]. Taking advantage of the fact that naphthalene derivatives may be reduced to tetrahydro derivatives with sodium and amyl alcohol, dehydro-neo-ergosterol, III, m. p. 147–150°, was reduced to give tetrahydro-dehydro-neo-ergosterol, IV, m. p. 170.5–171.5°. This substance is phenolic and forms sodium salts.

Anal. Calcd. for $C_{27}H_{41}O$: C, 85.1; H, 10.8. Found: C, 85.7; H, 10.8.

The tetrahydro-dehydro-neo-ergosterol was then acetylated and this product oxidized with chromic acid. The total neutral oxidation product was hydrolyzed with alcoholic sodium hydroxide and then treated with semicarbazide acetate. The crude semicarbazone was hydrolyzed with alcoholic sulfuric acid to the free ketone, which was then distilled at 200° under high vacuum. The sublimate was crystallized from 95% alcohol to give a white crystalline compound m. p. 259–261.5° (uncorr.). This gave no depression in melting point with a sample of natural oestrone of m. p. 255°. It is soluble in alkali. It gave a rotation of $[\alpha]^{32}_D$ +159° in alcohol, c = 514 mg. per 100 cc.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.9; H, 8.3. Found: C, 79.4; H, 8.4.

The product gave a benzoate by the Schotten–Baumann reaction, m. p. 205–207° (uncorr.), which gave no depression to a sample of natural oestrone benzoate m. p. 205° (uncorr.).

Anal. Calcd. for $C_{25}H_{26}O_3$: C, 80.2; H, 7.0. Found: C, 80.6; H, 7.2.

It gave a semicarbazone of m. p. 252–253° (uncorr.). From the analysis this semicarbazone calculates to have one-half molecule of water of crystallization. Butenandt [*Z. physiol. Chem.*, **208,** 129 (1932); **208,** 149 (1932)] observed the same thing on the preparation of the semicarbazone from natural oestrone.

Anal. Calcd. for $(C_{19}H_{25}O_2N_3)_2 \cdot H_2O$: C, 67.9; H, 7.9. Found: C, 68.1; H, 8.2.

This synthesis was repeated independently by two of us. We wish to thank Dr. George H. Fleming of this Laboratory for the micro-analyses reported in this paper.

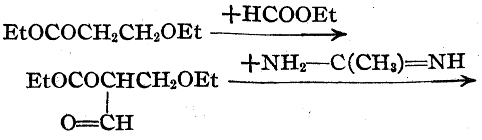
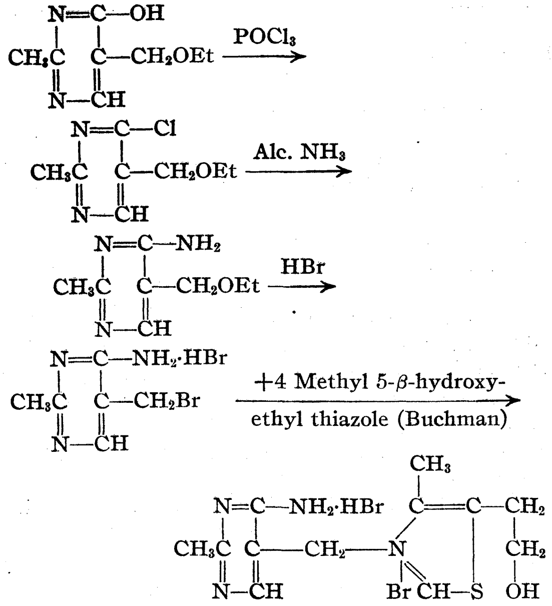
SYNTHESIS OF VITAMIN B_1

Sir:

As foreshadowed in a recent communication [THIS JOURNAL, **58,** 1063 (1936)] we have effected a synthesis of the vitamin by the following route.



$$EtOCOCH_2CH_2OEt \xrightarrow{+HCOOEt} \underset{\displaystyle O{=}CH}{EtOCO\underset{|}{C}HCH_2OEt} \xrightarrow{+NH_2{-}C(CH_3){=}NH}$$



The resulting bromide agreed in molecular absorption with the natural vitamin and when air dried analyzed for the composition $C_{12}H_{17}N_4SOBr \cdot HBr \cdot {}^1/_2H_2O$. The curative dose for polyneuritic rats is $6\ \gamma \pm 1\ \gamma$.

Converted into the chloride, it was found identical with the natural in composition (5 elements) ultraviolet absorption and antineuritic potency (5 γ). Comparing melting points led us to observe two crystal forms in varying proportions in the natural chloride and especially in the picrolonate; the synthetic chloride and picrolonate respectively correspond in appearance to one of these forms. The synthetic chloride melts at 232–234°; our present specimen of natural at 246°; mixed melting point is 242–244°. Kinnersley, O'Brien and Peters have called attention to a variably low melting antineuritic chloride [*Biochem. J.*, **27,** 232 (1933)] and it seems probable that the natural as isolated is often a mixture of two stereoisomers [*cis-trans* on 5 C of pyrimidine? Nishikawa, *T. Mem. Ryojun Coll. Eng.*, **3,** 277 (1931)] of equal potency and that in our synthetic material the low form predominates in higher degree.

The details of structural evidence and of the method of synthesis will appear in forthcoming papers.

In making this announcement the writers wish to express their indebtedness to all those who have participated in the work and whose names have appeared in the authorship of the current series of papers "Studies of Crystalline Vitamin B_1." Mention should also be made of Mr. Jacob Finkelstein, who has performed many syntheses of both known and new compounds.

The senior author is grateful to Dr. E. R. Buchman, who continued to participate in the work when financial support was lacking during the greater part of 1935 and to Mr. R. E. Waterman who joined the writer in meeting this emergency. Through the kindness of Dr. Walter H. Eddy, laboratory space was provided at Teachers College during this as well as earlier phases of the undertaking. More recently funds and facilities have been provided by Merck & Co., Inc., under the auspices of the Research Corporation of New York. Grateful acknowledgment is made to Dr. Eddy and to both of these corporations.

NEW BOOKS

Physical Chemistry for Colleges. A Course of Instruction Based upon the Fundamental Laws of Chemistry. By E. B. MILLARD, Professor of Physical Chemistry, Massachusetts Institute of Technology. Fourth edition. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York, N. Y., 1936. ix + 524 pp. 73 figs. 14.5 × 21 cm. Price, $3.75.

The present edition of this well-known text is a revision of the third edition with the size and character remaining virtually unchanged. The revision has involved greater clarity of presentation of certain topics, substitution of new concepts for older ones, and substitution of many new problems for old problems. Portions of four or five of the chapters have been partially rewritten, notably the chapters on equilibrium, kinetics of reaction and atomic structure. The chapter on "Physical Properties and Molecular Structure" has been omitted and a new chapter on "Free Energy of Chemical Changes" has been added. The changes which have been made, while not extensive, serve to maintain the up-to-date character of this meritorious book.

F. E. BARTELL

Textbook of Quantitative Inorganic Analysis. By I. M. KOLTHOFF and E. B. SANDELL, University of Minnesota. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1936. 749 pp.

It requires only a cursory examination of this book to dispel the feeling of satiety with which one is apt to greet the appearance of a new textbook of analytical chemistry. The reader soon realizes that this text enters a new field and satisfies a need which is not met by other English books. To the advanced student of quantitative analysis the book offers a thorough treatment of the fundamental principles upon which the subject rests, a comprehensive discussion of the apparatus, reagents and practical technique employed in analysis and a valuable key to the literature of analytical chemistry. It should prove invaluable in the training of analytical chemists as contrasted with chemical analysts.

Sections of the book are devoted to gravimetric analysis, volumetric analysis, physico-chemical methods, and analyses of complex materials. In the first two of these sections theoretical parts precede parts given over to practical details and specific directions. The outstanding characteristic of this book is the thoroughness with which the theoretical fundamentals of the subject are treated. The authors justify their remark, "The theory of analytical chemistry does not constitute a special branch of chemistry; rather it comprises the application of our entire scientific knowledge to the particular purpose." The phenomena of precipitation and coprecipitation are given particularly extensive treatment.

In the practical and specific parts the same logical completeness is maintained. Thus nine pages of small print are devoted to the precipitation of barium sulfate. There is no falling away into the cookbook style sometimes found in elementary texts. Particularly pleasing are the ample references given to the original literature. These as well as the methods treated in the text are thoroughly up-to-date.

In the third section upon physico-chemical methods a wide variety of general methods are briefly explained. Colorimetry is treated in some detail. Here again the student is given an excellent start in the literature. In the final section upon the analyses of complex materials, directions are given for the analyses of brass, steel and silicate rocks.

The book is set in three sizes of type to facilitate its use in elementary courses, material of a more advanced nature being in small type. Problems with answers are given at the end of the chapters. It is a book to be recommended for serious students.

CHARLES H. GREENE

Der Aufbau der Zweistofflegierungen. Eine kritische Zusammenfassung. (The Constitution of Binary Alloy Systems. A Critical Compilation.) By M. HANSEN. Verlag von Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1936. xv + 1100 pp. 456 figs. Price, RM. 87.

This book adequately fills a long felt need in metallurgical research. The available data for each binary system are critically discussed and where possible a probable equilibrium diagram is chosen. An exhaustive bibliography follows each discussion, including most 1935 and even some 1936 references. In all, 828 systems are treated, although a few of these receive very brief notice indeed. The longest is the 18-page discussion and 3-page bibliography devoted to the copper–zinc system.

The only comparable work is the set of diagrams in the "International Critical Tables." But these deal with only 200 odd systems and omit discussion. Since there are points of doubt about nearly all the diagrams, discussion is a necessity.

Practically all the important facts one could glean from an extensive survey of the literature seem to be listed under each alloy system. The discussions might be improved by adopting a standardized order of presentation. Suitable subheadings such as liquidus, solidus, miscibility, intermediate phases, etc., might well be common to all systems extensively discussed.

Since experimental data on solid transformations are often meager, contradictory, or subject to varying interpretations, it is not to be expected that the author's chosen equilibrium diagrams will be final or complete. But no general criticism can be made of his selections.

Naturally it is possible to criticize details. For example, the equilibrium diagrams of cobalt do not show the high temperature transformation to hexagonal cobalt discovered in 1930 by Hendricks, Jefferson and Shultz and since abundantly verified. In the Fe-Ni system the author states that it is impossible to detect superstructures by x-ray diffraction because of the nearly equal atomic numbers. However, Jette and Foote recently pointed out that in this and some other cases it is possible to take advantage of critical absorption limits. Nickel radiation is largely absorbed by Fe atoms, leaving the Ni atoms as the only effective scatterers, so that superstructures could be detected.

Such criticisms could be multiplied without altering the fact that the book contains an essentially complete summary of all the experimental data on binary metallic systems. Alloys of nitrogen, sulfur, carbon, phosphorus, and other nonmetals which form metallic alloys are also included.

The systems are printed in the order of the initial letter of the chemical symbol and so can be found rapidly without referring to the index. An anthor index is lacking. The book is beautifully printed and bound.

RALPH HULTGREN
ALDEN B. GRENINGER

Organic Chemistry. A Brief Introductory Course. By JAMES BRYANT CONANT, President of Harvard University, Formerly Sheldon Emory Professor of Organic Chemistry, Harvard University. Revised, with the assistance of MAX TISHLER, Ph.D. The Macmillan Company, New York, 1936. ix + 293 pp. 27 figs. 14.5 × 22 cm. Price, $2.60.

This brief text is intended primarily for students in pre-medical, biological, and general science curricula. It gives an excellent presentation of the fundamental notions of organic chemistry and their relations to biology and to industry. The 1928 edition[1] has been revised thoroughly—some changes have been made in the arrangement of material and new sections have been added. The additions include a chapter on unsaturated alcohols and acids, and on compounds of biological interest. The subject of geometrical isomerism, which was not covered in the first edition, is given a brief but adequate discussion. The revision retains a novel feature of the first edition, namely, the introduction to the subject by way of the alcohols. This book is so arranged that a teacher who prefers to start in the more orthodox fashion, with the hydrocarbons, may do so with little difficulty.

The revision includes reference to newer industrial processes and products such as the synthesis of higher alcohols from olefins, *n*-butyl alcohol from acetaldehyde, chloroprene from acetylene, and fluorine derivatives of methane. The traditional exposition of degradation through the series, $R—CH_2OH \longrightarrow R—CO_2H \longrightarrow RCONH_2 \longrightarrow R—NH_2 \longrightarrow ROH$, has been abandoned for reasons of scientific integrity. In the last step rearrangements occur so frequently and are sometimes so complete as to render this method valueless in the determination of structure. Unfortunately no suitable substitute can be offered in a book of this scope.

It is pleasing to note that the idea of structural units has been introduced in dealing with the natural polymers, rubber and cellulose. It would have been possible to extend a similar treatment to the proteins.

The present volume differs from the author's larger book[2] in the omission of mechanisms and theoretical interpretations. The brief text is unusually adequate and differs from many similar books in that a sound exposition of the principles of organic chemistry has not been sacrificed for the sake of brevity, and no undue emphasis has been given to fields of the author's special interests.

JOHN R. JOHNSON

Invisible Radiations of Organisms. By OTTO RAHN, Professor of Bacteriology, Cornell University. With an Introduction to the Physics of Radiation, by Sidney W. Barnes, Research Associate in Physics, University of Rochester. Verlag von Gebrüder Borntraeger, Koester-Ufer 17, Berlin W 35, Germany, 1936. x + 215 pp. 52 figs. 15 × 22.5 cm. Price, RM. 13.20.

This book is a very clear and precise presentation of the problem of mitogenetic radiation. It is extremely well written and the subject matter is arranged in a logical order.

The work has been written primarily to awake the interest of biologists. Hence, the introductory chapter (30 pages) gives an elementary description of the physics of radiation. The results of the electromagnetic and quantum theory of light are presented in a somewhat popular style and the various methods of intensity and frequency measurements are discussed with special emphasis on the limitations of the physical methods. The second and third chapters discuss the spectra of the light emitted by chemical and biochemical reactions and the effects of radiation on such reactions and on living cells.

Chapters IV, V and VI give a lucid account of the work on mitogenetic radiation and the proposed explanations of the mitogenetic effect. The investigations of Gurwitsch and Reiter and Gabor on onion roots, of Baron, Siebert, Tuthill and Rahn on yeast cells, and the use of bacteria and larger organisms as detectors are discussed in considerable detail. Against the negative results of Moissejewa the author quotes the investigations of Paul. The work with physical and physico-chemical detectors is considered to be inconclusive. Chapter IV ends with a short account of other radiations of biological importance, injurious human radiations, necrobiotic rays, infra-red and beta radiations. The peculiar properties of mitogenetic radiations, the effect of intermittent irradiation, production of secondary radiation and retardation of mitosis by an overdose are discussed in Chapter V. In Chapter VI the various interpretations of the mitogenetic effects are compared with the experimental facts. The author concludes that a cell is susceptible to mitogenetic radiation only when it is in a particularly physiological state.

The concluding chapter, VII, deals with the radiation from nerves, tissues and blood and connects the problem of mitogenetic radiation with the problems of growth, healing of wounds and cancer.

[1] Reviewed by W. H. Hunter, THIS JOURNAL, 51, 1619 (1929).

[2] J. B. Conant, "The Chemistry of Organic Compounds. A Year's Course in Organic Chemistry," The Macmillan Company, New York, 1933. x + 623 pp.

This monograph can be highly recommended to biologists as well as to chemists and physicists. It is written with great ability and remarkable fairness. Dr. Rahn is convinced, from his own experiences, that mitogenetic radiations exist, but he very frankly admits the occasional failure of the experiments and the contradictory nature of some results. In pointing out the mistakes of the mitogeneticists and their opponents, he has succeeded in giving a valuable guide for further research, which is needed before the proof of existence of the mitogenetic effect can be accepted.

HANS MUELLER

Die Korrosion metallischer Werkstoffe. (The Corrosion of Metallic Materials.) Vol. I. **Die Korrosion des Eisens und seiner Legierungen. (Corrosion of Iron and its Alloys.)** By OSWALD BAUER, OTTO KRÖHNKE and GEORG MASING, Editors. Verlag von S. Hirzel, Königstrasse 2, Leipzig, Germany, 1936. 560 pp. 219 figs. Price, RM. 37.50; bound, RM. 39.

This, the first of a series of four volumes, deals only with iron and iron alloy corrosion. Three additional volumes are in preparation. The second will cover the corrosion of non-metals, the third corrosion prevention, and the fourth will discuss important technical corrosion problems.

The first chapter, theoretical (by G. Masing), pp. 31–126, discusses: A—Corrosion of metals in electrolytes, under the headings, fundamental electrochemical phenomena, inhibited electrode phenomena, solution of metals accompanied by formation of hydrogen, corrosion accompanied by electrochemical consumption of oxygen, protective films, passivity, electrochemical behavior of alloys; B—Corrosion of metals by gases, under the headings, general, optical determination of the thickness of films, oxidation of metals, thick films. A short appendix on the behavior of metals with liquid non-electrolytes is included. The second chapter, the corrosion of iron (by C. Carius and E. H. Schulz), pp. 127–407, deals with corrosion as a physical chemical phenomenon, formation of galvanic cells, formation of rust, corrosion in natural waters and aqueous salt solutions, and atmospheric corrosion. In discussing the corrosion of commercial irons they include the effect of composition, heat treatment, surface condition, method of working, corroding media including chemicals, the effect of stresses, etc. There is a chapter on highly corrosive steels (by K. Daeves), pp. 408–429, and a chapter on acid and scale resistant iron alloys (by E. Houdremont and H. Schottky), pp. 430–529. This last chapter discusses: A—Iron-chromium alloys under phase diagrams, heat treatment and strength, other physical qualities, corrosion resistance with extensive tables, commercial requirements of heat resistant alloys, technical behavior, possibilities for utilization, and discussion; B—A short section on iron–nickel; and C—Iron–silicon alloys is included. Two pages of corrections and a well arranged name and subject index are included.

The present book is a compilation of published and unpublished data. Most of the material is critically reviewed. The authors are apparently unfamiliar with much of the literature, especially that outside of Germany. They refer to the first edition only of Speller's "Corrosion, Causes and Prevention." Of the four English and two German bibliographies mentioned by Speller they refer only to that of Rabald. The reviewer has checked many of the articles mentioned in Speller's (second edition) selected bibliography and finds only a few of those dealing with the topics which one would expect to find mentioned by the authors in Volume I. One finds no mention of the extensive work on soil corrosion, very little mention of the principles and methods of corrosion testing. On the whole, however, the present work is a valuable, well-prepared addition to the literature on the important subject of corrosion.

MERLE RANDALL

Introduction to Quantum Mechanics with Applications to Chemistry. By LINUS PAULING, Ph.D., Sc.D., Professor of Chemistry, California Institute of Technology, and E. BRIGHT WILSON, JR., Ph.D., Society of Fellows, Harvard University. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York City, 1935. xiii + 468 pp. 15.5 × 23.5 cm. Price, $5.00.

In spite of the many introductions to quantum mechanics which have appeared in the last few years, there would still seem to be room for a book on this subject addressed to the chemist and emphasizing the aspects of particular interest to him; this niche is admirably filled by the volume under review. It begins with a survey of classical mechanics and the old quantum theory. Then the Schrödinger wave equation is introduced, and its properties and the physical significance of its solutions are discussed. The hydrogen atom is discussed in great detail, and tables of eigenfunctions for a number of the lower energy levels are given; these should be convenient for reference for anyone who is making calculations with hydrogen-like functions. A great deal of the book is devoted to perturbation theory and its application to the electronic structure of atoms and molecules and to the binding energies of molecules, topics of great importance to the chemist, presented in detail and in easily comprehensible form. An elementary account of electron spin, sufficient for the purposes of the book, is given in an early chapter. There are also chapters on the variation method (with applications also in later chapters), the rotation and vibration of molecules, absorption and emission of radiation, some miscellaneous applications, and the general theory, including matrix mechanics and the uncertainty principle. Some useful mathematical material is given in appendices. Some topics usually treated in elementary books on wave mechanics are omitted as of little immediate use to the chemist. The reviewer cannot agree with the authors that this ground for omission holds in the case of aperiodic processes, but the inclusion of this subject would undoubtedly have required considerably more space, and in general the topics are well selected to fulfill the purposes for which the book is intended. Detailed application of the theoretical development to experimental material is confined for the most part to a few of the simplest cases, such as the hydrogen atom, the helium atom, the hydrogen molecule, and the hydrogen molecule-ion (in which cases great detail is given). Inclusion of more material of this sort probably would have been desirable, but again would have lengthened the book, and enough of the theory is given to make reference to the original literature sufficiently easy.

The wave equation is introduced in an early chapter as a fundamental hypothesis. This course is quite as satisfactory as any other from a purely logical point of view, though the reviewer believes that some preliminary discussion of the relation between wave and corpuscle aspects of radiation and matter, designed to show the reasonableness of this hypothesis, would have made matters easier for the beginner. The first two chapters on classical mechanics and the old quantum theory do not quite seem to take the place of such a discussion. However, in general, the book is clearly and carefully written, so as to reduce the mathematical difficulties to a minimum. A reviewer's opinion of the clarity of an exposition of a subject with which he is already acquainted is perhaps to be questioned; in this case the reviewer's judgment on this matter has been corroborated by conversation with people who have been reading the volume with the purpose of learning the subject. He believes, therefore, that there is no doubt that this book will prove extremely valuable to those studying the subject for the first time. But, also, its later chapters constitute an excellent reference work for investigators doing research in this field, especially useful for the detailed accounts given of many important subjects.

O. K. RICE

Die Thermodynamik einheitlicher Stoffe und binärer Gemische, mit Anwendungen auf Verschiedene physikalisch-chemische Probleme. (**The Thermodynamics of Simple Substances and Binary Mixtures,** with Application to Various Physico-chemical Problems.) By DR. J. J. VAN LAAR. G. E. Stechert, New York, or P. Noordhoff N. V., Groningen und Batavia, 1936. 279 pp. Price, $8.00; bound, $9.00.

The first 145 pages are devoted to the chemical elements. Here the equation of state is developed in detail and the various constants entering into the thermodynamic equations are presented in tabular form. In the second part of the book there is a chapter on Gibbs' thermodynamic potential and the application of the theorem of homogeneous functions to the study of mixtures. The complexities of the equilibrium between phases of binary mixtures are treated in considerable detail. The book may find some use as a reference source for data and for the equations of classical thermodynamics, but it certainly will not prove of any value as a textbook in America. One looks in vain for the numerous experimental and theoretical advances which have been made in this country and abroad in recent years. The reviewer could locate nothing on the third law or the modern applications of statistics. Two pages are devoted to Debye's electrolyte theory which is followed by a page on Ghosh's theory. Both presentations were very disappointing. The activity concept is dismissed as "ein leeres Wort." There are very few data in the book which have been obtained since 1920. The entire presentation is not only mathematically formidable, but appears to be unduly complicated and terrifying.

VICTOR K. LA MER

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. Meyer. **Aluminium-legierungen.** Patentsammlung geordnet nach Legierungs-systemen. (Aluminium Alloys. A Collection of Patents.) Parts I–II. By A. Grützner with the Collaboration of G. Apel. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1936. 342 + 526 pp. Price, RM. 35 + 40.50.

This collection of patents on aluminum alloys is published as an Appendix to the volumes on Aluminum (Part A) of Gmelin's Handbook of Inorganic Chemistry, 8th Edition. The Introduction states that it covers completely the patent literature on these alloys from 1887 to May, 1935. The patents are arranged in a continuous table. The constituent elements of each alloy are listed serially in alphabetical order and the alloys thus characterized are themselves also arranged in alphabetical order. This makes it possible to find out quickly and easily whether an alloy of any given composition is protected by patents, and the very laborious and time-consuming search through the patent literature of all countries which would otherwise be required, is thus avoided.

This volume does not attempt to cover at all the literature dealing with aluminum alloys published in scientific journals, etc., since this information is available in the volumes on Aluminum (Part A) of the Gmelin Handbook.

ARTHUR B. LAMB

Dynamics of Rigid Bodies. By WILLIAM DUNCAN MACMILLAN, A.M., Ph.D., Sc.D., Professor of Astronomy, The University of Chicago. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York, N. Y., 1936. xiii + 478 pp. 80 figs. 16 × 23.5 cm. Price, $6.00.

This book is the third of a series on theoretical mechanics by the same author, the first two being "Statics and the Dynamics of a Particle" and "The Theory of the Potential." The present volume is independent of the first two, however, and contains a good deal of general dynamical theory besides the specialized applications to rigid bodies. Thus, the algebra of vectors, systems of free particles, impulsive forces, Lagrange's and Hamilton's equations are treated quite fully, in addition to a wide variety of problems involving rigid bodies.

Although this work covers a difficult field and will be especially useful to advanced students, the presentation is in general clear and complete, so that any reader with a knowledge of elementary physics and the usual undergraduate courses in differential equations should find it very profitable reading. A number of mathematical concepts are described in the text in connection with their application to dynamical problems; for example, the algebra of matrices, which is used in the last chapter in the discussion of the method of periodic solutions.

The index is satisfactory, and in general the mechanical details, such as choice of type, page arrangement, printing and binding are of the usual high standard maintained by the publisher. Very few misprints were noticed.

This reviewer regrets that the conventional method of defining the Eulerian angles was used, since it seems much simpler to call θ and φ the ordinary polar coördinates of the moving ζ-axis and then to define the third angle as usual (wave mechanicians would appreciate in addition the use of some other symbol besides ψ).

Except for the above trifling criticism, this reviewer found considerable pleasure and profit in reading the book and recommends it to anyone who is interested in dynamics.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE WEST VIRGINIA AGRICULTURAL EXPERIMENT STATION]

The Anthocyanin Pigment of the Winesap Apple[1]

BY IRA J. DUNCAN AND R. B. DUSTMAN

It is known that the coloration of fruits is affected by a number of factors including light, temperature, supply of nitrogen and moisture from the soil, concentration of carbohydrates and organic acids in the cells and perhaps by other factors. Due to the commercial importance of apple-growing in West Virginia and due to the desirability of high color on apples in the market, it was deemed advisable to undertake an investigation of the red pigment of the apple at this station. The first logical step in an investigation of this type involves a determination of the nature of the substance in question. The present work deals with the isolation, purification, identification and determination of the chemical nature of this pigment.

Historical

During the past fifty years considerable work has been done on the chemistry of the natural coloring matter of flowers, fruits and berries. Willstätter and his co-workers were pioneers in these investigations. In their work on the cornflower Willstätter and Everest[1a] cleared up many experimental difficulties encountered in the investigation of plant pigments. They also introduced a rapid test to distinguish glucoside from non-glucoside pigments. The work of Robinson,[2] Karrer,[3] Anderson[4] and many others during recent years has contributed much information to our knowledge of anthocyanin pigments.

These pigments occur in plants as glucosides, accompanied in a few instances by a small amount of sugar-free pigment. In the substances so far reported the sugar occurring in combination with the non-glucoside fraction is glucose, galactose or rhamnose, but by far the most common is glucose.

Robinson and Robinson[2] developed a rapid method for testing qualitatively the anthocyanins occurring in leaves, flowers and fruits. In this method the pigments are characterized by observing their color reactions with alkalies and ferric chloride, and considerable use is made of their distribution between immiscible solvents. The work of these investigators indicated that the skins of the Winesap and Jonathan apples contain the pigment cyanidin 3-monoside. The work of these and other investigators indicates that in the monoglucosides the sugar molecule is attached to the number three carbon atom.

Experimental

From time to time during the fall of 1933 and 1934 quantities of Winesap apples ranging from 7 to 25 bushels were procured and efforts were made to isolate the red pigment

from the skins by using various methods[4b,5] described for the preparation of the pigment of the grape, cranberry and certain flowers. These methods failed to give satisfactory yields of apple pigment. The difficulty was probably due to the relatively low percentage of red pigment in the skins as they were removed. Extracting a given weight of skins even when a minimum volume of extracting liquid is employed results in a relatively dilute solution of the pigment and a high concentration of sugars, waxes, gums and other impurities.

Finally, the method of Willstätter and Burdick[6] used for the isolation of asterin and callistephin from the flowers of the purple-red aster, with some modifications, was found to give fair results. Consequently the skins from fifteen bushels of apples were placed in two-gallon, wide-mouthed jars, and the red pigment was extracted with ethyl alcohol containing 0.1% hydrochloric acid. After twenty-four hours the alcoholic solution was filtered and the coloring matter in the filtrate was precipitated with neutral lead acetate solution. After standing for twelve hours the green gelatinous precipitate of the lead salt was filtered, washed with cold water and allowed to remain on the filter until practically air-dry. The precipitate on the filter was then treated with glacial acetic acid. This dissolved the coloring matter completely and left many colorless impurities undissolved. The pigment was precipitated from the dark-red acetic acid filtrate with two volumes of ether. The lead salt thus obtained was filtered and decomposed on the filter with a mixture of propyl alcohol and methyl alcohol containing 25% hydrochloric acid in the ratio of 10 to 1 by volume. This process left still other impurities undissolved. On treating the alcoholic filtrate with 3 or 4 volumes of ether the coloring matter was precipitated as the chloride salt. This precipitate was filtered, washed with ether and then dissolved in ethyl alcohol containing 0.1% hydrochloric acid. The lead salt was again formed by treating the alcoholic solution with neutral lead acetate solution. After filtering, washing and drying the entire purification process was repeated by resolution in acetic acid, precipitation with ether, decomposition of this precipitate with the propyl alcohol–methyl alcoholic hydrochloric acid mixture, and precipitation finally of the chloride salt with ether. The chloride salt was converted to the picrate by dissolving in warm water and treating the solution with warm picric acid solution. The picrate was again converted to the chloride by solution in methyl alcohol containing 5% hydrochloric acid and treating the acid alcoholic solution with 4 or 5 volumes of dry ether. The chloride precipitated as a red amorphous powder. Crystallization by slow evaporation of the alcohol from a mixture of aqueous hydrochloric acid and ethyl alcohol yielded long needle crystals having a bronze metallic luster. Five additional crystallizations yielded a product free from amorphous material and apparently pure.

A small amount of the chloride salt was again converted to the picrate and the picrate recrystallized from warm water. Fine brownish-red needles were formed. The picrate gave a cherry-red solution in ethyl alcohol and an orange-red solution in water. When a drop of the latter solution was placed on a filter paper it produced a spot with a violet center and yellow exterior. This is the result of hydrolytic dissociation according to Willstätter and Mallison.[5] The picrate is partially decomposed when an aqueous solution is heated above 70°.

The anthocyanin chloride is very soluble in water giving a brownish-red solution which assumes a bluish tinge when greatly diluted. The color does not fade entirely on standing, and a faint red color remains even after boiling. The salt is soluble in ethyl and methyl alcohols producing bluish-red solutions; it is soluble also in very dilute hydrochloric acid but in 7% hydrochloric acid it is almost insoluble. A number of color reactions with inorganic salts were observed. An aqueous solution of the glucoside, previously acidified slightly to prevent decolorization, gave a purplish-red color with a solution of sodium acetate, while sodium carbonate gave a violet color. Sodium or potassium hydroxide gave at first a blue color which changed to green and then to yellow. The red color was not restored on acidification, showing decomposition had taken place with these alkalies. The pigment is precipitated by neutral lead acetate from both alcoholic and aqueous solution, giving blue and purple lead salts, respectively. One drop of very dilute ferric chloride solution gave a deep purple color when added to an aqueous solution of the pigment and a blue color when added to an alcoholic solution.

The bronze luster of the air-dried chloride salt changed to a green color when the salt was dried over sulfuric acid but the bronze color returned on exposure to the atmosphere for a short time. The dry salt melted with decomposition at 210–212°. Apparently the glucoside loses all of its water of crystallization when dried over sulfuric acid at room temperature in a vacuum desiccator at one mm. pressure for forty-eight hours, since no further loss occurred when it was heated at 108° for an additional twenty-four hours in a vacuum of one to five mm. pressure.

Analyses of the air-dried chloride salt of the pigment gave C, 47.31; H, 4.88; Cl, 6.69; O, 41.12 (by difference); and H_2O, 8.58, respectively. Calculation of the empirical formula gave $C_{21}H_{21}O_{11}Cl \cdot 2.5H_2O$, which requires C, 47.58; H, 4.95; Cl, 6.70; O, 40.78 and H_2O, 8.51, respectively. No methoxy groups are present in the molecule. C, H, Cl and methoxy groups were determined by Pregl's micro methods.[7] The analytical values given are averages of triplicate determinations throughout the paper.

Calculation of the percentage composition of the water-free glucoside from the experimental values gave: C, 51.75; H, 4.30; Cl, 7.33; and O, 36.62 (by difference). $C_{21}H_{21}O_{11}Cl$ requires C, 52.01; H, 4.33; Cl, 7.32; and O, 36.44.

The analyses, the physical and chemical properties and the color reactions of the pigment of the Winesap apple agree closely with those of idaein chloride isolated from the cranberry by Willstätter and Mallison.[5]

Quantitative Hydrolysis of the Glucoside

The glucoside pigment, presumably idaein chloride, 0.2591 g., was hydrolyzed by dissolving in 10 cc. of water, adding 10 cc. of concentrated hydrochloric acid and boiling

the acid solution for two and one-half minutes. Crystals of the anthocyanidin chloride began to separate after the solution had boiled for one minute. At the end of two and one-half minutes the solution was immediately cooled and placed in the refrigerator for several hours. The non-glucoside salt separated from the solution as long red-brown needles with a metallic luster. These were collected in a weighed, fritted-glass bottom crucible, washed with a little cold 7% hydrochloric acid and dried over sulfuric acid. Recovery of the air-dried anthocyanidin chloride amounted to 64.09% of the original weight. $C_{21}H_{21}O_{11}Cl \cdot 2.5\ H_2O$ theoretically yields 64.24% of anthocyanidin chloride.

The sugar in the filtrate from the hydrolysis of the glucoside was identified in the following manner: the slightly red acid solution was neutralized with solid lead carbonate, the resulting lead chloride precipitate was filtered and the excess lead was removed from the filtrate by precipitation with hydrogen sulfide. The filtrate from the hydrogen sulfide precipitate was neutralized with solid sodium bicarbonate and the solution was concentrated to a small volume by evaporation at 40–45° before an electric fan. The yellow solution was decolorized with Norit and the colorless sugar solution in a test-tube was converted to the osazone by adding to it 0.160 g. of pure phenylhydrazine hydrochloride and 0.240 g. of sodium acetate and heating in a boiling water-bath. The osazone separated after several minutes as clusters of orange-yellow needles. After thirty minutes in the boiling water-bath the contents of the tube were allowed to cool. The osazone was then filtered, washed with cold water and twice recrystallized from hot 10% aqueous pyridine solution. The purified osazone melted at 195–196° with decomposition. The melting point corresponds to that of galactosazone. A mixture of galactosazone, prepared from pure galactose, and the unknown osazone mixed in about equal proportions also melted at 195–196° with decomposition. The identification of the sugar as galactose was further confirmed by saccharimetric readings and copper oxide reduction values on a solution of the sugar. The specific rotation of the unknown sugar calculated from the saccharimeter readings was +81.0° at 20°. The specific rotation of galactose is recorded as +80.2° at 20° when determined on a 1% solution.[8] Likewise, the copper oxide values for the unknown sugar averaged 4.3% higher than the corresponding values for an equivalent weight of pure galactose when the latter was subjected to the same acid treatment as that used to hydrolyze the glucoside.

The anthocyanidin chloride obtained by the hydrolysis of the glucoside was recrystallized by dissolving in ethyl alcohol, adding one-half its volume of 7% hydrochloric acid, and allowing the alcohol to evaporate slowly from a loosely covered beaker. After twenty-four hours the crystals were filtered and three times recrystallized by the same procedure. The final crystallization yielded a product free from amorphous material and apparently pure. The anthocyanidin chloride is soluble in methyl and ethyl alcohols giving beautiful violet-red solutions. It is much less soluble in water and only slightly soluble in dilute hydrochloric acid. The crystals failed to melt when heated to 350°. Dilute solutions of inorganic reagents gave the following results: ferric chloride changed the color of an aqueous solution of the pigment from red to violet; lead acetate gave a violet precipitate of the lead salt; sodium or potassium hydroxide gave a blue color which on standing turned green and then brown; sodium carbonate when added to an aqueous or alcoholic solution of the pigment gave first a violet then a blue color; ferric chloride when added to an alcoholic solution gave a pure blue color.

The non-glucoside salt loses its water of crystallization when heated to 108° for twenty-four hours at one to five mm. pressure.

Analyses of the air-dried sample of the anthocyanidin chloride gave C, 52.64; H, 3.95; Cl, 10.43; O, 32.98 (by difference); and H_2O, 5.55, respectively. Calculation of the empirical formula gave $C_{15}H_{11}O_6Cl \cdot H_2O$, which requires C, 52.85; H, 3.85; Cl, 10.41; O, 32.89; and H_2O, 5.29, respectively. Calculation of the percentage composition of the water-free salt gave C, 55.73; H, 3.53; Cl, 11.04; O, 29.70 (by difference). $C_{15}H_{11}O_6Cl$ requires C, 55.80; H, 3.44; Cl, 10.99; O, 29.77.

Here also the analyses, the physical and chemical properties and the color reactions of the unknown anthocyanidin chloride correspond very closely to cyanidin chloride. The identity with cyanidin chloride was further confirmed by the products formed when it was fused with alkali. The material was heated with potassium hydroxide and a small amount of water in a crucible at 210–220°. Decomposition took place in about one minute. After five minutes the temperature was raised rapidly to 250° for just a moment. After the melt had cooled it was dissolved in water, the solution was neutralized with hydrochloric acid and the slightly acid solution was shaken out with ether. After evaporation of the ethereal solution the residue was dissolved in warm water, made slightly alkaline with sodium bicarbonate and again shaken with ether. The sodium bicarbonate solution, from which the phenol was removed, was then acidified weakly and shaken with ether to remove the acid portion. The two ether solutions were evaporated to dryness and the residues dissolved in warm water. The aqueous solutions were decolorized with Norit, filtered and the filtrates were evaporated until crystals began to separate. Solid compounds separated on cooling. The phenolic constituent was shown to be phloroglucinol by the intense red color imparted to a pine shaving when immersed in concentrated hydrochloric acid. Also, the crystalline form appeared identical with that of pure phloroglucinol when both were crystallized under similar conditions. The acid constituent was probably protocatechuic acid as characterized by the greenish color produced with ferric chloride and by the sublimate it formed when heated. The sublimate gave the green color test for catechol when treated with ferric chloride. The identity of the acid portion could not be fully confirmed because of the small amount of material available. No other constituents were found. Since the alkali decomposition products of cyanidin chloride are phloroglucinol and protocatechuic acid, the identity of the anthocyanidin chloride obtained from the apple is further confirmed as cyanidin chloride.

Summary

The anthocyanin pigment in the skins of Winesap apples has been isolated in pure form and

---

(8) "International Critical Tables," Vol. II, p. 351.

identified as idaein chloride, a pigment which Willstätter and Mallison[5] isolated from the cranberry. The glucoside was isolated as the lead salt. By the use of differential solvents it was partially purified and was then converted to the picrate. The pigment was eventually obtained in pure form as the chloride salt. The anthocyanin chloride on hydrolysis yields molecular proportions of cyanidin chloride and galactose.

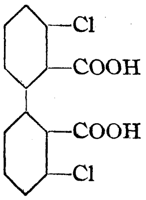
The Constitution of the Isomeric Dichlorofluorenone Carboxylic Acids Formed by the Action of Sulfuric Acid on 3,3′-Dichlorodiphenic Acid

BY ERNEST H. HUNTRESS AND EDWARD R. ATKINSON

Earlier work in this Laboratory[1] has shown that when 3,3′-dichlorodiphenic acid (I) is heated with concentrated sulfuric acid at 170° there is formed a ketocarboxylic acid isomeric with, but different from, the 1,6-dichlorofluorenone-5-carboxylic acid (II) quantitatively obtained at 125°. This isomeric acid (designated in the cited reference as "Acid X") has now been identified as 1,6-dichlorofluorenone-4-carboxylic acid (VII) and is identical with the product obtained by the action of sulfuric acid upon 5,5′-dichlorodiphenic acid (VI). Experiments undertaken to elucidate such an unexpected result have now led to the further discovery that 1,6-dichlorofluorenone (XI) and 1,8-dichlorofluorenone (XII) are converted to 3,6-dichlorofluorenone (XIII) on heating in concentrated sulfuric acid. The rearrangement of fluorenones with other substituents is being examined further.



I

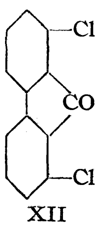
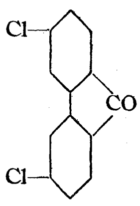
XI



XII



XIII

In carrying out the preparation of the isomeric ketocarboxylic acids from 3,3′-dichlorodiphenic acid (I), it is now evident that our previous isolation of 1,6-dichlorofluorenone-5-carboxylic acid (II) after heating the 3,3′-dichlorodiphenic acid in sulfuric acid at 125° for one hour was fortuitous, since if the treatment be continued longer (*e. g.*, for five hours) the product is 1,6-dichlorofluorenone-4-carboxylic acid (VII) ("Acid X"). A brief study of the temperature at which this isomerization occurs is given in the Experimental Part.

This change does not occur when phosphoric acid is used instead of sulfuric acid. With phosphoric acid at 215°, 3,3′-dichlorodiphenic acid yields only 1,6-dichlorofluorenone-5-carboxylic acid (II); 5,5′-dichlorodiphenic acid (VI) similarly treated gives only 1,6-dichlorofluorenone-4-carboxylic acid (VII). Thus, although phosphoric acid does not effect rearrangement, it does cause ring closure.

The Evidence for the Structure of 1,6-Dichlorofluorenone-5-carboxylic Acid (II)

The original data on this acid[2] have been confirmed and extended. The acid gives correct analysis for halogen and the expected neutralization equivalent. On treatment with thionyl chloride it yields the corresponding acid chloride (m. p. 180–181°, uncorr.) and this with ammonium hydroxide gives an amide (m. p. 281°, uncorr.). The latter yields[1] (p. 4268) an amine (m. p. 257°, uncorr.). These three derivatives are all distinctly different from the corresponding products of the "Acid X" series, and the depression of corresponding mixed melting points has been confirmed. Furthermore, this keto acid on heating gave 1,6-dichlorofluorenone (XI). In addition to the above results, we have also been able to effect the deamination of the aminodichloroflu-

renone obtained above from the keto acid chloride and have likewise obtained 1,6-dichlorofluorenone (XI). Finally the keto acid has been oximated and the resultant derivative hydrolyzed back to the original compound.

Characterization of "Acid X" as 1,6-Dichlorofluorenone-4-carboxylic Acid (VII)

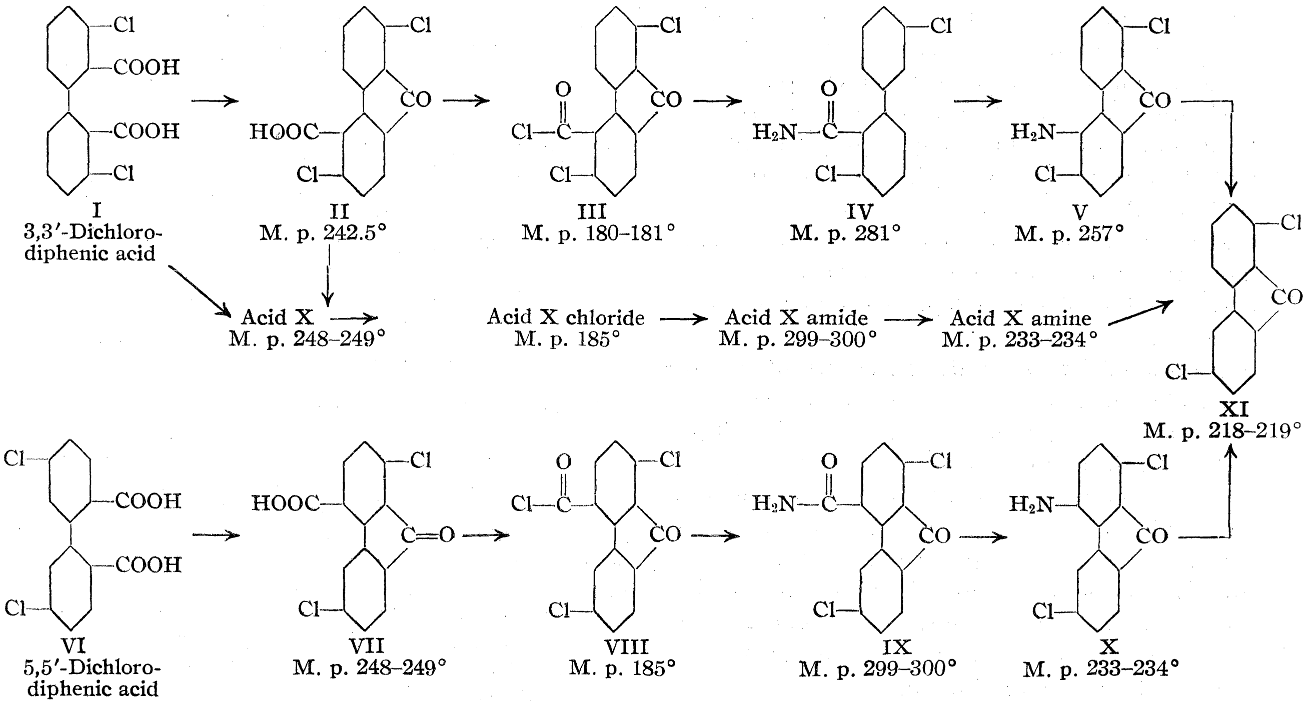
Improved Physical Constants of "Acid X" and its Derivatives.—As a result of much further experience in the preparation and purification of "Acid X" and its derivatives, products with higher melting points than those reported in the earlier paper[1] have been obtained. These are indicated in Chart I. The melting points of the acid, acid chloride, acid amide, amine, and corresponding deaminated ketone of the "Acid X" series, were found to be identical with those for the corresponding compounds of the 5,5′-dichlorodiphenic acid series. Furthermore, the melting points of mixtures of corresponding derivatives were *not depressed.* The structure of "Acid X," therefore, is that of 1,6-dichlorofluorenone-4-carboxylic acid and the relations of the various series of derivatives are portrayed in Chart I.

Our previous difficulty in obtaining satisfactory neutralization equivalents for "Acid X" was at first again experienced in the present work and, as might be expected, since the two are identical, a similar difficulty in obtaining satisfactory values for 1,6-dichlorofluorenone-4-carboxylic acid (VII) (in contrast to the satisfactory value for the latter obtained in our last paper where impure material was used).

Many determinations of the neutralization equivalent of this acid (either as "Acid X" or as 1,6-dichlorofluorenone-4-carboxylic acid) and also halogen analyses on various samples showed that it formed compounds with the solvents used for crystallization. The melting points of all samples, regardless of solvent present, was 248–249°. The samples were desolvated by methods described in the Experimental Part and then gave the theoretical values for the neutralization equivalent.

The Direct Decarboxylation of "Acid X."—Earlier attempts to decarboxylate "Acid X" by dry heating under reduced pressure had been unsuccessful, due to its sublimation in unchanged condition; 1,6-dichlorofluorenone-5-carboxylic acid, on the other hand, had readily lost carbon dioxide and given 1,6-dichlorofluorenone. Dur-

CHART 1.—RELATIONSHIPS OF 3,3′- AND 5,5′-DICHLORODIPHENIC ACIDS AND THEIR DERIVATIVES



The substances of the "Acid X" series are identical with the substances derived from VI and represented by VII to X, respectively.

ing this present work it was noticed that certain non-acidic substances were present in the crude product from the treatment of 3,3′-dichlorodiphenic acid (I) and 5,5′-dichlorodiphenic acid (VI) with sulfuric acid at the higher temperatures. This suggested that concentrated sulfuric acid might serve as an aid in the decarboxylation of "Acid X." Such proved to be the case and experiment showed that on heating in sulfuric acid at about 200° there was obtained 3,6-dichlorofluorenone (XIII) accompanied by small quantities of unidentified material. Identification of the 3,6-dichlorofluorenone was facilitated by the fact that it is the highest melting of the three dichlorofluorenones involved in this work. That the sulfuric acid was not merely serving as a medium for heat transfer is indicated by our observation that upon its replacement by phosphoric acid neither decarboxylation nor rearrangement occurred.

The Rearrangement of the Dichlorofluorenones

In the course of the work on the decarboxylation of "Acid X" (1,6-dichlorofluorenone-4-carboxylic acid) by heating in sulfuric acid, it was discovered that under the conditions employed 3,6-dichlorofluorenone (XIII) was obtained. Since the other evidence for the 1,6-position of the chlorine atoms in the acid seemed entirely reliable, the observation suggested that 1,6-dichlorofluorenone itself (and perhaps also other dichlorofluorenones) might suffer rearrangement on heating with sulfuric acid. It was then found that although 3,6-dichlorofluorenone is stable in concentrated sulfuric acid at 185–200° for forty-five minutes, both 1,6- and 1,8-dichlorofluorenone undergo rearrangement to 3,6-dichlorofluorenone. This was identified by the failure of it and of the corresponding oxime to depress the melting point of authentic samples.

Additional Proof for the Structure of the Dichlorofluorenones.—The previous evidence for the structure of the dichlorofluorenones was as follows.

1,6-Dichlorofluorenone.—Obtained by direct heat decarboxylation of 1,6-dichlorofluorenone-5-carboxylic acid. The oxime of this fluorenone described in an earlier paper[2] (p. 2565) (m. p. 230°) appears to be that individual of two possible stereoisomers which is formed in preponderant amount. On hydrolysis with dilute sulfuric acid it yielded 1,6-dichlorofluorenone.

1,8-Dichlorofluorenone.—The previous work showed that this product was obtained by the action of heat on 3,3′-dichlorodiphenic acid anhydride and that it formed an oxime with great difficulty. Its structure has now been further supported by its preparation from distillation of calcium 3,3′-dichlorodiphenate.

3,6-Dichlorofluorenone.—The structure of this product was assigned because of its previous formation by heating the anhydride of 5,5′-dichlorodiphenic acid. It has now been prepared by distillation of the calcium salt of that acid.

Experimental Part

All melting points reported in this paper were taken by the method described in Mulliken's "Identification of Pure Organic Compounds," Vol. I, page 218, on a 360° rod form melting point thermometer immersed in the sulfuric acid to the 0° point. All melting points are uncorrected.

Temperatures at which 1,6-Dichlorofluorenone-5-carboxylic Acid (II) Isomerizes to 1,6-Dichlorofluorenone-4-carboxylic Acid ("Acid X") (VII).—As indicated in the following table, the isomerization has been found to occur at a temperature considerably lower than that previously described. Since "Acid X" was much less soluble in solvents than its isomer, its detection in mixtures of the two compounds (even when present in small proportion) was readily effected. Such was not the case, however, with the isomeric acid.

The crude products were purified by the method previously described for the individual acids. Only those experiments are here cited in which the product consisted mainly of one isomer. In general 3 cc. of c. p. concd. sulfuric acid was used for every gram of original material. The identity of the purified substances was established by mixed melting points with authentic samples.

Table I

Original substance	Temp. of H_2SO_4, °C.	Time of heating, hr.	Product
3,3′-Dichlorodiphenic acid	150–160	1	"Acid X"
	135–145	4	"Acid X"
	125	1	1,6 - dichlorofluorenone-5-carboxylic acid
	125	5	"Acid X"
	95–104	1	1,6 - dichlorofluorenone-5-carboxylic acid
	80–90	24	1,6 - dichlorofluorenone-5-carboxylic acid
"Acid X"	95–99	10	"Acid X"

Phosphoric Acid as a Condensing Agent.—Sirupy phosphoric acid (85%) was heated at 160° for one hour until evolution of water ceased. One-tenth gram of 3,3′-dichlorodiphenic acid was heated in 2 cc. of this phosphoric acid at 200° but no solution occurred. At 215°, however, a brown solution formed after two hours and from this, by the purification used in the sulfuric acid condensations, there was obtained pure 1,6-dichlorofluorenone-5-carboxylic acid, with no detectable amounts of "Acid X." A similar experiment with 5,5′-dichlorodiphenic acid gave 1,6-dichlorofluorenone-4-carboxylic acid ("Acid X").

Oximation of 1,6-Dichlorofluorenone-5-carboxylic Acid (II).—Three-tenths of a gram of the acid in 15 cc. of alcohol was refluxed for forty-five minutes with 0.43 g. of hydroxylamine hydrochloride in 5 cc. of water. The oxime separated after further dilution. In some runs sodium bicarbonate solution was used and the oxime precipitated by acidification. The melting point of the resulting oxime varied irregularly on recrystallization from various solvents, but the product from dilute acetone generally melted at 263°, dec. No attempt was made to separate the possible stereoisomeric forms. The oxime was not hydrolyzed by boiling 6 *N* sodium hydroxide, nor by concentrated sulfuric acid, but when refluxed for two hours with 50% sulfuric acid, the original keto acid was regenerated.

1,6-Dichlorofluorenone (XI) from 1,6-Dichloro-5-aminofluorenone (V).—In a typical run, 0.1 g. of amine was suspended in a mixture of 10 cc. of alcohol with 0.8 cc. of concentrated sulfuric acid. To the suspension at 0° a concentrated aqueous solution of sodium nitrite was added slowly until excess was present, motor stirring being used. After a heavy precipitate of diazonium salt formed 20 cc. of alcohol was added and the mixture stirred ten minutes at 0°. One-half gram of copper bronze was added and the mixture warmed until evolution of acetaldehyde ceased. After standing for twelve hours the pale yellow product was filtered off and sublimed at 150–190° under 18 mm. pressure. The product weighed 0.05 g. and melted at 217–218°. It did not depress the melting point of an authentic sample of 1,6-dichlorofluorenone. It was converted to the oxime by the procedure previously described[2] (p. 2565); the product so obtained melted at 230° dec. and did not depress the melting point of an authentic sample of the oxime.

The Neutralization Equivalent of 1,6-Dichlorofluorenone-4-carboxylic Acid ("Acid X") (VII).—The titrations were carried out in neutral alcohol using 0.1 *N* sodium hydroxide with phenolphthalein as indicator. If a pure sample (m. p. 248–249°) was crystallized from glacial acetic acid and then titrated, values from 177.8 to 261.2 were obtained (calcd. 293). Either the material recovered from these determinations or fresh material again recrystallized from dilute alcohol, gave neutralization equivalents varying from 296.8 to 301.4. Similar results were obtained on products from aqueous dioxane.

Halogen analyses on the products from acetic acid or from dilute alcohol were always low: *e. g.*, from acetic acid, Cl found, 21.67, 22.41; from dilute alcohol: Cl found, 23.32, 22.75; calculated for $C_{14}H_{16}Cl_2O_3$: Cl, 24.23%. This suggested possibility of solvation.

The product from acetic acid was desolvated by drying in a vacuum oven for five hours at 110°, during which time the needle-like crystals effloresced completely. In some cases samples were desolvated by solution in anhydrous benzene, boiling with decolorizing carbon, and adding ligroin, the precipitated solid being dried at 110°. In one instance no ligroin was added and on cooling, brilliant yellow needles formed which apparently consisted of an addition compound with benzene since they effloresced rapidly at 110°.

All desolvated samples showed the same melting point as the solvates from which they were derived (248–249° in every case). Titration of the desolvated samples gave neutralization equivalents of 294.3, 291.6, 293.3, 291.6, calculated 293.

Direct Decarboxylation of 1,6-Dichlorofluorenone-4-carboxylic Acid ("Acid X") (VII).—In a typical experiment, 0.1 g. of the acid was heated in 1 cc. of C. P. concd. sulfuric acid at 200–215° for one hour. Gas evolution was noticed. The solution was poured on ice and the dark brown solid shaken with dilute sodium bicarbonate solution to remove acidic substances. The undissolved residue was then filtered off, dried and sublimed. At one atmosphere and 140–165° a light sublimate melting at 205–230° first formed which represented about 10% of the total product. The pressure was then reduced to 10 mm. and at 160–180° a bright yellow sublimate, melting at 299–300°, formed. There was also a non-sublimable sulfur-containing residue of high melting point. In other experiments the crude product was recrystallized from dilute acetone before sublimation. The low melting sublimate, obtained in all runs, was not identified.

The sublimate melting at 299–300° was shown to be 3,6-dichlorofluorenone. It did not depress the melting point of an authentic sample and it gave an oxime of m. p. 246–247° which also did not depress the melting point of authentic 3,6-dichlorofluorenone oxime. This portion usually represented about 90% of total sublimate.

The same results were obtained when 3,3'-dichlorodiphenic acid, 5,5'-dichlorodiphenic acid and 1,6-dichlorofluorenone-5-carboxylic acid, all of which are known to yield "Acid X" at the temperatures used, were heated in sulfuric acid at about 200°. The non-acidic material obtained during preparative runs on "Acid X" at 170° also consisted chiefly of 3,6-dichlorofluorenone.

The Rearrangement of the Dichlorofluorenones.—Fifty milligrams of pure 3,6-dichlorofluorenone (m. p. 300°) was heated in 1 cc. of C. P. concentrated sulfuric acid at 185–200° for forty-five minutes. The color of this solution was deep violet. After pouring on ice, the resulting solid was dried and sublimed. At 140–165° and 1 atm. a small amount of light yellow sublimate formed, but at 180° and 10 mm. pure 3,6-dichlorofluorenone was recovered. There was also a small sulfur-containing residue which did not sublime under these conditions.

Approximately 500 mg. of pure 1,8-dichlorofluorenone (m. p. 254°) was heated in 5 cc. of C. P. concd. sulfuric acid for forty-five minutes at 180–190°. The deep brown solution slowly changed to the violet color characteristic of 3,6-dichlorofluorenone. The product was separated in the usual way. At 140–160° and 1 atm., 20 mg. of a sublimate, m. p. 200–225°, was removed and at 180° and 10 mm. 70 mg. of pure 3,6-dichlorofluorenone sublimed. There was also a residue which did not sublime. The product of 3,6-dichlorofluorenone was converted into the oxime (m. p. 246–247°, dec.) and this oxime did not depress the melting point of an authentic sample.

Fifty milligrams of pure 1,6-dichlorofluorenone (m. p. 218°) was heated at 150° in 2 cc. of C. P. concd. sulfuric acid for thirty minutes. The color change from brown to violet was again noted. On subliming the product there was obtained at 150° and 1 atm. a small amount of sublimate, m. p. 195–215°, and at 180° and 10 mm., pure 3,6-dichlorofluorenone. This experiment was repeated using 70 mg. of 1,6-dichlorofluorenone and heating at 125° for forty minutes. The sublimate was separated into two fractions as before, which, however, were *equal* in amount.

the one having m. p. 199–230°, the other m. p. 299–300° (3,6-dichlorofluorenone). There was no residue from these sublimates. This experiment indicates that while the rearrangement occurred at 125° it was not complete in forty minutes. As before the product of 3,6-dichlorofluorenone gave an oxime identical with authentic 3,6-dichlorofluorenone oxime.

1,6-Dichloro-4-aminofluorenone (X) and its Deamination.—Both the preparation and deamination of this amine have been described previously[1] (p. 4268) when the substance was derived from "Acid X." In this work the substance has been derived from 1,6-dichlorofluorenone-4-carboxylic acid which had been prepared from 5,5′-dichlorodiphenic acid.

The preparation of the amine was carried out by a modified method which gave much better results. Potassium hydroxide was used; the ratio of excess alkali to hypobromite was 3/1; the amide–hypobromite ratio was 1/1.2; the concentration of the hypobromite was about 0.0002 mole per cc. of solution; motor stirring was used. Recrystallization from benzene and ligroin gave the amine of m. p. 233–234°, dec. The deamination of this amine was carried out by the procedure previously described for the amine derived from "Acid X."

Summary

1. "Acid X," formed by the rearrangement of 1,6-dichlorofluorenone-5-carboxylic acid in sulfuric acid, is identical with 1,6-dichlorofluorenone-4-carboxylic acid formed when 5,5′-dichlorodiphenic acid is heated with sulfuric acid.

2. The temperatures at which the two isomeric dichlorofluorenone carboxylic acids (formed from 3,3′-dichlorodiphenic acid) are stable have been examined.

3. Phosphoric acid has been found to condense both the 3,3′- and the 5,5′-dichlorodiphenic acids but not to effect the *rearrangement* by which "Acid X" is produced.

4. Certain anomalous observations in the determination of the neutralization equivalent of "Acid X" appear to have been due to formation of solvates with the recrystallizing solvents.

5. "Acid X" has been decarboxylated directly by heating in sulfuric acid to give 3,6-dichlorofluorenone.

6. 1,6-Dichlorofluorenone and 1,8-dichlorofluorenone rearrange in hot concentrated sulfuric acid to give 3,6-dichlorofluorenone.

7. The condensations of other substituted diphenic acids and the rearrangements of the fluorenones and fluorenone carboxylic acids derived from them are being examined.

The Properties of Unsaturated Sulfur Compounds. III. Alpha Beta Unsaturated Ketosulfones

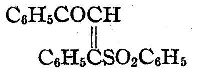
BY E. P. KOHLER AND R. G. LARSEN

In continuation of our investigation of unsaturated ketosulfones[1] we have prepared a representative in which one of the unsaturated carbon atoms holds both a phenyl and a phenylsulfonyl group, the relation between the present and the former sulfones being shown by the formulas

$C_6H_5COCH{=}C(C_6H_5)SO_2C_6H_5 \quad C_6H_5COCH{=}CHSO_2C_6H_5$

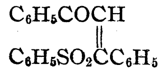
The preparation of this substance enabled us to compare a number of similarly constituted compounds with respect to their stereoisomerism, the facility with which they enter into addition reactions and the mode of addition of unsymmetrical addenda.

The new ketosulfone, like the one described in the earlier paper, occurs in two forms of which one is yellow and the other colorless. From the analogy with the most closely related compounds of which the configuration is known—dibenzoyl ethylene and phenyl-β-benzoylpropionic ester—one would expect the polar groups to be in the *trans* position in the more stable yellow form. We therefore represent this form with I and designate it the *trans* compound.



$$\begin{array}{c} C_6H_5COCH \\ \| \\ C_6H_5CSO_2C_6H_5 \end{array}$$

I *Trans*



$$\begin{array}{c} C_6H_5COCH \\ \| \\ C_6H_5SO_2CC_6H_5 \end{array}$$

II *Cis*

The relative melting points and solubilities of the two forms are the reverse of those of the unphenylated ketosulfones but the relative stabilities remain the same; a trace of base immediately produces a yellow color in solutions of the *cis* compound and in a short time converts it completely into the *trans* isomer. Owing to the reversal of the solubilities the effect of exposing concentrated solutions of the unphenylated and phenyl-

---

[1] Kohler and Larsen, THIS JOURNAL, 57, 1448 (1935).

ated compounds to sunlight is quite different; in the case of the former the *trans* compound is converted practically completely into the *cis* while in the case of the latter both forms are converted into an equilibrium mixture containing but little of the *cis* compound.

Nearly all methods of preparation yield only the *trans* compound but when benzene sulfinic acid is added to benzoyl phenylacetylene the *cis* compound is formed exclusively. The two stereoisomers add other substances with practically the same ease. Both are easily oxidized and reduced and both also add halogen acids rapidly. As this easy addition of halogen acids was rather surprising it was important to establish the mode of addition with certainty. To this end we prepared one of the possible hydrogen bromide addition products by a method which was certain to give a compound of known structure, namely, by the addition of benzene sulfinic acid to α-bromo benzalacetophenone. The two diastereomeric bromo compounds obtained by this reaction were quite different in chemical and physical properties from the product obtained by adding hydrogen bromide to the unsaturated ketosulfone. The relations are shown by the following equations

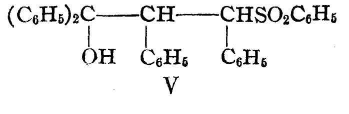
$$C_6H_5COCH{=}C(C_6H_5)SO_2C_6H_5 + HBr \longrightarrow C_6H_5COCH_2CBr(C_6H_5)SO_2C_6H_5 \quad \text{III}$$

$$C_6H_5COCBr{=}CHC_6H_5 + C_6H_5SO_2H \longrightarrow C_6H_5COCHBrCH(C_6H_5)SO_2C_6H_5$$

These results show that the additional phenyl group has but little effect on the ease and none at all on the mode of addition of hydrogen compounds. In contrast it greatly affects both the facility and mode of addition of Grignard reagents. As a consequence of the accumulation of groups in the β position the primary reaction between the phenylated ketosulfone and phenylmagnesium bromide is addition to carbonyl. By operating with excess of reagent and at a higher temperature it is possible to add a second molecule of the reagent but the mode of addition is the reverse of that which occurs with the unphenylated ketosulfone. The two compounds which can be obtained in this manner are represented by the formulas

$$(C_6H_5)_2C(OH)C{=}(C_6H_5)SO_2C_6H_5$$

IV



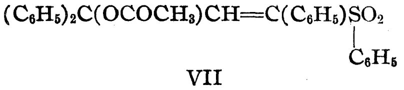
$$\begin{array}{ccccc}(C_6H_5)_2C & — & CH & — & CHSO_2C_6H_5\\ | & & | & & | \\ OH & & C_6H_5 & & C_6H_5\end{array}$$

V

The first of these substances is of special interest in connection with the peculiar behavior of the corresponding unphenylated compound $(C_6H_5)_2C(OH)CH{=}CHSO_2C_6H_5$.[2] The phenylated compound does not exhibit these peculiarities. All samples melt at the same temperature and decompose at the same rate regardless of origin and subsequent treatment. The substance not only does not itself undergo the allylic rearrangement but there also is no indication of rearrangement in metathetical reactions involving the hydroxyl group as, for example, when it is converted into its ethers, esters or chloride.

$$(C_6H_5)_2C(OCH_3)CH{=}C(C_6H_5)SO_2C_6H_5$$

VI



$$(C_6H_5)_2C(OCOCH_3)CH{=}C(C_6H_5)\underset{\underset{C_6H_5}{|}}{SO_2}$$

VII

$$(C_6H_5)_2CClCH{=}C(C_6H_5)SO_2C_6H_5$$

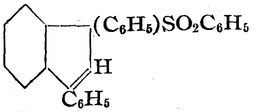
VIII

The structure of the products IV, VI and VII was established conclusively. Thus the carbinol IV on catalytic hydrogenation gives the same saturated compound that is formed when the ketosulfone is first reduced and then treated with phenylmagnesium bromide.

$$\begin{tikzcd}[column sep=small] \underset{\text{IV}}{(C_6H_5)_2C(OH)CH{=}C(C_6H_5)SO_2C_6H_5} \arrow[dr] & & \underset{\text{A}}{C_6H_5COCH_2CH(C_6H_5)SO_2C_6H_5} \arrow[dl] \\ & \underset{\text{IX}}{(C_6H_5)_2C(OH)CH_2CH(C_6H_5)SO_2C_6H_5} & \end{tikzcd}$$

The methyl ether VI can be oxidized to the corresponding ether of benzilic acid and the acetate VII reverts to the carbinol when it is hydrolyzed by weak acids—a process which is not accompanied by rearrangement. The structure of the chloro compound VIII was not established with the same certainty but its properties and its relations to other members of the series are in accord with the formula. Above its melting point it loses hydrogen chloride rapidly and passes into an indene derivative—presumably by way of an intermediate allene.

$$(C_6H_5)_2CClCH{=}C(C_6H_5)SO_2C_6H_5 \longrightarrow$$

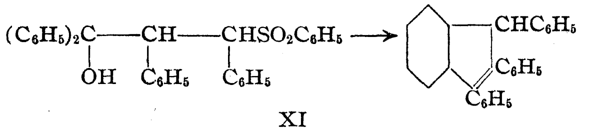


X

---

(2) In the earlier paper it was assumed that this compound spontaneously undergoes an allylic rearrangement into an isomer which decomposes at a lower temperature. As a result of a physical investigation of the two products—which is described in the following paper by H. E. Bent and his collaborators—this interpretation is no longer tenable.

While the mode of addition of the first molecule of the Grignard reagent is evidently due to the properties of the conjugated system C═C—C═O, that of the second depends on the character of the system C═C—SO$_2$. The structure of the di-addition product was established by converting it into a known triphenylindene



XI

The foregoing account shows that the introduction of a phenyl group in the β position of an α,β unsaturated ketosulfone does not greatly affect its chemical properties. Except in the case of Grignard reagents the mode of addition is dependent on the character of the conjugated system C═C—C═O and the properties of the addition products express the tendency to revert to this system.

Experimental

The unsaturated ketosulfone was made from benzalacetophenone in a series of steps which can be represented as follows

$$C_6H_5COCH{=}CHC_6H_5 \longrightarrow C_6H_5COCH_2CH(C_6H_5)SO_2C_6H_5 \longrightarrow$$

A

$$C_6H_5COCHBrCH(C_6H_5)SO_2C_6H_5 \longrightarrow$$

B

$$C_6H_5COCH{=}C(C_6H_5)SO_2C_6H_5$$

I

The saturated ketosulfone (A) had been made previously by Posner[3] by adding thiophenol to benzalacetophenone and oxidizing the addition product to the sulfone but we found it simpler as well as more economical to form the sulfone in a single step by adding benzene sulfinic acid. The structure of the bromo compound (B) was established definitely by a synthesis which gives a compound of known structure, namely

$$C_6H_5COCBr{=}CHC_6H_5 + HSO_2C_6H_5 \longrightarrow C_6H_5COCHBr{-}CH(C_6H_5)SO_2C_6H_5$$

α-Phenyl-β-benzoyl Ethyl Phenyl Sulfone (A).—Equimolar quantities of ketone and pure sulfinic acid were brought together in concentrated alcoholic solution. The mixture evolved heat and soon solidified. One recrystallization from alcohol gave a product which melted at 159°. The yield was 93%.

α-Phenyl-β-bromo-β-benzoyl Ethyl Phenyl Sulfone (B).—The bromination of the ketosulfone in chloroform presented no difficulty; once the reaction was started it proceeded smoothly at the ordinary temperature until one mole of bromine had disappeared. The crystalline product that remained after removing the chloroform was subjected to fractional crystallization from methyl alcohol, and was thus eventually separated into two diastereomeric bromo compounds. The principal product, obtained in a yield of 90%, crystallized in coarse needles and melted at 189°. The second product, the yield of which was less than 3%, crystallized in very fine needles and melted at 209°.

Anal. Calcd. for $C_{21}H_{17}O_3BrS$: C, 58.8; H, 3.9. Found: (189°) C, 58.5; H, 4.0. (209°) C, 58.9; H, 4.2.

For the purpose of establishing the structure of these compounds concentrated solutions of equimolar quantities of α-bromo benzalacetophenone and benzene sulfinic acid in ethyl alcohol were kept at the ordinary temperature. In the course of several days the bromo compound melting at 209° crystallized from the solution.

α-Phenyl-β-benzoyl Vinyl Phenyl Sulfone I.—Both of the β-bromo derivatives of the saturated sulfone lose hydrogen bromide slowly when boiled with excess of potassium acetate in methyl alcohol or in acetic acid. In methyl alcohol the reaction with the compound melting at 189° was complete after the solution had been boiled for eighteen hours while that of the higher melting bromo compound required three days. In both cases the product was the yellow *trans* compound. It separated in yellow prisms which after recrystallization from methyl alcohol melted at 151°. The yield was 72%.

Anal. Calcd. for $C_{21}H_{16}O_3S$: C, 72.4; H, 4.6. Found: C, 72.0; H, 4.7.

The Cis Unsaturated Sulfone II.—To a solution of 2.75 g. of benzoyl phenyl acetylene in hot methyl alcohol was added 2.6 g. of benzene sulfinic acid. The mixture was boiled for a short time, then set aside. It yielded 2.8 g. of a colorless product a part of which crystallized from the solution while the remainder was obtained on evaporation. The *cis* compound crystallizes from methyl alcohol in colorless prisms and it melts at 132°.

Anal. Calcd. for $C_{21}H_{16}O_3S$: C, 72.4; H, 4.6. Found: C, 72.0; H, 4.7.

Attempts to ozonize the unsaturated sulfones were unsuccessful. Both forms reduce permanganate in acetone rapidly, being oxidized to two molecules of benzoic acid and one of benzene sulfonic acid. Both forms can also be reduced catalytically and with zinc and acid. Catalytic reduction is extremely slow and incomplete, doubtless because there is some elimination of benzene sulfinic acid which poisons the catalyst. Zinc and acetic acid, however, rapidly reduce the unsaturated sulfones to the same saturated compound.

Interconversion of the Two Isomers by Light.—A solution of 6 g. of the *trans* compound, and a little iodine, in chloroform was exposed to sunlight for three days in a quartz apparatus. At the end of the first day one-third of the solution was evaporated to dryness. The residue, separated by extraction and crystallization from methyl alcohol, was found to contain 0.2 g. of the *cis* compound—indicating about 10% conversion. A similar procedure at the end of the second and third days, gave in each case nearly 0.3 g. of the *cis* compound. In the reverse operation, carried out in the same way but starting with one gram of the *cis* form, the residue after exposure for three days contained 0.85 g. of *trans* and 0.13 g. of *cis*.

Isomerization with Chemicals.—A small drop of sodium methylate was added to a warm solution of 0.5 g. of the

---

[3] Posner, *Ber.*, **35**, 810 (1902).

cis compound. The mixture was left to itself for ten hours, then evaporated in a current of air. It left 0.48 g. of *trans* compound and a trace of oil. A similar solution when treated with a little methyl alcoholic solution of hydrogen chloride turned yellow and deposited some *trans* compound but most of the acid was removed by addition.

Addition of Hydrogen Bromide: α-Bromo-α-phenyl-β-benzoyl Ethyl Phenyl Sulfone, III.—A solution of the *trans* sulfone in glacial acetic acid was saturated with hydrogen bromide and left in an ice-box for thirty-six hours. As nothing separated from the solution it was diluted with ether, and freed from acid by washing with water and dilute bicarbonate. The dried ethereal solution, on concentration, deposited the bromide in large needles which, after recrystallization from methyl alcohol, melted with decomposition at 124°.

Anal. Calcd. for $C_{21}H_{17}O_3BrS$: C, 58.8; H, 3.9. Found: C, 59.0; H, 4.0.

The bromo compound is much less stable than the isomeric β-bromo derivative. At the melting point it rapidly loses hydrogen bromide and reverts to the *trans* unsaturated sulfone and when its alcoholic solutions are boiled they gradually turn yellow in color and become acidic.

The corresponding chloro compound—prepared in the same way—is more stable. It crystallizes in colorless needles and melts at 175°.

Anal. Calcd. for $C_{21}H_{17}O_3ClS$: C, 65.5; H, 4.4; Cl, 9.2. Found: C, 65.6; H, 4.6; Cl. 9.1.

Addition of Phenylmagnesium Bromide: the Mono-addition Product.—To an ethereal solution which contained four times the calculated quantity of reagent and which was cooled in ice, was added 7 g. of finely powdered yellow sulfone. The mixture was stirred vigorously for several hours, then decomposed with iced ammonium chloride solution. The product crystallized with two molecules of methyl alcohol in large colorless prisms melting at about 107°. Heated to 100° under diminished pressure, the crystals lost methyl alcohol and passed into a powder melting at 133°.

Anal. Calcd. for $C_{27}H_{22}O_3S \cdot 2CH_3OH$: C, 71.0; H, 6.1. Found: (Prisms) C, 71.2; H, 6.1. Calcd. for $C_{27}H_{22}O_3S$: C, 76.2; H, 5.4. Found: (Powder) C, 76.0; H, 5.1.

Reduction: α-Phenyl-γ-hydroxy-γ,γ-diphenyl Propyl Phenyl Sulfone, IX.—Catalytic hydrogenation with platinum oxide was almost impossible because of the rapidity with which the catalyst was poisoned. With palladium on calcium carbonate, however, the hydrogenation was accomplished without much difficulty, the sparingly soluble product separating from the ethyl acetate used as solvent as fast as it was formed. It crystallized in thin needles melting at 223°. The same compound was obtained, in a yield of 75%, when phenylmagnesium bromide was added to the saturated ketosulfone.

Anal. Calcd. for $C_{27}H_{24}O_3S$: C, 75.7; H, 5.6. Found: C, 75.5; H, 5.6.

The Methyl Ether, VI.—A drop of acetyl chloride was added to a solution of the unsaturated carbinol in boiling methyl alcohol and the solution was then allowed to evaporate in a current of air. It deposited the ether in hexagonal tables melting at 130°.

Anal. Calcd. for $C_{28}H_{24}O_3S$: C, 76.4; H, 5.5. Found: C, 76.6; H, 5.6.

Oxidation.—A dilute solution of the ether in acetone was acidified with a little acetic acid, then treated with the calculated quantity of permanganate in acetone and set aside until completely decolorized. Among the neutral products isolated by the usual manipulations was a substance which crystallized in needles melting at 100° and which was identified as the methyl ether of benzilic acid by comparison with a sample prepared directly from benzilic acid. The yield was 30%.

The Acetate, VII.—A solution of the mono-addition product in acetic anhydride was boiled for four hours, then cooled and poured into water. From the resulting suspension ether extracted a solid which recrystallized from absolute methyl alcohol in needles melting at 168°.

Anal. Calcd. for $C_{29}H_{24}O_4S$: C, 73.7; H, 5.3. Found: C, 73.7; H, 5.4.

The acetate was not affected by boiling water but when it was hydrolyzed with methyl alcoholic potassium hydroxide it reverted to the carbinol and when it was boiled with methyl alcohol that contained a trace of acetic acid it was slowly converted into the methyl ether.

α-Phenyl-γ-chloro-γ,γ-diphenyl Propyl Phenyl Sulfone, VIII.—Dry hydrogen chloride was passed through a solution of the carbinol in benzene until the turbidity, caused by the separation of water, was removed. The solution was then allowed to evaporate spontaneously and the residual green oil was diluted with dry ether. It deposited the chloride in long colorless needles which after recrystallization from dry ether melted with decomposition at about 142°. The yield was quantitative.

Anal. Calcd. for $C_{27}H_{21}OSCl$: C, 72.9; H, 4.8. Found: C, 72.4; H, 5.0.

The chloro compound is stable in the air. When it is boiled with methyl alcohol or with methyl alcoholic potassium acetate it is converted into the ether. Potassium acetate in glacial acetic acid converts it into the acetate.

1,3-Diphenyl-3-phenylsulfonyl Indene, X.—The chloro compound which has just been described loses hydrogen chloride rapidly at the melting point. The residue is an amber colored liquid that is readily soluble in ether. The ethereal solution gradually deposits colorless needles melting at 171°.

Anal. Calcd. for $C_{27}H_{20}O_2S$: C, 79.4; H, 4.9. Found: C, 79.2; H, 5.1.

In proof that the product is an indene derivative 1 g. was oxidized with 1.5 g. of sodium dichromate in glacial acetic acid. The product, isolated in the usual manner, was ortho dibenzoyl benzene—identified by comparison with an authentic sample. The yield was 70%.

$\alpha,\beta,\gamma,\gamma$-Tetraphenyl-$\gamma$-hydroxy Propyl Phenyl Sulfone, V.—To an ethereal solution of phenylmagnesium bromide prepared from 2.25 g. of magnesium was added 10 g. of finely powdered unsaturated ketosulfone. The mixture was boiled for two hours, then cooled and decomposed with iced acid. A part of the product was deposited during the acidification, the remainder being isolated by the usual manipulations of the solution. Three substances were obtained in this manner, namely: the mono-addition product (57%), a di-addition product melting at 178°

(15%), and a stereoisomeric di-addition product melting at 223° (12%). In a similar experiment in which the reacting mixture was boiled for six hours the yields were 22% of mono-addition product, 26% of product melting at 178° and 32% of product melting at 196°. Both of the di-addition products are sparingly soluble in common organic solvents. The lower melting—which is the less soluble—crystallizes from acetone in small prisms and the higher melting crystallizes in six-sided tables containing acetone of crystallization.

Anal. Calcd. for $C_{33}H_{28}O_3S$: C, 78.6; H, 5.6. Found: C, 78.6; H, 6.0. Calcd. for $C_{33}H_{28}O_3S \cdot C_3H_6O$: C, 77.1; H, 6.0; C_3H_6O, 10.3. Found: C, 77.1; H, 5.7; C_3H_6O, 10.1.

The structure of the di-addition products was established by converting them into triphenyl indene. To this end a solution of each in glacial acetic acid containing a small quantity of sulfuric acid was heated on a steam-bath for half an hour, then diluted first with methyl alcohol and finally with water. In each case the product was identified by comparison with a sample on hand.

Summary

The paper contains a comparison of $C_6H_5COCH{=}C(C_6H_5)SO_2C_6H_5$ and $C_6H_5COCH{=}CHSO_2C_6H_5$ with respect to their stereoisomerism, the facility with which they enter into addition reactions, the mode of addition of hydrogen compounds and the mode of addition of Grignard reagents.

A Physical Investigation of β-Hydroxy-β,β-diphenylvinyl Phenyl Sulfone

BY H. E. BENT, E. S. LARSEN AND H. BERMAN

In a recent paper Kohler and Larsen[1] described two compounds which "are interesting by reason of the very remarkable ease with which they undergo the allylic rearrangement.... Most solutions, on chilling, deposit a mixture of both isomers but by slow crystallization from properly selected solvents it is possible to secure both isomers in a pure condition—the tertiary alcohol VIII from benzene and the secondary alcohol X from methyl or ethyl alcohol." The tertiary alcohol, β-hydroxy-β,β-diphenylvinyl phenyl sulfone, has the structure  $\underset{\mathrm{OH}}{\underset{|}{(C_6H_5)_2C}}{-}CH{=}CHSO_2C_6H_5$ and the secondary alcohol, α-hydroxy-β,β-diphenylpropenyl phenyl sulfone, X, has the structure  $(C_6H_5)_2C{=}CH{-}\underset{\mathrm{OH}}{\underset{|}{CH}}SO_2C_6H_5$. The melting point of the tertiary alcohol is given as 193° and of the secondary alcohol as 164°. Both compounds crystallize readily but differ greatly in appearance. This apparent reversal of the direction of transformation by different solvents at the same temperature is, however, thermodynamically impossible, and we have therefore reëxamined more carefully the physical properties of these two substances.

Crystallographic measurements were made as follows:

OPTICAL CRYSTALLOGRAPHY

	Cpd. VIII	Cpd. X
α	1.608	1.607
β	1.656	1.657
γ	1.710	1.706
Opt. sign	(+) 2*V* med.	(+) 2*V* med.
Orientation	*Z* = *b*	*Z* = *b*
	*X*Λ*C* = 23°	*X*Λ*C* = 23°

CRYSTALLOGRAPHY

$a:b:c = 1.0597:1:0.3277$ $\beta = 99° \, 05'$

$p_0 = 0.30926$ $q_0 = 0.32362$ $e = 0.15784$

Form	Observed (averages) φ	ρ	Calculated φ	ρ	Number of observations
(010)	0°	90° 00′	0°	90° 00′	4
(100)	90° 00′	90° 00′	90° 00′	90° 00′	1
(110)	43° 42′	90° 00′	43° 42′	90° 00′	12
(011)	26° 00′	20° 02′	26° 00′	20° 02′	6
(101)	90° 00′	25° 17′	90° 00′	25° 19′	1

Ranges: for (110) 43° 32′ to 43° 55′
(011) 25° 40′ to 26° 41′ 19° 47′ to 20° 10′

Measurements on a single crystal of VIII

Form	φ	ρ
(010)	0°	90° 00′
(110)	39° 49′	90° 00′
(011)	25° 51′	20° 09′

Crystals X are much superior in quality and the angles of these are to be relied upon for a good axial ratio for the substance. Crystals VIII were difficult to measure since they were of the order of 0.1 mm. in maximum size. Several crystals

---

[1] Kohler and R. G. Larsen, THIS JOURNAL, 57, 1448 (1935).

yielded rather poor measurements, the best being given above. The data given above indicate that substances VIII and X are crystallographically identical and that although they do have a different superficial appearance they are actually similar in habit as well as in the prevalence of particular forms.

The melting points were carefully re-determined, first by conventional methods and second by the use of the copper block. The results obtained with an ordinary melting point tube depend upon the rate of heating, rapid heating giving much higher results. The following table gives typical results obtained with a copper block.

T, °C.	Time required for melting, in sec. VIII	X
159	180	60
165	120	30
170	120	30
178	75	22
188	50	15
193	50	12
195	25	12
199.5	2-3	2-3

It is clear from these results that the melting points as determined in tubes are really decomposition or rearrangement points and as usual are greatly affected by variations in the rate of heating. Since decompositions are known to be very sensitive to the presence of impurities, the low apparent melting point of substance X may well be due to an impurity present in it when recrystallized from methyl alcohol, but absent or present in smaller amounts when recrystallized from benzene.

Finally, the solubilities of VIII and X were determined in benzene and methyl alcohol at several temperatures. The saturation was accomplished by shaking the solutions in a small container of about 10-cc. capacity surrounded by a jacket containing a boiling liquid. This vessel was conveniently made like a small Dewar flask with the boiling liquid in the space usually evacuated, to which a reflux condenser was sealed. To prevent evaporation of the solvent there was a ground glass stopper halfway down the neck of the flask. The whole apparatus was mounted on a shaker which not only served to agitate the solution but also to minimize superheating. The temperatures were read on a thermometer immersed in the solution itself and these remained constant to ±0.1°. One cubic centimeter samples were removed by means of a filter pipet and evaporated to constant weight on a steam-bath. Duplicate determinations usually agreed to about ±1 mg. depending on the concentration of the solution. The results are given in Table I.

Table I

Temp., °C.	Time of shaking	Vol. of soln. 1 cc. C_6H_6	Wt. of solute VIII, g.	Wt. of solute X, g.
34.4	10 min.	"	0.0054	0.0043
55.2	5	"	.0114	.0108
64.4	4	"	.0167	.0163
80.3	5	"	.0303	.0293
0	12 hr.	CH_3OH	.0030	.0027
0	12	C_6H_6	.0015	.0015
0	25 min.	satd. CH_3OH	.0030	.0032

These results are not as precise as perhaps one might wish, and if it seemed worth while a somewhat greater expenditure of time would doubtless improve them considerably. However, the values given for the solubilities of the two materials agree as well as values obtained on successive runs on the same material. The time was intentionally made as short as five minutes for the shaking in order to diminish the chance of a rearrangement taking place in solution. Perhaps the last row in the table is the most significant. In this case a saturated solution of one compound in methyl alcohol was shaken with the other solid. Unless there is a rapid equilibrium established at 0° one would have expected the total amount of solute to be about twice that observed. The only alternative is that both materials are the same.

The Accuracy of the Potentiometric Iodide–Silver Titration

BY I. M. KOLTHOFF AND J. J. LINGANE

This study of the potentiometric iodide–silver titration was undertaken with a three-fold purpose: (a) to determine the accuracy of the titration, (b) to locate the isoelectric point of freshly precipitated silver iodide, and (c) to study the adsorption of silver and iodide ions by flocculated silver iodide, at extremely low concentrations. A knowledge of the accuracy of the iodide–silver titration was necessary before the required data for topics b and c could be obtained. The present paper contains the results of the experiments made to determine the accuracy of the titration, and subjects b and c will be discussed in a subsequent communication.

Although the *precision* of the potentiometric iodide–silver titration has been studied exhaustively by Lange and Berger,[1] these authors did not establish the *accuracy* of the titration since they worked with solutions of potassium iodide and silver nitrate whose concentrations were not exactly known. In lieu of direct experimental evidence of the accuracy of the titration, they studied the adsorption of silver and iodide ions on silver iodide, and concluded from the data so obtained that the titration should give results accurate to at least ±0.01%, when performed under the most favorable conditions. They found that titration at room temperature was impractical because of the strong adsorption of silver and iodide ions by the precipitate with consequent slow attainment of steady e. m. f. They found that the deleterious effects of adsorption were practically eliminated when the titration was performed at 90°, and they showed that the results were highly precise under these conditions.

Unfortunately, Lange and Berger did not pay particular attention to the purity of the materials which they used. Since commercial samples of potassium iodide almost invariably are contaminated by traces of bromide and chloride, this neglect casts some doubt on their conclusions. In the present study we have taken special care to use materials of a high degree of purity. Instead of working in neutral solution, as Lange and Berger did, we performed all titrations in the presence of a small amount of nitric acid, since adsorption of silver ions on the glass wall of the container is eliminated under such conditions.

Materials Used

Potassium Iodide.—Since potassium iodide is not easily purified by usual recrystallization methods, because of its great solubility in water and because of the doubtful removal of possible traces of chloride and bromide, we prepared the salt from pure hydriodic acid and purified potassium bicarbonate. Hydrogen iodide was synthesized directly from purified iodine and hydrogen by the classical method in which platinized asbestos is used as catalyst, and the gas was dissolved in water to give a concentrated solution.[2] The solution of hydriodic acid was nearly neutralized with purified potassium bicarbonate, and evaporated in a hydrogen atmosphere until a considerable quantity of potassium iodide separated out, which was filtered off and dried.

Silver.—The preparation of the pure silver used in this study has been described in a previous paper from this Laboratory.[3]

Nitric Acid.—The nitric acid used in this work was obtained by distilling C. P. concentrated acid in an all-glass still, the middle fraction only being collected.

Water.—Conductivity water was used in all preparative work and in the preparation of all solutions.

Apparatus.—A silver iodide electrode was used as indicator electrode in the titrations, and a saturated calomel electrode was used as reference electrode. The silver iodide electrodes were prepared by plating platinum gauze electrodes (cylinders 1 cm. in diameter and 1 cm. long) with silver from a 10% potassium argentocyanide solution at low current density. The silver electrodes were then iodized by making them anodes in the electrolysis of a dilute potassium iodide solution for a few minutes at low current density, followed by thorough washing with water.

The titration vessel consisted of a one-liter beaker, painted black on the outside, and provided with a tightly fitting bakelite cover with suitable holes for the buret-tip, salt bridge, electrode, thermometer and stirrer. This arrangement provided efficient light protection. A saturated solution of potassium nitrate, free from chloride, was used in the salt bridge, which was filled with fresh solution for each titration. For the hot titrations, the titration beaker was placed in an electrically heated water-bath whose temperature could be held constant to ±0.5°.

Weights and volumetric apparatus were calibrated carefully by standard methods. Weighings were corrected to vacuum on the following density basis, weights (brass) 8.4, silver 10.5, potassium iodide 3.12 and air 0.0012 g. per cc.

[2] We are indebted to E. R. Caley and M. G. Burford (private communication) for suggesting the apparatus for this synthesis. Details of the methods of preparation are described by the authors in Volume I of "Inorganic Syntheses."

[3] I. M. Kolthoff and J. J. Lingane, THIS JOURNAL, **57**, 2126 (1935).

Preparation of Potassium Iodide for Weighing.—Potassium iodide decomposes slightly when fused in air or nitrogen,[4] and the fused salt is strongly alkaline. We have found, however, that the salt may be melted in pure dry hydrogen with no trace of decomposition. Solutions of the salt which had been fused in hydrogen were always perfectly colorless, and showed no trace of alkalinity. Portions of the salt were prepared for weighing by melting for ten minutes at 700–725° in pure dry hydrogen in a platinum boat. The fused sample was allowed to cool to below 200° in hydrogen, and was then removed to a desiccator containing fused potassium hydroxide, where it remained until weighed.

Technique of the Titrations

Separate samples of silver and potassium iodide were weighed out for each titration, the silver being in the form of buttons weighing from 1.0 to 1.5 g. each. A silver button was first carefully weighed and transferred to a small Kjeldahl flask in which it was dissolved in 3 cc. of concentrated nitric acid with gentle heating. The solution was then heated to remove oxides of nitrogen, the heating being continued for at least fifteen minutes after the disappearance of brown fumes. The solution was cooled, transferred to the titration beaker, and diluted to approximately 500 cc. The resulting solution was approximately 0.02 *N* in silver and 0.04 *N* in nitric acid.

The carefully weighed sample of potassium iodide was dissolved in approximately 100 cc. of water in a special dropping funnel previously described,[3] and the solution was mixed thoroughly. The potassium iodide solution was run dropwise into the silver solution with constant mechanical stirring, from ten to fifteen minutes being required for the addition. The funnel and platinum boat were rinsed out with eight to ten portions of water, which brought the total volume of solution to between 750 and 850 cc., after which the bakelite cover was placed on the beaker. The beaker was placed in the water-bath, the electrode, stirrer, thermometer and salt bridge were put in place, and after heating to the desired temperature, the titration was completed with 0.01 *N* potassium iodide solution added from a microburet. Efficient mechanical stirring was employed, and the titrations were carried out in very faint diffuse daylight in a room with closely drawn shades, although this latter precaution was probably unnecessary because the titration vessel itself served as an efficient protection against light.

Titrations were made at room temperature, at 70 and at 90°, and some experiments were also made in which the precipitate was digested for some time at 95 to 100° before finishing the titration. A reflux condenser was used in the long digestion experiments to prevent evaporation of the solution.

In the majority of the titrations the end-point was found in the classical way from the maximum in $\Delta E/\Delta V$. However in the titrations at room temperature (without digestion) the maximum in $\Delta E/\Delta V$ was not well defined, and in these titrations the end-point was found by titrating to the equivalence potential.[5,3] The equivalence potential was determined by titrating very small amounts of silver with the dilute potassium iodide solution under the same conditions of acidity, temperature, and volume as in the actual titrations. At room temperature the equivalence potential found in this way was +0.098 volt against the saturated calomel electrode, in a 0.035 *N* nitric acid solution. The average solubility product of silver iodide in 0.035 *N* nitric acid, calculated from the data of several such "dilute" titrations, was 2.18×10^{-16} at 25°. Titration at room temperature is not practical because of the long time required for the e. m. f. to reach steady values, and furthermore (Table II) the error of the titration is greatest at this temperature. As long as an hour is required to obtain steady e. m. f. readings between each addition of reagent at 25°. The drift is particularly bad in the immediate vicinity of the end-point, and the exact position of the maximum in $\Delta E/\Delta V$ is difficult to locate. Under the conditions described, the end-point determined by titrating to the equivalence potential agreed within the limits of the experimental error with that determined from the maximum in $\Delta E/\Delta V$. This was no longer true when the titration was performed in the more usual manner, by taking e. m. f. readings five minutes after each addition of reagent without waiting until the potential had attained constant values. By titrating to the equivalence potential, exactly the same result was obtained as in the slow titration; however, the values of $\Delta E/\Delta V$ changed in an irregular way in the neighborhood of the equivalence potential and two maxima were found. For this reason, fast titration at room temperature is not recommendable.

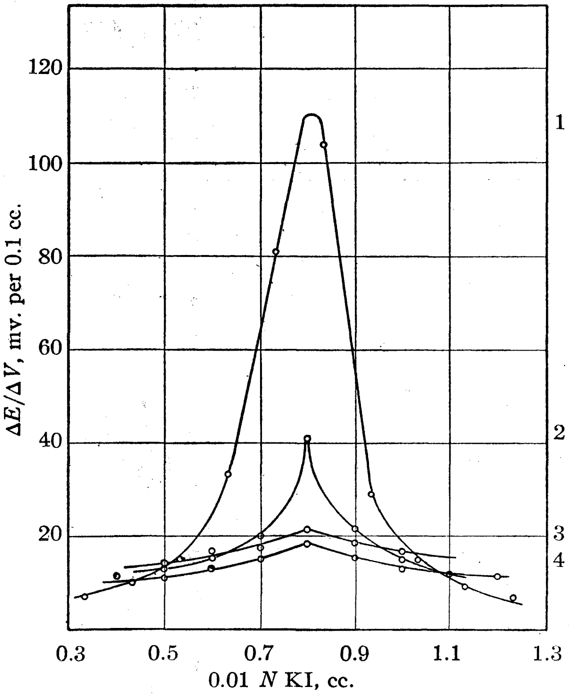

Fig. 1.—$\Delta E/\Delta V$ curves in region of equivalence point under various conditions: (1) digested 40 hours at 95°, titrated at room temp.; (2) direct titration at 70°; (3) direct titration at room temperature; (4) direct titration at 90°.

[5] I. M. Kolthoff and N. H. Furman, "Potentiometric Titrations," John Wiley and Sons, Inc., New York, 1932, p. 100.

Constant e. m. f. readings can be obtained in a relatively short time at 70 or 90°, except in the immediate vicinity of the end-point where fifteen to thirty minutes are required. The same is true when the precipitate is digested previous to titration at room temperature. Under the latter conditions the most pronounced break in the potential is found, since the adsorptive properties of the precipitate have become extremely small, and the solubility is much smaller than at higher temperatures (Curve 1, Fig. 1).

In Fig. 1 the change of $\Delta E/\Delta V$ in the region of the equivalence point is plotted against the volume of 0.01 N potassium iodide solution, under various conditions of titration. To simplify comparison the curves have been drawn so that the maximum value of $\Delta E/\Delta V$ came at the same point on the abscissa in each case. The numerical values of the volumes are thus without significance.

The final volume of the solutions varied between 750 and 850 cc., and the final concentration of nitric acid was 0.03 to 0.04 N.

Data of the Titrations

The data of a typical titration at 90° are given in Table I, which is self-explanatory. Table II contains a summary of all the various titrations. The values of the atomic weights given at the head of Table II were taken from the International Table of Atomic Weights for 1935.

Table I

Data of a Typical Titration at 90°

1.33153 g. of silver (vacuum) dissolved in 3 cc. of concd. nitric acid and diluted to 500 cc. 2.04659 g. potassium iodide (vacuum) dissolved in 100 cc. of water and added to silver solution at room temperature. Mixture heated to 90 ± 0.5°, and titrated at this temperature with 0.01036 N potassium iodide from microburet.

0.01036 N KI, cc.	E, volts	$\frac{\Delta E}{\Delta V}$	$\frac{\Delta^2 E}{\Delta V^2}$

Discussion of Results

A comparison of curves 2 and 4 in Fig. 1 shows that the magnitude of the break decreases with increasing temperature above about 70°, due to an increase in the solubility of silver iodide with increasing temperature. However, if the titration is made at a lower temperature, the magnitude of the break again decreases because of the increased adsorptive power of the precipitate. Curve 3 was obtained by performing the entire titration at room temperature, and it furnishes a striking illustration of the way in which the maximum is depressed by adsorption effects. Comparison of curves 1 and 3 illustrates the drastic decrease in the adsorptive power of silver iodide on aging. Although the solubility product of silver iodide at 70° is several hundred times greater than at room temperature, the adsorptive power of the precipitate as a result of aging is much less at the higher temperature, and hence the maximum is much more pronounced than that obtained in a titration carried out at room temperature in which the precipitate is not digested.

Although curves 3 and 4 of Fig. 1 indicate that the magnitude of the break is about the same at room temperature (without digestion) as at 90°, the e. m. f. readings obtained at the higher temperature are much more reliable, and hence the end-point can be accurately found from the location of the maximum in $\Delta E/\Delta V$ (Table I). In the titration at room temperature without digestion, the end-point can be found much more accurately by titrating to the equivalence potential than from the maximum in $\Delta E/\Delta V$.

An inspection of the data of Table II shows that the precision (reproducibility) of the titrations is very good; the average deviation from the mean of all the experiments at 70 and 90° is only ±0.005%. Titration at 90° gives the most accurate results, and the accuracy decreases in a very regular manner as the temperature of titration decreases. Digestion of the precipitate at 90°, and finally finishing the titration at room temperature, gives results almost as accurate as those at 90°. Furthermore, the e. m. f. in the final titration at room temperature after digestion, becomes steady more quickly than under any of the other conditions of titration.

A critical survey of the analytical data reported in Table II reveals that in the slow titration at room temperature the precipitate contains 0.1% of iodide in excess at the equivalence potential. In subsequent work it could be shown that this excess of iodide was present in the adsorbed state. On the basis of their study of electrodialyzed silver iodide sols, Verwey and Kruyt[6] predicted that the potentiometric iodide–silver titration should be in error by some tenths of a per cent. at

room temperature, since they deduced from their data that aged silver iodide at the equivalence potential ($C_{\mathrm{Ag}^+} = C_{\mathrm{I}^-}$) will contain adsorbed iodide. Under the experimental conditions described in this study it has been found that in the direct titration at room temperature the error due to the asymmetric location of the isoelectric point amounts to 0.10 ± 0.02%.

When the titration is carried out at 70° the precipitate is subjected to a fairly drastic aging process, consequently the error due to adsorption decreases to 0.05%. The error decreases to 0.017% when the titration is carried out at 90°. Under these conditions the aging is so drastic that the adsorptive power of the precipitate becomes virtually negligible. The error found at 90° is greater than the experimental error, and may be attributed to an extremely slight adsorption of iodide at the equivalence potential or to a slight error in the atomic weight of iodine, since the second decimal place in the latter is still somewhat uncertain.[7]

The fact that the error increases from 0.017 to 0.028% when the precipitate is titrated at room temperature after a drastic aging at 90°, lends support to the former assumption. Actually it could be shown that such a precipitate at room temperature exerted a slight adsorptive power toward silver and iodide ions.

Acknowledgment.—We wish to express our appreciation to the Graduate School of the University of Minnesota for a grant which enabled us to pursue this study.

Summary

1. Pure potassium iodide has been synthesized from hydriodic acid and potassium bicarbonate. The salt can be melted in a hydrogen atmosphere without decomposition.

2. The accuracy of the potentiometric iodide–silver titration has been investigated in a precise manner. The results show that in the slow titration of silver with iodide, the error at room temperature amounts to 0.1%, at 70 to 0.048% and at 90° to 0.017%. When the precipitate was digested at 90° near the equivalence point, and the titration finished at room temperature, the error was 0.028%. In all cases the precipitate contained an excess of iodide at the equivalence potential.

---

(7) G. P. Baxter, O. Hönigschmid, P. LeBeau and R. J. Meyer, THIS JOURNAL, **57**, 787 (1935).

3. The errors found in the titration are caused by adsorption of iodide ions by the precipitate, and the error (adsorption) can be reduced to a very small value by titrating at 90°, or by digesting the precipitate at 90° in the presence of a slight excess of silver previous to finishing the titration at room temperature.

The Adsorption of Silver and Iodide Ions by Freshly Precipitated Silver Iodide. The Isoelectric Point of the Fresh Precipitate

BY I. M. KOLTHOFF AND J. J. LINGANE

In a previous communication,[1] we described the results of an investigation of the accuracy of the potentiometric iodide–silver titration. It was found that when the titration was performed at room temperature, to the equivalence potential, approximately 0.10% too much potassium iodide was required. In this paper we present experimental evidence which proves that the excess requirement of potassium iodide at room temperature is due to an adsorption of iodide ions by the fresh precipitate at the potentiometric end-point.

We have also directly determined the "isoelectric point" of freshly precipitated silver iodide. The isoelectric point, or "zero-point charge," is defined as the silver-ion concentration at which neither silver nor iodide ions are adsorbed by the precipitate.

In their study of the precision of the potentiometric iodide–silver titration, Lange and Berger[2] determined the adsorption of silver nitrate and potassium iodide on freshly precipitated silver iodide at various temperatures. They found that the adsorption of the "potential determining" silver and iodide ions agreed with the expression, $\Delta X = K \Delta \log C$; in which X is the amount adsorbed, K is a constant and C is the equilibrium concentration of the ion being adsorbed. They found that this relation was valid at temperatures between 30 and 90°. It is very doubtful, however, whether the values of X determined at the higher temperatures are really significant, because the fresh precipitate ages quite rapidly at higher temperatures, causing a continuous decrease in its adsorptive power with resultant continuous desorption of the ion initially adsorbed. We have found that this desorption process is very slow at room temperature in the presence of an excess of silver, but is greatly accelerated at the higher temperatures.

Lange and Berger concluded from their experiments that silver ions are adsorbed more strongly than iodide ions at equal equilibrium concentrations. Their conclusion was based on the erroneous assumption that neither adsorption of silver nor iodide ions occurs at the potentiometric end-point, or "equivalence potential," where $c\text{Ag}^+$ in solution is equal to $c\text{I}^-$. Actually, as will be shown in the present paper, the isoelectric point of freshly precipitated silver iodide at room temperature is found at a silver ion concentration of approximately 10^{-6} molar, the silver ion concentration thus being nearly 10,000 times as great as the iodide-ion concentration.

In agreement with Lange and Berger, Verwey and Kruyt[3] found in their work with well aged electrodialyzed silver iodide *sols* that the adsorption of iodide ions follows the expression $\Delta X = K \Delta \log C$. They could not determine the location of the isoelectric point directly without flocculating the sols, but with the aid of the foregoing expression they extrapolated to the point of zero adsorption (isoelectric point), and found that this point corresponded to a silver-ion concentration of 10^{-6} molar. This value agrees very well with the value we determined directly with a fresh *precipitate*.

Gorochovsky[4] found that the isoelectric point of silver iodide sols depended greatly on the silver iodide concentration of the sols. The results of his experimental work, however, are inconclusive since he did not correct for adsorbed silver or iodide ions on the surface of the silver iodide.

Lange and Berger mention the possibility of an

adsorption of silver ions from neutral solution on the glass walls of containing vessels, but they made no attempt to determine its extent. In order to exclude such possible adsorption we worked in dilute nitric acid medium.

Experimental

The materials and apparatus used in this work have already been described.[1] In all experiments the iodide solution was added at room temperature to a slight excess of silver solution, slightly acidified with nitric acid, and the same titration technique was followed as in the paper already referred to.[1]

In order to obtain quantitative information regarding the absorption of silver and iodide ions, it was necessary to know the relation between the measured e. m. f. of the titration cell and the silver-ion concentration of the solutions. As a result of many measurements of the e. m. f. obtained with solutions of known and widely varied silver-ion concentration, in which the total ionic strength and the concentration of nitric acid were the same as in the titrations, we found the following empirical relation: $E_{298} = 0.560 + 0.0591 \log (\mathrm{Ag^+})$. This equation holds at 25° for measurements in solutions 0.035 N in nitric acid, and 0.01 N in potassium nitrate, the potential of the silver iodide electrode being measured against the saturated calomel electrode with saturated potassium nitrate in the salt bridge.

The interpretation of the experimental data also required a knowledge of the solubility of silver iodide under the conditions of the titrations. We determined the solubility product by performing titrations with extremely dilute silver and iodide solutions, and calculated the desired quantity from the data so obtained.[5,6] The average value of the solubility product of silver iodide determined in this way was 2.18×10^{-16} at 25° in 0.035 N nitric acid ($\sqrt{S_{\mathrm{AgI}}} = 1.48 \times 10^{-8}$). Hence at the equivalence potential $p\mathrm{I} = p\mathrm{Ag} = 7.83$, and $E = +0.098$ v.

Adsorption of Iodide at the Equivalence Potential.—The amount of iodide adsorbed at the equivalence potential was first determined by measuring the amount of iodide desorbed when a fresh precipitate at the equivalence potential was aged by digestion at 90°.

It was found that such a fresh precipitate aged only very slowly at room temperature. For example, in a typical experiment the titration was stopped when the e. m. f. reached 0.113 v. and had remained steady at this value for an hour. The mixture was allowed to age overnight at room temperature with constant stirring, during which time the e. m. f. only decreased to 0.098 v.; in other words, the pAg only increased from 7.56 to 7.83. Therefore, only a very slight desorption of iodide takes place during the time required to reach steady e. m. f. at room temperature (*ca.* two hours), previous to digestion at 90°.

The amount of excess iodide retained by a fresh precipitate at room temperature at the equivalence potential was then determined in the following way. A titration was carried out according to the careful technique described in a previous paper,[1] using exactly known amounts of silver and potassium iodide. The titration was stopped when the e. m. f. reached +0.091 v. (practically the equivalence potential), and had remained steady at this value for an hour. A slight excess of pure solid potassium bicarbonate was added to neutralize free nitric acid, and thus eliminate the possibility of oxidation of desorbed iodide by the acid during the digestion. The mixture was then heated to 90–95°, and digested for twenty hours at this temperature under reflux. After cooling to room temperature, the mixture was again acidified to a concentration of 0.035 N in nitric acid, the e. m. f. was measured and found to be −0.075 v., corresponding to a change in pAg from 7.94 to 10.74, showing that much iodide was desorbed during the digestion. This desorbed iodide was titrated potentiometrically with 0.01 N silver nitrate, and found to correspond to 1.39 mg. of potassium iodide. 1.6241 g. of potassium iodide was used in the preparation of the silver iodide, hence the error due to adsorption of iodide amounts to 0.086%, whereas in the precise titrations[1] an error of 0.1 ± 0.02% was found. Within the experimental error, therefore, this deviation can be attributed to iodide adsorbed on the precipitate at the equivalence potential.

Although the precipitate was obtained by adding the iodide solution to the silver solution, the objection might be raised that the excess iodide in the precipitate at the equivalence potential is occluded within, and not adsorbed on, the precipitate. In the following manner it was shown that the excess iodide was actually absorbed. If iodide ions are primarily adsorbed by silver iodide, then either hydrogen or potassium ions (or both) must be adsorbed as counter ions, since these are the only cations present in the solution. The univalent counter ions may be replaced by a cation of higher valence. Thus, if a dilute solution of aluminum is added to the system, the following replacement reaction will take place

$$\mathrm{AgII^-}\,\Big|\,\underset{\text{Counter ion}}{\mathrm{K^+}} + \underset{\text{Solution}}{1/3\mathrm{Al^{+++}}} \longrightarrow \mathrm{AgII^-}\,\Big|\,\underset{\text{Counter ion}}{1/3\mathrm{Al^{+++}}} + \underset{\text{Solution}}{\mathrm{K^+}}$$

The aluminum exchange experiments were carried out in the following way. Two fresh silver iodide precipitates were prepared by precipitating 0.01 mole of silver with slightly less than the equivalent amount of potassium iodide at room temperature, in a final volume of about 140 cc. The first precipitate was adjusted to a pAg of 6.0 (isoelectric point) by adding 0.01 N potassium iodide solution, and after the e. m. f. had become steady at this point, the precipitate was washed eight to ten times by decantation with 1.0×10^{-6} N neutral silver nitrate solution. The precipitate was then suspended in 50 cc. of a solution that was 6.0×10^{-5} molar in aluminum nitrate and 1.0×10^{-6} N in silver nitrate (isoelectric solution), and the suspension was stirred mechanically at room temperature for thirty minutes. The amount of aluminum in the solution was just sufficient to displace the adsorbed potassium or hydrogen ions equivalent to 0.1% adsorbed iodide, if iodide was adsorbed on the precipitate. The supernatant solution was poured off and tests for aluminum ion were made on 10-cc. portions, using 1,2,5,8-hydroxyanthraquinone as reagent, according to the procedure given by Kolthoff.[7] A pure water blank, and the original aluminum

solution, were used for comparison. The supernatant solution gave virtually as strong a reaction for aluminum as the original solution, showing that no aluminum ions were adsorbed or exchanged by the fresh silver iodide at the isoelectric point. In other words, there was no iodide adsorbed on the isoelectric precipitate.

The second fresh precipitate was adjusted to a *p*Ag of 7.8 (equivalence point) by the addition of dilute potassium iodide solution, and after the e. m. f. had become steady, the precipitate was washed by decantation with eight to ten portions of pure water. The washed precipitate was stirred with 50 cc. of 6.0×10^{-5} molar (18×10^{-5} *N*) aluminum nitrate solution for thirty minutes as in the case of the first precipitate, and the supernatant solution was tested for aluminum ion as before. The tests showed that practically all the aluminum (more than 80%) had disappeared from the solution on shaking with the equivalence-point precipitate. The amount of exchange found at this point corresponds to the presence of 0.08–0.09% *adsorbed* iodide.

The desorption and the exchange adsorption experiments furnish conclusive confirmation of the fact that freshly precipitated silver iodide (at room temperature) contains between 0.08 and 0.10% excess iodide in the adsorbed state at the equivalence potential. Incidentally it may be mentioned that from the change of the hydrogen-ion concentration of the supernatant liquid in the exchange experiments, it was found that potassium and not hydrogen ions were the counter ions originally adsorbed with the iodide.

Isoelectric Point of Freshly Precipitated Silver Iodide.—The silver ion concentration corresponding to the isoelectric point of silver iodide was determined in the following way. A slight deficiency of a solution of potassium iodide was added at room temperature to a solution of silver nitrate slightly acidified with nitric acid. Dilute potassium iodide solution was added until the *p*Ag indicated in Table I was reached, after which the mixture was stirred at room temperature for two to three hours until the e. m. f. became practically constant. The mixture was digested overnight at 90 to 95° in a closed glass-stoppered flask, and then cooled to room temperature and the e. m. f. measured. The direction in which the e. m. f. (*p*Ag) changed on digestion indicated whether silver or iodide ions had been desorbed, and the magnitude of the change was a measure of the amount desorbed. By repeating the experiments at various silver-ion concentrations, it was possible to locate the point at which there was no change in the e. m. f. on digestion (no desorption) and this point was the isoelectric point of the precipitate.

In the experiments in which iodide was desorbed, the free nitric acid in the solution (0.035 *N*) was neutralized with a slight excess of pure potassium bicarbonate before digestion, in order to prevent oxidation of the iodide. The solution was again acidified, after it had been cooled to room temperature for the final e. m. f. measurement.

The amount of silver iodide was the same in all experiments (0.01 of a mole), and the final volume of solution was 135 to 145 cc.

The data of the desorption experiments are given in Table I. The last column of the table gives the amount of silver or iodide desorbed, expressed in micro-equivalents (10^{-6} equivalents) per 0.01 mole of silver iodide.

8	.1828	.077	6.40	8.19	(.05) I$^-$

The data of the experiments in which iodide was desorbed are less reliable quantitatively, than in the experiments in which silver was desorbed, because of difficulty in obtaining steady e. m. f. readings in the acid iodide solutions. For this reason we have not extended the experiments very far to the iodide side.

An inspection of the data shows that the isoelectric point lies at a *p*Ag of about 6.05. This result is in excellent agreement with the value found by Verwey and Kruyt, who worked with well aged electrodialyzed silver iodide *sols*.

Adsorption of Silver and Iodide Ions by Freshly Precipitated Silver Iodide.—Precision titrations of silver with iodide were carried out at room temperature as described in a previous paper,[1] and the amounts of silver and iodide ions adsorbed by the fresh precipitate were calculated by comparing the titration curve obtained in this way with the theoretical curve. The theoretical curve is based on the assumption that the precipitate has no adsorptive properties.

The data obtained in a typical titration are given in Table II, and plotted in Fig. 1. The differences between points on the abscissas of the theoretical and experimentally observed titration curves at equal values of the e. m. f. are a direct measure of the amount of silver or iodide ions adsorbed by the precipitate.

The following examples will illustrate the method used to calculate the theoretical curve, and the amounts of silver and iodide ions adsorbed at various points on the experimental curve.

The initial amounts of potassium iodide and silver taken for the experiment were 1.61901 and 1.05426 g., respectively. Since the theoretical KI:Ag ratio is 1.53889, the theoretical amount of silver required to precipitate 1.61901 g. of potassium iodide is 1.05206 g. Therefore, the total amount of excess silver distributed between the liquid and solid phases, at the zero point on the curve before any dilute potassium iodide solution was added, was 1.05426 − 1.05206 = 0.00220 g. in 750 cc. If we assume that this excess silver is entirely in the liquid phase (no adsorption), the silver-ion concentration of the solution should be $2.72 \times 10^{-5} N$. Hence $p\text{Ag}_{\text{calcd.}}$ is 4.57, and $E_{\text{calcd.}}$ is +0.290 volt (see Fig. 1). However, the observed e. m. f. at this point was 0.283 volt, corresponding to a silver-ion concentration of $2.04 \times 10^{-5} N$ ($p\text{Ag}_{\text{obsd.}} = 4.69$). The difference between the calculated and observed silver-ion concentrations is, therefore, 6.8×10^{-6} equiv. per liter, corresponding to 5.1×10^{-6} equiv. per 750 cc. (5.1 microequivalents) which is the amount of silver adsorbed (X_{Ag}).

The theoretical end-point of the titration, corresponding to the original excess of 0.00220 g. of silver, is 1.96 cc. of 0.0104 N potassium iodide. After the addition of 1.9 cc., the observed silver-ion concentration was greater than that calculated, the difference corresponding to an adsorption of 0.3 of a microequivalent of iodide. Upon addition of more than 1.96 cc. of dilute iodide solution, the calculated iodide-ion concentration is found from the difference between 1.96 cc. and the amount added. The difference between the calculated and observed iodide-ion concentrations (multiplied by 0.75) corresponds to the amount of iodide adsorbed, after allowance for the amount of silver in the solution ($p\text{Ag}_{\text{obsd.}}$). For example, after addition of 2.3 cc., the excess iodide in the system (actually in the precipitate) corresponded to 3.52 microequivalents per 750 cc. and the solution contained 0.25 microequivalents of silver. Therefore, $X_{\text{I}} = 3.52 + 0.25 = 3.77$ microequivalents.

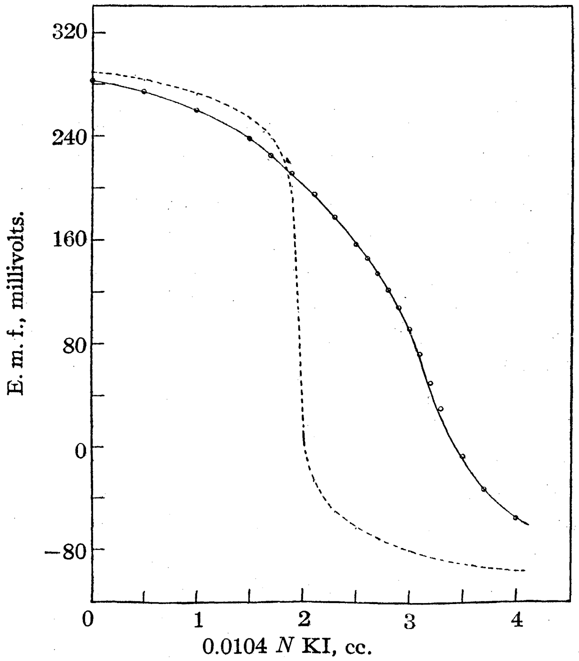

Fig. 1.—Titration curve at room temperature compared with theoretical (dotted) curve, data from Table II.

By reference to Fig. 1, it will be observed that the experimental and theoretical curves intersect at $E = +0.215$ v., corresponding to a pAg of 5.85, and hence there is no adsorption of silver or iodide ions at this point (isoelectric point). This value for the isoelectric point is in very good agreement with the value 6.05 determined in the desorption experiments. It must be clearly understood that the isoelectric point determined in this experiment and the method used to calculate the adsorption of silver and iodide ions by the precipitate, are entirely independent of any deductions or assumptions from the previous experiments. The calculations were based solely on the initial amounts of silver and potassium iodide taken and on the theoretical KI:Ag ratio.

Discussion

It is evident from Fig. 2, that the adsorption of silver ions by freshly precipitated silver iodide follows the expression $\Delta X = K \Delta \log C$. The same relation is found for the adsorption of iodide between *p*Ag = 5.85 and *p*Ag = 7.2, but at higher iodide-ion concentrations the values found for X_{I} are less than correspond to the foregoing equation.

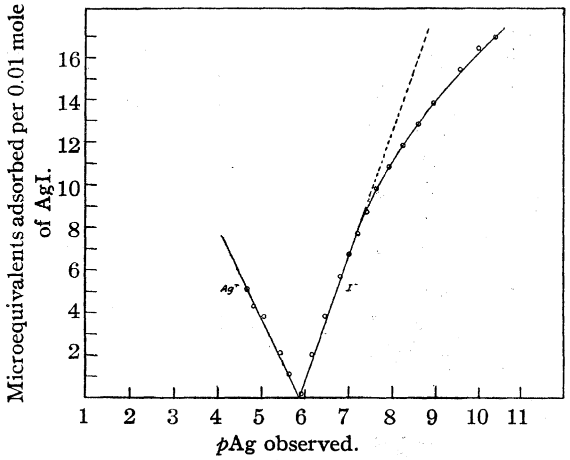

Fig. 2.—Adsorption of silver and iodide ions by freshly precipitated silver iodide, data from Table II.

It should be mentioned that this deviation is probably connected in some way with the fact that the e. m. f. measurements in the acid iodide solutions are somewhat unreliable. In addition, the precipitate ages more rapidly in the presence of excess iodide than when an excess of silver is present, and it is therefore to be expected that adsorption of iodide will become correspondingly less. It is possible, therefore, that the foregoing relation actually does hold over a wider range of iodide-ion concentrations, but it is very difficult to verify this possibility with a fresh precipitate. Working with an aged silver iodide *sol*, Verwey and Kruyt[3] found that the adsorption of iodide obeyed the foregoing relation over a much greater concentration range, than we have found with a fresh *precipitate*.

The K value found for iodide is greater than that of silver, indicating a greater adsorption of iodide than of silver ions. This result is contrary to that of Lange and Berger,[2] who failed to realize that over the region on their "silver adsorption" line between *p*Ag 6.0 and 7.8, there is actually an adsorption of iodide and not of silver ions.

If the foregoing deductions from the experimental data are correct, the precipitate should have the stoichiometric composition at the isoelectric point (*p*Ag = 6.0). As a matter of fact, we have found in the precise titrations that the theoretical KI:Ag ratio is found at the isoelectric point, when the proper correction is made for the excess silver in the solution. For example, in the titration whose data are given in Table II, if the end-point is assumed to be at the equivalence potential (+0.098 v.) the corresponding volume of 0.0104 N potassium iodide solution is 2.95 cc., the correction to the initial amount of potassium iodide taken is +5.1 mg., and hence the total amount of potassium iodide required to react with 1.05426 g. of silver is 1.6190 + 0.0051 = 1.6241 g. Therefore, the ratio KI:Ag calculated from these data is 1.5404, compared to the theoretical value 1.53889, and hence 0.10% too much potassium iodide was required. However, if the end-point of the titration is taken at the isoelectric point (E = 0.202 v., *p*Ag = 6.05), the corresponding volume of 0.0104 N potassium iodide solution is 2.01 cc., the correction to the initial amount of potassium iodide taken is 3.46 mg., and hence the total amount of potassium iodide is 1.61901 + 0.00346 = 1.62247 g. The amount of silver corresponding to *p*Ag = 6.05 in a volume of 750 cc. is 0.08 mg., and when this amount is subtracted from the initial weight of silver taken (1.05426 g.) the net amount of silver required is 1.05418 g. Therefore, the ratio KI:Ag is 1.62247 ÷ 1.05418 = 1.53908, which is only 0.006% larger than the theoretical ratio 1.53889. This result furnishes further striking confirmation of the deductions put forward in this paper.

Finally, this study shows that it is virtually impossible to obtain a true equivalent body of silver iodide by titration to the equivalence potential. Even if such a precipitate is washed repeatedly, it will be impossible to free it entirely of adsorbed iodide. A true equivalent body can be prepared by titration to the isolectric point (*p*Ag = 6.0), but such a precipitate will remain a true equivalent body only as long as it is kept in the isoelectric solution (*p*Ag = 6.0), because on washing with water it will again adsorb an excess of iodide.

Acknowledgment.—We wish to acknowledge our gratitude to the Graduate School of the University of Minnesota for the financial assistance which made this work possible.

Summary

1. The isoelectric point of freshly precipitated silver iodide has been found at a pAg of 6.0.

2. It has been shown that freshly precipitated silver iodide at the equivalence potential ($p\text{Ag} = p\text{I} = 7.83$) retains an excess of iodide adsorbed, corresponding to 0.09% of the total amount of iodide in the precipitate.

3. The adsorption of silver and iodide ions by the fresh precipitate follows the expression $\Delta X = K\Delta \log C$ in the pAg range between 4 and 7.2, iodide ions being more strongly adsorbed than silver ions.

4. The theoretical ratio KI:Ag is found in the potentiometric titration of silver with iodide at room temperature, if the end-point of the titration is taken at the isoelectric point ($p\text{Ag} = 6.0$), instead of at the equivalence potential, and if a correction is applied for the excess silver ions in the solution.

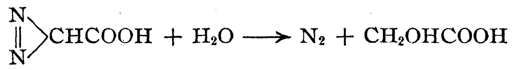
The Catalytic Decomposition of Diazoacetate Ion in Aqueous Solution[1]

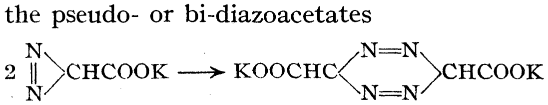
BY CECIL V. KING AND EDGAR DARE BOLINGER

Solutions containing salts of diazoacetic acid were first prepared by Curtius,[2] by alkaline hydrolysis of diazoacetic ethyl ester. The salts are, he found, stable in alkaline solution, but decompose with rapid evolution of nitrogen on neutralization with even carbonic acid, indicating that the acid is unstable



$$\begin{matrix}\mathrm{N}\\ \| \\ \mathrm{N}\end{matrix}\!>\!\mathrm{CHCOOH} + \mathrm{H_2O} \longrightarrow \mathrm{N_2} + \mathrm{CH_2OHCOOH}$$

Traube[3] made the sodium salt both by alkaline hydrolysis of the ester and by reduction of isonitroaminoacetic acid with sodium amalgam, and isolated the pure crystals from the solution. The preparation was further studied by Hantzsch and Lehmann[4] and by Müller,[5] who showed that the salts polymerize slowly in alkaline solution to the pseudo- or bi-diazoacetates



$$2\begin{matrix}\mathrm{N}\\ \| \\ \mathrm{N}\end{matrix}\!>\!\mathrm{CHCOOK} \longrightarrow \mathrm{KOOCHC}\!<\!\begin{matrix}\mathrm{N{=}N}\\ \\ \mathrm{N{=}N}\end{matrix}\!>\!\mathrm{CHCOOK}$$

(or isomers)

Pure solid potassium diazoacetate is stable if kept dry, cool and in the dark. It explodes on heating or on shock.

In this research it was found possible to study the rate of nitrogen evolution when the potassium salt is dissolved in dilute alkali or in buffers of very weak acids and their salts. The reaction is exceedingly sensitive to general acid catalysis, and is of particular interest because the reaction of a negative ion with the acid catalyst is involved. So far as the authors are aware, no other case of this type has been studied. If it is assumed that the rate-controlling step in such a catalysis involves the transfer of a proton from the acid to the reacting molecule, a negative ion should be much more sensitive to such catalysis than a neutral molecule. In accordance with this supposition it is found that the hydrogen-ion catalysis of this reaction is greater than the corresponding diazoacetic ester catalysis by some ten million-fold.

The reaction is of interest, too, because it shows abnormalities of a type first observed in the basic catalysis of nitramide decomposition in *m*-cresol solution.[6] In that case catalysis by anion bases was found to vary inversely with the concentration of the corresponding acid so that it was necessary to extrapolate the molar basic constants to $1/C_{\text{acid}} = 0$ to obtain comparable values. The catalysis by the anion of the solvent was variable and much lower than the value predicted from the catalysis by other bases. The latter abnormality was also found in the nitramide catalysis in water solution, *i. e.*, catalysis by the hydroxyl ion is lower than that predicted from the other

bases.[7,8] In the diazoacetate decomposition it has been found possible to study these abnormalities in greater detail. The catalysis by an acid decreases with increasing acid concentration, with increasing base concentration, and on addition of other acids. While it is possible to systematize these irregularities, no explanation has been found; one similar to that offered by Brönsted, Nicholson and Delbanco[6] is obviously inadequate.

In buffers of *p*H 10 or higher, the diazoacetate decomposition is strictly unimolecular. In neutral or slightly acid solutions, however, side reactions take place which increase the *p*H. The most important of these is replacement of nitrogen by the glycolic acid formed instead of water. This is analogous to the acid catalysis of nitrogen replacement by acids in the diazoacetic ester decomposition, which takes place to some extent in aqueous, but especially in non-aqueous solutions.[9]

Materials, Apparatus and Procedure

Potassium Diazoacetate.—Diazoacetic ethyl ester was hydrolyzed as described by Müller[5] by shaking with an equal weight of potassium hydroxide in 2 *M* solution. When the ester phase had just disappeared (about four hours) the solution was evaporated, as rapidly as possible, almost to dryness (at 25° *in vacuo* with an oil pump and "dry-ice" trap). The desired salt is somewhat soluble in alcohol, practically insoluble in ether; the polymer (which is formed to some extent) is practically insoluble in alcohol. Consequently the residue was extracted with alcohol and the diazoacetate precipitated by adding about 5 volumes of ether; potassium hydroxide remains in solution. This differs from Müller's method in that he recovered the salt by evaporating the solution almost to dryness, sucking off the mother liquor and washing the crystals with alcohol. This procedure, we found, almost invariably leads to a product containing 10–20% of the polymer, which seems to be formed rather rapidly in the presence of alcohol. In one preparation 22 g. of crude salt was obtained from 57 g. of diazoacetic ester, and 12 g. of pure salt was obtained on recrystallization (solution in alcohol, precipitation by adding ether). The best salt gave off 96–99% of the theoretical nitrogen on addition of acid; other samples containing 10–20% polymer were used in some of the experiments with no appreciable effect on the rate.

All water used was redistilled from acid permanganate in a quartz still. All alkaline solutions were made up free from carbonate, protected from the air with soda lime tubes, and withdrawn through side-arm burets. *Phenol* solutions were standardized by the bromate–bromide method[10] and the buffers made by mixing portions with the necessary amount of sodium hydroxide. Redistilled *piperidine* of the correct boiling point was dissolved and the solution standardized against hydrochloric acid (methyl red). All other solutions were made from C. P. or "Reagent" quality chemicals and standardized when necessary.

Apparatus.—Nitrogen evolution was followed with an apparatus similar to that used previously by Brönsted and Duus.[11] The reaction flasks were of 200-cc. capacity, and 100 cc. of solution was used in each run. The potassium diazoacetate was usually made 0.005 *M* (0.062-g. sample), although this was varied from 0.0025 to 0.01 *M* with not over 3% variation in rate constants. In very slow experiments the diazoacetate sample was dissolved, and a glass capsule containing solid oxalic acid was suspended in the flask neck; after sufficient pressure readings were obtained this was dropped in to hasten attainment of the final pressure. Since in this type of measurement the final reading is of greater importance than any other single reading, care was taken to check the final pressure over a period of several hours.

The reaction flasks were immersed in a thermostat maintained at 25 ± 0.01°. Since the manometers were not thermostated, care was taken to keep the room temperature constant to ±0.5° while readings were being made.

In a number of experiments it was necessary, as noted later, to measure the *p*H of the solutions after the decomposition. This was done with hydrogen electrodes of the Hildebrand type, the potential against a calomel half-cell being measured with a Leeds and Northrup type K potentiometer. Duplicate electrodes checked to 0.1 millivolt or less.

Velocity constants were obtained by plotting log $(a - x)$, or log (final pressure minus pressure at time t) against the time in minutes; the slope of the straight line obtained is $-1/2.303$. This method avoids errors due to lack of pressure equilibrium at the beginning of the run and was especially useful when the acidity decreased at the start and the reaction became unimolecular only after the first few minutes of the run.

Preliminary Experiments

Several experiments were made to determine whether the diazo salt contained any potassium hydroxide (especially the less pure samples), or was appreciably hydrolyzed. A solution containing 0.01 *M* phenol, 0.01 *M* phenate and a few drops of thymolphthalein solution was divided into two portions. To one, enough potassium diazoacetate to make the solution 0.005 *M* was added. No difference in color could be detected either immediately or after decomposition of some or all of the salt. Similar results were obtained when the *p*H of phosphate buffers was found to change little on addition and decomposition of the salt. When a sample of the salt was dissolved in water the *p*H rose to about ten; the *p*H, as measured with a glass electrode, did not change during the remainder of the decomposition. This could not indicate simple hydrolysis of the salt since in that case the *p*H should go back during the decomposition to that of potassium glycolate. It was caused by the initial formation of glycoylglycolate, to be described below. It can be concluded that the diazoacetic acid is at least as strong as glycolic acid, as would be ex-

pected from its molecular structure. The experiments with buffers also showed that potassium hydroxide was negligible as an impurity in the samples of diazoacetate prepared.

Experimental Results

1. Hydrogen (Oxonium) Ion and Water Catalysis.—The rate in dilute sodium hydroxide was found to give a constant molar value for the hydrogen-ion catalysis between concentrations of 0.4×10^{-12} and 2.0×10^{-12} *M*. The solutions were made up as indicated in Table I, the ionic strength being kept constant at 0.105 by additions of sodium chloride. The half-time of the reaction varied from seven to fifty hours. The hydrogen-ion concentrations were calculated from the sodium hydroxide concentrations, using 1.71×10^{-14} for the ion product constant of water in sodium chloride at 0.1 μ.[12]

TABLE I

CATALYSIS BY HYDROGEN ION: 25°, 0.105 μ

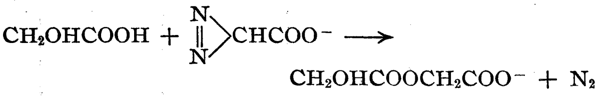
Expt.	C_{NaOH}, *M*	$C_{H_3O^+} \times 10^{12}$	$k \times 10^4$
31	0.008	2.14	7.76
27	.010	1.71	6.67
30	.0133	1.29	5.26
28	.020	0.85	3.45
29	.040	.43	2.08
32	.01	μ = .055	6.46
33	.01	μ = .015	6.22

The results are plotted in Fig. 1(A). The slope of the straight line, 3.57×10^8, is the molar catalytic constant for the hydrogen ion. The intercept, 5.5×10^{-5}, is the water constant, and when divided by the water concentration gives the molar water constant, 9.92×10^{-7}.

As shown by expts. 27, 32 and 33, catalysis in these solutions has a small, probably linear, positive salt effect amounting to 7% between μ = 0.015 and 0.105.

To obtain rates at higher hydrogen-ion concentrations, pure sodium chloride solutions were used, with or without the addition of very small amounts of hydrochloric acid. In these solutions a portion of the nitrogen was evolved very rapidly; the reaction then became slower and followed the unimolecular law for the remainder of the nitrogen evolution. The *p*H rose rapidly in this first period to the neighborhood of 10. A rate curve is shown in Fig. 2, compared with a normal rate curve in a phosphate buffer whose *p*H remains constant.

This abnormality was thought at first to be due to the formation of chloroacetic acid instead of glycolic acid, since a similar side reaction occurs with diazoacetic ester.[13] However, titration of the resulting solution with silver nitrate (dichlorofluorescein as indicator) showed no loss of chloride ion. The side reaction was finally shown to be formation of glycoylglycolate ion according to the reaction



$$CH_2OHCOOH + \overset{N}{\underset{N}{\|}}\!\!>CHCOO^- \longrightarrow CH_2OHCOOCH_2COO^- + N_2$$

Glycoylglycolic acid has been prepared and studied by Wolff and Lüttringhaus.[14] It is sufficiently stable, in cold solution, to titrate quantitatively with strong bases: heating on a water-bath with excess base hydrolyzes it completely to glycolate.

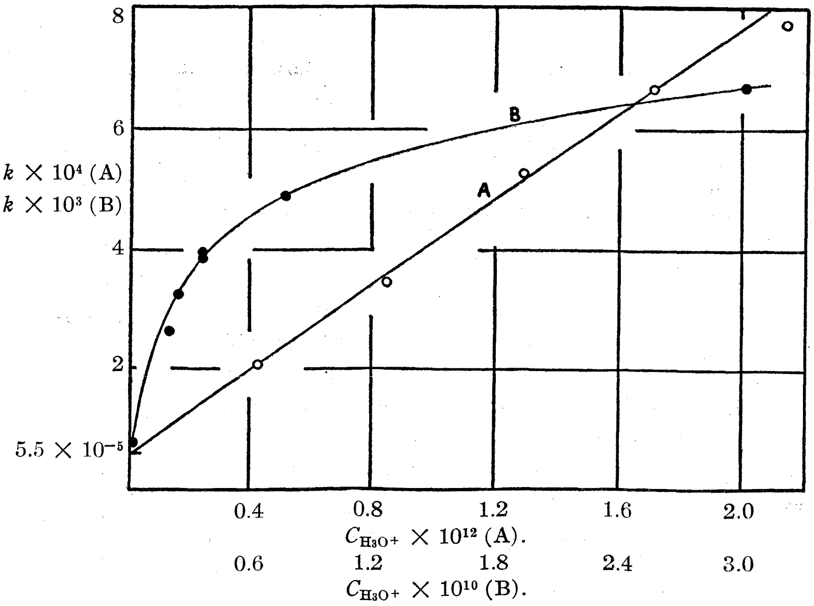


Fig. 1.—Catalysis by hydrogen ion.

The suspected formation of this ester was confirmed by experiments of the following type: 0.0005 mole of potassium diazoacetate was dissolved in 50 cc. of 0.2 *M* sodium chloride containing 0.000463 mole of hydrochloric acid. After

one hour titration with sodium hydroxide showed that 0.000142 mole of acid had disappeared. A slight excess of alkali was added and the solution was heated to 90° for forty-eight hours. Titration with acid showed that 0.000142 mole of base (within experimental error) had disappeared.

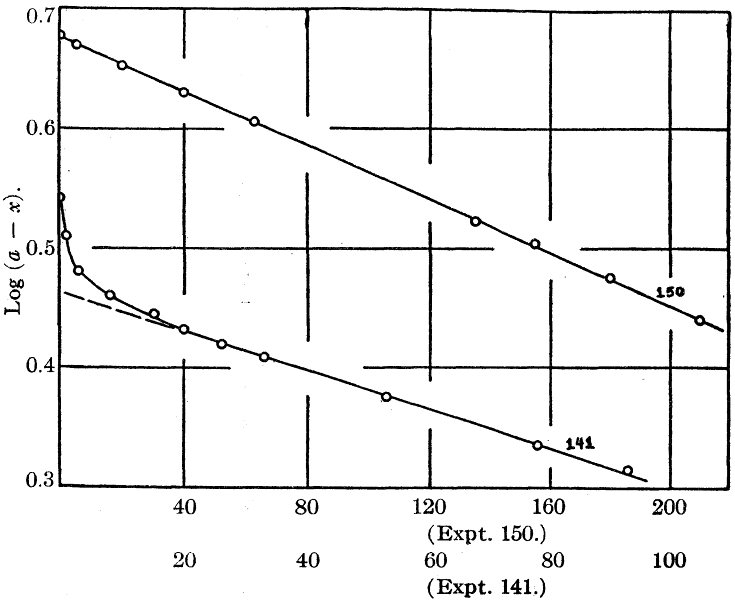

Fig. 2.—Typical time–rate curves: Expt. 150, phosphate buffer; Expt. 141, NaCl + a little HCl.

Heating for shorter periods (with these relatively low concentrations of reagents) showed partial return of the hydrogen ion which had disappeared initially.

In other solutions it was found by titration that the acid disappearing corresponded roughly with the amount of nitrogen evolved in the initial rapid reaction. Consequently it seemed safe to assume that the unimolecular rate after this initial rapid reaction was a measure of the catalysis by the hydrogen ion in the final solution, as measured a few hours later with the hydrogen electrode.

These rate constants are given in Table II with the corresponding hydrogen-ion concentrations, and are plotted in Fig. 1(B), the lowest point being the highest one of Fig. 1(A), expt. 29 (Table I). Most of these experiments were carried out at an ionic strength of 0.205; the results are comparable because of the low salt effect. The molar catalysis is constant only at very low values of the hydrogen ion concentration; however, it is still of the order of 10^7 at the highest concentration used.

TABLE II

CATALYSIS BY HYDROGEN ION AT HIGHER CONCENTRATIONS

Expt.	C_{NaCl}, M	C_{HCl} added $\times 10^4$	$C_{H_3O^+}$ at end $\times 10^{12}$	$k \times 10^4$
138	0.20	1.0	20.0	26.4

2. Phenol Catalysis.—The experiments in phenol–sodium phenate buffers are summarized in Table III; the phenol concentration is designated by C_{HP} and the sodium phenate by C_{P^-}. The ionic strength was made 0.105 in every case by suitable additions of sodium chloride. The values of k are plotted in Fig. 3; the solid lines represent the effect of keeping the buffer ratio and consequently the pH constant. The phenol has a decided catalytic effect; but since the curves are not straight lines, are not parallel, and do not extrapolate satisfactorily to values to be ascribed to the hydrogen ion, it is evident that the catalysis is not of a simple type. The molar phenol catalysis decreases with increasing phenate concentration. Since the hydrogen ion catalytic constant in a one-to-one phenol–phenate buffer should be only about 0.005, this effect cannot be explained entirely by repression of the hydrogen-ion catalysis by the phenate.

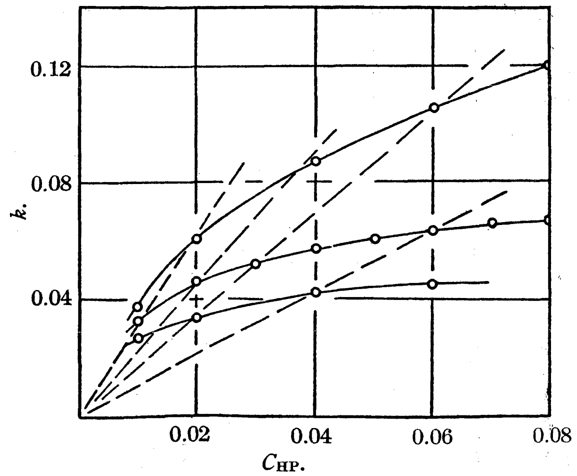

Fig. 3.—Catalysis by phenol: solid lines—constant phenol–phenate ratio; broken lines—constant phenate concentration.

The broken lines of Fig. 3 show that the molar catalysis by phenol at constant phenate concentration is approximately constant. Consequently, following the procedure of Brönsted, Nicholson and Delbanco,[6] the slopes of these lines were taken as molar constants, and plotted against $1/C_{P^-}$. The first three values (Fig. 5) lie on a straight line

$$k_m = 0.45 + 0.0344/C_{P^-}$$

The value 0.45 can be taken as the molar phenol constant at high base concentration.

18	.02	.010	.0600
19	.04	.020	.0872
20	.06	.030	.1055
21	.08	.040	.1202
25	.10	.050	.130
22	.01	.01	.0290 (μ = 0.015)
24	.01	.01	.0306 (μ = 0.055)

Salt effect in the phenol buffers was found to be small and probably of the linear type. It is about 12% between μ = 0.015 and 0.105, as shown by expts. 22, 24 and 3.

3. Ammonium-Ion Catalysis.—Concentrations were planned for this system to define better the effect of varying the ammonium-ion concentration at constant ammonia concentration. The details are given in Table IV and the values of k are plotted in Fig. 4. The molar catalysis constants may be represented by

$$k_m = 0.57 + 0.0274/C_{NH_3}$$

which is the equation for the straight line of Fig. 5.

There is a pronounced negative salt effect on the rate in ammonia–ammonium chloride solutions at low ionic strengths, and a number of experiments were run to investigate this. Table V gives the results, and in Fig. 6 the values of log k are plotted against $\sqrt{\mu}$. It was necessary, of course, to use a constant ammonia concentration throughout; since the secondary salt effect is small this is approximated in the solutions of Table V. At low ionic strengths the rates conform to the Brönsted requirement of a slope of −1.

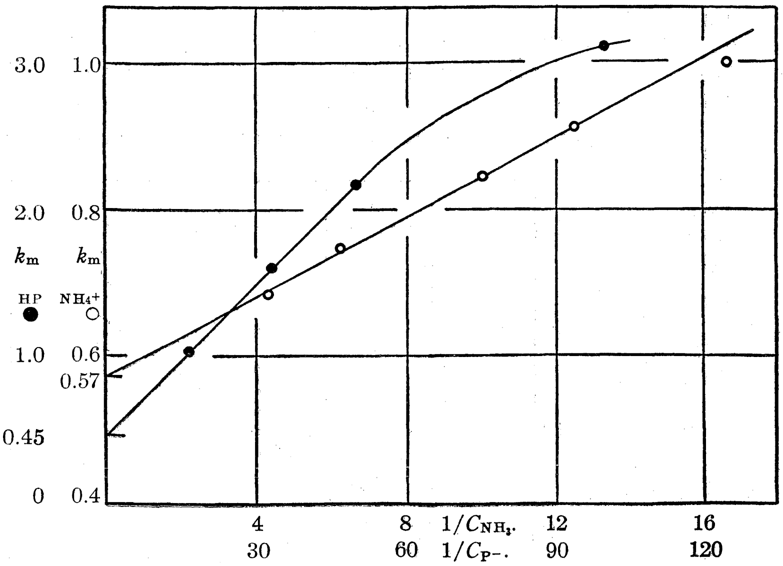

Fig. 5.—Plot of k_m *vs.* reciprocal of ammonia and phenate concentration.

4. Piperidinium-Ion Catalysis.—The piperidinium ion is an acid of the same charge type as the ammonium ion, but is much weaker. The experiments of this series are summarized in Table VI, where the piperidine and piperidinium-ion concentrations are represented by C_P and C_{PH^+}, respectively. The rate constants are plotted in Fig. 7 where the solid and broken lines have the same significance as before. The lines for constant buffer ratios are apparently straight and extrapolate to approximately the values expected for the hydrogen-ion catalysis (see Fig. 1); but the piperidinium-ion catalysis again decreases with increasing piperidine concentration. The slopes of the broken lines are taken as molar catalysis constants for the corresponding values of the piperidine concentration, and plotted in Fig. 9 against the reciprocal of the latter. The three lowest points lie approximately on the straight line

$$k_m = 0.0060 + 0.00086/C_P$$

5. Secondary Phosphate-Ion Catalysis.—Buffers of secondary and tertiary phosphate ions were made by adding sodium hydroxide to solutions of pure disodium hydrogen phosphate. All the experiments were carried out with the ionic strength 0.205 to make it possible to vary the ion concentrations sufficiently. Sodium sulfate was used as the inert salt to make up the ionic strength, in order to keep the valence types as nearly comparable as possible. The data are shown in Table VII and the values of *k* are plotted in Fig. 8. The solid curves are for constant ratios of $HPO_4^=$ and $PO_4^\equiv$ introduced into the solution rather than for the equilibrium mixtures, and this partly accounts for their slopes and lack of extrapolation to reasonable values for the hydrogen-ion catalysis. The points on the broken lines also do not represent quite the same base ($PO_4^\equiv$) concentrations, but this is not of great importance in analyzing the results. The slopes of the broken lines are plotted against $1/C_{PO_4^\equiv}$ in Fig. 9; the straight line is represented by the equation

$$k_m = 0.0050 + 0.00079/C_{PO_4^{=}}$$

TABLE VII

CATALYSIS BY SECONDARY PHOSPHATE ION: 25°, 0.205 μ

Expt.	$C_{HPO_4^-}$, M	$C_{PO_4^{=}}$, M	$k \times 10^3$
143	0.010	0.020	1.16
144	.020	.020	1.66
145	.030	.020	2.11
148	.005	.010	1.50
147	.010	.010	1.83
146	.015	.010	2.30
149	.005	.005	2.15
150	.0075	.005	2.56
151	.010	.010	1.58 (μ = 0.105)
152	.010	.010	2.15 (μ = 0.305)

This system shows a decided positive salt effect, which is to be expected theoretically. No attempt was made to study this at low ionic strengths, but expts. 151, 147 and 152 of Table VII indicate its magnitude.

6. Acetic Acid Catalysis.—The catalytic effect of acetic acid is far too great to be measured in ordinary buffers; the reaction proceeds at a measurable speed in pure sodium acetate solutions. Consequently this series was made in 0.2 M sodium acetate to which small amounts of acetic acid or sodium hydroxide were added; the pH of each solution was measured with the hydrogen electrode after the run. The acetic acid concentration was then calculated, using K_c for acetic acid = 2.18×10^{-5} in such solutions.[15] There was an initial rapid evolution of nitrogen as in the dilute hydrochloric acid solutions (Table II), though not as great; and this was accompanied by an initial rise in pH. The rates again were unimolecular during the remainder of the reaction. Data are given in Table VIII. The rate constants are corrected by subtracting values for the hydrogen-ion catalysis, estimated from the curve of Fig. 1. The validity of this procedure is rather doubtful since addition of acetic acid probably represses the hydrogen-ion catalysis somewhat; however, the correction is only about 10% of the total rate. The values of k fall reasonably well on the straight line of Fig. 10, considering the difficulties of obtaining accurate results in such solutions. The slope of this line, 1.20×10^4, is taken as the molar catalytic constant of acetic acid. The value is probably somewhat higher, however, than would be obtained for infinite acetate-ion concentration.

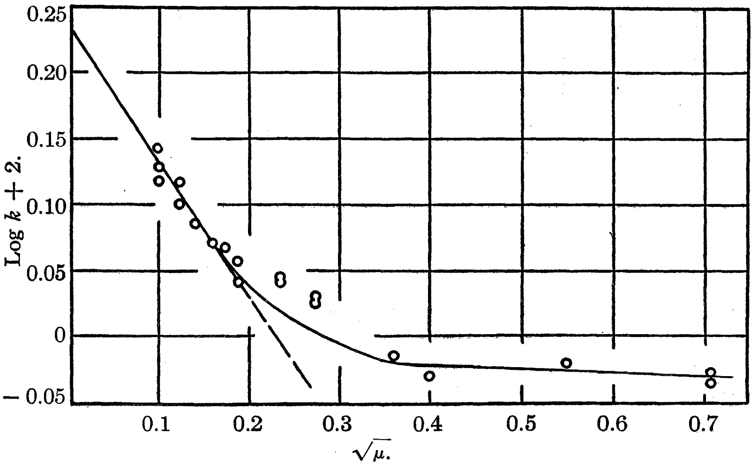

Fig. 6.—Salt effect on catalysis by ammonium ion.

Correlation and Discussion of Results

The molar catalytic constants conform well with the Brönsted expression for such catalysis.[16]

$$k_m = GK_A^x q^x p^{1-x}$$

The necessary data for applying this relation are given in Table IX. The values of k_m are those extrapolated to infinite base concentration except for hydrogen ion and acetic acid. The values of p and q are taken as the number of atoms in the acid molecule from which a proton can be detached and the number of atoms in the base molecule to which a proton can attach itself, as suggested by Pedersen.[17] Acid dissociation constants at infinite dilution are used in accordance

---

(15) Cohn, Heyroth and Menkin, THIS JOURNAL, **50**, 696 (1928).

(16) Brönsted, *Chem. Rev.*, **5**, 231 (1928).

(17) Pedersen, *J. Phys. Chem.*, **38**, 581 (1934).

with the suggestion of Pedersen that these are a better measure of the "inner acid strength" than values at finite ionic strength. Conformity to the equation is somewhat improved by these modifications.

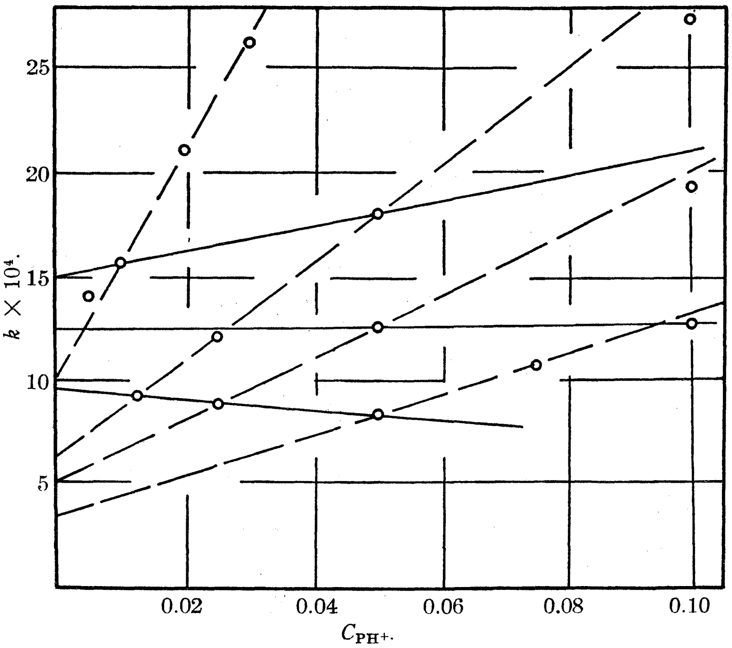

Fig. 7.—Catalysis by piperidinium ion: solid lines—constant buffer ratio; broken lines—constant piperidine concentration.

TABLE IX

THE RELATION BETWEEN VELOCITY CONSTANTS AND ACID STRENGTH

Acid	p	q	k_m	K^0_A
H_2O	1	1	9.92×10^{-7}	1.80×10^{-16}
$HPO_4^=$	1	4	0.0050	4.90×10^{-13}
$C_5H_{10}NH_2^+$	1	1	.0060	8.00×10^{-12}
C_6H_5OH	1	1	.45	1.06×10^{-10}
NH_4^+	1	1	.57	5.52×10^{-10}
$HC_2H_3O_2$	1	2	1.32×10^4	1.75×10^{-5}
H_3O^+	1	1	3.57×10^8	55.5

The values of K^0_A in Table IX for water, phenol and acetic acid were taken directly from the literature.[12,18,19] Those for piperidinium ion and ammonium ion were calculated from values for the basic constants[18] (pp. 273, 260) and Harned's value for water.[12] The value for the phosphate ion was determined from the data of Brönsted and King for the hydrolysis of the tertiary phosphate ion at 15°.[20] Their values of K_c were plotted against $\sqrt{\mu}$ and extrapolated to zero μ by drawing a straight line with the theoretical slope (−2) through the point of lowest concentration. The value obtained is probably not accurate, but seems more satisfactory than any value found in the literature. The value for the piperidinium ion was checked satisfactorily from the data of Brönsted and King.

In Fig. 11 values of log k_m/p are plotted against log (q/pK^0_A). The straight line corresponds to the equation

$$k_m/p = 1.90 \times 10^7 (q/pK^0_A)^{0.833}$$

The excellent conformity to this relation over a range of velocity constants from 10^{-6} to 10^{+8} and of dissociation constants from 10^{-16} to 10^{+2}, with such a variety of acid types, is rather remarkable. A detailed study would probably show some variation of both G and x with acid type, as in the nitramide decomposition. However, the effect of the charge type of the proton donor is small compared to that of the proton acceptor; the molar constant for hydrogen ion, 3.57×10^8, may be compared with that for hydrogen ion catalysis of diazoacetic ethyl ester decomposition, 13.6 at zero ionic strength at 15°.[21] This seems to indicate that formation of the true "critical complex" is intimately connected with the proton transfer.

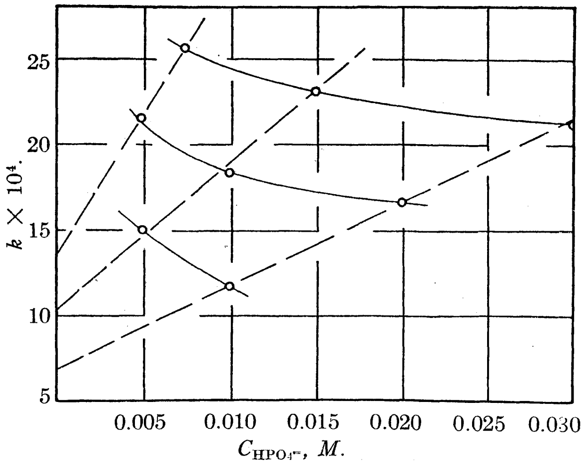

Fig. 8.—Catalysis by secondary phosphate ion.

Salt Effects and Mechanism.—It has been assumed in the preceding sections that the rate-controlling step is

$$N_2CHCOO^- + HA^z \longrightarrow \underset{\text{Intermediate Complex}}{(N_2CHCOO,HA)^{z-1}}$$

---

(18) "International Critical Tables," Vol. VI, p. 271.

(19) Harned and Ehlers, THIS JOURNAL, **54**, 1350 (1932); MacInnes and Shedlovsky, *ibid.*, **54**, 1429 (1932).

(20) Brönsted and King, *ibid.*, **47**, 2523 (1925).

(21) Guggenheim, *Phil. Mag.*, [7] **2**, 538 (1926).

This is in agreement with the salt effects found. With hydrogen ion as the catalyst there should be a negative primary salt effect of the exponential type. In ordinary concentrations of a strong acid secondary salt effect would be negligible; but in the solutions used here (Tables I and II) the concentration of hydrogen ion is controlled through the equilibrium

$$2H_2O \rightleftarrows H_3O^+ + OH^-$$

Since this has an exponential positive salt effect of the same magnitude as the primary salt effect, the net result is the small linear effect found.

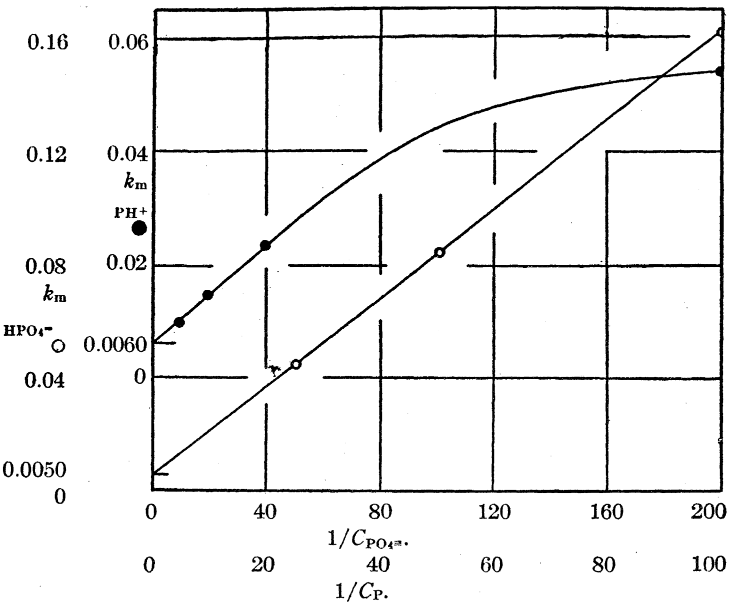

Fig. 9.—Plot of k_m *vs.* reciprocal of tertiary phosphate and piperidine concentration.

In the phenol–phenate buffers both primary and secondary salt effects are small, the largest effect being an increase in the hydrogen-ion concentration on addition of salt. In the ammonium ion buffers, however, the primary effect is of the negative, exponential type, while the secondary effect is small. The net effect at low ionic strengths is represented by the equation

$$\log k_c = \log k_a - \sqrt{\mu} \text{ (at 25°)}$$

as shown in Fig. 6. This relation is valid over only a very limited range, however, because of the several salt effects involved.

In the secondary phosphate solutions, the primary effect is of the negative exponential type, the secondary of the positive exponential type. The secondary phosphate ion increases in concentration on addition of salt sufficiently to make the net effect positive, although the hydrogen ion decreases in concentration simultaneously.

Other possible mechanisms for the reaction would be: (1) spontaneous reaction of the undissociated acid; (2) acid catalysis of the undissociated acid reaction; and (3) base catalysis of the undissociated acid reaction. The first is excluded by the general acid catalysis. The second would be compatible with the salt effect in some of the buffer systems, but not in the sodium hydroxide solutions. For if the rate equation were

$$dx/dt = kC_{N_2CHCOOH}C_{H_3O^+} f_0 f_1/f_1$$

the primary salt effect would be small; but since

$$C_{N_2CHCOOH} = K\frac{C_{N_2CHCOO^-} f_1}{C_{OH^-} f_0 f_1} \text{ and } C_{H_3O^+} = \frac{K^0_w}{C_{OH^-}} \frac{1}{f_1^2}$$

the rate would be proportional to the square of the hydrogen-ion concentration and have a large exponential salt effect. The third possibility would lead, in sodium hydroxide solutions, to a rate independent of the hydroxyl-ion concentration.

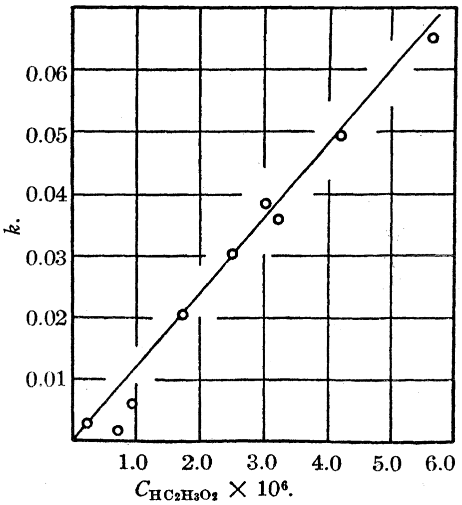

Fig. 10.—Catalysis by acetic acid.

Abnormalities.—The repressive effect of base on the acid catalysis was found in every system where the base concentration could conveniently be varied. The decreasing molar catalysis at higher acid concentration was most evident with the hydrogen ion, but sometimes appeared in the other systems. In Fig. 7 especially, all the points for the highest piperidinium-ion concentration fall below the straight lines for rates at constant base concentration. The acetic acid catalysis seems to fall off at higher concentrations, though the experimental accuracy is not great enough to warrant definite conclusions.

These abnormalities are probably generally characteristic of extremely high acid or base catalysis. In the nitramide decomposition in *m*-cresol[6] where similar effects were first found, the value of *G* in the Brönsted expression ($10^4 - 10^6$) is far higher than in any other case studied except the diazoacetate reaction described here. Even in the hydroxyl-ion catalysis of the nitramide decomposition in water, molar constants calculated from the data of Brönsted, Pedersen and Duus[7,11] are variable and lower than predicted from catalysis by other bases; and Marlies and La Mer[8] found, at an hydroxyl-ion concentration of 10^{-11} in hydrochloric acid solution, a molar catalytic constant 0.8×10^6 while the Brönsted relation predicts a value close to 10^9. If it were possible to measure the hydroxyl ion effect at lower concentrations, higher values would probably be found.

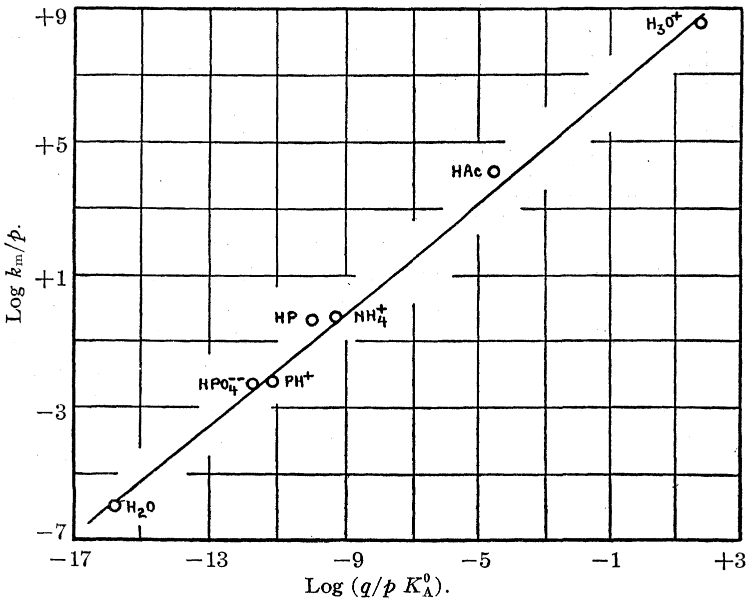

Fig. 11.—The relation between rate constants and acid dissociation constants: PH^+, piperidinium ion; HP, phenol; HAc acetic acid.

It is of interest to note that the value of *x* for the diazoacetate reaction, 0.833, is practically the same as that for the nitramide decomposition with some base types, both in aqueous and non-aqueous solution. This may be coincidence or may indicate a similar rate-controlling mechanism. According to the Brönsted picture the exponents for K_A and K_B should be the same for conjugate acids and bases when the rate-controlling mechanisms are similar, but this has not been found to hold for any systems studied previously.

Summary

The preparation of potassium diazoacetate, obtained by hydrolyzing diazoacetic ethyl ester, has been improved; the salt can easily be prepared free from alkali or polymerization products.

The reaction of the diazoacetate ion with water, giving nitrogen and glycolate ion, has been found to be phenomenally sensitive to general acid catalysis. The molar catalytic constant for the hydrion, 3.57×10^8 at 25°, is the highest recorded for any reaction. It may be compared with the corresponding molar constant for the decomposition of the neutral diazoacetic ethyl ester molecule, which is 13.6 at zero ionic strength at 15°. The exceptionally high rate indicates that in such catalysis the electric charge of the proton acceptor is far more important than the charge of the proton donor.

The catalysis shows abnormalities of a type found previously for the decomposition of nitramide in *m*-cresol solution. The molar catalysis constants decrease with increasing base concentration, and also with increasing acid concentration. A linear relation is found between the molar constants and the reciprocal of the base concentration except at low values of the latter.

The molar acid constants at high base concentration show excellent conformity with the equation

$$\frac{k_m}{p} = 1.90 \times 10^7 \left(\frac{q}{p} K_A^0\right)^{0.833}$$

and thus with the Brönsted theory. The value of *G*, 1.90×10^7 is the highest yet recorded; the value of *x*, 0.833, is practically the same as that found for basic catalysis of nitramide decomposition.

Salt effects in several buffer systems have been found to be in agreement with the general theory and with the mechanism postulated for this reaction.

[Contribution from the School of Chemistry of the University of Minnesota]

The Adsorption of Barium Salts on Barium Sulfate from Solutions in 50% Ethanol

By I. M. Kolthoff and Wm. M. MacNevin

In work previously reported in this Journal,[1] it was mentioned that a considerable adsorption of barium nitrate on barium sulfate was found from a medium containing approximately 50 volume per cent. ethanol, whereas the adsorption from aqueous medium was negligibly small. This medium effect upon the adsorption of electrolytes on ionic lattices has not been studied in the literature. The results of the investigation described in this paper constitute a first approach to the problem. Moreover, they allow us to test the quantitative relation between the adsorption of potential determining ions and the concentration of the latter under equilibrium conditions, and the relation between adsorbability and solubility (Paneth–Fajans rule).

Materials Used

Barium Sulfate.—The preliminary experiments were carried out with a fine product of barium sulfate used in previous work,[1a] the average particle size of which was about 0.14 micron. A large amount of a product prepared in a similar way was used in the determination of the adsorption isotherm of various barium salts.

Solvent.—A mixture of equal volumes of 95% undenatured ethanol and conductivity water was used as a solvent, and designated as 50% ethanol, although the alcohol content is slightly less.

Barium Nitrate.—A c. p. product was twice recrystallized from water, dried at 110° and stored over anhydrous calcium chloride.

Barium Chloride and Barium Bromate.—C. p. products were twice recrystallized from water, dehydrated and rehydrated over deliquescent sodium bromide. They were weighed as dihydrate and monohydrate, respectively, and dehydrated at 150° before dissolving in 50% ethanol. In the solubility experiments the anhydrous salts were used.

Barium Perchlorate.—This salt was prepared by neutralizing barium hydroxide with perchloric acid, and recrystallizing the salt from water. The monohydrate was dried at 150° before dissolving in 50% ethanol. In the solubility experiments Baker's "Dessicchlora" was used.

Barium Iodide.—A c.p. product was used without further purification.

Barium Bromide and Barium Thiocyanate.—C. p. products were recrystallized three times from water and dried over fused sodium hydroxide.

Barium Formate.—This salt was prepared by neutralizing formic acid with barium hydroxide. The product was recrystallized three times and dehydrated over fused sodium hydroxide.

Calcium Bromate.—To a suspension of barium bromate in water an equivalent amount of sulfuric acid was added and the mixture shaken until the transformation was complete (seventy-two hours). After shaking for five more days the barium sulfate was filtered off and the bromic acid in the filtrate neutralized with a calcium hydroxide suspension. The crystals separating out upon evaporation showed pronounced triboluminescence, either when dry or suspended in the mother liquor. The salt was recrystallized three times from water and dried at 120°.

Potassium Bromate.—A c. p. product was used.

Analytical.—The *barium* concentration was determined before and after adsorption by evaporating measured portions to a small volume and adding an excess of 0.1 molar potassium chromate to the hot solutions. The mixture was made alkaline with ammonia, digested for an hour and cooled. The barium chromate was filtered, washed, dissolved in 6 *N* hydrochloric acid and the chromate determined iodometrically after diluting with water.

Bromate was determined iodometrically. In order to get accurate results it was necessary to remove the alcohol by evaporation. The solution was made slightly alkaline with sodium hydroxide to prevent reduction of bromate by the alcohol and evaporated to dryness. The residue was taken up in water and the bromate determined iodometrically by the standard procedure.

Nitrate was determined by reduction to ammonia with Devarda's alloy.[2] The ammonia was distilled into an excess of dilute hydrochloric acid and determined iodometrically by the hypochlorite–bromide method.[3] Calcium was determined after removal of the alcohol by precipitation as calcium oxalate and titrating the precipitate with permanganate.

Experimental Results

Solubility Determinations in 50% Ethanol

An excess of the anhydrous salt was shaken at room temperature (25 ± 1°) in the 50% ethanol for forty-eight hours. The solution was filtered and 25 ml. of the filtrate evaporated in a weighed platinum dish. The residue was weighed after drying to constant weight at 150°. The results are given in Table I.

Table I

Solubility of Barium Salts in 50% Ethanol

Barium salt	Bromate	Nitrate	Formate	Chloride
Solubility in mols per liter	1.72×10^{-3}	5.71×10^{-2}	0.14	0.384
	Bromide	Iodide	Perchlorate	Thiocyanate
Solubility in mols per liter	1.46	2.53	2.77	2.89

---

[3] I. M. Kolthoff and V. A. Stenger, *Ind. Eng. Chem., Anal. Ed.*, **7**, 79 (1935).

The solubility of potassium bromate was found to be 0.051 molar and that of calcium bromate 1.05 molar.

Adsorption Experiments

Experiments were made in which samples of barium sulfate were shaken for half an hour, one hour and twenty-four hours with solutions of the barium salts in 50% ethanol. It was found that after a period of one hour of shaking the amount of salt adsorbed remained constant. A shaking period of one hour was adopted in the final experiments. Working with the fine product of barium sulfate used in previous work[1] it was ascertained first that an equivalent adsorption of barium ions and anions occurred. Experiments were carried out with barium nitrate and bromate at various concentrations and the amounts of barium and anion adsorbed determined separately (for details see doctor's thesis of junior author). Within the experimental error an equivalent adsorption of barium and anion was found. Thus, after shaking 0.6 g. of barium sulfate with 50 ml. of 0.0002 molar barium bromate in 50% ethanol, 24.8% of barium and 24.0% of bromate were found to be adsorbed. In the case of barium nitrate 28.0 (±1)% of nitrate and 26.6(±1)% of barium were found to be adsorbed from the 0.0002 molar solution. From the 0.001 molar solution 13.0% of nitrate and 12.4% of barium had disappeared.

The determination of the amount of salt adsorbed was attempted in a direct way by making use of the washing process described and applied by Miss de Brouckère.[4] This method did not yield useful results in our hands. After shaking, the suspensions were centrifuged, the supernatant liquid decanted and the precipitate shaken for one minute with 10 ml. of a saturated solution of barium sulfate in 50% ethanol. The mixture was centrifuged and the process repeated. After three such washings, 88% of the total amount of barium bromate originally adsorbed in a certain case was removed from the surface.

After the above results were obtained, it was decided to determine the amounts adsorbed in the following way. A given amount of the new sample of finely divided barium sulfate was shaken with 50 ml. of the barium salt solution in 50% ethanol for one hour, the suspension centrifuged and the barium or anion concentration determined in 25 ml. of the clear centrifugate.

The results are given in the following tables. It was found that within the range of concentrations studied, the adsorption was given quantitatively by the expression

$$x/m = ac^{1/n} \qquad (1)$$

in which x is the amount adsorbed expressed in moles, m the amount of adsorbent used in grams, c the final concentration in the solution, and a and $1/n$ constants.[5] The values of the latter, computed from the experimental results, and the values of x/m calculated with the aid of the above equation are reported in the tables.

TABLE II

ADSORPTION OF BARIUM BROMATE

1 g. of $BaSO_4$; 50 ml. of solution; BrO_3^- determined; $a = 1.80 \times 10^{-4}$; $1/n = 0.40$

Init. concen., molar × 10^3	Final concen., molar × 10^3	Absorbed in, %	$x \times 10^5$ Found	$x \times 10^5$ Calcd.
1.527	1.287	15.7	1.20	1.26
1.000	0.795	20.5	1.02	1.04
0.500	.348	30.4	0.76	0.76
.250	.146	41.7	.52	.52
.100	.039	61.2	.31	.32

TABLE III

ADSORPTION OF BARIUM NITRATE

5 g. of $BaSO_4$; 50 ml. of solution; Ba determined; $a = 0.69 \times 10^{-4}$; $1/n = 0.32$

Init. concn., molar × 10^3	9.48	3.79	1.90	0.948[a]
Final concn., molar × 10^3	8.01	2.74	1.14	.68
Adsorbed in %	15.4	27.8	40.0	28.3
$x/m \times 10^5$ found	1.46	1.05	0.76	0.67
$x/m \times 10^5$ calcd.	1.50	1.12	.79	.68

[a] Barium sulfate used, 2 g.

The adsorption of barium nitrate increases upon addition of alkali nitrate to the solution. The first experiment in Table III was repeated, the solution also containing 0.1 mole of sodium nitrate per liter. In the latter case 21.6% of the barium nitrate was adsorbed, as compared with 15.4% in the absence of sodium nitrate.

TABLE IV

ADSORPTION OF BARIUM PERCHLORATE

10 g. of $BaSO_4$; 50 ml. of solution; Ba determined; $a = 0.59 \times 10^{-4}$; $1/n = 0.40$

Init. concn., molar × 10^3	9.77	4.89	0.98[a]
Final concn., molar × 10^3	8.04	3.67	.65
Adsorbed in %	17.7	25.0	33.6

Final concn., molar $\times 10^3$	0.52	0.54	0.63	0.73
Adsorbed in %	48.0	45.9	36.8	27.0
$x/m \times 10^5$	0.24	0.23	0.18	0.67

Discussion

1. One of the most interesting results of this study is that the Freundlich adsorption isotherm was found to hold for the adsorption of barium salts on barium sulfate from a medium of 50% ethanol. One certainly would expect to be dealing here with the adsorption of a "potential determining ion,"[6] in which case it is claimed[7] that the relation between the amount adsorbed x and the concentration c is given by an expression

$$\Delta x = k\Delta\log c \qquad (2)$$

and not by the expression

$$\log x = k\Delta\log c \qquad (3)$$

The only experimental proof of the validity of expression (2) has been found in the case of silver iodide[8] where the adsorption of silver and of iodide apparently occurs on the active surface. In our study we worked with well-aged barium sulfate. Although in none of the cases investigated (Tables II–VI) a saturated surface corresponding to a monomolecular layer of adsorbed barium salt was obtained, it is quite evident that in the present study we are mainly dealing with an adsorption on the normal surface and not on active surface. In the derivation of expression (2) assumptions have been made which, theoretically, are not entirely justified. On the basis of the present study it becomes doubtful whether equation (2) holds generally for the adsorption of potential determining ions. That the barium ions actually behave as potential determining ions is evidenced by their peptizing effect upon the barium sulfate. When the solid (average diameter about 0.14 micron) is shaken with aqueous solutions of barium nitrate or other barium salts a clear centrifugate is obtained readily. In 50% ethanol solutions of barium salts, it is difficult to obtain a clear centrifugate after shaking with barium sulfate. As much as two hours of centrifuging at 3000 r. p. m. was required to obtain a clear supernatant liquid. A maximum peptizing effect was found at a certain concentration of the barium salt, in the case of barium bromate in 0.002 molar solutions.

There is a possibility that only a small fraction of the adsorbed barium acts as potential determining ion and that we are dealing mainly with a "true adsorption" on the entire surface comparable to the adsorption of salts having no ion in common with the lattice, for which expression (3) holds within wide limits of concentration.[7b] Actually it was found that salts such as potassium bromate and calcium bromate from solutions in 50% ethanol gave a pronounced adsorption on barium sulfate. Upon shaking 10 g. of barium sulfate with 50 ml. of 0.002 molar potassium bromate, 15.7% of the salt was found to be adsorbed, corresponding to 1.6×10^{-6} mol per g. of barium sulfate. Equivalent amounts of cation and anion were adsorbed. The adsorption of calcium bromate was measured at different concentrations by determining the bromate content before and after adsorption. The results are given in Table VII; it is seen that the percentage of bromate adsorbed changes in an irregular way with the concentration. In order to decide whether an equivalent adsorption of calcium and bromate occurred, it was decided to determine the amount of calcium adsorbed from the 0.001 molar solution (first solution in Table VII). It was found that 45.7% of the calcium was adsorbed, which is just double the amount of bromate adsorbed (23.6%). This result indicates that a hydrolytic adsorption has taken place and that the salt is adsorbed in the form of $Ca(OH)(BrO_3)$. In agreement with this conclusion it was found that the supernatant liquid after the adsorption

showed a strongly acid reaction. The hydrolytic adsorption accounts for the irregular change of the bromate adsorption at different salt concentrations as it will be a function of the *p*H of the solution in equilibrium with the solid.

TABLE VII

ADSORPTION OF BROMATE FROM CALCIUM BROMATE

10 g. of $BaSO_4$; 50 ml. of solution

Init. concn., molar × 10^3	1	0.5	0.4	0.2
Final concn., molar × 10^3	0.764	0.358	0.303	0.169
Adsorbed BrO_3^- in %	23.6	28.4	24.3	15.5
$x/m \times 10^5$	0.12	0.071	0.049	0.015

2. In Table VIII the relation is given between adsorbability from and solubility of the barium salts in 50% ethanol. The value of the constant *a* in the expression for the adsorption isotherm (equation 1) is taken as a measure of the adsorbability. From the experimental data, *a* and $1/n$ were calculated for four barium salts, an average value of 0.38 for $1/n$ being found. For the other barium salts, the adsorption of which was determined at one concentration only, the value of $1/n$ equal to 0.38 was used in the calculation of the "*a*" values.

It is seen that there is no close parallelism between adsorbability and solubility.[9] Barium formate is adsorbed more strongly than the nitrate, although the latter is much less soluble. Particularly the perchlorate is out of place. Its adsorbability is of the same order as that of the chloride and much greater than that of the bromide or iodide, although its solubility in 50% ethanol is greater than that of the halides.

TABLE VIII

SOLUBILITY AND ADSORBABILITY

	Barium salt	Order of absorbability expressed in $a \times 10^4$	Relative solubility in 50% ethanol	Order of increasing solubility
1	Bromate	1.80	1	1
2	Formate	0.91	81	3
3	Nitrate	.69	33	2
4	Perchlorate	.59	1610	7
5	Chloride	.54	223	4
6	Bromide	.37	848	5
7	Iodide	.35	1477	6
8	Thiocyanate	.26	1663	8

Summary

1. The adsorption of barium salts on barium sulfate and of salts not having an ion in common with the lattice is much greater from 50% ethanol than from water.

2. Contrary to the expectation, the adsorption of barium salts from 50% ethanol on barium sulfate follows the Freundlich adsorption isotherm.

3. No close parallelism has been found between adsorbability and solubility.

4. Potassium bromate gives an equivalent adsorption of cations and anions. Calcium bromate yields a hydrolytic adsorption and was found to be adsorbed in the form of $Ca(OH)(BrO_3)$.

(9) For a similar conclusion on the adsorption of silver salts on silver iodide compare the study of J. S. Beekley and H. S. Taylor, *J. Phys. Chem.*, **29**, 942 (1925).

MINNEAPOLIS, MINN. RECEIVED MAY 25, 1936

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, WOOLWICH POLYTECHNIC]

The Primary and Secondary Dissociation Constants of Malonic, Succinic and Glutaric Acids by Potentiometric Titration

BY WILLIAM L. GERMAN AND ARTHUR I. VOGEL

The primary thermodynamic dissociation constants at 25° of malonic, succinic and glutaric acids have been determined by conductivity methods by Jeffery and one of us[1] but it has not yet been found possible to calculate the true secondary dissociation constants satisfactorily from conductivity data alone. Attention was therefore directed to the potentiometric method for the simultaneous evaluation of both constants. Previous electrometric titrations for these three acids have been carried out by Britton[2] at 18°, Gane and Ingold[3] at 25° for malonic acid; by Bjerrum[4] at 18°, Auerbach and Smolczyk[5] at 20°, Britton[2] at 18°, Kolthoff and Bosch[6] at 18°, Gane and Ingold[3] at 25°, Ashton and Partington[7] at 25° for succinic acid; and by Gane and Ingold[3] at 25°

for glutaric acid. The large differences between the results of the various investigators for succinic acid cannot be attributed solely to the varying concentration and temperatures at which the titrations were performed; a particularly large discrepancy is that for succinic acid obtained by Gane and Ingold with the hydrogen electrode and by Ashton and Partington with the quinhydrone electrode. Gane and Ingold[3b] (p. 2153) remark in connection with the correction of their data for interionic effects that "the application of the Debye and Hückel equation for activities of electrolytes . . . involves practical difficulties" and they have accordingly employed an empirical method involving the determination of "K" at a series of concentrations and extrapolating to zero concentration. We have carried out new potentiometric titrations of malonic, succinic and glutaric acids against sodium hydroxide with the quinhydrone electrode at 25° and have calculated the thermodynamic dissociation constants by the method described recently by German, Jeffery and Vogel.[8] Table I summarizes our results: the conductivity values of Jeffery and Vogel[1] and Gane and Ingold's figures calculated by their empirical method, are included for purposes of comparison.

TABLE I

Acid	K_1 therm. $\times 10^5$ (Cond.)	Authors K_1 therm. $\times 10^5$	 K_2 therm. $\times 10^6$	Gane and Ingold K_1 therm. $\times 10^5$	 K_2 therm $\times 10^6$
Malonic	139.7	143	2.20	149	2.03
Succinic	6.626	6.37	2.54	6.41	3.33
Glutaric	4.535	4.46	3.77	4.53	3.80

It will be noted that the agreement of our potentiometric with the conductivity values for K_1 is within 2.5, 4 and 2% for malonic, succinic and glutaric acids, respectively.

Calculation shows that an error of one millivolt will cause a variation of *ca.* 5% in both K_1 and K_2. Our measurements were in general reproducible to 0.2–0.3 millivolt so that no greater accuracy than 1–2% could be expected in the final figures for K_1 and K_2. The somewhat greater difference for K_1 actually found must be attributed to the inherent disadvantages of the method of calculation. It would appear therefore that no greater accuracy than 2–4% can be realized in the determination of K_1 and K_2 by potentiometric titration with the quinhydrone electrode under the experimental conditions that we have employed.

The mean values of the true dissociation constants together with the intercarboxylic distances, expressed in Å., calculated after Bjerrum[4] (A) and Gane and Ingold[3b] (p. 2161) (B) are collected in Table II. Gane and Ingold's values[3b] (p. 2153) (G. and I.) for these acids are added for comparison.

TABLE II

Acid	K_1 therm. $\times 10^5$	K_2 therm. $\times 10^6$	r (A)	r (B)	r (G. and I.)
Malonic	143	2.20	1.39	3.47	3.43
Succinic	6.37	2.54	3.89	5.13	5.58
Glutaric	4.46	3.77	6.60	7.15	7.11

Experimental

Preparation of Materials. Acids.—The details have been described by Vogel[9] and by Jeffery and Vogel[1] (p. 23). Kahlbaum pure malonic acid was recrystallized twice from benzene–ether–light petroleum (b. p. 60–80°) and melted at 136° (dec.). Kahlbaum pure succinic acid was recrystallized from acetone and melted at 185–185.5°. Glutaric acid was prepared from the nitrile, b. p. 149–150° (14 mm.), and after crystallization from chloroform melted at 97.5–98°.

Sodium Hydroxide Solutions.—These were prepared by the electrolysis of chemically pure sodium chloride solution with a mercury cathode as described by Jeffery and Vogel[10] and were standardized immediately before use with constant b. p. hydrochloric acid.[11] All dilutions were carried out with equilibrium water prepared in a "Vogel" still.[12] The quinhydrone and calomel were prepared as detailed by German and Vogel.[13]

Apparatus.—Full details have been given by German and Vogel[13] and by German, Jeffery and Vogel.[8] An electrically-controlled oil thermostat maintained at 25 ± 0.01° was used. Stirring was effected with purified nitrogen. All titrations are accurate to 0.01 cc. The cell employed was

$$\mathrm{Hg} \mid \mathrm{Hg_2Cl_2},\ \mathrm{KCl}\ (\text{satd.}) \parallel \text{Solution, quinhydrone} \mid \mathrm{Pt}$$

The liquid junction potential was assumed to be negligible. Standardization was effected before and after each titration against at least two independent 0.1 N calomel cells[14] for which a value of 0.3376 volt was assumed,[15,16] and also against 0.05 M potassium hydrogen phthalate (chemically

pure).[16,17] The value of 0.3337 volt recently suggested by Guggenheim and Schindler[18] was not adopted in the present work as this figure was not in agreement with the value yielded by the standard buffer and, further, this would have led to values for the primary dissociation constants differing considerably from the strictly thermodynamic constants deduced from conductivity by Jeffery and Vogel[1] and would also have led to a similar deviation for phenylacetic acid.[13,19] The agreement, within 2–3%, of our values for K_1 with those deduced from conductivity provides the strongest evidence in support of our procedure and the neglect of diffusion potentials. Should, however, a new value for E_0 be *universally* accepted at some future date, our results can be recalculated readily.

The values of $K_{1\text{incomp.}}$ and $K_{2\text{incomp.}}$ (the "incomplete" or "unvollstandige" constants of Bjerrum and Unmack[20]) were computed by Britton's method[2] and are incorporated in Table IV for comparison with published data. The "ther-

[20] Bjerrum and Unmack, *Kgl. Danske Videnskab. Selskab.*, **9**, 11 (1929).

modynamic" dissociation constants[21] were calculated from $pK_{1\text{therm.}} = pK_{1\text{incomp.}} + 0.505\ \mu^{0.5}$ (i) and $pK_{2\text{therm.}} = pK_{2\text{incomp.}} + 1.515\ \mu^{0.5}$ (ii), where $pK_{1\text{therm.}} = -\log K_{1\text{therm.}}$ etc., and the total ionic strength, which was deduced from the expression[8]

$$\mu = 0.5\left(a + h + c\left\{\frac{1}{(h/K_1 + 1 + K_2/h)} + \frac{4}{(h/K_2 + 1 + h^2/K_1K_2)}\right\}\right)$$

where c is total acid concentration, a is concentration of sodium hydroxide added, h is hydrion concentration, and K_1 and K_2 are the "incomplete" (previously termed "classical") values.

The use of the approximate expressions (i) and (ii) over the concentration range ($\mu = 0.0015$ to 0.006) that we have employed is justified by the following considerations. Morton[22] has deduced the equation

$$p_k = p\text{H} + \log\,[\text{Acid}]/[\text{Salt}] + \log f_a/f_s$$

in which f_a and f_s are the activity coefficients of the undissociated acid and of the salt anions or of the acid anions of lower and higher valency, respectively. This may be written in the form

$$\begin{aligned} pK_{\text{therm.}} &= pK_{\text{incomp.}} + \log f_a/f_s \\ &= pK_{\text{incomp.}} + (n - 0.5)\mu^{0.5} - B\mu \end{aligned}$$

since $\log f_a/f_s = (n - 0.5)\mu^{0.5} - B\mu$; n is the basicity of the acid. For phthalic acid, which is the acid most closely allied to those that we have studied, the highest value of B found by Morton was approximately 1 and this was in the presence of $M/3$ potassium sulfate. It can be readily shown that with $B = 1$ in the most concentrated solutions that we have employed, the maximum error introduced by the neglect of this term is *ca.* 1%. Actually the error will be much less than this.

Summary

The thermodynamic dissociation constants of malonic, succinic and glutaric acids have been determined by potentiometric titration with the quinhydrone electrode. The values for the primary dissociation constants agree within 2–4% with those determined by conductivity.

LONDON, S. E. 18, ENGLAND RECEIVED DECEMBER 20, 1935

---

[21] It is appreciated that this term should be strictly confined to values obtained by experimental technique which does not involve uncertainties in liquid junction potentials and by strict thermodynamic methods, as in the precise work of Harned and co-workers. It is believed, however, that the approximations introduced are sufficiently precise for the ultimate accuracy of 2–3% which is claimed to justify the use of the term.

β-Amoxyethyl Esters of *p*-Aminobenzoic Acid

BY H. V. ASHBURN, A. R. COLLETT AND C. L. LAZZELL

In continuation of our work on the β-alkoxyethyl esters of *p*-aminobenzoic acid,[1] we have prepared a series of six amoxyethanols, three of which are new, together with the corresponding *p*-nitro and *p*-aminobenzoates. The alcohols used were purified by fractional distillation, until a sample having a boiling point range of 0.5° or less was obtained.

β-Amoxyethanols

The β-amoxyethanols were prepared by heating the desired alcohol with ethylene oxide in the presence of a small amount of sulfuric acid as a catalyst[2] except in the case of the tertiary amoxyethanol, for which acid aluminum fluosilicate was used as a catalyst.[3]

The method was as follows: 20 to 30 moles of the alcohol, 7 moles of ethylene oxide, and 1 cc. of concentrated sulfuric acid were placed in an autoclave and heated at 130–150° for eight to ten hours. The autoclave was then emptied and the contents fractionally distilled. The tertiary amyl compound was prepared by using acid aluminum fluosilicate as the catalyst and heating at 130–150° for twenty-five hours.

These compounds are all colorless, sweet smelling liquids, very soluble in alcohol and ether. The iso primary amyl, active primary amyl and tertiary amyl compounds are all appreciably soluble in water at 25° while the *n*-primary amyl, secondary amyl and active secondary amyl compounds are only slightly soluble.

Table I lists the yields and physical constants of all the amoxyethanols prepared, together with the analyses of the new compounds. The tertiary butoxyethanol has been prepared since the only physical property recorded in the literature is the boiling point, 150–153°. Its density is 0.8935

[a] Crystallized after setting for several weeks; recrystallized from ligroin gave a melting point of 74.5°. [b] Pressure 0.42 mm.

($d^{25}_{abs.}$), refractive index is 1.41322 $n^{25}D$, and it boils at 151.3 under 750 mm. pressure.[3]

All boiling points were taken with a certified thermometer completely immersed in the vapor. Refractive indices were taken with a dipping refractometer at 25°. The yields are based upon the amount of ethylene oxide used.

***p*-Nitrobenzoates.**—The *p*-nitrobenzoates of these β-amoxyethanols were prepared according to the method of Conn, Collett and Lazzell.[4] These esters are viscous, practically odorless liquids having a pale yellow color. They are insoluble in water but soluble in all the common organic solvents. Table II lists the analyses, physical constants and yields of all the new *p*-nitrobenzoates prepared.

The analyses were made by titration with titanous chloride. Refractive indices were determined by means of an Abbé refractometer at 25°. Surface tensions were obtained by means of a du Noüy tensiometer at 25° and Harkins' correction for the ring method was applied. The yields are based upon the amount of glycol ether used.

***p*-Aminobenzoates.**—The *p*-aminobenzoates were prepared from the corresponding nitro compounds as described in the previous article,[1] except for the distillation. After the removal of the alcohol, a small amount of zinc dust was introduced into the distilling flask and the distillation carried out at pressures of 1 mm. or less. This removed the red by-product which was formed upon exposure of the reduced solution to the air.

Table III lists the analyses and yields of the *p*-aminobenzoates, and the melting points of the picramides.

TABLE III

p-AMINOBENZOATES ($ROCH_2CH_2OOCC_6H_4NH_2$-*p*)

Succinic-α-*d*,α'-*d* Acid and its Derivatives. II. Stereochemistry of the Type RR'CHD

BY MARLIN T. LEFFLER[1] AND ROGER ADAMS

The effect of deuterium upon the optical activity of organic molecules and the possibility of obtaining an answer to the question as to whether RR'CHD may be optically active has engaged the attention of investigators in several laboratories.[2]

Schoenheimer and Rittenberg[3] compared the optical activity of coprostanone-d_2 and coprostanone and noted that the difference in optical activity was very small, if at all appreciable. Erlenmeyer and Gärtner[4] were unable to resolve phenylpropionic-α-*d*,β-*d* acid of which they obtained an impure sample by reduction of cinnamic acid with deuterium iodide and phosphorus.

In the research now reported the reduction of diethyl fumarate and diethyl maleate was carried out using practically 100% deuterium in the presence of platinum catalyst. The resulting diethyl succinate-α-*d*,α'-*d* corresponds to the stereochemical R'CHD-CHDR' type, separable into a *meso* and a *racemic* modification. It is well known that the action of permanganate on maleic acid produces *meso*-tartaric acid while the *racemic* modification results from fumaric acid. Although the deuterium reduction of an ethylenic linkage probably does not follow the above "*cis*" addition, the reduction of diethyl maleate should still be capable of yielding a different form from that given by diethyl fumarate. As shown by the constants (Table I), the diethyl succinic-α-*d*,α'-*d* specimens from both sources appeared to be identical, nor was the presence of isomers in either sample noticed during the distillation of the ester.

The densities of diethyl succinate-α-*d*,α'-*d* (Table I) from different reductions of the same material show some variance, possibly due to varying amounts of hydrogen "impurity." In a previous paper[1b] it was pointed out that the observed densities of dimethyl succinate-α-d_2,α'-d_2 and succinic-α-d_2,α'-d_2 anhydride were lower than and did not agree with the calculated values. The calculation of these values was based primarily upon the assumption of identical molecular volumes for deuterium and hydrogen. Since that time it has been observed[5] that the molecular volumes of the two isotopes are not identical and may differ sufficiently to affect the densities of deuterium compounds. However, it is evident that this effect must vary with the substances in question, as the densities[6] of several deuterium compounds, of established purity, agree very well with the calculated values; others show less agreement. In any case, it is worth mentioning that the densities (Tables I, II) observed for diethyl succinic-α-*d*,α'-*d* and its derivatives show fair agreement with the theoretical values. It is entirely probable that the discrepancy which does exist may be due both to a difference in molecular volumes and to hydrogen "impurities."

Succinic-α-*d*,α'-*d* acid was prepared by the hydrolysis of the ester from both of the abovementioned sources. These specimens of dideu-

[a] In order to obtain satisfactory analyses on the acids and the anhydrides, only copper oxide was used in a combustion tube of twice the ordinary length. [b] A mixed melting point of the d_2-acid from fumarate and maleate showed no depression. A mixture containing approximately 50% of either the d_2-acid from fumarate or from maleate and succinic acid melted at 184–185°. [c] The method of calculation was that used previously.[1b] [d] Mixtures containing varying amounts of succinic anhydride and either of the d_2-anhydrides melted at 119.3–119.6°.

terio acid were identical in melting point, and fractional crystallization (Table II) failed to indicate the presence of more than one form. The two samples of dideuterio acid, on treatment with acetyl chloride, gave two identical specimens of succinic-*α-d,α'-d* anhydride (Table II).

As previously pointed out,[1b] carbon analyses of deuterium compounds may indicate semi-quantitatively the presence of deuterium, while hydrogen isotope analyses are generally of little value. The carbon analyses (Table II) are sufficiently different from the anhydride analogs to show clearly that deuterium was not entirely replaced during any of the previous treatments, and the density determinations (Table II) indicate that if any replacement at all occurred it was not appreciable in amount.

All of the evidence derived from the above-mentioned experimental results points, in a negative sense, to the symmetry of the carbon RR'CHD. It was thought to be of additional and equal interest to compare the degree of optical activity of several deuterium and hydrogen analogs. This was made possible by studying the rotations of the brucine, quinine, strychnine and cinchonine salts of both succinic-*α-d,α'-d* acid and succinic acid. The rotations of the hydrogen and deuterium salts (Table III) were observed under as nearly identical conditions as possible. Within the limits of experimental accuracy, these rotations were identical.

Granted that the one form of succinic-*α-d,α'-d* acid obtained from the above-mentioned reductions might have been the *meso* modification, it

[a] All readings were taken at 20 ± 0.1° to prevent variations in ionization. [b] This weight was made up to 10.00 cc. [c] l = 1 dec.

was nevertheless desirable to attempt the resolution of this acid. The cinchonine salt was selected for this purpose as cinchonine has been used successfully to resolve tartaric acid.[7] The fractionation gave four crops of dideuterio salt, identical in crystalline form, melting point, and rotation. None of these fractions gave any evidence of mutarotation.

Experimental

Diethyl Fumarate.—This ester was prepared according to the method described in "Organic Syntheses,"[8] and was purified by two distillations at atmospheric pressure followed by a final distillation *in vacuo*. The fraction used in the reduction experiments below had the following physical constants: b. p. 218–218.5° (corr.) at 740 mm. or 109–110° at 16 mm.; $n^{20}_{\rm D}$ 1.4410.

Diethyl Maleate.—The product from esterification of maleic acid with absolute alcohol by the same procedure had, after careful fractionation, the following physical constants: b. p. 225° (corr.) at 740 mm. or 115–116° at 16 mm.; $n^{20}_{\rm D}$ 1.4415. These constants check those described in the literature.

Diethyl Succinate-α-d,α'-d (from Diethyl Fumarate).—The apparatus employed for the reduction was identical to that previously described.[1b] Two separate reduction experiments were carried out, the same conditions prevailing in each. Each reduction tube was charged with 4.00 g. of diethyl fumarate, 0.05 g. of platinum catalyst, and 7 cc. of dry ethyl acetate (acetic acid free). An excess of practically 100% deuterium was available. The reduction was complete at the end of eight hours and no additional absorption took place in an additional three hours. At the end of this time the reaction mixture was filtered from the catalyst and the ethyl acetate solvent distilled off below 60° at slightly reduced pressure. The residue was distilled *in vacuo* at two different pressures, the latter being carefully controlled by a constant pressure regulator. The boiling point (Table I) was constant and gave no indication of the presence of isomers. The yield of purified diethyl succinate-α-d,α'-d from 4.00 g. of diethyl fumarate was 3.4–3.7 g. (83–91%). This product was free from any unsaturated material as shown by an alkaline permanganate test.

Diethyl Succinate-α-d,α'-d (from Diethyl Maleate).—Complete reduction of diethyl maleate carried out in a similar manner was attained in six hours, and no additional absorption of deuterium took place in two more hours. The boiling point of the product was constant, gave no indication of the presence of isomers, and was identical with the boiling point of the product obtained from diethyl fumarate (Table I) (yield 88%). This product gave no indication of unsaturation as shown by alkaline permanganate.

Diethyl Succinate.—This ester was prepared by the reduction of either diethyl fumarate or diethyl maleate with hydrogen. The same conditions were used as in the reduction experiments with deuterium. The constants check those recorded in the literature (Table I).

Succinic-α-d,α'-d Acid (Origin: Diethyl Fumarate).—The hydrolysis of diethyl succinate-α-d,α'-d (origin: fumarate; d^{20}_4 1.0533) was accomplished by boiling 10 g. of the ester for five to six hours with 100 cc. of water containing three drops of concentrated nitric acid. After the hydrolysis was complete, the clear solution was cooled and the nitric acid was neutralized by adding the calculated quantity of sodium carbonate. The solution was then evaporated to dryness *in vacuo* at 40–50° to give 6.6 g. of crude acid. The latter was fractionally crystallized in the following manner. The entire amount of crude succinic-α-d,α'-d acid was dissolved in 90 cc. of hot water, filtered, and the resultant solution allowed to evaporate slowly. The evaporation was carried out in stages; a crop of crystals was separated after each 20% decrease in volume. These crops were purified by further crystallization.

In no case was the presence of isomers indicated during the fractionation of the acid, as the solubilities and melting points were essentially identical in all fractions. Succinic-α-d,α'-d acid crystallized in colorless needles which appeared to be identical to those obtained from the reduction of diethyl maleate and identical to succinic acid itself. The melting point of the deuterio acid was about 0.5° lower than that of succinic acid (Table II).

Succinic-α-d,α'-d Acid (Origin: Diethyl Maleate).—Diethyl succinate-α-d,α'-d (d^{20}_4 1.0543) obtained by the reduction of diethyl maleate was hydrolyzed in exactly the same manner as used in the hydrolysis above. The latter was fractionally crystallized by the procedure outlined for the dideuterio acid from diethyl fumarate. The melting points and solubilities were identical for the various fractions and also identical with the values of the acid from diethyl maleate reduced with deuterium (Table II).

Succinic Acid.—A pure specimen of succinic acid was prepared in the same way as the above by the saponifica-

---

(7) Pasteur, *Ann. chim. phys.*, **38**, 469 (1853).

(8) "Organic Syntheses," Vol. X, 1930, p. 48.

tion of diethyl succinate. Both the diethyl succinate resulting from the reduction of diethyl fumarate and diethyl maleate were used in preparing succinic acid. The acid so obtained was recrystallized from water, which method gave a product with the same melting point as that obtained by sublimation. It was found that at low pressure (1 mm. at 145°) sublimation could be conveniently used to recover deuteriosuccinic acid (or succinic acid) from otherwise unworkable residues. Samples purified in this way had the same melting point as crystallized material.

Succinic-*α-d,α′-d* Anhydride.—The purified deuterio acid (2.36 g.; origin, diethyl fumarate) was refluxed for three hours with acetyl chloride (4.7 g.). At the end of this time, the clear solution was allowed to cool spontaneously whereby colorless prisms of succinic-*α-d,α′-d* anhydride were deposited. After further cooling in ice-water, the product was separated by filtration, washed with cold, absolute ether, and vacuum dried over soda-lime to remove traces of acid chloride. The crude succinic-*α-d,α′-d* anhydride (yield 91%) was fractionally crystallized from freshly distilled acetic anhydride. Only a single form was indicated, m. p. 119.3–119.6°.

Succinic-*α-d, α′-d* acid (origin: diethyl maleate) was converted in the same way as the above into the anhydride. The succinic-*α-d,α′-d* anhydride was identical with the product from diethyl fumarate, m. p. 119.3–119.6°. The density of both this and the sample above was determined by the procedure previously described.[1b] The values from these density determinations (Table II) indicate that under the conditions used in the previous hydrolyses there was no appreciable amount of deuterium lost by exchange with hydrogen.

Succinic Anhydride.—This anhydride was prepared in the same way as the dideuterio compound.

ALKALOIDAL SALTS OF SUCCINIC-*α-d,α′-d* ACID

A Comparison of the Rotations of Deuterium and Hydrogen Analogs

Brucine Salt of Succinic-*α-d,α′-d* Acid.—To a solution of 0.1800 g. of succinic-*α-d,α′-d* acid in 20 cc. of hot absolute alcohol was added 0.6994 g. of *l*-brucine (hydrate). The solution was boiled for several minutes after all of the alkaloid had dissolved, was filtered while hot, and set aside to crystallize. The first crop of colorless clusters amounted to 0.55 g. and the second, 0.12 g. Both crops melted at 216–218° (dec.) and the melting point was not changed by further recrystallization from absolute alcohol. Rotations of various fractions were identical.

Anal. (micro-Dumas). Calcd. for $C_4H_4D_2O_4 \cdot 2C_{23}H_{26}O_4N_2$: N, 6.16. Found: N, 6.04.

Brucine Salt of Succinic Acid.—This salt was prepared in the same manner as above for the deuterium analog. On recrystallization from absolute alcohol it formed colorless prism clusters melting at 216–218° (dec.).

Anal. (micro-Dumas). Calcd. for $C_4H_6O_4 \cdot 2C_{23}H_{26}O_4N_2$: N, 6.17. Found: N, 6.06.

Quinine Salt of Succinic-*α-d,α′-d* Acid.—To a solution of 0.150 g. of succinic-*α-d,α′-d* acid in 30 cc. of hot water was added 0.405 g. of *l*-quinine. The alkaloid went into solution immediately, and on allowing the solution to cool, colorless, soft needles of the salt separated. The first crop amounted to 0.32 g. and the second, 0.1 g. Both crops melted with shrinking at 175°, becoming entirely liquid at 201°. As indicated by the melting point, the salt was evidently hydrated.[9] The melting point was not altered by further recrystallization from water, but when the sample was dried *in vacuo* at 100° for twenty-four hours it melted without shrinking at 198–201°. All fractions were identical in properties.

Anal. (micro-Dumas). Calcd. for $C_4H_4D_2O_4 \cdot C_{26}H_{24}O_2N_2 \cdot H_2O$: N, 6.06. Found: N, 6.21.

Quinine Salt of Succinic-*α-d₂,α′-d₂* Acid.—This salt was prepared from the tetradeuterio acid[1b] by the same method used for the dideuterio compound. It crystallized from water in the same form and was dried in the same way as the analogs; m. p. 198–201°.

Anal. (micro-Dumas). Calcd. for $C_4H_2D_4O_4 \cdot C_{20}H_{24}O_2N_2 \cdot H_2O$: N, 6.03. Found: N, 6.06.

Quinine Salt of Succinic Acid.—This salt was prepared in the manner used above for the analogs. It crystallized from water in colorless, fluffy needles which, after drying *in vacuo* at 100°, melted at 198–201° (dec.).

Anal. (micro-Dumas). Calcd. for $C_4H_6O_4 \cdot C_{20}H_{24}O_2N_2 \cdot H_2O$: N, 6.08. Found: N, 6.11.

Strychnine Salt of Succinic-*α-d,α′-d* Acid.—An amount of 0.2400 g. of succinic-*α-d,α′-d* acid was dissolved in 20 cc. of hot absolute alcohol, followed by the addition of 0.668 g. of *l*-strychnine. The mixture was allowed to evaporate above 35° and two fractions separated. These were identical. After drying *in vacuo* at 100°, the crystals softened at 190° and melted at 210°. By the usual procedure of crystallization, strychnine crystallized and had to be separated mechanically from the salt.

Anal. (micro-Dumas). Calcd. for $C_4H_4D_2O_4 \cdot 2C_{21}H_{22}O_2N_2$: N, 7.11. Found: N, 7.29.

Strychnine Salt of Succinic Acid.—This was prepared as described for the deuterium analog. The colorless spurs[10] which crystallized from absolute alcohol were dried *in vacuo* at 100°. They softened at 190° and melted at 210°.

Anal. (micro-Dumas). Calcd. for $C_4H_6O_4 \cdot 2C_{21}H_{22}O_2N_2$: N, 7.13. Found: N, 7.19.

Attempted Resolution of Succinic-*α-d,α′-d* Acid

Cinchonine Salt of Succinic-*α-d,α′-d* Acid.—To a solution of 0.3600 g. of succinic-*α-d,α′-d* acid in 10 cc. of hot water was added 0.883 g. of *d*-cinchonine. The mixture was refluxed for several minutes to give a clear solution. As the salt crystallized only with great difficulty from an unseeded aqueous solution, crystalline salt was prepared from dioxane as a solvent, allowing the dioxane to evaporate very slowly. These crystals were later used to seed the water solution which was preferred to dioxane as a fractionating solvent. After two days of standing, large colorless prisms had separated. Several fractions were obtained as follows: (1) 0.26 g.; (2) 0.19 g.; (3) 0.27 g. and (4) 0.13 g., totalling 0.85 g. (68.5%). All of these fractions were obviously hydrated[11] as they effloresced on exposure to the air. The above weights of the various

[11] Hesse, *Ann.*, **176**, 232 (1874).

fractions were taken after drying the samples for a day in a vacuum desiccator over sulfuric acid. After this treatment, all of the crops melted over the range, 130–160°. The rotations were first read at 0°, then at 20°, and finally again at 0° in order to observe any possible mutarotation. All fractions exhibited, within the limits of experimental error, the following identical rotations: $[\alpha]^{0}\text{D}$ +158 ± 1 (c = 1.000, l = 1 dec., $\alpha^{0}\text{D}$ +1.58); $[\alpha]^{20}\text{D}$ + 152 ± 1 (c = 1.000, l = 1 dec., $\alpha^{20}\text{D}$ +1.52). There was no indication of mutarotation in any of the fractions.

Anal. (micro-Dumas). Calcd. for $C_4H_4D_2O_4 \cdot 2C_{19}H_{22}ON_2$: N, 7.90. Found: N, 7.80.

Cinchonine Salt of Succinic Acid.—This salt, used as a comparison standard, was prepared in the manner described above for the deuterium analog. The dried sample melted over a range of 130–160°. As in the above instance all rotations were taken on solutions of the same concentration and at temperatures controlled to within 0.1°. The latter precautions were taken to prevent ionization. The following rotations were observed for this hydrogen analog: $[\alpha]^{0}\text{D}$ +159 ± 1 (c = 1.008, l = 1 dec., $\alpha^{0}\text{D}$ + 1.60); $[\alpha]^{20}\text{D}$ + 153 ± 1 (c = 1.008, l = 1 dec., $\alpha^{0}\text{D}$ +1.54).

Summary

1. Diethyl succinate-α-d,α'-d was prepared from both diethyl maleate and diethyl fumarate by reduction with deuterium. The presence of more than one compound was not indicated.

2. Succinic-α-d,α'-d acid from diethyl succinate-α-d,α'-d from either diethyl maleate or fumarate appeared to be a homogeneous substance. It melted 0.5° lower than succinic acid. Its alkaloidal salts exhibited the same rotation as the corresponding salts of succinic acid. No separation of diastereoisomeric salts was possible.

3. Succinic-α-d,α'-d anhydride melted at the same point as succinic anhydride.

4. The densities of diethyl succinate-α-d,α'-d and of succinic-α-d,α'-d anhydride indicated no appreciable replacement of deuterium by hydrogen during the various reactions. The values were slightly lower than those calculated from the densities of the hydrogen analogs on the basis of the assumption that the molecular volume of hydrogen and deuterium is identical.

Stereochemistry of Deuterium Compounds of the Type RR'CHD: Camphane-2,3-d_2

BY MARLIN T. LEFFLER[1] AND ROGER ADAMS

A recent article by Biilmann, Jensen and Knuth[2] described the preparation and subsequent study of the optical properties of camphane-2-d. Although camphane, due to its symmetry, is optically inactive, camphane-2-d was found to have an observed rotation of αD + 0.08° (c = 10.00 of ether, l = 2 dec.). This was presented as direct evidence in favor of the asymmetry of the molecule RR'CHD. As pointed out by the above authors, the preparation of the hydrogen and deuterium analogs of camphane by the hydrolysis of bornylmagnesium chloride with water and deuterium oxide, respectively, is accompanied by the formation of several other optically active products. The latter must necessarily be removed completely by repeated crystallizations before any comparison can be drawn between the optical properties of camphane and camphane-2-d. The difficulty with which camphane derivatives are purified renders any process of purification questionable as to its thoroughness. No attempt was made by Biilmann to characterize the camphane or camphane-d used for comparative rotation studies either by analysis, density or other physical constants with the exception of melting points, which are not significant. Since the results of these investigators are not in complete accord with the present and previous[1,3] researches concerning this problem of asymmetry, it seems advisable to make the herein described report at this time before the investigation is satisfactorily finished. In addition, it is worth mentioning that the first mentioned authors found that the sample of active camphane-2-d was converted into an inactive product, presumably camphane, by treatment with hydrogen in the presence of platinum and carbon at room temperature. It is rather odd that cleavage by hydrogen of an ordinary carbon–deuterium bond would occur with

such ease and completeness. At least this does not seem in accord with our present knowledge of the hydrogen–deuterium interchange reactions.

The desirability of using a structure of the camphane type in studying this problem is worth emphasizing and may be most clearly brought out by mentioning briefly the difficulties involved in other modes of attack. A stereochemical study of a molecule of the type I, as described in the previous paper by the present authors,[1,4] is complicated by at least two factors: namely, the production of this type by the reduction of either the

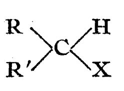
$R'CHD—CHDR'$ I

$RCHD—COOH$ II

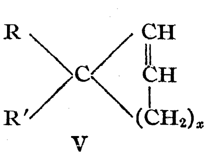
$RCHD—(CH_2)_xCOOH$ III

cis or *trans* unsaturated compound might lead to the formation of one and the same stereo form, thus making the search for a *meso* and a *racemic* modification of no consequence; in addition, if the *meso* modification was the one form so produced, obviously any attempts at resolution would be meaningless. The use of acids of the structure II in investigating the problem adds to the complication due to the possibility of racemization through the enolization of the alpha hydrogen or deuterium. The latter difficulty would be materially avoided by the use of the molecule shown in III. It is to be noted, however, that all of these three types involve either the isolation of diastereoisomers or the resolution into optically active forms. This evidence when obtained in the form of negative results is, at best, only indirect proof of the symmetry of the RR'CHD molecule.

A more direct and definite proof is possible through the utilization of an optically active substance which loses its activity on reaction with hydrogen, such as the structures illustrated in IV and V. Since the substitution of X in IV by

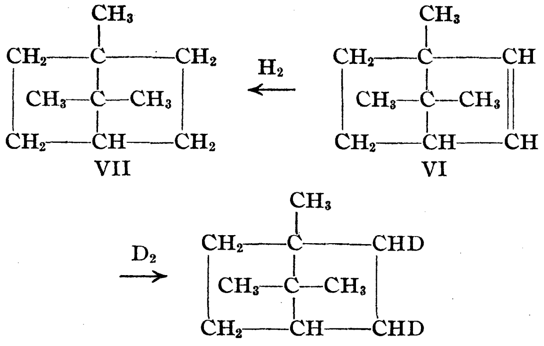


IV



V

deuterium involves the replacement of a group directly attached to the asymmetric center and thus the possibility of inversion and racemization, the structure V is the more desirable of the two. In addition, cyclic structures commonly have a higher rotation than open chain molecules. The latter is of distinct advantage in comparing the rotation of the products resulting from the action of hydrogen and deuterium on the original molecule. The terpene bornylene, VI, corresponds to the structure V and thus lends itself to the study of the problem at hand. On reduction of *l*-bornylene with hydrogen, camphane VII results, inactive due to the symmetry of the molecule; on the other hand, the reduction of *l*-bornylene with deuterium leads to the formation of camphane-2,3-d_2, VIII, which if deuterium differs properly from hydrogen should still be optically active.



VII VI VIII

Although *l*-bornylene represents, from a theoretical standpoint, a most ideal type of structure for the study of this problem, its use involves several experimental difficulties. Due to its extreme volatility, purification is by no means an easy task. Furthermore there seems to be no practical method of preparing the substance in a pure state. The decomposition of methyl bornylxanthate,[5] although the most practical and convenient method of preparation, is accompanied by the formation of a rearrangement product, tricyclene,[5,6] from which *l*-bornylene cannot be separated easily. Henderson and Caw[7] described a method for the purification of bornylene containing this impurity by the preferential oxidation of the tricyclene by hydrogen peroxide. However, this was not found to be entirely satisfactory[8] due to the poor yields and incompleteness of the purification. Fortunately, however, the presence of tricyclene as an impurity in the bornylene does not interfere with the results of the following experiments, since by its symmetry, it is optically inactive.

It has been shown previously by Henderson

and Pollock[9] that the catalytic nickel–hydrogen reduction of bornylene to camphane proceeds without rearrangements, even at temperatures of 170–190°. The *l*-bornylene obtained in the present investigation by the decomposition of methyl bornylxanthate was completely reduced catalytically by both hydrogen and deuterium at room temperature and practically atmospheric pressure, yielding camphane and camphane-2,3-d_2, respectively. Although pure camphane is optically inactive, the sample obtained by the reduction with hydrogen was found to have an observed rotation of $\alpha^{25}\text{D} + 0.02°$ (±0.01) (Table I). This small degree of activity could not have been due to incomplete reduction, as the rotation of the original bornylene was negative and the final product was shown to be completely saturated. It is to be explained by the presence of some dextro rotatory impurity. Camphane-2,3-d_2 resulting from the reduction of bornylene with deuterium gave an observed rotation of $\alpha^{25}\text{D} + 0.02°$ (±0.01) (Table I) under identical conditions. Care was exercised to run control experiments with blank samples and the rotations of the hydrogen and deuterium analogs were each checked in triplicate. In every case there was an observable but identical rotation.

A density determination (Table I), using the method of McLean and Adams,[4] on both camphane and camphane-2,3-d_2 definitely distinguished these two substances.

It is to be conceded that the above evidence, due to its qualitative nature, should not be accepted as definite proof of the inactivity of the RR′CHD structure. It is certain, however, that the effect of the deuterium atom on the optical activity of this structure is of an extremely small order of magnitude. Further studies along these lines are in progress; in particular a similar investigation is being conducted on menthene and a further attempt is being made to obtain pure bornylene in order to repeat the experiments reported here.

Experimental

***l*-Bornylene.**—*d*-Borneol was converted into *d*-methyl bornylxanthate as described by Tschugaeff.[5] After two recrystallizations from alcohol, the xanthate melted at 57–58°; rotation in dioxane was $[\alpha]^{24}\text{D} + 31.5°$ (c = 2.00). The rotation and melting point checked those previously reported and were unchanged by further purification. *l*-Bornylene was obtained from methyl bornylxanthate by dry distillation[5] at 170–190° and freed from sulfur impurities by repeated sublimations from metallic sodium. The sample of *l*-bornylene prepared in this manner melted at 105–106.5°; rotation was $[\alpha]^{25}\text{D} - 10.66°$ (c = 4.627 in toluene), $[\alpha]^{25}\text{D} - 9.57°$ (c = 16.00 in ethyl acetate); density, $d^{131}{}_4$ 0.7666. As the first two constants indicate and as was earlier pointed out by Bredt and co-workers,[6] bornylene prepared in this manner is contaminated by a rearrangement product, tricyclene, from which it cannot be completely separated by ordinary methods of purification. Bredt and Sandkuhl[10] obtained a sample of bornylene melting at 113° and having a rotation of $[\alpha]\text{D} - 21.69°$ which they believed to be essentially pure. The presence of tricyclene as an impurity should have no effect, however, on the optical inactivity of camphane formed by the reduction of the impure bornylene.

Camphane.—The apparatus employed for the reduction of bornylene by hydrogen (or deuterium) was the same as that previously described by McLean and Adams.[4] Two reduction tubes were used, the charge in each tube being 1.36 g. of *l*-bornylene, 0.05 g. of platinum catalyst and 8 cc. of ethyl acetate (dry and acid and alcohol free). One-half of the theoretical amount of hydrogen was absorbed in one and one-half hours. There was no further absorption in an additional hour. That complete reduction had been obtained was substantiated by the settling of the catalyst in the reduction tubes.

The contents from the reduction tubes, after separation from the catalyst, were shaken with 1 liter of cold water in order to precipitate the crude camphane. The crude material was separated by filtration, dried for a short time over phosphorus pentoxide, and finally allowed to sublime at room temperature from metallic sodium. The camphane obtained in this manner gave no test for unsaturation as shown by bromine in glacial acetic acid and had the physical constants listed in Table I.

The rotations recorded in Table I were checked in triplicate, care being taken to maintain a constant temperature of ±0.2° during the observations and to use a blank control in each case. In every instance there was evidence of slight activity due to the presence of some dextro-rotatory impurity.

Camphane-2,3-d_2.—Practically 100% deuterium was prepared as earlier described[4] by the electrolysis of deuterium oxide. This deuterium was employed for the reduction of *l*-bornylene, using conditions identical to those given above for the hydrogen analog. Complete reduction was attained in two hours as compared with one and

TABLE I

CONSTANTS ON CAMPHANE AND CAMPHANE-2,3-d_2

Compound	M. p., °C.[a]	Density[b] obs., $d^{15}{}_4$	$\alpha^{25°}\text{D}^{\pm 0.2}$ [c]
Camphane	145	0.7458	+0.02 (±0.01)
Camphane-2,3-d_2	143	0.7552	+0.02 (±0.01)

[a] These low melting points for camphane indicate the presence of the impurity of tricyclene carried through from bornylene.

[b] The method employed for the density determination was that described in a previous paper.[4]

[c] Concentration = 0.85 g. in 5 cc. of ethyl acetate. l = 1.

---

[9] Henderson and Pollock, *J. Chem. Soc.*, **97**, 1620 (1910).

[10] Bredt and Sandkuhl, *Ann.*, **366**, 11 (1909).

one-half hours for the absorption of an equivalent amount of hydrogen. The product, camphane-2,3-d_2 (plus impurity from the bornylene) was isolated in the same manner used for camphane and gave no test for unsaturation. The physical constants are listed in Table I. In measuring the rotation and in making comparisons with the hydrogen analog, care was exercised to maintain identical conditions throughout. In no instance was there any observable difference between the optical activity of the samples of camphane and camphane-2,3-d_2.

Summary

l-Bornylene upon reduction with hydrogen gives a camphane having a rotation of +0.02 (±0.01) due to some impurity. Reduction with deuterium results in a molecule of identical rotation. The densities of camphane and camphane-2,3-d_2 were shown to be markedly different.

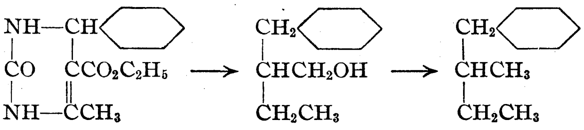
Hydrogenation and Hydrogenolysis of a 2-Keto-1,2,3,4-tetrahydropyrimidine Derivative to 2-Benzyl- and 2-Hexahydrobenzylbutanol-1[1]

BY KARL FOLKERS[2]

The action of hydrogen on 2-keto-1,2,3,4-tetrahydropyrimidines over nickel and copper–barium–chromium oxide catalysts at approximately 200 atmospheres pressure and at temperatures up to 200° was recently described.[3] It was shown that 2-keto-4-phenyl-5-carbethoxy-6-methyl-1,2,3,4-tetrahydropyrimidine, I, was reduced to a mixture of at least two isomeric hexahydropyrimidine derivatives. The reduction of the pyrimidine 5,6-double bond took place at 200°, and the yield of the isolated hexahydropyrimidines was 77%. There was evidence for the presence of side products resulting from further reactions with hydrogen. It was to be expected that a higher temperature would increase the extent of these reactions, and this paper summarizes the results of allowing the 2-keto-1,2,3,4-tetrahydropyrimidine derivative, I, to react with hydrogen at 250° over a copper–barium–chromium oxide catalyst.

It could be predicted that, as the temperature of the reaction neared 250°, a rather complex combination of hydrogenation and hydrogenolysis reactions would occur. Thus, the pyrimidine 5,6-double bond and the carbethoxy group would be definitely susceptible to reduction. The formed carbinol group would be somewhat susceptible to reduction to a methyl group. The ring 3,4-bond and the 1,6-bond would be susceptible to cleavage because of the neighboring activating influences. Theoretically, it could be said that the initial reaction of hydrogen might follow four courses leading to four different products. These four products, on further reaction with hydrogen, could lead to seven new products, and these, in their turn, could lead to seven more. These last seven molecules could lead to four products, and these four would lead to a single molecule, 2-benzylbutane, III. Thus, in this theoretical stepwise transformation of I to III, there are twenty-two intermediates to be considered, exclusive of stereoisomers, and exclusive of change in the -NH-CO-NH-grouping.



I II III

It was never possible, in this hydrogenation at 250°, to obtain full hydrogen absorption, and there was isolated a small amount of a low boiling fraction which appeared to be the product II, 2-benzylbutanol-1. After repeated purifications, only traces of impurities containing nitrogen remained, and the carbon and hydrogen analyses were not quite satisfactory for 2-benzylbutanol-1.

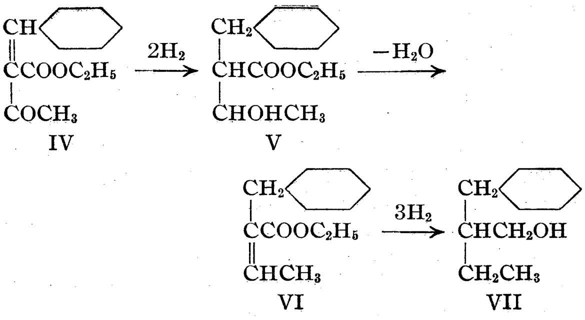
For further identification, the alcohol, II, was synthesized in order that comparable derivatives, etc., could be made. It was readily obtained by the following series of reactions

---

(1) Researches on Pyrimidines CLII.

(2) Post-doctorate Research Fellow, 1933–1934, Yale University. The greater part of this study was made at Yale University under the administration of Professor Treat B. Johnson. The courtesy of Dr. Randolph T. Major for permission to complete the investigation in the Merck Laboratory is gratefully acknowledged.

(3) Folkers and Johnson, THIS JOURNAL, **56**, 1180 (1934).



In carrying out the last step, VI ⟶ VII, the second stage, or carbethoxy group reduction, reached completion very readily, and if the reaction were not stopped, further hydrogenation slowly took place.

Apparently, the benzenoid nucleus was slowly undergoing reduction. Analysis of the product showed a low percentage of carbon and a high percentage of hydrogen, such as would be expected; and when this product was hydrogenated completely over nickel, a low amount of hydrogen was absorbed as calculated for 2-benzylbutanol-1, and analysis of the product indicated that it was 2-hexahydrobenzylbutanol-1.

Interpreting the pyrimidine hydrogenation in accord with the above results, the alcohol product undoubtedly was essentially a mixture of 2-benzyl- and 2-hexahydrobenzylbutanol-1. There were fractions which might have contained the corresponding butane derivatives, but the quantity was much smaller than that of the alcohol fraction.

These experiments contributed toward the knowledge of a characteristic of the copper–barium–chromium oxide catalyst. It has been generally expressed that copper–chromium oxide catalyst is inactive for true benzenoid nuclei reduction.[4] This study would suggest that it is probably a question of relative activity for these catalysts. In other words, there is usually a tremendous difference in the rates of phenyl group reduction with respect to the other many reactions for which these catalysts are valuable, and the control of the reactions and isolation of pure phenyl substituted products is entirely practicable. However, when certain factors (temperature, time, catalyst amounts and ratios, etc.) are forced, advertently or not, the amount of phenyl group reduction may become appreciable, as in the case of ethyl α-benzylcrotonate. In the case of complex heteronuclear phenyl substituted compounds, such as the pyrimidine I, the extent of phenyl group reduction may be sufficient as to make impracticable the isolation of pure phenyl substituted products, when rather drastic conditions must be employed in order to secure appreciable conversion of the hydrogen acceptor.

Experimental Part[5]

Hydrogenation of the Pyrimidine, I.—The literature citations on apparatus, catalysts, and special methods have already been recorded.[3] The preparation of 2-keto-4-phenyl-5-carbethoxy-6-methyl-1,2,3,4-tetrahydropyrimidine, I,[6] and the corresponding hexahydropyridine have been described.[3]

When 10 g. (0.038 mole) of the pyrimidine I was hydrogenated at 250° for 7.25 hours over 5 g. of copper–barium–chromium oxides in 100 ml. of ethanol solvent, the resulting solution was colorless and practically free from volatile ammonia or amines. The catalyst, to all appearances, was in an active state. The hydrogen absorption was not over 0.176 mole. The residue, after ethanol removal, was distilled: Fraction I, b. p. essentially 77–79° at 2.5 mm., 1.8 g. (approximately 28.6%); Fraction II, b. p. 80–160° continuous, and large resinous residue.

When the hydrogenation was conducted over 3 g. of catalyst, first for two hours at 200°, then for four hours at 250°, there was isolated only 0.5 g. (8.0%) of Fraction I boiling essentially at 70–72° at 1.5 mm.

Fraction I was also obtained in small yield from the hydrogenation of 2-keto-4-phenyl-5-carbethoxy-6-methylhexahydropyrimidine under similar conditions.

The residues from distillation of Fraction I (or Fraction II, continuous b. p. of 80–160–200° plus its residue) were dissolved in alcoholic sodium hydroxide solution and the mixture refluxed for two to three hours. After removal of the ethanol, there were no basic or neutral substances present other than an occasional trace of Fraction I. On acidification there precipitated carboxy acids. The properties of the acid indicated a complex mixture, and, in one instance, some impure 2-keto-4-phenyl-5-carboxy-6-methylhexahydropyrimidine was isolated.

When the product from the hydrogenation of 20 g. of pyrimidine I under similar conditions was directly saponified, etc., there was obtained 2.6 g. (20.6%) of Fraction I, and the distillation residue of 4.3 g. comprised the remaining basic or neutral products.

The various Fractions I were combined and fractionated. The forerun of b. p. 47–74° at 2 mm. darkened in color on standing and was found to contain 2–3% nitrogen. The greater amount of the material boiled at 75–78° at 2 mm., and, after treatment with acid and alkali, was found to distil at 77–77.2° at 2 mm. Undoubtedly, this liquid was essentially 2-benzylbutanol-1. *Anal.* Calcd. for $C_{11}H_{16}O$: C, 80.42; H, 9.82. Found: C, 79.25, 79.20; H, 9.38, 9.33; N, trace (0.1–0.2%). The discrepancy on carbon

and hydrogen content was probably due in part to the presence of 2-hexahydrobenzylbutanol-1, as explained elsewhere, and to the nitrogen containing impurities.[7]

Ethyl α-Benzalacetoacetate.—This ester was made by the method of Knoevenagel.[8] It was finally distilled through a Widmer column, b. p. 129–130° at 2.5 mm.

Ethyl α-Benzyl-β-hydroxybutyrate.—The ethyl α-benzalacetoacetate was hydrogenated at 150° and 160 atm. in absolute ethanol solvent, and over copper–barium–chromium oxide catalyst. The yield of ethyl α-benzyl-β-hydroxybutyrate was 90%, b. p. 124–126° at 3 mm. *Anal.* Calcd. for $C_{13}H_{18}O_3$: C, 70.22; H, 8.16. Found: C, 70.14, 69.96; H, 8.12, 8.34.

Ethyl α-Benzylcrotonate.—To 20 ml. of dry benzene and 8 g. of phosphorus pentoxide in a distilling flask and cooled in an ice-bath was added 22.8 g. of ethyl α-benzyl-β-hydroxybutyrate. Benzene was now slowly distilled by immersing the flask in an oil-bath and heating slowly to a temperature of 140°. The pressure was then reduced to 15 mm., and, after removal of the last benzene, the dehydrated ester distilled at 133–138° (bath temp. 190–200°), yield 17.1 g. or 81.4%. The ester was purified by washing its ethereal solution with a sodium carbonate and chloride solution and then a sodium chloride solution. The ester after ether removal, on distillation yielded a few drops of a yellow low boiling fraction and then distilled at 125–127° at 13 mm. *Anal.* Calcd. for $C_{13}H_{16}O_2$: C, 76.42; H, 7.89. Found: C, 76.38, 76.29; H, 7.80, 7.67.

2-Benzylbutanol-1.—A solution of 15.5 g. of ethyl α-benzylcrotonate and 25.5 ml. of absolute ethanol was hydrogenated over 4 g. of copper–barium–chromium oxide at 250° and 190 atm. for five minutes. The product was dissolved in alcoholic sodium hydroxide solution and refluxed for five hours. The alcohol, on ether extraction, etc., distilled at 81–81.5° at 2 mm. It was a rather viscous liquid and its odor was not so characteristic or pleasant as that of the hexahydrobenzylbutanol. *Anal.* Calcd. for $C_{11}H_{16}O$: C, 80.42; H, 9.82. Found: C, 80.65, 80.55; H, 9.75, 9.64.

2-Benzylbutyric Acid.—The alkaline solution of the above experiment, freed from 2-benzylbutanol, was acidified and ether extracted. A few drops of acid were obtained and distilled in a minute flask, b. p. 123–124° at 2 mm. *Anal.* Calcd. for $C_{11}H_{14}O_2$: C, 74.11; H, 7.92. Found: C, 74.17, 73.88; H, 8.12, 8.14.

2-Hexahydrobenzylbutanol-1.—When 15.3 g. of ethyl α-benzylcrotonate was hydrogenated as described above, except for a period of five and one-half hours, the product, on fractionation, gave a forerun, undoubtedly containing the corresponding butane derivatives, and then the principal fraction, b. p. 86–87.5° at 3 mm. This fraction was, nevertheless, taken in three parts, and the middle one, representing 21% of the total, was estimated to contain 44% of 2-hexahydrobenzylbutanol-1 and 56% of 2-benzylbutanol-1. *Anal.* Calcd. for $C_{11}H_{22}O$: C, 77.56; H, 13.02. Found: C, 79.30, 79.16; H, 11.32, 11.14.

When this mixture of butanols was hydrogenated to completion over Raney nickel catalyst at 180°, 2-hexahydrobenzylbutanol-1 was obtained, b. p. 83–84° at 2 mm. *Anal.* Found: C, 77.01, 77.09; H, 12.94, 12.67. This completely saturated alcohol had a very characteristic and perfume-like odor, and there seemed no doubt but that the odor of Fraction I from the pyrimidine hydrogenation was due to the presence of this alcohol.

Summary

The principal final product of hydrogenation of 2-keto-4-phenyl-5-carbethoxy-6-methyl-1,2,3,4-tetrahydropyrimidine over copper–barium–chromium oxides at 250° under elevated pressures was a mixture of 2-benzyl- and 2-hexahydrobenzylbutanol-1. These two alcohols were synthesized by other reactions. It appears that copper–barium–chromium oxide catalyst has a very weak activity for hydrogenation of the phenyl group, and that this slight activity is exhibited only under certain forced conditions.

The Halogenation of Ortho-Sulfobenzoic Anhydride

BY DANIEL TWISS AND LARKIN HUNDLEY FARINHOLT

The preparation of polyhalogenated *o*-sulfobenzoic anhydrides seemed interesting in several respects. In the first place, as starting materials for the preparation of new sulfonphthaleins, in view of their possible use as indicators, certain of these compounds have since been described by Harden and Drake.[1] Second, with regard to the possibility that the neutral sodium salts of some of these halogenated *o*-sulfobenzoic acids, in particular the tetraiodo derivative, might be useful as radiographic mediums: this phase of the investigation has been discussed by Macht and Twiss,[2] and by Keller.[3]

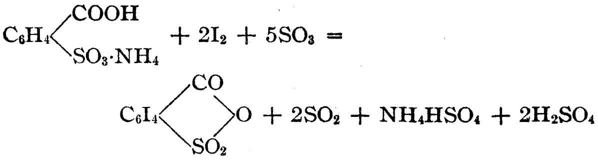
To date little is known concerning the halogenated *o*-sulfobenzoic acids. The 4-chloro acid was prepared by Roode[4] and the 4-bromo acid by Hübner, Post and Weiss[5] and by Remsen and Bayley,[6] by oxidizing the corresponding toluene sulfonic acid or sulfonamide.

In the present investigation, halogenated *o*-sulfobenzoic anhydrides were prepared by the halogenation of *o*-sulfobenzoic acid or its anhydride dissolved in fuming sulfuric acid, with or without the presence of some iodine as a catalyst.[7] This method of halogenation has also been used by Juvalta[8] in the preparation of di- and tetrahalogenated phthalic anhydride.

Without impairing the yield, it proved to be more convenient to use the acid ammonium salt of *o*-sulfobenzoic acid as the starting material since it is more readily available than the acid or anhydride. The acid ammonium salt may be obtained by the hydrolysis of saccharin with dilute hydrochloric acid.

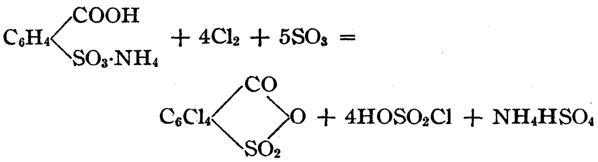
By the method described above, di-, tri-, tetraiodo-; mono-, di-, tri-, tetrabromo-; and di- and tetrachloro-*o*-sulfobenzoic anhydrides were prepared.

Concerning the mechanism of this halogenation nothing is known, but it is probable that *o*-sulfobenzoic anhydride forms an unstable addition complex with sulfuric acid or sulfur trioxide, which facilitates the substitution of halogen. The bromination and iodination take place according to analogous equations. The hydrogen iodide and bromide produced in the reactions are oxidized by sulfur trioxide, and the halogen thus made available again for further substitution. The formation of tetraiodo-*o*-sulfobenzoic anhydride, for example, may be represented by the equation



$$C_6H_4\left\langle\begin{matrix}COOH\\SO_3\cdot NH_4\end{matrix}\right. + 2I_2 + 5SO_3 = C_6I_4\left\langle\begin{matrix}CO\\SO_2\end{matrix}\right\rangle O + 2SO_2 + NH_4HSO_4 + 2H_2SO_4$$

The chlorination differs from the bromination and iodination only by the fact that the hydrogen chloride, generated in the chlorination process, is not oxidized by sulfur trioxide, but combines with it to form chlorosulfonic acid



$$C_6H_4\left\langle\begin{matrix}COOH\\SO_3\cdot NH_4\end{matrix}\right. + 4Cl_2 + 5SO_3 = C_6Cl_4\left\langle\begin{matrix}CO\\SO_2\end{matrix}\right\rangle O + 4HOSO_2Cl + NH_4HSO_4$$

The anhydrides of the halogenated *o*-sulfobenzoic acids are crystalline substances. With the exception of the tetraiodo derivative, they react very readily with water and are converted, even by moisture in the air, into the corresponding acids.

From a theoretical point of view, it seemed important to determine in what order the halogen atoms enter the available positions. The general procedure which was followed in order to settle this question consisted in eliminating the sulfonic acid group by hydrolysis and identifying the resulting halogenated benzoic acid. The removal of the sulfonic acid group was accomplished by heating the halogenated *o*-sulfobenzoic acid with sulfuric acid containing enough water to cause the mixture to boil between 200 and 210°. This procedure could not be applied to the iodinated acids,

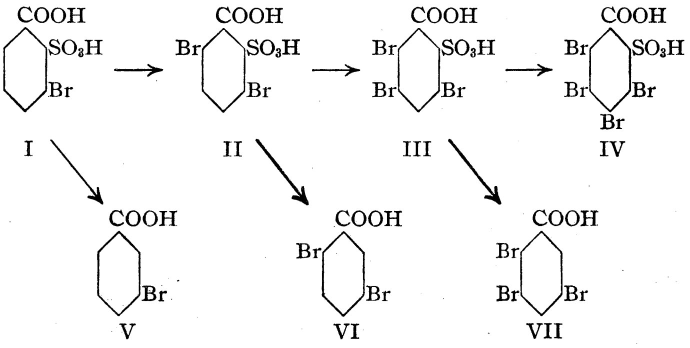
owing to the fact that iodine was split off and the compound destroyed. The positions assigned to the iodine atoms have therefore been based on the analogy between these compounds and the corresponding chlorinated and brominated acids.

The elimination of the sulfonic acid group from monobromo-*o*-sulfobenzoic acid yielded 3-bromobenzoic acid (V), while the dibrominated acid produced 2,5-dibromobenzoic acid (VI). From this it may be concluded that the sulfonic acids were 3-bromo- (I) and 3,6-dibromo-2-sulfobenzoic acid (II). Tribromo-*o*-sulfobenzoic acid yielded 2,3,5-tribromobenzoic acid (VII), so that the sulfonic acid was 3,5,6-tribromo-2-sulfobenzoic acid (III). Tetrabromo-*o*-sulfobenzoic acid should naturally be represented by formula IV.



By the same method dichloro-*o*-sulfobenzoic acid yielded 2,5-dichlorobenzoic acid, besides a small quantity of *p*-dichlorobenzene. The formation of the latter compound is due to the fact that not only is the sulfonic acid group removed, but in addition the carboxyl group is also partly split off.

The above facts show that the first halogen atom substitutes in the position meta to the carboxyl and ortho to the sulfonic acid group, and the second halogen atom in the position meta to the sulfonic acid and ortho to the carboxyl group. The third halogen atom enters in the second position meta to the carboxyl group, and the fourth in the remaining second meta position with regard to the sulfonic acid group. In the preparation of the mono-, di- and tri-halogenated *o*-sulfobenzoic anhydrides by direct halogenation, no evidence of the formation of isomers has been found.

It was noted that when an aqueous 10% solution of the neutral sodium salt of tetraiodo-*o*-sulfobenzoic acid was exposed to sunlight, a slow decomposition took place with liberation of iodine and formation of some sodium iodide. A small deposit of crystals consisted of the acid sodium salt of tetraiodo-*o*-sulfobenzoic acid, while the supernatant liquid contained a mixture of the sodium salts of tri- and tetraiodo-*o*-sulfobenzoic acids. The salt of the triiodo acid was converted into the anhydride, which was shown to be identical with 3,5,6-triiodo-*o*-sulfobenzoic anhydride, obtained by direct iodination of *o*-sulfobenzoic acid.

The neutral ammonium salt of the same triiodo acid was precipitated when a concentrated ammoniacal solution of tetraiodo-*o*-sulfobenzoic acid was treated with hydrogen sulfide. The filtrate contained, besides some sulfur and ammonium iodide, the neutral ammonium salt of a diiodo-*o*-sulfobenzoic acid. Its anhydride, obtained by the action of thionyl chloride, forms colorless crystals which are different from the 3,6-diiodo-*o*-sulfobenzoic anhydride prepared by direct iodination of *o*-sulfobenzoic acid. The position of the iodine atoms has not been determined.

Experimental

Halogenation of *o*-Sulfobenzoic Acid

The preparation of each of the following *o*-sulfobenzoic anhydrides was carried out in a three-necked flask provided with a monel metal stirrer and a reflux condenser. The latter was connected with an absorption tower through which circulated water, in order to remove escaping sulfur dioxide and trioxide as well as small quantities of halogen.

3,4,5,6-Tetraiodo-*o*-sulfobenzoic Anhydride.—In 1000 g. of 60% fuming sulfuric acid, 160 g. of *o*-sulfobenzoic acid was dissolved by heating in an oil-bath kept at 60–70°. To this solution, while stirring vigorously, 400 g. of iodine was gradually added. This caused foaming, especially during the latter part of the reaction. After the addition of the iodine, the temperature of the oil-bath was raised slowly to 110–120° and the heating continued for twenty-four hours. The reaction was finished by raising the temperature to 170–175° for one hour. By this time the reaction mass had become too thick for further stirring. After cooling, the reaction mass was mixed with 600 cc. of glacial acetic acid and, after cooling again, filtered by suction on a glass wool pad and washed with glacial acetic acid.

3,4,5,6-Tetraiodo-*o*-sulfobenzoic anhydride was thus obtained as a yellow substance, having no melting point but gradually decomposing in the neighborhood of 300°. The yield of the crude product was 400 g., or 75%.

In a similar manner, the anhydride of *o*-sulfobenzoic acid and its acid ammonium salt were both iodinated with the same results, the yield being approximately 70% in each case.

Free *o*-sulfobenzoic acid may be obtained from the anhydride by boiling with water, which slowly hydrolyzes it. The acid is very soluble in water. Its mono- and disodium salts are prepared by adding the calculated quantities of sodium hydroxide solution to the aqueous solution of the acid. The acid sodium salt is pale yellow and fairly insoluble in water, while the neutral sodium salt is dark yellow and quite soluble. Both are obtained in crystalline form. The acid salt precipitates when the aqueous solution of the neutral salt is acidified with hydrochloric acid.

A good method for preparing pure tetraiodo-*o*-sulfobenzoic anhydride from the sodium salts is to heat either the mono- or disodium salt of the acid with an excess of concentrated sulfuric acid in an oil-bath at 150–165° for one hour. The mixture is then poured on cracked ice and the anhydride filtered off. It is first washed thoroughly with water to free the anhydride of sulfuric acid, then with glacial acetic acid, and finally with a mixture of equal volumes of acetic anhydride and glacial acetic acid, and dried in an oven. It may also be obtained readily from the free acid by treating with acetic anhydride.

The anhydride is very insoluble in most solvents. It can, however, be crystallized from acetic anhydride, in which it is very sparingly soluble.

Anal. Calcd. for $C_7I_4SO_4$: I, 73.81; S, 4.66. Found: I, 73.78; S, 4.58.

3,4,5,6-Tetrabromo-*o*-sulfobenzoic Anhydride.—In the same manner as described above, 165 g. of *o*-sulfobenzoic acid was dissolved in 1000 g. of 60% fuming sulfuric acid. The bromination was carried out by heating the oil-bath to 80–100° and slowly adding 100 cc. of bromine below the surface while stirring. In order to avoid loss of bromine, the rate of addition was regulated according to the rate of absorption. The absorption of bromine went very slowly so that the reaction required a long period of time, between two or three days. In several experiments 10 g. of iodine was added as a catalyst. It has not definitely been established whether this increases the rate of reaction, but it is certain that good results were also obtained when the catalyst was omitted. After all the bromine had been added, the temperature of the oil-bath was slowly raised to 160–170°. On cooling, tetrabromo-*o*-sulfobenzoic anhydride crystallized out and was separated from the sulfuric acid by filtration on a glass wool pad. It was washed free of sulfuric acid with glacial acetic acid containing 25% acetic anhydride. The yield of crude anhydride thus obtained was about 75%. It was crystallized from glacial acetic acid containing 25% acetic anhydride.

3,4,5,6-Tetrabromo-*o*-sulfobenzoic anhydride forms colorless crystals melting at 216–217°.

Anal. Calcd. for $C_7Br_4SO_4$: Br, 63.97; S, 6.42. Found: Br, 63.44; S, 6.42.

It is much less stable toward water than the tetraiodo derivative and even takes up moisture from the air to change into tetrabromo-*o*-sulfobenzoic acid with considerable evolution of heat. The latter substance is extremely soluble in water. The addition of acetic anhydride will convert the acid back into the anhydride.

Instead of using *o*-sulfobenzoic acid as the starting material in the above preparation, the acid ammonium salt of *o*-sulfobenzoic acid and *o*-sulfobenzoic anhydride were used in several experiments with the same results.

3,5,6-Tribromo-*o*-sulfobenzoic Anhydride.—As a by-product in the preparation of the tetrabromo derivative, some 3,5,6-tribromo-*o*-sulfobenzoic anhydride was obtained. It is less soluble in the acetic acid–acetic anhydride mixture than the tetrabromo derivative and was separated from the latter by fractional crystallization. It forms colorless crystals melting at 224°.

Anal. Calcd. for $C_7HBr_3SO_4$: Br, 56.97; S, 7.62. Found: Br, 56.87; S, 7.57.

3,4,5,6-Tetrachloro-*o*-sulfobenzoic Anhydride.—To a solution of 51 g. of *o*-sulfobenzoic acid in 300 g. of 60% fuming sulfuric acid, 2 g. of iodine was added as a catalyst and a slow current of chlorine was passed through the solution, the oil-bath being kept at a temperature of 70–90°. After no more chlorine was absorbed, the reaction was completed by raising the temperature of the oil-bath to 150–160°. Tetrachloro-*o*-sulfobenzoic anhydride crystallized from the ice-cooled solution and was separated from the mother liquor by filtration. The crude anhydride was washed with an acetic acid–acetic anhydride mixture and was crystallized from a mixture of the same composition. Concentration of the liquids used for washing and crystallization gave a second crop of crystals. The total yield was 67%.

The anhydride was also obtained in about the same yield when the preparation was carried out with *o*-sulfobenzoic anhydride or the acid ammonium salt of *o*-sulfobenzoic acid.

3,4,5,6-Tetrachloro-*o*-sulfobenzoic anhydride forms colorless crystals, melting at 158–159°. It is even more sensitive toward the action of water than the tetrabromo derivative.

Anal. Calcd. for $C_7Cl_4SO_4$: Cl, 44.06; S. 9.96. Found: Cl, 43.83; S, 9.75.

3,5,6-Triiodo-*o*-sulfobenzoic Anhydride.—Using the same procedure as described above, 191 g. of iodine was added to a solution of 92 g. of *o*-sulfobenzoic anhydride in 500 g. of 60% fuming sulfuric acid while the oil-bath was kept at a temperature of 60–70°. The reaction was terminated by raising the temperature to approximately 170° for one hour. The yield of the crude triiodo-*o*-sulfobenzoic anhydride, thus obtained, was about 65%. This product contained a small amount of tetraiodo-*o*-sulfobenzoic anhydride.

A pure sample of triiodo-*o*-sulfobenzoic anhydride was obtained by boiling some of the crude anhydride with acetic acid to which a small amount of water had been added. It dissolved to form the free acid and the anhydride was then precipitated by adding an excess of acetic anhydride. The triiodo-*o*-sulfobenzoic anhydride was crystallized from a glacial acetic acid–acetic anhydride mixture, the relatively insoluble tetraiodo derivative remaining behind.

3,5,6-Triiodo-*o*-sulfobenzoic anhydride is obtained as yellow crystals melting at 287–288°.

Anal. Calcd. for $C_7HI_3SO_4$: I, 67.77; S, 5.71. Found: I, 67.75; S, 5.67.

3,6-Diiodo-*o*-sulfobenzoic Anhydride.—In a mixture of 400 g. of 60% fuming sulfuric acid and 200 g. of 95% sulfuric acid (which gives about a 40% fuming sulfuric acid), 109.5 g. of the dry acid ammonium salt of *o*-sulfobenzoic acid was dissolved. In the course of three days, at an oil-bath temperature of about 80°, 127 g. of iodine was added. The temperature was then raised to 105–110° and stirring continued for forty-eight hours in order to ensure complete reaction of the iodine. Finally, the temperature was gradually raised to 180° to eliminate part of the excess sulfur trioxide. The cooled reaction mixture was poured on cracked ice and the anhydride allowed to hydrolyze to the acid form. The amount of sulfate ions was determined quantitatively in a small sample, and the calculated amount of barium hydroxide, dissolved in hot water, added to the main solution. The filtrate from this then contained the acid ammonium salt of diiodo-*o*-sulfobenzoic acid. By evaporating to dryness in the presence of an excess of ammonia, the neutral ammonium salt was obtained in a yield of about 85%.

In order to convert the neutral ammonium salt into the anhydride, it was refluxed for four hours with a solution of an excess of thionyl chloride in benzene. The precipitate of ammonium chloride was extracted several times with hot benzene containing some thionyl chloride. The combined filtrates yielded mainly 3,6-diiodo-*o*-sulfobenzoic anhydride along with small amounts of the triiodo derivative as well as a product of lower iodine content which could not be purified. The 3,6-diiodo compound was obtained by fractional crystallization in a 55% yield. No isomeric diiodo-*o*-sulfobenzoic anhydride could be isolated.

Crystallized from dry benzene, or a mixture of glacial acetic acid and acetic anhydride, 3,6-diiodo-*o*-sulfobenzoic anhydride forms faintly yellow crystals melting at 243–245°.

Anal. Calcd. for $C_7H_2I_2SO_4$: I, 58.23; S, 7.35. Found: I, 58.19; S, 7.29.

The anhydride may also be prepared from the neutral as well as from the acid ammonium salt by heating with concentrated sulfuric acid at 150° for one hour. It is isolated by pouring the cooled solution on cracked ice, filtering off the anhydride rapidly, dissolving the moist product in glacial acetic acid and precipitating it by addition of acetic anhydride.

3,6-Dibromo-*o*-sulfobenzoic Anhydride.—At an oil-bath temperature of 50–60°, 109.5 g. of the acid ammonium salt of *o*-sulfobenzoic acid dissolved in 600 g. of 60% fuming sulfuric acid was brominated by adding 80 g. of bromine in the course of fifty hours. The reaction was finished by raising the temperature to 170–180° for one hour. The cooled reaction mass was poured on ice and the neutral ammonium salt isolated by the same procedure as that described for the 3,6-diiodo anhydride. It was obtained in a yield of 80%. The anhydride was prepared by the action of thionyl chloride in benzene solution in the same manner as above. 3,6-Dibromo-*o*-sulfobenzoic anhydride hydrolyzes readily, even in moist air.

3,6-Dibromo-*o*-sulfobenzoic anhydride crystallizes from benzene containing a little thionyl chloride as colorless crystals, melting at 167–168°.

Anal. Calcd. for $C_7H_2Br_2SO_4$: Br, 46.75; S, 9.38. Found: Br, 46.93; S, 9.05.

3,6-Dibromo-*o*-sulfobenzoic acid is not changed back into its anhydride under the influence of acetic anhydride, unlike most of the other halogenated *o*-sulfobenzoic acids, but the conversion may be accomplished by the action of thionyl chloride.

3,6-Dichloro-*o*-sulfobenzoic Anhydride.—A slow current of chlorine was passed into a solution of 109.5 g. of the acid ammonium salt of *o*-sulfobenzoic acid dissolved in 400 g. of 60% fuming sulfuric acid at an oil-bath temperature of 60–65°. The reaction was completed when the increase in weight of the reaction mass had reached 70 g. The excess of sulfur trioxide was converted into chlorosulfonic acid by passing dry hydrogen chloride gas into the solution and was eliminated by distillation from a retort. On cooling, 3,6-dichloro-*o*-sulfobenzoic anhydride crystallized from the remaining solution. Recrystallized from a glacial acetic acid–acetic anhydride mixture, it forms colorless crystals melting at 121–122°. It may also be purified by adding ligroin to the solution of the crude product in dry toluene. The compound was obtained in a yield of 40–45%. It hydrolyzes very readily when exposed to moist air.

Anal. Calcd. for $C_7H_2Cl_2SO_4$: Cl, 28.03; S, 12.67. Found: Cl, 27.80; S, 12.59.

3-Bromo-*o*-sulfobenzoic Anhydride.—In the course of fifty hours, 40 g. of bromine was added to a solution of 109.5 g. of the dry acid ammonium salt of *o*-sulfobenzoic acid in 600 g. of 60% fuming sulfuric acid at an oil-bath temperature of 50–60°. The temperature was then gradually raised to 180°, and then allowed to cool. After standing for one week, 17 g. of 3,6-dibromo-*o*-sulfobenzoic anhydride had separated. The remaining solution was poured on cracked ice and the neutral ammonium salt isolated in the same manner already described for the diiodo derivative. The reaction yielded 130 g. of neutral ammonium salt from which 34 g. of 3-bromo-*o*-sulfobenzoic anhydride was obtained. In view of the low yield, the possibility that an isomeric monobromo derivative is formed in the reaction should be taken into account. None was isolated, however.

3-Bromo-*o*-sulfobenzoic anhydride crystallizes from benzene containing some thionyl chloride to form colorless needles, melting at 175–176°. It is very sensitive toward moisture.

Anal. Calcd. for $C_7H_3BrSO_4$: Br, 30.39; S, 12.19. Found: Br, 30.16; S, 12.04.

Determination of the Positions of the Halogen Atoms

The method of determining the positions of the halogen atoms in the halogenated *o*-sulfobenzoic acids consisted in the elimination of the sulfonic acid groups to form halogenated benzoic acids of known constitution. These reactions were carried out in the following manner.

The halogenated *o*-sulfobenzoic anhydride was converted into the corresponding acid by heating with some water, an equal volume of concentrated sulfuric acid was then added and water distilled off until the boiling point of the mixture had reached a temperature of 200–210°. It was then refluxed for several hours at this temperature and again distilled, this time collecting the distillate. The halogenated benzoic acid was carried over with the water.

By the above method, tribromo-*o*-sulfobenzoic acid yielded 2,3,5-tribromobenzoic acid, m. p. 185–187°. The methyl ester of the latter was prepared and gave a melting point of 77°. Dibromo-*o*-sulfobenzoic acid gave 2,5-dibromobenzoic acid, m. p. 151–152°, and monobromo-*o*-sulfobenzoic acid gave 3-bromobenzoic acid, m. p. 155°. Dichloro-*o*-sulfobenzoic acid yielded 2,5-dichlorobenzoic acid, m. p. 151–152°, along with a small quantity of *p*-dichlorobenzene, m. p. 53°.

Attempts to convert the iodinated *o*-sulfobenzoic acids into the corresponding iodobenzoic acids were unsuccessful since the acids were destroyed completely under the conditions of the reaction.

Action of Ammonium Sulfide on Tetraiodo-*o*-sulfobenzoic Acid

A concentrated solution of tetraiodo-*o*-sulfobenzoic acid was prepared by boiling 22.4 g. of the corresponding anhydride with 50 cc. of water. Fifty cc. of concentrated aqueous ammonia was then added (causing the neutral ammonium salt to precipitate partially), the solution was saturated with hydrogen sulfide and allowed to stand for twenty-four hours. The white precipitate thus obtained in a yield of 11.5 g. was the neutral ammonium salt of triiodo-*o*-sulfobenzoic acid. It was crystallized from water.

Anal. Calcd. for $C_7H_9O_5I_3N_2S$: I, 62.02; S, 5.22; N, 4.56. Found: I, 61.98; S, 5.26; N, 4.80.

When heated with concentrated sulfuric acid at 160° for one hour, the neutral ammonium salt was converted into the anhydride of triiodo-*o*-sulfobenzoic acid. The cooled sulfuric acid mixture was poured on cracked ice and, after washing with water, the moist yellow solid was dissolved in hot glacial acetic acid. The anhydride was precipitated again by adding acetic anhydride. It is a pale yellow substance, melting at 287–288°, and identical with the 3,5,6-triiodo-*o*-sulfobenzoic anhydride obtained by direct iodination. A mixed melting point with the latter substance did not show a depression.

After the white crystals of the neutral ammonium salt of 3,5,6-triiodo-*o*-sulfobenzoic acid were filtered off, a yellow solution remained. It was evaporated to dryness and extracted with water. The residue consisted of 1.3 g. of sulfur. The evaporated extract yielded 6.4 g. of an alcohol-soluble portion, which was shown to be ammonium iodide. The analysis of the alcohol-insoluble fraction, consisting of 5.7 g. of a white substance, showed it to be the diammonium salt of a diiodo-*o*-sulfobenzoic acid.

Anal. Calcd. for $C_7H_{10}O_5I_2N_2S$: I, 52.02; S, 6.57; N, 5.74. Found: I, 51.78; S, 6.79; N, 5.9.

Treatment with concentrated sulfuric acid at 150° did not produce an anhydride as in the case of the 3,6-diiodo derivative, but a diiodo-*o*-sulfobenzoic anhydride was apparently obtained by refluxing the diammonium salt with thionyl chloride for several hours. It dissolved in the excess of thionyl chloride and was isolated by separating the solution from the precipitate of ammonium chloride and evaporating the thionyl chloride. It was dissolved in water, the solution decolorized with charcoal, and again evaporated to dryness. The residue was treated with acetic anhydride and recrystallized several times from that solvent. In this manner, a diiodo-*o*-sulfobenzoic anhydride was isolated, different from the one obtained by direct iodination. The compound melted at 221–223°. The position of the iodine atoms was not determined.

Anal. Calcd. for $C_7H_2I_2SO_4$: I, 58.23; S, 7.35. Found: I, 57.97; S, 7.27.

Our thanks are due to Mr. Grant Spurrier for carrying out much of the analytical work.

Summary

1. Mono-, di-, tri- and tetrahalogeno substitution products of *o*-sulfobenzoic anhydride were prepared by halogenation in fuming sulfuric acid.

2. The positions of the halogen atoms were determined by eliminating the sulfonic acid group by hydrolysis and identifying the resulting halogenated benzoic acids.

A Study of Some Substituted Hydroxybenzyl Alcohols[1]

BY BROWN DUNNING, JR., FITZGERALD DUNNING AND E. EMMET REID

As saligenin (*o*-hydroxybenzyl alcohol) has three distinct types of physiological action, anesthetic, antispasmodic, and antiseptic, it seemed desirable to prepare a number of its derivatives in which one or more of these might be accentuated and to study these in connection with the derivatives, homologs and analogs already known to see how these properties are altered by changes of structure and composition. It was also of interest to find out how far the physiological activities of these compounds can be correlated with their physical properties, particularly their solubilities and partition coefficients. Eight new compounds have been prepared and studied along with ten that were already known. These include halogen and alkyl substituted saligenins and halogen substituted *m*- and *p*-hydroxybenzyl alcohols.

The unsubstituted hydroxybenzyl alcohols were made by the reduction of the corresponding hydroxybenzaldehydes through the use of the Adams platinum catalyst.[2] The halogen derivatives of these were prepared by direct halogenation. The alkyl derivatives were synthesized from various

substituted phenols by means of the well-known Reimer–Tiemann reaction,[3] which gave hydroxyaldehydes which were subsequently reduced. In those cases where the alkyl phenols were not available, they were obtained by reduction of the appropriate hydroxyphenones, using the Clemmensen reduction method.[4]

The partition coefficients were determined indirectly for each compound by dividing the solubility in olive oil by the water solubility.

The water solubility was determined by weighing the residue from evaporation of a known volume of a saturated solution in distilled water. For the oil solutions since the refractive index was found to be practically a straight line function of the concentration for each individual compound, it was possible to determine the concentration of a saturated solution by comparing its refractive index with the refractive indices of solutions of known concentration.

There was found to be a very definite relationship between partition coefficients and bactericidal power in each series, but changing the relative positions of the functioning groups, as in the case of the analogs (*o*-, *m*- and *p*-hydroxybenzyl alcohols) changes the physiological properties without regard to partition coefficients. The pharmacological results, although of necessity only roughly comparative, in most cases support the bacteriological results.

Experimental

The preparation of 5-ethyl-2-hydroxybenzyl alcohol may be taken as an example of the general method of preparing the compounds.

p-Hydroxyacetophenone was reduced by the Clemmensen method[4] using amalgamated zinc and hydrochloric acid. The *p*-ethylphenol obtained was purified by steam distillation and the aldehyde group introduced by treating with sodium hydroxide and chloroform according to the method of Reimer and Tiemann.[3] The 5-ethyl-2-hydroxybenzaldehyde was purified by making the sodium bisulfite addition compound which was washed with alcohol and ether, dried, and decomposed with warm dilute acid to liberate the aldehyde. Yields from most of the Reimer–Tiemann reactions were about 30%.

The purified aldehyde was reduced in alcohol solution by passing in hydrogen under about 500 mm. excess pressure in the presence of 1% of the Adams platinum oxide catalyst[2] while shaking on a mechanical shaker. After removal of the catalyst by filtration, the alcohol was evaporated off on a water-bath and the product of the reduction purified by crystallization from carbon tetrachloride.

The purified product of the Reimer–Tiemann reaction on *m*-cresol is a heavy yellow oil which is a mixture of two isomers, 2-hydroxy-4-methyl-benzaldehyde and 6-hydroxy-2-methyl-benzaldehyde. These were separated as suggested by Chuit and Bolsing[5] by steam distilling the mixture with a solution of sodium carbonate from which the former less acidic isomer distils leaving the latter behind. Upon reduction the two corresponding isomeric benzyl alcohols are obtained which melt at 103 and 80°, respectively. These are incidentally isomers of the alcohol obtained by starting with *p*-cresol.

Analyses of the new compounds are included in Table I.

Bacteriological

All the compounds prepared were tested for their bacteriological activity. The organism used was *Staphylococcus aureus*. A modification of the F. D. A. test was employed, which was essentially as follows: 0.5 cc. of a standard twenty-four hour culture was added to 5 cc. of diluted antiseptic. Transfers were made at the end of forty-five minutes with a 4-mm. platinum loop made from No. 23 B. and S. gage wire. The culture media used was a sterile nutrient, beef extract broth, 10 cc. being used in each subculture tube. All dilutions were made with 20% alcohol, the use of which was necessary in order to dissolve some of the compounds. Although the presence of the alcohol has a slight effect on the killing power, it was, however, used throughout all the tests and the results are therefore comparable.

The results of the bacteriological tests are contained in Table I. The figures show the relative bactericidal strengths of equimolar quantities of the respective compounds calculated from their maximum killing dilutions, saligenin being given an index value of 1. In Fig. 1 these are plotted against the partition coefficients for the mono substituted saligenins. Figure 2 shows the same for the di-halogenated compounds. No attempt has been made to compare these two series with each other.

Attention is called to the analogs of saligenin, 3-hydroxy- and 4-hydroxybenzyl alcohol and their respective bromo derivatives. As was expected, the partition coefficient relationship holds between each analog and its derivative, but not between the members of the different series, in which the relative positions of the functioning groups are different.

Pharmacological

Most of the compounds have been tested for anesthetic and antispasmodic action and also for toxicity.

The best method of obtaining comparable values of the anesthetic efficiency was by the frog-skin method in which a 1% hydrochloric acid solution was used as the stimulus on the skin of a pithed frog, both before and after soaking the skin in various concentrations of the anesthetic. The factors taken into consideration in calculating the figures are the time of the normal reflex, the time of immersion in the anesthetic solution, the concentration of the solution, the time of the reflex after anesthesia and the duration of anesthesia. The anesthetic effects on mice and on goldfish were also studied and while they confirm the results of the frog-skin tests, the type of data obtained

does not well lend itself to comparison on a numerical basis. These results have been in part reported elsewhere.

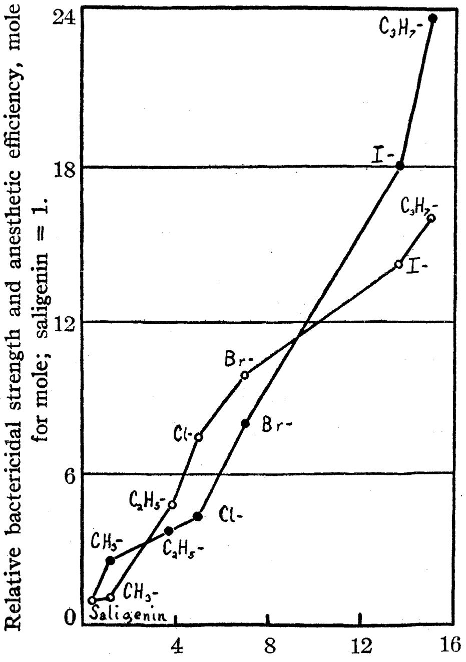

Fig. 1.—Mono-substituted saligenins: ○, relative bactericidal strength; ●, relative anesthetic efficiency.

The figures in Table I represent the relative local anesthetic efficiency of the compounds obtained by the frog-skin method on a weight for weight basis, saligenin being given an index value of 1. It was found that a molecule for molecule comparison would give a relationship more nearly corresponding to the partition coefficients, and a comparison of this kind may be seen in Fig. 1 for the mono substituted saligenins.

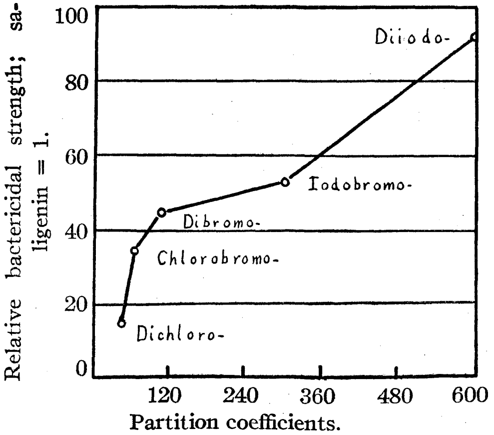

Fig. 2.—Di-halogen derivatives of saligenin.

Also included in Table I are figures for the antispasmodic activity of the compounds. These were calculated from the amounts required to produce antispasmodic action on the smooth muscle of cat's intestine in 50 cc. of Locke's solution oxygenated at 38°, saligenin again being given an index value of 1. No attempt has been made to relate these figures with the partition coefficients since there is no obvious reason why lipoid solubility should be related to effects of this kind.

The toxicity of the compounds was determined on cats and on the seedlings of lupinus albus. No relationship was expected in these figures, since such an effect as toxicity could hardly be predicted from any one set of physical properties; hence they are not included in this paper.

Discussion

It is felt that from the preceding data it may be stated that there has been demonstrated herein a definite relationship between physical and physiological properties of hydroxybenzyl alcohols. It is interesting to note how the actions of the mono-alkyl and mono-halogen derivatives are related according to their partition coefficients without regard to the great difference in chemical nature of the substituent groups, as may be seen in Fig. 1.

The question of the position of the substituent group in the parent molecule has also been considered in the case of the three isomeric methyl saligenins. It is seen that the bactericidal power depends more on the physical properties of the molecule than on the position of the inert group.

As mentioned previously, shifting the relative positions of the functioning group changes the nature of the molecule, so that there can be no comparison between saligenin and its analogs. It is to be noted, however, that in comparing each analog to its respective derivatives, the relation of physical to physiological properties holds good.

Summary

The partition coefficients between oil and water of a series of derivatives, analogs and homologs, of saligenin (*o*-hydroxybenzyl alcohol) have been determined and compared with the bacteriological and pharmacological properties of the compounds. A definite relationship exists, even in cases where the structures of the inert substituent groups differ greatly.

Studies in the Phenanthrene Series. XI. Propanolamines of the Type $C_{14}H_9CHOHCH_2CH_2NR_2$[1]

BY JACOB VAN DE KAMP AND ERICH MOSETTIG

The pharmacological study of a number of amino alcohols in the phenanthrene series[2] has shown that some of these compounds, carrying the side chain $-CHOHCH_2NR_2$ (type I)[3] and $-CHOHCH(CH_3)NR_2$ (type II),[4] exhibit a decided analgesic action. In both types of compounds the nitrogen atom is located in the side chain in the β-position to the phenanthrene nucleus. Through the systematic investigations by Barger and Dale and associates[5] of the amines $Ar(CH_2)_xNH_2$ (Ar being the phenyl, hydroxyphenyl or iminazolyl group), it became evident that almost universally the greatest physiological action (in particular with respect to blood pressure) is exerted by the compounds in which $x = 2$. As Barger points out, compounds of this type occur frequently in nature and are probably in some instances intermediates in the phytosynthesis of isoquinoline derivatives. In the compounds with $x < 2$ or $x > 2$, the physiological action is greatly diminished. It was of interest to determine, by comparison of the phenanthrene alkamines of type I and II[6] on the one hand with the compounds of the type $C_{14}H_9CHOHCH_2CH_2NR_2$ on the other, whether or not a similar regularity may be observed with the phenanthrene derivatives of these series, particularly in respect to their analgesic action.

The propanolamines described in this communication were prepared essentially by the Mannich method,[7] starting from 2-, 3- and 9-acetylphenanthrenes: $C_{14}H_9COCH_3 + CH_2O + HNR_2\cdot$

$HCl \longrightarrow C_{14}H_9COCH_2CH_2NR_2 \cdot HCl \xrightarrow{\text{cat. red.}} C_{14}H_9CHOHCH_2CH_2NR_2 \cdot HCl$, where $-NR_2$ represents the dimethylamino-, diethylamino-, piperidino- and tetrahydroisoquinolino group.

We wish to express our gratitude to Merck and Co., Rahway, N. J., for their generous coöperation in the large scale preparation of the 2- and 3-acetylphenanthrenes.

Experimental

A mixture of 2-, 3-[8] or 9-acetylphenanthrene[9] (0.1 mole), paraformaldehyde (0.15 mole), and the secondary amine hydrochloride (0.15 mole) (dimethylamine-, diethylamine, piperidine- and 1,2,3,4-tetrahydroisoquinoline hydrochloride) in 60 to 80 cc. of isoamyl alcohol was kept at a gentle boil for five to twenty minutes. The advantage of using the higher boiling solvent, isoamyl alcohol, in this

---

(8) Mosettig and van de Kamp, THIS JOURNAL, **52**, 3704 (1930).

(9) Mosettig and van de Kamp, *ibid.*, **55**, 3442 (1933).

condensation is that the reaction proceeds much quicker, whereas in ethyl alcohol, the solvent used by Mannich, the condensation takes place very slowly. By prolonged boiling in ethyl alcohol, furthermore, the yield of the expected amino ketone is considerably lowered, on account of the formation of by-products. These are both neutral and basic in nature and in part crystalline. In the preparation of most of the piperidino and tetrahydroisoquinolino ketones the hydrochlorides crystallized out after five to ten minutes. They were filtered off from the cooled reaction mixture and recrystallized. In the cases where the hydrochlorides did not precipitate, the reaction mixture was cooled, after having been kept boiling for fifteen to twenty minutes. After the addition of a few drops of concentrated hydrochloric acid, in order to depolymerize unchanged paraformaldehyde, unreacted ketone and formaldehyde were taken up in ether. The aqueous layer was alkalified and extracted with ether and the residue left from evaporation of the ether was warmed slightly in a vacuum in order to remove aliphatic amines. The amino ketones subsequently were purified through the hydrochlorides.

The amino ketones were reduced in the form of the hydrochlorides, in 50–70% ethyl alcohol, using platinum oxide as a catalyst. In two cases where the free amino ketones were reduced, namely, in the cases of the 3-dimethylamino ketone and the 9-(1,2,3,4-tetrahydroisoquinolino) ketone, two moles of hydrogen were absorbed, and in the case of the 2-dimethylamino ketone, approximately three moles of hydrogen were taken up. The reduction of the 3-(1,2,3,4-tetrahydroisoquinolino) ketone was effected with good results either by hydrogenating the free base in 95% ethyl alcohol, or by reducing the hydrochloride in 60% ethyl alcohol.

Summary

1. A series of amino ketones of the type $C_{14}H_9COCH_2CH_2NR_2$ (NR_2 representing the dimethylamino-, the diethylamino-, the piperidino- and tetrahydroisoquinolino group) has been prepared by the Mannich method from 2-, 3- and 9-acetylphenanthrene.

2. By catalytic hydrogenation the corresponding amino alcohols $C_{14}H_9CHOHCH_2CH_2NR_2$ have been prepared. These substances will be investigated to determine the result pharmacologically of lengthening the carbon chain of amino alcohols of the phenanthrene series.

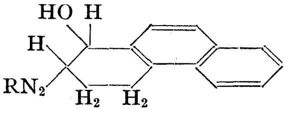
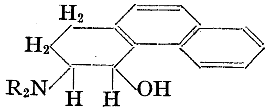
Studies in the Phenanthrene Series. XII.[1]
Amino Alcohols Derived from 1,2,3,4-Tetrahydrophenanthrene[2]

BY ALFRED BURGER AND ERICH MOSETTIG

Among the synthetical substances which have been prepared in this Institution in the attempt to find morphine substitutes, 2-piperidino-1-hydroxy-1,2,3,4-tetrahydrophenanthrene (type I), and 3-(1,2,3,4-tetrahydroisoquinolino)-4-hydroxy-1,2,3,4-tetrahydrophenanthrene (type II) proved to have the strongest analgesic action (minimal effective doses administered orally to cats, 20 and 15 mg. per kilogram, respectively, comparable with doses of 20 mg. for pseudocodeine, 10 mg. for codeine, and 1 mg. for morphine).[2] Experiments are under way to resolve these compounds and eliminate or "muzzle" their alcoholic hydroxyl in the hope of increasing their physiological activity.[3]

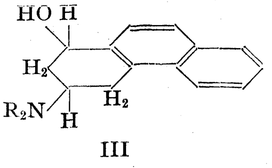


I

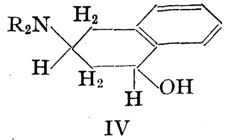


II

We are reporting in the present communication the preparation of compounds which differ from those of types I and II principally through the position of the nitrogen group. Compounds which may be represented by type formulas III and IV, analogs of the propanolamines reported in the foregoing communication, are obviously not readily accessible.



III



IV

---

[1] The work reported in this paper is part of a unification of effort by a number of agencies having responsibility for the solution of the problem of drug addiction. The organizations taking part are: The Rockefeller Foundation, the National Research Council, the U. S. Public Health Service, the U. S. Bureau of Narcotics, the University of Virginia and the University of Michigan.

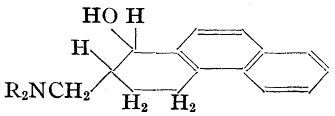
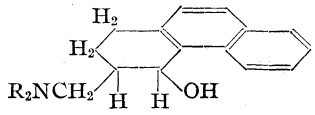
[3] Elimination and muzzling of the alcoholic group in morphine and its derivatives produce generally a marked increase in analgesic action. Eddy, *J. Pharmacol.*, **55**, 127 (1935); Eddy and Howes, *ibid.*, **55**, 257 (1935).



V



VI

The compounds of type V and VI, however, carrying the nitrogen group in the same relative position to the alcoholic hydroxyl group as in the propanolamines and in types III and IV could be conveniently prepared, essentially by the Mannich method,[4] that is, by the action of the hydrochlorides of secondary amines (dimethylamine, diethylamine, piperidine and tetrahydroisoquinoline) and paraformaldehyde on 1- and 4-ketotetrahydrophenanthrenes, and subsequent reduction of the amino ketones.[5]

We have not proved experimentally formulas V or VI for the new amino alcohols described in this communication, but the formation of the corresponding amino ketones by the method of Mannich hardly leaves any doubt as to the constitution of the amino alcohols, since the formulas of the amino ketones prepared by Mannich and Braun[4,6] from cyclohexanone, amine hydrochloride and formaldehyde appear to be well established. In the reduction of our amino ketones to the amino alcohols, only one of the possible diastereomeric forms is obtained.

It was observed that two of the amino alcohols (V and VI, NR_2 represents the diethylamino- and tetrahydroisoquinolino group) split off water with ease when an attempt was made to acetylate them with acetic anhydride in pyridine. This loss of water also takes place under the influence of alcoholic hydrogen chloride. The resulting unsaturated amine readily can be reduced catalytically. We have not sufficient experimental data to make any conjecture concerning the structural features upon which the tendency to split out water is dependent. This question will be investigated in another connection.

The 1- and 4-tetanthrenones are also convenient starting materials for the synthesis of 1- and 4-aminotetanthrenes, which are obtained in good yields by reduction of the corresponding ketoximes.

Experimental

Preparation of Amino Ketones.—A mixture of 1- or 2-ketotetrahydrophenanthrene (1 mole), the amine hydrochloride (1.2 moles), and paraformaldehyde (2.5 moles) in isoamyl alcohol was heated under reflux for ten to fifteen minutes. Generally portions of 5 to 10 g. of ketone in 50 to 100 cc. of isoamyl alcohol were used. A clear solution resulted after two or three minutes. The excess of paraformaldehyde was depolymerized by addition of a few drops of alcoholic hydrogen chloride. The solution was cooled, diluted with ether and extracted with dilute aqueous hydrochloric acid. The amino ketones were liberated, extracted into ether and purified by crystallization or in the form of their salts. The secondary amines used in the reaction were dimethylamine, diethylamine, piperidine and tetrahydroisoquinoline. No definite reaction was observed with tetrahydroquinoline. In the case of the two tetrahydroisoquinolino ketones, the hydrochlorides crystallized directly from the reaction mixtures. They were filtered and washed with a little cold water.

Preparation of Amino Alcohols.—The amino ketones were hydrogenated as hydrochlorides in solution in 90% alcohol, using a platinum oxide catalyst. In most of the cases the reductions stopped when one mole of hydrogen had been absorbed.

1,2-Dihydro-3-[(1,2,3,4-tetrahydroisoquinolino)-methyl]-phenanthrene.—In the attempt to acetylate 4-hydroxy-3-[(1,2,3,4-tetrahydroisoquinolino)-methyl] - 1,2,3,4-tetrahydrophenanthrene with acetic anhydride and pyridine at room temperature, the unsaturated amine was formed. The same substance was obtained by allowing 4-hydroxy-3-[(1,2,3,4-tetrahydroisoquinolino)-methyl] - 1,2,3,4-tetrahydrophenanthrene to stand with alcoholic hydrogen chloride overnight. The base crystallized from dilute alcohol; m. p. 81–82°.

Anal. Calcd. for $C_{24}H_{23}N$: C, 88.56; H, 7.13; N, 4.31. Found: C, 88.55; H, 7.39; N, 4.40.

The hydrochloride was crystallized from alcohol–ether and melted at 227–228°.

Anal. Calcd. for $C_{24}H_{24}NCl$: C, 79.62; H, 6.69; N, 3.87. Found: C, 79.41; H, 6.84; N, 4.09.

The hydrochloride readily absorbs one mole of hydrogen (platinum oxide catalyst).

3,4-Dihydro-2-[(diethylamino)-methyl]-phenanthrene.—1 - Keto-2 - [(diethylamino) - methyl] - 1,2,3,4 - tetrahydrophenanthrene hydrochloride readily absorbed one mole of hydrogen, but neither the free amino alcohol nor any of its derivatives could be obtained in a crystalline state. On treatment with either acetic anhydride or alcoholic hydrogen chloride as described above, a colorless hydrochloride was obtained; recrystallized from alcohol–ether, m. p. 231–232°.

Anal. Calcd. for $C_{19}H_{24}NCl$: C, 75.58; H, 8.02; N, 4.64. Found: C, 75.88; H, 8.52; N, 4.88.

The free base from the hydrochloride was oily. The hydrochloride absorbed one mole of hydrogen on catalytic reduction.

---

(4) Mannich and Braun, *Ber.*, **53**, 1874 (1920).

(5) By employing 1,2,3,4-tetrahydroquinoline no definite reaction could be initiated. The same observation was made by Mannich in the case of aryl methyl ketones [Mannich and Lammering, *Ber.*, **55**, 3510 (1922)]. It should be recalled that it was impossible to obtain definite reaction products in the attempt to exchange the bromine in the bromotetanthrenones with tetrahydroquinoline.[2]

[a] Prepared by reduction of 1-tetanthrenone oxime [Schroeter, Müller and Huang, *Ber.*, **62**, 645 (1929)] with 2.5% sodium amalgam in alcohol solution, acidified with acetic acid, or with aluminum amalgam in moist ether. [b] Prepared by the method of Decker, *Ann.*, **395**, 362 (1913). [c] Prepared by heating the primary amine with methyl iodide and sodium acetate at 100° for five hours and separating the reaction mixture by the Hinsberg method. [d] Prepared by reduction of 4-tetanthrenone oxime with aluminum amalgam in moist ether.

Summary

1. The synthesis of a series of amino alcohols derived from 1,2,3,4-tetrahydrophenanthrene is described. The synthesis is effected by condensing 1-keto-1,2,3,4-tetrahydrophenanthrene and 4-keto-1,2,3,4-tetrahydrophenanthrene, respectively, with paraformaldehyde and the hydrochlorides of dimethylamine, diethylamine, piperidine and 1,2,3,4-tetrahydroisoquinoline, respectively, by the method of Mannich, and subsequent catalytic hydrogenation of the resulting amino ketones.

2. By reduction of the oximes of the above-mentioned tetanthrenones with sodium amalgam or aluminum amalgam, 1- and 4-aminotetanthrene can be prepared in satisfactory yields. The amino alcohols will be investigated for comparison of their physiological action with that of the next lower homologs.

The Reactivity of Nuclear Chlorine in the Isomeric 1,2- and 2,1-Chloronaphthalenearsonic Acids

BY GEORGE W. BOWERS AND CLIFF S. HAMILTON

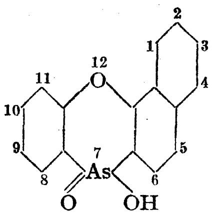
In the benzene nucleus the reactivity of chlorine ortho or para to the arsono group has been investigated[1,2,3] in this Laboratory. The object of this study was to extend the work to naphthalenearsonic acids.

In the preparation of the parent chloronaphthalenearsonic acids, the methods worked out previously[4] were found helpful. β-Naphthylamine was used in the production of both the isomers and 1-chloro-2-naphthalenearsonic acid was prepared readily. However, the synthesis of 2-chloro-1-naphthalenearsonic acid presented several difficulties and experimental methods finally developed must be followed carefully particularly in the arsonation reaction in order to obtain workable yields.

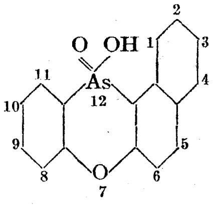
The most favorable conditions for the condensation reactions were determined by a series of experiments in which variations were made in the temperature, solvent, catalyst, time and proportion of reactants. Nitrobenzene proved the best solvent and the optimum temperature was approximately 140°. A small piece of bright copper foil was found the best catalyst and the reaction time was ten to twelve hours.

The reactivity of chlorine in these naphthalenearsonic acids is less than that found in the benzenearsonic acids, for neither the aliphatic nor the aromatic amines showed any evidence of reaction and, in general, the yields are smaller for the condensation product with phenols. Of the two chloroarsonic acids, the 1-chloro-2-naphthalenearsonic acid is apparently more reactive but due to the formation of tars the ethers were very difficult to isolate.

When the ethers resulting from the reactions of these chloronaphthalenearsonic acids and the phenols were boiled with glacial acetic acid they, without exception, lost the elements of water and two series of heterocyclic naphthalene arsenicals were produced. The following structures and names are proposed



α-Benzophenoxarsinic acid



γ-Benzophenoxarsinic acid

These structures are assigned for the following reasons: (1) the arsenic and oxygen atoms are in the same relative positions as in the parent ether compounds. (2) The arsenic analyses indicate the loss of water from the parent ethers. (3) These arsinic acids do not hydrolyze even by treatment with hot sodium hydroxide solution. They certainly would do so if the arsono group alone were involved in the dehydration. (4) The parent chloroarsonic acids are not dehydrated by the action of glacial acetic acid. This fact indicates again that the dehydration is not due to the arsono group alone. (5) It is assumed that ortho hydrogen of the phenolic group is involved because of the stability of six-membered rings. (6) The insolubility of the sodium salt of the similar phenoxyphenylarsinic acid in an excess of sodium carbonate has previously been observed.[5]

Experimental

1-Chloro-2-naphthalenearsonic Acid.—Twenty-one and two-tenths grams of 1-amino-2-naphthalenearsonic acid, prepared according to Saunders and Hamilton's[4] directions, was precipitated in a finely divided state by dissolving the pulverized compound in 2 *N* sodium hydroxide and acidifying to Congo red paper with 2 *N* hydrochloric acid. The mixture was diluted to 400 cc., 30 cc. of concentrated hydrochloric acid added, and diazotization carried out at −5° by adding dropwise 8 g. of sodium nitrite in 32 cc. of water over a period of one hour.

Meanwhile a cuprous chloride suspension was prepared in the usual way from 25 g. of crystallized copper sulfate and was dissolved in 72 cc. of concentrated hydrochloric acid. To this solution the diazotized amine was added in small portions. The resulting mixture was made alkaline by the addition of solid sodium carbonate and then filtered. Upon acidification of the filtrate to Congo red paper with hydrochloric acid, a light red precipitate of 1-chloro-2-naphthalenearsonic acid separated; purified by dissolving in sodium carbonate and reprecipitating by hydrochloric

acid, followed by recrystallization from 50% acetic acid; white needles; m. p. 317°; yield 82%; soluble in methyl and ethyl alcohols, but insoluble in water and benzene.

Anal. Calcd. for $C_{10}H_8O_3ClAs$: As, 26.16; Cl, 12.38. Found: As, 25.99, 26.10;[6] Cl, 12.21, 12.20.[7]

2-Chloro-1-nitronaphthalene.—From α-nitro-β-naphthylamine in 82% yields following the method of Hodgson and Walker,[8] for diazotization.

2-Chloro-1-aminonaphthalene.—Five grams of 2-chloro-1-nitronaphthalene was dissolved in 100 cc. of 95% alcohol, about 1 g. of Raney nickel added and the mixture exposed with shaking to molecular hydrogen under 40 lb. (2.66 atm.) pressure. Reduction was complete in twenty minutes. The catalyst was filtered from the mixture, the filtrate evaporated to 25 cc., 10 cc. of water was added and the solution placed in the refrigerator. The amine separated in long white needles; yield, quantitative; m. p. 56°.

2-Chloro-1-naphthalenearsonic Acid.—In a 600-cc. beaker was placed 17.7 g. of crude 2-chloro-1-aminonaphthalene and 196 cc. of 6 *N* hydrochloric acid. The mixture was cooled to 0° and 8 g. of sodium nitrite dissolved in 47 cc. of water was added dropwise over a period of two hours. Meanwhile in a 2-liter beaker an arsenite solution was made up by dissolving 50 g. of sodium metarsenite in 206 cc. of water in which was dissolved 2 g. of copper sulfate. This solution was cooled to 5°. The 2-liter beaker was fitted with a mechanical stirrer, and two funnel tubes extending to the bottom. A dropping funnel was adjusted at the top of each funnel tube. In one was placed 146 cc. of 6 *N* sodium hydroxide and in the other the filtered diazotized amine. With stirring the two solutions were dropped in rapidly at such a rate that the mixture in the beaker was always slightly basic. After the diazotized amine had all been added, stirring was continued for fifteen minutes longer and the mixture filtered through a carbon mat. Upon acidification to Congo red paper with hydrochloric acid the 2-chloro-1-naphthalenearsonic acid separated as an almost white precipitate. After dissolving in a sodium carbonate solution and reprecipitating with hydrochloric acid, the arsonic acid was used in this state of purity for subsequent condensations; purified by dissolving in 50% acetic acid and decolorizing with activated charcoal. Upon cooling colorless needles appeared, m. p. 296°; yield 56%; soluble in ethyl alcohol but insoluble in ether and benzene.

Anal. Calcd. for $C_{10}H_8O_3ClAs$: As, 26.16; Cl, 12.38. Found: As, 25.99, 26.10; Cl, 12.48, 12.38.

Phenyl Ether Derivatives

General Procedure.—A mixture of 5 g. of 2-chloro-1-naphthalenearsonic acid or 1-chloro-2-naphthalenearsonic acid, 10 g. of phenol or substituted phenol, 5 g. of anhydrous potassium carbonate, 25 cc. of nitrobenzene and a small piece of bright copper foil was placed in a 125-cc. Erlenmeyer flask fitted with ground-glass connections. The mixture was agitated by means of a stirrer extending through the length of the reflux condenser. The flask and its contents were heated in an oil-bath at 140° for ten to twelve hours. The resulting mixture was steam distilled to remove the nitrobenzene and excess phenol, and treated with activated charcoal. After filtering, the mixture was acidified to Congo red paper with hydrochloric acid, whereupon the phenyl ether derivatives of the arsonic acid precipitated. The crude products were charcoaled and crystallized from 50% acetic acid. The melting points are high, and more or less decomposition takes place as indicated by darkening.

Benzophenoxarsinic Acids and Derivatives

General Procedure.—The corresponding phenoxynaphthalenearsonic acids were boiled with glacial acetic acid and an equal volume of water was added. A portion of the arsinic acids precipitated and sufficient 50% acetic acid was added to bring them into solution at the boiling temperature. Upon cooling, the benzophenoxarsinic acids crystallized out in quantitative yields. No further puri-

fication was necessary if the corresponding phenoxynaphthalenearsonic acids used were pure. All were insoluble in sodium carbonate and cold sodium hydroxide solutions, but were soluble in hot sodium hydroxide solutions.

Summary

1. The isomeric 1,2- and 2,1-chloronaphthalenearsonic acids have been prepared for the first time. The synthesis of the latter involved the developing of methods for the quantity production of the intermediates 2-chloro-1-nitronaphthalene and 2-chloro-1-aminonaphthalene and the necessary modifications of the Bart reaction.
2. Two new series of naphthyl phenyl ether derivatives have been prepared by the condensation of the parent compounds with phenol and substituted phenols. 1-Chloro-2-naphthalenearsonic acid has been condensed with phenol and *o*-cresol. 2-Chloro-1-naphthalenearsonic acid has been condensed with phenol, *o*- and *p*-cresols, and *o*- and *p*-chlorophenols.
3. By the elimination of water, heterocyclic benzophenoxarsinic acids have been prepared from all the above naphthyl phenyl ethers. No benzophenoxarsinic acids have been reported previously.
4. No condensations were possible, under the conditions employed, with either aniline, the aliphatic amines or the aliphatic alcohols.
5. Chlorine in these naphthalenearsonic acids was found less reactive than chlorine in a similar position in the benzene nucleus.

The Normal Potential of the Silver–Silver Bromide Electrode from 5 to 40°[1]

BY BENTON BROOKS OWEN AND LOUISE FOERING

Experimental difficulties inherent in the direct comparison of certain electrodes with the hydrogen standard have led to the extensive use of secondary standards such as the familiar calomel half-cells. Because of the thermodynamic objections to the estimation of liquid junction potential involved in the ordinary use of such standards, it is important to be able to perform the comparison in cells without liquid junctions. It has recently been shown[2] that cells containing dilute borax buffers can be very conveniently employed in this connection. Although the method is general in principle, the use of borax solutions, under certain prescribed conditions, has the peculiar advantage of eliminating the need for an extrapolation to infinite dilution. This labor-saving feature and the convenience of borax as a buffering agent make it desirable to test the accuracy and reliability of the method by investigating a system which can be readily checked by more orthodox procedures.

For this purpose we have measured the electromotive forces of cells of the type

$$H_2 \mid HBO_2(m),\ NaBO_2(m),\ KX(m) \mid AgX - Ag$$

in which X represents either bromide or chloride, and $m \eqsim 0.005$ molal. After a small correction[2] to the electromotive forces to make them correspond exactly to $m = 0.005$, the equation

$$E^0_{\mathrm{HBr}} = E^0_{\mathrm{HCl}} + E^{0.005}_{\mathrm{KBr}} - E^{0.005}_{\mathrm{KCl}} \qquad (1)$$

permits the calculation of E^0_{HBr} in terms of known values of E^0_{HCl} taken as standard. Comparison can then be made with values of E^0_{HBr} obtained by direct extrapolation of measurements on cells containing dilute hydrobromic acid. We have employed electrodes containing fused silver bromide because the corresponding normal potentials have

recently been reported[3] over a wide temperature range.

Materials and Technique

Since the concordance among some of the earlier estimations of E^0_{HBr} is not very satisfactory, we have paid particular attention to the purity of our materials upon the supposition that the uncertainty in the older measurements may have been due to impurities in the hydrobromic acid.

We employed two samples of potassium bromide. Sample A was prepared from carefully purified potassium oxalate and bromine, and recrystallized three times from conductivity water. The purification of the bromine was essentially the procedure used by Baxter and Grover.[4] Sample B consisted of Baker "analyzed" potassium bromide recrystallized six times from conductivity water. Both samples were dried over solid sodium hydroxide, and then heated in platinum to constant weight at 120°.

The borax was a re-fused Kahlbaum product previously described.[5]

All concentrations were calculated from the weights of the "dry" salts, and expressed as moles per kilogram of solvent weighed *in vacuo*. The effect of the presence of 0.1% of moisture in the borax would be unmeasurable under the conditions of our experiment, but would amount to 0.02 or 0.03 mv. if present in the potassium bromide.

The silver–silver bromide electrodes were prepared by heating a mixture of 90% silver oxide and 10% silver bromate for seven minutes at 650°.[6] Several different samples of silver bromate were employed. One was a recrystallized fresh preparation, and the other two were carried over from previous researches.[6,7] Fresh and old[2] silver oxides were also used. Six electrodes were prepared from a silver bromate–silver oxide mixture left in the laboratory by Dr. Keston. They were used in the measurement marked by the superscript *a* in Table I.

Intercomparison of electrodes prepared from various combinations of these silver compounds showed them to be indistinguishable. They were kept dry until used, and no effort was made to protect them from diffuse daylight.[2]

Special care was taken in washing the hydrogen electrodes free from chlorides of the platinizing bath, and in the exclusion[2,5] of oxygen during the preparation and use of the cell solutions. Solutions were always used within one to four days after their preparation.

Discussion of the Results

The observed electromotive forces of the cells containing borax and potassium bromide were corrected to a partial pressure of hydrogen of one atmosphere, and to the round concentration $m = 0.005$. They are recorded as $E^{0.005}_{\mathrm{KBr}}$ in Table I.

The actual concentrations, *m*, of the solutions used in each series of cells is also included. Each value of $E^{0.005}_{\mathrm{KBr}}$ is the mean value of five or six independently filled cells agreeing within 0.1 mv. The same set of cells was never used over a temperature range greater than 20°.

Solutions (1) and (2) were prepared from sample B of potassium bromide. The others were made from the elaborately purified sample A. It can be seen that no *consistent* difference was observed in the electrochemical behavior of the two samples of potassium bromide. Since the source of the bromate and oxide used in the electrodes was also without noticeable effect upon the results, it is reasonable to conclude that the silver bromide electrode is not sensitive to such traces of impurities as may have remained in *any* of our chemicals.

In the calculation of E^0_{HBr} by equation (1), we employed the smoothed values of E^0_{HCl} given by equation (7) of Harned and Ehlers,[8] the mean values of $E^{0.005}_{\mathrm{KCl}}$ previously reported,[2] and the mean values of $E^{0.005}_{\mathrm{KBr}}$ derivable from the data given in Table I. The resulting values of E^0_{HBr} are recorded in the next to last column. Their temperature variation can be represented empirically by the quadratic equation

$$E^0_{\mathrm{HBr}} = 0.07134 - 498 \times 10^{-6}(t - 25) - 3.6 \times 10^{-6}(t - 25)^2 \quad (2)$$

[7] Owen, *ibid.*, **55**, 1922 (1933).

[8] Harned and Ehlers, *ibid.*, **55**, 2179 (1933).

The "fit" of this equation is indicated by the deviation in millivolts ($\Delta = E^0$ (obsd.) $- E^0$ (Eq. 2)) given in the last column.

Comparison with the corresponding values reported by Harned, Keston and Donelson[3] shows that our results are higher by two or three tenths of a millivolt, the agreement being best at the higher temperatures. In view of the indirect nature of our method and the combined uncertainties of the extrapolations for E^0_{HCl} and E^0_{HBr} involved in the comparison, it is probable that the agreement obtained is as good as could be expected. Nevertheless it should be remarked that Donelson's data for the 0.01 molal hydrobromic acid cell (fused silver bromide) are also two or three tenths of a millivolt higher than Keston's at the same concentration.[9]

Upon this basis we regard the reliability of electrode comparisons in borax buffers as established, and the accuracy of the method as limited only by the reproducibility of the measurements and the absolute accuracy of the electrode employed as standard.

Summary

1. The normal electrode potential of the silver–silver bromide (fused) electrode has been determined from 5 to 40° by comparison with the silver–silver chloride electrode in borax solutions without liquid junctions.

2. The reliability of the method is indicated by satisfactory agreement with results obtained with similar electrodes in hydrobromic acid solutions.[3]

3. By using materials from a variety of sources and subjected to different degrees of purification, it was shown that the silver–silver bromide (fused) electrode is highly reproducible.

NEW HAVEN, CONN. RECEIVED JUNE 22, 1936

[9] In a private communication Mr. Donelson informs us that the extrapolation of his data on the cells $H_2 \mid HBr(0.01), LiBr(m) \mid AgBr - Ag$ leads to values of E^0_{HBr} in excellent agreement with our own—maximum difference about 0.1 mv.

Contribution to the Chemistry of Europium

BY HERBERT N. MCCOY

Introduction.—The easy preparation of bivalent europium salts which, though powerful reducing agents, are sufficiently stable to be handled, invited further study of these unique rare earth compounds. This work has included determination of the velocity of oxidation by air of such europous compounds, the measurement of their reduction potential, the development of new methods of electrolytic reduction, the observation of the absorption spectrum of europous solutions, and the discovery that this spectrum is wholly different from that of trivalent europium solutions. As no method for the determination of europium in both of its stages of oxidation had been described, the first necessity for the work was the development of such a method.

Determination of Europium.—In a preliminary note[1] it was mentioned that europium may be determined iodometrically. The method may be illustrated by the following example.

A solution of europium chloride was made by dissolving 2.1619 g. of nearly pure europium oxide in 8.2 ml. of 6 *N* hydrochloric acid and diluting to 250 ml. Standard iodine and thiosulfate solutions, approximately 0.04 *N*, were prepared. The Jones reductor used[1] contained 150 g. of 20 to 30 mesh amalgamated zinc which gave a column 1.7 cm. in diameter and 21 cm. high. Immediately before each series of titrations 0.05 *N* hydrochloric acid was poured into the reductor tube and the zinc and acid were well shaken together. The reductor was then thoroughly flushed with more of the dilute acid, leaving sufficient barely to cover the top of the zinc column. The nozzle of the reductor dipped into a measured volume (usually 20 ml.) of standard iodine solution in a 400-ml. covered beaker into which a stream of carbon dioxide was passed to exclude air. For an analysis, 20 ml. of the europium chloride solution was run through the reductor, followed by a wash of 150 ml. of approximately 0.05 *N* hydrochloric acid. Reduction and washing required about twenty minutes.

The excess iodine was titrated with standard thiosulfate. The reactions are $2EuCl_3 + Zn \longrightarrow 2EuCl_2 + ZnCl_2$ and $Eu^{++} + I \longrightarrow Eu^{+++} + I^-$. In four determinations the net volumes of iodine solution required were 18.12, 18.05, 18.08 and 18.11 ml., mean 18.10 ml. indicating 0.1685 g. of europium oxide (Eu = 152.0) while the amount of oxide taken was 0.1730 g. The purity of the oxide was therefore 97.5%. In determinations, when no carbon dioxide was used, the results were 1 to 3% too low, due, doubtless, to partial oxidation of reduced europium by air.

Using this technique, the europium content of rare earth mixtures containing 1% or even less of this element may be determined if other reducible substances are

---

[1] McCoy, THIS JOURNAL, **57**, 1756 (1935).

absent. A chloride solution of the rare earths of monazite in nearly their natural proportions was freed from iron, phosphate and sulfate. This material had been precipitated previously as double sodium sulfate and in consequence was nearly free from ytterbium, which may react like europium. The solution had a density of 1.13 and contained 0.11 g. of oxides per ml. Fifty ml. of this solution was reduced and titrated. Its titer indicated a europium oxide content of 0.0033 g., assuming no other reducing substances present. To two further 50-ml. portions of this solution known amounts of europium were added. Analyses gave the following results.

	I	II
Eu_2O_3 in 50 ml. sol., g.	0.0033	0.0033
Eu_2O_3 added, g.	.0625	.0424
Total	0.0658	0.0457
Found	0.0659	0.0440

Oxidation of Europium by Air.—The observation of Urbain[2] that a dilute solution of europous chloride can be kept and that it is not oxidized by iodine or nitric acid even at 100° can only mean that complete oxidation by air had occurred before the small amount of material in hand was tested. A like explanation may be made regarding the statement of Jantsch, Alber and Grubitsch[3] who were unable to titrate with iodine a solution thought to contain europous chloride and concluded that a state of equilibrium was reached. Yntema[4] and also Selwood[5] found no difficulty in oxidizing solid europous sulfate with nitric acid.

On exposure to air a solution of europous chloride is oxidized more or less rapidly depending on conditions. A few ml. of a dilute solution in an open beaker may be oxidized completely in an hour or less, but 300 to 400 ml. of a 30% solution has often stood three or four days under similar conditions without being wholly oxidized. When thus oxidized, solutions with excess hydrochloric acid remain clear, europium trichloride being formed. If there is a deficiency of acid, white basic material precipitates.

A rough determination of the speed of oxidation of europous chloride by air was made. A 30 to 50-fold excess of air was blown through dilute solutions under such conditions that the concentrations of the dissolved oxygen remained nearly constant. The set-up used comprised a 70-ml. wide-mouthed jar with a rubber stopper carrying a small zinc reductor, the tip of a buret for standard iodine solution, a tube through which either carbon dioxide or air could be led to the bottom of the jar, and a narrow vent for the escape of gases. The solutions used were half molar europium chloride, normal and decinormal hydrochloric acid, and 0.04 N iodine and thiosulfate; only the last two were standardized. In making a run, 5 ml. of N acid was put in the jar, the stopper with attached tubes adjusted, and the air displaced by carbon dioxide. Two ml. (exactly) of the europium solution followed by 25 ml. of decinormal acid were run through the reductor in five or six minutes while a slow stream of carbon dioxide was passed into the jar.

This finished, the latter gas stream was replaced at zero time by 8 or 10 bubbles of air per second for an exactly measured interval. Next a measured excess of iodine solution was run in rapidly and, after waiting a few minutes for the completion of the ensuing reaction, the excess of iodine was titrated with thiosulfate. A fresh 2-ml. portion of europium solution was used for each oxidation run. The results lead to a fair constant for a first order reaction.

Speed of Oxidation of $EuCl_2$ Solutions by Air at 23°

Interval, min.	Net ml. $N/25$ I	$K \times 10$
0	26.33	..
1	21.99	1.80
2	18.32	1.81
3	15.09	1.85
5	11.53	1.65
7	7.31	1.83
9	4.62	1.93
	Mean	1.81

It is thus seen that a 0.04 molar solution is half oxidized in about four minutes in a solution kept saturated with oxygen from air. The speed of oxidation by air of a concentrated solution standing in a beaker is very much slower for obvious reasons.

Electrolytic Reduction of Europium.—In the electrolytic reduction of a europium chloride solution Yntema[4] used a two-compartment cell which required 65 volts to give a current of 0.18 amp. Its high resistance was due to the great separation of the electrodes. A one compartment cell having electrodes close together fails to give much reduction because of the reverse change at the anode.

The electrolysis of europium formate (made from the oxide and acid) overcomes these difficulties. The cathode is mercury, the anode a short stout platinum wire. At the anode carbon dioxide and hydrogen from the formate ion come off steadily. In a one-compartment cell with 50 ml. of 0.1 molar formate 6 volts (4 no. 6 dry cells) give an almost steady current of 0.08 amp. Practically no hydrogen is liberated at the cathode, which remains bright and mirror-like until the larger part of the europium is reduced. Finally when 75 or 80% has been reduced hydrogen begins to be liberated at the cathode and the current efficiency falls off. Europous formate so made shows the typical reactions of europous solutions, including the immediate formation of the insoluble sulfate when treated with a solution of sulfuric acid or a sulfate. Europium may be separated from other rare earths by the electrolysis of formate solutions containing some sulfate.

The electrolysis of the acetate works well. It is also possible to reduce a chloride solution in a one-compartment cell, using a silver anode.

The Reduction Potential of the Eu^{++}/Eu^{+++} Electrode.—The many indications that a solution of Eu^{++} has a high reducing potential were confirmed by direct measurement which led to a value of E_0 of about 0.43 volt. The arrangement of the cell was as follows: $Pt/Eu(COOH)_3 + Eu(COOH)_2 + HCOOH + N\ KCl/ + N\ KCl/N\ KCl + Hg_2Cl_2/Hg$. For the potential measure-

[5] Selwood, *ibid.*, **57**, 1145 (1935).

ments the following Leeds and Northrup instruments[6] were used: potentiometer, galvanometer, double throw switch, Eppley standard cell and Hildebrand (normal) calomel electrode. The total concentration of the europium was approximately 0.1 molar, the concentration of the free formic acid was small and variable, being sufficient only to prevent precipitation of the base by reason of oxidation by air during the measurements. A 150-ml. tall form beaker (without lip) with a fiber board cover and rubber band seal served both for the partial electrolytic reduction of the europium formate solution and later for the measurement of the electrode potential. In the beaker were placed 20 ml. of pure mercury and 50 ml. of approximately 0.1 molar europium formate containing a small excess of formic acid. The cover had seven holes, one central, the others peripheral. The central hole carried the glass insulated anode for the electrolysis, 1.5 cm. of stout platinum wire. Three glass-insulated platinum wires passed through other holes—one led to the mercury, the others, 3 mm. exposed lengths of small wires, served as alternate electrodes for the potential measurements. These electrodes were made of new wire carefully cleaned and kept in acidified europous chloride solution for twenty-four hours before being used. They quickly came to definite potentials during measurements. A salt bridge with normal potassium chloride connecting with a normal calomel electrode and a glass mechanically operated reciprocating stirrer passed through two holes while the seventh hole, closed by a plug, permitted the introduction of a 5-ml. pipet. The electrolysis was carried out as already described with four dry cells. The current of 0.07 to 0.08 amp. ran for two to two and one-half hours and reduced half or more of the europium to the bivalent state. The electrolyzing circuit was now disconnected and sufficient solid potassium chloride was dissolved in the reduced solution to make the concentration of this salt exactly one molar. If this addition is made prior to the electrolysis several difficulties arise.

During the series of potential measurements requiring about one hour, a little oxidation of the bivalent europium by air took place. For this reason potentiometric readings for each of the alternate platinum electrodes in the reduced solution were made immediately before and after removal of a 5-ml. sample for titration. This sample was run into a small (measured) excess of 0.04 *N* iodine. The excess was titrated with thiosulfate a few minutes later. Following the second pair of potential readings 5 ml. of a solution of europium trichloride and potassium chloride was run into the reduced solution. The former solution had exactly the same composition as the latter excepting that the europium of the solution added was entirely in the trivalent form. The ratio of Eu^{+++} to Eu^{++} of the solution in the cell was thus increased by stages. Following this addition, the titration of the excess iodine was made.

The solution in the cell was now stirred well for a few minutes and another series of potential measurements and another analysis were made, etc.

The two consecutive readings for the alternate electrodes usually agreed within 0.1 millivolt while the pair made before drawing the sample differed from those afterward by about one millivolt. The mean of the four readings of a set and the time of drawing the sample are given in the following table.

After the measurements were completed the total europium concentration was found by reduction of four 5-ml. portions in the zinc reductor and titration with standard iodine. The potential of a platinum electrode in the Eu^{+++} and Eu^{++} solution with normal potassium chloride was calculated by the equation

$$E_0 = (V - 0.2805) + 0.05915\ (\log_{10} Eu^{+++}/Eu^{++})$$

V being the observed e. m. f. including the normal calomel electrode. The reaction is $Eu^{++} = Eu^{+++} + e$. The platinum electrode in the europium solution is charged negatively.

POTENTIAL OF THE Eu^{+++}, Eu^{++} ELECTRODE

Temp. 25°. Total Eu concn. 0.0900 Molar

65	.6720	.0162	.0738	.4304
			Mean	.4313

Another set of similar measurements gave $E_0 = 0.4283$ volt.

In these experiments liquid potentials have not been entirely eliminated, but it is thought that they have been made quite small by reason of the preponderating concentration of potassium chloride in all solutions. The value found for E_0, about 0.43 volt, is one of the highest reducing potentials so far observed.[7] It is in good accord with the powerful reducing properties of europous solutions.

Europous Sulfate.—Progress in the work of isolation of europium by the europous sulfate method[1,4,5] is easily followed by titration of this salt with standard permanganate. In a typical case the sulfate was made from a chloride solution which showed but faintly the strongest absorption bands of neodymium in addition to those of europium. After being well washed on the filter with dilute hydrochloric acid and methyl alcohol and dried at 75°, portions of about 0.1 g. were covered with 30 ml. of 3 *N* sulfuric acid and titrated with 0.04 *N* permanganate, 0.6 to 0.8 ml. excess being added and the excess titrated with standard ferrous solution after the difficultly soluble europous sulfate had completely dissolved.

	I	II
$EuSO_4$ taken, g.	0.1113	0.1119
0.04 *N* $KMnO_4$, ml.	10.83	10.86
Purity of $EuSO_4$, %	96.6	96.3

It is possible to titrate the sulfate with iodine but the solid dissolves so slowly that the method is tedious.

Europous sulfate exists in two forms: (α) tufts of minute needles which are feathery and bulky; and (β) still smaller crystals, appearing nearly globular when highly magnified, of high density and settling to a very

---

(7) "Int. Crit. Tables," Vol. VI, p. 332.

compact mass. The α-form is frequently obtained when a solution of europous chloride from a zinc reductor is run into a solution of magnesium sulfate or dilute sulfuric acid. It soon passes into the stable β-form. The latter is but slightly soluble in 3 *N* sulfuric acid, while the former is dissolved by acid of this concentration. The analyses quoted were of the β-form.

The dry β-form keeps surprisingly well. In one case a sample, kept in a corked vial, showed the same permanganate titer after two, sixteen and fifty-five days and but 2.8% less after one hundred and forty-three days. Another sample, known to contain some rare-earth contamination, showed a purity of 94.7% after sixty-four days. The resistance of europous sulfate to oxidation by air is doubtless in large measure due to its marked insolubility.

Europous sulfate can be oxidized by and dissolved in nitric acid.[4,5] It can also be oxidized by chlorine, bromine, bromic acid and other active oxidizing agents. When europous sulfate is boiled for a few minutes with a solution of one equivalent of sodium carbonate and 0.4 equivalent of sodium hydroxide it forms a yellow, compact, easily filtered carbonate (probably $EuCO_3$). The carbonate dissolves readily in most acids.

The Absorption Spectrum of Europous Chloride.—The chloride ($EuCl_2$) solution of 20 to 30% concentration has a greenish yellow color like that of a concentrated solution of chlorine. The absorption spectrum of this solution, in the visible range, differs in a remarkable way from one of the trichloride. It does not show any of the several bands of the latter.[8] Instead, below approximately 4480 Å. all visible light is absorbed. The exact maximum wave length at which complete absorption begins depends upon the concentration of the solution and the thickness of the layer. Characteristic results are obtained when 30 ml. of a 1.2 molar solution of europium trichloride is run through a zinc reductor and viewed in a 20-cm. tube. The spectrometer used was a Bausch and Lomb instrument Cat. no. 2700. The light was that of a 75-watt Mazda bulb. It thus appears that the shift of the valence electron in the change $Eu^{+++} \rightleftharpoons Eu^{++}$ is responsible for a profound change in the absorption spectrum.

Summary

1. New methods permit the electrolytic reduction of trivalent europium to bivalent in simple cells at 6 volts or less.

2. Solutions of bivalent europium do not show any of the bands of the absorption spectrum of the trivalent salts; instead, complete absorption of visible light occurs below 4480 Å.

3. The reduction potential E_0 of Eu^{++}, Eu^{+++} solutions is approximately 0.43 volt.

4. Dilute europous solutions are half oxidized by a rapid stream of air bubbles in about four minutes. Crystalline europous sulfate, $EuSO_4$, is quite stable in air.

5. Iodometric methods for the determination of europium are described.

The Vibrational Levels of Cyclopropane

BY GILBERT W. KING,[1] ROBERT T. ARMSTRONG AND LOUIS HARRIS

Cyclopropane has considerable interest stereochemically and from the point of view of the mechanics of vibration of polyatomic molecules. A unique assignment of frequencies to its normal vibrations is not possible from its Raman spectrum[2] alone; infra-red data, even of a semi-quantitative nature, would aid in such an assignment. Together, the two spectra permit an analysis of the fundamental modes of vibration of cyclopropane.

Infra-red Absorption.—The preparation and purification of the cyclopropane has been described in a previous paper.[3] The infra-red spectrum has been mapped in the following manner.

Region	Method of measurement	State of cyclopropane
I. 0.8 μ to 2.8 μ	Quartz monochromator. 1000 watt projection lamp. 15 mm. length quartz cell.	Liquid at −78°. Gas at 25° and 1 atm. pressure.
II. 0.8 μ to 1.1 μ	Hilger E1 spectrograph (Glass optics); also 21 ft. grating. 1000 watt projection lamp. 1 meter length cell, quartz windows.	Gas at 25° and 1 atm. pressure.

[a] 1191 cm.$^{-1}$ was the only Raman line observed from gas.

Selection Rules.—The symmetry of the molecule may be decided definitely from qualitative considerations. The manner of distribution of the twenty-one ($3\,N - 6$) fundamental frequencies of cyclopropane among the representations of the most likely symmetry groups is given in the following table, together with their infra-red (IR) or Raman (R) activity.

C_{3v}			C_{2v}			D_{3h}		
R, IR,	A_1	5	R, IR,	A_1	7	R,	A_1'	3
	A_2	2	R,	A_2	4		A_2'	1
R, IR,	E	7	R, IR,	B_1	5		A_1''	1
			R, IR,	B_2	5	IR,	A_2''	2
						R, IR,	E'	4
						R,	E''	3

C_{3v}.—This symmetry group requires twelve frequencies (seven of the twelve being doubly degenerate) active in both the Raman and infra-red spectra, which is not in agreement with our data.

C_{2v}.—This requires seventeen frequencies active in the infra-red, all of them also active in the Raman spectrum, totaling twenty-one different active fundamentals in the latter spectrum, again not in agreement with observation.

Furthermore, of the three groups given, C_{3v} and C_{2v} require strong Raman frequencies (the totally symmetrical A_1) to be active also in the infra-red. No absorption was detected in the region corresponding to the strongest Raman frequency, 1191 cm.$^{-1}$ (absorption was less than 5% with cyclopropane at one atmosphere pressure in a cell with an effective length of 10 cm.), so that these two symmetry groups are not further considered.

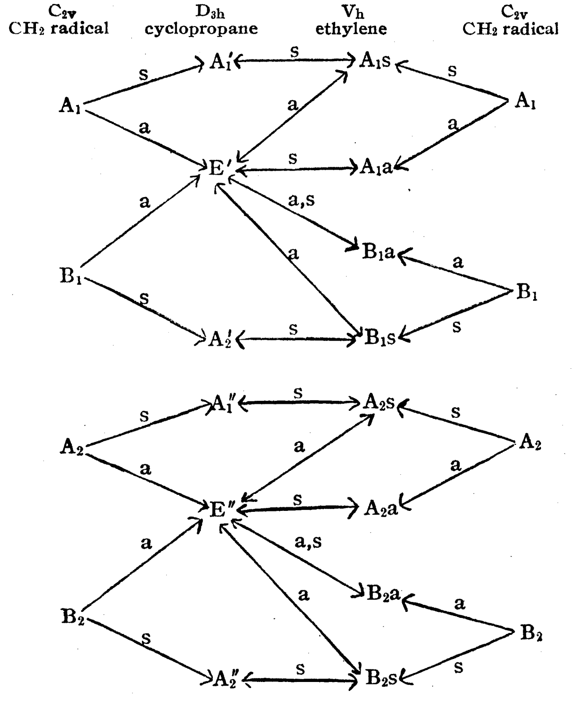
D_{3h}.—This requires six (four doubly degenerate) infra-red active fundamentals, and ten (seven doubly degenerate) Raman active frequencies, which is more compatible with the data. These frequencies may be identified by the following semi-quantitative considerations, pending exact perturbation calculations.

Symmetry Coördinates.—In general there is a correspondence of the representations of a symmetry group of a system and the representations of the symmetry groups of parts of the system, or system under perturbation. If all equivalent bonding energies are permitted to decrease simultaneously (*e. g.*, allow the three CH_2 groups to recede to a large distance yet preserve their geometrical relations) the symmetry of the (enlarged) molecule is unchanged. In the enlarged molecule the normal vibrations are such combinations of the nine orthogonal motions of the isolated radical CH_2 (3 vibrations, 3 rotations, 3 translations) as conform to the symmetry of the group D_{3h}. The fact that the symmetry operators of the combined system (C_3H_6), for example rotation through 120°, must carry any vibration of the enlarged molecule into a linear combination of the vibrations of the same level, indicates that the three isolated CH_2

groups must be vibrating in the same mode, all either in phase (s) or one of the three groups out of phase (a). A more accurate statement concerning the composition of systems from radicals is provided by the resolution of representations into those of component radicals. Table II correlates the representations of CH_2, ethylene and cyclopropane.

TABLE II

CORRELATION OF THE REPRESENTATIONS OF THE SYMMETRY GROUPS OF CYCLOPROPANE, ETHYLENE AND THE CH_2 RADICAL WITH CORRESPONDING RELATIONS FOR THE NORMAL VIBRATIONS



The corresponding relations hold for the actual vibrational states belonging to the various representations. These are described by vector models for CH_2 and $(CH_2)_3$ in Fig. 1.

Figure 1 illustrates the use of the above principles in determining the normal vibrations of cyclopropane from those of its component radicals, $3CH_2$'s. The nine (3 N) normal vibrations of a non-linear tri-atomic molecule (translations, T_z, T_h and $T_\perp$, and rotations, R_z, R_h and $R_\perp$, may be regarded as vibrations of zero frequency) are described by vector models in the center column of Fig. 1. These vibrations are perturbed by the coupling action of the other two CH_2 groups and each frequency (including the translations and rotations) combines anti-symmetrically (doubly degenerate, a-levels) or symmetrically (s-levels) to give the vibrations of cyclopropane as shown on the left and right of the figure, respectively. Similarly the vibrational levels of the symmetrical triangular C_3 molecule (Group D_{3h}), or of a constrained cyclopropane molecule, where the CH_2 groups are rigid, may be resolved into the levels of the actual cyclopropane molecule.

Assignment of Observed Frequencies to Normal Modes of Vibration

a. Carbon Interaction: (T_{zs} and $T_{\perp a}$).—Calculations based on central forces[4,5] of the frequencies of the constrained cyclopropane molecule identify the intense symmetrical vibration (labeled T_{zs} in Fig. 1) at 1191 cm.$^{-1}$ (properly inactive in the infra-red) and a doubly degenerate deformation frequency at 869 cm.$^{-1}$ (labeled $T_{\perp a}$ from its construction from CH_2 levels). The latter was beyond the spectral region (infra-red) investigated (see note 10 at end of paper).

b. CH_2 (Vibration) Interaction: $\sigma_{s,a}$; $\pi_{s,a}$; $\delta_{s,a}$).—The principles used in deriving the normal modes of vibration lead to further definite assignments. Each of the three normal vibrations of CH_2, σ, π, δ, should split slightly to form a- and s-levels of ethylene, and to almost the same degree to form the corresponding a- and s-levels of cyclopropane, in the same region of the energy scale. These frequencies can be identified more precisely by means of Mecke's Rule II.[6] The infra-red spectrum was not resolved enough to decide, by means of selection rules, which of the Raman frequencies (1505, 1437, 1454 and 2953, 3013, 3030 cm.$^{-1}$) are the a- and s-combinations of the δ_a and π_a levels. The doublets (1437–1454 and 3013–3030) may be the doubly degenerate levels δ_a and π_a whose degeneracy has been removed either by interaction of the angular momentum of the doubly-degenerate motions with that of pure rotation[6] (p. 125), or by resonance due to a slight difference in the C–C bonds requiring both components to be active in the Raman and infra-red spectra.

Dr. E. Bright Wilson, Jr., has kindly suggested that these doublets are more likely to be ascribed to accidental degeneracy of δ_s and 2 × 745 (leading to 1437 and 1454) and of π_s with 2 × 1505 (leading to 3013 and 3030). The frequency 745 cm.$^{-1}$ is probably to be assigned to $R_{\perp a}$ of repre-

sentation E″, as indicated below. Thus its overtone belongs to E′ and A′, and so may couple with δ_s of A′, both frequencies being active in the Raman, and the component with symmetry *E′* of the overtone being active in the infra-red. An analogous situation obtains for the π_s level. Much greater resolution than was used here will be required to decide whether one or both components of the doublets appear in the infra-red. The relative positions of the a- and s-levels of cyclopropane and ethylene oxide[7] are the same according to this assignment, as shown in Table III. The separations of the a- and s-levels are computed assuming that the coupling of the CH_2 radicals is due predominantly to central forces between the atoms of one radical and those in the other, whose magnitudes are estimated from the types T_{zs}, R_{ha} and $R_{\perp a}$. (No assumptions are necessary regarding the potential function within the CH_2 radicals, other than a rough estimate of the amplitudes of motion in each vibration.) Since the results for ethylene agree in order of magnitude and sign with observation (Table III) some weight may be given to the values obtained for cyclopropane.

c. **Hydrogen (CH_2 Rotation) Interaction:** ($R_{ha, s}$; $R_{za, s}$; $R_{\perp a, s}$).—All the frequencies of cyclopropane except those that are a and s combinations of the *rotational* modes of the CH_2 radical, have now been assigned and correlated. Of these R_{ha} (of C_3H_6) is to be ascribed to 1022 cm.$^{-1}$, for this is the only vibration of this group that is active in both the infra-red and Raman spectra. Another frequency of this group, $R_{\perp s}$, is also unique since it is the only one predicted to occur in the infra-red alone. The band at 1800 cm.$^{-1}$ was observed only in absorption; but since this is a high frequency for such a (fundamental) mode, it is probably a combination frequency and $R_{\perp s}$ probably lies in the unexplored region < 1000 cm.$^{-1}$. The only permitted combinations and harmonics of appreciable intensity active only in

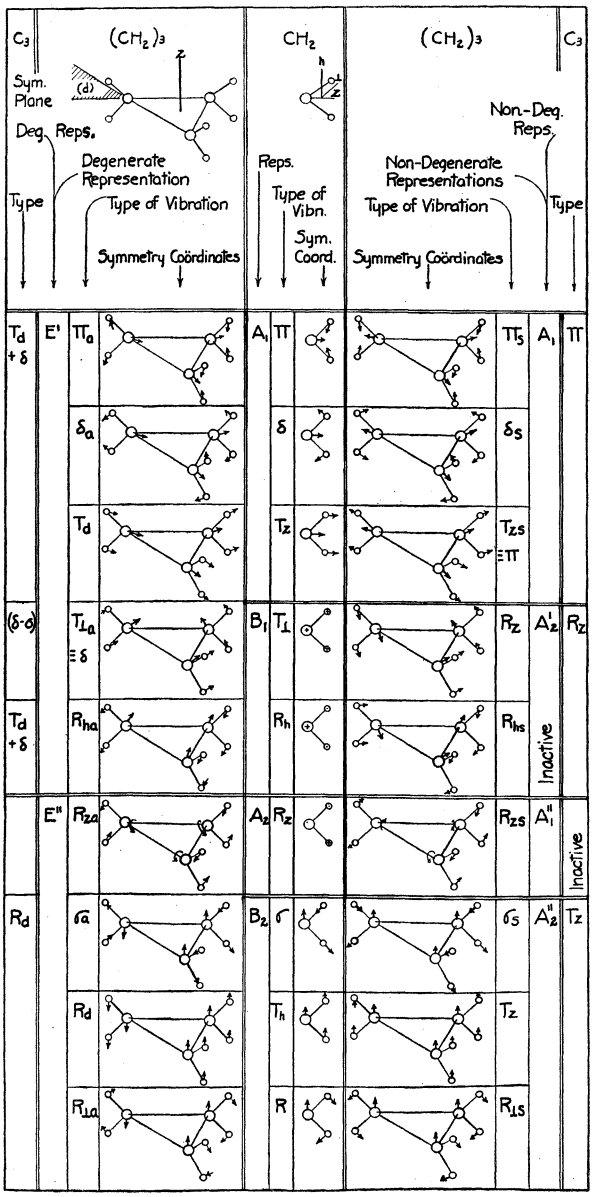

Fig. 1.—Symmetry coördinates and derivation of the fundamental vibrational modes of cyclopropane.

---

[7] B. Timm and R. Mecke, *Z. Physik*, **97**, 221 (1935).

absorption are $T_{zs} + R_{\perp s}$ (giving $R_{\perp s} = 1800 - 1191 = 609$ cm.$^{-1}$ + anharmonicity) and the combination $R_{zs} + R_{hs}$. The latter modes should be inactive in both spectra as fundamentals.

The unassigned lines in the Raman spectrum (382, 745 and 1873 cm.$^{-1}$, all of low intensity) are attributed to the two remaining fundamentals, $R_{\perp a}$ and R_{za}. The following tentative assignment is made $R_{\perp a} = 745$ cm.$^{-1}$, $R_{za} = 382$ cm.$^{-1}$, and $R_{ha} + T_{\perp a} = 1873$ cm.$^{-1}$.

Further Confirmation of Assignments.—As indicated in Table II, the anti-symmetrical levels of cyclopropane are composed from the anti- *and* symmetrical levels of ethylene. The anti-symmetrical levels of cyclopropane are, to a first approximation, the mean of the corresponding (squared) frequencies of ethylene

$$\underbrace{\nu_s^2 + \nu_a^2}_{\text{Ethylene}} = \underbrace{2\nu_a^2}_{\text{Cyclopropane}}$$

This formula holds quite well for all the levels except R_{za} (giving 500 cm.$^{-1}$ instead of 382 cm.$^{-1}$) and $R_{\perp a}$ (950 cm.$^{-1}$ instead of 745 cm.$^{-1}$).

Similarly the vibrational modes of cyclopropane can also be constructed from the motions of the "radicals," C_3 and H_3. Due to much larger perturbation here the levels more closely related to CH_2 levels are split to such an extent that this composition is purely formal. However, the π and δ (doubly degenerate) levels of C_3 (whose frequency ratio based on central forces[4,5] would be $\sqrt{2}$) are only slightly perturbed to form T_{zs} and and $T_{\perp a}$ (ratio 1.372) and δ_s and R_{ha} (ratio 1.476). The motions of the hydrogen planes (π and δ) are similar in each pair, but are in opposite phase relative to the carbon motions, accounting for the four per cent. perturbation in each direction from $\sqrt{2}$. These ratios confirm the previous method of assignment and may be extended to modes involving only π and δ vibrations of the hydrogen rings. It is interesting to note that the ratio of 1022 to 745 is also 1.372, but it is difficult to attach significance to this.

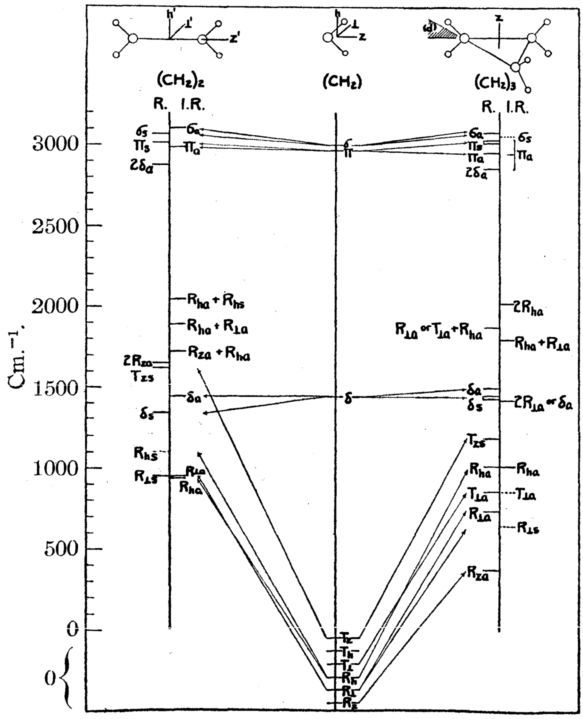

Fig. 2.—Relation of the frequencies of the CH_2 radical, ethylene and cyclopropane.

Acknowledgment

We wish to thank Professor Hoyt C. Hottel for the use of the rock-salt spectrometer.

Summary

The fundamentals of cyclopropane have been identified by group theoretical correlation with the frequencies of ethylene[8] and of the CH_2 radical.[9] The results are summarized in Figure 2. The frequencies predicted but not observed here ($T_{\perp a}$, $R_{\perp s}$) are indicated by dotted lines.[10] Such semi-quantitative analysis should act as a guide in the deduction of a suitable type of potential function for these hydrocarbons.

The measurements reported for the infra-red absorption bands in the 0.8 μ to 3.6 μ region (listed in Table I) are inadequate to justify an assignment of the combination frequencies.

[9] C. B. B. M. Sutherland and D. M. Dennison, *Proc. Roy. Soc.*, **148**, 258 (1935).

[10] Since this paper was submitted we have learned through the kindness of Professor E. F. Barker, of the University of Michigan, of some measurements of the infra-red absorption of cyclopropane made there by Doctor W. W. Sleator. He observed the following: a strong unresolved triplet at about 675 cm.$^{-1}$, another similar one at 870 cm.$^{-1}$, a strong narrow peak at approximately 1400 cm.$^{-1}$ and several weaker ones at higher frequencies, one near 1437 cm.$^{-1}$. Absorption in the 3 μ region was strong, but was not completely resolved.

Infra-red absorption at 870 cm.$^{-1}$ confirms the assignment of T_{zs} and $T_{\perp a}$ given above. Absorption at 675 cm.$^{-1}$ is probably due to $R_{\perp s}$ (predicted at 609 + cm.$^{-1}$).

A Study of the Preparation and Quantitative Determination of Elementary Fluorine[1]

BY WILLIAM T. MILLER, JR., AND LUCIUS A. BIGELOW

A program of research now in progress in this Laboratory[2] deals with the action of fluorine upon organic compounds. Until recently, the element has been prepared by the electrolysis of molten potassium bifluoride, in an open generator of the Mathers type, and the fluorine produced has been regarded as fairly pure, in common with the views of others.[3] However, it was found that the gas was not completely absorbed by potassium iodide solution, the residue being largely oxygen; and also that it was partly condensable at the temperature of liquid air, which indicated that it contained a good deal of oxygen fluoride. The formation of these impurities was undoubtedly due to the presence of water in the molten electrolyte. The purpose of the present paper is to set forth the general conditions necessary for the production of pure fluorine, and to describe a generator embodying these principles, together with apparatus and methods for analyzing the product.

Apparatus and Methods

As the result of a rather careful survey of the literature,[4] we have considered, first, that fluorine must be generated free from oxygen and other impurities, rather than subjected to later purification; second, that the electrolysis of molten potassium bifluoride is the most promising and convenient method available for the purpose; and finally that the essential requirements for the formation of a pure product are an efficiently closed generator and an anhydrous electrolyte.

We have designed a new closed generator of the U-type, in contrast to the V-type described by Dennis, Veeder and Rochow.[5] It was constructed of heavy cast nickel and is illustrated in Fig. 1. It was strong, efficient and durable, as well as being suitable for pressure work. Nickel was chosen because it was resistant at operating temperatures, and formed a persistent, insoluble coating of nickel fluoride during the electrolysis. The apparatus was cast with flanged ends, and the caps were made by turning and drilling cast nickel forms. Lead washers were placed between the turned surfaces of the caps and the U-tube, and the connections made gas tight and rigid by drawing these parts together with heavy clamps, consisting of 13-mm. steel plates, provided with six 13-mm. steel bolts.

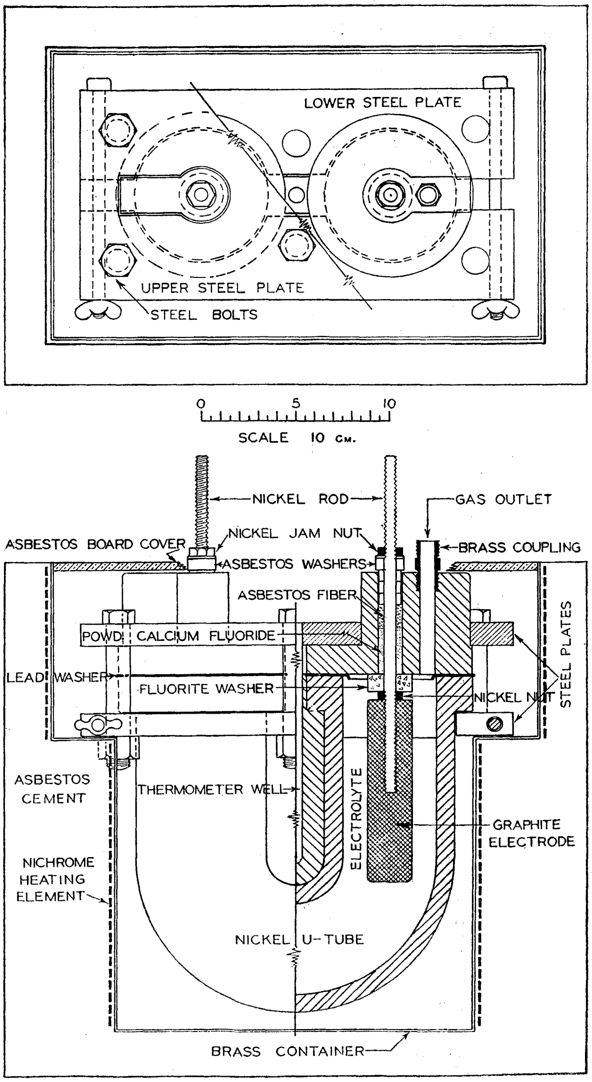

Fig. 1.—The fluorine generator.

Graphite electrodes were used, and threaded directly onto 6-mm. nickel rod supports. These, in turn, were centered in 13-mm. holes in the caps, and were held in place, made gas tight, and also insulated by means of a cement prepared from ground fluor spar and sodium silicate. Handles were made from 6-mm. iron rod, in the form of rectangles, which fitted under the ends of the steel clamp plates, and were folded and grasped together above the generator.

(5) Dennis, Veeder and Rochow, THIS JOURNAL, **53**, 3263 (1931).

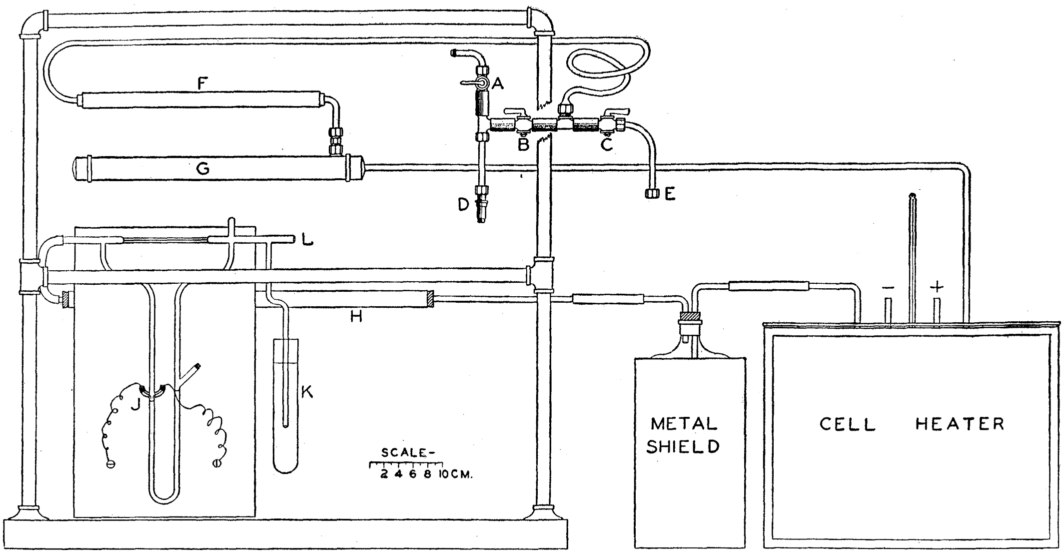

Fig. 2.—The apparatus assembly.

The construction of the heater is shown in Figs. 1 and 2. It consisted, essentially, of a brass container wound with a nichrome wire heating coil having resistance of 20.0 ohms. This unit was packed into an asbestos board box with dry asbestos cement hardened at the surface. The generator was placed in the heater in such a manner that the caps and couplings were kept sufficiently hot to fuse the low-melting sublimate from the electrolyte.

A special apparatus was designed to dehydrate the charge. It consisted essentially of a vertical copper pipe, approximately 48 × 8.3 cm., closed at the lower end, wound with nichrome wire (11.5 ohms), and insulated with asbestos cement. The top was closed by a cover, bolted on, using a lead washer, and carrying a copper exit tube and a thermometer well. From the bottom of the apparatus there extended a length of 13-mm. (i. d.) copper tubing, in the form of a spout, into the upper horizontal surface of which was soldered a 6-mm. brass coupling. In this apparatus, dry air, and finally fluorine gas, were passed through the salt, at an elevated temperature, entering from below. The salt was allowed to stand in contact with the fluorine for some time,[6] to complete the dehydration. Finally, by raising the temperature of the oven to 245° the salt was liquefied, and under these conditions ran down into the uninsulated spout, where it froze. With this arrangement, the dry electrolyte could be transferred very neatly to the generator by placing the latter, in its heater, and at about 260°, directly beneath the spout, and then melting the frozen salt with a Meker burner. The molten charge then flowed rapidly into the generator, which was immediately closed, thus ensuring a minimum exposure of the bifluoride to air and moisture in the process.

The set-up of apparatus which has been used for generating and handling the fluorine is illustrated in Fig. 2. The copper tubes G and H were filled with powdered sodium fluoride, which has been shown[5] to combine quantitatively with hydrogen fluoride. The tube F was filled with copper oxide wire, which, while not affected by the fluorine, would decompose quantitatively any ozone which might possibly be present. The container in the metal shield was a surge bottle in the hydrogen line, leading to a flow meter, which served also as an important safety device. It was arranged by means of a relay so as to sound an alarm whenever the flow of hydrogen was interrupted during the time that the apparatus was in operation. This avoided the danger of building up high pressures inside the generator by continuing the electrolysis with the exit tubes obstructed. However, by closing the hydrogen outlet L with a rubber cap and passing the gas through K, it was possible to apply any desired small pressure to the cathode chamber of the generator, in order to compensate for any such which might be built up in the anode compartment and the fluorine line.

The simplest, reasonably accurate analytical method for determining the efficiency of the generator consisted in allowing the fluorine produced in a measured time, at a definite current density, to react with a potassium iodide solution, and then to titrate the liberated iodine in the usual way. In the absence of oxygen fluoride, this method may be expected to give good results. No apparatus has been described in detail for carrying out this procedure, however, and the set-up which we have used is illustrated in Fig. 3. The U-tube was coated completely on the inside with a thin layer of ceresin wax, which was shown not to be attacked significantly by diluted fluorine (50% in air) at 0°. The rapid counter current flow of the solution produced by the screw pump promoted the complete absorption of the gas, without introducing any appreciable head of liquid. Gas samples, suitably diluted with air, were taken directly from the fluorine line through a slip joint, sealed with ceresin wax, at B. The 50-cc. bulb provided at C effectively prevented splashing, and the mercury seal made it possible to collect any unabsorbed gases quantitatively at A.

The precise determination of the fluorine contained in a gas sample, followed by the analysis of the residual gas,

---

(6) Henglein and Stauf, U. S. Patent 1,914,425 (1933).

proved to be no simple problem. However, we have found experimentally that metallic mercury, when shaken, absorbed fluorine quantitatively. Also, we have observed that no significant absorption of the gas took place when it was stored for six hours at room temperature in a Pyrex glass bulb, and confined by means of mercury in a tube of small diameter. This was due to the perfect protective coating formed at the undisturbed surface of the metal, and to the fact that fluorine did not react with the glass under such conditions.

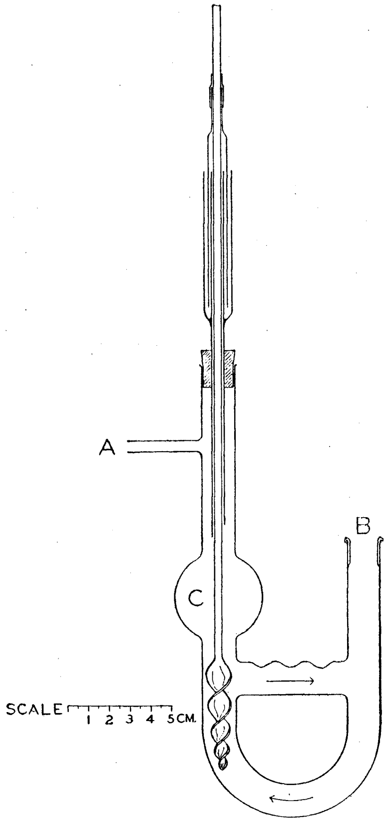

Fig. 3.—Absorption tube for the efficiency measurements.

Accordingly, a Pyrex glass buret, of the constant volume type, using mercury as the absorbent, has been designed, and is illustrated, with the jacket removed, in Fig. 4. Perhaps the most significant feature of this apparatus was the device for sealing in the fluorine sample with mercury at A and C. The arrangement at H and K served as a means of reference, so that manometer readings could be corrected for different positions of the buret, and also as a necessary bubble trap. The most satisfactory way to make clear the advantages and uses of the other connections shown is to describe at this point, in some detail, the method of collecting and measuring a sample of fluorine.

The buret was clamped in position, and the manometer attached at M, Fig. 4, using a little glycerol to prevent this connection from sticking. After lowering the level of the mercury in the manometer about 760 mm. below M, rubber caps were placed over tubes A, B and C, and the apparatus pumped out through J with an oil pump. Stopcocks D and G were both opened alternately in the two possible ways, in order to exhaust their bores as well as the rest of the apparatus, which was rinsed several times with dry air. Stopcock D was then closed and mercury admitted through G and its connecting tubes until the level of the liquid approximately reached F. After closing H and G the pump was shut off and the leveling bulb raised. The vacuum in the apparatus was then released through A or C, and the relative positions of K and F determined on the manometer scale by adjusting the mercury level to the respective marks, with H open. The tube B was filled about three-fourths full of mercury, which was freed from all adsorbed gases by gently warming and tapping the tube, which was exhausted at the same time from above. After again exhausting the apparatus, mercury was allowed to pass through D, in such a way as to fill the capillaries to the bottoms of both U-tubes as shown below C (Fig. 4). Similarly, E and the central tube leading up from F were filled with mercury, as shown in the figure, and the vacuum in the apparatus was then released with dry air. Before collecting the sample to be analyzed, the anode tube system from the generator was swept out for two hours, with a gas flow corresponding to a 5 amp. current. Then capillary C (Fig. 4) was slipped into the Monel metal fitting D (Fig. 2), the connection wrapped tightly with thin copper foil, and painted on the outside with ceresin wax. Fluorine was then passed through the pipet at the usual 5 amp. rate for one hour. The brass stopcock A (Fig. 2)

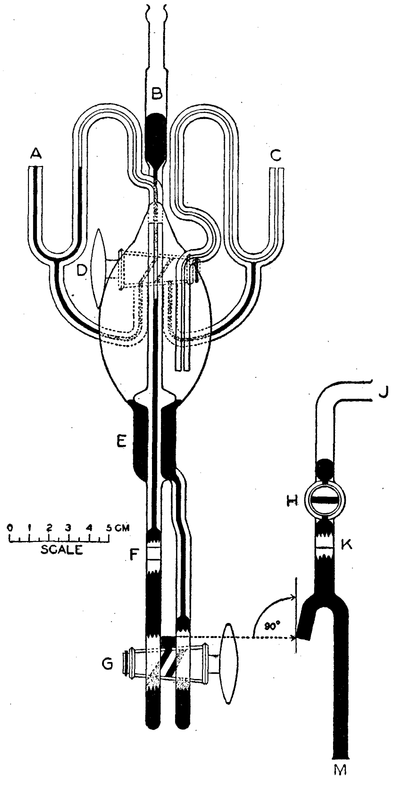

Fig. 4.—Gas buret for the quantitative estimation of fluorine.

was then opened, to by-pass the fluorine, and mercury allowed to fill the outlet U-tube of the absorption apparatus through D (Fig. 4), to the position shown at A in this figure. Then A was warmed with a small flame and a drop of sealing wax melted across the end of the tube and the mercury, taking care to exclude any air bubbles. After allowing the sample to stand in this way for five minutes, the brass stopcock B (Fig. 2) was closed, C opened, and the inlet U-tube likewise filled with mercury, disconnected at D (Fig. 2), and sealed. By passing heated air through the system in place of the generator gas, this method was shown experimentally to give a sample in the buret at the water-jacket temperature, and at atmospheric pressure, after the five-minute period of standing.

When the seals were completely hard, the buret was held in the hands, tilted to an angle of about 45°, with stopcock D leaning backward, and shaken so as to swirl the mercury in a thin film over the back portion of the bulb. A coating was formed at first, which quickly darkened as the fluorine reacted with it. The shaking was continued at short intervals, until this film remained bright for five minutes. The end-point was sharp, and signified the complete absorption of the fluorine. The pressure was then read at F, and the value thus obtained correlated with the atmospheric reading by correcting it to the corresponding position of K (Fig. 4) on the manometer scale.

To remove the residual gas from the pipet, mercury was admitted through G, until the pressure inside the bulb was approximately atmospheric. Then the tube B was connected by means of a section of 1-mm. capillary tubing, to a gas analysis apparatus similar to that described by Ambler.[7] The air was displaced from the tube by passing mercury out through the inlet capillary of the absorption apparatus through D and B. The residual gas was finally led out through the outlet capillary, also through D and B, into the Ambler apparatus, and analyzed in the usual way for carbon dioxide, oxygen and inert constituents.

Discussion of the Results

The new generator, set up and connected as described above, gave excellent results. It was easy to charge, quiet and steady in operation, and gave a closely reproducible product. The unit stood up very satisfactorily in service, being hardly at all corroded after five hundred hours of operation. The current efficiency measurements obtained showed a variation from 89–61%, falling off somewhat with time of electrolysis. The current was measured to 0.5%, the titration to about 0.2% and the time to about 0.3%, making a total of 1%. The error due to pressure changes was negligible. However, it should be noted that when the fluorine from the generator was passed into concentrated neutral potassium iodide solution, some hydrogen ion was formed, presumably due to the direct action of the halogen on the water, and to the extent of about 3% of the oxidizing value of the sample, under our operating conditions. According to Cady[8] when fluorine reacted with cold neutral water, oxidizing agents capable of liberating iodine were formed to the extent of 70% of the halogen absorbed. From this it was indicated that in our work the loss in oxidizing value from this cause should not exceed 0.30×3 = approximately 1%. Consequently, the maximum total error in the efficiency measurements was considered to be not over 2.5%.

The purity of the fluorine generated, as measured by means of the mercury absorption buret described above, varied from 94 to 99% by volume, according to the age of the charge, and its initial moisture content. When the potassium bifluoride was finally dried with fluorine gas, the quality of the product was improved significantly. The best sample measured, prepared from an electrolyte which had been dried in this way, contained 99% fluorine, 0.4% oxygen, 0.2% carbon dioxide plus carbon oxyfluoride, and 0.4% inert gas, presumably carbon fluorides. The end-point of the absorption was sharp, as indicated by the appearance of the mercury. The principal experimental error of this method occurred in making the pressure readings, each of which could be observed to within ±0.2 mm., leading to a possible maximum error of 0.8 mm. This could affect the fluorine value by about ±0.15%, although it was more than likely that the errors would be at least partially compensating. Any variations due to temperature or pressure at the time of sampling, or volume changes due to the formation of mercury fluoride in the buret, have been shown to be entirely negligible. The values obtained for the composition of the residual gas were probably quite accurate, in terms of the total sample, because of the comparatively small portion of the latter which they represented. It should be pointed out, of course, that serious errors in all of these values would have resulted if the gas had contained any significant amounts of oxygen fluoride, which reacted slowly with mercury, with the evolution of oxygen.

From all of these considerations, it was clear that the closed generator described above was dependable, convenient, and yielded a closely reproducible product of a proven high degree of purity.

Experimental Part

The Preparation of Fluorine.—One kilogram of Merck purified potassium bifluoride, free from chloride and sulfate, was placed in the drying oven already described, and the lower opening of the spout closed with a rubber stopper. Then a current of dry air at reduced pressure was drawn through the salt at 150°, and at a rate of about 1.5 liters per hour, for twenty-four hours. After this, fluorine gas was passed into the oven from below until it issued from the top, and the salt allowed to stand in contact with the halogen for twelve hours at 150°. This treatment was repeated twice more with fresh fluorine. Then the bifluoride was melted in the oven by heating it to 245°, and transferred to the generator in the manner already described.

A preliminary electrolysis for one hour at 3 amp., and one-half hour at 5 amp. was carried out, in order to form a good insulating coating on the inside of the U-tube, and after this the generator was connected with the system shown in Fig. 2. It would then produce fluorine smoothly, either continuously or otherwise, for about 125 ampere-hours. Under normal operating conditions at 250°, a current of 5 amperes corresponded to a potential drop across the generator of 18–20 volts, and to a gas flow of approximately 2 liters per hour. In operating the unit, the safety alarm already mentioned was used always, and care taken to avoid any pressure changes which might force the molten electrolyte into either of the outlet tubes. Also between runs, the apparatus was maintained at 175°. It should be noted, in addition, that according to Fredenhagen and Cadenbach[4c] the exhausted electrolyte may be regenerated by treating it with anhydrous hydrogen fluoride, which was readily absorbed by the salt. However, we have not employed this technique up to the present time.

Current Efficiency of the New Generator.—The system was swept out with fluorine by operating the generator for one hour at 5 amp., with A and B closed, C open and E connected to a glass tube extending just under the surface of concentrated sulfuric acid. Meanwhile, the absorption apparatus was charged with 34 cc. of a 50% solution of potassium iodide in water, and attached to the system at D, by means of a metal sleeve, painted on the outside with ceresin wax. It was then surrounded by a small ice-bath, and rigidly clamped to avoid vibration. A right-angled glass tube was connected at A (Fig. 3), and arranged to lead the outlet gases through a little potassium iodide solution, in order to test the completeness of the absorption, although this was always practically quantitative. The stirrer was started at high speed, A (Fig. 2) was opened, and a slow current of air drawn in by applying a slight suction to the supplementary trap, in such a way that the generator gas would be diluted with about twice its volume of air. To do this the system was kept under a pressure of approximately 1–1.5 mm. of mercury less than atmospheric. Then the current was adjusted to a flow of precisely 5.00 amp., the exact time noted and the two stopcocks B and C turned simultaneously, the one on and the other off. The absorption was run for exactly fifteen minutes and was discontinued by again turning B and C simultaneously. The solution was finally washed out of the apparatus and an aliquot portion titrated with sodium thiosulfate in the usual way. The results obtained have been summarized in Table I.

TABLE I

THE CURRENT EFFICIENCY OF THE NEW GENERATOR *vs.* THE TIME OF THE ELECTROLYSIS

No.	Time of electrolysis to start of measurement Hrs.	Min.	Time interval between measurements Hrs.	Min.	Temp. of the electrolyte, °C.	Current eff., %

F-2	23	20	257	99.0	0.22	0.38	.40

The procedure for drying the charge with fluorine was introduced just before making run D-1, and the resulting improvement is clearly obvious.

Summary

1. A generator suitable for producing pure fluorine has been described. It consists of a heavy nickel U-tube, tightly closed to the air, and proved to be very efficient.

2. A novel apparatus for the quantitative determination of fluorine by absorption in metallic mercury has been designed. This has made possible a precise estimation of the constituents of the gas produced by the new generator.

3. A detailed procedure for the preparation of fluorine of known purity has been described for the first time. The product was found to contain 94–99% of the halogen.

Interatomic Distances in Orpiment, Realgar, Sodium Sulfantimonate Enneahydrate, and Calcium Mercuric Bromide[1]

BY WILLIAM V. MEDLIN

The method of direct determination of radial distribution of atoms from x-ray photographs was first used by Debye and Menke,[2] who applied it to mercury as an example of a monatomic liquid substance. It was extended by Gingrich and Warren[3] to solid substances, both crystalline and amorphous. In this field it has been found to be quite useful in determining distances between heavy atoms as a preliminary step in the determination of crystal structures, and in studying the bonding between atoms without determining complete structures. With the latter purpose in view I have applied the method to orpiment, realgar, sodium sulfantimonate enneahydrate, and calcium mercuric bromide. In all cases an approximate form of the method was used, in which visual estimates of the intensities of the lines of the powder photograph replaced the absolute intensities required by the formula, thus making impossible a quantitative measurement of the scattering power of the atoms concerned. The distances obtained by the rough treatment, however, are quite reliable, as shown by the fact that reasonable changes in the estimates of the intensities do not alter appreciably the positions of the peaks in the resulting distribution curves.

The method of treatment was the same as that used with diphenyliodonium iodide in a previous work.[4] The samples were all mounted with collodion on the outside of fine tubes of low absorbing glass; the radiation used was the Kα line of copper, obtained by passing copper radiation through nickel. The estimated intensities of the lines on the resulting photographs were multiplied by a small arbitrary factor, $e^{-B\sin^2\theta}$ and used directly as I_i in the formula

$$4\pi r^2\rho(r) = 4\pi r^2\rho_0 + \frac{2r}{\pi}\sum_{i=1}^{\infty} s_i I_i \sin s_i r$$

where $s = (4\pi \sin \theta)/\lambda$ and θ is one-half the angle of scattering. ρ_0 is a constant proportional to the number of scattering electrons per unit volume; its value is not known if absolute values of the intensities are unknown. The curves shown in this article do not include this term.

Orpiment and Realgar

Orpiment and realgar are naturally occurring sulfides of arsenic; the stoichiometrical formula of the former is As_2S_3 and that of the latter AsS. Both are monoclinic; measurement of the layer lines on a rotation photograph of orpiment gave b = 11.41 ± 0.05 Å. The axial ratios of orpiment are $a:b:c = 0.5962:1:0.6650$ with β = 90°41′.[5] In orpiment the coördination numbers of arsenic and sulfur can be three and two, respectively, with each arsenic atom bonded to three sulfur atoms and each sulfur bonded to two arsenic atoms. If the same coördination numbers are to prevail in realgar there must be As–As bonds, with each arsenic atom bonded to another arsenic and two sulfur atoms. The normal As–As distance is 2.42 Å., and the As–S distance should be 2.25 Å., from the corresponding covalent radii.[6] We may expect that application of the radial distribution method will disclose those bonds that exist.

Powder photographs of the two substances are quite different in arrangement of their lines; their similarity lies in the fact that the strongest lines of both patterns occur at approximately the same scattering angles. We see from Fig. 1, calculated with the use of 45 and 74 powder lines, respectively, that the resulting radial distribution curves are alike in the interesting region with r less than 5.5 Å. In the case of orpiment the first small peak occurs at r = 2.24 Å., the second peak at 3.46 Å., and a third at 4.39 Å. In the curve for realgar the first peak is at 2.16 Å., the second at 3.54 Å., and the third at 4.52 Å. Only the first peak in each case may be attributed to two atoms that are bonded together; the position of the peaks is correct for the As–S separation. In realgar a peak representing the As–As bond should be one-half as important as the As–S peak, since there must be four As–S bonds for each As–As bond, and the atomic number of arsenic is approximately twice that of sulfur. Hence if there

are As–As bonds at 2.4 Å. we might observe that a separate peak exists to represent it or that a single peak occurs at a value of r somewhere between the As–S and As–As separations, and closer to the former. Actually the observed peak is at a slightly smaller value of r than expected.[7]

If in orpiment we assume coördination numbers of three and two, respectively, for arsenic and sulfur we must attribute the first peak to the As–S bond and the second peak to unbonded As–As interaction with the x-ray beam. On this basis we can calculate for the bond angle for sulfur the value 97°14′. The third peak represents a distance more than twice that between sulfur and arsenic, and thus it cannot represent the nearest S–S distance. This distance must then be approximately 3.4 Å. and the arsenic bond angle approximately that of sulfur. The comparatively low scattering power of sulfur makes measurement of the S–S distance much less reliable and increases the reliability of the As–As distance obtained. A similar calculation for realgar gives the value 102°32′ for a bond angle, perhaps the average for sulfur and arsenic.

Sodium Sulfantimonate Enneahydrate (Schlippe's Salt)

Sodium sulfantimonate enneahydrate, $Na_3SbS_4 \cdot 9H_2O$, was treated by this method, using 86 powder lines, with the result shown in Fig. 1. The first peak occurs at 2.26 Å., and must be attributed to the Sb–S interaction as being by far the most important at this small distance. The second peak is found at r = 4.31 Å.; this is presumably an average S–S distance, with perhaps other distances involving atoms of smaller atomic numbers also contributing, unresolved from the main peak. It is interesting to note the simplicity of the radial distribution curve for a substance consisting of many light atoms; we see that resolution of distances involving these atoms is quite poor. In order to resolve distances in such cases it would be necessary to use accurate intensities to much larger values of (sin Θ)/λ.

The Sb–S distance found for this substance is appreciably smaller than the sum of the normal covalent radii for sulfur and antimony, 2.40 Å. It was suggested in a similar observation by Brockway and Wall[8] on stannic chloride and similar compounds that differences in residual charge on the atoms act in shortening the bonds between them, and that double bonded structures may be contributing to some extent to the normal state of the molecule. Both suggestions are valid in this case.

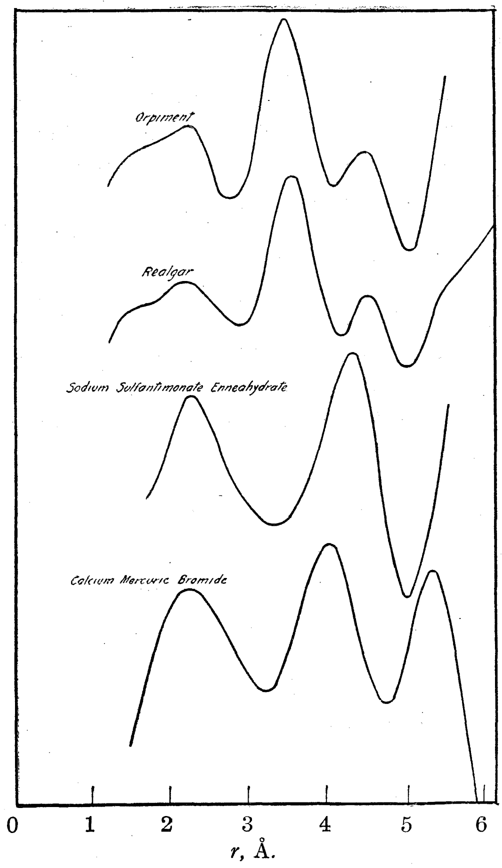

Fig. 1.

Calcium Mercuric Bromide[9]

Figure 1 also shows the density distribution curve obtained for calcium mercuric bromide, $CaHgBr_4$, with the use of 61 powder lines. The three peaks shown occur at 2.24 Å., 4.01 Å. and 5.35 Å. The first peak is rather broad, indicating that several rather widely differing unresolved distances are contributing. It is likely, then, that the value 2.24 Å. does not represent accurately a single Hg–Br distance, but that there are several such distances existing in the crystal. If there are $HgBr_4$ tetrahedra and the position of the second peak is taken to represent the Br–Br distance, the Hg–Br distance is calculated to be 2.47

(7) M. J. Buerger, *Am. Mineral.*, **20**, 36 (1935) reports a_0 = 9.27 Å., b_0 = 13.50 Å., c_0 = 6.56 Å., β = 73° 22.7′, 16 AsS, space group $C_{2h} - P_2/n$ for realgar.

(8) Brockway and Wall, THIS JOURNAL, **56**, 2373 (1934).

(9) It was shown in 1922 by Professors R. G. Dickinson and L. Pauling that the face-centered cubic unit of structure of this crystal has a_0 = 19.14 Å. and contains 32 $CaHgBr_4$ (unpublished investigation).

Å. If on the other hand the structure is built upon bromide ions in contact, the Br^-–Br^- distance would be expected to be approximately 3.90 Å., the diameter of the bromide ion,[10] agreeing with the observed position of the second peak.

Conclusion

Application of the rough radial distribution method of these four substances shows in a general way to what extent the method may be relied upon. The results seem to be accurate when there is only one distance involving large atoms near a given value; otherwise resolution is poor. In a large number of cases in which the structure is not known it is impossible to state whether or not this condition is being fulfilled. The use of reflections at large values of $(\sin \Theta)/\lambda$ gives increased resolutions; with intense photographs and accurate estimates of intensities of the weak lines being reflected at large angles one could use these important lines to much greater advantage. It is a particularly useful method when applied to large molecules containing a comparatively small number of heavy atoms.

I wish to express my gratitude to Professor Linus Pauling for his valuable coöperation, and to Dr. Sidney Weinbaum for his assistance in preparing the curves for presentation.

Summary

The radial distribution method has been applied to orpiment, realgar, sodium sulfantimonate enneahydrate and calcium mercuric bromide. The environment about the atoms in realgar is shown to be remarkably like that in orpiment, and in both cases the distance between arsenic and sulfur atoms agrees within experimental error with the sum of the corresponding covalent radii. A value for the sulfur bond angle is given, and the *b*-axis of the unit cell of orpiment was measured. The sulfur–antimony distance in sodium sulfantimonate enneahydrate was found to be definitely less than the sum of the covalent radii. Application of the method to calcium mercuric bromide led to indefinite results, consistent either with a closest packing of bromide ions, or with a structure consisting of tetrahedral covalent $HgBr_4$ groups.

Improvements in Technique for the Determination of Microgram Quantities of Iodine

BY R. H. HAMILTON, JR.[1]

Because a small amount of iodine has to be extracted from a large mass of other salts before determination, and because extraction with alcohol, as advocated by von Fellenberg,[2] requires the iodine to be in the form of iodide, it is necessary to reduce iodates that may be present. Such reduction has been done in the past with sulfites in acid solution. Acidification increases the amount of salts present, and thus increases the difficulty of extraction, because the salt mixture must again be made alkaline before extraction with alcohol.

Harvey[3] used hydrazine sulfate to reduce iodate when purifying potassium hydroxide solutions. He did not show how nearly quantitative such reduction was. In the present investigation hydrazine sulfate was found to give quantitative reduction. Hydrazine hydrate was later tried and found to have the same action. It should be preferable to the sulfate, as the excess is completely volatile when hydrate is used, whereas added sulfate ions remain as potassium sulfate. When an excess of hydrazine sulfate or hydrate has been added, a small drop of carbonate solution produces a dark spot when placed upon paper dipped in a 5% mercuric chloride solution and dried.

The salt mixture from which iodide is to be extracted usually contains much potassium carbonate, since von Fellenberg advocated the use of this substance.[2] The usual practice has been to evaporate the solution until a solid phase of carbonate appeared. Then the two-phase system was extracted by rubbing with alcohol, which formed a third phase. Occlusion of iodide by crystals becomes marked if there is no aqueous phase present. This fact suggested the use of a two-phase system consisting of saturated potas-

[3] C. O. Harvey, *Analyst*, **59**, 479 (1934).

sium carbonate solution and 92% by volume alcohol, without the presence of any solid carbonate. Experiments showed that extraction under these conditions could be made quantitative.

It was noted that when potassium carbonate solutions were boiled for some time in porcelain dishes, silicates dissolved and hindered quantitative extraction of iodides.

Incidentally, it was also noted that sodium fluoride exerted a definite and marked inhibiting action on the re-oxidation of iodide which ordinarily occurs within a few minutes to a few hours if the titration flask is allowed to stand after the end-point is reached. This observation is of theoretical interest, but it will probably not find application in titration methods, as re-oxidation is not a serious factor when they are properly carried out.

Experimental

In all cases, the method of determination of iodine present, after separation from salt masses, was that described by Reith.[4] In no case did the amount of iodide ion in the aliquot taken for analysis exceed 5 micrograms.

Quantitative Reduction of Iodate in Alkaline Solution by Means of Hydrazine Sulfate.—To 2 cc. of saturated potassium carbonate solution (expt. A, Table I) was added 50 micrograms of iodine as potassium iodate, in 5 cc. of water. The solution was boiled for thirty minutes, water being added to maintain the volume, and was then evaporated to dryness, moistened, and extracted by trituration with 94% alcohol, three 5-cc. portions of alcohol being used.

TABLE I

REDUCTION OF IODATE BY HYDRAZINE SULFATE

Expt.	Satd. K_2CO_3, cc.	Iodine as iodate, γ	Hydrazine sulfate, mg.	Time of boiling before starting evaporation, min.	Total iodine extracted, γ
A	2	50	..	30	1.6
B	2	50	10	30	48.8
C	2	50	10	30	50.5
D	2	1	10	30	1.16
E	2	50	10	..	49.1
F	2	1	10	..	1.04

In expts. B, C and D, a similar procedure was followed, except that each time 10 mg. of hydrazine sulfate was added before the carbonate–iodate solution was boiled for thirty minutes. In expts. E and F, the thirty-minute boiling period was omitted, and extraction was carried out as described below.

Two-phase Extraction of Iodide from Potassium Carbonate Solution.—In expts. E to J, inclusive, a glass-stoppered test-tube was used for the extraction. In expts. G and H, the tube, containing iodide, saturated carbonate solution, and 92% (by volume) alcohol, was stoppered and shaken vigorously 200 times, and laid on its side until the emulsion settled out.

TABLE II

TWO-PHASE EXTRACTION OF IODIDE

			3	10	18.6		..	47.8

[a] See text.

Separation of the layers was effected by means of a pipet shaped like, and about the dimensions of, a 10-cc. graduated pipet. The tubing at the top of the pipet should have a small lumen (about 2 mm.), to prevent alcohol from wetting the finger upon inversion, and should be 5 or 6 cm. long. The pipet was wet inside with alcohol before use; otherwise the additional partial pressure of alcohol vapor would cause some of the contents to be spilled upon inversion. The alcoholic layer was sucked up into the pipet along with some of the aqueous layer. The latter was allowed to run back into the extraction tube, and the pipet was inverted, the alcoholic contents being allowed to run into an evaporating dish through the top of the pipet. By this procedure, admixture of aqueous phase was avoided. A second extraction was made similarly, without rinsing of the pipet between extractions of the same sample.

In expt. I, 1 cc. of carbonate solution was used, and the two extracts were analyzed together.

A test of this method of extraction was made when other ions than carbonate were present (expt. J). In a platinum dish were placed, in solution, 100 mg. each of potassium nitrate, potassium sulfate and potassium chloride, 50 micrograms of iodine as potassium iodide, and 2 cc. of saturated potassium carbonate, containing about 1.46 g. of the anhydrous salt. The solution was heated gently on an asbestos-covered wire gauze until crepitation ceased, and the salt mixture was transferred mechanically to a glass-stoppered test-tube. The platinum dish was rinsed several times with water, the rinsings being added to the test-tube until the volume of salt solution was slightly over 2 cc. This material was extracted as above with alcohol. Two more extractions were made, no iodine being found in the third extract.

Discussion

After hydrazine sulfate or hydrate is added to the carbonate solution, the latter should be evaporated to dryness over a low flame in order to drive off excess hydrazine, which will otherwise reduce bromine at a later step.

The proposed method of extraction is not usable unless the salt mass is mostly potassium carbonate, as so much water is required to dissolve other salts that the alcohol used is diluted, and interfering ions will be extracted by the dilute alcohol. As

---

[4] J. F. Reith, *Biochem. Z.*, **216**, 249 (1929).

will be noted in Table II, the salt extracted by alcohol when carbonate alone is present amounts to only 0.6 to 0.7 mg. per cc. of alcohol. After careful trituration of crystals of potassium carbonate and saturated solution with 94% alcohol, the amount of carbonate extracted was found, as an average of nine determinations, to be about 1.09 mg. per cc. of alcohol.

Much of this work was done in the Rijksinstituut voor de Volksgezondheid, Utrecht, Holland. The author's sincere thanks are due Dr. J. F. Reith, Head of the Chemical Division there, who demonstrated his methods, and offered valuable suggestions and criticisms.

Summary

1. Iodate can be quantitatively reduced in hot alkaline solution by means of hydrazine sulfate.

2. Efficient extraction of iodide can be made with alcohol from a saturated solution of potassium carbonate, without danger of occlusion by crystals.

3. Alkaline solutions containing iodide should not be boiled in porcelain dishes before extraction of the iodide.

4. Fluoride delays the re-oxidation of iodide which takes place after a titrimetric determination of iodine.

The Reduction of Aromatic Compounds with Hydrogen and a Platinum Oxide–Platinum Black Catalyst in the Presence of Halogen Acid

BY J. H. BROWN, H. W. DURAND AND C. S. MARVEL

While reducing hot alcoholic solutions of some bromophenylolefins to the corresponding paraffins by hydrogen in the presence of Adams, Voorhees and Shriner's platinum catalyst,[1] we observed that in some runs more than the expected amount of hydrogen was absorbed, and hydrogen bromide was formed. Further investigation showed that this reaction involved not only removal of bromine from the benzene ring, but also reduction of the benzene ring to a hexahydro derivative. Since Adams and Marshall[2] have found that, in general, aromatic compounds are very slowly reduced in alcohol and only with moderate rapidity in glacial acetic acid, with platinum oxide–platinum black as a catalyst, it has seemed worth while to investigate our chance observation in greater detail.

When bromobenzene was dissolved in alcohol at about 55° and shaken with the catalyst in the presence of hydrogen, rapid absorption of hydrogen occurred, and cyclohexane was formed. By interrupting the reduction when one equivalent of hydrogen per molecule of bromobenzene had been absorbed, the product obtained was an impure sample of benzene, but the reaction did not seem to offer a satisfactory scheme for removal of halogen from a benzene derivative. Other aryl halides, such as *o*-, *m*- and *p*-bromotoluene, *p*-dibromobenzene, chlorobenzene and *p*-dichlorobenzene, were also readily reduced to halogen acid and the cyclohexane derivative. However, not all aryl halides could be reduced readily, as shown by the fact that iodobenzene, *o*-bromobenzoic acid, α-chloronaphthalene and α-bromonaphthalene were not affected in our experiments.

Since the reduction of an aryl halide apparently was taking place in two steps—first, removal of halogen acid, and then reduction of the ring—and more rapidly than the usual reduction of the ring alone, it seemed probable that the liberated halogen acid must be an activator for the platinum catalyst for reduction of aromatic compounds. This was verified by reducing various aromatic compounds in alcoholic solution in the presence of various concentrations of hydrogen chloride and bromide. Some of the first reductions were carried out after preheating the solutions to 50–70°, but later it was found that this was not necessary, as reduction took place rapidly, and the temperature of the mixture soon rose to this point without outside heating. Benzene, toluene, xylene, mesitylene, ethylbenzene, cymene, diphenyl and anthracene were readily reduced, whereas naphthalene and phenanthrene were not affected. There seemed to be no choice between hydrogen chloride and hydrogen bromide as an activator.

When functional groups are present in the aro-

TABLE I

REDUCTION OF ARYL HALIDES

Compound reduced	Mols of H_2 absorbed[a]	Time, min.	Halogen acid formed, mols	Product of reduction
Bromobenzene	0.185	240	0.0486	Cyclohexane d^{20}_4 0.7767 n^{20}_D 1.4274
Bromobenzene	.06	14	.0422	Benzene
o-Bromotoluene	.17	135	.0479	Methylcyclohexane d^{20}_4 0.7689 n^{20}_D 1.4227
m-Bromotoluene	.2	240	.047	Methylcyclohexane n^{20}_D 1.4362
p-Bromotoluene	.14	300	.044	Methylcyclohexane n^{20}_D 1.4357
p-Dibromobenzene	.22	210	.085	Cyclohexane n^{20}_D 1.4261
Chlorobenzene	.2	210	.049	Cyclohexane n^{20}_D 1.4255
p-Dichlorobenzene	.21	300	.073	[b] Cyclohexane n^{20}_D 1.4282

[a] Calculated roughly from drop in pressure during reduction. [b] Some *p*-dichlorobenzene remained at the end of this run.

matic molecule, there is very little regularity in the effect of halogen acid on the ease of reduction. Phenol and ethyl benzoate were reduced more rapidly in the presence of halogen acid than in its absence. Benzaldehyde and benzoic acid were no more readily reduced in the presence of halogen acid. Anisole, in the presence of halogen acid, gave cyclohexane. It is of interest that, while naphthalene and its α-chloro and α-bromo derivatives were unaffected, α- and β-naphthol both reduced readily in the presence of hydrogen chloride to give the corresponding tetrahydronaphthols. This is the normal course of reduction for α-naphthol, but in the case of β-naphthol sodium and amyl alcohol reduction gives mainly the alcohol[3] and very little phenol.

Adams and Marshall[2] pointed out that alcohol is usually the best solvent for reductions making use of this platinum catalyst, although for aromatic hydrocarbons they had better results with acetic acid. When the catalyst is activated with halogen acid, alcohol again becomes the better solvent, although the activity of the catalyst in acetic acid is slightly improved by hydrogen chloride.

Hamilton and Adams[4] have shown that pyridine derivatives reduce much more readily if they are first converted to the halogen acid salt. This may be due to the same sort of activation of the catalyst which has been observed with hydrocarbons of the benzene series. Zelinsky, Packendorff and Packendorff[5] have reported that ketones can be reduced to the corresponding hydrocarbons over a catalyst of platinized charcoal, provided a little palladium chloride is added to raise the activity of the catalyst. Later Packendorff[6] showed that reduction of chloroplatinic acid in the presence of platinized charcoal gave a catalyst which was effective for the reduction of a carbonyl group to a methylene group. This probably was an activating effect of halogen acid similar to that which we have observed.

Experimental Part

Reduction of Aryl Halides.—A solution of 0.05 mole of the aryl halide in exactly 100 cc. of ethyl alcohol was placed in a reduction outfit[7] and warmed to 55°. To the warm mixture 0.1 g. of platinum oxide catalyst[1] was added and the mixture was reduced under a hydrogen pressure of about 3 atmospheres. The drop in pressure was noted from time to time in order to know when reduction was complete. When no more hydrogen was absorbed, the reaction mixture was removed from the outfit and an aliquot portion of the solution was titrated to show the amount of halogen acid produced. The reaction mixture was then diluted, and the reduction

TABLE II

EFFECT OF HALOGEN ACID ON CATALYTIC REDUCTION OF BENZENE

Halogen acid used	Time for complete reduction, min.	Pressure drop[a]
None	70	None
1 drop alcoholic HCl[b]	49	6.9
0.2 cc. alcoholic HCl	29	7.3
1.0 cc. alcoholic HCl	31	7.0
5.0 cc. alcoholic HCl	30	7.3
6.0 cc. alcoholic HCl	23[c]	7.3
1 drop alcoholic HBr[d]	36	7.4
0.5 cc. alcoholic HBr	34	7.1
5.0 cc. alcoholic HBr	79	5.9
0.02 g. I_2	720	None
0.2 cc. alcoholic HCl[e]	39	7.6

[a] The theoretical absorption of hydrogen should cause a drop in the pressure of 7.1–7.2 lb. [b] This solution was prepared by saturating 95% ethyl alcohol with dry hydrogen chloride at room temperature. [c] In this experiment 0.25 g. of catalyst was used. [d] This solution was prepared by saturating 95% ethyl alcohol with dry hydrogen bromide at room temperature. [e] The solution was not preheated in this reduction.

[a] No halogen acid has added to this run. [b] This material contained a little ethylbenzene.

product isolated in the usual manner. The results of some of the experiments are summarized in Table I.

Under the same experimental conditions iodobenzene, α-bromonaphthalene, α-chloronaphthalene and *o*-bromobenzoic acid were not affected.

Reduction of Benzene.—A series of experiments, using 5 cc. of freshly distilled, thiophene-free benzene in 100 cc. of 95% ethyl alcohol at 70° with 0.125 g. of platinum oxide catalyst, different amounts of hydrogen chloride and bromide and a hydrogen pressure of about three atmospheres, gave the results shown in Table II.

From these results, it is evident that both hydrogen chloride and hydrogen bromide activate the platinum oxide catalyst for the reduction of benzene. With hydrogen chloride, any amount beyond a trace seems to have little effect. Too much hydrogen bromide seems to be undesirable. Iodine is not an activator for the catalyst. No attempt was made to isolate the product of reduction in these runs.

To test the effect of halogen acid on the catalyst in acetic acid solution, two reductions were carried out, using 5 cc. of benzene, 0.1 g. of platinum oxide and 50 cc. of glacial acetic acid. To one of these batches, 0.5 cc. of alcoholic hydrogen chloride was added. The run without hydrogen chloride was complete in seventy minutes, whereas the run with it was complete in fifty-four minutes.

Reduction of Aromatic Hydrocarbons.—The standard reduction experiment was carried out by dissolving the aromatic hydrocarbon in 100 cc. of alcohol at 70°, using 0.1 g. of platinum oxide catalyst and 45 pounds (3 atm.) of hydrogen pressure. The halogen acid used to activate the catalyst was varied. The reduction products were isolated and identified, although little effort was made to determine exact yields. The results of some of our experiments are collected in Table III.

No evidence of reduction of either naphthalene or phenanthracene could be obtained using the general conditions outlined above, although various amounts of aqueous and alcoholic hydrogen chloride and bromide were added as activators for the platinum catalyst.

Reduction of Some Aromatic Derivatives.—Attempts were made to reduce some phenols, aromatic ethers, acids, esters, aldehydes and ketones, using the platinum oxide catalyst and halogen acids. Some of these derivatives reduced readily, and some not at all. The standard procedure was to use about 0.1 mole of compound, 100 cc. of alcohol, 0.1 g. of catalyst and 0.5 cc. of alcoholic hydrogen chloride at 70° under 3 atmospheres of hydrogen. The results are summarized in Table IV.

Benzaldehyde and benzoic acid were not reduced under the same conditions.

Summary

Small amounts of hydrogen chloride and hydrogen bromide increase the effectiveness of platinum oxide–platinum black as a catalyst for the hydrogenation of most aromatic rings.

Molecular Rotation in Solid Aliphatic Alcohols

BY C. P. SMYTH AND S. A. MCNEIGHT

A previous investigation has given indications of the occurrence of dipole rotation in solid methyl alcohol.[1] This paper presents the results of measurements of the dielectric constants of methyl, tertiary butyl and *n*-octyl alcohols from liquid air temperatures to the melting points. The apparatus and technique employed were essentially the same as that described in earlier papers from this Laboratory,[2] the same bridge being used.

Purification

Methyl Alcohol.—C. P. synthetic methyl alcohol was refluxed over lime for several hours and fractionally distilled. The middle fraction was then fractionally distilled from shiny magnesium ribbon, b. p. 64.74 ± 0.05°.

Tertiary Butyl Alcohol.—An Eastman Kodak Co. product was washed with a saturated solution of sodium bisulfite, the alcoholic layer decanted and refluxed for several hours with 10% sodium hydroxide solution. The alcohol was distilled off and dried with sodium sulfate and potassium carbonate and then refluxed over lime for several hours before distilling. The lime treatment was repeated, after which the distillate stood over calcium turnings for two days before distilling. The final fractional distillation was made from tartaric acid; b. p. 82.3°. The distillate was then recrystallized from its own melt four times; m. p. 24.8°.

Octanol-1.—The material was part of a sample employed in a previous determination of dipole moment.[3]

Experimental Results

The dielectric constants ϵ and the specific conductances k (ohm^{-1} cm.^{-1}) are given in Table I, the absolute temperatures being given in the first column and the frequencies in kilocycles across the top of each group of data. Many determinations at intermediate temperatures and frequencies are omitted for the sake of brevity. Unless otherwise indicated, the values were obtained with rising temperature. The values for methyl alcohol could not be extended to higher temperatures because increasing conductance made the bridge measurements too inaccurate.

Discussion of Results

The melting point found for methyl alcohol, 175.4°K., is sharp and is in very good agreement with the value 175.3°K. given in "International Critical Tables" but indicates a less pure sample

than that for which Timmermans and Hennaut-Roland[4] report 176.1°K. It is to be regretted that the difficulty of purification has prevented the removal of the last traces of impurity, which have some effect upon the results in the neighborhood of the melting point. The dielectric constant curve in Fig. 1 for a frequency of 5 kilocycles shows a transition at 159.9°K. with a sharp rise in value with rising temperature. The transition is somewhat obscured by anomalous dispersion both below and above it but for high frequencies the change in the value of the dielectric constant is quite sharp and a time–temperature curve shows a halt at 159.9°K. for a period of between thirty and forty minutes for rising temperature. The apparent conductance at 5 kc. also shows a maximum at this temperature. This is 0.8° higher than that previously reported but differs by only 0.1° from the transition temperature found for another sample and lies between the values found from specific heat measurements, 157.4°K. by Kelley[5] and 161.1°K. by Parks.[6] Falling temperature gives a very much delayed transition, for with decreasing temperature the high temperature form has been observed as far down as 133°K., whereas with rising temperature a lag of more than 0.1° has never been detected.

The solid, in spite of every effort to purify it, contains a small amount of impurity, presumably water, as shown by the slightly low melting point and the slight premelting indicated by a time–temperature curve taken over the melting range. As the eutectic point of the methyl alcohol–water system is about 134°K.,[7] a minute trace of liquid would remain down to this temperature, which is just about where the cooling dielectric constant curve dips downward toward the rising temperature curve. This apparent hysteresis loop, which, unfortunately, was not completed experimentally, is not unlike that found for phenol containing a trace of water. It may arise from the presence of a minute quantity of liquid, which would raise the dielectric constant, or it may be due merely to an unusually large lag in the transition, supercooling undoubtedly occurring. Probably, both factors contribute to the seeming discrepancies and the changes of dielectric constant and conductance with time observed here and in the earlier work. The considerable variation of the dielectric constant and the conductance with frequency is doubtless contributed to by the liquid, but the uniform rise of dielectric constant with temperature below and above the eutectic point of the methyl alcohol–water system, the difference between it and the much lower values, almost constant in this region, found for *t*-butyl and octyl alcohols, and the sharp rise at the transition followed by a further rapid increase as the temperature rises toward the melting point indicate a very small amount of rotation at low temperature, increasing with temperature and rising sharply at the transition, which loosens the structure. Even above the transition, rotation encounters a resistance which diminishes with rising temperature and causes the dielectric constant to be higher at lower frequencies. The approxi-

mate value calculated for the polarization at 108.4°K. is 13.8 as compared to a molecular refraction 8.23 for the D sodium line while at 173.8° it is 27.4, values indicative of rotation, as the difference 5.6 between the polarization at the low temperature and the refraction seems too high to arise entirely from the atomic polarization of so small a molecule.

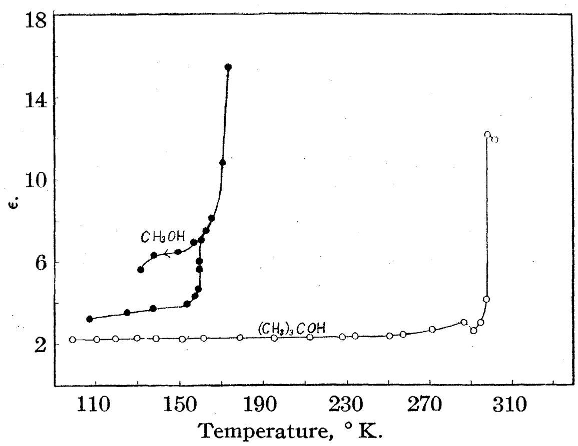

Fig. 1.—Variation with temperature of the dielectric constants (5 kc.) of methyl and *t*-butyl alcohol.

The dielectric constant of solid *t*-butyl alcohol at 5 kc. (Fig. 1) is as low as that of liquid benzene and other non-polar substances, showing the absence of any freedom of the dipole in the molecule to rotate. The small rise in the dielectric constant and the considerable rise in the conductance as the melting point is approached is the normally observed behavior, and is, presumably, due to the presence of traces of impurities which cause very small quantities of liquid to form in this region of temperature. The small break in the curve at 287.9°K. is the effect of twenty-four hours' standing between measurements, which is apt to cause a setting of the structure and reduction of molecular freedom. The increase of dielectric constant with decrease in frequency is reduced by this setting and the apparent conductance is cut in half. In the case of *n*-octyl alcohol, the resolidified sample gave a slightly lower dielectric constant depending less on frequency and a lower conductance except at the first temperature measured after solidification. The dielectric behavior of *n*-octyl alcohol (Fig. 2) is practically identical with that of *t*-butyl, the curves being hardly distinguishable at the lower temperatures. A slight rise with some dependence upon frequency develops near the melting point, probably due mainly to the presence of minute quantities of liquid, but possibly due in part to an occasional molecular rotation with loosening of the structure just below the melting point. In general, however, there is obviously no appreciable amount of rotation of the molecule as a whole or of the hydroxyl group in the molecule in either of these two alcohols in the solid state.

Dielectric constant measurements on phenol[2] and specific heat measurements on many alcohols have failed to show rotation. It is evident, therefore, that the rotation in solid methyl alcohol must be a rotation of the entire molecule rather than of the hydroxyl group within the molecule, since the latter could occur equally well in the other alcohols. As rotation of the methyl alcohol molecule around its C–O axis should involve little change in the space occupied by the molecule, such rotation would probably not be blocked by the surrounding molecules. The main hindrance would be the strong intermolecular attraction probably expressing itself in the formation of a hydrogen bond between molecules such as seems to exist in ice.[8] The opportunity for such bond formation is not as good as in ice and, even in ice, the dielectric constant gives evidence of some molecular rotation. The anomalous dispersion in ice is much stronger than in solid methyl alcohol, probably because of the stronger internal field of the crystal. Because of the presence of the methyl group in the molecule, the freezing point of methyl alcohol is much lower than that of water and molecular rotation can occur in the solid at a low temperature with higher frequencies than in ice.

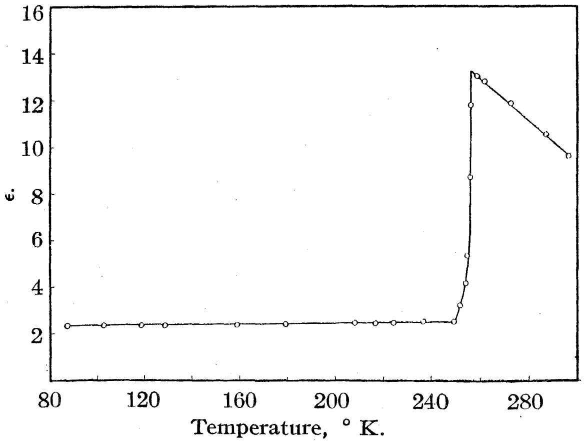

Fig. 2.—Variation with temperature of the dielectric constant (5 kc.) of octanol-1.

---

(8) Pauling, THIS JOURNAL, **57**, 268 (1935).

Although the molecule of *t*-butyl alcohol is not very far from spherical in shape, reasonably close packing of the molecules, such as would naturally occur in the crystal lattice, would probably cause the rotation of a molecule to be blocked by its neighbors. In the crystal of *n*-octyl alcohol, the molecules probably lie as extended zig-zag chains parallel to one another. As many cases are known in which carbon chains parallel to one another in a solid rotate about their long axes,[9] there would seem to be a possibility of rotation of this type here, which is evidently not realized. Bernal has found by x-ray analysis[10] that *n*-dodecyl alcohol shows a transition from a monoclinic to a hexagonal crystal at 289°K. with molecular rotation setting in around the axis of the carbon-chain. It is probable that the higher temperature attainable before melting gives the energy necessary to overcome the resistance to rotation, lacking in the *n*-octyl alcohol, which melted 32° below this transition temperature.

Summary

The dielectric constants of solid methyl, *t*-butyl and *n*-octyl alcohols have been measured from liquid air temperatures up to the melting point in order to investigate the question of dipole rotation in the solid state. The high dielectric constant of methyl alcohol just below the melting point, dropping to a low value at a transition temperature 159.9°K., gives evidence of dipole rotation in this region. The absence of dipole rotation in solid *t*-butyl and *n*-octyl alcohols and the failure of specific heat measurements to show transitions in many other alcohols, indicate that the hydroxyl group does not rotate inside the molecule, but that the entire methyl alcohol molecule rotates above the transition point.

The Magnetic Rotation of Lanthanum and Neodymium Chlorides in Aqueous Solution

BY CHARLES M. MASON, ROGER D. GRAY AND GRACE L. ERNST

The magnetic rotation of the plane of polarized light is particularly interesting in the case of the rare earths. The chemical properties of these substances in aqueous solutions are so nearly identical that it is only by physical measurements of this type that any differentiation of properties can be made.

In this work the Verdet constants of aqueous solutions of lanthanum and neodymium chlorides have been measured over a temperature interval of from 10 to 50°. The concentration of the solutions was varied from zero (water) to 3.7 molal for the lanthanum chloride and 0.5 molal for the neodymium chloride. For comparison the Verdet constants were determined for aluminum chloride solutions from zero to 2.8 molal over the same temperature range.

Experimental Details

The rotations were measured with a Franz Schmidt and Haensch Model 55 "Landolt" half shade polarimeter, which could be read to hundredths of a degree.

The two light sources used were a mercury "Lab-Arc" with Corning filters G-555-Q and G-35-Y to transmit λ 5460.7 Å. and a sodium "Lab-Arc." This latter was used without filters since the accuracy attained in setting the polarimeter without any filters more than offset any error due to wave lengths other than the principal doublet λ 5893 Å.

The solution, the rotation of which was to be measured, was placed in a water-jacketed cell of Pyrex glass. This was equipped with optical windows of the same, fused on to the ends. The cell, which is shown in Fig. 1, was provided with an entrance through which a calibrated thermometer could be placed in the solution while the rotation was measured.

The magnetic field was provided by a coil of fourteen layers of No. 20 B. and S. cotton and enamel covered copper wire. The total number of turns was 2,059 and the length of the coil was 23.57 cm. The inside diameter was 2.84 cm. and the outside diameter 6.70 cm. The length of the light path through the solution was 21.74 cm. From these data the field strength, *H*, of the coil at any point along the axis is easily calculated. The product of the effective field strength times the length of the light path in the cell was determined by integration. The value of this integral was found to be 2218.2 gauss-cm. per ampere of current through the coil. This value, when used to calculate the Verdet constants for water and carbon bisulfide, checked the standard values[1] within 0.5%. This is a good check when we consider the irregularities of the coil winding as shown by an examination of Fig. 1.

---

[1] "International Critical Tables," McGraw-Hill Book Co., Inc., New York, Vol. VI, 1926, p. 425.

A current of 4.000 ± 0.001 amperes was used, supplied from storage batteries. Current regulation was obtained by the use of a manually operated potential divider similar to that described by MacInnes and Longsworth.[2]

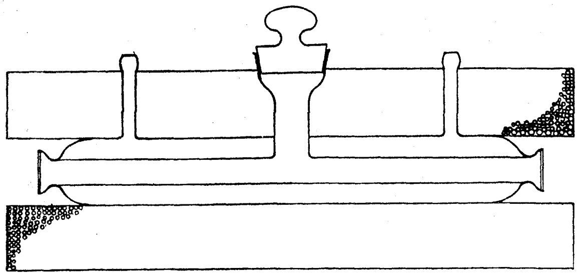

Fig. 1.—Magnetic rotation cell.

In order that the current adjustment might be made accurately, a Leeds and Northrup student type potentiometer was used to measure the potential drop across a standard 0.10 ohm resistance in series with the coil. The potential divider was operated during a reading of the rotation so that the galvanometer connected in the potentiometer circuit showed no deflection while the observation was made.

Temperature control was obtained by circulating water from a thermostat through the water jacket of the cell. The temperature could be controlled to within ±0.05° of any chosen point.

The rare earth salts had been carefully prepared by repeated recrystallization. The chlorides were prepared from the oxalates by ignition to the oxides and solution of these in redistilled hydrochloric acid. These chlorides were then twice recrystallized by concentration of the mother liquor and shaking out with hydrogen chloride gas. They were then dried at room temperature and placed for several weeks in a vacuum desiccator over potassium hydroxide. Examination of the solutions with the hand spectroscope and chemical test showed the absence of other rare earths.

The commercial c. p. grade of aluminum chloride hexahydrate was used without further purification. It was guaranteed by the manufacturer to be better than 99.85%. For the present investigation this slight percentage of impurity would not vitiate the result.

Concentrated aqueous solutions of these salts were prepared with conductivity water. These were analyzed gravimetrically for the chloride. The dilute solutions were then prepared from these by weight. The water used was of conductivity grade.

The c. p. grade of carbon bisulfide was purified by the method of McKelvey and Simpson.[3]

Results

The Verdet constant[4] is given by the expression

$$V = \Theta / \int H dl \qquad (1)$$

where Θ is the angle of rotation in minutes and $\int Hdl$ is the average field strength over the whole light path.

If we choose to calibrate our apparatus with some liquid whose Verdet constant is known, such as water or carbon bisulfide, we find that

$$V = \frac{\Theta}{\Theta_s} V_s \qquad (2)$$

where Θ_s and V_s are the rotation and Verdet constant of the standard liquid used and Θ and V are those for the solution under investigation. In the present work equation (2) was employed to calculate the Verdet constants obtained. Water was employed as the reference liquid in these calculations. This was done because the irregularity of the coil made exact calculation of the field strength impossible.

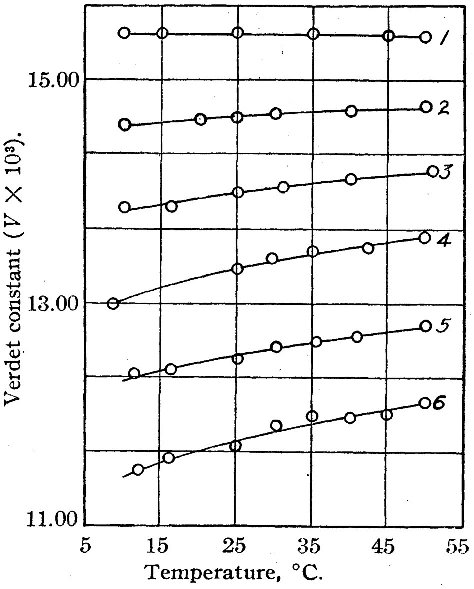

Fig. 2.—The Verdet constants of neodymium chloride solutions as a function of the temperature: 1, water; 2, 0.1 molal; 3, 0.2 molal; 4, 0.3 molal; 5, 0.4 molal; 6, 0.5 molal.

It was difficult to take readings rapidly at fixed temperature intervals due to the heating effect of the coil. The data were therefore often taken at odd temperature intervals. These data were then plotted on a large scale as shown by the plot for neodymium chloride in Fig. 2. The data taken from these plots are presented in Tables I, II and III for aluminum, lanthanum and neodymium chlorides, respectively. No data were obtained for neodymium chloride for the wave length λ 5893 Å. because of the strong absorption band in this region of the spectra.

.50	11.45	11.67	11.72	11.82	11.95	12.14

[a] All values of this constant at 25° are the mean of at least five measurements.

In order to show more clearly the relationship between the Verdet constant and the concentration, the data obtained at 25° have been plotted in Fig. 3.

Discussion

Comparison with Other Data.—The value obtained for the Verdet constant of 0.1 molal lanthanum chloride with the green line λ 5460.8 Å. at 20°, 15.73×10^{-3}, may be compared with that obtained by Roberts, Wallace and Pierce[5] for a solution of lanthanum sulfate, 0.094 molal in lanthanum ion. They obtained 15.40×10^{-3}. The maximum error of measurement in this work for the wave length λ 5460.8 Å. is about ±0.01° of arc which corresponds to a total possible error of 0.14×10^{-3} min. per gauss-cm. in the Verdet constant.

These authors do not state the error in their visual observations. If it is presumed to be of the same order of magnitude as in the present investigation the difference between the two values is within the experimental error. They do state, on the basis of one measurement of magnitude less than the probable error, that aqueous solutions of lanthanum sulfate have a negative rotation. In this investigation lanthanum chloride has consistently a positive rotation in solutions of all concentrations. This difference of sign is not significant however in view of the limits of error discussed above and the different negative ions present.

Direction of Rotation.—The theory of Serber[6] for the Faraday effect in molecules points out that the Verdet constant may be expressed by an equation of three distinct terms. Two of these terms are diamagnetic and the third is paramagnetic. For diamagnetic substances the third term drops

---

[5] Roberts, Wallace and Pierce, *Phil. Mag.*, **17**, 934 (1934).

[6] Serber, *Phys. Rev.*, [2] **41**, 489 (1932).

out and the theory predicts that the Verdet constant should be positive.

Lanthanum chloride and aluminum chloride are known to be weakly paramagnetic and diamagnetic, respectively. It would be expected therefore in both cases, since the third term in the equation mentioned above would either be insignificant or vanish, that these substances would have a positive effect on the Verdet constant.

Examination of the data in Tables I and II shows the experimental verification of these conclusions, as in both cases the Verdet constant of the solutions is increased positively by the added salt.

Neodymium chloride on the other hand is strongly paramagnetic and would be expected by Serber's theory to have a negative effect on the Verdet constant. Examination of the data in Table III shows the marked negative effect of neodymium chloride as predicted by the theory.

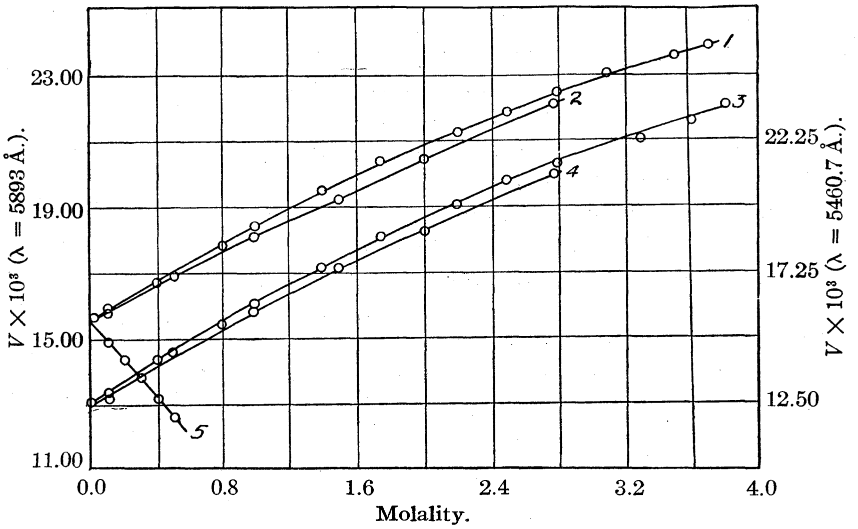

Fig. 3.—Verdet constants of the solutions as a function of concentration at 25°: 1, $LaCl_3$, λ 5460.7 Å.; 2, $AlCl_3$, λ 5460.7Å.; 3, $LaCl_3$, λ 5893 Å.; 4, $AlCl_3$, λ 5893 Å.; 5, $NdCl_3$, λ 5460.7Å.

Temperature Effect.—In the equation mentioned by Serber[6] the third or paramagnetic term contains the expression $1/T$ where T is the absolute temperature. From this the conclusion may be drawn that the Verdet constant for paramagnetic substances should vary with temperature and that diamagnetic substances should not vary with temperature. From the "International Critical Tables"[1] (p. 359) it is noted that the magnetic susceptibilities of aluminum chloride, lanthanum chloride and neodymium chloride (estimated) are in the ratios $-0.6:5.6:25$. From these the theoretical conclusions may be drawn that aqueous solutions of aluminum chloride should have no temperature coefficient, those of lanthanum chloride should have a slight temperature coefficient and neodymium chloride solutions a marked temperature coefficient. Examination of the data in Tables I, II and III shows that the conclusions are justified by the experimental results. No temperature coefficient was observed for the aluminum chloride solutions within the experimental error. A slight temperature coefficient was observed for the lanthanum chloride solutions in the higher concentrations. Neodymium chloride solutions, on the other hand, showed a marked temperature coefficient, even in dilute solutions.

It was found that the Verdet constants of the neodymium chloride solutions gave a straight line when plotted against $1/T$. From these straight lines a family of equations of the type

$$V = a/T + b \tag{3}$$

were obtained, where a and b are constants. The data for these constants for equation (3) and the maximum deviation of the calculated values from the experimental values are given in Table IV.

TABLE IV

CONSTANTS FOR THE TEMPERATURE EQUATIONS (3) FOR NEODYMIUM CHLORIDE SOLUTIONS

Molality, m	a	b	Max. dev.
0.10	− 325.0	16.94	0.04
.20	− 662.5	16.60	.04
.30	−1212.5	17.37	.03
.40	−1220.0	16.21	.03
.50	−1553.6	15.75	.02

Recently several authors[7] have shown that the Curie–Weiss law of magnetic susceptibilities may be applied to the molecular magnetic rotation. This law is usually stated

$$(T - \Delta)\chi_m = C_m \tag{4}$$

where χ_m is the gram-molecular magnetic susceptibility, T the absolute temperature, C_m a constant and Δ a constant called the Curie point.

(7) Ollivier, *Compt. rend.*, **186**, 1001 (1928); Ollivier, *ibid.*, **191**, 130 (1930); Pernet, *ibid.*, **195**, 376 (1932); Gorter, *Physik. Z.*, **34**, 238 (1933).

In order to make this application to the present data the molecular rotations for the neodymium chloride solutions have been calculated from the equation

$$D = \frac{M}{pd_s}(V - d_1 V_w/d_w) \qquad (5)$$

where D is the molecular rotation of the solution, M is the molecular weight of the neodymium chloride, d_s is its density, p is the number of grams of salt per gram of solution, d_1 is the density of the solution, d_w is the density of pure water and V and V_w are the Verdet constants of the solution and pure water, respectively. The densities of the solutions at 25° were obtained from the data of Mason and Leland.[8] The densities for the other temperatures were calculated from these on the assumption that the temperature coefficient of the density of the solutions was the same as that for pure water. The values of D obtained are listed in Table V.

TABLE V

THE MOLECULAR ROTATION OF $NdCl_3$ IN AQUEOUS SOLUTION

Molality, m	p	D at the indicated temperature 10°	20°	25°	30°	40°	50°
0.1	0.0245	3.07	2.96	2.91	2.85	2.80	2.67
.2	.0477	3.06	2.91	2.85	2.76	2.71	2.63
.3	.0699	3.15	2.97	2.87	2.81	2.72	2.62
.4	.0911	3.23	3.17	3.12	3.02	2.95	2.87
.5	.113	3.32	3.19	3.17	3.11	3.03	2.92
Ave.		3.16	3.04	2.98	2.93	2.82	2.72

There is some drift toward the higher concentrations but this may be due to slight error in the density calculation.

The average data in Table V were used to calculate the values of C and Δ in the equation

$$(T - \Delta)D = C \qquad (6)$$

which is analogous to equation (5), the Curie–Weiss law.

The value of Δ was found to be close to 32.6° which was taken as the best value. Equation (6) was tested by calculating the values of C for the several temperatures. The values of C obtained, which checked with each other within one part in a thousand, gave an average value of −790.1. This constancy of C shows that the equation

$$(T - 32.6)D = -790.1 \qquad (7)$$

is applicable to the data for neodymium chloride over the temperature range studied.

Concentration Effect.—For the wave length λ 5460.8 Å. the Verdet constants of the aluminum and neodymium chloride solutions were found to be a linear function of the concentration over the range studied. None of the other data give linear relationships, as may be seen by examination of Fig. 3.

The authors wish to express thanks to Dr. H. C. Fogg for advice regarding the purification of the rare earth salts.

Summary

The magnetic rotations of aqueous solutions of aluminum, lanthanum and neodymium chlorides have been measured from 10 to 50° at wave lengths λ 5893 and 5460.8 Å.

The Verdet constants of these solutions have been calculated and those for neodymium chloride solutions found to vary linearly with $1/T$.

The molecular rotations of the neodymium chloride solutions have been calculated and found to vary with temperature according to the equation $(T - 32.6)D = -790.1$.

The variations of the Verdet constants with temperature were found to agree qualitatively with the predictions of Serber.[6]

The Ionization Constant of Hydrazinium Hydroxide[1]

BY G. C. WARE, J. B. SPULNIK AND E. C. GILBERT

A systematic investigation of the ionization constant of hydrazinium hydroxide ("hydrazine hydrate"), its variation with temperature and with ionic strength, has never been reported. Bredig[2] measured the conductivity of aqueous solutions of hydrazine and calculated the ionization constant at 25°. He reported some difficulty due to decomposition and his values varied from 4.4 to 2.2×10^{-6} depending upon the concentration. The mean of these two, 3×10^{-6}, is the value commonly accepted and used in text and reference works, although the "International Critical Tables"[3] accepts the lower value 2.2×10^{-6}. Hughes using the glass electrode made a single measurement[4] and reported a value of 1.4–1.7×10^{-6} depending upon the interpretation of his results. Gilbert studied the equilibrium[5] between ammonia and hydrazine in aqueous solutions and obtained the ratio of the constants of the two bases at 20° and two ionic strengths. The method is not suitable for extension to a general study at various temperatures and concentrations such as made in the present investigation.

The work described in this paper was carried out by the use of the glass electrode. The highly reactive nature of hydrazine and its instability in the presence of platinum black makes it impossible to use the quinhydrone or hydrogen electrode satisfactorily. Furthermore, it is impossible for the same reason to use the ordinary reference electrodes (calomel, mercuric oxide, or silver chloride) except through the medium of a liquid junction or salt bridge. However, the recent important work of Guggenheim and Schindler[6] on cells with liquid junction justifies confidence in this type of measurement within certain limits. The method has moreover been applied recently for a similar study of hypochlorous acid.[7]

Experimental Part

The hydrogen ion activity of a series of solutions was determined, each containing exactly equivalent amounts of hydrazinium hydroxide and hydrazinium ion, the ionic strength being varied by the addition of potassium sulfate, sodium chloride or sodium perchlorate. Measurements were made at 15, 25 and 35°, using a vacuum tube potentiometer of the type devised by De Eds.[8] Considerably more shielding was found advisable than specified by De Eds. The following cell arrangement was used

$$\text{Hg, Hg}_2\text{Cl}_2\text{, KCl (0.1 }N\text{) | KCl (satd.) | unknown solution, glass, buffer | KCl (0.1 }N\text{), Hg}_2\text{Cl}_2\text{, Hg}$$

When a reading had been made with the "Unknown Solution" in the cell, this was replaced with a buffer of similar ionic strength whose hydrogen ion activity had been determined accurately by the use of a hydrogen electrode at the same temperature. From these quantities the hydrogen ion activity of the hydrazinium buffer may be calculated readily.[9] Voltage readings could be duplicated within 0.3–0.5 mv., corresponding to ±0.01 *p*H. Calculation of the liquid junction potentials by Henderson's formula[10] as recommended by Guggenheim and Schindler showed them to be less than the uncertainty in the voltage readings. The liquid junction was made with the type of salt bridge devised by Ingham and Morrison,[7] which proved to be highly reproducible if subject to careful temperature control. In measuring the *p*H of the standard buffers with the hydrogen electrode the value given by Guggenheim and Schindler,[6] 333.7 mv., was used for the 0.1 *N* calomel electrode at 25°, 334.2 at 15° and 332.9 at 35°.

The solutions were made by weight, adding the calculated amount of carbonate-free sodium hydroxide solution to hydrazinium perchlorate solutions or in one series by adding barium hydroxide to hydrazine sulfate. The barium hydroxide was standardized gravimetrically. The ionic strength was adjusted by the addition of neutral salts such as potassium sulfate, sodium chloride or perchlorate. The water was de-oxygenated and the solutions were protected from the atmosphere at all times. Readings were constant with the glass electrode and easily duplicated.

Results

In Table I are given the results of the measurements. At each temperature determinations were made at a series of salt concentrations permitting extrapolation to zero ionic strength. The measurements at 25° were repeated with different salts. In agreement with Brönsted's principle of specific ionic interaction the slopes of the curves for different salts were different but extrapolation led to the same value at zero ionic strength. The rather small salt effect observed

agrees with the predictions of Brönsted's extended theory of acids and bases, namely, that for bases of the ammonia type the dissociation constant should be little affected by salts.[11]

TABLE I

HYDROGEN ION ACTIVITY OF HYDRAZINIUM BUFFER SOLUTIONS[a]

(a) In presence of K_2SO_4

μ (total)	15°	25°	35°
0.000	8.24	7.99	7.82
.009	8.25	7.99	7.82
.029	8.24	7.99	7.82
.044	8.27	....	7.83
.095	8.30	8.02	7.87
.170	8.37	8.09	7.90

(b) In presence of NaCl

μ (total)	25°
0.000	7.99
.010	7.99
.050	8.00
.100	8.02
.150	8.04

(c) In presence of $NaClO_4$

μ (total)	25°
0.000	8.00
.010	8.00
.050	8.01
.100	8.02
.150	8.03

[a] Expressed as *p*H.

Since the experimentally determined quantity in this work is the hydrogen ion activity, the calculations follow more simply if made on the basis of treating the hydrazinium ion as an acid.

$$N_2H_5^+ \rightleftarrows N_2H_4 + H^+$$

then

$$(a_{N_2H_4}a_{H^+})/a_{N_2H_5^+} = K_A$$

and

$$pK_A = pH + \log (a_{N_2H_5^+}/a_{N_2H_4})$$

At zero ionic strength where $a_{N_2H_5^+} = m_{N_2H_5^+}$ and in an equimolal solution of N_2H_4 and $N_2H_5^+$ such as used in this work pK_A may be taken as equal to *p*H.

Values for K_A obtained in this manner are shown in Table II. Now from the ion product of water as recently accurately determined by Harned and Hamer[12] the corresponding conventional ionization constant of the hydrazinium hydroxide may be calculated since $K_B = K_w/K_A$. These values are also shown in Table II, together with the corresponding values for $\Delta F°$ for the basic ionization. The value for $\Delta H_{291\cdot1}$ calculated from these results is 3850 cal., which may be compared to the value 3950 cal. obtained calorimetrically by Bach.[13] This quantity has a very large temperature coefficient. Since different salts affect the ionization constant to a different degree, it is not possible to set up a general equation for the constant as a function of the ionic strength. The observed salt effect however is not large.

TABLE II

IONIZATION CONSTANT OF HYDRAZINIUM ION AS AN ACID, AND OF HYDRAZINIUM HYDROXIDE AS A BASE

	15°	25°	35°
$K_A \times 10^9$	5.75	10.2	15.2
$K_B \times 10^6$	0.785	0.984	1.37
$\Delta F°$, cal.	8052	8200	8270

The values which have been found are considerably lower than those commonly accepted. They are of course the extrapolated values as opposed to those which have previously been determined in the presence of salts.

Summary

The ionization constants for the hydrazinium ion as an acid and hydrazinium hydroxide as a base have been determined at 15, 25 and 35° from glass electrode measurements.

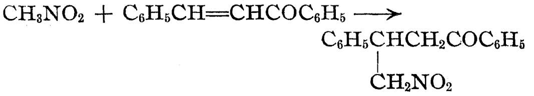
Alcoholic Ammonia as a Reagent for Nitro Compounds and Unsaturated Ketones

BY DAVID E. WORRALL AND CYRIL J. BRADWAY

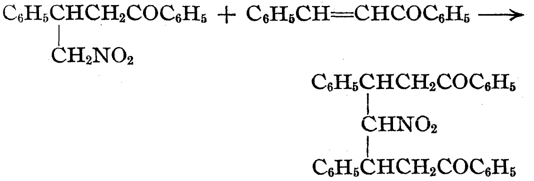
Although it has been known for some time that secondary amines[1] promote certain additions to unsaturated systems, the superior reactivity of sodium alcoholates has diverted attention from the use of such substances. Kohler[2] for example used sodium methylate to obtain a reaction between nitromethane and benzalacetophenone. Yet the organic bases possess some virtues and it has been shown recently[3] that ammonia causes the formation, through the interaction of nitrostilbene with nitro compounds, of substances otherwise inaccessible. We have now found ammonia useful with unsaturated ketones.

In the presence of sodium methylate a nitro ketone is eventually formed from benzalacetophenone and nitromethane.



$$CH_3NO_2 + C_6H_5CH{=}CHCOC_6H_5 \longrightarrow C_6H_5\underset{\begin{array}{c}|\\CH_2NO_2\end{array}}{CH}CH_2COC_6H_5 \quad \text{I}$$

It can also be obtained in the presence of ammonia, a reaction that we believe involves 1,4-addition of the ammonium salt of nitromethane followed by spontaneous decomposition into the enol of I. Since the latter still contains mobile hydrogen, it not only rearranges into I but tends to react with unchanged benzalacetophenone, repeating the cycle of changes.



$$C_6H_5\underset{\begin{array}{c}|\\CH_2NO_2\end{array}}{CH}CH_2COC_6H_5 + C_6H_5CH{=}CHCOC_6H_5 \longrightarrow \begin{array}{l}C_6H_5CHCH_2COC_6H_5 \quad \text{II}\\ \qquad\;\;|\\ \qquad CHNO_2\\ \qquad\;\;|\\ C_6H_5CHCH_2COC_6H_5\end{array}$$

Eventually I entirely disappears and a good yield of II results. Tertiary amines are effective and the presence of water promotes the reaction.

A number of trimolecular compounds have been synthesized (previously only one had been isolated),[4] using nitromethane with various unsaturated ketones. I may be used with derivatives of benzalacetophenone, thus producing nonsymmetrical combinations, but attempts to prepare trimolecular compounds from nitroethane or phenylnitromethane failed. Equally futile were attempts with unsaturated ketones prepared from *o*-substituted aldehydes.

Experimental

α,α′-Diphenyl-β,β′-dibenzoyldiethylnitromethane.—Ammonia gas, prepared by heating concd. aqueous ammonia solution, was bubbled into a mixture of 8 g. of nitromethane and 50 g. of benzalacetophenone in 250 cc. of ordinary ethyl alcohol until it was well saturated. The initial product separating out on standing overnight consisted largely of Kohler's compound. On longer standing the solution gradually acquired a dark red color due to the presence of a highly colored fluorescent substance, which after four to five days began to discolor the product. The process was interrupted at this point; yield of crude substance approximately 45 g. The substance was a mixture of two stereoisomers. It was extracted with hot toluene from which clumps of tiny needles melting at 229–230° separated on cooling.

Anal. Calcd. for $C_{31}H_{27}O_4N$: C, 78.0; H, 5.7. Found: C, 78.0; H, 5.5.

Several volumes of alcohol were added to the filtrate concentrated to a small volume. The resulting precipitate was recrystallized from hot alcohol, separating in feathery clusters of needles melting at 157–158°.

Anal. Calcd. for $C_{31}H_{27}O_4N$: C, 78.0; H, 5.7. Found: C, 78.0; H, 5.6.

The isomers are easily separated since the high melting form is insoluble in alcohol, while the other is very soluble in toluene. The low melting isomer was present in greater amount. Substitution of absolute alcohol resulted in a much poorer yield. On standing for a similar period of time excellent yields were obtained with diethylamine and piperidine, using the molar equivalent in each case. Primary amines (amylamine) were less satisfactory, while tertiary ethylamine was noticeably more sluggish in its action. It produced a substance unusually free from colored impurities. No reaction was observed with aniline.

α-Bromo-α,α′-diphenyl-β,β′-dibenzoyldiethylnitromethane was prepared in chloroform solution by the action of bromine in the presence of sunlight on the low melting isomer of II. The resulting oil after removal of solvent and all traces of hydrogen bromide by evaporation on the water-bath became crystalline on standing. It separated from alcohol solution in microscopic crystals melting rather indefinitely around 80° and easily becomes oily. We were unable further to purify the substance which was thought to represent a mixture of isomers as the analysis for bromine was satisfactory. A more tractable substance was obtained from the high melting isomer, brominating in nitrobenzene. The resulting mixture was filtered from unchanged material, steam distilled and the residue crystallized from hot alcohol. Small needles

Preparation and Properties of Trimolecular Addition Products.[5]—Unsaturated ketones obtained from anisaldehyde and other substituted aldehydes were prepared and allowed to react with nitromethane. These additions went much less readily in many cases than with benzalacetophenone and it was necessary to work with dilute solutions because of the insoluble character of the reactants. Consequently, only one substance was isolated as a rule. Non-symmetrical combinations were made by using I or similar compounds with unsaturated ketones of a different species. Thus benzalacetophenone was treated with the anisal compound corresponding to I. The reverse combination was much less suitable, hardly changing after standing for three weeks in alcohol saturated with ammonia. No evidence of reaction was obtained with the ketone prepared from *o*-chloro or *o*-nitrobenzaldehyde. This was also true using diethylamine or sodium methylate as a substitute for ammonia. The substances obtained were usually quite insoluble in alcohol, but crystallized from toluene or acetone–water mixture in small needles. When heated, these compounds melt with partial decomposition. The primary addition products of nitromethane with anisal and piperonalacetophenone, used as intermediates, have not previously been described. They were eventually obtained (Kohler's method) as needles melting respectively at 50–51° and 94–95°. The analyses agreed with the formula in each case.

The primary addition products of nitromethane with anisal and piperonalacetophenone, used as intermediates, have not previously been described. They were eventually obtained (Kohler's method) as needles melting respectively at 50–51° and 94–95°. The analyses agreed with the formula in each case.

Summary

It has been shown that nitromethane in the presence of alcoholic ammonia can be combined with two equivalents of the same or different unsaturated ketones of the benzalacetophenone type, producing nitro diketones.

The Reaction of Metal Halides with Acetylenic Grignard Reagents

BY JAMES P. DANEHY AND J. A. NIEUWLAND

That particular type of reaction between a Grignard reagent and a metal salt which involves the reduction of the salt and the coupling of the organic radicals was first observed by Bennet and Turner,[1] who treated phenylmagnesium bromide with chromic chloride in an attempt to prepare organochromium compounds of the type $RCrCl_2$. However, they obtained diphenyl and chromous chloride in almost theoretical yields.

$$2CrCl_3 + 2C_6H_5MgBr \longrightarrow C_6H_5\text{—}C_5H_6 + 2CrCl_2 + 2MgClBr$$

This reaction was extended by the original investigators and others,[2] who showed that it is general for many types of Grignard reagents as well as for most metal salts which can be reduced to lower salts or, in the case of iron and silver, to the free metal. The intermediate formation of organometallic compounds is indicated by the work of Reich and of Krause and Wendt,[3] who obtained phenyl-silver from phenylmagnesium bromide and silver halides. The phenyl-silver so formed underwent decomposition to silver and diphenyl. The ephemeral nature of such intermediates is emphasized by Job and Champetier[4] who, working with ferric chloride and phenylmagnesium bromide, attempted unsuccessfully to isolate intermediate organoiron compounds but stated that their existence is probable, particularly at low temperatures.

We have investigated the reaction between certain metal halides and acetylenic Grignard reagents in order, first, to determine whether or not the general reaction as just described is applicable to acetylenic Grignard reagents and, second, to seek corroborative evidence for the intermediate formation of organometallic compounds in reactions of this type.

Results

It was found that the general reaction is applicable to acetylenic Grignard reagents and that the action of cupric bromide on acetylenic Grignard reagents produces diacetylenes and cuprous bromide in good yields. In the case of phenylacetylenemagnesium bromide the addition of the stoichiometric amount of cupric bromide resulted in the formation of diphenyldiacetylene with a yield of 72%. A small amount of phenylacetylene was recovered from the hydrolyzed reaction mixture and the formation of no other products was observed.

When an equivalent amount of cupric bromide was added to *n*-butylacetylene magnesium bromide at 25° dibutyldiacetylene was obtained in 60% yield. In addition to the expected product a 7% yield of 1-bromo-1-hexyne was obtained. It was found that if the *n*-butylacetylene magnesium bromide was cooled to −5° by an ice–salt mixture and maintained at this temperature during the addition of the cupric bromide a 55% yield of dibutyldiacetylene was obtained and the yield of 1-bromo-1-hexyne was increased to 14%. Attempts to further increase the yield of 1-bromo-1-hexyne by maintaining the *n*-butylacetylene magnesium bromide at −33° (by immersing the reaction vessel in liquid ammonia) were unsuccessful since at this temperature no reaction takes place appreciably, even after four hours.

When cupric chloride was added to *n*-butylacetylene magnesium bromide at 25° dibutyldiacetylene was formed with a yield of 35%. No 1-chloro-1-hexyne was found but 5% of 1-bromo-1-hexyne was obtained in this case also. When cooling (−5°) was used the yield of 1-bromo-1-hexyne was increased by 2% and the yield of dibutyldiacetylene was found to be 30%. Cupric chloride, like cupric bromide, does not react appreciably with *n*-butylacetylene magnesium bromide at −33°. Cupric bromide reacts with *n*-butylacetylene magnesium chloride to yield dibutyldiacetylene (30%) and about 1% of 1-bromo-1-hexyne. Despite the variation of halogen in both Grignard reagent and salt no 1-chloro-1-hexyne was formed in any experiment. The behavior of ferric chloride toward the acetylenic Grignard reagent was similar to that of the copper halides, the yield of dibutyldiacetylene at 25° being 50%.

In no cases were higher boiling residues left; *n*-butylacetylene not accounted for as dibutyldi-

[4] Job and Champetier, *Compt. rend.*, **189**, 1089 (1929).

acetylene and 1-bromo-1-hexyne was recovered as *n*-butylacetylene.

Since substituted silver acetylides are stable it was believed that the action of silver bromide on an acetylenic Grignard reagent would give a stable silver derivative. When butylacetylene magnesium bromide was treated with the calculated amount of silver bromide the reaction product was found to contain no dibutyldiacetylene whatsoever. Silver butylacetylide was obtained in 60% yield. This offers corroborative evidence that the first stage of reaction between a Grignard reagent and a metal halide in the type of reaction under consideration is the formation of an organometallic compound and, if the organometallic compound is sufficiently unstable, decomposition ensues.

Experimental

Materials.—The substituted acetylenes used in this work were prepared in liquid ammonia by the usual method. The metal halides used were of analytical reagent grade.

Preparation of Diphenyldiacetylene.—In a three-necked, one-liter flask equipped with a motor-driven, mercury-sealed stirrer, a reflux condenser and a dropping funnel, 0.4 mole of ethylmagnesium bromide was prepared. To this was added dropwise and with stirring 40 g. (0.4 mole) of phenylacetylene diluted with an equal volume of ether. The contents of the flask were refluxed on a water-bath for two hours to expel all ethane. In eight small portions 90 g. (0.4 mole) of cupric bromide was added with rapid stirring. Vigorous reaction occurred after each addition. When almost all the cupric bromide had been added the precipitation of a large amount of flocculated material occurred. It was found that the reaction was quite complete within fifteen minutes after the addition of all the cupric bromide; refluxing did not increase yields. Water was added slowly through the top of the reflux condenser until no further action occurred. The ether layer was separated from the sludge of cuprous bromide, dried over calcium chloride and the ether was evaporated under diminished pressure. The non-volatile residue consisted of 29 g. of diphenyldiacetylene and 3 g. of phenylacetylene. The diphenyldiacetylene was recrystallized from the minimum amount of boiling ethanol; m. p. 87°; 72% yield.

The technique was essentially the same for all experiments except that the dibutyldiacetylene (b. p. 104° at 8 mm.) and 1-bromo-1-hexyne (b. p. 46° at 26 mm.) were isolated by fractional distillation.

Preparation of Silver Butylacetylide.—The addition of 75 g. (0.4 mole) of silver bromide to the Grignard reagent made from 33 g. (0.4 mole) of *n*-butylacetylene resulted in the formation of 46 g. of crystalline silver butylacetylide (62% yield). The *n*-butylacetylene was regenerated from the silver butylacetylide by refluxing with twice the theoretical amount of aqueous potassium cyanide.

Summary

1. Acetylenic Grignard reagents react with cupric bromide, cupric chloride and ferric chloride to yield diacetylenes predominantly and some 1-bromo-1-alkyne.

2. Confirmatory evidence is given for the intermediate formation of organometallic compounds in all reactions of this type.

Urethans as Local Anesthetics. III. Alkyl N-(8-Quinolyl) Carbamates

BY R. E. DAMSCHROEDER AND R. L. SHRINER

A study of *p*-aminophenyl urethans[1] showed that these compounds possessed high local anesthetic power, but were very irritating to the tissues. The irritation appeared to be associated with the *p*-phenylenediamine grouping and not with the urethan structure.[2] Since many different types of substituted quinolines exhibit local anesthetic action,[3] and are not especially irritating, it was thought that a combination of the quinoline nucleus with the urethan grouping would produce compounds with interesting pharmacological properties. Accordingly, a series of urethans derived from 8-aminoquinoline was prepared. These particular quinoline derivatives were chosen because the derivatives of 8-aminoquinoline, such as plasmoquin, are of value in treating malaria. Hence, these alkyl N-(8-quinolyl) carbamates would be of interest not only from a study of their local anesthetic action, but also because of the possibility of their antimalarial action.

8-Nitroquinoline was prepared by the Skraup reaction and reduced to 8-aminoquinoline. Treatment of the latter with alkyl chloroformates in the presence of saturated sodium carbonate solution produced the urethans.

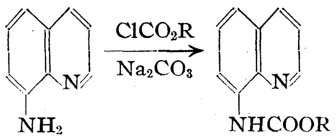
[3] Hirschfelder and Bieter, *Physiol. Rev.*, **12**, 190 (1932); Miescher, *Helv. Chim. Acta* **15**, 163 (1932).



Since the bases were insoluble, they were converted to the hydrochlorides which were used for the pharmacological tests.

Experimental

8-Nitroquinoline and 8-Aminoquinoline.—The procedures described by Smith and Getz[4] were followed. The average yield on six runs was 37% of 8-aminoquinoline, (based on the *o*-nitroaniline used) melting at 64–65° and boiling at 159–161° at 16 mm.

Alkyl Chloroformates.—The series of alkyl chloroformates was prepared from phosgene and the anhydrous alcohols according to the method of Adams, Kamm and Marvel.[5]

Alkyl N-(8-Quinolyl) Carbamates.—Two methods were used in order to obtain the urethans. The first method consisted in adding a slight excess of alkyl chloroformate to an ether solution of 8-aminoquinoline. The mixture was vigorously stirred and the precipitate of 8-aminoquinoline hydrochloride was removed by filtration. The ether was distilled, and the residue recrystallized from absolute alcohol. By this method only half of the 8-aminoquinoline was used to form the urethan, and difficulty was experienced in obtaining complete reactions, even though the mixture was stirred for several days. Better yields were obtained when the reaction was carried out in the presence of sodium carbonate.

A solution of 10 g. of 8-aminoquinoline in 75 cc. of ether and 75 cc. of saturated sodium carbonate solution was placed in a flask and stirred vigorously. A very slight excess of the alkyl chloroformate was added slowly. The mixture was stirred until a test portion of the ether layer failed to give a precipitate of 8-aminoquinoline hydrochloride upon addition of hydrochloric acid. The ether layer was then separated, dried with sodium sulfate and the ether distilled. After recrystallization from absolute alcohol the pure bases were obtained. The lower alkyl chlorocarbonates gave 80–90% yields, but the yields dropped as the alkyl group increased in size, so that the yield of the *n*-hexyl derivative was only about 10%. The properties and analyses are given in Table I. The *n*-amyl, *i*-amyl and *n*-hexyl derivatives were oils which could not be crystallized. They were converted to the hydrochlorides for analysis.

TABLE I

ALKYL N-(8-QUINOLYL) CARBAMATES

Alkyl group	M. p., °C.	Mol. formula	Nitrogen analyses, % Calcd.	Found
Methyl	61.5–62.5	$C_{11}H_{10}O_2N_2$	13.84	14.05
Ethyl	66–67	$C_{12}H_{12}O_2N_2$	12.95	12.84
n-Propyl	58–59	$C_{13}H_{14}O_2N_2$	12.16	12.07
n-Butyl	40	$C_{14}H_{16}O_2N_2$	11.46	11.83
i-Butyl	69–70	$C_{14}H_{16}O_2N_2$	11.46	11.67
n-Amyl	Oil	$C_{15}H_{18}O_2N_2$	...	...
i-Amyl	Oil	$C_{15}H_{18}O_2N_2$	...	...
n-Hexyl	Oil	$C_{16}H_{20}O_2N_2$	...	...

Hydrochlorides.—The urethans were dissolved in anhydrous ether and the solution saturated with dry hydrogen chloride. The hydrochlorides precipitated at once as amorphous solids or viscous oils which solidified on stirring or standing. Recrystallization from absolute alcohol yielded the pure hydrochlorides as white or light yellow crystals. The salts hydrolyzed when dissolved in water and the free base precipitated. In order to obtain solutions for the pharmacological tests, it was necessary to add sufficient hydrochloric acid in order to prevent hydrolysis. The minimum normality of hydrochloric acid necessary to prevent separation of the free base is shown in Table II along with the analyses.

TABLE II

HYDROCHLORIDES OF ALKYL N-(8-QUINOLYL) CARBAMATES

Alkyl group	Minimum *N* of HCl for solution	M. p., °C. (dec.)	Chlorine analyses, % Calcd.	Found
Methyl	0.05	199–201	14.86	14.83
Ethyl	.09	165–166	14.04	14.02
n-Propyl	.19	156–157	13.30	12.83
n-Butyl	.35	146–149	12.63	11.98
i-Butyl	.7	155–165	12.63	12.33
n-Amyl	1.0	147–149	12.03	11.80
i-Amyl	1.0	149–152	12.03	11.72
n-Hexyl	1.0	145–147	11.50	12.21

Pharmacological Data

Through the courtesy of the Lilly Research Laboratories, the toxicity and local anesthetic action of the compounds shown in Table II were determined. The hydrochlorides were dissolved in the proper strength of hydrochloric acid, so as to obtain 1% solutions which were used for the tests. A brief summary of the essential data is given in Table III.

TABLE III

PHARMACOLOGICAL ACTION OF HYDROCHLORIDES OF ALKYL N-(8-QUINOLYL) CARBAMATES

Alkyl group	Toxicity Mice–intravenous, mg. per kg.	Anesthesia duration Rabbit eyes, min.	Guinea pig skin min.	Irritation rabbit eyes and rabbit skin
Methyl	65	None	56	
Ethyl	200	24	46	Severe
n-Propyl	100	None	None	Severe
n Butyl	70	None	None	Severe
i-Butyl	50	None	None	Severe
n-Amyl	70	None	None	Severe
i-Amyl	60	None	None	Severe
n-Hexyl	250	None	None	Severe

Examination of the data in Table III shows that these quinoline derivatives are not especially toxic as compared to other anesthetics, but that their local anesthetic effect is very low or absent. The severe irritation is undoubtedly due to the fact that the solutions tested were strongly acid,

the *p*H being between 1 and 2. The tests against the malarial parasite are not completed.

Summary

The hydrochlorides of a series of alkyl N-(8-quinolyl) carbamates in which the alkyl group was varied from methyl to *n*-hexyl were prepared and tested for their local anesthetic activity. The methyl and ethyl derivatives produced local anesthesia for a short time. All the compounds were irritating.

The Binary System Potassium Dichromate–Sodium Dichromate

BY ALEXANDER LEHRMAN, HARRY SELDITCH AND PHILIP SKELL

The literature lists no determination of the liquidus curve of the system potassium dichromate–sodium dichromate. These are two fairly stable compounds having low melting points as compared with most salts and there existed the possibility of a low temperature eutectic mixture which could be used as a bath liquid. Furthermore as potassium dichromate has a transition point at about 240° the system offered the possibility of detecting the formation of solid solution by a change in the transition point due to solid solution. Still further the melting point of sodium dichromate is recorded in the literature on the basis of a determination made in 1886.[1] The report of this early work does not state the method of purification of the salt, nor the method of determining the melting temperature. It was thought advisable to measure it with more modern instruments.

In the work being reported the points on the liquidus curve were determined by two methods. The first was that of thermal analysis using copper–constantan couples and a potentiometer. The second was that of observing the temperature on a thermometer when crystallization of a homogeneous melt started or when the last crystal of a previously melted and solidified mix disappeared. The melting point of sodium dichromate and the transition point of potassium dichromate were determined by thermal analysis using time–temperature and time–differential temperature curves.

Experimental

Materials.—The potassium dichromate was twice recrystallized from a filtered solution of the C. P. salt and then fused in an electric furnace which was kept just above the melting point of potassium dichromate. As potassium dichromate expands on passing through its transition point the tube containing the molten salt was tilted before solidification to an almost horizontal position to prevent cracking of the tube when the expansion took place. On changing crystal form and expanding, the solid mass disintegrates and was poured from the tube as a coarse powder. In separating the crystals from the mother liquid and in subsequent handling care was taken to avoid contact with organic material.

Sodium dichromate was prepared from C. P. hydrated salt by recrystallizing twice after rejecting the first crop of crystals.[2] The recrystallized hydrate was kept in a porcelain dish at 170° for eight hours in which time it was converted to the anhydrous salt. It was then fused in Pyrex tubes set in a furnace which was maintained at a temperature just above the melting point. The molten salt was poured into a porcelain dish and the resulting solid ground to a powder and kept over phosphorus pentoxide.

The mixtures were made by weighing by difference, the weights being taken to the nearest centigram. The salts were poured from the weighing tubes directly into the Pyrex test-tubes used for the determinations.

Apparatus.—The apparatus for thermal analysis consisted of a cylinder of electrolytic copper 7.6 cm. in diameter and 12.7 cm. high, having three drilled wells. Two of the wells held Pyrex test-tubes 2.5 × 20 cm., one of which contained the dichromates and the other shredded asbestos. A thin layer of asbestos paper surrounded the test-tubes and ensured a small temperature difference between the salt and the copper block when the temperature of the block was changing. The third well, much smaller in diameter, held a chromel–alumel couple which was connected with a millivoltmeter graduated to read in degrees centigrade. This was used for the convenience of knowing the temperature of the copper block. The cylinder fitted snugly into a resistance furnace which was only slightly lagged. A rheostat and ammeter in series permitted control of the rate of heating and cooling.

The temperature measuring system consisted of two copper–constantan couples (24 gage wire) combined in the well-known way to allow a reading of the temperature of the sample, and of the difference in temperature between the sample and the shredded asbestos hereafter referred to as ΔT. Leeds and Northrup potentiometer indicators

were used to read the e. m. f. produced. A switch made it possible to read both the temperature and ΔT on the same instrument, but generally two potentiometers were used. A second switch reversed polarity in the ΔT circuit. All leads were of the same copper wire as used in the couples and the switches were protected from radiation from the furnace. The cold junction was cracked ice in an unsilvered Dewar flask. With these potentiometers the e. m. f. could be estimated to 0.01 mv. for temperatures up to 313°. For higher temperatures the scale allowed estimation only to 0.5 mv. It is our opinion that the error in reading the potentiometer was within 0.2° on the lower scale and within 0.5° on the higher one. The same potentiometer was always used for the temperature measurement. The couples were held in a shield of small bore Pyrex tubing.

Method.—The mixed salts in a Pyrex tube were inserted in the copper cylinder and the temperature raised to above the melting point. The couple in the guard tube was inserted into the melted salt, used to stir the liquid and then held in the center of the liquid by a cork stopper at the top of the tube. The rate of cooling of the copper cylinder was set as desired and readings taken every one-half or full minute of the temperature, and on alternate half or full minutes of ΔT when desired. The time–ΔT curve proved valuable in many cases, such as determining the transition point, and the eutectic temperature where the original mixture differed greatly from the eutectic mixture and the eutectic halt was of small duration.

The couple was calibrated against the boiling point of water, the melting point of Bureau of Standards tin and of twice crystallized potassium nitrate,[3] and a curve of its deviation from the standard curve of Adams[4] was prepared. The deviation curve was found to be a straight line and the melting point of potassium dichromate determined using this curve was 397.4°, which agrees with the value 397.5° found by Roberts.[5] While the melting point of potassium dichromate is about 10° higher than the limit set for the copper–constantan couple by the standard tables, it was considered justifiable to extrapolate through this short range.

There was no stirring during the cooling of the melts and supercooling generally took place. To find the temperature at which crystallization would have started had supercooling not occurred, the cooling curve after crystallization had set in was extended back to its intersection with the cooling curve previous to crystallization. This point of intersection was taken as the initial crystallization point of the mix.

Sodium dichromate supercools much more than potassium dichromate. In one case pure sodium dichromate supercooled 40°. There was usually considerable supercooling at the eutectic point as well as at the temperature of initial crystallization, so much so in many cases that when crystallization of the second solid finally set in the temperature was so low that the heat of crystallization was insufficient to bring the temperature up to the eutectic point, and many of the runs resulted in useless curves. In the range between 15 and 45% of potassium dichromate it was impossible to get a melting point without stirring. Even inoculation by dropping in a crystal of sodium dichromate did not help as the rate of solidification was too slow. The melting point of 22.9% potassium dichromate was obtained by using the guard tube and the couple as a stirrer.

The melted dichromates form a very dark liquid, impossible to see through to more than a few millimeters. Accordingly, for visual determinations of the temperature of initial crystallization, small Pyrex test-tubes were used as the containers and of course smaller charges. With the thermometer inserted the liquid in the annular space was short in depth and with good light the appearance or disappearance of the crystals could be observed. A thin glass rod was used to stir the mixture. The test-tube was suspended in a kerosene lamp chimney and the flame of a Tirril burner kept a short distance below the lower end of the chimney.

A nitrogen-filled mercury thermometer (5 to 500°) was used. It was calibrated in the apparatus for the depth of immersion used in the dichromate mixtures against the copper–constantan couple used in the other portion of this work. The temperature of the appearance and disappearance of the crystals could be found on repeated trials within a range of 2°. Due to the stirring there was practically no supercooling.

Results.—Five determinations of the melting point of sodium dichromate using different batches of the purified compounds gave the following values: 356.4, 356.6, 356.9, 356.4 and 357.2°; average 356.7°. The error all things included is probably within ±1.0°. This value of the melting point of sodium dichromate is 36° higher than that obtained by Stanley[1] and chosen by the "I. C. T."[6] Table I contains the results of measurements on the binary system obtained by thermal analysis, Table II contains those obtained by the visual method. The values are plotted in Fig. 1.

slight inflection. This was to be expected, previous workers having shown the heat of transition to be quite small.[7,10,11] Two determinations on different batches of purified potassium dichromate gave the values 241.3 and 242.0°; average, 241.6° with an error probably within ±1.0°.

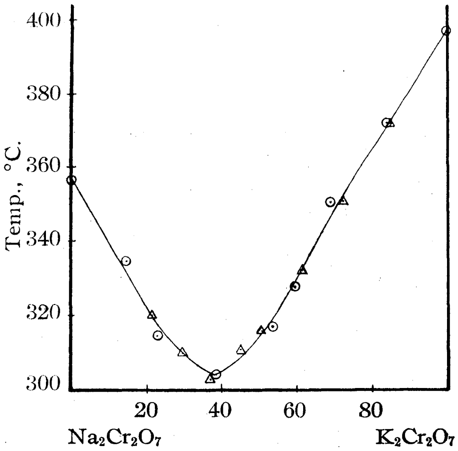

Fig. 1.—Liquidus of the $Na_2Cr_2O_7$–$K_2Cr_2O_7$ system: △, visual m. p.; ⊙, m. p. by thermal analysis.

This value is higher than any recorded in the literature and about 5° higher than the value chosen by the "I.C.T."[8] The most recent determination is that of Robinson, Stephenson and Briscoe.[9] They found the transition point to be 236.8° using a platinum resistance thermometer and 241° using a mercury thermometer. Their paper does not state the method of calibrating the resistance thermometer, nor of the purification of the potassium dichromate. Earlier determinations are those of Schemtschuschny, trans. p. 236°,[10] and Tammann, trans. p. 240°.[11]

No mixture of potassium and sodium dichromates used in determining the liquidus curve gave any indication of passing through a transition point between the eutectic temperature and room temperature. The ΔT curve showed no break and furthermore the solid masses formed around the thermocouple guard tube could be slid up and down the test-tubes after room temperature had been reached. When pure potassium dichromate was used the tube cracked due to expansion on passing through the transition. Robinson, Stephenson and Briscoe pointed out that the transition of potassium dichromate could be observed by dipping a rod into the molten salt, withdrawing the rod and letting it cool rapidly in the air.[9] At the transition point the adhering salt changes color, swells and cracks into minute pieces which drop off leaving the rod clean. This phenomenon was used to find approximately the minimum concentration of sodium dichromate needed to prevent the transition of potassium dichromate. A 10% sodium dichromate on cooling on the rod became lighter in a few spots, but the change in color did not travel through the mass, as it does in pure potassium dichromate. A 5% sodium dichromate mixture on cooling turned lighter throughout, the color change traveling slowly. The resulting mass however adhered to the rod though it crumbled off easily when touched.

Cooling and ΔT curves were determined for the 5% and a 2.3% sodium dichromate mixture. The tube containing the 5% mixture cracked when the temperature reached 202° but the curves did not indicate the position of a transition point. The 2.3% mixture in one run cracked the tube at 215° and gave a slight but inconclusive break in the ΔT curve at 221°. A second run on the same mixture did not result in a cracked tube and gave no break in the ΔT curve.

Discussion

This binary system is of the simple eutectic type. That no extensive solid solution takes place is shown by the presence of a eutectic halt for mixtures far removed in composition from the eutectic mixture.

The results of efforts to measure a change in the transition point of potassium dichromate due to possible solid solution are inconclusive. Probably a slight amount of solid solution takes place which lowers the transition temperature and also slows the rate of transition.

That the transition point of pure potassium dichromate obtained in this work is higher than the values obtained by previous investigators is

due probably to its detection by a differential temperature curve. It should be pointed out that one temperature used in standardizing the thermocouple was 231.9° (m. p. of Bureau of Standards tin) which is quite close to the temperature of the transition in question.

Résumé

The liquidus curve of the binary system potassium dichromate–sodium dichromate has been determined. It is of a simple eutectic type.

The melting point of sodium dichromate and the transition point of potassium dichromate have been redetermined.

The effect of the presence of sodium dichromate on the transition point of potassium dichromate has been noted.

A Study of the Heat Capacity of Aqueous Solutions of Barium Chloride

BY CHESTER M. WHITE

Thomsen[1] measured the specific heat of barium chloride solutions at 18° while some years later Marignac[2] reported values at 24.5°. More recently Urban[3] has determined the specific heat at several temperatures for a number of solutions. Also Tippetts and Newton[4] have made e. m. f. measurements on barium amalgam cells at several temperatures from which differences in partial molal heat capacities may be calculated. By an indirect method Richards and Dole[5] have probably obtained the most precise data for barium chloride solutions, although the precision of their experiments is somewhat in doubt. Specific heats were redetermined for these solutions to provide precise results by the direct method. They will be useful as a test of recent theories of strong electrolytes for higher valence salts. The measurements were made with a twin adiabatic calorimeter.[6] While the general design of the apparatus was similar to that of Gucker,[7] the precision was of the order of 0.02%. This paper will stress the changes which were made in the construction and operation of the calorimeter to increase the precision to 0.01%.

Experimental

Modified Apparatus.—Figure 1 shows the construction of one of the calorimetric units. A threaded joint was used to secure the calorimeters in place. Internally threaded collars (A) and externally threaded rings (B) were cast of brass. These were sweated to the original annular rings (C) which were secured permanently to the studs on the calorimeter cover by four special nuts (D). Originally the calorimeters were sealed to the annular rings, but the ground joint was not water tight after being in use two years. A coating of litharge and glycerol was placed between the calorimeter cover and the ring so that the joint would be water tight. A coating of de Khotinsky cement (E) was placed around the outside of the joint as a further protection. The Dewar jars (F), which served as calorimeters, were sealed to the rings by litharge and glycerol.

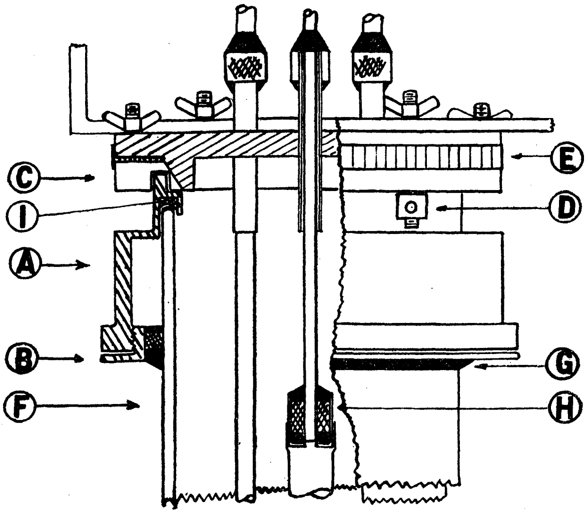

Fig. 1.—One unit of calorimeter.

After this mixture was dry, a 3.2-mm. coating of Bakelite cement (G) was applied above and below the litharge seal. After baking for a week at 60°, several coatings of Bakelite varnish were applied. The threads were lubricated with a water-proof grease, since the entire unit was submerged in water. The joint was entirely water tight during the entire series of measurements. A flat gasket (I) of soft rubber was fitted into the top of the collar so that the vapor

space in the calorimeters was fairly tight. Thus the method of securing the calorimeters in place was modified without dismantling the apparatus.

The calorimeter heaters were made along the same general plan as before. The heating elements were made of No. 30 bare constantan wire. At the ends of this wire 3.2-cm. pieces of No. 28 copper wire were soldered, to which the lead wires (No. 18 bell wire) were soldered.[8] The wire was wound bifilar on a slotted strip of mica. Thin protecting pieces of mica were tied with thread to the slotted strip and the whole was slipped into the case of the heater. The case was flattened and closed with a small amount of solder. The case[9] was of thin copper chromium plated. A copper sleeve (H) was soldered to the neck of the heater. There was a shoulder inside the sleeve to support the Pyrex tube through which the lead wires ran. Asbestos fibers were packed around the bottom of the tube and a layer of litharge and glycerol poured over them. When this was dry, a layer of Bakelite cement was applied. The insulation resistance of the heaters was measured by the Meggar.[10] Both heaters showed an infinite resistance between the case and either lead wire. The insulation resistances of the thermels were tested in the same way. The difference thermel (24 junctions) had an infinite resistance while the two adiabatic thermels (8 junctions each) showed resistance greater than 10 megohms.

In order to obtain an increased sensitivity without disturbing the thermels, Leeds and Northrup supplied a galvanometer with about five times the sensitivity of the original galvanometer but with the same damping resistance. The sensitivity with the difference thermel in series was 1.8 cm. μv (or 0.00006°/mm.). Since this galvanometer was more sensitive to vibrations, the simple Julius suspension was replaced by the improved type of Brevoort.[11] The entire suspension was enclosed by a double wall of shellacked paper to protect it from air currents.

It was found necessary to increase the speed of the calorimetric stirrers from 138 to 250 r. p. m. in order to establish thermal equilibrium in a relatively short time, fourteen minutes.

A large capacity Becker balance, which had a sensitivity of 3 mg. per scale division at 2000 g., was available for all but a few runs.

Materials, Constants, Molecular Weights, etc.—Baker C. P. barium chloride was used to make the solutions. The salt which was dehydrated at 120°[12] was always kept in the oven except when preparing the solutions. The usual precautions were taken in weighing the anhydrous material. A definite quantity of salt was added to a weighed amount of distilled water in the solution calorimeter. In some experiments a solution was weighed directly in the solution calorimeter. Its molality was determined by weighing the silver chloride residues and also by weighing the anhydrous salt after evaporation of the water. The results of these two methods were in good agreement.

The lithium chloride was Baker C. P. material. It was recrystallized three times from distilled water but was not analyzed for alkali chlorides.[13] The solution was made up and analyzed by weighing the silver chloride residues.

The molecular weight of barium chloride was calculated from the 1934 International Atomic Weight.[14] The heat capacities are expressed in 15° calories. The specific heat of water at 25° in 15° calories is taken as 0.9979.

Experimental Procedure.—In these experiments a 1° temperature interval was employed. The Beckmann thermometer was used to measure the rise in temperature. As a result of a careful comparison with a thermometer standardized by the Bureau of Standards, suitable corrections were applied to the total rise in each determination. The fore and after drifts, which were followed for forty minutes, were plotted in the usual way and a straight line was fitted to the linear portion of each drift by the method of averages.[15] The equations were used to extrapolate the drifts to the middle of the heating period. Equilibrium was usually established in 14 ± 4 min. for the after drifts following the cessation of the input of electrical energy. The atmospheric conditions were recorded for the purpose of reducing the weight of water in the solution calorimeter to the vacuum basis.

Water standardization and heat capacity runs were made at 24.5 and 25.5°. The specific heat in 25° calories was obtained by averaging the specific heat at 24.5 and 25.5° (in 24.5 and 25.5° calories). The averaged value was translated to 15° calories. Thus in each run the specific heat at 25° depends on two separate determinations (24.5 and 25.5°) and more confidence may be placed on the extrapolation of the drifts.

The tare always contained 700 g. of water (uncorr.). It would be better theoretically to correct the weight of water in the tare, but since the correction factor presented some difficulty, no account was taken of the change in the weight with atmospheric conditions. The maximum effect on the specific heat amounted to less than 0.003% in one experiment. The results at 24.5 and 25.5° are plotted in Fig. 2. The radius of the circle for each point represents a deviation of 0.005%. The weight of water in the solution calorimeter varied from 704 to 706 g. (uncorr.). The data at each temperature were fitted to a linear equation by the method of least squares. The equation was of the form

$$W = A + B\Delta G$$

where W is the weight of water and ΔG is the deflection of the galvanometer in cm. No runs were omitted at 24.5° while one run was cast out at 25.5° since its deviation was greater than four times the average deviation. The constants and the probable error at each temperature are given in Table I. The curves shown in Fig. 2 were determined by least squares.

TABLE I

WATER STANDARDIZATION SUMMARY

Temperature, °C.	24.5	25.5
No. of runs	32	33
Water equivalent (A), g.	705.901	705.933
Sensitivity (B/10), g./mm.	0.048	0.049
Probable error, %	.007	.006

During the salt measurements a standardization run was made occasionally to test the integrity of the apparatus.

The apparatus in its original form had checked some of Randall and Rossini's data to 0.01%. Since several changes had been made in the construction and the operation of the calorimeter, it seemed advisable to compare the results of the modified apparatus with the recent precise results of Gucker and Schminke on lithium chloride solutions. The results in 25° calories are recorded in Table II.

TABLE II

SUMMARY OF RESULTS FOR LiCl SOLUTIONS AT 25°, MOLALITY 0.0492

Expt.	Soln., g.	ΔG(24.5) cm.	ΔG(25.5) cm.	Sp. heat, cal.$_{25}$ deg.$^{-1}$ g.$^{-1}$	Φ	Φ (calcd.)
R 2	707.735	−0.36	−0.39	0.99717	−14.8	−14.5
R 3	707.735	− .06	− .70	.99717	−14.8	
R 4	707.735	− .40	− .20	.99722	−13.8	
R 5	707.742	− .40	− .14	.99724	−13.3	

The average deviation for these runs is 0.003% and they check the curve of Gucker and Schminke to 0.003%, which is about half of his precision. Thus the results are in good agreement with Gucker's precise measurements. These determinations were performed after the work on barium chloride was completed so that they constitute an added check on their reliability.

Experimental Results

The specific heats for barium chloride solutions are summarized in Table III. The experiments are numbered in chronological order. All weights are *in vacuo*. The averaged value of ΔG_{25} is recorded in Table III for a one degree rise. The average difference between $\Delta G_{24.5}$ and $\Delta G_{25.5}$ is 1.5 mm. The maximum difference amounts to 6.9 mm. in one run. The empirical equations were used to calculate the equivalent weight from ΔG. The apparent molal heat capacity as well as the specific heat is tabulated. The maximum deviations from the nominal temperature of 25.00° change the specific heat by ±0.001% in three runs. One run was discarded from each of the series *D* (out of 3), K (out of 4) and M (out of 4), while three were discarded from series N (out of 6). In each case the average deviation was greater than four times the average with the questionable run omitted. As far as was known, nothing went wrong during these determinations but it was felt that they should be discarded for the above reason. The concentration of all these runs except D was below 0.01 molal.

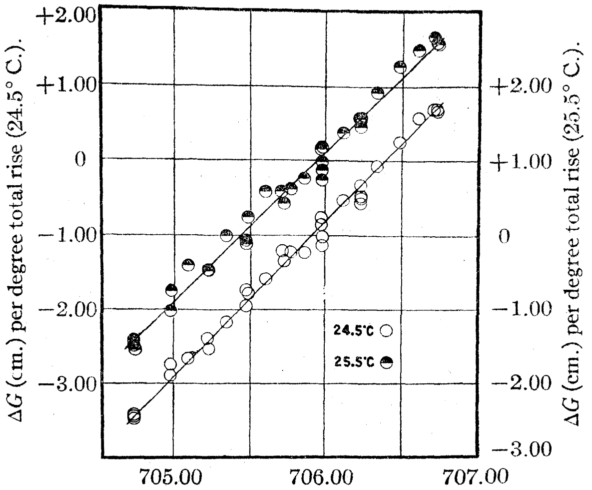

Fig. 2.—Calibration curves.

The so-called "evaporation error," which results from the substitution of a salt solution for the water in the solution calorimeter, depends on the lower vapor pressure and greater density of the salt solution. Because of the lack of vapor pressure measurements over a temperature range, it is difficult to correct for this effect in the case of barium chloride solutions. For an approximate calculation the vapor pressure lowering and density data in the "International Critical Tables" were used. The volume of the air space above the liquid level in the calorimeter was estimated at 265 cc. This error influenced the specific heats by about 0.003% at 0.5 molal. Thus, the above heat capacities need not be corrected for this effect.

The temperature difference for the two calorimeters was noted just before the heating current was stopped. It was usually about 0.007°, which compares favorably with Gucker's value of 0.005°.[7]

Two series of measurements were made at 0.12 molal (P and Q). The Q series was made by direct weighing of the salt in the usual manner, while in the P series an analyzed solution was weighed out directly in the solution calorimeter. While the Φ values differ by slightly more than 0.01% the average deviations are about large enough to account for this difference. Thus, it makes no difference by which method the solution is prepared.

Discussion

An equation was fitted to the heat capacities by the method of least squares. In dilute solution a given error in the specific heat produces a large percentage error in Φ, but the error rapidly diminishes as the concentration increases. It was felt that this difficulty would be largely eliminated if the curve was fitted to the ΔC_p values, since ΔC_p is defined as $m\ \Phi$.[16] The following equation was obtained

$$\Phi = -73.46 + 36.1\, m^{1/2}$$

with a probable error of 0.007%. An inspection of Fig. 3 will show the magnitude of the deviations of the experimental points from the empirical equation. The average value at each concentration and the empirical equation are plotted in Fig. 3. The dotted lines indicate an error of 0.01% from the straight line. The apparent molal heat capacities are adequately represented by the linear equation. The dotted lines indicate that large percentage errors in Φ occur below 0.01 molal. Several determinations were made at the same concentration for these very dilute solutions in the hope that the average value would yield some information as to the shape of the curve in this region. Since the results fall within the 0.01% band in a fairly random manner, they are in agreement with the linear equation.

It is a simple matter to calculate the partial molal heat capacity of the solvent and the solute from the empirical equation for Φ. The necessary thermodynamic equations which connect with $\overline{C}_{p_2}$ and $\overline{C}_{p_1}$ are given by Randall and Rossini. $\overline{C}_{p_2}$ curve is also plotted in Fig. 3.

The results of Richards and Dole (recalculated to cal.$_{15}$) are plotted in Fig. 3. This calculation was unnecessary for comparison with the present data, since the correction amounts to 0.003% at 0.3 molal. It reaches 0.007% at 1.0 molal. Their heat capacities were calculated from heats of dilution and specific heat measurements at two temperatures by the Person–Kirchoff relation. The curve for these results as drawn by Rossini[17] has a definite curvature at the higher concentrations. Richards and Dole pointed out in their paper that the specific heats of the $BaCl_2 \cdot 100H_2O$ might be in error by 0.05 to 0.1%. An error of 0.1% in the heat capacity of this solution would cause an error of 0.05% in the calculated specific heat at $BaCl_2 \cdot 200H_2O$. Therefore as the solutions become more dilute the original error decreases. If the procedure is reversed, an error of

---

(16) This method of treatment was developed several years ago in connection with an unpublished research on the specific heat of sodium chloride solutions.

(17) Rossini, *Bur. Standards J. Research*, **4**, 313 (1930).

0.1% in $BaCl_2 \cdot 100H_2O$ will cause an error of 0.2% in $BaCl_2 \cdot 50H_2O$. This is their most concentrated solution. The curvature is established by the results at $BaCl_2 \cdot 50H_2O$ and $BaCl_2 \cdot 100H_2O$, which are the least precise. Therefore their data were fitted to a linear instead of a parabolic equation by the same procedure as mentioned above. The following equation was obtained

$$\Phi = -74.36 + 35.5m^{1/2}$$

with a probable error of 0.013%. This equation as well as the individual runs of Richards and Dole in dilute solution are in good agreement with the present data. The results of Marignac check the equations to about 0.1%, while the data of Urban show differences of the order of 0.5%.

Recently Tippetts and Newton reported relative partial molal heat contents which compared favorably with the values of Richards and Dole. Their $\bar{C}_{p_2} - \bar{C}^0_{p_2}$ values, however, did not agree with those calculated from Richards and Dole's or the present empirical equation. In Table IV values at several concentrations are compared for the three methods. It is evident that the e. m. f. measurements merely indicate the order of magnitude of the results—a fact which Tippetts and Newton recognized.

TABLE IV

A COMPARISON OF $\bar{C}_{p_2} - \bar{C}^0_{p_2}$ VALUES FROM THREE SOURCES

Molality	Heat capacities	Heat capacities and heats of dilution	E. m. f.
0.1	17.1	16.8	74
.3	29.7	29.2	96
.5	..	37.7	100
1.0	..	53.3	91

The e. m. f. measurements usually agree more closely with the calorimetric values than in this case.[18] The extrapolation of the e. m. f.'s to infinite dilution is eliminated when the results are expressed as $(\bar{C}_{p_2} - \bar{C}_{p_2})_{m = 0.05}$. While somewhat better agreement is obtained by this procedure, the e. m. f. values still differ by a factor of 2.

In Table V the slope of $\bar{C}_{p_2}$ curve for barium chloride is compared with the limiting value as predicted by the Debye–Hückel theory[8a] and the modified form which was put forth by La Mer and Cowperthwaite.[19] It is also interesting to compare the slopes of biunivalent and unibivalent salts. Present theories predict the same slope for both valence types. The values of sodium and potassium sulfate in the table were determined by Randall and Rossini.

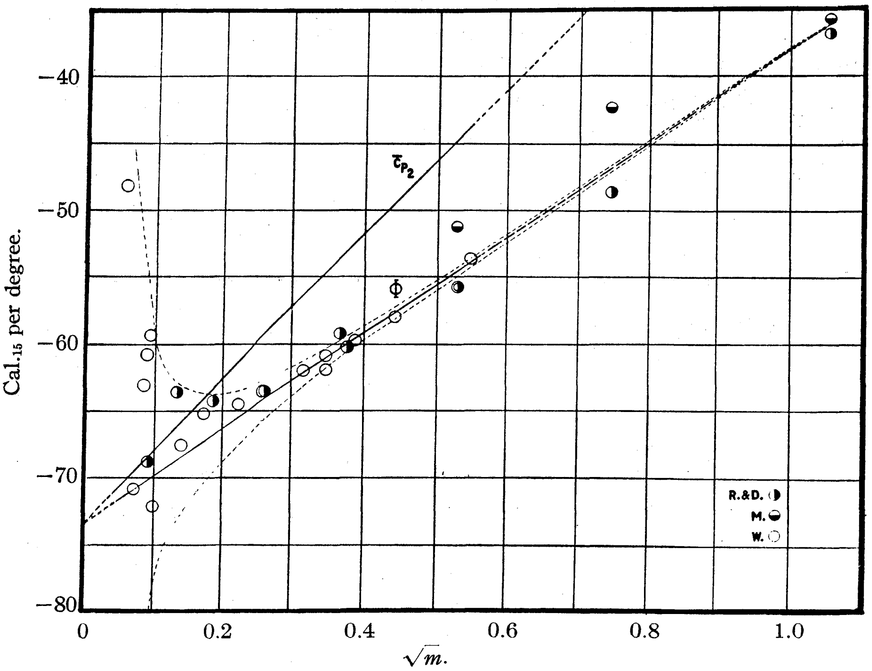

Fig. 3.—Apparent molal heat capacity (Φ) and partial molal heat capacity ($\bar{C}_{p_2}$) of barium chloride solutions.

TABLE V

COMPARISON OF THE SLOPE OF THE PARTIAL MOLAL HEAT CAPACITY CURVES WITH THE LIMITING VALUES

$BaCl_2$	Na_2SO_4	K_2SO_4	Debye–Hückel	La Mer and Cowperthwaite
54	76	62	31	69

The slopes of the three salts merely show the same order of magnitude, since the differences greatly exceed the precision of measurement. The barium chloride slope seems to agree with limiting value somewhat closer than the 1-2 salts and other uniunivalent electrolytes where the slopes are about three times the limiting value. Gulbransen and Robinson[20] have suggested that the

---

(18) Harned and Hecker, THIS JOURNAL, **55**, 4838 (1933).

(19) La Mer and Cowperthwaite, *ibid.*, **55**, 1004 (1933).

(20) Gulbransen and Robinson, *ibid.*, **56**, 2637 (1934). The dilution measurements of these authors for sodium chloride have been recalculated recently by Young and Groenier, *ibid.*, **58**, 187 (1936). Their values of the slope differ from the theory by 5%.

rather good agreement for sodium chloride solutions with the La Mer and Cowperthwaite modification is "largely fortuitous." Because of the uncertainty in $f(DT)$ there is probably an error of 15 calories or more in the limiting value for a 2-1 salt. Although the present results were extended to 0.003 molar, the slope as given by the least squares is determined by runs in relatively concentrated solutions, where the theory is not applicable. As far as these theories are concerned specific heat measurements apparently cannot be used to verify the limiting law. When a theory is proposed for relatively concentrated solutions, the heat capacity data should be of value.

The author wishes to express his appreciation to Dr. A. A. Sunier for many helpful suggestions during the course of this work.

Summary

1. A twin adiabatic calorimeter was used to measure the heat capacity of barium chloride solutions from 0.003 to 0.3 molal at 25° with a precision of better than 0.01%.

2. The apparent molal heat capacity of the salt plotted against the square root of the molality follows the usual linear relationship. An empirical equation is given from which the apparent heat capacity and partial molal heat capacity of the solute, and the partial molal heat capacity of the solvent may be computed.

3. The present data have been shown to be in satisfactory agreement with the results of indirect determinations.

ROCHESTER, N. Y. RECEIVED MAY 18, 1936

[A CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY OF ROCHESTER]

A Study of the Heat Capacity of Aqueous Solutions of Urea and Mannite

BY CHESTER M. WHITE

Several investigators have studied the specific heat of solutions of electrolytes in a precise manner. Richards and his co-workers[1,2] have presented precise values for some weak electrolytes, but substances which are strictly non-electrolytic have been largely neglected in recent years. Some semi-precision results on amino acids were reported recently by Zittle and Schmidt.[3] The determinations reported in this paper were made with a view to supplying specific heats for such solutions with a precision of ±0.01%. The present work will be concerned with aqueous solutions of urea and mannite from 0.01 to 1.0 molal. Many years ago Magie[4,5] determined specific heats for both of these solutions at several concentrations. The precision of his experiments was believed to be about 0.05%. Recently Funzel, Burian and Haas[6] reported heat capacities at several temperatures for urea solutions from heats of dilution. Their precision was placed at ±0.1%. Apparently no other workers have reported measurements for urea or mannite solutions.

The experiments were performed with a previously described twin calorimeter.[7,8] No changes were made in the construction or method of operation of the calorimeter. The reader is referred to the previous paper for a complete description of the apparatus and the experimental technique.

Materials

Merck and E. K. Co. urea was used. It was twice recrystallized from methanol. After pulverizing, it was dried for two weeks at a temperature which was always maintained below 55° so that ammonium cyanate would not be formed. Shnidman and Sunier,[9] who had highly purified some urea for solubility determinations, kindly supplied the author with some of this material. The runs at 0.125 molal were made with this urea. Since these experiments were in satisfactory agreement with the other determinations, the above method of purification was sufficient for specific heat work.

The mannite, which was Pfanstiehl product, was thoroughly dried for all the runs. For some of the experiments it was recrystallized from distilled water and dried to constant weight at 130°. The experiments in which the purified mannite was used showed no substantial deviations from the other runs. The urea solutions were prepared by adding a known amount of solute to the solution calorimeter, which contained a weighed quantity of distilled water. Since a noticeable cooling effect takes place on the solution of mannite above 0.2 molal, the concentrated

solutions had to be prepared in a flask and a portion of this solution was weighed in the solution calorimeter.

Experimental Results

In Tables I and II the results are summarized for the urea and mannite solutions. The deviations from 25.00° were such that no corrections to the specific heat were necessary. The experiments are numbered in chronological order. All weights are on the vacuum basis. The 1935 atomic weights were used. The molality is expressed in moles per 1000.0 g. of water. ΔG is the galvanometer deflection which corresponds to a 1° rise. The average of $\Delta G_{24.5}$ and $\Delta G_{25.5}$ is given in the table. These two values differed by 1.4 mm. on the average. The maximum difference amounted to 6.6 mm. in one run. The equivalent weights of water were calculated from the empirical equations given in the previous paper.[7] Water standardizations were made frequently during the course of the experiments. These runs did not show deviations greater than ±0.01% from the linear equations. The specific heats are given in 15° calories. The specific heat of water was taken as 0.9979 at 25°. The apparent molal heat capacity Φ was calculated in the manner described by Randall and Rossini.[10] The magnitude of the "evaporation error" is less than 0.001% at 1.0 molal with a vapor space of 265 cc. Thus, no correction is necessary for this effect.

B	.9995	753.107	+ .67	.93581	+108.3

The heat capacities, expressed as ΔC_p, were fitted to an empirical equation by least squares. The constants and the probable error of an individual run from the equation are given in Table III for the two non-electrolytes.

TABLE III

CONSTANTS AND PROBABLE ERRORS FOR LINEAR EQUATIONS

Solute	Urea	Mannite
Intercept (A)	20.52	105.16
Slope (B)	1.72	3.23
Probable error (cal.)	±0.065	±0.069

The individual determinations of Φ are plotted against the $\sqrt{m}$ for urea and mannite solutions in Figs. 1 and 2, respectively. The least square curves are also plotted and the dotted lines indicate an error of ±0.01% from the linear equation. An inspection of Figs. 1 and 2 will indicate the magnitude of the deviations of the experimental points from the empirical equations.

The relation between the partial molal heat

[10] Randall and Rossini, THIS JOURNAL, **51**, 326 (1929).

capacity of the solute (or the solvent) and the apparent molal heat capacity has been derived by Randall and Rossini. It is only necessary to differentiate the empirical equation for Φ and substitute in their equation to obtain an expression for the variations of $\bar{C}_{p_2}$ (or $\bar{C}_{p_1}$) with m. The following empirical expressions were obtained for the partial molal quantities.

UREA

$$\bar{C}_{p2} = 20.52 + 2.58\, m^{1/2}$$
$$\bar{C}_{p1} - \bar{C}^0_{p1} = -0.0154\, m^{3/2}$$

MANNITE

$$\bar{C}_{p2} = 105.16 + 4.85\, m^{1/2}$$
$$\bar{C}_{p1} - \bar{C}^0_{p1} = -0.0291\, m^{3/2}$$

The $\bar{C}_{p_2}$ curves for urea and mannite are also plotted in Figs. 1 and 2, respectively.

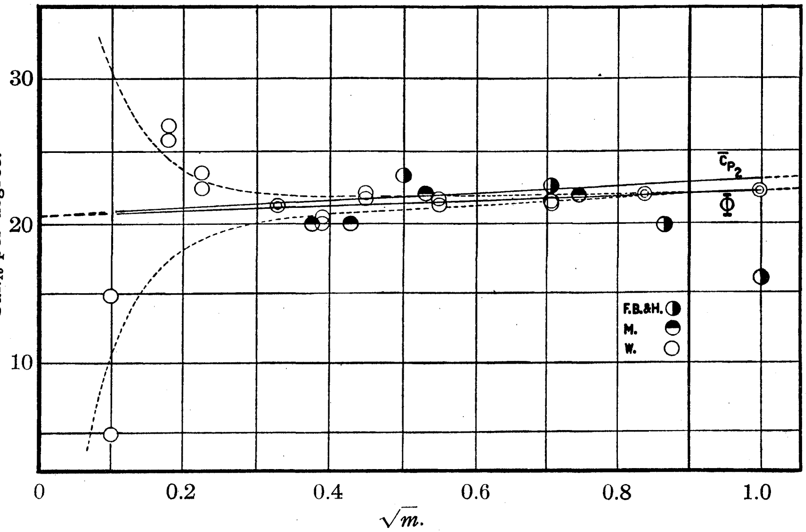

Fig. 1.—Apparent molal heat capacity (Φ) and partial molal heat capacity ($\bar{C}_{p2}$) of urea solutions.

The data of Magie[4] for urea solutions are also plotted in Fig. 1. These values are in excellent agreement with the present results since the average deviation of the points from the empirical equation is about 0.02%. The recent results of Funzel, Burian and Haas, which were determined with a precision of ±0.01%, are shown in Fig. 1. The plotted values of Φ were calculated from the specific heats at 24° (without converting to 25°) and the specific heat of water which they used. The average deviation of the Φ values from the empirical equation is 0.2%. In view of their precision of measurement the agreement with the present data is satisfactory.

Magie[4,5] is apparently the only worker who has studied mannite solutions. His results are plotted in Fig. 2. They appear to be in good agreement with the present data except for three points which differ from the empirical equation by 0.1 to 0.3%. Magie pointed out in the first paper that these three determinations were probably in error. The points, which show deviations of only 0.05% from the equation, were published in the second paper. While Magie does not record the temperature of his experiments he gives a quantity which is equivalent to Φ. This uncertainty in the temperature introduces an insignificant error in the Φ values.

It is apparent from the plots that the Φ values for urea are equally distributed about the linear equations in dilute solution. The mannite solutions show a break at 0.06 m below which the apparent molal heat capacities decrease. However, it is evident that the deviations are equal to the probable experimental error so that no importance may be attached to them. If the lowest points had been discarded in the least square calculation, the slope of the equation would not be substantially altered.

It is interesting to compare the extrapolated intercept of the $\bar{C}_{p_2}$ (or Φ) curve with the molal heat capacity of the solute in the pure state (c_p). c_p for crystalline urea and mannite at 25° are 19.2 and 58.3 cal., respectively. $\bar{C}^0_{p_2}$ for urea is in very close agreement with c_p. In the case of mannite there is an appreciable difference. It is interesting to note that this deviation is positive while all electrolytes show negative deviations from c_p. Presumably the intercepts for the two types of compounds are equally uncertain because of the extrapolation from 0.01 m to zero concentration which has been shown for electrolytes, at least, to be a questionable procedure. Edsall[11] has suggested that non-electrolytes which possess polar groups have Φ values which approximate rather closely the heat capacity of the pure solid while a single polar group attached to a long hydrocarbon chain yields Φ values which show positive deviations from c_p.

---

(11) Edsall, THIS JOURNAL, **57**, 1506 (1935).

Because of the lack of data for these solutions, his conclusions were based on results at various concentrations. Since these rules are expected to apply in concentrated solution, it is suggested that the apparent value of $\overline{C}^0_{p_2}$ be used. On this basis the present results for urea follow his rule while those for mannite do not. Edsall found that the available data for glycerol, which is also a polyhydric alcohol, are in satisfactory agreement with the theory at 1 m. Obviously more data must be obtained before the validity of these rules may be tested.[12]

In the derivation of the theoretical slope of the C_{p_2} curves for electrolytes from the Debye–Hückel theory, Randall and Rossini considered that the free energy change, on passing from a definite concentration to the infinitely dilute solution, was composed of the part due to the ions taken as ideal solutes and the part due to the effect of the charged ions. For non-electrolytes the second term is zero and the total free energy is given by $RL \ln c$. The second derivative of this expression with respect to the temperature is zero. Thus Φ or $\overline{C}_{p_2}$ would be independent of the concentration. Zwicky[13] is led to the same conclusion on the basis of his theory. The present results for urea and mannite show small but appreciable slopes. Gucker[14] has shown that the apparent molal volume and compressibility for urea solutions also have small slopes when plotted against the $\sqrt{c}$. Apparently these properties have not been studied for mannite solutions. It should not be implied that all non-electrolytes have small slopes because Gucker has shown that Φ (V) and Φ (K) for sucrose solutions have slopes equal to a 2-1 electrolyte. These properties have been studied over a wide range of concentration and very definitely follow a linear equation when plotted against $\sqrt{c}$. Since the apparent molal heat capacities in the present paper cover a relatively limited range of concentration and change only slightly with m, it is difficult to determine whether the Φ values for urea and mannite are strictly proportional to $\sqrt{m}$ or to m itself. On the basis of these results it may be said that they seem to cluster more closely about a straight line when plotted against $\sqrt{m}$.

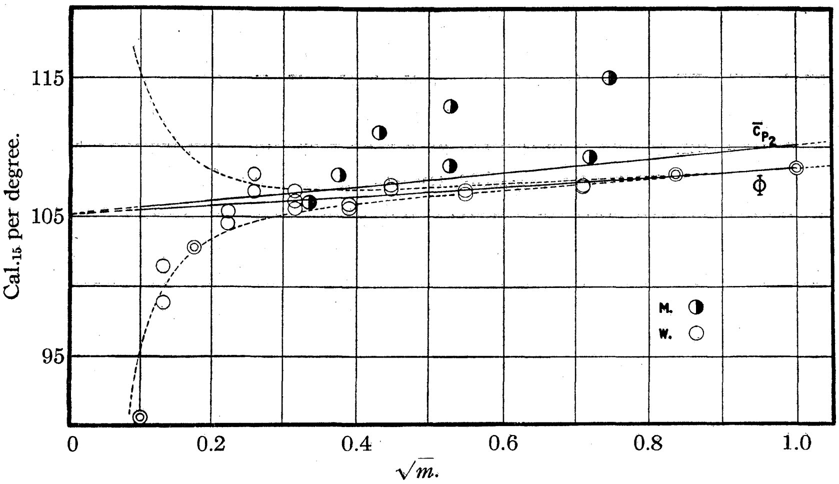

Fig. 2.—Apparent molal heat capacity (Φ) and partial molal heat capacity ($\overline{C}_{p_2}$) of mannite solutions.

The author wishes to thank Professor A. A. Sunier for suggesting the problem and for his helpful suggestions in the preparation of the manuscript.

Summary

1. The twin adiabatic calorimeter method was used to determine the specific heats of aqueous solutions of urea and mannite at 25° from 0.01 to 1.0 m with a precision of ±0.01%.

2. The apparent molal heat capacities were calculated and they seem to follow a linear equation when plotted against the $\sqrt{m}$. The intercepts are positive and the slopes are small for these solutes. Empirical equations are given for the apparent and the partial molal heat capacities of the solutes and the relative partial molal heat capacity of the solvent.

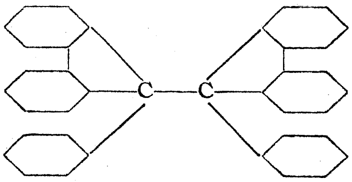
Single Bond Energies. III. The C–C Bond in Diphenyl Di-biphenylene Ethane

By H. E. Bent and J. E. Cline

The first two papers of this series give an answer to a question regarding the strength of the C–C bond in hexaphenylethane.[1] Until the approach to the problem with the aid of wave mechanics it had been assumed that the C–C bond is weak in those ethanes which dissociate to give free radicals. Quite the opposite point of view has been suggested by Pauling and Wheland[2a] and by Hückel.[2b] These authors assume that the C–C bond is normal and that dissociation is caused by a stabilization of the free radical as a result of the resonance energy made possible by the presence of an odd electron and the unsaturated structures in the benzene rings. The evidence presented from a study of the heat of oxidation and the heat of hydrogenation of hexaphenylethane leads to the conclusion that neither point of view is entirely correct but that about half of the "*apparent*" weakening of the C–C bond is due to a weakening of the bond in the ethane. We have assumed that this bond is weaker than normal on account of steric hindrance.

Many problems are suggested by these experiments. The one with which we wish to deal in this paper is the question as to what extent variation in the degree of dissociation of various ethanes is due to differences in steric hindrance in the ethane and to what extent due to different amounts of resonance energy in the various free radicals.

Diphenyl di-biphenylene ethane is chosen for this study on account of its remarkable properties.



Although very closely related to hexaphenylethane it exhibits a very different behavior. The loss of four hydrogens and tying together of the benzene rings produces an ethane which dissociates much less than hexaphenylethane. Pauling and Wheland have accounted for this decreased dissociation by a smaller amount of resonance energy in the free radical. Conant[3] has pointed out the striking difference between the properties of phenyl xanthyl and phenyl fluoryl. In one case the benzene rings are tied together by means of oxygen and in the other case are tied together directly. Yet phenyl xanthyl is less associated than triphenylmethyl and phenyl fluoryl is more associated. If one constructs models for these free radicals it becomes apparent that steric hindrance might be much less in the case of phenyl fluoryl. We therefore wished to compare experimentally the strength of the C–C bond in diphenyl di-biphenylene ethane with the bond in hexaphenylethane. In the first two papers of this series we evaluated the strength of the C–C bond by making use of Pauling's single bond energies. For the purpose of the comparison which we now propose to make it is not necessary to know any values for single bond energies. We may interpret our experimental results with the aid of the assumption that the strength of the C–O and O–O bonds in the various peroxides formed is the same.

Another reason for studying the heat of oxygenation of this particular compound arose in connection with the determination of the free energy of addition of sodium to diphenyl di-biphenylene ethane. These experiments indicated that the free energy of addition of sodium to phenyl fluoryl is more negative than in the case of triphenylmethyl by about 12 kcal.[4] This was a very unexpected result since Wheland has suggested from theoretical considerations that the electron affinity as a first approximation should be a constant for organic free radicals. His conclusion is quite in accord with experimental investigations of these compounds.[5] If the resonance energy of phenyl fluoryl is large, then steric hindrance must be very small in order to give a compound which is only very slightly dissociated. A small steric effect should lead to a stronger C–C bond and hence a much lower heat of oxidation.

Experimental

The apparatus has been considerably improved and changed in a number of important respects since the work

reported in the first papers of this series. The purpose of these modifications is to increase the ruggedness and permanence of the apparatus and reduce the number of materials in contact with the liquid or vapor in the reaction vessel. In the earlier apparatus cement was used at various points and thermocouple wires and heater leads were not only exposed to the vapor of the solvent but also subjected to mechanical motion when the capsule was broken. In the present apparatus all wires are enclosed in glass with the exception of the platinum heater wire and a silver lead which may be changed to platinum if desired. No cement is used to hold the heater wire in place or at other points in the apparatus. We are now quite free from any possible solvent action and can use the apparatus for chlorination if desired.

In order to save space only the changes in the apparatus will be mentioned and the figure given in the first paper of this series will be used for reference. The chief alteration consisted in sealing the tube which carries the thermocouple and the heater to the stationary tube above the ground joint "D." Two ring seals are used for this purpose, one just below the tube marked "C" in the original figure and the other just above this side tube. The thermocouple leads then pass through this side tube and down through an annular space to the bottom. The annular space is necessary in order that the magnet may now move a glass rod which passes through the whole length of the apparatus and pushes the capsule "J" out at the bottom and breaks it on the Dewar. The lower side tube, at the left in the original figure, is now used for the heater leads which are sealed through the glass by the method of Cox, Kraus and Fuoss.[6] We have used No. 22 silver wire for part of the lead. The heater has a resistance of 17.845 ohms and is made by winding No. 40 platinum wire on glass supports which hold it out about 1 mm. from the glass tube. This is accomplished by first sealing eight pieces of glass rod 1.8 cm. long and 1 mm. in diameter to the bottom of the tube. Tiny dots of glass are then fused to these rods and the wire wound between the glass dots. By using alternate spaces in winding the wire down from the top the two ends can be anchored at the top and crossing of the wire avoided.

The electrical measurements have also been considerably improved since the report of earlier work. All measurements of temperature and current are made with the aid of a type K potentiometer. By means of appropriate switches the potentiometer can be connected to the thermocouple for the measurement of temperature or to the heater, with the aid of a potential divider, to determine the potential drop across the latter. Another switch connects the potentiometer to a standard resistance in series with the heater, this potential drop giving a measure of the current.

The use of platinum as a heater made necessary an automatic control of the energy input on account of the change in resistance of the platinum with temperature. This is accomplished by putting in series with the heater an external resistance of the same size. The latter coil is made from 13.7 meters (45 ft.) of No. 22 Advance wire which has a very small temperature coefficient and is wound without a core in order to dissipate heat rapidly. This arrangement maintains the energy input constant with a fluctuating resistance provided the voltage supply is constant. This can easily be shown to be true as a first approximation and is due to the fact that as the resistance of the heater increases the current decreases but this is appropriately compensated by an increase in the potential drop across the heater. By measuring the resistance of the heater we were able to calculate its rise in temperature above that of the solvent. Using a current of 0.2 amp. we find the rise in temperature to be about one degree, and the increase in resistance to be about 0.3%. An increase in resistance of 1.0% would have caused a decrease in the power input of only 0.002%. Appropriate calculations of heat loss by thermal conduction in the lead wires indicate that this factor introduces less than 0.2% error. The method of calibrating the apparatus electrically at the end of each run takes care of all constant heat losses.

Materials

Diphenyl Di-biphenylene Ethane.—Phenylbiphenylene carbinol was first prepared according to the directions of Ullmann and von Wurstemberger.[7] This was converted to the chloride according to the method of Gomberg and Cone[8] and the chloride converted to the ethane using the procedure of Dorfman.[5] Since the ethane is much less soluble than the chloride or carbinol, which might be present as impurity, crystallization of the ethane from benzene and washing with solvent gave material of satisfactory purity.

Tetraphenyl Di-α-naphthyl Ethane.—Diphenyl α-naphthyl chloromethane was prepared according to the directions of Halford for preparing triphenyl chloromethane.[9] The chloride was converted to the free radical with lead amalgam using the procedure of Dorfman as for the previous compound.

Experimental Results

Table I gives the experimental data on the heat of oxidation of diphenyl di-biphenylene ethane in benzene as a solvent. The first column gives the weight of the sample and the second the purity of the compound as indicated by the amount of oxygen absorbed. The chief uncertainty in the figure for the impurity arises from the fact that the reaction flask contains a vapor phase which is a mixture of benzene and oxygen and the connecting tube contains pure oxygen. It is impossible to estimate with high precision the volume which is to be considered saturated with benzene when making a correction for the change in vapor pressure of benzene during the course of a run. The value for the purity of the compound is probably good to about 0.5%. The third column gives the heat of oxidation per mole based on the amount of oxygen actually absorbed. This value refers to

[9] Halford, THIS JOURNAL, **53**, 105 (1931).

the solid ethane as the reactant and peroxide in solution in benzene as the product of the reaction. The next column gives a small correction which it seemed proper to add for the heat of solution of unreacting material. The heat of solution of the ethane is found to be 4.6 ± 0.3 kcal. per mole. If we assume that the material which did not add oxygen has the same heat of solution and make the correction we obtain the values given in the last column of the table. The average given in the last column of the table is obtained by weighting those runs which gave the smoothest curves and thereby permitted the best corrections for heat loss to the surroundings.

Table I

Heat of Oxidation of Diphenyl Di-biphenylene Ethane

Sample, g.	O_2 abs., %	$-\Delta H$ per mole	Correction	$-\Delta H$ corrected
0.4352	96.4	24.05	0.17	24.2
.6600	92.0	22.3	.4	22.7
.5086	97.2	20.25	.13	20.4
.9945	99.5	20.8	.0	20.8
.9905	98.9	22.5	.05	22.55

The heats of solution of the ethane and peroxide have also been determined in order to calculate the value for ΔH when the reaction is carried out either entirely in solution or referred to the solid state. The value for the ethane is 4.6 ± 0.3 kcal. per mole and for the peroxide is 5.4 ± 0.4 kcal. From these figures we obtain the value -26.6 kcal. for the addition of oxygen to the ethane dissolved in benzene to give the peroxide in solution. Similarly if solid ethane is converted to the peroxide the value of ΔH is -27.4 kcal.

The solution of peroxide at the completion of a run was invariably red in color, apparently due to some highly colored substance. As much as 80% of the theoretical amount of white peroxide was obtained from the reaction but all attempts to isolate another compound from the remaining material were unsuccessful. Undoubtedly the yield of peroxide was considerably more than 80% but this was all we were able to isolate, apparently due to the presence of the red colored material which formed an oil when attempts were made to crystallize it.

Tetraphenyl di-α-naphthyl ethane gave results which are less satisfactory. The amount of oxygen absorbed was about 86% of the theoretical amount and the insolubility of the peroxide made it impossible to determine its heat of solution. The results of two representative runs are as follows

Wt. of ethane	O_2 absorbed	ΔH exp.	ΔH corr.
0.3788	85.3	-34.3	-35.3
.8318	87.8	-34.1	-35.1

The values given in the next to the last column are calculated on the basis of the amount of oxygen absorbed and are for the addition of oxygen to solid ethane to give chiefly solid peroxide. A small correction should be made for the heat of solution of the peroxide which remained in solution, about 17 mg. in 150 cc. of benzene. This correction cannot be of much significance, however, due to the very small amount of material involved. A correction should also be applied for the heat of solution of the material which did not react with oxygen. The heat of solution of the ethane is found to be 11 ± 3 kcal. Since this includes the heat of dissociation of part of the material, we have taken a somewhat smaller value for the heat of solution of the material which did not react with oxygen and used this to correct our experimental values and give the values in the last column of the table.

An attempt was made to improve the technique of these oxidation reactions by using pyrogallol as suggested by Ziegler, Ewald and Seib.[10] The results of these experiments were not satisfactory as the amount of oxygen absorbed was less than expected. This may be due to the fact that in our experiments solid ethane is introduced into a solution which contains oxygen. It may be that some of the normal peroxide and some $(C_6H_5)_3$-COOH is formed under these conditions.

Attempts to hydrogenate diphenyl di-biphenylene ethane were unsuccessful. Either the ethane was too insoluble, the rate of hydrogenation was too slow or else the amount of hydrogen absorbed was greater than that expected.

Discussion

The value previously reported for the oxidation of hexaphenylethane is -45.5 ± 0.5 kcal. when the reaction is from solid to solid and -39.3 ± 2.0 kcal. when the reaction is in solution. The values here reported for diphenyl di-biphenylene ethane of -26.6 and -27.4 for the corresponding reactions are so much smaller as to be very striking. The conclusion suggested by these data is that the C–C bond is stronger in diphenyl di-biphenylene ethane than it is in hexaphenylethane by about 20 kcal. This is quite in harmony with the conclusions of our previous papers which indi-

---

(10) Ziegler, Ewald and Seib, *Ann.*, **504**, 182 (1933).

cated that the C–C bond in hexaphenylethane is weaker than a normal bond by about 35 kcal., which we attributed to steric hindrance. If one assumes that the C–C bond in hexaphenylethane is a normal bond then there is no way of explaining a bond in diphenyl di-biphenylene ethane which is 20 kcal. stronger. The inference from these data is that steric hindrance is much less when the benzene rings are tied together as they are in this compound, in agreement with the appearance of the model of the molecule.

The surprising result from these experiments is that the decrease in steric hindrance is so large in this compound. If this were the only factor involved in the dissociation of the ethane it would be impossible to explain the fact that the difference in the free energy of dissociation of this compound and hexaphenylethane is only three or four kcal. A solution to the problem is possible if one assumes that phenyl fluoryl has a much larger resonance energy than triphenylmethyl, thereby canceling to some extent the increased strength of the bond in diphenyl di-biphenylene ethane. This is just the opposite of the conclusion reached by Pauling and Wheland in their discussion of this compound.

The above conclusions are based on data involving materials in solution or in the solid state. A much more satisfactory treatment would be based on reactions in the vapor phase. We hope to have some such data to report in the near future but since this work is being interrupted for the present it seems desirable to report the progress which has been made to this time.

In comparing tetraphenyl di-α-naphthyl ethane with hexaphenylethane we are dealing with a difference in heats of oxidation which is not as large as in the case just discussed and therefore the interpretation is more in doubt. Since we have no data on the heat of solution of the peroxide it will not be possible to study this reaction in the vapor phase by the method which we are using with hexaphenylethane.

Summary

1. The heat of oxidation of diphenyl di-biphenylene ethane is found to be about 20 kcal. less than that of hexaphenylethane.

2. This datum indicates that steric hindrance is less than in the case of hexaphenylethane and that the free radical formed by dissociation, phenyl fluoryl, has more resonance energy than triphenylmethyl.

Antioxidants and the Autoxidation of Fats. VI. Inhibitols[1]

BY H. S. OLCOTT AND H. A. MATTILL

Previous work from this Laboratory[2,3,4] has demonstrated that the unsaponifiable lipid fractions of vegetables and vegetable oils contain compounds which are active antioxidants toward lard. It is proposed to call these compounds as a class "inhibitols," a name which indicates their function as inhibitors and also the invariable occurrence of hydroxyl groups, upon which their inhibiting action depends. Although concentrates have been prepared from various sources,[5] only the lettuce inhibitol has been crystallized.[3] The present paper contains a description of the preparation and properties of the inhibitol concentrates from wheat germ, cottonseed and palm oils.

The method used for obtaining the most active concentrates from wheat germ or cottonseed oil is exactly the same as that described for obtaining vitamin E concentrates.[6] Indeed, the physical and chemical properties of vitamin E

---

[4] E. M. Bradway and H. A. Mattill, THIS JOURNAL, **56**, 2405 (1934).

[5] Inhibitols are present in lettuce, tomatoes, carrots, alfalfa, spinach; in wheat germ, cottonseed, corn, sesame, palm, soy bean and peanut oils; and probably in many other vegetable substances. No demonstrable amounts of inhibitols are present in yeast, lard; or in olive (trace), cod-liver, palm kernel or castor oils.

[6] H. S. Olcott and H. A. Mattill, *J. Biol. Chem.*, **104**, 423 (1934).

and the inhibitol from these oils are so similar that it has thus far been impossible to separate the two. The demonstration that the vitamin E and inhibitols of lettuce and tomatoes could be separated by preferential solubilities,[3,4] thus providing a vitamin E concentrate free of antioxygenic activity, has been the principal basis for the assumption that the two properties are not inherent in the same molecule.

Experimental

Preparation.—Wheat germ or cottonseed oil is saponified with alcoholic potash,[7] and extracted with ether (previously shaken with 10–20% aqueous sodium hydroxide to remove peroxides). The ether extracts are evaporated to dryness and the residue dissolved in petroleum ether, from which most of the sterols separate on cooling. The sterols are removed by filtration, and the residue obtained after removal of the solvent is extracted several times with hot methanol. The methanol-soluble fractions are combined and cooled. If more sterols crystallize they are removed. The solvent is evaporated under reduced pressure and the residue is then carefully distilled in a high vacuum. The inhibitol distils at 190–210° (0.1 mm.).

The palm oil inhibitol was concentrated as follows. The unsaponifiable fraction was dissolved in petroleum ether, diluted with an equal volume of methyl alcohol and allowed to stand cold for several weeks. Some of the carotene crystallized and was removed. The petroleum ether was then evaporated from the filtrate and an insoluble oil separated; the methanol solution was poured off, the oil was washed twice with methanol and the extracts combined and hydrogenated with platinum as the catalyst. The purpose of this step was to destroy the remaining pro-oxygenic carotenoids.[8] The catalyst was removed by filtration and the filtrate evaporated to dryness. A white inactive powder separated from a petroleum ether solution of the residue and was filtered off. The limpid oil remaining after evaporation of the filtrate amounted to 0.1% by weight of the original oil. It was carefully fractionated in high vacuum (0.03 to 0.04 mm.) and the antioxidant obtained most highly concentrated in the fraction distilling within the 165–180° range. Several of a number of runs with palm oils have yielded concentrates of high vitamin E potency. With palm oil as with wheat germ and cottonseed oils, it was not possible to separate the inhibitol from vitamin E.

Attempts further to concentrate the inhibitol from these sources or to obtain a crystalline product have not been promising. Physical methods have included crystallization from solvents at low temperatures (−80°), careful fractional distillation in high vacuum (0.002 mm.), and adsorption on silica, alumina and magnesia. No notable concentration has been effected by any of these methods. In each case all of the fractions were antioxygenic to lard. Separation of the material into soluble and insoluble fractions from methanol at 0° consistently yielded somewhat more active fractions in the soluble portion. Diphasic separation between 92% methanol and petroleum ether removed a small amount of an inactive oil in the 92% methanol layer. The inhibitol was preferentially soluble in petroleum ether.

Physical and Chemical Properties.—Inhibitol concentrates are light yellow transparent oils of medium viscosity, which do not crystallize on long standing. They are stable under ordinary laboratory conditions for years. Some physical constants and chemical analyses are given in Table I. The concentrates are soluble in the following organic solvents: ether, petroleum ether, methyl and ethyl alcohols, pyridine, glacial acetic acid, chloroform, benzene, dioxane, etc.

[a] Dr. Ing. A. Schoeller. [b] Ralls' method.[11] [c] Rosenmund–Kuhnhenn method.[10] We have found it difficult to obtain consistent iodine numbers of unsaponifiable lipid fractions.

The effects of various reagents on the activity of inhibitol concentrates have been used to characterize the structure of the inhibitols. Table II includes representative results of such experiments. The inhibitols are always inactivated by reagents which combine with a free hydroxyl group, including acetyl chloride, acetic anhydride in pyridine, benzoyl chloride, methyl iodide with silver oxide, dimethyl sulfate, diethyl sulfate, phenyl isocyanate, *p*-nitrophenyl isocyanate and many others. None of these derivatives yielded crystalline products. Those which contained ester linkages, including the substituted ure-

---

[7] For the complete saponification of large or small amounts of fat with a minimum of time, effort and opportunity for oxidation, the following proportions of reagents have been used in this Laboratory: 26 g. of potassium hydroxide is dissolved with stirring in 22 cc. of water and poured while hot into 89 cc. of 95% ethanol. This mixture is poured directly into a flask containing 100 g. of the oil or melted fat. The flask is swirled vigorously until the mixture becomes homogeneous; usually less than a minute is required. For the extraction of unsaponifiable constituents, the soaps are allowed to cool to 40–50° and poured into 450 cc. of water; 450 cc. of ethyl ether is added and the mixture is shaken. The ether layer separates immediately. The water–alcohol solution of the soaps may be extracted repeatedly with ether without emulsification. This procedure was developed by Dr. R. B. French, who also devised a method for large scale saponification and extraction which will be described in another place.

[8] Newton [*J. Oil and Soap*, **9**, 247 (1932)] found that fats containing carotene were more stable than colorless ones, and, further, that lards could be protected from oxidation by the addition of palm oil which contains carotene. However, we had previously demonstrated that purified crystalline carotene acted as a prooxidant in lard–cod-liver oil mixtures [H. S. Olcovich and H. A. Mattill, *J. Biol. Chem.*, **91**, 105 (1931); H. S. Olcott, THIS JOURNAL, **56**, 2492 (1934)]. It now seems clear that the fats containing carotene also contained inhibitols, which, in fact, ensured the presence of carotene by protecting it from oxidation. The palm oil inhibitol was responsible for the protection afforded by the addition of palm oil to lard. The method of incorporation described was such as to destroy the pro-oxygenic carotene by heat treatment and thus stabilize the fat still further.

thans, were hydrolyzed with alcoholic sodium hydroxide. The recovered material was again antioxygenic although in most cases some of the activity was lost. Diazomethane did not affect the antioxygenic action.

TABLE II

EFFECT OF REAGENTS ON INHIBITOL ACTIVITY

Concentrate[a]	Fat	Treatment	Induction period (75°C.)	
			With inhibitor (0.02%) hrs.	Without inhibitor, hrs.
C5-9	Lard	None	34	8
		Chlorine	7	8
		Chlorine + Zn + HCl	34	8
C65	Lard–cod-liver oil	None	158	16
		Ozone	11	11
W5-10	Lard	None	62	15
		Methyl iodide	13	12
		Dimethyl sulfate	13	12
		Ethyl iodide	17	15

		Acetic anhydride	4	4
		Phenyl isocyanate	4	4
		Phenyl isocyanate + NaOH	50	6
W3-18	Lard–cod-liver oil	None	23	7
		Acetic anhydride	5	5
		Acetic anhydride + NaOH	12	4

[a] C indicates cottonseed oil inhibitol, W that from wheat germ oil.

The inhibitols are destroyed by direct bromination or chlorination, presumably by addition to a double bond. The activity can be regenerated by boiling with zinc and hydrochloric acid in methanol. Hydrogenation has uniformly failed to inactivate the inhibitols. One sample was subjected to hydrogen at 250° and 230–280 atmospheres for two hours without loss of activity.[9] The recovered material was still unsaturated, although the iodine number[10,11] had been reduced from 105 to 70. Perbenzoic acid in the cold destroyed the inhibitols. Ozone was also destructive. These facts have been interpreted to mean that inhibitol contains a difficultly hydrogenated double bond which is essential to its activity.

The inhibitols are not destroyed by dry hydrogen bromide in methanol, nor by phosphorous tribromide, at room temperature. Potassium permanganate in pyridine, chromic acid in glacial acetic acid, potassium amide in liquid ammonia, potassium ethylate in ethyl alcohol and lead tetraacetate in glacial acetic acid destroyed the activity.

The methods used for determining the effect of some of these reagents upon concentrates have been described briefly elsewhere.[12,13]

The ultraviolet absorption spectra of inhibitol concentrates show a distinct broad band with maximum at 2940 Å., the height of which is roughly proportional to the antioxygenic activity. Acetylation causes a loss in height and migration of the peak to 2810 Å. Several authors have suggested that this band is a property of vitamin E.[14,15] In our experience, the height of the band has been more nearly proportional to the antioxygenic than to the physiological activity. Most striking of such experiments is a comparison of the properties of concentrate, P16-9, from palm oil with those of concentrates from wheat germ or cottonseed oil. Although P16-9 contained less than one-fifth as much vitamin E as did the others, the band in the ultraviolet was equally strong (Table III). Concentrates W5-156 and W5-157 were consecutive fractions from a fractional vacuum distillation, equally effective as antioxidants, but not containing equal amounts of vitamin E.

TABLE III

THE RELATION OF THE INHIBITOL CONCENTRATION AND THE VITAMIN E CONTENT TO THE ABSORPTION BAND AT 2940 Å.

Concentrate	Antioxidant index[a]	$E^{1\%}_{1\ \mathrm{cm.}}$ at 2940 Å.	Minimum dose,[b] mg.
C65	4–7	70	4
P16-9	5–8	90	>30
W5-10	5–8	100	3
W5-156	5–8	65	>10
W5-157	5–8	70	2

[a] Antioxidant index is the ratio of the induction period of the protected sample to that of the control. The figures are approximations because of the natural variability in duplicate assays (Table VI). [b] The minimum amount required to ensure the birth of a litter in a vitamin E-deficient animal.

Assay.—All fractions obtained during these studies were assayed for antioxygenic activity by the procedure

previously described,[16,17] which measures the induction period of lard or lard–cod-liver mixtures by the oxygen absorption method. The flasks containing the samples were placed in constant temperature baths at 75°, and the time of the beginning of active oxygen absorption was recorded automatically. The most active inhibitol concentrates protected lard to a degree approaching that afforded by the phenolic inhibitors (Table IV) and were much more effective than other compounds which have been suggested for use in edible fats.

Inhibitol concentrates are effective antioxidants for purified fatty acids and esters (Table V). Preliminary observations suggest that they also protect other easily oxidized organic compounds. They are, however, ineffective as antioxidants for the vegetable fats and oils from which they are prepared.

TABLE V

EFFECT OF AN INHIBITOL CONCENTRATE ON VARIOUS SUBSTRATES

Substrate fat	Inhibitol concentrate W5–10 %	Induction period at 75° With inhibitor, hrs.	Without inhibitor hrs.
Ethyl ricinoleate	0.10	56	16
Ethyl linolate (58°)	.10	8	0.5
Methyl oleate	.03	10	4
	.10	40	4
Oleic acid	.02	30	4
β-Ionone	.10	4	0.5
9,10-Octadecene	.13	84	13

The assays are subject to interference by many factors, some unknown. Attention has been called elsewhere[17] to the variability in fats and among samples of the same fat, not only in keeping quality, but in their reactions to added inhibitors. Table VI indicates the results which may be expected in assays of inhibitol concentrates on different lots of the same kind of fat.

[a] Antioxidant index.

Furthermore, the mere fact that an inhibitor is effective in one fat at an elevated temperature does not mean that it will be effective in other fats or at other temperatures. Preliminary experiments do show, however, that inhibitols protect lard at room temperature.

The authors are indebted to Lever Brothers Company for a grant in support of this research and to Dr. R. B. French and Dr. Lyle A. Hamilton for their help in the preparation and assay of inhibitol concentrates.

Summary

The unsaponifiable lipid fractions of many vegetables and vegetable oils contain compounds which are active antioxidants to lard and which are here named inhibitols. The inhibitols from wheat germ and cottonseed oils may be concentrated by processes of crystallization and distillation similar to those used for obtaining vitamin E concentrates from which the inhibitols have not been separated. The preparation of inhibitol concentrates from palm oil is aided by the destruction by hydrogenation of the accompanying pro-oxygenic carotenoids.

Inhibitol concentrates are transparent oils which have resisted crystallization. Some chemical and physical properties are outlined. The inhibitols are destroyed by reagents which attack a hydroxyl group or saturate a double bond. Inactive esters may be hydrolyzed to regenerate the activity. They are resistant to hydrogenation. Chlorine or bromine addition products can be reactivated with zinc and hydrochloric acid. The concentrates have a strong absorption band at 2940 Å. roughly proportional to their activity.

The inhibitol concentrates have been assayed by an oxygen absorption method. They are shown to be much more effective antioxidants in lard than any edible compounds which have been suggested for use as commercial antioxidants. The inhibitols protect purified fatty acids and esters but do not protect the vegetable oils from which they are obtained.

The Hydrolysis of 1,2-Dichloro-2-methylpropane Producing Isobutyraldehyde[1,2]

BY J. M. HERSH AND R. E. NELSON

Moderate quantities of 1,2-dichloro-2-methylpropane have been available from the thermal chlorination of isobutane.[3] The ready production of this material has made it desirable to study the possibility of its conversion into more desirable derivatives, such as isobutyraldehyde. The first study of this subject was that of Newlin,[4] who succeeded in showing that the hydrolysis of 1,2-dichloro-2-methylpropane resulted in the formation of a considerable amount of hydrochloric acid and an aldehyde accepted as isobutyraldehyde. This work was carried out in the liquid phase at temperatures below 100° using the 1,2-dichloride from the thermal chlorination of isobutane. In it there were several anomalies that called for further study and clarification. The present study of this reaction had as its objectives, (1) the preparation of pure 1,2-dichloro-2-methylpropane from some source other than isobutane, (2) the comparison of dichlorides from several sources in typical hydrolysis reactions, (3) the study of the hydrolysis reaction in the liquid phase and in the vapor phase in the presence of substances which might have a catalytic effect on the reaction, and (4) the separation and identification of isobutyraldehyde. Purified 1,2-dichloro-2-methylpropane prepared from *t*-butyl alcohol was hydrolyzed, mainly in the vapor phase in the presence of contact catalysts, to produce isobutyraldehyde.

Experimental

Preparation of 1,2-Dichloro-2-methylpropane.—The desired synthesis from some source other than isobutane led to the use of tertiary and isobutyl alcohols. The procedures followed in this preparation were: (a) dehydration to isobutene with subsequent chlorination,[5] (b) direct chlorination of *t*-butyl alcohol,[6] and (c) the low temperature chlorination of 2-chloro-2-methylpropane prepared from the alcohol by treatment with hydrochloric acid.[7] Of these methods, the last was markedly successful in producing 1,2-dichloro-2-methylpropane of desirable purity. This dichloride has a clean, mild, sweetish odor; even after six months' standing it is free of hydrogen chloride. No product of thermal chlorination has yet been prepared which compares with this synthesized material in stability, freedom from hydrogen chloride and mildness. The above preparation of 1,2-dichloro-2-methylpropane allowed a reasonable assumption that it was not contaminated with 1,1-dichloro-2-methylpropane, the only other dichloride which would be difficult to remove by distillation. Pure 1,2-dichloro-2-methylpropane has the following physical constants: b. p. 38.6–39.2° (70 mm.), 59–60° (150 mm.) and 106.5° (760 mm.) (corr.); $n^{20}\text{D}$ 1.4370 (Abbe); d_{20} 1.093 g./cc.

Aldehyde Analysis.—The titration of isobutyraldehyde by the hydroxylamine hydrochloride method was found to give unreliable results. The more reliable method of Seyervetz and Bardin[8] using a sodium sulfite solution was standardized against known isobutyraldehyde–water solutions. An analytical factor was established for use in the analysis of the products of hydrolysis of subsequent reactions, and the method was found to give concordant results.

Hydrolysis in Liquid Phase.—The first hydrolysis studies followed the simpler liquid phase procedure used by Newlin. The results of these studies indicated moderate hydrolysis with the formation of appreciable quantities of aldehyde, with yields obtainable as high as 33–35%. The effective conversion to aldehyde was improved with higher water to dichloride ratios, a ratio of 20:1 giving satisfactory yields.

Throughout these hydrolysis studies it was generally apparent that the hydrochloric acid capable of titration was far in excess of the aldehyde found by analysis. This condition was especially true in liquid phase hydrolysis where the tendency toward pyrolysis was at a minimum. It was evident then, that hydrochloric acid was evolved as several intermediate products were formed; these were then incompletely converted to isobutyraldehyde. Thus the acidity of the reaction products was bound to be high without the formation of an equivalent amount of isobutyraldehyde.

Catalytic Hydrolysis in Vapor Phase.—A hydrolysis unit was set up to operate at 300–450°. The apparatus designed for this purpose is shown diagrammatically in Fig. 1. Following the diagram, the apparatus was operated in the following manner: air under pressure (A) from an adjustable hydrostatic head, varied by the mercury pressure regulators (C), forced water from a graduated cylinder (G) and a constant flow (E) of dichloride from a reservoir (F) into the preheater (H). A line (B) to a vacuum pump permitted the dichloride reservoir to be filled readily. The preheater had concentric Pyrex coils so that the water

and dichloride were vaporized individually in the desired ratio, preheated to 200°, and sent into the adjoining reaction tube (I), which was a 22-mm. Pyrex tube 60 cm. long packed with a contact mass and held at a fixed temperature by a Hoskins electric heating unit (K). A thermocouple (J) extending into the reaction zone permitted temperature recording and regulation by a recording pyrometer and thermal regulator. The products of the reaction were condensed (L) and collected in flasks (M).

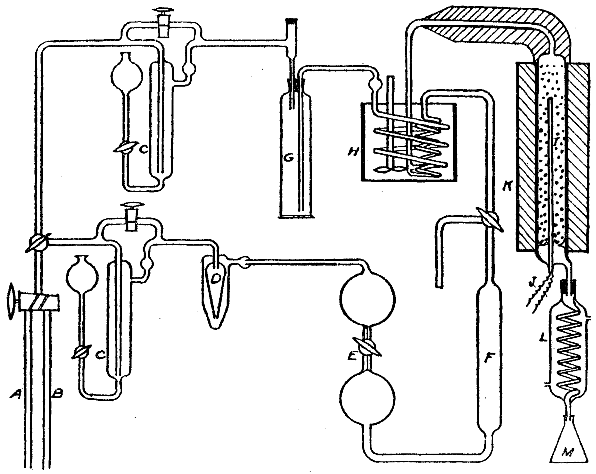

Fig. 1.

The procedure in each reaction carried out was to maintain a ratio of approximately 20:1 of water to dichloride, and to use generally 10 cc. of dichloride in each run. All the hydrolysis products were measured in volume, and the aqueous fraction containing aldehyde and hydrochloric acid was separated from the oily fraction consisting largely of unconverted dichloride. From each run two 10-cc. samples were taken from the aqueous portion and titrated for total acidity to determine the degree of conversion. The resulting neutral solution was analyzed for isobutyraldehyde by the method described. A 3-cc. sample from the aqueous portion was treated with fuchsin-aldehyde reagent for a color test of the aldehyde.

The first group of vapor phase hydrolysis studies made use of a series of fifteen catalyst filled reaction tubes. Subsequent studies made use of a series of sixteen reaction tubes in which a unit weight (10 g.) of a catalyst was mixed with a large amount of granular pumice filler. While the first reaction tubes required replacement before any large number of runs were completed, the reactors beginning with number six held up well, and ten or more runs were completed on each tube. Though fifteen catalyst filled reaction tubes were studied, at temperatures between 350 and 450°, a summary is presented in Table I of only typical catalysts, with a comparison based on the first ten hydrolysis runs completed on the reactor at 350°. The series of reaction tubes in which unit weights of catalyst were mixed with pumice is similarly summarized and presented in Table I. The average yields are given for

[a] Based upon first ten hydrolysis runs completed, using approximately 10 cc. of dichloride and 20 volumes of water.

each type of catalyst in order to give a measure of the degree of conversion, and the completeness of reaction.

Deterioration of Catalysts.—On reviewing any series of hydrolysis runs it was apparent that the catalyst was generally rapidly deactivated. This effect was first apparent with reactor number six using silica gel. The same effect was observed with each subsequent reactor and was apparent in the maximal to minimal change in conversion shown between the first and subsequent runs. This deterioration of catalysts was more pronounced at elevated temperatures where pyrolysis and carbonization were more evident, and varied also with the specific catalyst studied.

Separation of Hydrolysis Products.—The major part of the dichloride fed into the system was returned with the products of reaction as an oily, insoluble material, which was separated, filtered, dried and distilled. From 66–68% of this fraction appeared as crude dichloride which distilled over at 102–110°. It was further purified and fractionated to produce an additional quantity of 1,2-dichloro-2-methylpropane. Each batch of aqueous hydrolysis product containing isobutyraldehyde was distilled to remove an aldehyde-rich aqueous fraction. These aldehyde–water concentrates were further fractionated through a small column of the type described by Weston,[9] and the isobutyraldehyde was stripped from the large amount of water accompanying it. The crude aldehyde was purified and compared with Eastman isobutyraldehyde and with its known physical constants. Thus it was shown that the aldehyde isolated was the aldehyde expected in the reaction.

On reviewing the comparison of catalysts it was apparent that there was a pronounced difference in the catalytic influence of the several substances tested. The high value shown was that of activated alumina, and the lowest value that of granular pumice. Calculating the criterion value of these catalysts as dependent mainly (50%) on the percentage of aldehyde found by analysis, with additional consideration (25%) given to each the percentage of conversion and the percentage of dichloride consumed, the two series of catalysts were evaluated and arranged in the order of decreasing activity in Table I.

Summary

1. Pure 1,2-dichloro-2-methylpropane was prepared by the low temperature chlorination of 2-chloro-2-methylpropane. This compound was compared in hydrolysis with the dichloride from other sources; in each case isobutyraldehyde was produced in comparable yields.

2. The hydrolysis of 1,2-dichloro-2-methylpropane was quite effective in the vapor phase at 350°, with a ratio of 20:1 of water to dichloride, especially in the presence of catalysts. Yields of isobutyraldehyde were obtained as high as 33–35% per pass, or 90–100% based upon the dichloride consumed in the reaction.

3. Of the catalysts investigated, activated alumina showed a marked superiority, being especially resistant to deactivation at 350° as contrasted with catalysts such as silica gel.

4. The products of the hydrolysis of 1,2-dichloro-2-methylpropane were separated and the aldehyde produced was identified as isobutyraldehyde.

Tetraalkyl Barbituric Acids

BY ARTHUR W. DOX

For the preparation of 1,5,5-trialkylbarbituric acids two methods are available: (1) condensation of the dialkylmalonic ester with an alkylurea, and (2) direct alkylation of the 5,5-dialkylbarbituric acid. The first of these procedures was used by Fischer and Dilthey[1] and subsequently extended by Dox and Hjort.[2] The second method was studied by Dox and Jones[3] in the case of the more reactive halides such as benzyl chloride and allyl bromide, and by Lyons and Dox[4] with the still more reactive *p*-nitrobenzyl chloride.

Although the 5,5-dialkylbarbituric acids exist theoretically in two tautomeric forms, so that both N-alkyl and O-alkyl derivatives might be expected to result from direct alkylation of the sodium salt, only the former have actually been obtained and identified. The 1-benzyl-5,5-diethylbarbituric acid obtained by Dox and Jones[3] by direct alkylation of sodium barbital was identical with that prepared by them from ethyl diethylmalonate and benzylurea.

Marotta and Rosanova[5] recently claim to have obtained both tautomeric forms in the methylation of barbital by diazomethane. Their N-methyl derivative melted at 154° and was obviously identical with that which Fischer and

Dilthey[1] had obtained from ethyl diethylmalonate and methylurea. In addition to this crystalline product Marotta and Rosanova obtained a non-crystallizing sirup which they assume to be the tautomeric O-methyl barbital having the isourea structure. Mention is made of methoxyl determinations but no analytical data are given. They make no mention whatever of the possibility that *both* nitrogens may have been methylated. As will be shown presently this is undoubtedly what occurred, and the non-crystallizing sirup which they assume to be the tautomeric monomethylbarbital was in reality an impure preparation of the low-melting dimethylbarbital.[6]

Experimental

Methylation was performed by dissolving the di- or trialkylbarbituric acid in a dry ether solution of diazomethane prepared by distilling ethyl N-nitroso-N-methylcarbamate with alcoholic potassium hydroxide in ether. Except in one instance where it was desired to obtain the monomethyl barbital, an excess of diazomethane was used. At room temperature the evolution of nitrogen began almost immediately and the reaction was complete in about an hour. Evaporation of the ether left a sirup which in a few instances crystallized readily, but more often required cooling or seeding, and occasionally did not crystallize at all. In two instances diazoethane, prepared similarly from the nitrosoethylurethan, was used for ethylation.

In the first experiment barbital was methylated with one equivalent of diazomethane. Evaporation of the solvent gave a crystalline product which on recrystallization from alcohol formed large prisms melting at 154°. Mixed with authentic methylbarbital the melting point showed no depression. A sirupy mother liquor failed to crystallize. This corresponds to the supposed O-methylbarbital of Marotta and Rosanova.

1,3-Dimethyl-5,5-diethylbarbituric Acid. (Dimethylbarbital.)—When barbital was treated with an excess of diazomethane, as shown by persistence of the yellow color after the evolution of nitrogen had ceased, evaporation gave only the sirup. This did not crystallize on cooling and stirring, but when seeded with a small crystal that had formed on the stem of the funnel through which the ether solution had been filtered, the sirup crystallized promptly and completely. The crystals melted at 32–34°, and recrystallization from ether raised the melting point to 37°. A peculiar property of the substance is its tendency to form a super-cooled sirup which immediately crystallizes when seeded with a crystal of the same substance. The yield was practically quantitative. The substance is readily volatile with steam, and is soluble in the usual organic solvents including petroleum ether, but insoluble in sodium hydroxide. It separates as an oil when the alcohol or acetone solution is diluted with water.

Anal. Calcd. for $C_{10}H_{16}O_3N_2$: C, 56.60; H, 7.55; N, 13.21. Found: C, 56.29; H, 7.37; N, 13.41.

The identity of the substance was corroborated by another method of synthesis. Diethylmalonyl chloride was condensed with symmetrical dimethylurea[7] by heating the mixture in an oil-bath for twelve hours at 135–140°, finally raising the temperature to 150°. The reaction product was dissolved in ether and shaken successively with water, *N* sodium hydroxide, *N* sulfuric acid, water, and finally dried with calcium sulfate. Evaporation of the ether left a sirup which immediately crystallized when seeded with a crystal of the product described above. The melting point was 37°, and mixed melting point showed no depression.

1,3-Dimethyl-5-ethyl-5-phenylbarbituric Acid. (Dimethyl-phenobarbital.)—Phenobarbital was methylated in the same manner. In contrast to the corresponding barbital derivative it crystallized spontaneously, possibly because of its higher melting point, 88–89°.

Anal. Calcd. for $C_{14}H_{16}O_3N_2$: C, 64.61; H, 6.15; N, 10.77. Found: C, 64.27; H, 6.57; N, 10.67.

These tetraalkyl barbituric acids, like the following homologs prepared from other 5,5-dialkylbarbituric acids and diazomethane or diazoethane, contain no replaceable hydrogen and hence are insoluble in sodium hydroxide. The yields were practically quantitative. Several of these products have failed to crystallize, but from the peculiar behavior of the dimethyl-barbital it may be assumed that crystallization will readily occur when once a crystal for seeding has been obtained. In three instances a 1,5,5-trialkylbarbituric acid was alkylated on the second nitrogen by the diazoalkane method.

Several of these substances possess asymmetric structure and should be separable into optical isomers. This was not attempted because the substances have neither acidic nor basic properties and cannot form salts with optically active bases or acids.

The action of diazomethane on barbituric acids containing only one alkyl in the 5-position has been studied

---

(7) The dimethylurea was kindly supplied by Dr. Henry Gilman of Iowa State College.

by Biltz and Wittek.[8] They obtained the same trimethylbarbituric acid by diazomethane treatment of barbituric, 1-methylbarbituric and 1,3-dimethylbarbituric acids. Both nitrogens are thus amenable to methylation by diazomethane, but only one of the methylene hydrogens. To obtain a tetraalkylbarbituric acid with this reagent both of the methylene hydrogens must be previously substituted. The other method in which a symmetrical dialkylurea is used requires a condensation with the acid chloride instead of the ester of the dialkylmalonic acid. Fischer and Dilthey thus prepared the tetraethylbarbituric acid but failed to crystallize it, possibly because of its low melting point. Otherwise its properties were similar to those of the 1,3-dimethyl-5,5-diethylbarbituric acid prepared by both methods and described above.

---

(8) Biltz and Wittek, *Ber.*, **54**, 1035 (1921).

Summary

Treatment of 5,5-dialkyl- or 1,5,5-trialkylbarbituric acid with diazomethane in ether solution gives practically quantitative yields of tetraalkylbarbituric acids in which both nitrogens have been methylated. A similar reaction occurs with diazoethane.

The statement of Marotta and Rosanova that the two tautomeric monomethyldialkylbarbituric acids are thus formed is erroneous. The supposed O-methylbarbital which they obtained as a sirup is in reality the low melting di-N-methyl derivative.

Absorption Edges in the X-Ray Patterns of Native and Mercerized Cellulose

BY WAYNE A. SISSON,[1] GEORGE L. CLARK AND EDWARD A. PARKER[2]

In addition to the spacings of the currently accepted unit cell of cellulose,[3] numerous reports of other long spacings have appeared from time to time in the literature. Spacings of 16.0 and 35.3 Å.;[4] 7.9 or 8.3 Å.;[5] 50.0 Å.;[6,7] 274, 168, 156 and 85 Å.;[8,9] 42.2, 44.9, 66.5 and 83.5 Å.;[10] and 40 to 50 Å.,[11] have been interpreted as being due either to micellar dimensions, or to periodicities larger than the usual diffracting planes of the cellulose unit cell.

The authors[12] recently reported three new "interferences:" two (10.1 and 13.4 Å.) in native cellulose and one (14.2 Å.) in mercerized cellulose, which appear most intense in the pattern when the x-ray beam (Cu K) is parallel to the fiber axis. Regardless of the fibers used, these "spacings" were found to be constant, which indicated that they were not due to non-cellulosic constituents.

With other radiations (Mo, Fe and Cr), the "spacings" were found to vary, while the usual cellulose diffraction lines remained constant, as can be seen by comparing the original negatives of Figs. 1 and 2. The "spacings" were parallel to the 101 and 002 planes in native and the $10\bar{1}$ plane in mercerized cellulose. They were very weak with molybdenum radiation, but increased in intensity with larger values of λ, until with chromium radiation they are almost as intense as the usual diffraction lines. It is the purpose of the present paper to show that these new "spacings" are absorption edges.

It is well known that any element placed in an x-ray beam will absorb to a greater extent those wave lengths just shorter than that element's absorption edges, and on the long wave length side of this edge the x-ray beam will be less affected. If the planes in cellulose diffract general as well as characteristic radiation, definite bromine and silver absorption edges for each plane will appear on the x-ray film which would be similar to and might be mistaken for true diffraction lines.

Since the 002 (3.98 Å.) and 101 (6.10 Å.) planes in native and the $10\bar{1}$ (4.40 Å.) plane in mercerized cellulose diffract characteristic radiation to the greatest degree, they should behave likewise

[a] Absorption edge superimposed on diffraction line.

are interpreted as being due to diffracted monochromatic radiation from the anticathodes listed in column 5, then the spacings to which they would correspond are given in column 7. In column 9 the experimentally observed spacings (assuming monochromatic diffraction) are listed opposite the nearest calculated spacing in column 7. It is readily seen that the observed spacings correspond to calculated absorption edges for the 002 and 101 planes. Similar data for mercerized cellulose appear in Table II.

There are four criteria for testing the validity of the assumption that the "spacings" listed in column 9 of Tables I and II are absorption edges:

(a) That these edges, for a specified specimen to film distance, will remain at exactly the same place on the film regardless of the radiation.

(b) If a "Flurazure" intensifying screen is used there should be no sharp discontinuities at the bromine and silver absorption edges, but a general fogging throughout the whole region.

(c) It will be necessary to have a peak voltage on the x-ray tube of at least 25 k.v. to produce the silver absorption edge and a peak voltage of 13.5 k. v. to produce the bromine edge.

(d) If a strictly monochromatic beam (*i. e.*, the x-ray beam diffracted from the 101 face of a crystal of calcite) is used, absorption edges will not appear.

Experimental

The x-ray tubes used for the various radiations were: copper—Philips Metalix, line focus, electron tube and a Leiss–Siegbahn, self-rectifying, gas tube; iron—Leiss–Siegbahn, self-rectifying, gas tube; chromium—Leiss–Siegbahn, self-rectifying, gas tube and a modified Langsdin–Wyckoff gas tube; molybdenum—Philips Metalix, line focus, electron tube.

For the fiber patterns, the samples consisted of parallel fibers held firmly and compactly together. For the patterns with the x-ray beam parallel to the fiber axis, the fibers were tied in a parallel bundle and then a small cross section—two millimeters in length giving the best results—was cut and fastened to a mount.

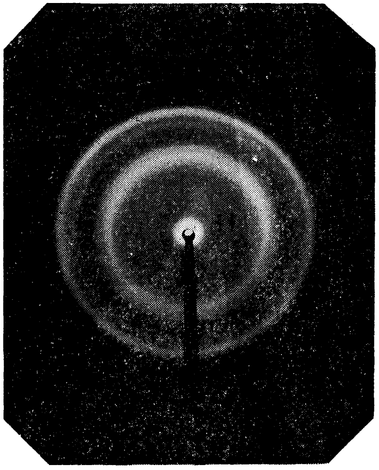

Fig. 1.

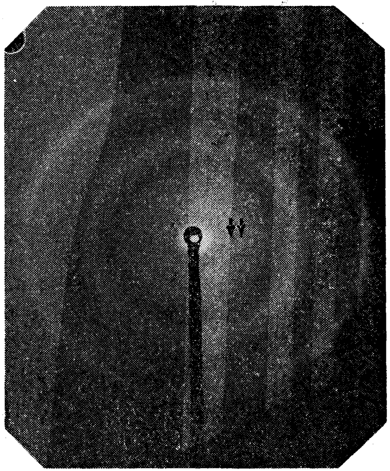

Fig. 2.

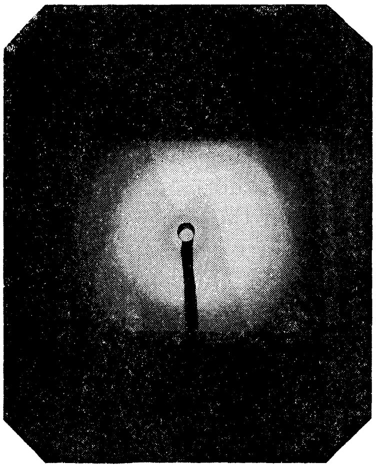

Fig. 3.

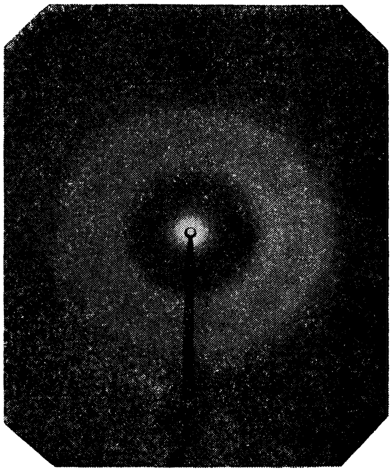

Fig. 4.

1 and 2 show x-ray diagrams of ramie fibers (beam parallel to fiber axis) taken with Cu and Fe radiation, respectively.
3. Same as Figure 2 but with intensifying screen.
4. Same as Figure 1 but with peak 13 k. v. instead of 40 k. v.

With the exception of chromium radiation, where a vacuum camera was used and a specimen to film distance of 4 to 7 cm., all patterns were taken in air and at 5 cm. specimen to film distance.

With iron and copper radiation patterns were taken at peak voltages of 13, 15–24 and 40–60 k. v. At the lowest voltage approximately fifty hours were necessary for the Leiss–Siegbahn tube operating at 2 milliamperes. The Philips copper tube at 25 milliamperes and 13 kilovolts produced patterns in twelve to fifteen hours.

Results

Figures 1 and 2, and column 8 of Tables I and II show how point (a) was fulfilled. All values for column 8 are in centimeters, corresponding to the outer diameter (*D*) of the absorption edges, and are for a specimen to film distance of 5 cm.

For point (b), a study of two diffraction patterns, shown in Figs. 2 and 3, made under exactly the same experimental conditions with the exception that an intensifying screen was used for Fig. 3, shows that with an intensifying screen the absorption edges are missing, and that the fogging due to the shorter wave lengths is quite noticeable.

For point (c), the silver edge was absent for voltages below 25 k. v., and both bromine and silver below 13.5 k. v. This is illustrated in Figs. 1 and 4.

As for point (d), owing to the experimental difficulties involved, the effect of a strictly monochromatic beam reflected from a calcite crystal was not tried, but when a nickel filter was used with copper radiation the intensity of the absorption edges diminished.

The presence of these absorption edges apparently explains some of the large interferences and micellar dimensions which have appeared in the literature. For example, Yoshida and Park's 100 spacing with iron radiation[5] may be explained as a bromine absorption edge. Likewise, if magnesium and aluminum anticathodes are used, the absorption edges for native cellulose would correspond to 36.2, 55.2, 68.4 and 104.8 Å. for aluminum radiation and 42.9, 65.5, 81.2 and 124.3 Å. for magnesium radiation, and these edges approximate some of the spacings found by Corrigan.[10] They also may explain why Sisson[11] was unable to obtain check results with aluminum and magnesium radiation and also why 15 k. v. was necessary to produce interferences. On the other hand, the micellar spacings of 150 to 280 Å. reported by Clark and Corrigan;[8,9] the 50 Å. spacing found in wood by Mark,[6] which he believed to be the cross-sectional size of the micelle; and the 35.3 and 16.0 Å. reported by Herzog and Jancke,[4] do not correspond to absorption edges.

A small strictly parallel pencil of copper radiation, at a sample to film distance of 15 to 20 cm., has been used successfully to identify spacings up to 200 Å. in protein fibers,[13] but no evidence of correspondingly large spacings was found when the method was applied to cellulose.

Summary

1. Diffracted general radiation from the 002 and 101 planes in native and the $10\bar{1}$ plane in mercerized cellulose produces, on the x-ray negative, well-defined bromine and silver absorption edges which are similar in appearance to diffraction lines.

2. Criteria for distinguishing absorption edges from diffraction lines are discussed.

3. Absorption edges correspond to some, but not all, of the large interferences or micellar dimensions for cellulose reported in the literature.

4. No spacings larger than the cellulose unit cell were found.

The Interdiffusion of Acid and Base in Aqueous Solution

BY CECIL V. KING AND WILLIAM H. CATHCART

The interdiffusion of hydrochloric acid and glycine has been studied in some detail by McBain and Dawson.[1] An interesting feature of this double diffusion is the greatly increased rate of passage of material (notably the chloride ion) through the porous partition of the diffusion cell due to the chemical reaction. McBain and Dawson have interpreted the increased diffusion rates in terms of increased over-all diffusion coefficients. In view of the fact that the hydrogen-ion concentration falls to a low value at the point within the porous disk where it meets the glycine, the increased diffusion rates should be interpreted in terms of sharpened concentration gradients rather than enhanced diffusion coefficients. Analysis of the data from this viewpoint is impossible since sufficient details are not given by the authors. The presence of the glycinium ion is a complicating factor and also, as shown below, the experimental method used was probably inadequate for obtaining correct diffusion rates in this type of system.

The present paper reports measurements of the interdiffusion rates of hydrochloric acid and sodium hydroxide in the porous disk cell.[1] It is assumed that the diffusion coefficients are unaffected by the neutralization (the heat of reaction is unimportant with the dilute solutions used), and this assumption is confirmed by the results. The diffusion coefficients are affected, however, by the sodium and chloride ions accumulating in the disk, and this factor must be taken into account.

The interdiffusion of hydrochloric acid and sodium hydroxide has been studied previously by Barry and Smith,[2] by a method of superposing one solution upon the other and following the movement of the boundary and the heat evolved by the neutralization. For our purpose experiments in the porous disk cell are much easier to interpret since under suitable conditions the diffusion gradients are confined to the porous partition.

If A and δ are the effective (not the measured) area and thickness, respectively, of the porous disk, we may assume that the neutralization of acid and base occurs in a plane at a distance y from the surface in contact with base, $\delta - y$ from the surface in contact with acid. The rates are then given, assuming Fick's law to be valid for the experimental arrangement, by

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{AD_A}{\delta - y}\,\frac{a - x}{V_A} = \frac{AD_B}{y}\,\frac{b - x}{V_B} \qquad (1a)$$

where a, b = initial moles acid and base in cell compartments of volumes V_A, V_B; x = moles neutralized at time t; D_A, D_B = diffusion coefficients of the acid and base.

Solving for y and substituting,

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{A}{\delta}\left[\frac{V_BD_A(a - x) + V_AD_B(b - x)}{V_AV_B}\right]$$

If D_A and D_B are constants under the conditions of the experiment, this expression can be integrated as follows

$$kt = \frac{V_AV_B}{V_BD_A + V_AD_B}\ln\frac{V_BD_Aa + V_AD_Bb}{V_BD_A(a - x) + V_AD_B(b - x)}$$

where $k = A/\delta$, a "cell constant" dependent on the characteristics of the porous disk only and not on the volumes of the cell compartments. This equation may be rewritten

$$kt = \frac{V_AV_B}{V_BD_A + V_AD_B}\ln\frac{D_AC_A + D_BC_B}{D_AC'_A + D_BC'_B} \qquad (1)$$

where C_A, C_B are initial concentrations of acid and base, C'_A, C'_B are concentrations at the time t.

The corresponding equation for a single diffusion is, in a form convenient for use

$$kt = \frac{V_AV_B}{(V_A + V_B)D}\ln\frac{C_A}{C_A - (1 + V_B/V_A)C''_A}$$

where C''_A is the concentration of diffusing solute in the cell compartment which initially contained pure solvent. This equation was used in establishing cell constants and for the other single diffusions reported.

Experimental

Several cells were used in the course of this work, but all the final experiments were run in one rotating cell of the type described by Mouquin and Cathcart.[3] McBain and Dawson have given 2.71 sq. cm./day as the diffusion coefficient of 0.1 molar hydrochloric acid into pure water at 25°,

and this value was used in determining all cell constants.

Rotating Cell Constant.—The volumes of the cell compartments were V_A = 69.6 cc., V_B = 71.2 cc. The cell was rotated approximately forty times per hour, both in determining the cell constant and in the double diffusion experiments. Data are given in Table I.

TABLE I

ROTATING CELL CONSTANT DETERMINATION (25 ± 0.02°)

C_{HCl}, *M*	Time, hours	C'_{HCl}, *M*	*k*
0.1002	17.75	0.00962	3.78
.0995	18.25	.00996	3.85
.0983	26.67	.01377	3.87
.0982	26.83	.01380	3.88

Salt Effect on the Diffusion Coefficients.—The diffusion coefficient of an electrolyte varies somewhat with its own concentration, but, in general, this variation amounts to only a few per cent. up to 0.1 *N* solution. The variation has been explained quantitatively for very dilute solutions in terms of the interionic attraction theory. The effect of salts on the diffusion coefficients of dilute acids and bases is much greater and has not yet been accounted for quantitatively. Since in the interdiffusion experiments acid and base diffuse into the disk, sodium and chloride ions outward in both directions, the diffusion coefficients will vary continuously with the concentration gradients unless the experiments are carried out in such a medium that the salt formed will not have this effect.

For this reason, the diffusion coefficients of acid and base were determined in solutions containing added sodium chloride. This was first done in stationary cells but, as shown below, it was found necessary to establish the curves with the rotating cell also. The coefficients of both acid and base reach maxima between 0.2 and 0.4 molar salt and apparently decrease again at higher concentrations. Measurements in the rotating and stationary cells check well with sodium hydroxide, but this is not true with hydrochloric acid. Presumably the coefficients of both should continue to rise with increasing salt concentration, the hydrogen ion reaching a value near 8 sq. cm./day when freed of all retarding effects of the negative ion.[1] This value assumes, however, no effect due to the increased viscosity of the concentrated salt solution, and ionic mobilities of the same value as at infinite dilution. In practice, 6 sq. cm./day is about the highest value reached in sodium chloride (Table II); the decrease at higher salt concentration may be real or may be due to inadequacy of the experimental method. Since the rotating cell gives higher values than the stationary cell and results below show that these higher values are substantially correct, it is possible that inadequate stirring in the cell compartments of even the rotating cell is responsible for the decreasing values obtained at high salt concentrations.

[a] Approximately the same as 0.1 *M* HCl. S = stationary, R = rotating cell.

Interdiffusion Experiments.—All these experiments were run with 0.4 molar sodium chloride in both compartments of the rotating cell, since the diffusion coefficients have their maximum value at this concentration and the higher concentration accumulating within the disk cannot affect the coefficients much. Three experiments were run, in duplicate, with acid and base concentrations between 0.04 and 0.06 molar, since the single diffusions were run at approximately 0.05 molar. The values do not change much with acid or base concentration, however, and one pair of experiments was run with 0.1 molar acid, 0.05 molar base. The values D_A = 6.05, D_B = 3.55 were selected as the approximate maxima from Table II and Fig. 1 and used in equation (1) in calculating the cell constant *k* as shown in Table III.

TABLE III

CELL CONSTANTS FROM INTERDIFFUSION EXPERIMENTS IN ROTATING CELL (25°). 0.4 *M* NaCl IN BOTH CELL COMPARTMENTS

Expt.	C_A	C_B	Time, hours	C'_A	C'_B	k
6	0.0498	0.0497	22.33	0.0301	0.0304	3.915
7	.0498	.0497	41.5	.01915	.0200	3.955
8	.0598	.0397	18.5	.04225	.0220	3.89
9	.0598	.0397	25.0	.0378	.0172	3.86
10	.04025	.0595	25.17	.0195	.0383	4.06
11	.04025	.0595	24.6	.0199	.0388	4.03
4	.0997	.0537	23.0	.0679	.02185	3.685
5	.0997	.0537	26.75	.0641	.0183	3.67

Samples of both acid and base were titrated before and after the diffusion, and a comparison of the values in Table III shows that the method is not very precise unless more precautions are taken than were thought necessary for the present purpose. The greatest discrepancy in moles of acid and base disappearing is 4.4% in experiment 9. The error in k caused by an error of 1% in any one term of equation 1 (*i. e.*, in D, V, C, C', etc.) is approximately 1%.

In Table IV are given the results of two interdiffusion experiments carried out in the same cell without rotating, the first with the acid in compartment A above, the second with base in compartment B above. The density of the sodium hydroxide solution was found by measurement to be greater than that of the acid. More moles are neutralized in less time with the base above the acid; in neither case does the diffusion proceed with the theoretical speed as shown by the very low values of k. The constant of this cell was not determined (with 0.1 molar hydrochloric acid diffusing into water) with the cell stationary, but it should be approximately 3.65.[3]

TABLE IV

INTERDIFFUSION WITH CELL STATIONARY, 25°C., 0.4 *M* NaCl

Expt.	C_A	C_B	Time, hours	C'_A	C'_B	k
20[a]	0.04925	0.0484	27.33	0.0367	0.0360	1.89
21[b]	.04925	.0484	24.17	.0348	.03405	2.53

[a] HCl above. [b] NaOH above.

Discussion.—While the greatest variation of k in Table III is 5.6% from the mean value of Table I, the average of all results is only 1.0% different. The variations are evidently due largely to the difficulty of choosing correct values of D_A, D_B and the change of the latter with acid and base concentration. The picture of the interdiffusion represented by equation (1) is fully substantiated.

The fact that the maximum coefficient for hydrochloric acid obtained with the rotating cell must be used to obtain the agreement of cell constants, as well as the fact that interdiffusion experiments in the stationary cell give abnormal results, indicates that the rotating cell has a wider range of applicability. The latter experiments especially indicate that the diffusion gradients are not confined to the porous disk unless the density relations allow adequate stirring to be maintained by convection currents, or mechanical stirring is introduced.

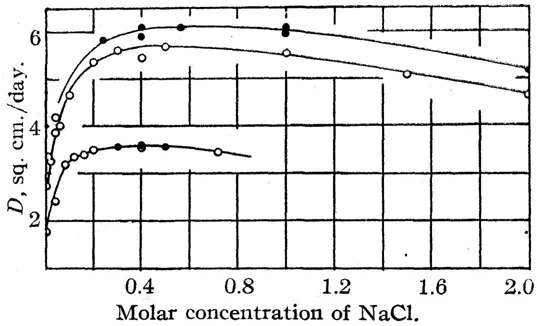

Fig. 1.—Diffusion coefficients in sodium chloride solutions: lower curve, NaOH; upper curves, HCl; ○, stationary cell; ●, rotating cell.

The point within the disk at which the neutralization occurs varies with the diffusion coefficients and concentrations of the reagents, and can be calculated from equation (1a). In the present case with equal acid and base concentrations in the presence of 0.4 molar sodium chloride, it occurs at a distance 0.37 δ from the surface in contact with the base.

Since this paper was written, an interesting and useful "multimembrane" method of studying diffusion processes has been published by Teorell.[4] In one interdiffusion experiment, the "diffusion layer" between equimolar hydrochloric acid and sodium hydroxide solutions was separated into seven portions by cellophane membranes; samples from the several compartments were analyzed after twenty-four hours, and the concentration gradients of the various ions thus recorded. The solutions contained no added salt; the neutralization occurred 0.375 of the total distance from the base compartment.

Summary

The diffusion coefficients of hydrochloric acid and sodium hydroxide have been measured in the presence of added sodium chloride over a wide concentration range.

---

(4) Teorell, *J. Biol. Chem.*, **113**, 735 (1936).

The rate of interdiffusion of the same acid and base in sodium chloride solution has been studied. It is shown that the diffusion coefficients are unchanged if sufficient sodium chloride is present initially; in the porous disk cell, the diffusion *rates* are, however, greatly increased since the concentration gradients become much sharper because of the neutralization within the disk.

Some limitations of the porous disk diffusion cell are demonstrated. Adequate mixing must be maintained in the cell solutions either by natural convection or by auxiliary stirring.

The Conductance of Salts (Potassium Acetate) and the Dissociation Constant of Acetic Acid in Deuterium Oxide

BY VICTOR K. LA MER AND JAMES P. CHITTUM

The accurate calculation of the dissociation constant of a weak acid, like acetic acid, in deuterium oxide requires values of comparable accuracy of the limiting conductances Λ_0, of deuterochloric acid, potassium chloride and potassium acetate. In ordinary water the problem is solved by measuring a series of conductance values at increasing dilutions and controlling the extrapolation to infinite dilution by the Onsager[1] equation.

The limited quantities of heavy water available do not permit execution of this tedious and experimentally difficult problem at this time. We are accordingly interested in establishing the validity of two approximate rules, which will permit the calculation of Λ_0 for the deuteronium ion and for the anion of the weak acid with sufficient precision for present purposes from a single measurement at an experimentally convenient concentration ($C = 0.01$) in heavy water which is not necessarily 100% D_2O.

These rules are

$$[\Lambda_c/\Lambda_0]_{H_2O} = [\Lambda_c/\Lambda_0]_{D_2O} \qquad (1)$$

valid for acids and salts in pure D_2O, but presumably accurate only for salts in intermediate mixtures of D_2O–H_2O, owing to the complication of the exchange reactions which acids suffer in the mixed waters.[2]

$$\Lambda\eta = \text{Constant};\ \eta = \text{Viscosity}, \qquad (2)$$

valid for interpolation and for extrapolation to pure D_2O of the data obtained for the salts in H_2O–D_2O mixtures.

The justification of (1) follows from the Onsager equation[3]

$$\Lambda_c = \Lambda_0 - [\alpha\Lambda_0 + 2\beta]\sqrt{C} \qquad (3)$$

where

$$\alpha = \frac{8.173 \times 10^5}{(DT)^{3/2}} \text{ and } \beta = \frac{41.7}{(DT)^{1/2}} \times \frac{1}{\eta} \qquad (4)$$

Let $\beta' = 2\beta\eta$, then α and β' differ in H_2O and D_2O only by the ratio of the dielectric constants of H_2O and D_2O which ratio appears to be almost unity.[4,5]

$$\Lambda_c/\Lambda_0 = 1 - [\alpha + \beta'/\Lambda_0\eta]\sqrt{C} \qquad (5)$$

and

$$\frac{[\Lambda_c/\Lambda_0]_{H_2O}}{[\Lambda_c/\Lambda_0]_{D_2O}} = 1 + \frac{\beta'\sqrt{C}\,[1/(\Lambda_0\eta)_{H_2O} - 1/(\Lambda_0\eta)_{D_2O}]}{1 - [\alpha + \beta'/(\Lambda_0\eta)_{D_2O}]} \qquad (6)$$

The experimental data on potassium chloride and on potassium acetate presented below show that $(\Lambda_0\eta)_{H_2O}$ differs from $(\Lambda_0\eta)_{D_2O}$ by only 1.93%. Hence equation (6) reduces without appreciable error to equation (1).[6]

The error in $\Lambda_0(D_2O)$ calculated through equations (1) and (6) is thus less than 0.1% and less than our present experimental errors. The Λ_c *vs.* $\sqrt{C}$ curves in D_2O are, therefore, sensibly parallel to those in H_2O, and the D_2O curve can be constructed from a measurement of Λ at a single low concentration.

Since the only difference in the limiting conductance of non-acid ions in D_2O and in H_2O appears to be resident in the change in β, the electrophoretic part of the Onsager equation, we expect

[6] η does not change significantly on passing from $C = 0.01$ to $C = 0$.

TABLE I

$\frac{\Delta S}{0.1079} = N_{D_2O}$	0.0	27.4	77.0	93.0	97.0	100.0
$10^5 K'$ acetic	1.84	1.352	0.741	0.608	0.575	(0.555)
Λ_{0KAc}	114.4	108.1	98.2	96.0	95.5	(94.7)
$(\Lambda_0\eta)$ KAc	114.4	115.0	115.8	116.4	116.5	(116.6)
$\Lambda_0\eta^{0.913}$ KAc	114.4	114.4	114.1	114.5	114.5	
Λ_0 (HAc-DAc)	390.6	345.6	297.5	285.9	285.2	
A (Eq. 8)	148.6	134.8	117.2	114.2	113.7	

that $\Lambda_0(H_2O)/\Lambda_0(D_2O)$ is practically constant for all completely dissociated salts of the same valence type and equal to approximately η_{D_2O}/η_{H_2O}.

Experimental.—The measurements on potassium acetate have been made at 25°, using a Jones bridge and the semi-micro method described previously,[2] at approximately 0.015 N at different mixtures of H_2O–D_2O. Λ_0 obtained by linear extrapolation from 93 and 97% D_2O is 94.8 Kohlrausch units (K. U.), a decrease of 17.1% from the H_2O value. The corresponding decrease for potassium chloride is 17.2%. Table I shows that the empirical equation

$$\Lambda_0\eta^{0.913} = \text{Constant} \qquad (7)$$

shown in the previous paper to be valid for potassium chloride, applies equally well to potassium acetate. The value of Λ_0(KAc) at 100% D_2O calculated either from equation (1) or (7) is 94.7 K. U.

Dissociation Constant of Acetic Acid.—The stoichiometric constant for approximately 0.02 N acetic acid, has been calculated using the MacInnes–Shedlovsky[7] method for each H_2O–D_2O mixture (Table I), by omitting the last (empirical) term in the equation

$$\Lambda_\epsilon(\text{HAc}) = \Lambda_0 - A\sqrt{C_i} + Bc\,(1 - \alpha\sqrt{C}) \qquad (8)$$

Λ_0 (HCl) and Λ_0 (KCl) were calculated by means of equation (1). A short series of approximations gives Λ_ϵ and hence C_i from $(1000\,\bar{L})/\Lambda_\epsilon$. ($\bar{L}$ = specific conductance of solution.)

The stoichiometric constant K' is defined as $C_i^2/(C - C_i)$, where C is the stoichiometric concentration of the acid. Linear extrapolation from 93 to 97% D_2O (Fig. 1, curve 1), gives $K' = 0.555 \times 10^{-5}$ for deutoacetic acid, which compares favorably with Lewis and Schutz' estimate of 0.59×10^{-5} obtained on less than one cc. of solution. Our value proves to be in excellent agreement with the value of 0.55×10^{-5} obtained by Korman and La Mer[8] from the e. m. f. of quinhydrone–silver chloride, Ag cells without transference and a formula defined by them for extrapolating K to 100% D_2O.

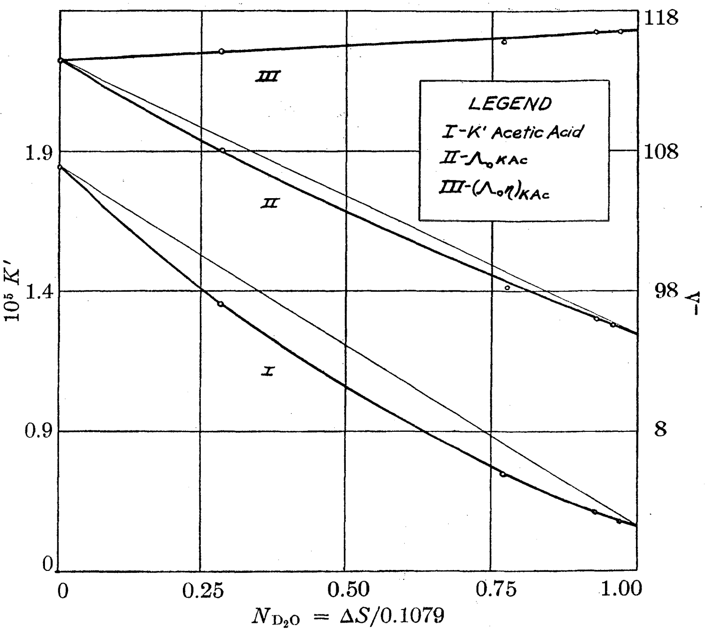

Fig. 1.

As was found previously for potassium chloride Λ_0 for potassium acetate exhibits a small negative deviation of approximately 2% at $N_{D_2O} = 0.5$. On the other hand, the dissociation constant of hydrogen acetate exhibits a much larger negative deviation from linearity amounting to 10% at $N_{D_2O} = 0.5$. The nonlinear behavior of the dissociation constant when plotted against the deuterium content of the solvent $N_{D_2O} = \Delta S/0.1079$ arises from the complications of the proto- and deuterotropic exchanges in the mixtures as was suggested for the Λ hydrogen chloride curve, which exhibits a negative deviation of 6.5% at the midpoint. Similar deviations from linearity are uniformly

---

(7) MacInnes and Shedlovsky, THIS JOURNAL, **54**, 1429 (1932). We did not attempt the precautions taken by these authors, namely, of adding traces of HAc to KAc solutions because of the small volumes of D_2O available.

exhibited in the kinetic processes of acid–base catalysis.[9,10]

Summary

The Walden constant = $\Lambda_0\eta$ increases (linearly) by 1.93% on passing from H_2O to D_2O for both potassium acetate and potassium chloride. With this equation and the rule

$$[\Lambda_c/\Lambda_0]_{H_2O} = [\Lambda_c/\Lambda_0]_{D_2O}$$

which follows from the Onsager equation and the Walden rule, it is shown how the dissociation constants of weak acids in D_2O may be calculated with satisfactory accuracy from a limited amount of conductance data. K' (acetic acid) equals 0.55×10^{-5} in pure D_2O, and exhibits a marked negative deviation (10%) from linearity on passing from H_2O to D_2O.

Ternary Systems. XXI. Lead Nitrate, Ammonium Nitrate and Water at 25°

BY ARTHUR E. HILL AND NATHAN KAPLAN

The effect of potassium nitrate in increasing the solubility of lead nitrate inwater led Le Blanc and Noyes[1] to the explanation of double salt or complex ion formation in the liquid phase. Solubility determinations by Glasstone and Saunders[2] at temperatures between 25 and 100° gave no evidence of double salts as solid phase, and similar experiments by Ehret[3] at 0° gave likewise a negative result. The work of Glasstone and Saunders[2] with sodium nitrate as added salt showed a decrease in solubility of lead nitrate, also without formation of double salt in the solid phase. The effect of ammonium nitrate, which has a much higher solubility than the corresponding sodium and potassium salts, permitting the investigation to cover a wider range of concentrations, is here reported.

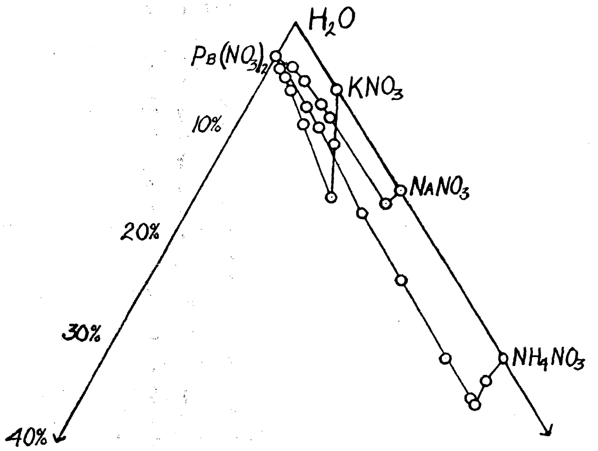

Fig. 1.—25° Isotherm, $Pb(NO_3)_2$–NH_4NO_3–H_2O, in mole per cent.

Pure recrystallized lead nitrate and ammonium nitrate were used in making up the complexes, which were rotated in closed tubes for several days at 25 ± 0.03°. The solutions at equilibrium were analyzed by evaporation of a weighed sample to give total solids, and the determination of lead as lead sulfate by the standard method. The results are given in Table I.

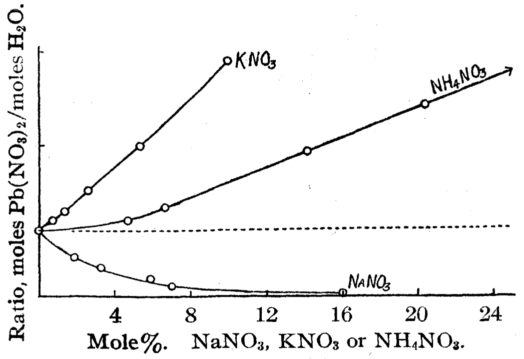

Fig. 2.—Effect of added nitrate on solubility of $Pb(NO_3)_2$ at 25°.

The solubility curves, plotted in molar percentages, are shown in Fig. 1. On the same diagram are shown the results of Glasstone and Saunders[2] for potassium nitrate and sodium nitrate. It is apparent that the effect of ammonium nitrate upon the solubility of lead nitrate is intermediate between the effects of the potassium and sodium salts, at similar molar concentrations. There is no indication of double salt formation as solid phase; tie lines drawn through the compositions

...	...	0.00	68.17		NH_4NO_3

of saturated solution and original complex pass through the compositions of the two simple salts with average deviation of 1.1%.

From the molar ratio of lead nitrate to water, shown in column 5, it is apparent that addition of ammonium nitrate increases the solubility of the salt markedly. A plot of the change in solubility, as thus defined, is shown in Fig. 2, in which are shown also curves for potassium nitrate and sodium nitrate calculated from the work of Glasstone and Saunders.

Summary

The solubilities in the system $Pb(NO_2)_2$–NH_4NO_3–H_2O at 25° have been determined. The solubility of lead nitrate is increased by ammonium nitrate, but to a smaller degree than by potassium nitrate. No double salts have been found as solid phases.

Studies in the Mechanism of Decomposition. I. The Vapor Phase Photolysis of Acetic Acid

BY MILTON BURTON

In order to explain certain observations on the pyrolysis of acetic acid, Hurd[1] suggested the formation of ketene as an intermediate reaction product. F. O. Rice[2a] showed that such formation might be considered a logical consequence of a free radical chain mechanism. However, Franck and Rabinowitsch,[3] in discussing the photolysis of organic molecules by the intermediary of free radicals and atoms, pointed out that certain polyatomic molecules might decompose directly into stable molecules and that the work of L. Farkas and Wansbrough-Jones[4] indicated that acetic acid is an example of such a compound. That conclusion was based primarily upon an analysis of the ultimate products of the decomposition, which showed such a clear correspondence of yields among the products that the two reactions following appeared to be the only tenable ones in the gaseous state

$$CH_3COOH + h\nu \longrightarrow CH_4 + CO_2 \qquad (1)$$

$$(CH_3COOH)_2 + h\nu \longrightarrow C_2H_6 + CO + CO_2 + H_2O \qquad (2)$$

Although they reported a yield of approximately 1% by volume of hydrogen, Farkas and Wansbrough-Jones favored the idea that that substance, as well as traces of acetylene found, might be a product of some subsequent reaction of the resultant molecules.

This appears to be a clear-cut case in which to test whether decomposition takes place by rupture into free radicals or by rearrangement of a stable constellation of groups into stable constellations of ultimate molecules. The mirror methods developed by Paneth[5] and by F. O. Rice and his co-workers[6] and used by Pearson[7] in the study of the photochemical decomposition of aldehydes and ketones are well suited to the test. In a previous communication[8] the writer described a procedure for the detection of hydrogen atoms in the presence of free radicals and indicated evidence for the reactions

$$CH_3COOH + h\nu \longrightarrow CH_3 + COOH \qquad (3)$$

$$COOH \longrightarrow CO_2 + H \qquad (4)$$

to account for at least part of the photolysis of acetic acid.

In this report, evidence will be presented which will show that the photolysis of acetic acid can be explained entirely by a free radical mechanism but that the above indicated mechanism is incorrect.

Experimental

Light Sources.—In the work reported in the previous communication and referred to briefly in Part I following, a quartz Hanovia mercury vapor lamp operating in series with a rheostat on a 110-volt storage battery line was used. At that time no special precautions were employed to maintain constancy of current, which was held at about 4–5 amperes.

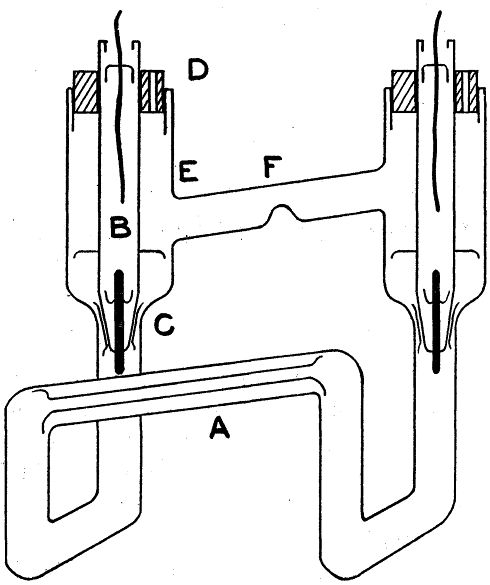

Fig. 1.—Capillary mercury arc.

In all later work the quartz capillary mercury arc shown in Fig. 1 was employed. It is a modification of the lamp described by Forbes and Heidt.[9] The capillary tube A has a slight slope and is 4 cm. long and about 2 mm. in internal diameter. The entire lamp is of quartz except for the tubes B, which are of Pyrex glass. The bottoms of those tubes have tungsten wires sealed in as shown and are ground to fit into the quartz tubes at C. The openings at C may be regulated by withdrawing the tubes B slightly. The tubes are thereafter held in fixed position by the rubber stoppers D, which are grooved to permit ready access of air into the reservoirs E. The tube F serves to permit flow of mercury from one reservoir to the other as described by Forbes and Heidt. (In the writer's experience with this lamp no such flow of mercury was observed even on three-hour periods of operation. The mercury levels were never that far displaced.) Contact is made by inserting nickel or iron wires in the mercury in the tubes B. The wires are so connected that the upper end of the capillary is negative. The lamp as described was used in a 110-volt battery circuit containing a rheostat so adjusted as to permit a current of 4.0 amperes. In starting the lamp the mercury column in A was broken by heating with a sharp flame. During operation a rapid stream of water was flowed over the capillary tube from an ordinary wing-top which had been cut down so that its edge would rest evenly on the full length of the tube. The lamp was supported in a glass funnel in such a way as to drain off the water. It was not necessary to keep the legs of the lamp immersed, for water was flowing down them constantly during operation. The filling of the tube was conducted simply by boiling out the air while holding the tube at a convenient angle to promote entrance of mercury. From time to time, between runs, the outer surface of the capillary was cleaned with hydrochloric acid.

Chemicals.—The acetic acid used was the analyzed product of General Chemical Co., of A. C. S. grade. It was subjected to four recrystallizations and decantations before introduction into the apparatus. Only about 25% of the original sample was used. The acetone was the A. C. S. grade of Eimer and Amend further purified by the method of Shipsey and Werner[10] to a constant boiling point of 56.0° uncorrected. The sodium bromide and sodium chloride were Eimer and Amend T. P. grades and were merely dried to constant weight at 130° before use.

Apparatus and Technique.—The methods used were very similar to those already described by Pearson.[7] The apparatus is indicated in Fig. 2. The purified liquid was introduced into reservoir A, frozen (or cooled) in carbon dioxide–toluene mixture, evacuated, and then allowed to warm to room temperatures (above the melting points both of acetone and of acetic acid). This process of cooling, evacuation and warming was repeated once in reservoir A. Then, by suitable manipulation of the stopcocks and application of the freezing mixture, the liquid could be distilled to either of the reservoirs B or C where it was subjected to further repeated cooling, evacuation and warming as already described for at least three additional successive times. In this way entrapped gases were eliminated.

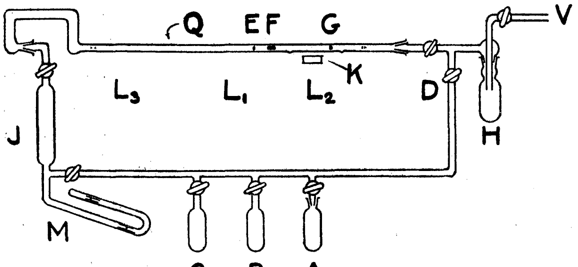

Fig. 2.—Reaction system.

Regular stopcock grease was used in all stopcocks and joints. The length of the constricted portion of the tubing, including the quartz reaction tube Q and allowing for the ground glass joints to which it was sealed, was fixed at 88 cm. The tube Q had an average internal diameter of almost exactly 5 mm. The tube J contained silver turnings intended to trap out mercury vapors. The mercury manometer M had a slope ratio of 25:1 and permitted

[a] Expt. 24 followed sixteen hours after expt. 23.

readings accurate to 0.01 mm. The apparatus was connected to a carbon dioxide–toluene trap and a mercury vapor pump system at V. During a run, the path of the vapors was from one of the reservoirs A, B or C through J and the reaction tube Q to the receiver H, which was cooled in a carbon dioxide–toluene mixture. After the reservoir was exhausted the liquid was then distilled back from the receiver H through the now opened stopcock D to the reservoir. It was found that the small amount of product impurity formed during the photolyses did not sensibly affect the results in subsequent runs. The irradiated zones were at either L_1, L_2 or L_3, as will be indicated below. K represents a light filter (cooled with flowing water during runs) containing a suitable solution between crystal quartz plates 1 cm. apart. A copper cylinder around the reaction tube served as a screen which was used while the arc and the flow of gas were adjusted. It was slipped aside at zero time, exposing the irradiated zone but shielding the mirror or mirrors. When the filter was not used, the reaction tube itself was cooled with running water. Under no circumstances did the temperature of the reaction tube rise above that of the room.

Part I. Detection of Atomic Hydrogen in the Presence of Methyl.—In these early experiments, the results of which have already been reported,[8] the apparatus was not quite the same as shown in Fig. 2. The reaction tube system was sealed to the rest of the apparatus and not affixed with ground glass connections. In other respects it was substantially the same as in the latter experiments.

In this part the depression between F and G contained a small pellet of lead; that after G contained one of antimony. A transparent lead test mirror of the weight desired was deposited at E (after suitable preparation of the surface[2]) and a heavy lead guard mirror was deposited at F. A very light antimony mirror was then deposited at G. Such mirrors were deposited only when desired. On some occasions, as is evident from Table I, a mirror might be used for more than one experiment.

In Table I there are indicated the results of a typical series of experiments on the vapors of acetone and of acetic acid. During the experiments of this part, the reaction tube was illuminated at L_1, approximately 40 cm. from its beginning, by the unfiltered Hanovia arc located about 0.7 cm. from the tube. The arc was not always located at the same distance from the beginning of the tube in this series. It is for that reason that the distances of the mirrors from the irradiated zone vary from experiment to experiment.

The efficacy of the heavy lead mirror as a guard to prevent the passage of methyl radicals is indicated with acetone as a known case[7] in expt. 22. It will be shown below that under similar conditions of operation irradiated acetone will yield more than ten times as many mirror-active particles as acetic acid. Lead mirrors may be shifted, but not removed, by hydrogen atoms, while antimony mirrors are attacked both by free methyl radicals and hydrogen atoms.[11] Consequently, it can be concluded from this experiment that, if acetic acid produces only free methyl radicals and no hydrogen atoms, it could be passed through the reaction tube under these same conditions for at least eight hundred and fifty minutes without any visible effect on the antimony mirror. However, expt. 23 showed that acetic acid vapor removed that mirror under similar conditions of operation in seventy-five minutes. A fresh lead mirror was simultaneously attacked in that experiment. The fact that the guard mirror used in expt. 23 was still effective at the end of the run was shown in expt. 24 with acetone, which again failed to remove a fresh antimony mirror. The fact that the antimony mirror used in expt. 24 was

---

(11) Pearson, Robinson and Stoddard, *Proc. Roy. Soc.* (London), **142**, 275 (1933).

sensitive to mirror-active particles was verified in expt. 25 with acetic acid vapor.

Similar experiments were performed from time to time and on the basis of these results it appeared clear that acetic acid was yielding particles capable of attacking lead mirrors and others which would attack antimony although they had no effect on lead. It was concluded and reported[8] consequently that the photolysis of acetic acid yielded both methyl radicals and hydrogen atoms. However, the subsequent results of Part II showed that the effect on the lead mirror could not be quantitatively duplicated. A check-up of the results indicated that, although methyl radicals and hydrogen atoms had been observed simultaneously during the photolysis of acetic acid, they did not both originate in that compound. The hydrogen atoms came from the acetic acid; the methyl radicals came from the acetone which had been adsorbed in the system (perhaps in J) and swept along with the acetic acid. Whenever a series such as shown in Table I was run, there would be apparent formation of methyl radicals during the photolysis of acetic acid. It was only when particular precautions were taken to eliminate the last traces of acetone before the acetic acid runs that no lead mirror removal was observed with the latter.

The conclusions to be drawn from this part are: (1) hydrogen atoms can be detected by this process in the presence of methyl radicals. (2) Acetic acid vapor of itself does not interfere with the sensitivity of lead mirrors to free methyl radicals. (3) Hydrogen atoms apparently are produced during the photolysis of acetic acid vapor.

Part II. Comparisons of Rates of Mirror Disappearance.—The previous part is not conclusive as to the possibility of free methyl formation during the photolysis of acetic acid. It may well be, for example, that under the conditions of the experiments hydrogen atoms are more mirror-active than free methyl radicals, so much so that the latter would not be detected within the time required to establish the presence of the atoms.

This group of experiments was initiated when it was still believed that methyl radicals detected in such experiments as expt. 23 (Table I) were originating in the acetic acid. The purpose was to compare the rates of removal of standard lead and antimony mirrors by acetone and by acetic acid. The former yields only methyl radicals;[7] the product of the latter was in question.[12] The conditions of the test were kept constant for each of the mirrors. The pressure of the vapors was set at approximately 2.3 mm. at the manometer. Standard mirrors were deposited as described by Pearson[7] by comparison with a smoked-glass tube. To obtain some measure of accuracy by this method the results of a large number of runs were averaged. For convenience, the water filter was used with the arc light shown in Fig. 1 at L_2 2.3 cm. from the reaction tube in the antimony tests; in the lead tests the light was placed 1 cm. from the tube at L_1 without a filter. In the first experiments neither the standard lead mirrors nor the standard antimony mirrors were ever satisfactorily removed in the photolysis of acetic acid in a reproducible manner. As already indicated, the erratic results were finally traced to the presence of residual acetone. Satisfactory results for lead and antimony mirrors with acetic acid were obtained only either after the acetone had been thoroughly removed from the system or before it had been introduced. The averaged results of this part are shown in Table II.

TABLE II

COMPARISON OF TIMES OF REMOVAL OF MIRRORS BY ACETIC ACID AND BY ACETONE

	Acetic acid	Acetone
Antimony	35.5 min.	137 sec.
Lead	$\gg$120 min.	39 sec.

Under the conditions of the test it is clear that free methyl caused the disappearance of lead more quickly than that of antimony. If the mechanism of reactions 3, 4 were correct, it could be concluded that half the effect on the antimony mirror with acetic acid might be due to free methyl, *i. e.*, that such radicals by themselves would have caused the removal in about seventy minutes. It would then be expected that the photolyzed acetic acid would remove the lead mirrors in about twenty minutes. It consequently must be concluded either that no free methyl is formed during the photolysis of acetic acid or that its mirror-activity compared with that of hydrogen atoms is so slight that it is unobservable.

In check experiments to find what effect, if any, free methyl might have on the photolysis of acetic acid, a small amount of acetone was introduced deliberately into the acetic acid. The rate of

---

[12] See Rice, ref. 2, pp. 51–54, for the treatment of a parallel case in a mixture containing free methyl and free methylene.

lead mirror removal was then found to depend on the actual quantity of acetone in the acetic acid.

Part III. Effect of Distance of Mirror from the Irradiated Zone.—The evidence so far presented is not absolutely conclusive that no free methyl is formed during the photolysis of acetic acid. It is known that at room temperatures hydrogen atom has a much greater half-life than free methyl.[2b] The shape of the curve showing variation of time of disappearance of the mirrors with distance from the irradiated zone might consequently be used to establish whether or not free methyl is formed during the photolysis of acetic acid.

In this group of experiments no filter was used. The arc of Fig. 1 was located at L_3 so that the edge of the irradiated zone near the mirrors was now 22.8 cm. from the beginning of the constricted portion of the system. The light itself was fixed 1 cm. from the reaction tube. The pressure of the vapors was set at approximately 2.3 mm. at the manometer corresponding to a streaming velocity for acetic acid vapor at the beginning of the constricted region of approximately 29.7×10^2 cm. per sec.

The results of all these experiments (not the averages) are shown graphically in Fig. 3. Pearson's values are plotted from his average figures[7] for acetone entering at a pressure of 1.65 mm. and a streaming velocity of 12.3×10^2 cm. per sec. No explanation is offered at this time for the opposed concavity of the curves obtained by Pearson and by this writer. It should be pointed out that the difference may be related to the different pressures at which the work was conducted as well as to the fact that Pearson's work may have a higher accuracy in view of the greater number of his experiments. It is, however, clear that the general trends of the two curves are similar and quite different from the curve for acetic acid, which is almost a horizontal straight line. Evidently, the half-life of the active product from the photolysis of acetic acid is much greater than that from acetone and is probably hydrogen atom. Also, we are forced to assume either that free methyl is far less effective than hydrogen atom in causing removal of antimony mirrors or that it is entirely absent in the photolysis of acetic acid.

The first assumption is excluded by the findings of Paneth and Lautsch,[13] who report that methyl and ethyl radicals adhere to a mirror on the first collision. It will be shown below that the slight slope of the acetic acid line is reasonably traceable to the clean-up reactions involving hydrogen atom. Consequently, there is evidence that no free methyl is formed during the photolysis of acetic acid. The upper curve of Fig. 3 shows the ratios of times of disappearance of mirrors under the influence of acetic acid and acetone, respectively. It is calculated from the two curves below. It is this curve which is the basis for the previous statement that under similar conditions acetone yields more than ten times as many mirror-active particles as does acetic acid.

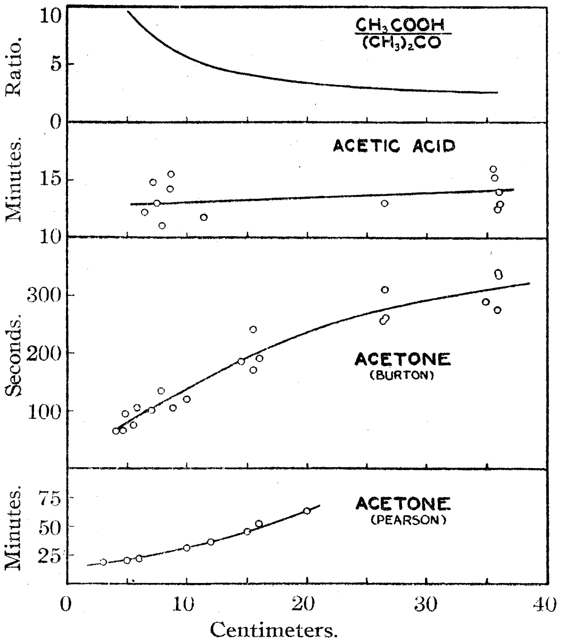

Fig. 3.—Effect of distance from irradiated zone on time of antimony mirror removal.

The formula, given by Paneth and Lautsch,[14]

$$t = \frac{X_2 - X_1}{V} - a\,\frac{(X_2^2 - X_1^2)}{2VP}$$

is used for an estimation of the time required for a particle to travel from the irradiated zone to any point under consideration. In that formula, X_1 and X_2 are, respectively, the distances of the edge of the irradiated zone and of the point from the beginning of the tube, V is the streaming velocity, a is the average pressure gradient, in this case 0.00261 cm. Hg per cm., and P is the pressure (*i. e.*, 0.23 cm.). The time required for a particle to travel 30 cm. from the irradiated zone comes out to be 0.58×10^{-2} sec. The average pressure between the irradiated zone and that

---

(13) Paneth and Lautsch, *Ber.*, **64**, 2702 (1931).

(14) Paneth and Lautsch, *ibid.*, **64**, 2708 (1931).

point readily may be calculated to be about 0.13 cm. If N be the number of collisions which a hydrogen atom would suffer[15] in an atmosphere of acetic acid at 76 cm. pressure, then it is evident that the number of collisions suffered under the conditions of these experiments in these 30 cm. would be

$$N_{30} = N\frac{\text{Average press.} \times t}{76}$$

If $N = 10^{10}$, $N_{30} = 10^5$; on the other hand, if $N = 10^{11}$, $N_{30} = 10^6$.

If we now examine the acetic acid curve of Fig. 3, it may be seen that the extrapolated time of mirror disappearance at the irradiated zone is 12.1 minutes and that the estimated time at a distance of 30 cm. is 13.9 minutes. The difference of the reciprocals of the times is a measure of the fraction of hydrogen atoms which have disappeared in that 30 cm. That fraction is 1.8/13.9 or approximately 0.13 and is equal to the probability of an individual hydrogen atom undergoing reaction in that 30 cm.

Since the rate of reactive collisions may be expressed[16] by

$$k = Ae^{-E/RT}$$

where we may here take k as the total number of reactive collisions (in the unit of time chosen), A as the total number of collisions per hydrogen atom (in the same time), E as the energy of activation per mole, R as the gas constant and T as the absolute temperature, it is found that, substituting 0.13 for k and the appropriate values for A and T, at room temperature E is 8.1 kcal. if N is 10^{10} or 9.5 kcal. if N is 10^{11}. These figures are only approximate. There is the implicit assumption that the steric factor is 1. They also depend on the estimate of the decrease in the concentration of hydrogen atoms along the tube, which in turn depends upon data which are not extremely accurate. If we assume that the change in concentration may really be either a quarter or four times as great as the estimate, then the limiting values for E will be 7.3 and 10.3 kcal.

Part IV. Effect of Wave Length.—The absorption spectrum of acetic acid has been investigated by Ley and Arends.[17] The continuum begins at about 2300 Å., reaches a maximum at 2040 Å., falls to a slight minimum at about 1925 Å. and rises thereafter to the limit of the study at about 1850 Å. Inasmuch as Farkas and Wansbrough-Jones[4] indicate evidence for decomposition into stable molecules and this paper on the other hand offers evidence for a free radical mechanism, it may be surmised that the shape of the absorption curve is related to a variation in the production of free radicals with wave length. The following tests were conducted to discover whether there is any threshold of free radical production other than the beginning of the continuum.

All traces of acetone were removed from the system. The arc of Fig. 1 was removed to a distance of 2.3 cm. from the reaction tube at L_2. The filter vessel already described, containing either distilled water, 0.1 N sodium chloride or 0.125 N sodium bromide solutions, was inserted between them as indicated in Fig. 2. The data of Fromherz and Menschick[18] show that in 1-cm. layers of these concentrations sodium chloride cuts off fairly sharply at 2000 Å., whereas the sodium bromide solution cuts off at about 2300 Å. Tests of the arc lamp with a Moll thermopile and galvanometer indicated a slightly higher photon intensity in the region 2300–2000 Å. than in the 2000–1849 Å. region. About 94% of the energy was above 2300 Å. Standard antimony mirrors were deposited 2.5 cm. from the irradiated zone and the acetic acid was passed through, as before described, at a pressure of approximately 2.3 mm. The results of these experiments are summarized in Table III.

TABLE III

EFFECT OF WAVE LENGTH ON TIME OF ANTIMONY MIRROR REMOVAL BY PHOTOLYZED ACETIC ACID

Filter	Range, Å.	Index of energy intensity	Average time of mirror removal, min.
Water	>1849	10	35.5
0.1 N NaCl	>2000	9.74	95
.125 N NaBr	>2300	9.4	$\gg$133

No indication of mirror removal with the sodium bromide filter was ever obtained although after one such test the activity of the mirror was checked in a run with the water filter. Although one hundred and thirty-three minutes was the maximum time employed for such a test, it was not considered necessary to prolong it any further since no characteristic sharpening of the mirror, which always occurs long before complete removal, was ever observed.

The results show a somewhat higher yield of atomic hydrogen per photon below 2000 Å. than

---

[18] Fromherz and Menschick, *ibid.*, **B3**, 1 (1929).

above that value. If that be true, it may possibly indicate that the absorption maximum at 2040 Å. is associated with decomposition into stable molecules. At any rate, the evidence is clear that there is decomposition into atomic hydrogen in the range 2300–2000 Å. and that the beginning of the continuum is probably also the threshold of free radical production. The tests with the sodium bromide filter establish that it is a true photo decomposition which is being observed and not a secondary effect due to the intense line 2537 (*e. g.*, photosensitization by excited mercury vapor).

Discussion

The experimental results indicate that hydrogen atoms are formed in the photolysis of acetic acid but that methyl radicals are not. Reaction 3, suggested previously,[8] therefore cannot be the primary step of the photolysis. Also, all primary steps which yield radicals, such as CH_3CO, which decompose readily[19] into free methyl and another molecule, are eliminated. Consequently, although Terenin[20] reports the emission bands of hydroxyl during the photolysis of acetic acid, it cannot be formed in the primary decomposition. Finally, any mechanism suggested must account for the production of free hydrogen and free hydroxyl and must be the chemical equivalent of reactions 1 and 2 or otherwise agree with the analysis reported by Farkas and Wansbrough-Jones.[4]

Mechanism 1.—The mechanism summarized below meets the requirements just indicated.

$$\begin{array}{rl}
CH_3COOH + h\nu \longrightarrow CH_3COOH^* & (5')^{21,22} \\
CH_3COOH^* \longrightarrow CH_3COO + H & (6') \\
CH_3COO + H \longrightarrow CH_4 + CO_2 & (7') \\
CH_3COOH + H \longrightarrow CH_4 + COOH & (8') \\
COOH \longrightarrow CO + OH & (9) \\
CH_3COOH + OH \longrightarrow CH_3COO + H_2O & (10')^{23} \\
2CH_3COO \longrightarrow C_2H_6 + 2CO_2 & (11)
\end{array}$$

Hydrogen atom should also disappear by the reaction

$$CH_3COOH + H \longrightarrow CH_3COO + H_2 \qquad (12')$$

and to a very much smaller extent (of no quantitative significance) by

$$2H + M \longrightarrow H_2 + M \qquad (13)$$

The suggested mechanism fits previously estimated activation energies. Rice[2c] assigns a value of E for the reaction step 5,6 of 96 ± 8 kcal., well below the 123 kcal. corresponding to the beginning of the continuum at 2300 Å.[24] It is possible that Rice's value may be somewhat low and that the beginning of the continuum actually corresponds to the energy of activation. For the decomposition $CH_3COO \longrightarrow CH_3 + CO_2$ he assigns a value of 40–70 kcal. which would account for the fact that no free methyl is observed in this photolysis. On the other hand, he assigns a value of only 10–25 kcal. for reaction 9, which would indicate a fairly rapid reaction yielding hydroxyl and carbon monoxide.

If, in addition, we assume on the basis of the vapor pressure measurements of Holland,[25] as did Farkas and Wansbrough-Jones, that double molecules of acetic acid also enter into the decomposition reactions, the mechanism may be modified in the following respects

$$(CH_3COOH)_2^* \longrightarrow \left(\begin{matrix} CH_3COO \\ CH_3COOH \end{matrix}\right) + H \qquad (6'')$$

The hydrogen atom in this case will have somewhat less translational energy than in the single molecule case and the chances of recombination before the particles have left their mutual spheres of influence will be greater. The H will react then with the CH_3COO part of the molecule or the CH_3COOH part, with the probability that the former part, being nearer to the H atom, will enter into more frequent collisions. Thus, we have the reaction

$$\left(\begin{matrix} CH_3COO \\ CH_3COOH \end{matrix}\right) + H \longrightarrow CH_4 + CO_2 + CH_3COOH \qquad (7'')$$

which is equivalent to reaction 7′. On the other hand, if the H atom reacts with the CH_3COOH part of the molecule, we have reactions equivalent to 8′ and 12′ and all the accompanying and succeeding reactions. In order to explain the lower yield of carbon dioxide than might be expected on the basis of the evidence that there are only half as many single as double molecules present, Farkas and Wansbrough-Jones were forced to assume that the nature of the orientation in the molecule determined the direction of the reaction. While

---

[19] Norrish, *Acta Physicochim. U. R. S. S.*, **3**, 171 (1935).

[20] Terenin, *ibid.*, **3**, 181 (1935).

[21] Reactions denoted by a single ′ refer to single acetic acid molecules; reactions denoted by double ″ refer to double molecules. When the primes are not indicated in a reaction involving the acetic acid molecule, the reference is to both reactions.

[22] The activation of acetic acid is chosen as the correct primary step in order to show a presumable relationship to results obtained with formic acid, as is discussed in a following report. However, in contradiction to the assumption of activation, the evidence in this report indicates immediate dissociation.

[23] The possibility of such reactions as $CH_3COOH + OH \longrightarrow CH_3OH + COOH$ and $CH_3COOH + OH \longrightarrow H_2O + CH_2COOH$ is generally excluded at low temperatures *Cf.* ref. 2, p. 190–191.

[24] The continuum may perhaps begin at 2400 Å., corresponding to 117 kcal.

[25] Holland, *Z. Elektrochem.*, **18**, 234 (1912).

such a view might also apply in this case, it is interesting to note that no special assumptions have to be adopted in order to explain all the products formed.

Farkas and Wansbrough-Jones give the following analysis of the products (neglecting water): 41% CO_2, 23% CH_4, 17.5% CO, 17.5% C_2H_6 and 1% H_2. The small yield of H_2 compared with CO indicates that reaction 8 proceeds much faster than reaction 12. Reaction 7 must be presumed to occur as a primary reverse reaction before the product particles of reaction 6 have had an opportunity to depart from each other's fields of influence. In other words, reaction 7 must be expected to take place entirely within the irradiated zone in a time too small for the particles to move any perceptible distance in the streaming vapor. Consequently, it seems logical to conclude that the energy of activation determined in Part III corresponds to reaction 8; *i. e.*, the energy of activation of reaction 8 is 7.3–10.3 kcal. per mole. From the ratio of H_2 yield to CO yield it may be calculated that the energy of activation of reaction 12 is correspondingly 9.0–12.1 kcal. per mole if the steric factor be assumed to be unity. However, the energy emitted in the reaction $2H + M \longrightarrow H_2 + M$ is known to be about 102 kcal.[26] and the difference between that figure and the energy of activation of step 5,6 is certainly higher than the just calculated value for reaction 12. This seems improbable and it accordingly appears likely either that the calculated values for reactions 8 and 12 are too low and that the acetic acid curve of Fig. 3 should correspond more closely to a horizontal straight line than is indicated by the data or that the beginning of the continuum may be nearer 2500 Å. than supposed. The latter conclusion would be contradictory to the results of Part IV.

Mechanism 1 is not the chemical equivalent of reactions 1 and 2. This may readily be seen by reference to reactions 8 and 11 from which it is evident that the production of one ethane molecule is necessarily accompanied by the formation of one methane and two carbon dioxide molecules. There is no such requirement in reaction 2. On the other hand, the requirements of the analysis of the product are met. The total yield of carbon dioxide according to mechanism 1 is equal to twice that of ethane plus that of methane minus that of carbon monoxide or $2 \times 17.5 + 23 - 17.5 = 40.5\%$, which is in good agreement with the analysis. The correspondence of yields of carbon monoxide and ethane is also required by this mechanism. Furthermore, the free radical mechanism explains the formation of hydrogen quite naturally. There is no need to make special assumptions. The traces of acetylene are not explained by this mechanism but they might well arise from some rarer reactions of atomic hydrogen.

The conclusions of Farkas and Wansbrough-Jones are founded on the assumptions of associated acetic acid molecules at extremely low pressures, not all of which are properly orientated. The mechanism suggested here does not involve such an assumption. Reference to the reactions indicates that the quantum yield of carbon dioxide will vary depending on the relative rates of the competing reactions 7 and 8. At higher wave lengths where reaction 7 would be favored, the quantum yield of carbon dioxide should be nearer 1; at lower wave lengths, because of the greater initial velocities of the product particles, reaction 8 would be favored and the quantum yield would be raised with 2 as the upper limit. Similarly, the observed yield of atomic hydrogen should be favored by lower wave lengths. The conclusion as to hydrogen is in agreement with the results of Table III. The conclusion as to carbon dioxide is in disagreement with the figure of approximately 1 for the quantum yield reported by Farkas and Wansbrough-Jones. Using their figures for the analysis of the products, it is apparent that the calculated quantum yield, using mechanism 1, is approximately 1.9. Either their single estimate of the quantum yield has even less accuracy than they indicate or mechanism 1 must be incorrect.

Mechanism 2.—There is, however, another free radical mechanism which may be valid. It is based entirely on the assumption that both single and double molecules are present, and is given below because its calculated quantum yield of carbon dioxide, assuming that each photon absorbed leads to reaction, is 1. Until there is more accurate information about the quantum yield of the photolysis of acetic acid, there is no basis for choice between mechanism 1 and this one.

For single molecules the principal reactions are 5′, 6′ and 7′. For double molecules the principal reaction is

$$(CH_3COOH)_2 + h\nu \longrightarrow (CH_3COOH)_2^* \qquad (5'')$$

---

[26] Birge, *Proc. Nat. Acad. Sci.*, **14**, 12 (1928).

followed by 6′′ and either 7′′ or

$$\begin{pmatrix} CH_3COO \\ CH_3COOH \end{pmatrix} + H \longrightarrow C_2H_6 + CO_2 + CO + H_2O \qquad (14'')^{27}$$

The reactions just indicated are the exact stoichiometric equivalent of Farkas and Wansbrough-Jones' suggested mechanism. They are consequently in agreement with the analysis of the products and the reported quantum yield of one for carbon dioxide. Reactions 7″ and 14″ are the equivalent in effect of their so-called properly orientated double molecules. Reactions 5′ and 5″ are the activation reactions, 6′ and 6″ the decomposition reactions. In the latter are produced the hydrogen atoms reported herein. Not all of them, however, escape from the field of influence of the other product radical. At the longer wave lengths nearly all of them react with the residual body in reactions 7′ and 7″ or 14″. No such hydrogen atoms can be detected by the mirror method. Only those that escape are detectable. Evidently, as the wave length decreases beyond the limit required to effect decomposition, the excess energy is divided up among the various degrees of freedom and some of it goes to give the radicals increased velocity relative to each other. For the double molecule, more excess energy is required to produce the same velocity of separation, so that it might be expected that somewhat more of the hydrogen atoms will escape the back reaction after 6′ than after 6″. Once free of the residue, however, there is no distinction between them. When the residue is that of a double molecule, a simple decomposition may be expected to occur

$$\begin{pmatrix} CH_3COO \\ CH_3COOH \end{pmatrix} \longrightarrow CH_3COO + CH_3COOH \qquad (15'')$$

The hydrogen atoms may then enter reactions 8′, 12′ and 13. On energetic grounds reaction 8′ might be favored over reaction 12′ since the C–C bond is weaker than the O–H bond.[28] The termolecular reaction 13, because of the relative scarcity of hydrogen atoms, may be considered so rare that it is non-occurring. The hydrogen atoms may also enter equivalent reactions with double acetic acid molecules. In effect they will be the same as those just given for 8′ and 12′.

As a result of the escape of the hydrogen atoms and their entrance into reactions 8 and 12, the radicals CH_3COO and COOH are liberated. The reaction $CH_3COO \longrightarrow CH_3 + CO_2$, as has been shown, would not be expected to occur. Reaction 9 would occur as already indicated and account for Terenin's observation of OH; the OH might also enter into reactions such as 10′. Reaction 11 would also follow. The relative scarcity of products other than CH_4, C_2H_6, CO, CO_2 and H_2 would indicate either that very little atomic hydrogen becomes available for reactions 8 and 12 or that reaction 12 is favored over 8 or that reaction 10 is favored over other possible reactions involving OH.[23] If mechanism 2 is correct, the first hypothesis must be near the truth (irrespective of the others); it is supported by the only available data for the quantum yield of carbon dioxide, *i. e.*, approximately 1.0. Were reaction 11 to occur to any great extent, the observed quantum yield might be nearer 2.0. (It may be said that the principal weakness of mechanism 2 lies in the necessity of this hypothesis. It seems unreasonable to believe that the great majority of the hydrogen atoms should not escape the influence of the other product particle even at very short wave lengths.)

It may now be seen that the suggested mechanism fits all the known data on this reaction including estimated energies of activation.

It has been shown that the energy of activation for the reaction involving the disappearance of hydrogen atom may be about 7.3–10.3 kcal. If the quantum yield of carbon dioxide be nearly 1.0, reaction 8 could not be an important factor in the production of CH_4. Therefore, reaction 12, which is known to produce 1% of H_2, would account for most of the disappearance of atomic hydrogen. The value of E of 7.3–10.3 kcal. would then apply to that reaction. It is probably much too low, as already indicated under mechanism 1. (The discrepancy here is even greater than for mechanism 1 and may be interpreted against the validity of mechanism 2.)

The principal advantage of the free radical mechanism here suggested over that indicated in reactions 1 and 2 is that it explains the formation of molecular hydrogen quite naturally as well as the formation of hydroxyl, which incidentally need be present in but very small concentration

---

(27) Reasoning *ad hoc*, the explanation of reaction 14″ is that the close proximity of the CH_3COO group with its free valence force loosens the C–O bond in the CH_3COOH and thus causes the H to act preferentially on that bond to form water with the —OH.

(28) The C–C bond has in general a strength of about 84 kcal. while that of the O–H bond in acetic acid has been estimated to be 96 ± 8 kcal. (see Rice, ref. 2c) and according to these results may have an even higher value. On the other hand, steric factors may retard 8′ as compared with 12′ (ref. 2, Chap. VI).

to be detected by its emission spectrum.[29] The remarks as to traces of acetylene and variation of yield of atomic hydrogen and of quantum yield of carbon dioxide with wave length made in reference to mechanism 1 also apply to mechanism 2. However, the effect on quantum yield of carbon dioxide would not be so marked in this case as in mechanism 1. The increased production of atomic hydrogen at the lower wave lengths would be just as perceptible and in agreement with Table III.

Patat and Sachsse[30] and Rollefson[31] have both indicated reasons why, in the event of competition between decompositions into stable molecules and into free radicals, the free radical yield should be favored by the lower wave lengths. Consequently, there appears to be no way with the data at hand to decide whether a decomposition into stable molecules is occurring.

Furthermore, the interpretation to be put on the data is questionable. Either of mechanisms 1 or 2 will fully explain all the reactions involved. Apart from the doubts expressed above as to mechanism 2, there is no fundamental reason why either one may not be correct. There is no *a priori* reason why we should expect a quantum yield of one molecule decomposed per photon absorbed in the case of a molecule as complicated as that of acetic acid.[32] Norrish, Crone and Saltmarsh[33] have shown, for example, in the case of acetone that the low quantum yield in the continuum may be ascribable to an intramolecular stabilization because of the dissipation of energy within the large number of degrees of freedom before it becomes available for disruption of a bond. In that case they have also established the existence of decomposition in the discrete fluorescence region before the continuum. If the quantum yield of decomposed molecules were actually one, it would be expected that rupture takes place at the locus of absorption and that there would be no decomposition (*i. e.*, predissociation) before the continuum.

The results of Table III indicate that acetic acid suffers no photolysis (yielding atomic hydrogen) before the continuum. Farkas and Wansbrough-Jones' estimate of a quantum yield of carbon dioxide of 1.0 may be interpreted as evidence in favor of mechanism 2 and a conclusion that rupture takes place immediately and at the locus of absorption. A decisive choice between mechanisms 1 and 2, however, awaits a more certain determination of the quantum yield.

Conclusions.—The only well-founded conclusions are that at least part of the reaction takes place by a free radical mechanism such as here indicated and that no other mechanism is required to explain all the facts so far known.

Acknowledgment.—The author wishes to express his appreciation to Professor James Franck of Johns Hopkins University, who suggested this investigation, and to Professor H. Austin Taylor for his frequent advice and suggestions.

Summary

1. Details are given of a method for detecting hydrogen atoms in the presence of free methyl.
2. Hydrogen atoms but no free methyl radicals are formed during the photolysis of acetic acid.
3. A free radical mechanism is indicated which fits all the facts known about that photolysis.
4. Energies of activation have been computed for two reactions involving atomic hydrogen and acetic acid.
5. It is shown that according to the mechanism suggested the quantum yield of carbon dioxide should increase at shorter wave lengths, the lower and upper limits being 1 and 2, respectively. Farkas and Wansbrough-Jones report a quantum yield of approximately 1.0.
6. The production of atomic hydrogen is apparently slightly favored by decrease in wave length.
7. No production of atomic hydrogen is observed above 2300 Å. The results and other data available are in harmony with a conclusion that the acetic acid spectrum does not have a predissociation region and that in the continuum rupture takes place immediately at the locus of absorption.

Studies in the Mechanism of Decomposition. II. Note on the Photolysis of Formic Acid

BY MILTON BURTON

Using the para–ortho hydrogen conversion method of Farkas[1] and of Geib and Harteck,[2] Gorin and H. S. Taylor[3] adduced good evidence that no atomic hydrogen is produced during the photolysis of formic acid and that the decomposition probably proceeds by a rearrangement of bonds to yield stable molecules in one primary act by one of the two reactions

$$HCOOH + h\nu \longrightarrow H_2O + CO \quad (1)$$
$$HCOOH + h\nu \longrightarrow H_2 + CO_2 \quad (2)^4$$

Inasmuch as evidence has been presented[5] that hydrogen atom is formed during the photolysis of acetic acid, the question naturally arose as to whether Gorin and Taylor's failure to observe similar results for formic acid might not be a consequence of the method they employed. Accordingly, the tests described below were undertaken to discover whether the mirror method might detect hydrogen atoms in the photolysis of formic acid.

Experimental

The apparatus and methods used were similar to those described for acetic acid.[5] A sample of Kahlbaum Formic Acid 95% was dried over Drierite for three days, introduced into the carefully evacuated system and degassed as already described for acetic acid. In the runs the pressure of formic acid was fixed at about 2.4 mm. at the sloping manometer before the constricted region of the reaction system. Only antimony mirrors were used in the reaction tube. With the capillary mercury arc previously described[5] located 22.8 cm. from the beginning of the reaction tube and 1 cm. from it, antimony mirrors were deposited in the usual manner at about 9 cm. from the irradiated zone.

Tests for Atomic Hydrogen.—In none of the experiments with illuminated formic acid was removal of the antimony mirrors ever observed. In one case, a typical run failed to affect a very light antimony mirror, which would not have lasted four minutes with acetic acid under the same conditions, even though continued for seventy-eight minutes. The system was checked with fresh acetic acid according to the methods previously described and the mirrors were found to possess their normal sensitivity.

There is, of course, the possibility that the energy of activation of secondary reactions between H and HCOOH may be so low that reaction takes place on the first collision or, at most, after a very few collisions and that consequently the hydrogen atoms, though formed, never reach the mirror. This possibility was checked by making a run with a mixture containing approximately 4 parts of acetic acid to about 1 of formic acid. It being already known that photolyzed acetic acid yields hydrogen atoms, such a run should afford a direct test of a possible very fast reaction between H and HCOOH. With the pressure of the mixed vapor adjusted at about 2.4 mm. at the sloping manometer and the other conditions being as already described, it was found that a mirror which would not last in pure acetic acid vapor for more than about four minutes now took about sixteen minutes to disappear. It may be concluded from this test either that formic acid acts like acetaldehyde[6] and reduces normal mirror activity or that there is a rather rapid reaction between H and HCOOH, faster than that between H and CH_3COOH but not fast enough to account for a failure to observe hydrogen atoms during the photolysis of formic acid if there formed.

In order to check the first alternative a formic acid run was made in which the antimony mirror was heated with live steam. Although continued for fifty-two minutes, not the slightest effect was observed on a very light antimony mirror such as used in this group of experiments. Inasmuch as the mixed run with acetic acid had already demonstrated that formic acid did not have a completely deadening effect on the antimony mirror, it may be concluded from this experiment that the failure to observe mirror removal was not due to a cause similar to that reported for acetaldehyde; *i. e.*, the mirrors were not being made inactive by a condensed layer of formic acid.

In a final experiment with formic acid, the arc was brought up to within 0.7 cm. of the reaction tube and a very light antimony mirror deposited 1.9 cm. from the irradiated zone. Although the run was continued for forty-seven minutes, no indication of sharpening of the mirror (a phenomenon always occurring long before removal) was observed.

The absorption spectra of formic acid and of acetic acid are very similar,[7] the extinction coefficients throughout the continua being almost the same, except that the spectrum of formic acid is displaced slightly toward the long wave side. Inasmuch as decomposition of acetic acid has been detected under the conditions of these experiments and Gorin and Taylor have already demonstrated the photolysis of formic acid at wave lengths which the arc used has been shown to cover,[5] it appears reasonable to assume that decomposition of the formic acid also occurred. Consequently, the evidence recited above appears to indi-

cate that no hydrogen atoms are formed during the photolysis of formic acid.

The stability of HCO.—The results of Blacet and Roof[8] on the photolysis of acetaldehyde indicate that the HCO radical is rather stable. On the other hand, although the data used by Rice and Herzfeld[9] in considering the chain mechanism involved in the pyrolysis of that compound would indicate a fair stability of HCO at room temperature, Mecke,[10] in discussing the photolysis of formaldehyde, favored the idea that HCO is very unstable and requires only about 4 kcal. to dissociate it further.

Using the guard mirror method previously described[5,11] and employing the precautions indicated to be necessary by the work of Pearson and Purcell,[6] it was found in a preliminary experiment with acetaldehyde, purified[12] and evacuated (using liquid air) in the regular manner, that the light lead mirror, before the lead guard mirror, was removed in five minutes while the light antimony mirror, after the guard, was not in the slightest degree affected after seventy-one minutes.

Inasmuch as CH_3 was formed, HCO must have been formed and the inference logically follows that HCO must be very stable at room temperatures since, had it decomposed, atomic hydrogen would have been formed and would have removed the antimony mirror.

Discussion

Terenin[13] has reported the emission spectrum of hydroxyl during the photolysis of formic acid. If we assume a possible mechanism to account for this production as follows

$$HCOOH + h\nu \longrightarrow HCOOH^* \qquad (3)$$
$$HCOOH^* \longrightarrow HCO + OH \qquad (4)$$

it is evident that no H atom need be observed, since, as has been shown, HCO does not appear to decompose readily. Although OH had been similarly discovered in the photolysis of acetic acid, its formation in a primary step had been excluded because of the known instability of CH_3CO.[14] In the case of formic acid the strength of the C–H bond may be presumed to be greater than that of the C–C bond in acetic acid.[15] It consequently seems that the C–O bond may be much weaker in formic acid than in acetic acid. Since the evidence of absorption spectra indicates that absorption in both compounds is in the COOH group, it may well be possible that the C–O bond is weaker than the O–H bond in formic acid and that the decomposition takes place at the weaker bond.

The para–ortho hydrogen conversion should be as sensitive to a free radical such as OH as to free H.[16] However, if it be ignored for the moment that the results of Gorin and Taylor, contrary to the findings of Terenin, exclude the possibility of any considerable formation of OH, it would still be difficult to write a completely satisfactory free radical reaction mechanism to fit the known data (except by a process of strictly *ad hoc* reasoning) because of the complication introduced by the predominance of double formic acid molecules at pressures greater than 10 mm. and temperatures below 30°.[17] It would be hard to explain why double molecules decompose exclusively by reaction 2. It consequently appears advisable in view of the present state of knowledge of this reaction not to attempt the hypothesis of a mechanism beyond reactions 3 and 4.

The antimony mirror indicates, in agreement with the results of Gorin and Taylor, that no hydrogen atoms are formed in the photolysis of formic acid at room temperatures. This result, it has been shown, is not inconsistent with the findings of Terenin that OH is formed during such photolysis. However, it appears that it may be difficult to reconcile Terenin's results with those of Gorin and Taylor. In view of the evidence, it still appears advisable to consider the photolysis of formic acid as being predominantly a decomposition into stable molecules in one primary act[18] for very little OH has to be produced to be detectable by its emission spectrum.[19]

Acknowledgment.—The author wishes to express his appreciation to Professor H. Austin Taylor for his advice and suggestions.

Summary

1. No hydrogen atoms are detectable by the antimony mirror method during the photolysis of formic acid. This agrees with the findings of Gorin and Taylor.

2. Evidence presented indicates that a reaction takes place between H and HCOOH with a fairly low energy of activation.

[19] Oldenberg, *J. Chem. Phys.*, **3**, 266 (1935).

3. A mechanism is suggested for the formation of OH during the photolysis of formic acid. This mechanism is consistent with the mechanism previously suggested for acetic acid.

4. A preliminary experiment with acetaldehyde showed HCO to be a stable radical at room temperature.

5. In view of the difficulty in reconciling the results of Gorin and Taylor with those of Terenin, it appears probable that the major portion of the photolysis of formic acid takes place by decomposition into stable molecules in one primary act.

Cyclohexyltrichloromethylcarbinol

BY JOSEPH W. HOWARD AND ROBERT J. BROWN

This compound was prepared by the reaction of chloral and cyclohexylmagnesium bromide. The most satisfactory results were obtained when this was carried out as an "inverse Grignard" reaction.

The Grignard reagent was prepared by adding 82 g. of monobromocyclohexane in 60 cc. of ether to 14 g. of magnesium ribbon and a crystal of iodine in 70 cc. of ether. The reaction was completed after three hours of stirring and gentle heating. The resultant solution was decanted from any unchanged magnesium and added with stirring over a two-hour period to 74 g. of freshly distilled chloral in 150 cc. of ether. The product was decomposed with 30% sulfuric acid and the ether washed in turn with water, sodium bicarbonate solution, sodium bisulfite solution and water. It was dehydrated over anhydrous sodium sulfate, the ether removed by distillation and the alcohol distilled in vacuum. A yield of 35 g. of an oily liquid boiling at 119 to 121° at 15 mm. was obtained; d^{20}_{20} 1.2839, n_{25} 1.4820. *Anal.* Calcd. for $C_8H_{13}OCl_3$: Cl, 45.95. Found: Cl, 45.99.

This carbinol darkens on standing. It is insoluble in water but soluble in ether, ethyl alcohol, methyl alcohol, acetone, benzene, chloroform and carbon tetrachloride.

Preparation of the Esters

The acetate and propionate were prepared by refluxing the carbinol for one and one-half hours at 135° with the corresponding acid chloride. The same method was used to prepare the butyrate but butyric anhydride was found to give more satisfactory results than butyryl chloride. The benzoate was prepared by treatment with benzoyl chloride according to the usual procedure of the Schotten–Baumann reaction.

ESTERS OF CYCLOHEXYLTRICHLOROMETHYLCARBINOL

		Formula	Analysis for Cl, % Calcd.	Found
1	Acetate	$C_{10}H_{15}O_2Cl_3$	38.89	39.08
2	Propionate	$C_{11}H_{17}O_2Cl_3$	36.97	37.14
3	Butyrate	$C_{12}H_{19}O_2Cl_3$	35.44	35.28
4	Benzoate	$C_{15}H_{17}O_2Cl_3$	31.71	31.56

	B. p., °C.	Mm.	d^{20}_{20}	n_{25}
1	173	680	1.3612	1.4945
2	188	681.6	1.2119	1.4989
3	185	682.6	1.1872	1.4995
4	210	683.3	1.2893	1.5259

The average yields of these esters was 85%. They are all insoluble in water but soluble in ether, ethyl alcohol, methyl alcohol, acetone, benzene, chloroform and carbon tetrachloride.

Summary

Cyclohexyltrichloromethylcarbinol as well as its acetic, propionic, butyric and benzoic esters have been prepared and studied.

The Synthesis of Some Dioxole Derivatives from Alkylacetylenes[1]

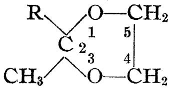
BY D. B. KILLIAN, G. F. HENNION AND J. A. NIEUWLAND

Glycol ethylidene oxide, or 2-methyl-1,3-dioxolane, was first prepared by Wurtz[2] by heating glycol and acetaldehyde in sealed tubes for eight days on a water-bath. Later work[3,4,5] showed that aldehydes could be condensed with polyhydric alcohols with greater ease when phosphoric or sulfuric acid was used as a catalyst. Acetylene reacts with polyhydroxy compounds, in the presence of mercuric sulfate and sulfuric acid, to yield dioxolanes and dioxolones.[6,7] Nieuwland, Vogt and Foohey[8] have shown that cyclic acetals result in high yields from acetylene and polyhydroxy compounds when mercuric oxide and a solution of boron fluoride in methanol are used as catalysts.

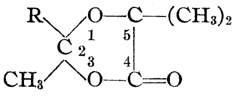
The 2,2-dialkyl-1,3-dioxolanes have been reported in the literature in a limited number only. Acetone or other ketones of low molecular weight may be condensed with polyhydroxy compounds in the presence of mineral acids to yield cyclic ketals. Various methods[9,10,11] have been proposed for the synthesis of these compounds, but none of them is generally applicable. The number of references to this field is so large that an exhaustive literature survey of the subject cannot be made here.

Staedler[12] first described chloralide, 2,5-bis-trichloromethyl-1,3-dioxol-4-one, prepared by the action of sulfuric acid on chloral. Other 1,3-dioxol-4-ones have been described from time to time by various investigators.[13–15] Many techniques have been described for the preparation of such compounds by condensing an α-hydroxy acid with a ketone, an aldehyde or acetylene.

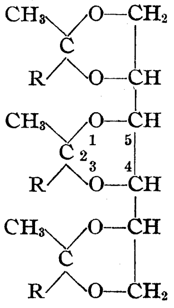
The authors have previously shown[16] that amylacetylene reacts with ethylene glycol, in the presence of mercuric oxide and boron fluoride, to yield 2-amyl-2-methyl-1,3-dioxolane. The addition of polyhydroxy alcohols and α-hydroxy acids to an alkylacetylene furnishes a convenient method for the synthesis of many dioxole derivatives. Dihydric alcohols, such as ethylene glycol, yield with alkylacetylenes compounds of type I; α-hydroxy acids, for example α-hydroxyisobutyric acid, give rise to compounds of type II; and polyhydric alcohols, such as mannitol, produce compounds of type III.



I

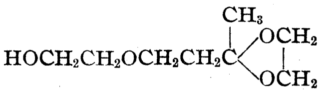


II

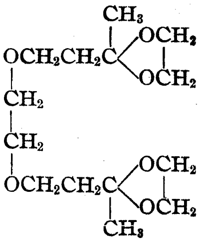


III

The addition of polyhydroxy alcohols to monovinylacetylene is of some interest since it has been shown that methanol reacts with monovinylacetylene in the ratio of three molecules of the alcohol to one of the acetylene to produce 1,3,3-trimethoxybutane.[17] We have found that ethylene glycol and monovinylacetylene yield two addition compounds, one formed from two molecules of glycol and one of the acetylene (IV); and the other from three molecules of glycol and two of the acetylene (V).



IV



V

Experimental

General Procedure.—The catalyst was prepared by heating together momentarily, 5 g. of red mercuric oxide, 2 ml. of $(C_2H_5)_2O \cdot BF_3$, and 2 ml. of anhydrous methanol. To this was added 1–2 g. of trichloroacetic acid, and the

[a] Second reactant, monovinylacetylene.

resulting mixture placed in a three-necked flask equipped with a mercury-sealed motor-driven stirrer, a reflux condenser and a dropping funnel. The appropriate polyhydroxy compound was then added to the catalyst mixture and the alkylacetylene added dropwise, if liquid, and, if a gas, as is the case with monovinylacetylene, in a slow stream using a liquid ammonia condenser[18] on the reaction flask.

The reactions were spontaneous and occasionally required cooling by immersing the flask in a water-bath. After stirring for two hours the contents of the flask was mixed with a small amount of sodium methylate and fractionated *in vacuo*. The yields were in all cases good, namely, between 70 and 90% of the theoretical amounts.

The characteristics and analyses of the dioxoles synthesized are given in Table I.

Acknowledgment.—The authors gratefully acknowledge the kind assistance of Dr. Austin M. Patterson for reading the manuscript of this article and suggesting the nomenclature used.

Summary

1. Various dioxolanes and dioxolones have been synthesized from polyhydric alcohols and α-hydroxy acids with butylacetylene and monovinylacetylene.

2. Monovinylacetylene reacted with ethylene glycol to yield two products. The first was formed by the condensation of two moles of glycol with one of monovinylacetylene; the second by the condensation of three moles of glycol with two of the vinylacetylene.

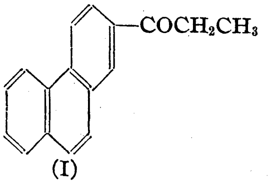
Synthesis of Phenanthrene Derivatives. IV. Propionylphenanthrenes

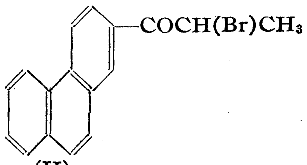
BY W. E. BACHMANN AND W. S. STRUVE

From the reaction between propionyl chloride, phenanthrene and aluminum chloride in nitrobenzene a mixture of propionylphenanthrenes is formed from which it is possible to isolate 2-propionylphenanthrene (I) and 3-propionylphenanthrene. This result is similar to those obtained with acetyl chloride,[1] benzoyl chloride[2] and *o*-toluyl chloride.[3]

The structures of the propionylphenanthrenes were established by their oxidation to 2- and 3-phenanthroic acid by sodium hypochlorite solution as well as by synthesis from the corresponding 2- and 3-cyanophenanthrenes by means of ethylmagnesium bromide. By the Grignard reaction we have also synthesized 9-propionylphenanthrene.



(I)



(II)

By interaction of bromine and 2- and 3-propionylphenanthrene α-bromo-2-propionylphen-

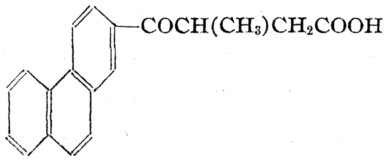
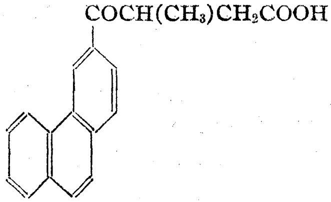
(3) Bachmann and Pence, *ibid.*, **57**, 1130 (1935).

anthrene (II) and α-bromo-3-propionylphenanthrene are formed. By condensation of the bromopropionylphenanthrenes with sodiomalonic ester, followed by decarboxylation of the malonic acids obtained on hydrolysis of the esters, β-(2-phenanthroyl)-butyric acid (III) and β-(3-phenanthroyl)-butyric acid (IV) were obtained.



(III)



(IV)

Experimental

Reaction of Propionyl Chloride with Phenanthrene.—To an ice-cold solution of 320 g. of aluminum chloride and 200 g. of phenanthrene in 1750 cc. of nitrobenzene was added 140 g. of propionyl chloride at one time. After being kept cold for half an hour, the mixture was allowed to stand at room temperature for twelve hours. After hydrolysis by ice and dilute hydrochloric acid, followed by removal of the nitrobenzene by steam distillation, the product was dissolved in a hot mixture of acetone and alcohol. On cooling 20 g. of 2-propionylphenanthrene crystallized out. By recrystallization from alcohol the 2-propionylphenanthrene was obtained in the form of colorless needles; m. p. 104–105°.

Anal. Calcd. for $C_{17}H_{14}O$: C, 87.2; H, 6.0. Found: C, 87.1; H, 6.2.

After standing in a refrigerator for three weeks the filtrate from which the 2-isomer had been removed deposited 60 g. of 3-propionylphenanthrene. By recrystallization from alcohol the 3-propionylphenanthrene was obtained as colorless needles; m. p. 55–57°.

Anal. Calcd. for $C_{17}H_{14}O$: C, 87.2; H, 6.0. Found: C, 87.3; H, 6.1.

A further quantity of the two ketones was obtained from the filtrate through their picrates.

Oxidation of 2- and 3-Propionylphenanthrenes.—A suspension of 1 g. of propionylphenanthrene in 100 cc. of 3% sodium hypochlorite solution containing 1 g. of potassium hydroxide was refluxed for four hours. The solution was filtered and the filtrate was acidified; the phenanthroic acid which precipitated was filtered off and recrystallized from chlorobenzene. From the 2-propionylphenanthrene 2-phenanthroic acid (m. p. 258–260°) was obtained; it gave a methyl ester whose melting point was not depressed when the compound was mixed with authentic 2-phenanthroic acid methyl ester. Similarly 3-propionylphenanthrene gave 3-phenanthroic acid (m. p. 265–270°) whose identity was likewise established through the methyl ester.

Synthesis of Propionylphenanthrenes.—To the Grignard reagent which had been prepared from 10 g. of ethyl bromide in 30 cc. of ether was added 30 cc. of benzene and 10 g. of cyanophenanthrene (2-, 3- or 9-isomer). After the mixture had been refluxed for four hours, it was cooled and hydrolyzed with ice-cold ammonium chloride solution. The aqueous solution was removed and the ether-benzene solution was shaken with dilute hydrochloric acid; from the aqueous solution of the ketone-imine hydrochloride the ketone was obtained by hydrolysis. The 2- and 3-propionylphenanthrenes were identical with those obtained by reaction of propionyl chloride with phenanthrene. The yields were: 2-propionylphenanthrene, 77%; 3-propionylphenanthrene, 22%; 9-propionylphenanthrene, 86%. The 9-propionylphenanthrene was purified by distillation under reduced pressure followed by recrystallization from alcohol; from this solvent it was obtained in the form of colorless, heavy hexagonal plates; m. p. 55–57°.

Anal. Calcd. for $C_{17}H_{14}O$: C, 87.2; H, 6.0. Found: C, 87.6; H, 6.3.

Picrates of Propionylphenanthrenes.—On cooling hot saturated alcoholic solutions of equal parts of propionylphenanthrene (2-, 3- and 9-isomer) and picric acid the picrates crystallized in the form of yellow needles composed of ketone and picric acid in a 1:1 ratio.

TABLE I

PROPIONYLPHENANTHRENE PICRATES

Picrate of	M. p., °C.	Anal. for N Calcd.	Anal. for N Found
2-Propionylphenanthrene	104.5–107	9.05	9.01
3-Propionylphenanthrene	111–113	9.05	9.05
9-Propionylphenanthrene	105.5–107	9.05	9.01

Bromopropionylphenanthrenes.—A solution of 21.6 g. of 3-propionylphenanthrene in 500 cc. of absolute ether was treated at 0° with a solution of 4.6 cc. of bromine in 125 cc. of ether. After forty minutes the precipitate of α-bromo-3-propionylphenanthrene was filtered off; an additional quantity of the compound was obtained by evaporation of the filtrate after the latter had been treated with anhydrous sodium carbonate in order to neutralize the hydrogen bromide. α-Bromo-3-propionylphenanthrene crystallizes from methyl alcohol and benzene in the form of long colorless needles; m. p. 117–118°; yield, 20 g. (70%).

Anal. Calcd. for $C_{17}H_{13}OBr$: Br, 25.6. Found: Br, 26.3.

For the preparation of the 2-isomer 10 g. of 2-propionylphenanthrene was treated with 2.2 cc. of bromine in 800 cc. of ether; after two hours the mixture was worked up in the manner described for the 3-isomer. α-Bromo-2-propionylphenanthrene crystallizes from benzene–alcohol in colorless plates; m. p. 131.5–133°; yield 11 g. (82%).

Anal. Calcd. for $C_{17}H_{13}OBr$: Br, 25.6. Found: Br, 25.5.

β-Phenanthroylbutyric Acids.—Five grams of α-bromo-3-propionylphenanthrene was added to a solution of sodiomalonic ester which had been prepared from 5 g. of malonic ester and 0.5 g. of sodium in 20 cc. of benzene. After being refluxed for four hours the mixture was hydrolyzed and the substituted malonic ester was heated with 40 cc. of 5% sodium hydroxide solution. From the aqueous solution the phenanthroyl-isoglutaric acid was obtained by acidification. The acid was decarboxylated by heating a suspension of the acid in water for three hours. The β-(3-phenanthroyl)-butyric acid which was formed was purified through its ammonium salt followed by recrystallization of the acid from acetic acid. β-(3-Phenanthroyl)-butyric acid crystallizes from acetic acid in colorless prisms; m. p. 144–146°; yield 1.5 g. (32%).

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 78.1; H, 5.5. Found: C, 78.0; H, 5.6.

In a similar manner α-bromo-2-propionylphenanthrene was condensed with sodiomalonic ester. The substituted malonic acid which was obtained was heated at 180° for one hour in order to decarboxylate it to β-(2-phenanthroyl)-butyric acid. The latter acid was obtained as fine colorless crystals from acetic acid; m. p. 173–174°; yield 32%.

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 78.1; H, 5.5. Found: C, 78.0; H, 5.8.

Summary

2- and 3-Propionylphenanthrene have been isolated from the reaction between propionyl chloride, phenanthrene and aluminum chloride in nitrobenzene. The same ketones in addition to 9-propionylphenanthrene have been synthesized from the corresponding cyanophenanthrenes through the Grignard reaction.

β-(2-Phenanthroyl)-butyric acid and β-(3-phenanthroyl)-butyric acid have been synthesized.

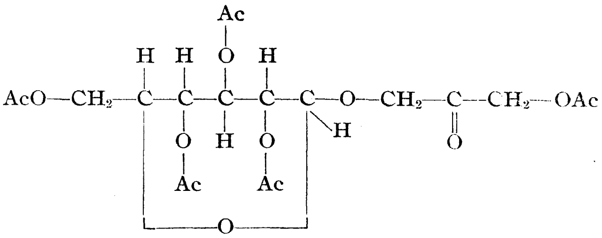
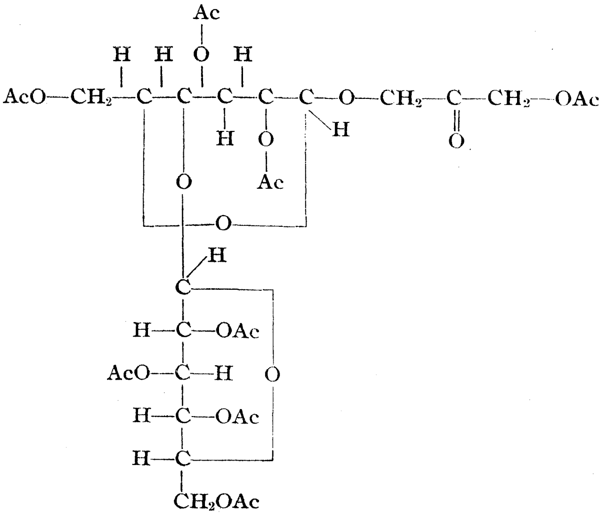
The Mechanism of Carbohydrate Oxidation. XX.[1] The Preparation of Oligosaccharide Acetates Containing Dihydroxyacetone Constituents

BY LEONARD C. KREIDER AND WM. LLOYD EVANS

When Evans and Hockett[2] advanced a mechanism to explain the action of potassium hydroxide on gentiobiose (6-glucosidoglucose) to produce lactic acid, they pointed out that 3-glucosidoglyceraldehyde was a theoretically possible intermediate in this degradation. In the alkaline environment of this reaction it is possible for this glyceraldehyde derivative to undergo the well-known Lobry de Bruyn and van Ekenstein rearrangement to give 3-glycosidodihydroxyacetone. In order to test the Evans and Hockett mechanism it was desirable to subject a 3-glucosidotriose, the postulated reaction intermediate, to the action of potassium hydroxide. At that time glucosidotrioses were unknown. We then succeeded in devising a general method for the synthesis of oligosaccharides that contain dihydroxyacetone as the reducing portion of the molecule. This synthesis has already been applied to the preparation of 3-glucosidodihydroxyacetone (described in a preliminary report[3]), β-*d*- and β-*l*-arabinosidodihydroxyacetone and β-*d*- and β-*l*-xylosidodihydroxyacetone, all as their acetates.[1] The present paper gives detailed directions for the preparation, in a pure crystalline form, of



β-*d*-Glucosidodihydroxyacetone pentaacetate



β-Cellobiosidodihydroxyacetone octaacetate

β-Gentiobiosidodihydroxyacetone octaacetate

Their crystalline *p*-nitrophenylhydrazones were also prepared and characterized.

The action of potassium hydroxide on the three oligosaccharides described here will be published later.

Experimental Part

Preparation of Starting Materials.—Dihydroxyacetone monoacetate was prepared according to the directions of Fischer, Baer and Feldmann.[4] Acetobromoglucose was made by the classical method of Fischer[5] except that the final crystallization was from absolute ether instead of amyl alcohol. Acetobromocellobiose was prepared from cellobiose octaacetate following the directions of Fischer and Zemplén,[6] and acetobromogentiobiose was prepared from gentiobiose octaacetate by the method of Brauns.[7] The final recrystallizations were made again from absolute ether. The acetobromo sugars were each left in a vacuum desiccator for a day over phosphorus pentoxide before being used. The benzene, Drierite and silver carbonate were prepared as before.[1]

All the following compounds reported here were obtained in crystalline condition and were recrystallized to constant melting point and rotation.

β-*d*-Glucosidodihydroxyacetone Pentaacetate.—The preparation of this compound was conducted in a 500-cc. three-necked round-bottomed flask which carried in the middle neck a high speed motor stirrer of efficient design running under a mercury seal. One side neck carried a drying tube charged with granular Drierite and the other a solid stopper. The stirring was then started and the following materials added: 14.1 g. (2.0 moles) of dihydroxyacetone monoacetate, 115 cc. (25 moles) of benzene, 14.5 g. (1.0 mole) of silver carbonate and 50 g. (7 moles) of finely powdered Drierite. That the reactants might be absolutely anhydrous the above mixture was stirred vigorously for twenty minutes and then 22.0 g. (1.0 mole) of β-acetobromo-*d*-glucose was added in ten equal portions at fifteen-minute intervals. Vigorous stirring was continued throughout this time and for at least three hours after the last addition of acetobromoglucose.

At this point the stirring was stopped and the solid materials removed from the benzene solution by suction filtration. The residue was washed twice with small amounts of benzene and the washings added to the filtrate. The combined benzene solutions were then placed in a separatory funnel and washed four times with about equal volumes of water to remove the excess dihydroxyacetone monoacetate. The resulting benzene solution was dried over calcium chloride and then evaporated under vacuum to a thick, light yellow sirup at a bath temperature below 45°. This sirup was dissolved in 100 cc. of warm ether to which was added about one-third of its volume of isoamyl alcohol. This was then placed in the ice box in a stoppered flask. Crystallization began after a few hours and was practically complete after four days.[8] The crystals were filtered from the mother liquor and washed with a little cold ether. The yield of crude product was 11.4 g. or 46% of the theoretical based on the amount of β-acetobromo-*d*-glucose used. For purification, the crystals were dissolved in chloroform, warmed and treated with Norite, filtered and then carefully evaporated to a sirup of moderate consistency. This was warmed to 40° and then ten times its volume of warm ether was added and mixed to homogeneous solution. Crystallization usually took place on cooling, but when it was not spontaneous it was induced by gentle rubbing with a glass rod. After the fourth recrystallization as above was completed both the melting point and the rotation were constant: m. p. 103° (corr.); $[\alpha]^{18}\text{D}$ −25.2° (*c*, 4.2; $CHCl_3$). This compound is very soluble in acetone and chloroform, fairly soluble in benzene, ether, and ethyl alcohol, sparingly soluble in butyl and amyl alcohols and insoluble in petroleum ether and water.

Anal. Calcd. for $C_9H_{11}O_8(COCH_3)_5$: acetyl, 10.82 cc. 0.1 *N* NaOH per 100 mg. Found: acetyl, 10.81 cc.

β-*d*-Glucosidodihydroxyacetone Pentaacetate *p*-Nitrophenylhydrazone.—This compound was most easily prepared by taking 1.0 g. (1.0 mole) of β-*d*-glucosidodihydroxyacetone pentaacetate and 0.39 g. (1.05 moles) of *p*-nitrophenylhydrazine and dissolving them in 25 cc. of absolute alcohol. Complete solution was effected by heating under slow reflux, which was continued for two hours. Often during this heating, and always after cooling in the ice box, feathery light yellow needles separated. It was recrystallized four times from ethanol. The yield was

[8] In case crystallization does not begin at the end of the first day it is because there has been some mistake made in following the directions as they are given here. Of all the Königs-Knorr reactions we have run, this is by far the most sensitive to changed conditions, and if the stipulated procedure is not carried out exactly as directed the yield may fall as low as half the amount this preparation records. When this happens the first crystallization of the product is often difficult, but we have found from experience that crystallization can nearly always be effected by the following simple device. Add another volume of isoamyl alcohol equal to the amount already in the flask, mix thoroughly and then leave the flask unstoppered in a warm place (25°) to allow the ether to evaporate spontaneously. Crystals often do not form for several days until the ether concentration is considerably diminished, and it may take as long as two weeks for crystallization to be complete, but if one is patient the method seldom fails. The last day before the crystals are removed the flask should be stoppered and placed in the ice box. From this point, proceed as in the regular directions.

nearly quantitative: m. p. 187° (corr.); $[\alpha]^{19}\text{D}$ −129.8° (*c*, 1.76; $CHCl_3$).

Anal. Calcd. for $C_{15}H_{16}O_9N_3(COCH_3)_5$: acetyl, 8.37 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 8.37 cc.

β-Cellobiosidodihydroxyacetone Octaacetate.—The following materials were used: 4.0 g. (2.0 moles) of dihydroxyacetone monoacetate, 65 cc. (50 moles) of benzene, 4.2 g. (1.0 mole) of silver carbonate, 14 g. (7.0 moles) of Drierite and 10.5 g. (1.0 mole) of acetobromocellobiose. The procedure for the synthesis and subsequent purification of this compound was exactly like that for β-*d*-glucosidodihydroxyacetone pentaacetate through the point where the benzene solution had been evaporated to a thick sirup. Here the product was dissolved in warm, absolute ethanol, treated with Norite, filtered and concentrated to about 40 cc. by boiling. Crystallization occurred by allowing this solution to cool to room temperature and was completed after the solution had been left in the ice box for an additional three hours. The yield of well crystallized product was 5.92 g. or 52.5% of the theoretical based on the amount of acetobromocellobiose used. It was recrystallized for analysis alternately from chloroform–ether and from acetone–ether, using each thrice, after which its melting point and rotation did not change further: m. p. 169° (corr.); $[\alpha]^{20}\text{D}$ −27.1° (*c*, 3.78; $CHCl_3$). This compound is very soluble in acetone and chloroform, moderately soluble in hot ethyl alcohol, sparingly soluble in warm ether and benzene and practically insoluble in cold petroleum ether and water.

Anal. Calcd. for $C_{15}H_{18}O_{13}(COCH_3)_8$: acetyl, 10.67 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 10.59 cc.

β-Cellobiosidodihydroxyacetone Octaacetate *p*-Nitrophenylhydrazone.—The preparation of this compound was similar to that of β-*d*-glucosidodihydroxyacetone pentaacetate *p*-nitrophenylhydrazone as described above. A nearly quantitative yield of fine, light yellow needles resulted. This was recrystallized from ethanol twice and then from benzene once, after which it had a constant melting point and rotation: m. p. 176° (corr.); $[\alpha]^{20}\text{D}$ −72.9° (*c*, 1.4; $CHCl_3$).

Anal. Calcd. for $C_{21}H_{23}O_{14}N_3(COCH_3)_8$: acetyl, 9.04 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 8.98 cc.

β-Gentiobiosidodihydroxyacetone Octaacetate.—The procedure for the preparation of this compound is exactly like that of β-cellobiosidodihydroxyacetone octaacetate. The following materials were used in a typical experiment: 3.6 g. (2.0 moles) of dihydroxyacetone monoacetate, 60 cc. (50 moles) of benzene, 3.75 g. (1.0 mole) of silver carbonate, 13.0 g. (7 moles) of finely powdered Drierite, and 9.5 g. (1.0 mole) of acetobromogentiobiose.

The yield of well crystallized product was 6.0 g. or 59% of the theoretical based on the acetobromogentiobiose used. Its solubility behavior is very nearly the same as that of its cellobiosido analog: m. p. 172° (corr.); $[\alpha]^{23}\text{D}$ −25.9° (*c*, 3.3; $CHCl_3$).

Anal. Calcd. for $C_{15}H_{18}O_{13}(COCH_3)_8$: acetyl, 10.67 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 10.55 cc.

β-Gentiobiosidodihydroxyacetone Octaacetate Methyl Alcoholate.—When β-gentiobiosidodihydroxyacetone octaacetate is recrystallized from methyl alcohol, a crystalline alcoholate appears to be formed. When this substance is heated slowly it melts at 110–112°, but on heating further it crystallizes again, melting the second time more sharply at 171–172°. The methyl alcohol may also be removed from the complex by heating it in a vacuum oven at 50° at 20 mm. of mercury pressure. A micro-rotation of this alcoholate was made and gave $[\alpha]^{20}\text{D}$ −25.0° (*c*, 2.1; $CHCl_3$). If the alcoholate would readily dissociate in chloroform solution we might expect this ratio to hold:

$$\frac{\text{mol. wt. alcoholate}}{\text{mol. wt. gentiobiosido-}} = \frac{\text{rotation gentiobiosido-}}{\text{rotation alcoholate}}$$

$$782/750 = -25.9/X$$

X may be calculated to be $[\alpha]\text{D}$ −24.9°, which is in good agreement with the observed $[\alpha]^{20}\text{D}$ −25.0°. Hence, it is probable that this compound is β-gentiobiosidodihydroxyacetone octaacetate methyl alcoholate, in which one molecule of the methyl alcohol is loosely bound.

β-Gentiobiosidodihydroxyacetone Octaacetate *p*-Nitrophenylhydrazone.—The method of its preparation and purification was very similar to that used for β-cellobiosidodihydroxyacetone octaacetate *p*-nitrophenylhydrazone. Again a nearly quantitative yield of fine light yellow needles was obtained, which after recrystallization twice from ethanol and once from benzene gave a constant melting point and rotation; m. p. 155° (corr.); $[\alpha]^{20}\text{D}$ −77.2° (*c*, 1.5; $CHCl_3$).

Anal. Calcd. for $C_{21}H_{23}O_{14}N_3(COCH_3)_8$: acetyl, 9.04 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 9.00 cc.

Deacetylation of the Oligosaccharide Acetates.—It is known that great care must always be exercised in the deacetylation of any carbohydrate if it contains either a free aldehyde or a free ketone group. Ketone sugars are especially sensitive in this respect.[9] As all the new oligosaccharide acetates contained the alkali-sensitive ketone group, only the mildest deacetylation agents were employed. The acetyl groups were easy to remove, but we invariably encountered the difficulty of the deacetylating agent attacking the sensitive free ketone group and causing deep-seated changes in the free oligosaccharide that had been liberated. This yielded a complex mixture of substances from which it was impossible to separate a pure crystalline product.

For this work we chose what appeared to be the three mildest deacetylating agents in the literature: the barium methylate–methyl alcohol method of Isbell[10] where the barium methylate is eventually decomposed by an exact titration with sulfuric acid; Levene and Tipson's modification[11] of Isbell's method where the excess reagent is decomposed with carbon dioxide; and finally the slightly more vigorous ammonia–methyl alcohol method where the directions of Fischer and Taube[12] were followed. All three methods caused the formation of small amounts of yellow to brown decomposition products that seemed similar in character, but much smaller in amount, to the prod-

ucts formed by sugars through alkaline degradation according to methods of Evans and co-workers.[13]

Discussion

It should be pointed out that the use of finely powdered Drierite as an internal desiccant in Königs–Knorr reactions is a very worthwhile practice. In the past when this reaction was used to prepare oligosaccharides (without the use of internal desiccants), yields ranging from a low of 0.25%[14] to a maximum of about 25%[15] were recorded. Yields of from 10 to 20% were the most common.[16] This is in sharp contrast to the 46, 52 and 59% yields recorded in this paper for the preparation of the same type of compounds.

The use of the new oligosaccharide acetates reported here in further elucidating the mechanism of the alkaline degradation of the more complex carbohydrates will be discussed in detail in a later paper.

The assignment of the β-configuration follows from the fact that the values of Hudson's *A* for the new oligosaccharide acetates are in each case positive, as was explained in a previous paper.[1]

β-*d*-glucosidodihydroxyacetone pentaacetate $A = +32{,}200$
β-cellobiosidodihydroxyacetone octaacetate $A = +29{,}300$
β-gentiobiosidodihydroxyacetone octaacetate $A = +35{,}400$

The configuration of the *p*-nitrophenylhydrazones and of the methyl alcoholate follows from the configuration proved for the parent oligosaccharide acetates from which they were prepared.

In connection with the deacetylation of the oligosaccharide acetates it is very interesting to note that C. L. Bernier[17] found that the Kunz method[18] of acetyl determination was inapplicable to dihydroxyacetone monoacetate, as the results were invariably high. We also observed that the Kunz method failed for oligosaccharide acetates that contained dihydroxyacetone as a reducing constituent, for here too the results were about ten per cent. high. (In a typical analysis, 0.2132 g. of β-*d*-glucosidodihydroxyacetone pentaacetate required 25.42 cc. of 0.1 *N* NaOH; calcd. is 23.07 cc.) The acetyl analyses recorded in this paper were all made by the Freudenberg absolute method[19] and in no case was there any difficulty in either duplicating results or getting values that checked closely with theory. These facts indicate an unusual susceptibility of dihydroxyacetone to degradation by alkali.

Attention should also be called to the fact that the preparation of β-*d*-glucosidodihydroxyacetone pentaacetate and of β-gentiobiosidodihydroxyacetone octaacetate now make possible the study of a fairly complete sugar series where each higher member differs from the preceding one by the addition of three carbohydrate carbons to the carbohydrate chain as it lengthens:

	M. p., °C.	$[\alpha]_D$ in $CHCl_3$
Dihydroxyacetone diacetate[20]	42–45	...
β-*d*-Glucose pentaacetate[21]	132	+3.8°
β - *d* - Glucosidodihydroxyacetone pentaacetate	103	−25.2°
β-Gentiobiose octaacetate[22]	192–193	−5.3°
β - Gentiobiosidodihydroxyacetone octaacetate	172	−25.9°
6 - β - Gentiobiosido - β - *d* - glucose hendecaacetate	221	−8.0°

These may be thought of as constituting an "homologous series" among the carbohydrates, as it is analogous to the various homologous series among the hydrocarbons. A detailed study of the physical and chemical properties of the members of this series should prove interesting and profitable. The periodic rise and fall both of the melting points and the magnitude of the optical rotations are apparent from the data presented above.

Summary

1. The following new compounds were prepared in pure crystalline form and their characteristic properties determined: β-*d*-glucosidodihydroxyacetone pentaacetate, β-*d*-glucosidodihydroxyacetone pentaacetate *p*-nitrophenylhydrazone, β-cellobiosidodihydroxyacetone octaacetate, β - cellobiosidodihydroxyacetone octaacetate *p* - nitrophenylhydrazone, β-gentiobiosidodihydroxyacetone octaacetate, β-gentiobiosidodihydroxyacetone octaacetate methyl alcoholate and β-gentiobiosidodihydroxyacetone octaacetate *p*-nitrophenylhydrazone.

2. The first trisaccharide to contain a triose

constituent has been synthesized as its acetate.

3. A postulated intermediate in alkaline degradation of gentiobiose has been synthesized in a pure form as its acetate.

4. Attention is directed to the importance of using Drierite as an internal desiccant when the Königs–Knorr reaction is used to prepare oligosaccharides.

5. The susceptibility of dihydroxyacetone to degradation by alkali is pointed out.

6. With the synthesis of β-*d*-glucosidodihydroxyacetone pentaacetate and β-gentiobiosidodihydroxyacetone octaacetate the first six members of a homologous series among the carbohydrates are now available for study.

The Relative Rates of Combination of Hydrogen and Deuterium with Ethylene

BY A. WHEELER AND R. N. PEASE

In the present investigation the relative rates of combination of hydrogen and deuterium with ethylene have been measured, both for the homogeneous reaction and on a copper catalyst at 0°. Preliminary results with deuterium of unknown purity have already been published.[1] The present data are in good agreement with the earlier experiments, indicating that the heavy hydrogen used in the first experiments contained about 20% of the light isotope. This considerable contamination in the earlier experiments was due to the fact that, for the removal of oxygen, the heavy isotope was passed through a supported nickel catalyst often exposed to the light isotope for the same purpose. (The contamination of light hydrogen by deuterium probably did not occur, since the catalyst was always subjected to copious sweeping out before a sample of the light isotope was taken.) As is obvious, the earlier experiments were performed before the importance of exchange reactions between hydrogen and deuterium was realized.

Experimental Procedure

The apparatus and experimental procedure have been described by one of us elsewhere.[2] Both light and heavy hydrogen were prepared by electrolysis from caustic solution. The light hydrogen was passed subsequently through a calcium chloride tube, over a supported nickel catalyst at 500°, and finally through a trap at −80°. The deuterium was led over a hot platinum wire spiral and through a trap at −80°. Analysis (mass spectrographic and gas balance) showed the purity of the deuterium to be >99%. Compressed ethylene of high purity was subjected to fractional distillation before use. For the catalytic experiments, Kahlbaum copper oxide granules, "zur analyse," were reduced in light hydrogen at 200°, and the resulting product deactivated by heating *in vacuo* for one hour at 500°.

Since preliminary experiments indicated that exchange reactions of the type $D_2 + C_2H_4 \longrightarrow C_2H_3D + HD$ were to be looked for in the runs with deuterium, provision was made for the analysis of the light hydrogen content in the residual gas at the end of a run. The analysis was effected by freezing out ethylene and ethane with liquid air, and measuring the viscosity of the residual hydrogen gas in a Rankine-type viscometer.[3] By comparing the viscosity of the residual gas with that of pure deuterium, the approximate light hydrogen content of the sample could be found. The reproducibility of the viscometric readings was better than 1%, but the presence of methane (vapor pressure about 93 mm. at liquid air temperature) in the high temperature homogeneous runs, together with the possibly incomplete freezing out of the ethylene and ethane, make the viscometric results somewhat uncertain. However, they should set an upper limit for the light hydrogen content in the residual gas at the end of any given run.

I. The Homogeneous Reaction.—Reaction was carried out at four temperatures, namely, 534, 555, 567 and 574°. In agreement with the earlier work[2b] on the reaction of light hydrogen with ethylene, it was observed that one does not obtain good second order rate constants by extrapolating the pressure measurements to zero time and computing the rate constants from this point. Instead the procedure adopted, as before,[2b] was to use the fifth minute as zero time, the partial pressure of hydrogen and ethylene at this point being calculated from the extrapolated value for the initial pressure. In this way good rate constants were obtained, leading to the same value for the relative rates of the hydrogen and deuterium reaction which one calculates by comparing directly the times necessary for corresponding pressure drops. In Table I the rate constants are in the units (mm. × sec.)$^{-1}$. The second column indicates whether light hydrogen or deuterium was used in a given run, while the fifth column gives the ratio of the rate of the light hydrogen reaction to the rate of the deuterium reaction. The sixth and seventh columns contain the extrapolated initial partial pressures of hydro-

gen and ethylene. In all runs three parts of hydrogen to one of ethylene were used, in order to cut the methane formation to a minimum.[2b]

It is to be noted that the observed temperature coefficient of the light hydrogen reaction agrees well with that found in the earlier research on this reaction. There is, however, a small discrepancy in the absolute values of the rate constants at a given temperature. This consistent discrepancy undoubtedly is due to temperature calibration errors, amounting to about four degrees. An error of two degrees in each research, working in opposite directions, is well within the realm of possibility.

Table I shows that over the temperature range investigated light hydrogen reacts with ethylene two and a half times as fast as the heavy isotope. Although this would apparently point to no difference in the activation energies of two reactions, a difference of one thousand calories might easily escape detection.

The evidence with regard to exchange reactions given by the viscometric measurements is as follows: (1) at 580° deuterium does not exchange with Pyrex glass previously exposed to the light isotope.

TABLE I

Run	H_2 or D_2	T, °C.	$k \times 10^7$ (mm. × sec.)$^{-1}$	$\alpha = \frac{k_{H_2}}{k_{D_2}}$	$P^0_{\text{Hyd.}}$ mm.	$P^0_{C_2H_4}$, mm.
17	H_2	534	6.5	2.5	577.5	192.5
21	D_2	534	2.6		580.8	193.6
22	H_2	555	14.8	2.57	583.2	194.4
23	D_2	555	5.75		577.5	192.5
6	H_2	567	21.7	2.47	596.4	198.8
7	D_2	567	8.8		590.4	196.8
26	D_2	574	11.0		613	204.3

A sample of pure deuterium was allowed to remain for three hours in a Pyrex bulb maintained at 580°. The time of fall for the mercury pellet in the viscometer was 50.5 seconds for the sample, while for untreated deuterium it was 50.7 seconds, and for pure light hydrogen 36.4. It is to be noted that the ratio of viscosities η_{D_2}/η_{H_2} was consistently observed to be 1.395 ± 0.003. This is to be compared with the theoretical ratio of 1.41 obtained by Maass.[4] (2) Below 534° exchange reactions such as $D_2 + C_2H_4 \longrightarrow C_2H_3D + HD$ are absent or of negligible importance. The time of fall for the mercury pellet with pure D_2 filling the viscometer was 72.7 seconds, and with the D_2 residue from a run at 534° the time was 72.5. For pure light hydrogen the time was 52.0 seconds. (3) In the temperature region 570° exchange reactions may play roles of some importance. The time of fall for the mercury pellet with the deuterium residue from a run at 567° was 70.5 seconds, for pure D_2, 72.7 seconds, and for pure H_2, 52.0 seconds. For the deuterium residue from a 3 to 1 deuterium–ethylene mixture maintained at 567° for twenty-four hours, the time of fall was 66.5 seconds, indicating a maximum of about 20% light hydrogen.

Discussion of Homogeneous Reaction.—It has been shown[2b] that the reaction of ethylene with hydrogen in Pyrex bulbs is unambiguously homogeneous and second order. The actual mechanism of the reaction is, however, in dispute at the present time. Two mechanisms have been put forward: (1) that the reaction is a straightforward bimolecular association reaction[2b] and (2) that reaction proceeds through the following free-radical chain mechanism[5]

$$\begin{array}{llll}
\text{I} & C_2H_4 + H_2 \rightleftarrows C_2H_5 + H & E_1, E_1' \\
\text{II} & C_2H_4 + H \rightleftarrows C_2H_5 & E_2, E_2' \\
\text{III} & C_2H_5 + H_2 \longrightarrow C_2H_6 + H & E_3 \\
\text{IV} & C_2H_5 + H \longrightarrow C_2H_6 & E_4
\end{array}$$

The double arrows in reactions I and II indicate that the reactions are reversible, not that equilibrium is maintained. E_1 is the activation energy for reaction I in the forward direction; E_1' the activation energy for the reverse reaction, etc. It has been shown[5] that the above mechanism gives a second order rate of formation of ethane, with approximately the correct temperature coefficient. The actual expression is

$$-\frac{d\,C_2H_4}{dt} = \sqrt{\frac{k_1k_2}{k_1' + k_4}}\,(C_2H_4)(H_2)$$

Here the k's and k''s are the rate constants for the corresponding forward and reverse reactions. It was hoped that the difference in the rates of hydrogenation and deuterization of ethylene might enable one to decide whether the reaction is a straightforward association or a chain reaction. Unfortunately no clear-cut decision may be made. However, the following evidence may be brought forward. Since in the chain mechanism $k_2/(k_1' + k_4)$ involves in each k only the reaction of a hydrogen or a deuterium *atom* (no zero point considerations for reactants) it is reasonable to suppose that this ratio is the same for both the hydrogen and deuterium reactions. This being so, according to the chain mechanism the ratio of rates of the hydrogenation and deuterization processes must depend solely on the ratio of $\sqrt{k_1}$ for the two processes. In terms of a collision theory this means that

$$2.5 = \left[1.4\,e^{-\frac{\Delta E_0}{RT}}\right]^{1/2}$$

where ΔE_0 is the difference in zero-point energy for H_2 and D_2 as they enter into reaction I of the chain mechanism. In order for the above equation to be fulfilled, ΔE_0 must equal 2400 calories. It is well known,[6] however, that the *maximum* zero-point energy difference for reaction involving H_2 or D_2 is 1800 calories. It would appear, then, that the chain mechanism given above is

---

(4) Maass, *Can. J. Research*, **12**, 57–62 (1935).

(5) F. O. Rice and K. F. Herzfeld, THIS JOURNAL, **56**, 284 (1934).

(6) Eyring and Sherman, *J. Chem. Phys.*, **1**, 6 (1933).

in questionable agreement with the experiments. In addition it may be cited that packing the reaction vessel[2b] in no way affects the rate of formation of ethane, and that in the present investigation the addition of one-half an atmosphere of nitrogen to a deuterium–ethylene mixture had no marked effect on the observed rate. Recent experiments on the reverse reaction[7] (*i. e.*, the decomposition of ethane) indicate that free radicals are absent during the initial stages of reaction. In view of the total lack of evidence for a chain reaction, it seems more likely that the hydrogenation of ethylene proceeds by a straightforward association mechanism.[8]

If, then, the hydrogenation of ethylene proceeds through a bimolecular association, the observed ratio of 2.5 for the hydrogen and deuterium reactions is easily accounted for. In terms of collision theory

$$k_{H_2}/k_{D_2} = 2.5 = 1.4\ e^{+\Delta E_0/kT}$$

where ΔE_0 is the effective difference in zero-point energy of H_2 and D_2, as they enter into this reaction. At 550°, ΔE_0 must be 950 cal. in order to satisfy the above equation.

According to an activated complex picture

$$\frac{k_{H_2}}{k_{D_2}} = \left(\frac{m^*_{H_2}}{m^*_{D_2}}\right)^{3/2} \left(\frac{I^*_{H_2}}{I^*_{D_2}}\right)^{1/2} \left(\frac{V^*_{H_2}}{V^*_{D_2}}\right) \left(\frac{m_{D_2}}{m_{H_2}}\right)^{3/2} \left(\frac{I_{D_2}}{I_{H_2}}\right) e^{+\frac{\Delta E_0}{kT}}$$

Here the m^*, I^*, V^* are respectively the masses, products of moments of inertia, and vibrational partition functions, for the activated complexes. A quantity referring to a complex formed by the union of H_2 with C_2H_4 is denoted by the subscript H_2, and has an asterisk after it; similarly for D_2. m_{D_2} and I_{D_2} are the mass and moment of inertia of the normal deuterium molecule; and similarly for the subscript H_2. If we denote the zero-point energy of a species by E_0, ΔE_0 is defined by $E_0 = E_{0D_2}^* - E_{0H_2}^* + E_{0H_2} - E_{0D_2}$. We know all quantities in the above except for the I^*'s, V^*'s and ΔE_0. Substituting numerical values we find

$$\frac{k_{H_2}}{k_{D_2}} = 2.5 = 5.14 \left(\frac{I^*_{H_2}}{I^*_{D_2}}\right)^{1/2} \left(\frac{V^*_{H_2}}{V^*_{D_2}}\right) e^{\Delta E_0/kT}$$

For the normal ethane molecule in the region 850°K., V, the vibrational partition function, is only about eight,[9] and some, if not most, of the low frequencies contributing to this are associated with motions of the carbon atoms. A reasonable value for $V^*_{H_2}/V^*_{D_2}$ is 0.9. A reasonable value for $(I^*_{H_2}/I^*_{D_2})^{1/2}$ is $^1/_2$. This is equivalent to assuming that each of the three moments of inertia of the activated complex is 60% larger for the deuterium complex than in the light hydrogen complex. This may seem like a large percentage, but it must be remembered that the distended hydrogen atoms are contributing heavily to the moments of inertia, and hence the effect of the heavier deuterium atoms will be considerable.

Putting these values in our expression we get

$$\frac{k_{H_2}}{k_{D_2}} = 2.32\ e^{\frac{\Delta E_0}{kT}} = 2.5 \text{ (observed)}$$

From this it follows that ΔE_0 must be a very small quantity, about 120 calories. Indeed, this is what one would expect. Since the activated complex has seventeen modes of vibration, many of them with high frequencies, it is reasonable to suppose that zero-point energy differences for H_2 and D_2 would almost cancel, and it would not even be surprising if ΔE_0 were negative. In the case of $H_2 + I_2 \longrightarrow 2HI$, and $D_2 + I_2 \longrightarrow 2DI$, calculations by one of us[10] show that zero-point energy differences cancel, even though the activated complex has only five modes of vibration.

II. The Catalytic Reaction.—Reaction was carried out at two temperatures, 0 and 20°, on an active copper catalyst. The results are shown in Table II. In the earlier work[2a] on the light hydrogen reaction, it was shown that the reaction rate is unimolecular with respect to hydrogen and is inhibited by ethylene. It was found in the present experiments that this is also true for deuterium.

TABLE II

Run	Temp., °C.	H_2 or D_2	$k \times 10^{+3}$ (min.$^{-1}$)	$\alpha = \frac{k_{H_2}}{k_{D_2}}$	P^0_{Hyd}, mm.	$P^0_{C_2H_4}$, mm.
30	0	H_2	5.2	2.08	372	372
31	0	D_2	2.5	1.78	352	352
32	0	H_2	4.45	2.07	353	353
33	0	D_2	2.18		345	345
35	20	D_2	9.9	2.1	380	380
36	20	H_2	20.9		378	378
37	0	D_2	2.2	1.83	366	366
38	0	H_2	4.0		366	366

The rate constants in Table II are first order constants, calculated with respect to hydrogen. Pressures are in mm. and times in minutes. Otherwise the quantities in Table II have the same significance as in Table I. The activity of the freshly prepared catalyst was falling consid-

erably, and for this reason the quantity α goes through periodic variations. That is, α for two runs in which the deuterium run followed the hydrogen run is larger than for the inverted case, as one would expect if the catalyst is losing activity. The average value for α at 0° is 1.94. The data at 20° are insufficient to be conclusive, but the 2.1 value of α at 20° must be compared with 2.07 at 0°. Within the experimental error, then, the temperature coefficients (in the range 0–20°) for the hydrogen and deuterium reactions are the same. However, it is to be noted that a difference sufficient to take account of all the difference between the rates of the two reactions in terms of unequal activation energies would have escaped detection.

The observed ratio of two between the rates of the hydrogen and deuterium reactions might be due to any of a number of causes. Collision rates of hydrogen and deuterium with the surface would introduce a factor of 1.4; rates of adsorption may differ by as much as 3.3;[11] different rates of surface reaction may result in rates differing by a factor of 4.4, if the difference in zero-point energies of the Cu–H and Cu–D complexes be taken as 800 cal.[6] It is fairly obvious that we are dealing with something more than a collision frequency. However, extended discussion seems hardly profitable at this time.

Analysis showed no exchange between deuterium and ethylene on the copper catalyst at 0°.

Summary

It has been found that the rate of reaction of hydrogen with ethylene is greater than that of deuterium by a factor of 2.5 in the homogeneous reaction at ~ 500°; and by a factor of 2 in the catalytic reaction over copper at 0°. Exchange reactions are unimportant.

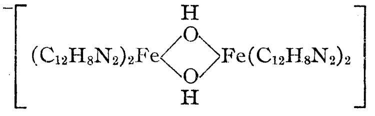
The Structure and Properties of Mononuclear and Polynuclear Phenanthroline-Ferric Complexes[1]

BY ALLISON GAINES, JR., LOUIS P. HAMMETT AND GEORGE H. WALDEN, JR.

The beautifully complete papers in which Blau[2] reported the discovery of the unusually stable complexes which the bases dipyridyl  and *o*-phenanthroline  form with metallic ions propounded, nevertheless, a puzzling problem for valence theory in the existence of two different ferric complexes. One of these, blue in color, is obtained only by oxidation of the ferrous complex. Analysis of the chloroplatinate showed that its formula is $[Fe(C_{12}H_8N_2)_3]^{+++}$ and it would indeed be difficult to reconcile any other composition with the fact that it forms a mobile oxidant–reductant system with the ferrous complex, whose formulation as $[Fe(C_{12}H_8N_2)_3]^{++}$ is well established. By contrast direct reaction of phenanthroline and ferric salts leads to the formation of brown solutions from which Blau isolated no solid compounds. He noted, however, color reactions which suggested the existence of a brown complex with the same ratio, 3:1, of phenanthroline to ferric ion as that which obtains in the blue complex.

We have, however, obtained from these brown solutions a crystalline salt of definite composition whose properties correspond to the formula



$$\left[(C_{12}H_8N_2)_2Fe\overset{H}{\underset{H}{\langle\overset{O}{\underset{O}{}}\rangle}}Fe(C_{12}H_8N_2)_2\right]Cl_4 \qquad (A)$$

of a tetraphenanthroline-diol-diferric chloride. The polynuclear complex ion contained in this salt appears to be the major constituent of the brown solutions. In spite of the fact that the phenanthroline–iron ratio in this complex is 2:1, there is no contradiction between our result and Blau's, which we have indeed confirmed, because in the formation of the bridge hydroxyl or "ol" groups, one hydrogen ion is set free from a water molecule for each ferric ion reacting. The combination of this hydrogen ion with phenanthroline raises to a value considerably above two

---

[2] Blau, *Monatsh.*, **19**, 647 (1898).

the proportion of phenanthroline which may become combined as a consequence of the reaction of one ferric ion.

The study of this compound has led to conclusions about the acidity of ol-compounds, about the magnetic properties of polynuclear complexes and about the solubility method of studying complexes which have considerable general interest for problems of complex chemistry.

The Crystalline Brown Chloride, Substance A

Preparation.—This new substance is conveniently prepared by the following method: 50 ml. of a 0.300 molar solution of ferric chloride (0.0150 mole of Fe^{+++}) is added to a well-stirred suspension of 5.400 g. of *o*-phenanthroline hydrate (0.0300 mole of phenanthroline) in 50 ml. of water. The phenanthroline dissolves, and after about an hour a brown crystalline precipitate begins to form. After standing overnight, this is filtered off, washed several times with small quantities of water and dried over sulfuric acid at 2–4 mm. absolute pressure. The yield is from 50 to 60% of the theoretical amount.

We have prepared six different samples from solutions of various compositions as follows.

TABLE I

Sample	Mole ratio phenanthroline/iron	Concn. HCl
a	3	0.00
b, d	3	.04
c, f	2	.00
e	2	.04

Analysis.—Iron was determined by heating the sample in 1 *M* hydrochloric acid to decompose the complex, followed by reduction in the silver reductor[3] and titration with ceric sulfate. The accuracy of this procedure was checked by analyzing aliquots of a ferric chloride solution in the presence and in the absence of two moles of phenanthroline per mole of iron. Three portions in the absence of phenanthroline required an average of 17.42 ml. of ceric sulfate solution with an average deviation of 0.75 part per thousand. Three portions in the presence of phenanthroline required an average of 17.46 ml. with an average deviation of 1.1 parts per thousand.

Phenanthroline was determined by dissolving the sample in about 15 ml. of 6 *M* hydrochloric acid, heating to decompose the complex, and adding saturated mercuric chloride solution slowly from a buret, while the solution was stirred, until the total volume was 192 ml. After standing overnight the precipitate was transferred to a tared crucible with a porous porcelain bottom, washed free from chloride, dried at 110° and weighed. This procedure was verified on amounts of phenanthroline ranging from 0.0500 to 0.3000 g. both in the absence and presence of an equimolar amount of ferric chloride. The average value for the ratio weight phenanthroline/weight precipitate was 0.4001 with an average deviation of 4 parts per thousand in eight determinations. The precipitate is probably $(C_{12}H_8N_2)$-$HgCl_2$[4] for which the above factor is 0.3983. Morgan and Burstall[5] have used the entirely analogous iodide for the quantitative determination of α,α'-dipyridyl.

Chloride was determined by two methods. Method A was a modification of the standard precipitation of silver chloride in which the $[H^+]$ was increased to decompose the complex and the filtration was carried out at 80–90°, to avoid contamination with the silver phenanthroline complex which precipitates from the cold solution. An empirically determined correction was applied for the solubility of silver chloride under the standardized conditions. Method B was the thoroughly tested chromyl chloride distillation method of Robertson.[6] The special all-glass apparatus of Hammett and Lowenheim[7] was used for the analyses.

Results of Analyses.—Samples (a), (b) and (c) were analyzed without intensive drying. They showed the following values of the ratio moles phenanthroline/moles iron, (a) 2.10, (b) 2.078, (c) 2.081, and for moles chloride/moles iron (a) 2.06, (b) 2.013, (c) 1.987. Samples (d), (e) and (f) were analyzed after long-continued drying over 98% sulfuric acid and fresh calcium chloride at 2–4 mm. absolute pressure with the following results.

TABLE II

Sample, found	Iron, %	Phenanthroline, %	Chloride, %
d	11.00	72.24	14.17
e	11.00	72.40	14.31
f	11.07	72.30	14.23
	11.05	72.40	14.16
Calcd. formula (A)	11.06	71.50	14.05

Hydration.—The dried compound is very hygroscopic. Two samples were exposed to the atmosphere until constant weight was reached. One gained 7.47% and the other 7.06%. Assuming formula (A) a tetrahydrate would require 7.16%.

Conductivity.—The specific conductivity of a solution whose concentration, based upon formula (A), was 0.0005023 mole per liter, was found to be 2.5152×10^{-4} mho. The specific conductivity of the water used in preparing the solution was 6.160×10^{-6} mho. The molar conductivity is therefore 488.5 mho, which is an entirely reasonable figure for a salt of this type, provided all of the chloride is ionogen. A consideration of the acidic properties of the compound does not change this conclusion.

Acid–Base Properties.—Twenty-five ml. of a 0.00491 *M* solution of substance (A) (preparation (f)) was titrated with 0.02013 *M* sodium hydroxide using a glass electrode.[8] The titration curve is shown in Fig. 1 in which the points are experimental and the solid curve is calculated for a dibasic acid whose *pK* values are 4.30 and 6.40. The agreement is satisfactory except toward the end of the titration where some other reaction, leading to precipita-

tion at the point marked by the arrow, overlaps the simple neutralization process.

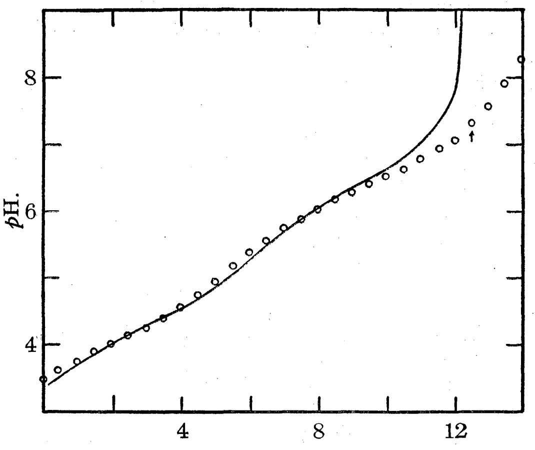

Fig. 1.—Titration of tetraphenanthroline-diol-diferric chloride solution with sodium hydroxide.

Magnetic Properties.—The magnetic susceptibilities of solutions of several ferric phenanthroline and other iron complexes were determined by the Gouy method.[9] Essentially, a definite volume of a solution of the substance to be investigated was placed in a glass tube which was suspended from one arm of an analytical balance so that the plane bottom of the tube was symmetrically placed in the magnetic field between the poles of a powerful electromagnet (*ca.* 20,000 gausses). The force exerted on the tube and contents was determined by weighing. Deducting the force exerted on the empty tube by the standardized field gives the force exerted on the solution. The equation relating the force on the solution with its susceptibility is $F = {}^1/_2A(\kappa_1 - \kappa_2)(H_1^2 - H_0^2)$ where

A = cross-sectional area of the column
κ_1 = volume susceptibility of the solution
κ_2 = volume susceptibility of air
H_1 = field at plane bottom of the tube
H_0 = field at upper level of liquid

For the tube used and the constant field which was maintained the force exerted when the tube was filled with water to the constant level which was also used for the solutions was −0.0296 g. Using Brant's[10] values obtained at 20° for the volume susceptibility of water, -0.71798×10^{-6}, and for that of air, $+0.0288 \times 10^{-6}$, this gave a value for the quantity ${}^1/_2A(H_1^2 - H_0^2)$, by means of which, together with the measured force when the tube was filled with the solution, the volume susceptibility of the latter can be calculated. Division of this figure by the density, which was determined at 27°, the average temperature of the experiments, gives the mass susceptibility of the solution, χ_1.

By Wiedeman's law of the additivity of susceptibilities the value for the solute may be calculated from the relation

$$m_1\chi_1 = m_s\chi_s + m_w\chi_w$$

in which m is mass in grams, χ is specific susceptibility, and the subscripts 1, s and w refer to solution, solute, and water, respectively.

Multiplication of χ_s by the formula weight associated with one gram atom of iron in the compound, and subtraction from the resulting figures of the sum of the Pascal additive values for the susceptibilities of the various atoms of carbon, nitrogen, etc., present gives a quantity which should be a good approximation (in spite of the constitutive effects and other inaccuracies of the Pascal relationship) to the atomic susceptibility of the iron atoms present in the compound. It is so listed in column 6 of Table III, which gives the results on solutions of the brown chloride (preparation (f)), of potassium ferricyanide, and of the blue triphenanthroline ferric sulfate. The latter solution was prepared by oxidizing a solution of phenanthroline ferrous sulfate in 0.7 molar sulfuric acid with lead dioxide, and filtering through porous porcelain. The susceptibility was determined immediately. The value of the magnetic pull in the table was obtained by graphical extrapolation to the time when filtration was started of the following values: 20 min., −0.0217; 40 min., −0.0187; 75 min., −0.0143; 125 min., −0.0117 g. The volume susceptibility of the 0.7 molar sulfuric acid was found to be identical with that of water, and its density was 1.0451.

Our value for the atomic susceptibility of the iron in potassium ferricyanide is in approximate agreement with the value of Gray and Birse[11] obtained from measurements on solution, and with that of Ishiwara[12] from measurements on the solid salt. The value for the susceptibility of the iron in the blue complex is nearly the same as that which it has in ferricyanide, which emphasizes the probability that this value is typical for ferric iron in complexes which involve electron sharing. The values of magnetic moment in Bohr magnetons (P_B) calculated from these susceptibilities by the equation

$$P_B = \sqrt{3RT\chi_{Fe}}/5593$$

are 2.4 for ferricyanide, 2.6 for the blue triphenanthroline ferric ion. These are considerably higher than the

theoretical value of 1.73 of the spin moment of a single unshared electron, but this excess is also observed with other ions containing a single unshared electron, and is generally attributed to incomplete quenching of the orbital moment.[13]

The magnetic moment of the iron atom in the brown ferric complex is, however, only 1.4 Bohr magnetons. It is therefore much smaller than the moment of ferric ion in other stable ferric complexes. It is even considerably smaller than the theoretical minimum value of 1.73, which corresponds to the spin moment only. This result is extremely important in connection with the question of the molecular weight of the complex ion.

Diffusibility.—Measurements of diffusibility offer one of the most promising means of studying the molecular dimensions of ions in solution, although their quantitative interpretation is still open to considerable question.[14]

Qualitative diffusion experiments were made with collodion bags, gelatin test-tubes and a fritted glass membrane. A solution initially 0.02 *M* in tri-*o*-phenanthroline ferrous chloride required some four hours to reach equilibrium by diffusion through a collodion membrane, while a comparable set-up for the brown phenanthroline ferric complex salt did not reach equilibrium on standing overnight.

The same solutions poured on gelatin gels in test-tubes showed about a 3:2 penetration ratio in an overnight test with the ferrous complex having the higher diffusion rate.

The technique of McBain and Liu,[15] using a 0.2-cm. membrane of G-4 fritted glass, was applied to the two solutions. The *KD* value obtained for the ferric complex salt was 0.0035 and for the ferrous complex salt 0.0042. Flushing the cell with distilled water effectively removed all coloration due to the ferric salt prior to the diffusion of the ferrous salt, but the ferrous complex stained the membrane so that a treatment with chromic acid mixture was required to clean it. A subsequent pair of diffusion runs gave a *KD* value of 0.0048 for the ferric salt and of 0.0055 for ferrous. The changed values, showing an increased membrane porosity, are nevertheless in the same direction, and support the conclusion that the ferric complex has a higher average molecular weight than has the ferrous complex, whereas the empirical formulas have the reverse relation.

We were unable to make diffusion measurements in the presence of a large concentration of another electrolyte, as is necessary if the diffusibility of the complex ion alone is to be obtained,[16] because the brown salt is so easily salted out by other electrolytes.

Particle Size.—An unfiltered solution of sample (f) showed a bright field in the ultramicroscope. However, a freshly prepared solution and the filtrate from the above solution were optically void. The substance must polymerize on standing in solution, a fact corroborated by visible precipitates formed in 0.01 *M* solutions after standing for a week, but the freshly prepared solution is probably a true solution, rather than a colloidal one. Because of this aging of the solutions all measurements reported in this article were made not more than three hours after the preparation of the solution.

Composition and Structure.—The substance is unquestionably a definite compound. It forms crystals of visible dimensions; its composition is independent of the composition of the solution from which it is prepared within a considerable range of variation of acidity and phenanthroline concentration (see Table I); and the analysis agrees closely with the simple proportion of 1 Fe to 2 Cl to 2 phenanthroline.

The composition is necessarily that represented by the formula $Fe(C_{12}H_8N_2)_2(OH)Cl_2$, because some negatively charged constituent other than the two chloride ions must be present to balance the three positive charges of the ferric ion, and hydroxyl ion is the only possibility. As Table II shows, the actual proportions of iron, chlorine and phenanthroline in the dried compound agree excellently with this composition.

While the interpretation of the conductivity results is complicated by the hydrolysis reaction, they demonstrate beyond question that the chlorine atoms are free chloride ions, and not non-ionogen chlorine in the complex.

Here as always with polynuclear complex ions, the molecular weight is difficult to establish. That we have to do with a polynuclear complex seems beyond doubt. The low diffusibility by comparison with the similar but mononuclear phenanthroline ferrous ion is practically conclusive evidence; moreover, the magnetic properties and the nature of the acid–base titration curve strongly support the conclusion. There is no physical picture to account for the existence in a mononuclear ferric complex of a magnetic moment less than the 1.73 Bohr magnetons which correspond to the spin moment of a single unpaired electron, and no moment less than this has in fact been observed in a substance containing an odd number of electrons. It is therefore extremely probable on this basis alone that we have to do with a polynuclear complex in which two or more ferric ions are rigidly bound together in such a way that their individual magnetic moments partially neutralize each other. The existence of such a phenomenon as this has been several times suggested, but it has not previously been observed with certainty.

---

[13] This question has been discussed by Noyes, Pitzer and Dunn, THIS JOURNAL, **57**, 1234 (1935), in connection with the susceptibility of argentic ion.

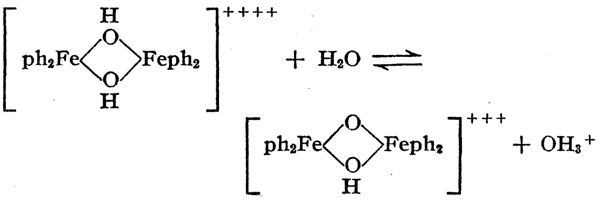
[14] (a) Jander and Jahr, *Kolloid Beihefte*, **41**, 1, 297 (1935); (b) Brintzinger, *et al.*, *Z. anorg. Chem.*, **220**, 201 (1934), and others.

[15] McBain and Liu, THIS JOURNAL, **53**, 59 (1931).

[16] Jander and Winkel, *Z. physik. Chem.*, **149A**, 102 (1930).

The binuclear structure  $\left[\text{ph}_2\text{Fe}\overset{\text{H}}{\underset{\text{H}}{\langle\text{O}_2\rangle}}\text{Feph}_2\right]^{++++}$ which we have proposed is consistent with the general principles of complex chemistry developed by Werner. The coördination number of the iron atoms is six, as it is in other stable ferric complexes (each phenanthroline molecule with its two nitrogen atoms counts of course two in reckoning this value). The ease of formation and stability of the double ol bridge are well established with cobaltic and chromic ammines and are basic features of those important theories of colloidal oxides which Stiasny[17] and Thomas[18] have developed.

The acidic properties of the substance (the *p*H of 0.00491 *M* aqueous solution is 3.5) might seem inconsistent with this structure but they are not so in reality. The only way in which a substance with the structure suggested can react acid is by loss of hydrogen ions from an ol bridge, forming an oxo bridge

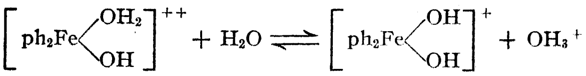


$$\left[\text{ph}_2\text{Fe}\overset{\text{H}}{\underset{\text{H}}{\langle\text{O}_2\rangle}}\text{Feph}_2\right]^{++++} + H_2O \rightleftharpoons \left[\text{ph}_2\text{Fe}\underset{\text{H}}{\langle\text{O}_2\rangle}\text{Feph}_2\right]^{+++} + OH_3^+$$

and it is true that this process does not occur to a significant extent with the cobalt derivatives, which are the most thoroughly studied examples of substances containing these bridges. Such substances as  $\left[(NH_3)_4\text{Co}\overset{\text{H}}{\underset{\text{H}}{\langle\text{O}_2\rangle}}\text{Co}(NH_3)_4\right]^{++++}$ are reported as giving neutral aqueous solutions. There is, however, every reason to expect that the hydrogen ions should be much less firmly bound in the iron compound than in the cobaltic compound.

Both the ol compounds and the simple aquo compounds are derivatives of oxonium ion, OH_3^+, in which one hydrogen ion in the case of an aquo compound (such as $[Co(NH_3)_5OH_2]^{+++}$), and two hydrogen ions in the case of ol compounds, have been replaced by a metallic ion. This substitution decreases the acidity cumulatively; in the cobalt case $[Co(NH_3)_5OH_2]^{+++}$ has an acidity constant of 2×10^{-6}, while the ol compounds are so weakly acid that their aqueous solutions are neutral. The work of Uémura and Suéda[19] shows, however, that aquo chromic ions are considerably more acid than are analogous aquo cobaltic ions, while the work of Brönsted and Volqvartz[20] shows that aquo ferric ions are more acid than are analogous chromic ions. That is to say, the introduction of one ferric ion into oxonium ion decreases the acidity much less than the introduction of one cobaltic ion; the second ferric ion likewise should have a smaller effect than the second cobaltic ion. It is therefore extremely probable that ol-ferric compounds will be more acidic and have less firmly bound hydrogen ions than do ol-cobaltic compounds.

On titration with alkali the behavior of the substance agrees with that to be expected of a dibasic acid, except when nearly two moles of hydroxyl ion have been added (for two iron atoms) when some other process which leads to a precipitation is superimposed. This is shown in Fig. 1 in which the points are experimental and the solid curve is calculated for a dibasic acid. The behavior is consistent with the proposed formula, which contains two dissociable hydrogen ions, one on each of the ol bridges. It does not serve to eliminate the possibility of a more highly polymerized ion, because the experimental curve also agrees with predicted ones for acids of higher basicity than two, but it does furnish another proof of the impossibility of a mononuclear formula. The only possible structure of the latter type is that of an aquohydroxo ion which must titrate as a monobasic acid



$$\left[\text{ph}_2\text{Fe}\begin{smallmatrix}OH_2\\OH\end{smallmatrix}\right]^{++} + H_2O \rightleftharpoons \left[\text{ph}_2\text{Fe}\begin{smallmatrix}OH\\OH\end{smallmatrix}\right]^{+} + OH_3^+$$

It is completely impossible to fit our experimental results to such a process.

On Solutions Containing Ferric Salts and Phenanthroline

The high yields obtained in the preparation of the crystalline brown chloride (A) suggest strongly that it is a major constituent of the solutions obtained by mixing ferric chloride and phenanthroline. It is not the sole constituent, as several kinds of evidence demonstrate.

The Magnetic Titration of Ferric Chloride with Phenanthroline.—We have determined the magnetic susceptibilities of a series of solutions con-

taining a constant concentration of ferric chloride and varying proportions of phenanthroline with the results shown in Table IV and Fig. 2. Except for the last point, each one represents the mean of two or more measurements with a maximum deviation of 0.0002 g. There are several points of interest about this "magnetic titration curve."

TABLE IV

Ferric chloride (mole/liter)	*o*-Phenanthroline (mole/liter)	Magnetic pull on soln., F_1, g.	Density of soln. (27°)	Atomic susceptibility of ferric ion × 10^6	Precision measure, %
0.03870	0.00	−0.0084	0.9965	13,760	..
.03867	.01935	− .01700	.9974	8,140	0.49
.03865	.03870	− .02337	.9997	4,020	.99
.03865	.05800	− .02630	1.0011	2,120	2.21
.03865	.07740	− .02765	1.0028	1,270	3.81
.03865	.1160	− .02715	1.0052	1,620	2.94
.03872	.1560	− .02425	1.0087	3,550	1.31
.03864	.2320	− .02340	1.0119	4,140	3.81

The gradual curvature shows that several overlapping equilibria are present. Because of the well-verified additivity of magnetic susceptibilities, the curve would consist of two intersecting straight lines if the solutions contained only mixtures of hydrated ferric ion and one phenanthroline complex.

The curve has a pronounced minimum in the neighborhood of the proportion of 2 phenanthroline to 1 iron, the ratio present in the crystalline salt. This is consistent with the hypothesis that the tetraphenanthroline diol diferric ion is a preponderant constituent of solutions containing this proportion of phenanthroline and iron. The rise on both sides, together with the curvature, demonstrates, however, that other compounds of phenanthroline and ferric iron of higher susceptibility are formed in which the ratio may be either greater or smaller than two.

The difference in susceptibility between solutions of the pure crystalline salt and solutions made by adding two moles of phenanthroline to one of ferric chloride is outside of the probable experimental error and indicates the presence in the latter solution of a certain amount of these complexes of higher susceptibility.

Colorimetric Work.—Tests were made in a colorimeter of the intensity of color developed by the addition of ferrous sulfate to solutions containing various proportions of phenanthroline and ferric chloride, the brown color of the ferric complex being compensated in the usual way. In all cases, the intensity of the color increased with time, the more rapidly the greater the proportion of phenanthroline. Extrapolation to zero time showed that solutions containing phenanthroline and ferric iron in the proportion of 1:1 or 2:1 contain no phenanthroline in a form which reacts immediately with ferrous iron, whereas solutions containing proportions of 3:1, of 4:1, and of 9.16:1 contain about two-thirds of the phenanthroline present above the ratio of 2:1 in a form which does not react immediately with ferrous ion. A part but certainly not all of this unreactive phenanthroline is in the form of phenanthrolinium ion. Further interpretation of these experiments must await a knowledge of the equilibrium and kinetics of the ferrous phenanthroline reaction which is now being sought in another research in this Laboratory.

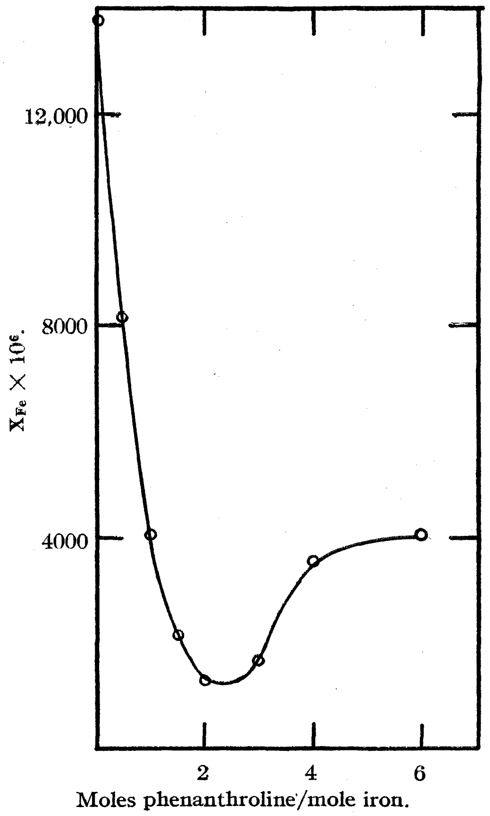

Fig. 2.—Magnetic titration curve.

Solubility Effects.—Attempts to investigate the nature of the phenanthroline complexes by the solubility method which has been so often applied to the investigation of complex compounds gave a most surprising result which led us to determine the solubility of phenanthroline in the various media shown in Table V. All measurements were made at 25° by rotating an excess of phenanthroline with the solution named in a thermostat until analyses made on two successive days showed no further change. Phenanthroline was determined by the mercuric chloride precipitation method previously described. Each figure shown in the table is the average of at least two determinations with a probable error of about 1%.

TABLE V

Soln.	Concn. of soln., moles per liter	Concn. of *o*-phenanthroline, moles per liter	Concn. of *o*-phenanthroline less water soly. of *o*-phenanthroline, moles per liter	Moles of *o*-phenanthroline per mole of other component
Pure water		0.01627		
$FeCl_3$	0.003640	.03834	0.02207	6.07
$FeCl_3$	.007240	.06567	.04450	6.04
HCl	.009953	.03824	.02197	2.21
NaCl	.002014	.01604	−.00023	..
$FeCl_2$	.009390	.06510	.04883	5.20
$NiCl_2$	.005614	.03937	.02310	4.11
H_2SO_4	.004898	.03762	.02135	4.36

There will be noted in every case except that of sodium chloride a large increase in solubility over that in water. Even in the case of the acids, where one would expect one equivalent of acid to dissolve at the most one mole of base, we find an increase in solubility which is of the order of 2.2 moles of base per equivalent of acid. Ferrous ion and nickel ion form extremely stable complexes in which the proportion of phenanthroline to metallic ion is three. There is no evidence whatsoever from the composition of solid salts of the existence of complexes in which the proportion is greater than three. Yet one mole of ferrous chloride dissolves 5.2 moles more of the base than does water; one mole of nickel ion increases the solubility by 4.1 moles. Evidently, then, the presence in a solution of phenanthroline combined either with hydrogen ion or with a metallic ion leads to a considerably increased solubility of phenanthroline in the solution, presumably as a result of the formation of some secondary complex of low stability. The quantity of this excess dissolved phenanthroline bears no simple ratio either to the quantity of combined phenanthroline or to the ionic charge of the complex in which it is present. This peculiar phenomenon may be confined to phenanthroline and bases of similar structure or it may not; it obviously must be reckoned with in any future studies on complex ions by the solubility method.

Of the somewhat over six moles of phenanthroline dissolved by ferric chloride, two can be assigned to the formation of the complex of structure A, about two more to the hydrogen ion liberated in the formation of that compound. The remainder may be due to the loose kind of combination which produces the excess solubility in the case of the other metallic ions, but it is difficult to see how this kind of combination could account for the increase in magnetic susceptibility which we have observed when the proportion of phenanthroline to iron is greater than two.

We wish to acknowledge the kindness of Professors Samuel J. Kiehl, Victor K. La Mer and Arthur W. Thomas in lending special apparatus and of Henry A. Boorse, in making preliminary magnetic susceptibility measurements.

Summary

A brown crystalline substance has been prepared by the direct reaction of phenanthroline and ferric chloride solution. The properties of this substance are consistent with the assumption that it is a tetraphenanthroline-diol-diferric chloride.

Evidence is presented showing the probable existence of other compounds in the mother liquor.

The acid–base properties of the polynuclear complex extend the knowledge of this characteristic of the ol bridge as established with cobaltic and chromic compounds.

The unusually low magnetic susceptibility of the new complex suggests the partial neutralization of the magnetic moments of the two iron atoms, and is additional evidence of a polynuclear structure.

The magnetic susceptibility of the blue triphenanthroline–ferric complex ion approximates that of the ferricyanide ion.

Evidence is presented showing that stable phenanthroline complexes whose composition has been established in the solid state may, in solution, add more phenanthroline, forming secondary complexes of lower stability.

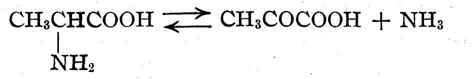
The Photochemical Deamination of Amino Acids in Water Solution. Part I

BY CH. WEIZMANN, E. BERGMANN AND Y. HIRSHBERG

The only method of de-amination of amino acids under physiological conditions is the oxidative de-amination, *e. g.*



$$\underset{\displaystyle NH_2}{CH_3CHCOOH} \rightleftarrows CH_3COCOOH + NH_3$$

which has been thoroughly investigated by many authors. The ordinary hydrolysis of amino acids

$$\underset{\displaystyle NH_2}{CH_3CHCOOH} + H_2O \qquad \underset{\displaystyle OH}{CH_3CHCOOH} + NH_3$$

has never been observed in biological systems and even against treatment with acid or alkali, the amino acids exhibit such a marked resistance that occasionally the view has been expressed that the occurrence of ammonia in the hydrolysis of proteins is not due to hydrolysis of amino, but rather of amide groups. (That this view is not correct has been demonstrated by Melville[1] in the case of glutamine containing peptides.)

Therefore, an observation made by Henri, Weizmann and Hirshberg[2] seemed to be worthy of further study. These authors reported that in aqueous solution glycine is hydrolyzed under the influence of ultraviolet rays according to the above scheme. The experiments have been extended to include alanine, betaine and aspartic acid. In all these cases the photolysis occurred markedly. The kinetics of the reactions could be studied easily, using the conductivity change or the *p*H change accompanying the photolysis, or, in a more accurate way, determining the amount of ammonia formed during the reaction. As a qualitative test showing whether the desired reaction has occurred or not, the color reaction with 2,7-dioxynaphthalene proved useful; it may be mentioned that the reaction is by no means specific for glycolic acid, as was assumed by Eegriwe,[3] but is a group test for α-hydroxy acids.

The attempt to become familiar with the details of the photolytic reaction meets with one main difficulty: one does not know, *a priori*, which is the reactive form of the amino acid molecules. In this connection, the observation of Henri, Weizmann and Hirshberg[4] is noteworthy that the effective radiation in the case of glycine has a wave length of $\lambda < 2265$ Å. Since, according to a recent paper of Henri and Lasareff,[5] methylamine shows an ultraviolet absorption between 2529 and 1986 Å., the most intense bands lying between 2320 and 2100 Å. the conclusion seems justified that the radiation effective in our photolysis is that absorbed by the C–N linkage, in other words, the photochemical primary process involves that linkage. Two arguments appear to show that the photolysis does not occur or, at least, does not occur markedly on the "Zwitterions." (1) The speed of the photolysis depends on the *p*H of the medium; at neutral reaction, the reaction velocity has a minimum; it increases both to the acid and to the alkaline side, giving a graph (Fig. 1) very similar to those obtained for the hydrolysis of certain esters[6] or the bromination of certain aliphatic ketones.[7] Since one knows[8] that at the neutral point the relative amount of

molecules occurring in the "Zwitter-ion" form is highest, that form cannot be the carrier of the photolysis reaction. (2) If one compares the photolysis of betaine with that of the unmethylated amino acids we have investigated, one will find that the photolysis of betaine is markedly slower (see *e. g.*, Fig. 1, where a 0.1 *N* solution of betaine is compared with a 0.01 *N* solution of aspartic acid).

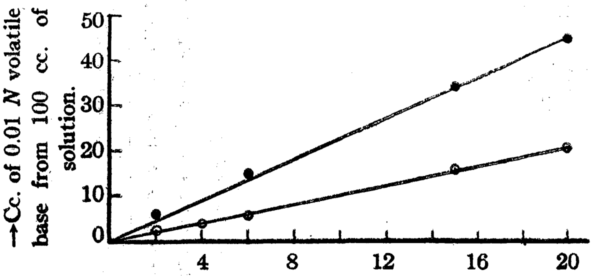

Fig. 2.—Speed of the photolysis of 0.01 *N* betaine (lower curve); 0.01 *N* aspartic acid (upper curve).

We suggest that the normal form of the amino acid molecule is "photo-active"; its C–N bond is split not by water molecules, but by H^+ and OH^-.

The quantum yield of the photolysis has been determined in several experiments by comparison with the photochemical decomposition of monochloroacetic acid. For glycine and alanine the quantum yield has been found to be about equal to unity, which corresponds to the case of, say, monochloroacetic acid.[9] It is surprising that the quantum yield for betaine under the same conditions is only 0.5. It is rather difficult to explain that figure definitely, but it may be due to the fact that in betaine there are two different kinds of C–N bonds absorbing the "active" light, one representing the CH_3N groups, one connecting the nitrogen with the trunk of the acetic acid molecule, and that only the latter one by absorption of light can lead to the desired photolytic process, the other one causing just a dissipation of the absorbed light energy.[9a]

As regards the various amino acids investigated, the details will be given in the experimental part of the paper, but a few remarks may be added here. In the case of alanine, the lactic acid formed has been isolated as zinc salt, in the case of betaine the trimethylamine as the chloroaurate. From aspartic acid, crystalline malic acid has been obtained. A few preliminary experiments were made with *l*-tyrosine, but without success, since the alkaline solution immediately turned yellow, afterward brown; the acid solution behaved similarly after a short period of irradiation. (At the neutral point, tyrosine is known to be insoluble in water.) We thought the color may be due to melanine formation, caused by unavoidable traces of oxygen, but the absorption spectrum of our solution was quite different from the absorption spectrum exhibited by tyrosine after treatment with tyrosinase.[10] Therefore, no conclusion can be drawn regarding the color change of our tyrosine solutions.

The experiments with aspartic acid were made on an optically active (levorotatory) preparation which gave us the opportunity of dealing with the question of the configurational relationship between the starting material and the end-product of the photolysis. The malic acid obtained was nearly completely racemic and only a negligible levorotation could be observed. According to the view of Polanyi and co-workers,[11] racemization can only occur in substitution reactions of the type suggested above when the trunk of the molecule passes a stage where it exists as a positively charged ion or a free radical. Obviously, we cannot decide definitely between these alternatives, but in view of the above conclusion that in this reaction hydrogen and hydroxyl *ions* take part, the former possibility seems more reasonable. The photochemical stretching of the C–N bond leads to the formation of ions RCH^+COOH and NH_2^-, which stabilize by the reactions

$$RCH^+COOH + OH' \longrightarrow RCH(OH)COOH$$
$$NH_2^- + H^+ \longrightarrow NH_3$$

Experimental Part

The preparations used were commercial samples which were purified by the usual methods. Betaine was prepared from its hydrochloride according to Husemann and Marmé.[12] The solutions of the amino acids in doubly distilled water were irradiated in two ways: (1) the quartz lamp was surrounded by two jackets, the first containing running water, the second the solution; (2) the solution was filled into a quartz cell which was irradiated by the direct light of a horizontal mercury arc (without any light filters) at a certain distance. After definite times, the am-

monia formed was determined in the usual way; the conductivity and the *p*H were measured, the latter with a glass electrode.

An absolute determination of the **quantum yield** proved tedious, since the reactions are relatively slow. Therefore, the reaction was compared in a rather crude way with the photo-decomposition of monochloroacetic acid for which the quantum yield is equal to unity. A parallel ultraviolet light beam was obtained from the light of an ordinary mercury lamp (Heraeus lamp) through a quartz lens of f = 10 cm. At a constant distance a quartz cell of 10 cm. length and 46 cc. volume was placed in the path of the light beam. The lamp worked constantly at 220 volts and 4 amperes.

We compared the amount of monochloroacetic acid decomposed in a second cell after passing (a) water, (b) the investigated solution. The difference between the two figures gave the quantity of energy absorbed in the photodecomposition of the solution investigated. The following results were obtained:

Glycine	0.93	0.88	0.86	0.85	0.82
Alanine	1.02	.98	.95	1.00	
Betaine	0.46	.49	.52		

In order to demonstrate our procedure in the **kinetic** experiments, the data obtained in some experiments may be given here.

100 cc. of a 0.01 *N* solution was irradiated as above; distance 10 cm.

Time, hours	*p*H	0.01 *N* NH_3, cc.
0	3.2	0
2	3.5	5.5
6	3.9	15.2
9	4.1	19.5
15	4.5	33.5
20	5.1	45.0

TABLE IV

Change of absorption during irradiation of alanine

(a) 0.02 *N* SOLUTION

λ, Å.	ε before irradiation	ε after 10 hours of irradiation
2150	17.5	17.5
2225	8.74	13.5
2240	6.72	8.74
2264	4.40	5.85
2280	3.36	4.40

(b) 0.05 *N* SOLUTION

		ε after 8 hours of irradiation
2144	28.08	28.08
2195	10.80	21.6
2240	6.92	10.8
2260	5.40	6.92
2328	1.58	2.81
2350	...	2.16
2360	...	2.05
2370	...	1.58

Isolation of the Irradiation Products.—The solution obtained by photolysis of *alanine* was concentrated, acidified with sulfuric acid, then extracted several times with ether. The ether was distilled off and the residue taken up with water and heated with zinc carbonate on the water-bath. The excess of the carbonate was filtered off and the solution evaporated in a desiccator. The residue was identified by micro-analysis. Calcd. for $C_6H_{10}O_6Zn \cdot 3H_2O$: C, 24.2; H, 5.4; Zn, 22.0. Found: C, 24.7; H, 5.4; Zn, 22.9.

The trimethylamine formed by irradiation of a *betaine* solution was distilled off—after addition of a few drops of alkali—into dilute hydrochloric acid. The acid solution was concentrated on the water-bath and a solution of gold chloride added. The precipitate was filtered off, washed with distilled water, dried to constant weight and analyzed. Calcd. for $C_3H_9NCl_4Au$: C, 9.0; H, 2.3; N, 3.5; Au, 49.4. Found: C, 9.5; H, 2.6; N, 3.7; Au, 49.2. The malic acid obtained from *aspartic acid* by irradiation was isolated in the same way as lactic acid. The crystalline product was recrystallized from a mixture of acetone and carbon tetrachloride; m. p. 121°. The analysis did not agree very well with theory (hygroscopicity?): Calcd. for $C_4H_6O_5$; C, 35.8; H, 4.5. Found: C, 36.2; H, 5.5.

Summary

1. In water solution glycine, alanine, betaine and aspartic acid are hydrolyzed under the influence of ultraviolet light, giving the corresponding hydroxy acids.

2. The kinetics and quantum yields of these reactions have been measured.

3. The following mechanism has been suggested.

(a) $\underset{NH_2}{RCHCOOH} \longrightarrow RCH^+COOH + NH_2^-$

(b) $RCH^+COOH + OH^- \longrightarrow \underset{OH}{RCHCOOH}$

(c) $NH_2^- + H^+ \longrightarrow NH_3$

4. The hydrolysis of optically active aspartic acid is accompanied by racemization, which is in accordance with the above mechanism.

5. The behavior of tyrosine has been studied qualitatively.

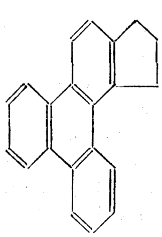
[CONTRIBUTION FROM THE DANIEL SIEFF RESEARCH INSTITUTE]

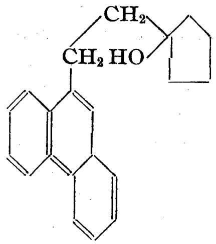
Cyclopentenotriphenylene

BY ERNST BERGMANN AND OTTILIE BLUM-BERGMANN

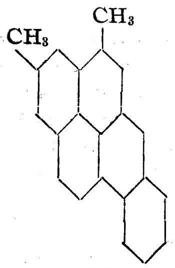
Jacobs and Elderfield[1] obtained by dehydrogenation of strophanthidin, *inter alia*, a hydrocarbon, the analysis of which gave figures corresponding to the formula $C_{21}H_{16}$. On the basis of a strophantidine formula which has since been abandoned, the authors suggested the structure of cyclopentenotriphenylene (I). In connection with other experiments we thought it interesting to synthesize the above hydrocarbon; its properties were quite different from those of the hydrocarbon obtained by the American authors. Our synthesis parallels the preparation of cyclopentenophenanthrene by Cook and co-workers.[2] Their work gave us some valuable information about the formation and structure of various by-products.



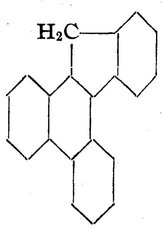
I



II



III



IV

β-(9-Phenanthryl)-ethanol was easily prepared from 9-phenanthrylmagnesium bromide and ethylene oxide or ethylene chlorohydrin and converted into the corresponding chloride. Its magnesium derivative reacted with cyclopentanone to give (9-phenanthrylethyl)-cyclopentanol (II). In accordance with the observations of Cook, we tried to convert (II) directly into (I) with glacial acetic acid and concentrated sulfuric acid, but without success, and also none of the two crystalline hydrocarbons resulting from the crude reaction product by subsequent dehydrogenation was the desired product (I). The first had the formula $C_{21}H_{14}$ and was characterized by a vermillion picrate. It is most probable that it corresponds to 2-methylpyrene[2a] obtained by Cook in the corresponding experiment in the naphthalene series, and therefore is 7-methyl-1,2-benzpyrene (III). We hope to confirm this suggestion, by spectroscopic comparison of our product with benzpyrenes of known structure, as 1,2- and 4,5-benzpyrene recently described by Cook and Hewett[3] and Fieser and Fieser,[4] respectively. The second isolated hydrocarbon, which occurred only in minor quantities, turned yellow on keeping. It resembles in this respect the complex fluorene derivatives prepared by Cook and Hewett;[2b] we therefore assume that it has the structure of 1,2,3,4-dibenzofluorene (IV) and is analogous to chrysofluorene isolated by Cook in his experiments in the naphthalene series. The corresponding fluorenone has recently

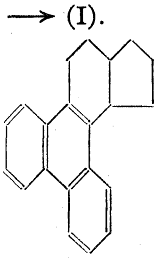
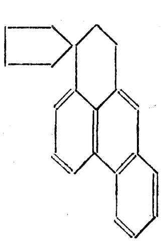
been described by Koelsch.[5] These hydrocarbons cannot be formed by dehydrogenation of the normal compound (V) which we expected from the treatment of II with concentrated sulfuric acid, as an intermediate product; they must derive from the two spirans (VI) and (VII), respectively, by thermal rearrangement and subsequent dehydrogenation.[5a] As a matter of fact we succeeded in isolating, from the crude product of the above treatment of (II), a crystalline substance $C_{21}H_{20}$ which was not identical with (V) and, since under our experimental conditions the *cis* isomer of (V) would not be stable,[6] must be one of the spirans (VI) or (VII).

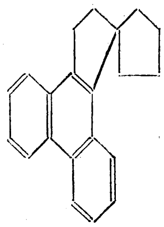
After this failure, we had to proceed by the way suggested by the formulas (II) ⟶ (VIII) ⟶ (V) ⟶ (I).



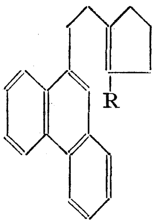
V



VI



VII



VIII

The dehydration of (II) was effected easily by heating with potassium bisulfate and the conversion of (VIII, R = H) into (V) by means of aluminum chloride. We prefer the olefinic double bond in (VIII, R = H) in the five-membered ring, rather than in the semicyclic position; but that question is of no importance for the course of the reaction.

Cook and his co-workers observed in several cases that 2-methylcyclopentanone is more suitable for syntheses of this kind, since the condensation with Grignard compound and subsequent dehydration and dehydrogenation gives more uniform products.[7] A series of experiments starting with the methylated ketone was unsuccessful, since 9-ethylphenanthrene formed prevented the easy isolation of the expected ethylene (VIII, R = CH_3).

The cyclopentenotriphenylene obtained by dehydrogenation of (V) is a well-crystallized compound characterized by its dark brown-red picrate. It is isomeric with methylcholanthrene and the melting points and those of their picrates show a striking resemblance; but the mixtures show a depression of the m. p. Obviously, methylcholanthrene could not be formed in our synthetical process. The spectroscopic analysis of cyclopentenotriphenylene and its comparison with similar hydrocarbons is now in progress.

Experimental

β-(9-Phenanthryl)-ethanol.—(a) An ethereal solution of ethylene oxide (10 g.) was added to 9-phenanthrylmagnesium bromide, prepared according to Bachmann[8] from magnesium (5 g.), 9-bromophenanthrene (48.5 g.) in a mixture of benzene (120 cc.) and ether (120 cc.). The rather violent reaction was completed by boiling for two hours; the reaction mixture was decomposed with ice and acid, washed with soda solution, dried and evaporated. The oily residue crystallized, on trituration with light petroleum and acetone; from benzine clusters of needles; m. p. 92°; yield 15–21 g. Calcd. for $C_{16}H_{14}O$: C, 86.5; H, 6.3. Found: C, 86.7, 86.7; H, 6.7, 6.6.

(b) According to Grignard[9] an ethereal solution of 9-phenanthrylmagnesium bromide (from 102 g. of bromophenanthrene and 11 g. of magnesium) was added to a solution obtained by addition of ethylene chlorohydrin (22.4 cc.) to ethylmagnesium bromide (8.1 g. of magnesium and 25.4 cc. of ethyl bromide). Since no reaction took place, the solvents were distilled off; at the end of the distillation reaction occurred, causing the mass to foam and swell violently. After addition of fresh ether the mass was treated as above and the product isolated by distillation (1 mm.). At 145–170° some phenanthrene passed over, then at 200° the reaction product, which crystallized quickly (40–50 g.).

β-(9-Phenanthryl)-ethyl Chloride.—The above alcohol (20 g.) was mixed with dimethylaniline (11.7 cc.) and benzene (24 cc.) and the mixture cooled with ice water. Then thionyl chloride (7.6 cc.) was added drop by drop and the dark red solution heated until the evolution of sulfur dioxide ceased. On addition of water a dark oil separated and was isolated with ether. The residue crystallized at once and was triturated with ethyl acetate and recrystallized from benzine mixed with a little benzene; m. p. 82–84°; yield, 15–17 g. Calcd. for $C_{16}H_{13}Cl$: C, 79.7; H, 5.4. Found: C, 79.9; H, 5.4.

(9-Phenanthryl-ethyl)-cyclopentanol (II).—The above chloride (29.6 g.) reacted smoothly with magnesium (3.2 g.) when activated with iodine and methyl iodide. After

two hours of boiling, cyclopentanone (10.8 cc.) was added; it reacted markedly and gave a crystalline precipitate. The mass was boiled for a further two hours and then decomposed with ice and ammonium chloride or ice and acid. An insoluble compound separated and was filtered off after some time (1.75 g.); it was recrystallized from xylene. The yellowish leaflets, m. p. 214–216°, exhibit a strong violet fluorescence and consist, according to the analysis, of α,δ-di-(9-phenanthryl)-butane, $C_{14}H_9CH_2CH_2CH_2CH_2$-$C_{14}H_9$. Calcd. for $C_{32}H_{26}$: C, 93.7; H, 6.3. Found: C, 93.8, 94.1; H, 6.1, 6.5. The residue of the ethereal filtrate crystallized on trituration with benzine. This carbinol was recrystallized from benzine and cyclohexane as transparent prisms, m. p. 108–109°; yield, 17.1 g. Calcd. for $C_{21}H_{22}O$: C, 86.9; H, 7.6. Found: C, 86.5; H, 7.6.

Reactions with Concentrated Sulfuric Acid.—(a) The carbinol (II) (4 g.) was heated for two hours on the water-bath with glacial acetic acid (40 cc.) and concd. sulfuric acid (4 cc.); a violet color and smell of sulfur dioxide was observed. Then water was added and the oily product, after isolation with ether, directly heated with selenium (10 g.) to 320–340° for sixteen hours. The mass was extracted with benzene and ethyl acetate and purified by distillation at 0.8 mm. (bath temperature 240–280°). The reddish oil (1.2 g.), on trituration with benzine, gave a crystalline powder (0.5 g.) melting at 132–142°; from propyl alcohol, then from glacial acetic acid, silky needles, m. p. 157.5–159.5°. Calcd. for $C_{21}H_{14}$ (III): C, 94.7; H, 5.3. Found: C, 94.3, 94.3, 94.6, 95.0, 94.6; H, 5.3, 5.6, 5.4, 5.6, 5.3. The picrate, prepared from equivalent amounts of the components in benzene and isolated by evaporation of the solvent, was recrystallized from alcohol, containing picric acid, as beautiful vermilion needles of m. p. 153–155°. Calcd. for $C_{27}H_{17}O_7N_3$: C, 65.5; H, 3.4; N, 8.5. Found: C, 66.0, 66.0; H, 4.1, 3.6; N, 7.6. From the benzine mother liquors of the above hydrocarbon (III), there separated, on standing, a second hydrocarbon (0.2 g.), which melted at 115–116°, after repeated recrystallization from benzine, and after purification through the picrate; needles turning yellow on exposure to air and light. The picrate prepared in hot alcohol, crystallized on cooling as orange-yellow needles, m. p. 165–167°. Calcd. for $C_{27}H_{19}N_3O_7 = C_{21}H_{16}$ (IV) + $C_6H_3N_3O_7$: C, 65.2; H, 3.8; N, 8.4. Found: C, 65.4; H, 4.2; N 8.0.

(b) The experiment was repeated as before but the crude oily product left for some time. A small amount of a crystalline powder separated which was triturated with ethyl acetate, filtered, washed with alcohol and recrystallized from the same solvent as leaflets of m. p. 117–120°. Undoubtedly, the substance is one of the spirans (VI) or (VII). Calcd. for $C_{21}H_{20}$: C, 92.6; H, 7.4. Found: C, 92.3; H, 8.2.

1′-β-(9-Phenanthryl)-ethyl-cyclopentene-(1) (VIII).—The carbinol (17 g.) and potassium bisulfate (25.5 g.) were heated at 160–170° for one hour; the mixture was poured into water, the product extracted with ether and distilled; b. p. 206–207° (1.3 mm.). The distillate (14.3 g.) was a viscous oil unsaturated toward bromine, which crystallized immediately; it melted at 50–54.5°, but it was impossible to recrystallize it and therefore it was converted into tetrahydro-cyclopenteno-triphenylene (V) by dissolving in carbon disulfide and adding finely powdered aluminum chloride (14 g.), at room temperature. After twelve hours the violet mass was decomposed with ice and hydrochloric acid and the product distilled; b. p. 210–215° (1 mm.). The oil crystallized spontaneously; on recrystallization from ethyl or propyl alcohol it gave beautiful prisms (6.9 g.) m. p. 105.5–107°. Calcd. for $C_{21}H_{20}$: C, 92.6; H, 7.4. Found: C, 92.6; H, 7.6. (Picrate, see below.)

Cyclopentenotriphenylene (I).—The tetrahydro compound (5 g.) was mixed with selenium (12 g.) and heated for twenty hours at 330–340°. The mass was powdered and extracted with ether in a Soxhlet apparatus. The solution was evaporated and the residue distilled at 1 mm. The yellow oil (2.5 g.) on trituration with acetone and benzene gave 0.4 g. of cyclopentenotriphenylene as a yellow powder which was recrystallized several times from glacial acetic acid and propyl alcohol as yellowish, small needles, m. p. 171–172.5°. Calcd. for $C_{21}H_{16}$: C, 94.0; H, 6.0. Found: C, 94.2, 94.1; H, 5.7, 5.8. The picrate, prepared in propyl alcohol, was recrystallized from a mixture of benzene and propyl alcohol, containing picric acid; it formed brownish-red needles; m. p. 172–173°. Calcd. for $C_{27}H_{19}O_7N_3$: C, 65.2; H, 3.8. Found: C, 65.4, 65.7; H, 4.1, 4.1. The mother liquor of the cyclopentenotriphenylene was treated with picric acid in benzene solution. The precipitate consisted of the above dark picrate and a small proportion of a yellow picrate which, after recrystallization from alcohol containing picric acid, proved to be the picrate of some unchanged tetrahydro compound (V); needles, m. p. 161–162°. Calcd. for $C_{27}H_{23}O_7N_3$: C, 64.7; H, 4.6. Found: C, 64.1, 64.1, 64.4; H, 4.7, 4.4, 5.0.

Experiments with 2-Methylcyclopentanone.—Methylcyclopentanone (7.6 g.; b. p. 135–136°; prepared according to Cornubert and Borrell,[10] was added to phenanthrylethylmagnesium chloride (from magnesium (2.1 g.) and the chloride (19.2 g.)); during the vigorous reaction a white product crystallized. After boiling for one hour, the mass was decomposed with ice and ammonium chloride (or ice and dilute sulfuric acid), the precipitate of 1,4-di-(9-phenanthryl)-butane (1.2 g.) filtered off and the reaction product isolated as usual. It could not be obtained in a crystalline state and free of 9-ethylphenanthrene and was therefore heated with twice its weight of potassium bisulfate at 160–170° for one hour. The product isolated as above was fractionated at 1.5 mm. The *first fraction*, b. p. 162–170°, crystallized spontaneously and was recrystallized from alcohol, containing a little light petroleum as white, silky prismatic needles, m. p. 62–64°. The melting point and the analysis showed that the substance was 9-ethylphenanthrene. Calcd. for $C_{16}H_{14}$: C, 93.2; H, 6.8. Found: C, 93.4, 93.3; H, 7.1, 7.0. The *second fraction*, b. p. 180–195° (0.8 mm.) was an unsaturated (bromine) yellow oil, n_D 1.6499, which crystallized after some time; from alcohol as needles, exhibiting blue fluorescence, m. p. 73–75°. The analysis showed that the desired 1-(phenanthryl-ethyl)-2-methyl-cyclopentene-(1) (IX) had been formed but the yield was so poor that further experiments with this substance had to be abandoned.

---

[10] Cornubert and Borrell, *Bull. soc. chim.* (IV), **47**, 304 (1930).

Calcd. for $C_{22}H_{22}$: C, 92.3; H, 7.7. Found: C, 92.3; H, 8.2. In view of the violence of the Grignard reaction, it is improbable that the ethylphenanthrene derives from unchanged Grignard compound. It could have been formed by dismutation of the expected carbinol, or when methylcyclopentanone inclines to react in an enolic form.[11]

---

Summary

1. Cyclopentenotriphenylene has been prepared, starting with β-(9-phenanthryl)-ethyl chloride and cyclopentanone.
2. The nature of several by-products has been discussed.

REHOVOTH, PALESTINE RECEIVED APRIL 9, 1936

[CONTRIBUTION FROM THE UNIVERSITY OF MARYLAND]

Cerin and Friedelin. III. A Study of the Oxidative Degradation of Friedelin[1]

BY NATHAN L. DRAKE AND WILLIAM P. CAMPBELL

Our previous study of cerin and friedelin[2] has shown that these substances are polycyclic in nature, the former a hydroxy ketone, the latter a ketone, both derived from the same nucleus. From evidence now available[3] it is apparent that this polycyclic nucleus contains five fused rings, and that cerin and friedelin are derived from a completely hydrogenated picene, and should be classed as derivatives of a triterpene.

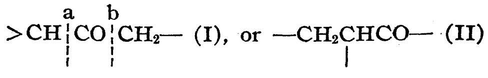
It is the purpose of this communication to describe certain degradation experiments in which the attack on the friedelin molecule is at the carbonyl group.

Sodium and amyl alcohol reduce friedelin to the corresponding alcohol, friedelinol, whose benzoate can be prepared readily by the action of benzoyl chloride on the alcohol in pyridine solution. This benzoate, when heated in an atmosphere of nitrogen to 300°, is converted into a hydrocarbon friedelene, $C_{30}H_{50}$, and benzoic acid. Similar unsaturated hydrocarbons with alkyl or aryl groups attached to the carbon which, in the original friedelin molecule, held the carbonyl oxygen, can be prepared by the action of the Grignard reagent on friedelin. Phenylmagnesium bromide yields such a hydrocarbon directly; the tertiary alcohol first produced undergoes spontaneous dehydration. Two products are obtained when methylmagnesium iodide reacts with friedelin. One is the expected methyl-substituted tertiary alcohol, the other methylfriedelene. The tertiary alcohol is readily dehydrated by acetic anhydride to methylfriedelene. All of these unsaturated substances give a pronounced yellow color with tetranitromethane, but the *purest* friedelin gives no color.

The ready dehydration which these alcohols undergo, and the formation of benzoic acid from the benzoate, prove the presence of a hydrogen atom adjacent the carbonyl group of friedelin, and indicate that this hydrogen is probably tertiary.

Because friedelene is so easily accessible it was chosen for further study. Oxidation of friedelene by chromic anhydride in glacial acetic acid yields a neutral substance, $C_{30}H_{48}O$. This compound gives a color with tetranitromethane and yields no methane when treated with methylmagnesium iodide. The substance $C_{30}H_{48}O$ must, therefore, be an unsaturated ketone, and since no methylene group of friedelin behaves in a similar fashion during oxidative degradations, it is reasonable to assume that the ketone $C_{30}H_{48}O$, which we have called friedelenone, owes its formation to the activating effect of the double bond on the hydrogens of an adjacent methylene group. The formation of α,β-unsaturated ketones by oxidation is a common reaction in the terpene series. Pinene can be oxidized to verbenone by treatment with chromic acid[4] and cedrin[4] and limonene can also be converted to α,β-unsaturated ketones by oxidation.[5] Similarly cholestene is converted to cholestenone under the influence of chromic anhydride.[6]

On the basis of this evidence the existence of the grouping



$$>CH\overset{a}{\vdots}CO\overset{b}{\vdots}CH_2\text{— (I), or —}CH_2\underset{|}{C}HCO\text{— (II)}$$

in friedelin is postulated. Evidence obtained from the oxidation of friedelin makes it possible

to assign the partial structure (I) to one ring of the friedelin molecule.

Friedelin is oxidized by chromic anhydride in glacial acetic acid mainly to a keto acid containing thirty carbon atoms $C_{30}H_{50}O_3$, for which we propose the name friedonic acid. The neutralization equivalent of the acid, the saponification equivalent of its methyl ester, and determination of its carbon and hydrogen content are all in accord with the formula written. It is obvious, therefore, that friedonic acid is produced by the opening of a hydroaromatic ring which holds some substituent on the carbon adjacent to the carbonyl group. Although it has not proved possible to obtain from this acid any derivatives by replacement of the carbonyl oxygen, it is possible to reduce friedonic acid to a neutral substance, $C_{30}H_{50}O_2$, the lactone of an hydroxy acid. In accord with this interpretation are the neutrality of the reduction product, the fact that it gives no color with tetranitromethane, thus excluding simple dehydration of an hydroxy acid with formation of an unsaturation, and its saponification equivalent. We propose to call this substance the lactone of friedolic acid.

In addition to friedonic acid, a keto acid containing twenty-nine carbon atoms is produced by the oxidation of friedelin.

It has proved impossible thus far to separate the more soluble C_{29} keto acid as such from the C_{30} acid, for both crystallize very poorly, but reduction of the more soluble fractions obtained during purification of the C_{30} acid yields a mixture of lactones from which that of the C_{29} acid can be separated. Analyses and determinations of saponification equivalent demonstrate the formula of this lactone to be $C_{29}H_{48}O_2$; it is therefore norfriedolo lactone.

The simplest interpretation of these reactions considered in conjunction with the oxidation of friedelene to friedelenone is that during the oxidation of friedelin the structure (I) is cleaved at (a) and at (b) forming, respectively, friedonic acid and a dibasic acid which, because it contains the grouping $>CH-$ adjacent to the carboxyl is very easily degraded further, yielding norfriedonic acid.

There is ample justification in the literature for the assumption that the intermediate dibasic acid would readily undergo further degradation, for isobutyric acid yields acetone when treated with hydrogen peroxide or chromic acid,[7] and methylheptylacetic acid is degraded by chromic acid to methyl heptyl ketone.

Oxidation of friedelene produces a very small acidic fraction, from which by reduction with sodium and alcohol norfriedolo lactone, identical with the compound obtained by oxidation of friedelin, is obtained. It should be stated that the evidence on which the identity of this acidic oxidation product of friedelene is based consists of a determination of the melting point of the compound mixed with norfriedolo lactone obtained from friedelin. This sort of evidence appears to be admissible in the light of our experience with other degradation products of friedelin.

Norfriedonic acid is formed, then, from friedelenone by cleavage of the ketone at the double linkage and further degradation of the α-keto acid so produced. The formation of norfriedonic acid in this reaction proves that the methylene group in friedelin must be adjacent to the carbonyl and not as represented in (II). Thus it is clear that the carbon which is lost in the formation of norfriedonic acid is the one which held the carbonyl oxygen in friedelin.

Experimental

Friedelinol.—To 1 g. of friedelin dissolved in 100 ml. of boiling *n*-amyl alcohol was added 2 g. of sodium. Refluxing was continued until the sodium had dissolved, whereupon the solvent was removed by distillation with steam, and the product crystallized from benzene–ethyl acetate or from amyl alcohol. Friedelinol crystallizes in hexagonal plates which melt 301–304°. The yield of friedelinol prepared from pure friedelin was 90%. When so called "friedelin-rich"[8] material is reduced, the yield is 50–65%, but this lower yield actually represents a larger friedelinol yield based on "friedelin-rich" substance, for a considerable loss is entailed in purifying friedelin through its enol ester.

Anal. Calcd. for $C_{30}H_{52}O$: C, 84.03; H, 12.23. Found: C, 83.81, 83.75; H, 12.10, 12.08.

Friedelinyl Iodide.—Friedelinol (0.5 g.), red phosphorus (0.2 g.), and iodine (1.3 g.) were heated in dry benzene under reflux for three hours. The warm solution was shaken with mercury to remove excess iodine and evaporated to 5 ml. *in vacuo*. Water was added, the benzene removed *in vacuo*, and the product recrystallized from benzene. Leaching with a small quantity of benzene removed contaminating mercuric iodide, whereupon recrystallization from benzene–ethyl acetate resulted in a product which melted with decomposition at 224–226°.

Anal. Calcd. for $C_{30}H_{51}I$: I, 23.57. Found: I, 23.59, 23.36.

The molecular weights of friedelin calculated from these analyses are 426 and 432, respectively. These values

---

[7] Schmidt, *Ber.*, **7**, 1363 (1874).

[8] *Cf.* paper I, THIS JOURNAL, **57**, 1571 (1935).

are in excellent agreement with those obtained from the saponification equivalents of certain enol esters of friedelin (*cf.* paper I).[8] The calculated molecular weight for $C_{30}H_{50}O$ is 426.

Friedelinyl Methyl Ether.—Friedelinol (0.04 g.) in methyl iodide (20 ml.) was heated under reflux for several hours with silver oxide. The solution was filtered, and the ether obtained by evaporation of the methyl iodide. After recrystallizations from ethyl acetate, from which the ether crystallizes in plates, the product melted at 265–267°.

Anal. Calcd. for $C_{31}H_{54}O$: C, 84.09; H, 12.30. Found: C, 84.04; H, 12.25.

Friedelinyl Acetate.—Friedelinol (1 g.) was heated for two hours under reflux in 100 ml. of acetic anhydride. The acetate which separated in long lath-like plates when the solution was cooled, was recrystallized from benzene. The product melted at 315–316°.

Anal. Calcd. for $C_{32}H_{54}O_2$: C, 81.63; H, 11.57. Found: C, 81.46, 81.55; H, 11.65, 11.55.

Friedelinyl Benzoate.—To a boiling solution of friedelinol (2.8 g.) in dry pyridine (125 ml.) was added benzoyl chloride (15 ml.). After the solution had been heated under reflux for one-half hour, 300 ml. of 95% ethanol was added and the solution allowed to cool to room temperature. The substance which separated was recrystallized from a benzene–alcohol mixture. Friedelinyl benzoate crystallizes in long laths which melt at 250–251°.

Anal. Calcd. for $C_{37}H_{56}O_2$: C, 83.39; H, 10.59. Found: C, 83.43, 83.29; H, 10.56, 10.71.

Friedelene.—Friedelinyl benzoate (5 g.) was heated in an atmosphere of nitrogen at 280–320° for three and one-half hours. The benzoic acid was removed from the product by 10% aqueous sodium hydroxide. After purification by crystallization from ethyl acetate–benzene the substance melted at 257–258°. It crystallizes in lath-like plates, and gives a yellow color with tetranitromethane.

Anal. Calcd. for $C_{30}H_{50}$: C, 87.72; H, 12.28. Found: C, 87.89, 87.98; H, 12.37, 12.26.

Attempts to dehydrate friedelinol directly by use of sulfuric acid, oxalic acid, sodium bisulfate, phosphorus pentachloride and thionyl chloride yielded products which would not crystallize.

Phenylfriedelene.—To a solution of phenylmagnesium bromide, prepared in ethyl ether from 25 ml. of bromobenzene and 6 g. of magnesium, was added an equal volume of dry benzene. This solution of Grignard reagent was then mixed at room temperature with a solution of 5 g. of friedelin in 500 ml. of dry benzene. To complete the reaction the mixture was heated under reflux for one-half hour. The crude product, obtained by pouring the solution into dilute acid and removing the benzene by steam distillation, was recrystallized several times from ethyl acetate from which it separated in the form of thin plates, which melted at 269–271°.

Anal. Calcd. for $C_{36}H_{54}$: C, 88.82; H, 11.18. Found: C, 88.84, 88.97; H, 11.26, 11.30.

Only 0.3 g. of phenylfriedelene was obtained; the balance of the reaction products was a gum which would not crystallize, and would not react with acetic anhydride to yield a crystalline product.

Methylfriedelinol.—This compound was prepared from 5 g. of friedelin by a method quite similar to that described directly above. The crude solid product was leached with 250 ml. of a boiling ethyl acetate–benzene mixture (2:1). Methylfriedelinol crystallized from the leachings, and after further purification by crystallization from benzene a product which crystallized in lath-like hexagonal plates, and melted at 316–319°, was obtained.

Anal. Calcd. for $C_{31}H_{54}O$: C, 84.09; H, 12.30. Found: C, 83.98, 84.19; H, 12.43, 12.42.

A small quantity of methylfriedelene was obtained from the residue left by the leaching process described above.

Methylfriedelene.—Methylfriedelinol was dehydrated by heating it under reflux in an acetic anhydride solution containing a little xylene to render the alcohol more soluble. After about two hours, a part of the solvent was removed by distillation, and the product which separated on cooling was recrystallized from benzene and ethyl acetate to constant melting point. Methylfriedelene crystallizes in hexagonal plates which melt at 272–274°.

Anal. Calcd. for $C_{31}H_{52}$: C, 87.65; H, 12.35. Found: C, 87.65, 87.70; H, 12.36, 12.47.

Oxidation of Friedelene to Friedelenone.—Friedelene (3.6 g.) dissolved in acetic acid (900 ml.) was oxidized at 97° by chromic anhydride (2.4 g.). After six hours 500 ml. of water and a little methanol were added, the mixture boiled for a few minutes and filtered; 3.5 g. of light green solid separated on cooling. This substance was dissolved in ether and shaken with 10% sodium hydroxide solution to remove any acidic fraction. The ether layer was separated and evaporated until crystallization started. The substance so obtained melted at 290–291° after one recrystallization from ether. Friedelenone crystallizes from ether in lath-like plates apparently monoclinic, which are easily differentiated under a petrographic microscope from all of the other oxidation products herein described. Friedelenone is the only oxidation product thus far examined which shows oblique extinction; the extinction angle measured from the long side of the crystal is approximately 24°.

Anal. Calcd. for $C_{30}H_{48}O$: C, 84.83; H, 11.40. Found: C, 84.83, 84.83; H, 11.32, 11.36.

Friedelenone gave a pronounced yellow color with tetranitromethane, and when treated with methylmagnesium iodide in amyl ether evolved no methane.

Acidification of the alkaline extract mentioned above produced 1.5 g. of amorphous solid. To this solid, dissolved in 50 ml. of boiling *n*-propyl alcohol, was added 3 g. of sodium cut in small pieces. When all of the sodium had dissolved, the solution was diluted with 500 ml. of water and acidified. The substance which separated was crystallized from ethyl acetate to yield a very small quantity of a compound which melted 287–289°. A mixture of this substance with norfriedolo lactone obtained from friedelin (m. p. 289–291°) melted at 288–289°.

Oxidation of Friedelin to Friedonic Acid.—Chromic anhydride (2.4 g.) dissolved in glacial acetic acid (125 ml.) was added slowly over a period of about four hours to a suspension of 5 g. of friedelin in 600 ml. of boiling glacial acetic acid. The mixture was heated under reflux for an additional eleven hours, during which time the friedelin gradually dissolved. After about two-thirds of the solvent had been removed by distillation, 500 ml. of water was added to the hot solution. After cooling and filtering, the solid was dissolved in ether, and shaken with 10% sodium hydroxide. Sodium salts precipitated in the aqueous layer and were rendered compact at the ether-water interface by the use of a centrifuge. The ether solution was separated and the mixture extracted with a fresh portion of ether. From the combined ether extracts was obtained 0.8 g. of friedelin and 0.2 g. of a resinous material.

The aqueous layer was made acid to Congo red paper, warmed to coagulate the acids and filtered. By recrystallization from aqueous alcohol and finally from 95% alcohol 1.3 g. of a product, which crystallized in narrow laths and melted 206–207°, was obtained.

Anal. Calcd. for $C_{30}H_{50}O_3$: C, 78.54; H, 11.00. Found: C, 78.83, 78.75; H, 10.91, 11.02. *Neutral Equiv.* Calcd. for $C_{28}H_{49}(CO)(COOH)$: 458. Found: 463, 461.

Methyl Friedonate.—This ester was prepared from the crude acid fraction obtained by oxidation of friedelin as above. Esterification was accomplished by heating the sodium salt in absolute ethanol with excess methyl iodide. Methyl friedonate crystallizes from methyl alcohol in narrow laths which melt at 249–251°.

Anal. Calcd. for $C_{31}H_{52}O_3$: C, 78.75; H, 11.09. Found: C, 78.60, 78.85; H, 11.21, 11.42. *Sapon. Equiv.* Calcd. for $C_{29}H_{49}(CO)(COOCH_3)$: 472. Found: 473, 471.

Friedolo Lactone and Norfriedolo Lactone.—Two and four-tenths grams of the lower melting crude acid fraction obtained from the oxidation of friedelin was dissolved in 140 ml. of *n*-propyl alcohol. This solution was heated under reflux and 6 g. of sodium cut in small pieces was added. When all the sodium had dissolved, the solution was diluted with 500 ml. of water, cooled and filtered. The resulting solid was crystallized from ethyl alcohol (160 ml.) and then several times from ethyl acetate. Friedolo lactone crystallizes from ethyl acetate in rods, which melt 309–312°.

Anal. Calcd. for $C_{30}H_{50}O_2$: C, 81.37; H, 11.39. Found: C, 81.24, 81.12; H, 11.26, 11.25.

The alcoholic filtrate from the first crystallization mentioned above was evaporated to half its volume, cooled and filtered. The crystals which separated were purified by further recrystallization from ethyl acetate. The compound norfriedolo lactone crystallizes from ethyl acetate in long needle-like laths, and melts 289–291°. This melting point is considerably depressed by admixture of friedolo lactone.

Anal. Calcd. for $C_{29}H_{48}O_2$: C, 81.24; H, 11.30; sapon. equiv., 428. Found: C, 81.09, 81.29; H, 11.29, 11.34; sapon. equiv., 431, 429.

We should like to acknowledge our indebtedness to R. P. Jacobsen for his analyses of friedelinyl iodide, and to J. R. Spies for analyses of friedelinol and friedelinyl methyl ether.

Summary

1. The oxidation of friedelin and friedelene by chromic anhydride in glacial acetic acid has been studied, and from evidence so obtained the structure $CHCOCH_2$- in the friedelin molecule is deduced.

2. The preparation of friedelinol and of several of its derivatives is described.

3. Several acidic and neutral degradation products of friedelene and friedelin have been prepared.

Cerin and Friedelin. IV. The Dehydrogenation of Friedelinol[1]

BY NATHAN L. DRAKE AND WILLARD T. HASKINS

In continuation of our studies on the structure of cerin and friedelin, we have subjected friedelinol to dehydrogenation by selenium in order to determine the type of aromatic nucleus to which friedelin is related. Friedelinol rather than friedelin was chosen for study because previous investigation had shown that friedelin, like most ketones whose carbonyl forms a part of a ring system, yielded products too complex and too far removed from the original nuclear structure to be a satisfactory substance for dehydrogenation studies.

The products obtained from friedelinol by dehydrogenation are 1,2,7-trimethylnaphthalene (sapotalene), 1,2,8-trimethylphenanthrene, a hydrocarbon $C_{25}H_{20}$, apparently identical with a polymethyl picene isolated by Ruzicka and coworkers from the dehydrogenation products of a number of triterpenes,[2] and a liquid hydrocarbon, $C_{11}H_{20}$, which has the properties of an alkyl substituted cyclohexene.

The evidence advanced by Ruzicka[3] in support of a picene nucleus in the hydrocarbon $C_{25}H_{20}$ is quite conclusive; consequently there must be in cerin and friedelin a pentacyclic nucleus of the

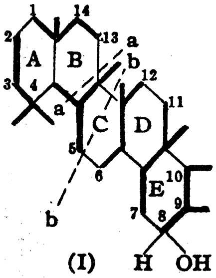
hydrogenated picene type. The formation of new rings during dehydrogenation is a reaction known to occur, but at the temperatures of our dehydrogenations such ring formation is highly unlikely. Extra cycle formation is most probable at temperatures above 350°,[4] and our dehydrogenations were carried out at temperatures from 315 to 325° (bath temp.).

It seems unlikely that alkyl group rearrangement occasioned by the dehydration of friedelinol occurred prior to the actual dehydrogenation, for both friedelin and friedelene gave the same product, norfriedonic acid[5] on oxidation, and friedelene was prepared at temperatures approximating those employed during the dehydrogenations. It seems logical to conclude, therefore, that the locations of the alkyl groups in the polymethylpicene actually represent the original structure. There is considerable doubt as to the exact number of these methyl groups. Ruzicka has synthesized 3,9,10-trimethylpicene and 3,8-dimethylpicene, neither of which[6] is identical with the product obtained by dehydrogenation, although the absorption bands of the trimethylpicene in the ultraviolet were very much like those of the unknown. All of our analyses on the hydrocarbon obtained from friedelinol and the same substance obtained from ursolic acid are better in accord with $C_{24}H_{18}$ than $C_{25}H_{20}$. Furthermore, our determinations of molecular weight on different specimens of the hydrocarbon from the sources mentioned above are considerably too low for the $C_{25}H_{20}$ formula and check the $C_{24}H_{18}$ formula almost exactly. The concordance of these two sets of determinations carried out by different operators on material from different sources might possibly be fortuitous, but we believe that our findings emphasize the necessity of considering the dimethylpicenes in any attempt to identify the unknown polymethylpicene.

Ruzicka has concluded as a result of certain degradation reactions of hederagenin[7] that the hydroxyl group of the triterpenes must be considered to be adjacent to a carbon atom holding two methyl groups. It is apparent from the behavior of friedelin on oxidation that this structure does not exist in friedelinol.[5]

We suggest as a tentative formula for friedelinol the following (I)



(I)

in which the heavy lines represent isoprene nuclei. This structure corresponds closely to one suggested by Ruzicka for certain triterpenoids,[7b] (p. 391) but differs in the location of the hydroxyl group, and in the absence of the Δ^8 unsaturation. It is entirely possible that the hydroxyl group of cerin corresponds in location to the hydroxyl of those triterpenoids which Ruzicka has studied and should be placed at 3 in Ring A.

Cleavage of the molecule at (a)------(a) would result in the formation of 1,2,8-trimethylphenanthrene and another substance containing eleven carbon atoms, corresponding to the compound $C_{11}H_{20}$, which apparently is a polyalkylcyclohexene. This substance was obtained in small quantity, but possessed properties which were in accord with the suggested structure. It had a refractive index like other known polyalkylcyclohexenes containing eleven carbons, absorbed bromine in cold carbon tetrachloride but yielded no solid bromide, and had a molecular weight and percentage composition which were excellently in accord with the formula $C_{11}H_{20}$. It was distilled several times over platinized asbestos at 300° and later at 420° without being further dehydrogenated. It was possible, however, by heating the substance in a sealed tube with selenium for twenty-four hours at 320° to accomplish further dehydrogenation as evidenced by the escape of hydrogen selenide when the tube was opened. The resulting substance possessed a considerably higher refractive index than the original material and was converted at 0° by the action of bromine in the presence of a bit of aluminum chloride into a solid bromide. The melting point of the bromide did not, however, correspond to that of any of the known derivatives of polyalkylbenzenes. The difficulty of dehydrogenating this material by platinum black is in accord with the findings of Zelinsky,[8] who has examined the

behavior of a number of hydroaromatic rings when subjected to the dehydrogenating influence of platinum at elevated temperatures. Only those rings containing no quaternary carbon atom were aromaticized at temperatures up to 300°.

Cleavage of (I) at (b)----(b) and migration of a methyl group from 4 to 3 would result in the formation of sapotalene. The migration of the alkyl group is certainly within the bounds of reason, for Mayer and Schiffner have shown[9] that α-methylnaphthalenes have a pronounced tendency to rearrange to β-derivatives when distilled over silica gel at temperatures above 400°, and α-phenylnaphthalene rearranges at about 350°.

The location of the hydroxyl group at the 8-position in (I) is based on results obtained in oxidation studies.[5] It is apparent from this work that the secondary hydroxyl of friedelinol must be present in a cycle which contains the unit of structure $CHCHOHCH_2$-; furthermore, we have isolated a lower oxidation product of friedonic acid which apparently is a keto acid containing twenty-seven carbon atoms.[10]

Experimental

Apparatus.—The dehydrogenations were carried out in a 200-ml. Pyrex flask to which was sealed a broad U-tube of 20 mm. tubing. One arm of the U, about a meter long, served as a reflux condenser, the other arm, which was somewhat shorter, was sealed to a small Pyrex flask with a side outlet. This flask served as an auxiliary condenser, and from its side-arm the gaseous products of the reaction were conducted through a small bubble counter to a tube containing moist calcium hypochlorite. The reaction flask was heated by a bath of Wood's metal whose temperature was determined by means of a thermocouple. Selenium was introduced through a short side-arm near the top of the reflux condenser.

Method.—Forty grams of friedelinol,[5] well mixed with 80 g. of powdered selenium, was heated in the reaction flask (metal bath temp. 315–325°), and 10-g. portions of selenium added every twenty-four hours until 40 g. had been added. The heating was continued until hydrogen selenide was no longer evolved (two hundred and forty hours). The reaction flask was then cut from the condenser and broken to recover the charge. The reaction products were finely ground in a mortar and exhaustively extracted with ether in a Soxhlet extractor. The reflux condenser and trap were rinsed with ether and the rinsings added to the ether extract. After extraction by ether was practically complete, the ether was replaced by benzene, and extraction continued until the residue was free from soluble material.

After evaporation of the ether from the first extract there remained 11.1 g. of dark red oil. A second dehydrogenation was conducted in the same apparatus using 50 g. of friedelinol mixed with 15 g. of powdered selenium as the initial charge. Selenium was added in 5-g. portions at intervals of an hour during the daytime until 150 g. in all had been added. Evolution of hydrogen selenide ceased at the end of seventy-five hours. The ether extract weighed 19.2 g., but 10 g. consisted of material boiling above 250° under 2 mm. pressure. The addition of selenium in small amounts appeared to speed up the dehydrogenation considerably, but had little effect on the type and amounts of products except that the first fraction described below was less than one-third as large in the second dehydrogenation as in the first.

Fractionation of the Ether Soluble Products.—The ether-soluble products were distilled under a pressure of 2 mm. in a Claisen flask with a short fractionating column. Fractions with the following boiling ranges, weights, $n^{25}D$ and $d^{20}{}_{20}$ were obtained: up to 70°, 2 g., 1.4585, 0.8232, sl. yellow liq.; 70–125°, 1.2 g., 1.5686, 0.9650, yellow liq.; 125–170°, 0.5 g., 1.6067, red-yellow liq.; 170–200°, 0.8 g., yellowish semi-solid; 200–250°, 1.0 g., yellowish solid; residue, 5.6 g., dark resinous solid.

The still residue was combined with the benzene extract, and the material left after removal of the benzene was sublimed under low pressure.

The Alkylcyclohexene.—The liquid hydrocarbon boiling up to 70° at 2 mm. pressure was redistilled at atmospheric pressure. Approximately 80% of the substance distilled from 180 to 185°. This substance would not form a solid bromide when treated with bromine in cold carbon tetrachloride, nor would it yield a picrate or a styphnate.

Anal. Calcd. for $C_{11}H_{20}$: C, 86.74; H, 13.26; mol. wt., 152. Found: C, 86.60, 86.32; H, 13.62, 13.61; mol. wt. (f. p. of benzene), 149, 152; $n^{25}D$ 1.4535; $d^{20}{}_{20}$ 0.8232.

The liquid was distilled several times over platinized asbestos at 300 and at 420°, but no dehydrogenation occurred. About 0.3 g. of the liquid was heated to 320° with 1.0 g. of selenium in a small sealed Pyrex tube for twenty-four hours. When the tube was opened hydrogen selenide escaped, proving dehydrogenation. The product was extracted with ether and later distilled; it boiled 187–192°, and had a considerably higher refractive index than before heating ($n^{25}D$ 1.4553). The liquid was cooled to 0° and a small amount of aluminum chloride and a few drops of bromine added. Hydrogen bromide was evolved and the mass partially solidified. After removal of excess bromine and recrystallization from alcohol the solid melted 169–175°. The melting point does not correspond to that of any of the recorded bromo derivatives of the polyalkylbenzenes.

1,2,7-Trimethylnaphthalene.—The liquid fractions which boiled from 70–125° and from 125–170° were converted into picrate, and recrystallized from ethyl alcohol. After eight recrystallizations a constant melting point of 125–127° was attained.

Anal. Calcd. for $C_{19}H_{17}N_3O_7$: C, 57.13; H, 4.29. Found: C, 57.27, 56.87; H, 4.04, 4.14.

The corresponding fractions from the second dehydrogenation were converted into styphnate and the latter

---

(9) Mayer and Schiffner, *Ber.*, **67**, 67 (1934).

(10) Unpublished work.

recrystallized from ethyl alcohol to a constant melting point of 153–154°.[11]

1,2,8-Trimethylphenanthrene.—The fraction which boiled 170–200° was converted to picrate, but this derivative dissociated readily after a few recrystallizations from methyl alcohol had removed excess picric acid. The fluffy white hydrocarbon so obtained melted at 141–142°. Similar treatment of the corresponding fraction from the second dehydrogenation yielded more of the same substance.

Anal. Calcd. for $C_{17}H_{16}$: C, 92.73; H, 7.27; mol. wt., 220. Found: C, 92.90, 92.45; H, 7.49, 7.23; mol. wt. (Rast), 204, 202.

The picrate of this hydrocarbon was crystallized from ethyl alcohol saturated at 0° with picric acid. The picrate melted 162–163°.

The solid fractions which boiled at 200–250° under 2 mm. pressure were recrystallized from ethyl alcohol five times. The resulting hydrocarbon was the same as the one described directly above; 0.03 g. of this substance was dissolved in boiling glacial acetic acid and 0.05 g. of chromic anhydride was added. The mixture was heated under reflux for thirty minutes, then cooled, and diluted with water. A small amount of an orange colored quinone which melted 189–190° was obtained. This quinone was dissolved in ethyl alcohol, an excess of *o*-phenylenediamine was added, and the solution was evaporated to dryness. The residue was taken up in ether, and extracted with 1% hydrochloric acid to remove unreacted diamine. Evaporation of the ether solution left a pale yellow quinoxaline which melted 129–131°. The melting points of hydrocarbon and the derivatives mentioned above (in the order discussed) are reported by Haworth[12] as 144–145, 163, 196–197, 131–132°, and by Ruzicka[13] as 142–143, 161–163, 194, 131–132°.

The Polymethylpicene.—The combined still residues from the ether extracts and the benzene extracts were sublimed at 300° under low pressure. The sublimed material was crystallized several times from benzene. After treatment with decolorizing carbon and further recrystallization, a product which melted 305–306° and crystallized in shiny flat platelets with a bluish luster was obtained.

Anal. Calcd. for $C_{25}H_{20}$: mol. wt., 320; C, 93.70; H, 6.30; for $C_{24}H_{18}$: mol. wt., 306; C, 94.09; H, 5.91. Found: mol. wt. (Rast), 306, 309; C, 93.80, 93.97; H, 6.17, 6.11.

The hydrocarbon dissolves in concentrated sulfuric acid with the production of a deep emerald green color, a reaction also given by picene,[14] and it is oxidized by chromic anhydride in glacial acetic acid to a reddish orange quinone which possesses no definite melting point (like picene quinone). Analysis of a sample of this quinone which had been recrystallized from dioxane indicated that it contained a considerable quantity of a substance richer in oxygen. Lack of material prevented further purification.

Summary

1. 1,2,7-Trimethylnaphthalene, 1,2,8-trimethylphenanthrene, a polymethylpicene and a polyalkylcyclohexene have been shown to be present among the products formed by dehydrogenating friedelinol by selenium.

2. Cerin and friedelin should be classed with the triterpenoids. They contain a hydrogenated pentacyclic nucleus.

3. A tentative structure has been assigned to friedelinol, the reduction product of the ketone, friedelin.

The Dehydrogenation of Ursolic Acid by Selenium[1]

BY NATHAN L. DRAKE AND HARRY M. DUVALL

During his study of polyterpenoid substances, Ruzicka dehydrogenated a small quantity (5 g.) of ursolic acid by means of selenium[2] and identified 1,2,7-trimethylnaphthalene (sapotalene) as one of the dehydrogenation products. In connection with certain other work in progress in this Laboratory, it seemed desirable to repeat this work using larger quantities of material, and we were very fortunate in obtaining for this purpose, through the courtesy of Drs. C. E. Sando and K. S. Markley of the U. S. Department of Agriculture, a considerable quantity of crude ursolic acid.

In addition to sapotalene we have obtained two other substances by the action of selenium at 320–340° on ursolic acid, *viz.*, 2,7-dimethylnaphthalene, and a polymethylpicene, apparently identical with a substituted picene obtained by Ruzicka[2] from related triterpenoid substances. This polymethylpicene is identical with the compound obtained by Drake and Haskins by the dehydrogenation of friedelinol.[3]

(3) Drake and Haskins, THIS JOURNAL, **58**, 1684 (1936).

Experimental

Purification of Ursolic Acid.—Two hundred grams of crude ursolic acid was dissolved in a hot solution of 50 g. of potassium hydroxide in approximately 600 ml. of methanol and 300 ml. of water. A small quantity of insoluble brown material was skimmed off and the solution filtered with suction while hot through a large Büchner funnel. The hot filtered solution was then treated with 40 g. of decolorizing charcoal, filtered, and the charcoal treatment repeated twice. The resulting solution was next heated on the steam-bath to remove some of the methyl alcohol (not enough to cause separation of potassium ursolate); 1500 ml. of hot water was then added and the ursolate salted out by the addition of 50% potassium hydroxide solution (about 50 g. of potassium hydroxide in 50 ml. of water was necessary).

The precipitated potassium ursolate was collected on a large Büchner funnel, sucked dry, and then dissolved in 500–600 ml. of hot methanol. This solution, after filtration while hot, was acidified to Congo red by 6 *N* hydrochloric acid. The resulting precipitate was filtered and washed carefully twice by stirring it in a beaker with about a liter of boiling water acidified with hydrochloric acid. One recrystallization from ethyl alcohol yielded a product which melted 278–280°.[4] Further recrystallization raised the melting point to 283–284°.

Anal. Calcd. for $C_{30}H_{48}O_3$: C, 78.88; H, 10.60. Found: C, 79.05, 78.86; H, 10.69, 10.53.

The Dehydrogenations.—Two 50-g. portions and one 200-g. portion of ursolic acid were dehydrogenated. The apparatus and procedure were essentially as in our earlier work.[5] The products of the second and third dehydrogenations were worked up together; 59.5 g. of ether-soluble products and 13.7 g. of benzene-soluble products were so obtained.

Fractionation of the Ether-Soluble Products.—The ether-soluble material was distilled from a 200-ml. flask with a sausage side-arm. Fractions with the following boiling ranges, weights and physical states, were obtained (l. = liquid; s. = solid): 115–150° at 12 mm., 2.5 g., l.; 150–175° at 11 mm., 3.6 g., l.; 175–200° at 12 mm., 21.1 g., l.; 200–250° at 12 mm., 8.9 g., l.; 265–285° at 6–8 mm., 8.0 g., l. and s.; 285–310° at 2 mm., 7.9 g., s.; 350–365° at 3 mm., 6.1 g., s.

By redistillation at 11–12 mm. in a small Claisen flask, fractions 1, 2, 3 and 4 were separated into a principal fraction boiling from 130–140°, and a number of lower and higher boiling fractions. This principal fraction was then subjected to careful fractionation at 1–2 mm. in a column about 92 cm. in height packed with Wilson rings. After a small fore-run, the bulk of the material had a refractive index of n^{25}_{D} 1.5997–1.6001. This material was combined with other fractions of nearly the same index and used for preparation of derivatives of sapotalene.

The lower boiling fractions from the second distillation were likewise carefully fractionated in the ring-packed column. From the intermediate fractions of this distillation a solid was obtained, which after further purification proved to be 2,7-dimethylnaphthalene.

2,7-Dimethylnaphthalene.—This substance, isolated as described directly above, had a melting point of 96.5°; its picrate melted at 135–136°, and its styphnate at 159–160°. The corresponding values given in the literature[3] are 97, 136 and 159°, respectively.

Anal. Calcd. for $C_{12}H_{12}$: C, 92.25; H, 7.75. Found: C, 91.93; H, 7.70. Calcd. for $C_{18}H_{15}O_7N_3$: C, 56.09; H, 3.93. Found: C, 56.25; H, 3.95. Calcd. for $C_{18}H_{15}O_8N_3$: C, 53.85; H, 3.77. Found: C, 53.84; H, 3.89.

1,2,7-Trimethylnaphthalene.—It did not prove feasible to purify sapotalene as such, so the substance was converted into picrate and purified by crystallization. The picrate was then decomposed by dilute aqueous ammonia and the styphnate prepared. The picrate melted at 128–129°, the styphnate at 157–157.5°; the melting points of these substances given in the literature[2] are 129 and 157°, respectively.

Anal. Calcd. for $C_{19}H_{17}O_7N_3$: C, 57.13; H, 4.27. Found: C, 57.42, 57.24; H, 4.53, 4.35. Calcd. for $C_{19}H_{17}O_8N_3$: C, 54.92; H, 4.11. Found: C, 55.19, 55.13; H, 4.19, 4.22.

The Polymethylpicene.—The fourth, fifth and sixth fractions from the initial distillation contained solid material. This solid was purified by recrystallization from benzene, and its melting point found to be 304°.

Anal. Calcd. for $C_{25}H_{20}$: mol. wt., 320; C, 93.70; H, 6.30; for $C_{24}H_{18}$: mol. wt., 306; C, 94.09; H, 5.91. Found: C, 94.07, 93.80; H, 5.92, 6.03; mol. wt. (Rast), 300, 296.

This hydrocarbon gave the same characteristic green color when treated with sulfuric acid as does picene,[6] and was oxidized by chromic anhydride in glacial acetic acid to a quinone which reacted with *o*-phenylenediamine to give a quinoxaline. To date we have not been able to obtain either quinone or quinoxaline in a state of analytical purity.

Summary

1. Sapotalene, 2,7-dimethylnaphthalene and a polymethyl picene have been obtained from ursolic acid by selenium dehydrogenation.

Studies of the Reducing Action of Mercury. II. Stability of Quinquivalent Molybdenum Solutions. A Method for the Determination of Molybdenum by Reduction with Mercury and Titration with Ceric Sulfate

BY N. HOWELL FURMAN AND W. M. MURRAY, JR.

Introduction

The volumetric determination of molybdenum has been studied frequently and many methods have been developed involving the reduction of molybdenum and subsequent titration with standard oxidizing agent. In practically all of these studies the reduced molybdenum solution has been protected from the air either by an atmosphere of some inert gas or by running the reduced solution into an excess of oxidizing agent. A few workers have reduced molybdenum to the quinquivalent stage and titrated this lower state without any precaution against air oxidation, but there seems to have been no systematic study of the stability of quinquivalent molybdenum solutions.

This investigation is concerned with the stability of quinquivalent molybdenum solutions and a new method for the determination of molybdenum based on reduction in acid solution with mercury, followed by titration with ceric sulfate solution using as indicator the ferrous complex of *o*-phenanthroline.

Chilesotti[1] observed that mercury would reduce a molybdic acid solution to the trivalent state if the hydrochloric acid concentration were about 9 *N*. This fact was carried no further than the preliminary observation. McCay and Anderson[2] observed qualitatively that molybdenum solutions were reduced by mercury.

Someya[3] reduced molybdenum to the quinquivalent state with bismuth amalgam. The extent of the reduction depended on the presence or absence of air and on the concentration of hydrochloric acid.

Stehlik[4] reduced molybdenum to the quinquivalent state with stannous chloride and titrated the reduced solution potentiometrically with standard ceric sulfate. Lang and Gottlieb[5] have proposed a new volumetric method for the determination of molybdenum. Their primary reducing agent is stannous chloride, and a thorough study of the effect of acidity on this reaction has been made.

Walden, Hammett and Edmonds[6] studied the reduction of molybdenum solutions in the silver reductor and also the titration of quinquivalent molybdenum with ceric sulfate using the *o*-phenanthroline ferrous complex indicator. The titration apparently was satisfactory, but the silver reduction technique did not give reproducible results.

Apparatus and Materials

All potentiometric titrations were performed in the classical manner using a saturated calomel reference electrode and bright platinum wire indicator electrode. Calibrated glassware was used.

The solutions used in the stability studies were prepared from purified molybdic oxide. The standard ammonium molybdate solutions were standardized by the silver molybdate method of McCay.[7] Typical data for the standardization of one such solution were: 0.1038, 0.1038, 0.1039. The standard ceric sulfate solutions which contain traces of iron were standardized against Bureau of Standards sodium oxalate according to the method of Willard and Young.[8]

In the experiments involving the shaking of molybdenum solutions and mercury, all the agitation was done by machine. This machine was run by an electric motor so that the rate of shaking was fairly constant. The motion was a short vertical stroke which kept the mercury splashing through the solution. The containers used were 250-ml. glass-stoppered soft glass bottles or, in case the solution was to be heated, glass-stoppered Pyrex Erlenmeyer flasks.

o-Phenanthroline Ferrous Complex as Indicator for the Titration of Quinquivalent Molybdenum with Ceric Sulfate

Several titrations of samples of quinquivalent molybdenum solutions with standard ceric sulfate were followed both potentiometrically and colorimetrically. It was soon found that the potentiometric end-point was vague, extending over a range of several drops of reagent. Graphs of the data showed a small secondary break within the larger one. Such behavior was encountered by Furman and Schoonover,[9] and they found the small secondary break was caused by iron in the ceric sulfate reagents. Iron was found to be present in the reagents used in our work, and the irregularity of the potentiometric curves is attributed to this cause. However, the end-point as indicated by the *o*-phenanthroline in the colorimetric titra-

[8] Willard and Young, *ibid.*, **50**, 1322 (1928).

[9] Furman and Schoonover, *ibid.*, **53**, 2561 (1931).

tions was very sharp and satisfactory. The ferrous iron formed during the addition of the reagent to the reduced molybdenum solution must be oxidized by more ceric sulfate before the *o*-phenanthroline end-point occurs, so that the error caused by the iron in the potentiometric titrations is eliminated in the colorimetric method.

For the colorimetric titration, the acid concentration must be at least 2 *N* and the molybdenum concentration at the end-point must not exceed 0.25 g. per 300 ml. of solution. Otherwise, a red precipitate which is not destroyed by an excess of ceric sulfate tends to form and obscures the end-point. The formation of this precipitate is dependent on the simultaneous presence of cerous, molybdate, and *o*-phenanthroline ferrous ions in acid solution.

The procedure adopted in this work was to add 5–10 ml. of concentrated sulfuric acid to the quinquivalent molybdenum solutions which were already 2 *N* in hydrochloric acid. If necessary, the mixture was diluted with 2 *N* hydrochloric acid in order to keep the molybdenum concentration below the limit mentioned. Then two drops of 0.025 *M* *o*-phenanthroline ferrous complex indicator solution was added and the titration with ceric sulfate carried out at room temperature. Such a procedure was entirely satisfactory, the reaction being very rapid at room temperature and the color change at the end-point exceedingly sharp.

Stability of Quinquivalent Molybdenum Solutions

A concentrated solution of quinquivalent molybdenum was prepared by electrolytic reduction according to the method of Foerster and Fricke.[10] Portions of this reduced solution were diluted with water and hydrochloric acid to give (1) a solution 0.1 *M* in molybdenum and 2 *N* in hydrochloric acid and (2) a solution 0.1 *M* in molybdenum and 4 *N* in hydrochloric acid.

During the course of this work, samples of these two stock solutions of quinquivalent molybdenum were titrated at intervals in order to determine their respective normalities and follow the slow air oxidation of the reduced molybdenum. The relative instability of the solutions is evident from the following data.

QUINQUIVALENT MOLYBDENUM IN 2 *N* HCl

Days	0	2	8	14	44	202
Normality	0.08092	0.07978	0.07854	0.07565	0.06981	0.00505

QUINQUIVALENT MOLYBDENUM IN 4 *N* HCl

Days	0	1	3	4	5	6
Normality	0.1356	0.1353	0.1344	0.1325	0.1315	0.1298

The foregoing data show that quinquivalent molybdenum solutions are relatively unstable over extended periods of time, but the solutions are not appreciably oxidized in six or eight hours. It is thus possible to work with quinquivalent molybdenum solutions without precaution to exclude air if the solutions are to be oxidized within a short time. The acid concentration of such solutions must be above 1 *N*, however, for quinquivalent molybdenum is very unstable in neutral solution and tends to deposit molybdenum blue.

Reduction of Molybdic Acid by Mercury

Procedure.—The method of reduction is very similar to that described by McCay and Anderson.[2] The bottles or flasks used as reductors contained about 25 ml. of pure mercury. The sample of molybdate solution was pipetted directly into the reductor and the calculated volume of concentrated hydrochloric acid added to bring the acid concentration up to 3 *N*. The reductors were then agitated by machine, but vigorous shaking by hand is quite satisfactory. The sample is completely reduced with only five minutes of shaking. After the reduction, the solution is decanted from the mercury onto a filter, the filtrate being received in a 600-ml. beaker. The mercury and calomel in the bottle are washed five times with 20-ml. portions of dilute (1–5) hydrochloric acid, the mercury mass being well shaken with the wash solution each time, the solution then decanted through the filter. (No detectable amount of hydrogen peroxide is formed during the few seconds the dilute hydrochloric acid wash liquid is shaken with the mercury.)[11] In this manner, all of the mercury and some of the calomel is kept in the bottle. Such bottles are ready for use as mercury reductors again, for it is not necessary to start with fresh mercury each time. Four reductors were used in this way for at least seventy-five times each with no more care than that described above.

The reduced solution from the mercury reductor was titrated colorimetrically with ceric sulfate as described in the preceding section.

The reduction by mercury of molybdic acid solutions containing hydrochloric acid is very rapid, the solution changing almost immediately to light reddish-brown in color, which is typical of quinquivalent molybdenum in dilute acid. Five minutes of vigorous shaking is sufficient to cause quantitative reduction, further shaking having no effect.

TABLE I

DETERMINATION OF MOLYBDENUM BY REDUCTION WITH MERCURY AND TITRATION WITH STANDARD CERIC SULFATE SOLUTION

Molybdenum taken, g.	Error in molybdenum found, g.
0.2494	−0.0002
.2494	− .0001
.2494	.0000
.1968	− .0004
.1968	− .0005
.0806	− .0001
.0806	− .0001
.0806	− .0002

Effect of Acid Concentration.—The hydrochloric acid content of the molybdate solutions at the time of reduction has a marked effect on the state to which it is reduced. When the acid concentration is below 1 *N*, molybdenum blue frequently precipitates and interferes with complete reduction. When the hydrochloric acid concentration is between 1.5 and 3.5 *N* the reduction proceeds quantitatively to the quinquivalent state. However, if the acid concentration is above 4 *N*, reduction to the trivalent state becomes evident and in 9 *N* hydrochloric acid it is easily possible to reduce molybdenum completely to the trivalent state by shaking with mercury. (In strong acid, the solution of molybdenum in the trivalent state is sal-

[11] Furman and Murray, THIS JOURNAL, **58**, 429 (1936).

mon pink in color.) The trivalent molybdenum solution is not stable in air, however, and if filtered and titrated with ceric sulfate the results may be low by 1% or more, due to air oxidation. Data illustrating this effect of acid concentration were obtained by reducing equal samples of molybdate at various acidities. The samples contained 0.1593 g. of molybdenum. When the hydrochloric acid concentration was 2, 3 and 3.5 *N*, the molybdenum found was 0.1592, 0.1591 and 0.1593 g. When the acid concentration was 4 *N*, the value for molybdenum found was 2% high, and when the acidity was stepped up to 9 *N*, the molybdenum found was 1.5% low on the basis of reduction to the trivalent state.

The dependence on acid concentration of the oxidation–reduction potentials of the systems Mo^6/Mo^5, Mo^5/Mo^3, and $Hg/Hg_2Cl_2/HCl$ has been studied. Curves showing these relations are plotted in Fig. 1. The data for the molybdenum systems were taken from the work of Foerster, Fricke and Hausswald[12] and the mercury system data were taken from the work of Ellis,[13] Linhart,[14] and Randall and Young.[15] Reduction to the trivalent state should begin when the Mo^5/Mo^3 system is less than 0.17 volt below the mercury system, and reduction to the trivalent state should be complete to 1 part per 1000 when the mercury system is more than 0.17 volt below the Mo^5/Mo^3 system. From the curves as plotted, reduction to the trivalent state should begin at about 1.5 *N* hydrochloric acid and be complete at about 6.5 *N* acid. Our experience was that reduction to the trivalent state did not interfere until the acid concentration became more than 3.5 *N*. Reduction to the trivalent state at lower acidities is probable, but any trivalent molybdenum formed is very likely oxidized by air during the filtration process.

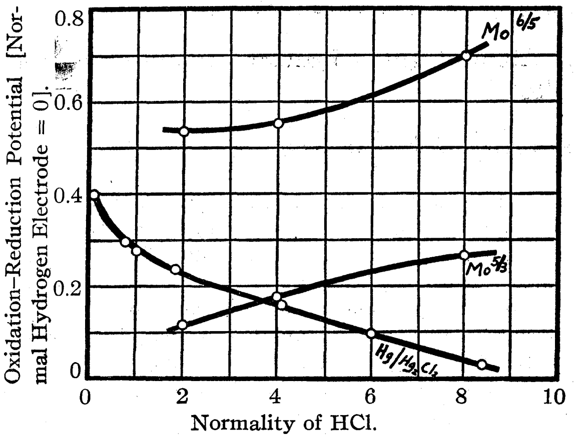

Fig. 1.—Graphs of oxidation–reduction potentials, E'_0 referred to the *N* hydrogen electrode as zero, against normality of hydrochloric acid. Equimolecular mixtures of Mo^{vi} and Mo^{v} or of Mo^{v} and Mo^{iii}, respectively, were present in the solutions.

Effect of the Wash Liquid.—It was evident at the start of this work that water is not a satisfactory wash liquid. It either does not get the molybdenum away from the mercury-calomel particles or some molybdenum is oxidized when pure water is used as a wash liquid. However, 2 *N* (1–5) hydrochloric acid was found to serve the purpose quite satisfactorily.

Determination of Molybdenum in the Presence of Certain Impurities.—Phosphate and arsenate frequently are associated with molybdenum and their effect on this procedure is of interest. It was found that the addition of either phosphate or arsenate ions in amounts up to 0.25 g. did not interfere with the determination of molybdenum samples of equal weight. There was a slight slowing of the rate of reduction with the occasional appearance of molybdenum blue in the early part of the reduction, but reduction to the quinquivalent state was complete in five minutes in every case.

In any analysis where the preliminary separation of other elements must be carried out before the molybdenum can be determined by this method, the solution will contain large amounts of ammonium salts. It was found that as much as five grams of ammonium salts as chlorides and sulfates did not interfere with the determination of 0.1 g. samples of molybdenum by this method.

Effect of Copper Salts.—Copper ions will cause a determination of molybdenum by this method to be seriously in error, even if the amount of copper present is only a fraction of a milligram. This subject of the interference of copper in the determination of molybdenum by the mercury reduction method will be considered more fully in a later paper. Suffice it to say at this time that the very slow air oxidation of quinquivalent molybdenum is apparently an autoxidation reaction and, like many reactions of this class, it is strongly catalyzed by minute amounts of copper.

Analysis of Unknowns by this Method.—Professor E. R. Caley prepared a solution of ammonium molybdate from pure molybdic oxide. The weight of molybdic oxide actually taken by Professor Caley was 6.0177 g. per 500 ml. of solution. Aliquot portions (25 ml.) of this solution were analyzed by one of us (M.) and the results calculated back to the original basis of 500 ml. of solution. The results found by the mercury reduction method were 6.0219, 6.0100, 6.0219, 6.0030 and 6.0129 g. of MoO_3 per 500 ml. of solution. The average of these values is 6.0139 g.

One of us (F.) prepared a mixture of iron and molybdenum by grinding known amounts of pure molybdic oxide, ferric oxide and potassium chloride in an agate mortar. The other (M.) then determined the percentage of molybdenum in the resulting powder by the mercury reduction method. Samples were dissolved in dilute hydrochloric acid, the iron removed by double ammonia precipitation according to the procedure of Hillebrand and Lundell,[16] and the molybdenum determined in the filtrate. The percentage of molybdenum found by the mercury reduction method was 33.20, 33.10, 33.09, 33.10—average 33.12. The percentage of molybdenum actually taken by weight in the preparation of the sample was 33.02.

Acknowledgments.—Gratitude is here expressed to Professors Leroy W. McCay and E. R.

Caley for their interest and suggestions in this work.

Conclusions

1. Solutions of quinquivalent molybdenum are sufficiently stable in air at room temperature to be employed in any analytical procedure which is complete in a few hours time.

2. Molybdic acid solutions may be quantitatively reduced to the quinquivalent state by shaking with metallic mercury for five minutes if the hydrochloric acid concentration of the solution is between 2 and 3.5 *N*.

3. Quinquivalent molybdenum may be titrated with ceric sulfate at room temperature using the *o*-phenanthroline ferrous complex indicator if certain critical conditions are observed.

4. The mercury reduction method for determining molybdenum is rapid and accurate. The presence of considerable quantities of phosphate, arsenate or of ammonium salts is without effect upon the accuracy of the molybdenum determination.

The Systems Lithium Chloride–Water–Ethyl Alcohol and Lithium Bromide–Water–Ethyl Alcohol[1,2]

BY JOHN P. SIMMONS, HENRY FREIMUTH AND HARRY RUSSELL

The lithium halides show a marked tendency to dissolve in organic liquids, particularly the alcohols,[3] and to form addition products with them. The systems lithium chloride–water and lithium bromide–water have been carefully explored and the existence of four hydrates of each halide has been shown.[4] A study based on the phase rule of the ternary systems, lithium chloride–water–ethyl alcohol and lithium bromide–water–ethyl alcohol has not been attempted, the only related work being that of Santiago Pina de Rubies[5] which consisted of solubility measurements of lithium chloride in mixtures of water and ethyl alcohol and analyses of the solid phases.

The following data are the experimental results of a phase rule study of the two systems lithium chloride–water–ethyl alcohol and lithium bromide–water–ethyl alcohol.

Preparation of Materials

Anhydrous Lithium Chloride and Lithium Bromide.—Hydrated lithium chloride or bromide dried by heating under ordinary conditions suffers some hydrolysis, giving products which contain about 98.50% lithium salt and 1.50% lithium hydroxide. Drying these salts in an atmosphere of hydrogen chloride or hydrogen bromide was avoided because of the special apparatus required and because but small amounts of the salt could be made at a time. Drying by heating a mixture of lithium salt and corresponding ammonium salt did not give a product sufficiently free of lithium hydroxide. The method finally adopted consisted in drying triply recrystallized hydrated lithium chloride and bromide in an electric oven at 110°. The residue was treated with absolute alcohol whereupon the lithium salt dissolved, giving a turbid solution due to the presence of lithium hydroxide in suspension. This solution was filtered until clear and the filtrate evaporated to dryness. Analyses of the residue gave for lithium chloride 99.90% purity and for lithium bromide a purity of 99.88%. These products were considered of sufficient purity for the purpose desired and were stored in an oven at 110° until needed.

Ethyl Alcohol.—Absolute ethyl alcohol was prepared by refluxing laboratory absolute alcohol with freshly ignited lime for twelve hours. The alcohol was then distilled off, again refluxed with lime and again distilled. The product obtained gave a boiling point of 78.2°. The alcohol was stored in a bottle from which it could be siphoned and which was equipped with a phosphorus pentoxide guard tube.

Experimental Part

Ten solutions of alcohol and water were prepared, varying in composition from 7.53 to 94.43% alcohol by weight. These with pure water and absolute alcohol were used with anhydrous lithium chloride and bromide in this investigation. Complexes of known content of lithium chloride, water and alcohol and of lithium bromide, water and alcohol were placed in solubility tubes and allowed to come to equilibrium at 25.00 ± 0.02°.

---

[1] The investigation of the system lithium bromide–water and ethyl alcohol was offered as partial fulfilment of the requirements for the degree of Master of Science by Mr. Henry Freimuth.

[2] The investigation of the system lithium chloride–water and ethyl alcohol was offered as partial fulfilment of the requirements for the degree of Master of Science by Mr. Harry Russell.

[5] S. Pina de Rubies, *Anal. soc. españ fís. quím.*, **11**, 422 (1912); **12**, 343 (1914).

A known weight of solution was then taken and the lithium salt determined by Mohr's volumetric method. The alcohol in the liquid phases was determined by taking a known quantity of the latter and distilling to dryness. The residue was twice moistened with water and the distillation repeated after each moistening in order to ensure as complete driving off of the alcohol as possible. The tube of the condenser was washed out several times with water, the total distillate and washings collected and made up to an exactly known volume. From density determinations the percentage of alcohol in the liquid phase was calculated. Preliminary investigation indicated that this distillation method for alcohol was accurate to about 1%. The percentage of water was obtained by difference. If the data obtained are plotted on triangular coördinate paper Figs. 1 and 2 result. A tie-line drawn through the known composition of the complex and the composition of the solution, when equilibrium is reached, will terminate at a point on the triangle which will indicate the composition of the solid phase present. As pointed out above, however, the method of analysis of the solution is liable to be in error to the extent of about 1% and thus may result in a composition of the solid phase slightly in error. The result obtained, however, will be sufficiently correct so that the exact composition of the solid phase may be determined by inspection. Knowing now the exact composition of the solid phase and of the complex, an exact method of plotting should enable us to arrive at a more accurate composition of the liquid phase than could be reached by the above method of direct analysis on the assumption that the analysis is correct with respect to lithium chloride and lithium bromide. As Hill and Ricci[6] have pointed out, this method of extrapolation is subject to error due to mechanical difficulties of exact plotting.

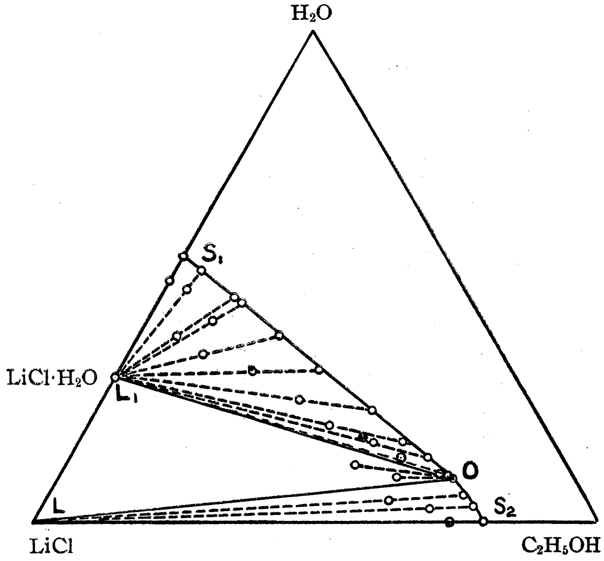

Fig. 1.

In this work the direct analysis of the liquid phase has been used to establish the composition of the solid phase and also as a check on results obtained by the Hill–Ricci method of extrapolation for the composition of the liquid phase. In the plotting of the results, Figs. 1 and 2, therefore, the composition of the solid phase has been determined by extrapolation using the known composition of the complex and the composition of the solution in equilibrium, determined by direct analysis, while the points representing the compositions of the solutions have been obtained by the Hill–Ricci method. The concentration of water and alcohol in the two transition complexes was determined from the intersection of the two curves checked by direct analyses using the distillation method for the alcohol. Tables I and II contain the data of these experiments.

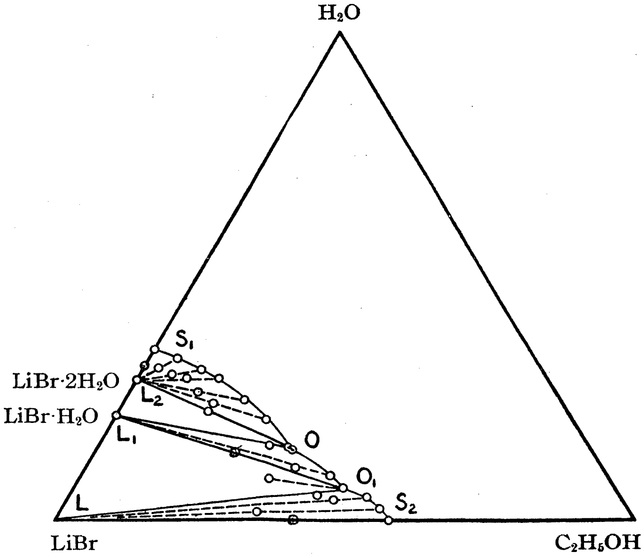

Fig. 2.

Discussion of Results

56.23	43.77	LiBr	41.22	58.78	

isothermally univariant. The solid phases resulting from complexes represented by points in these areas are lithium chloride monohydrate and anhydrous lithium chloride, respectively. The compositions of the liquid phases in equilibrium with the monohydrate are the points on the line S_1O while those in equilibrium with anhydrous lithium chloride are the points on line OS_2. The area L_1OL, since it gives a system of *four phases*, exhibits one degree of freedom and with the temperature fixed becomes isothermally invariant. A complex taken in this area will give a system containing two solid phases, monohydrated lithium chloride and the anhydrous salt, and a liquid phase having the composition represented by O.

In the case of the system lithium bromide–water–ethyl alcohol three isothermally univariant areas exist, S_1OL_2, L_1OO_1 and LO_1S_2, the solid phases present at equilibrium being lithium bromide dihydrate, lithium bromide monohydrate and anhydrous lithium bromide, respectively. The area L_2OL and L_1O_1L are isothermally invariant and complexes having the compositions represented by points in these areas will give at equilibrium, in the former a mixture of lithium bromide dihydrate and monohydrate and a liquid phase having the composition represented by O, while in the latter a mixture of lithium bromide monohydrate and anhydrous lithium bromide will be in equilibrium with a liquid phase having the composition represented by O_1.

Summary

1. A convenient and satisfactory method for preparing anhydrous lithium chloride and lithium bromide has been devised.

2. A phase rule study of the systems lithium chloride–water–ethyl alcohol and lithium bromide–water–ethyl alcohol at 25° has been completed.

3. In the case of the lithium chloride system at 25°, two solid phases, the monohydrate and anhydrous salt, or a mixture of the two, exist in equilibrium with the liquid phase.

4. In the case of the lithium bromide system the dihydrate, the monohydrate, or the anhydrous salt, or a mixture of the dihydrate and monohydrate or monohydrate and anhydrous salt may be the solid phases present.

5. No alcoholates were found in either system.

Equilibrium in Fluoride Systems. I. Solubility of Cryolite in Aqueous Solutions of Iron and Aluminum Salts at 25°

BY FRANCIS J. FRERE

The solubility of cryolite in aqueous solutions of aluminum chloride has been long known, although it has never been generally recognized. More than thirty years ago the laboratories of the Oresunds Chemiske Fabriker, in Denmark, employed this reaction as the basis of a determination of quartz in cryolite. Although there is no record to be found in the literature of these results, it is presumed that the work was carried out either by or under the supervision of Julius Thomsen.

Recently the author had occasion to investigate the solvent action of a great many salt solutions on cryolite. It was found that cryolite was appreciably soluble in all aluminum salt solutions as well as those of iron. Qualitative tests also indicated a moderate degree of solubility in chromium and uranium salts. Except in limiting cases, this is not in general a characteristic property of sparingly soluble salts. Indeed, such abnormalities are quite generally accepted as being typical of a double salt formation.

In view of these facts, therefore, it seems quite appropriate and desirable that an investigation be made of the mechanism of the reaction involved. Obviously, the most suitable means of obtaining the necessary data is by an investigation of the ternary systems of the various salts of iron and aluminum and their respective fluorides. This phase of the problem is now in progress and some of the results will be reported in this Journal within a short time.

It is felt that these data on the solubility measurements as well as those which are to be presented on the ternary systems will be of special interest by reason of the fact that these systems have not been heretofore thoroughly investigated.

Experimental

Materials Used.—The salts used in the solubility measurements were obtained by recrystallization of analytical reagent grade chemicals. Analysis showed these materials to be of excellent quality and that the ions were present in the correct stoichiometric ratio to conform to the normal salts. Sodium, the most objectionable impurity, was in no case found to exceed 0.01%.

Natural cryolite obtained from Greenland was used in these experiments. It was very carefully selected by hand and was found to be free of impurities.

Procedure.—The bottles containing the solutions to be saturated were treated with an excess of finely-divided cryolite, stoppered with pure gum stoppers, sealed, and rotated from seventeen to twenty-one days in a thermostatically controlled bath. The bath temperature was maintained at 25 ± 0.02°. In order to establish the reliability of using stoppered bottles, several duplicate experiments were made in which the solutions were placed in sealed tubes and saturated. The results by the two methods checked within the error of the determination.

After saturation had been attained, the solutions were allowed to settle while standing in the bath and portions were drawn out of each bottle through a cotton filter, transferred to a tared weighing bottle and reweighed. The samples were washed into platinum dishes, treated with perchloric acid, and decomposed by evaporating to fumes of the latter. The solutions were then diluted to the desired volume and reserved for analysis.

Sodium was determined by precipitating with zinc uranyl acetate according to Barber and Kolthoff.[1]

Aluminum was determined by precipitating with 8-hydroxyquinoline and weighing as the oxime salt after drying at 130 to 140°.

Iron was determined by reducing in a Jones reductor and titrating with potassium permanganate.

Results and Discussion

The data on these solubility measurements are contained in Table I. Column 1 represents the salt concentration, columns 2 and 3 represent the

From the data presented, the most obvious assumption is that there is some chemical reaction taking place by which a considerable amount of some new substance is formed by combination of the ions present in the solution. In the case of the aluminum salts, the most probable explanation of the mechanism involved would seem to be one in which there is a complete exchange of ions resulting in the formation of aluminum fluoride and the sodium salt of the solvent anion, the aluminum fluoride in turn combining with the aluminum salt present to form a double salt.

This inference seems to be amply justified by the following facts. When solutions of three aluminum salts were saturated with cryolite at an elevated temperature, no reprecipitation of cryolite occurred upon cooling or even after the addition of the respective sodium salts to the point of saturation. If, on the other hand, the sodium salt was added to the solution at the start it exerted a depressing effect upon the solubility due to the action of the common ion. The rate of decrease in solubility increased quite rapidly with increasing concentration of the added salt. From the foregoing, it is clear that the reaction is not reversible and, hence, true equilibrium is not attained.

Upon plotting the solubility data, a slight irregularity in the curves will be noted which might indicate the presence of a second solid phase. An examination of the residues, however, showed them to consist only of unchanged cryolite. The most reasonable explanation for these irregularities seems to be that equilibrium is very slowly attained after the solutions have become nearly saturated.

Apparently, a similar mechanism is involved for the iron salts. The presence of a fourth ion, however, gives rise to a more complicated system and as a result may require a knowledge of the quaternary as well as the ternary system in order to establish definitely the identity of the final reaction product.

It will be noted from the data that the solubility of cryolite in the different salt solutions in all cases, excepting ferric chloride, follows in the order of the solubility of the corresponding sodium salts. Ferric chloride solutions act normally in concentrations up to 10.0 molar, at which point the solubility reaches a maximum then falls below that of the sulfate and continues to decrease with any further increase in concentration. This difference in behavior is in accord with the facts of the case and may be readily interpreted by a consideration of the ferric chloride–sodium chloride system.

It will be seen also that cryolite dissolves to a greater extent in aluminum salt solutions and that the amount dissolved is practically the same for the different iron and aluminum salts at the lower concentrations. Undoubtedly, in these dilute solutions a considerable portion of the cryolite is dissolved at the expense of the free acid resulting from the hydrolysis of the salts.

Summary

The solubility of cryolite has been determined at 25° over a wide range of concentrations in aqueous solutions of iron and aluminum chloride, nitrate and sulfate. It has been found that the solubility was greatest in the aluminum salt solutions, and that the amount dissolved by the different salts was in all cases, excepting ferric chloride, in the order of the solubility of the corresponding sodium salt.

An explanation of the mechanism of the reaction has been offered based on the formation of a double salt.

Condensations by Sodium. VII. A General Method for Stopping the Wurtz Reaction at the Intermediate Organo-Metallic Stages

BY AVERY A. MORTON AND INGENUIN HECHENBLEIKNER

Previous work[1] has revealed that alkyl sodium compounds, if formed as intermediates in the Wurtz synthesis, are stable only at low or moderate temperatures. Their great reactivity enables the final stage of reaction with more alkyl chloride to be completed easily. Such considerations suggested that a Wurtz synthesis might be stopped at this intermediate point if the reaction were carried out at low temperatures in the presence of excess sodium. Experiments have amply confirmed this conclusion. When *n*-amyl chloride was added gradually with stirring to a suspension of sodium sand in pentane or ligroin, the mixture stirred until after no more evolution of heat occurred, and the product carbonated, there was obtained both caproic and butylmalonic acids. The yield of combined acids, around 50% in many experiments, was sufficiently high to remove any suspicion that they were formed because of a concurrent reaction during carbonation. The general application of this method for obtaining organo-metallic compounds was demonstrated by runs with butyl halides (chloride, bromide and iodide), and a secondary, a tertiary and an aromatic chloride.

So far the best yield, 57% of total carboxylic acids, has been obtained with *n*-amyl chloride. Other chlorides in order of decreasing yield are *n*-hexyl chloride, chlorobenzene, *n*-butyl chloride, *t*-amyl chloride, 2-chloro-3-methylbutane and *n*-propyl chloride. Factors such as the temperature at which the reagents could be induced to react, the thermal stability of the resulting organometallic compound, and the readiness with which the product reacts with more organic chloride to complete a Wurtz synthesis, must be considered in each case. The first attempts were unsuccessful because the importance of these factors was not recognized. Subsequent experiments with amyl chloride demonstrated the possibilities under controlled conditions and the preliminary test with other halides confirmed the conclusion that the proper factors for preparation of organometallic compounds by direct action of sodium on the chloride had indeed been recognized.

An earlier discovery of an organo-metallic compound in a Wurtz synthesis has been recorded in some interesting work by Gilman and Wright,[2] who studied the action of sodium–potassium alloy on 3-iodofuran. A very small yield, 0.5%, of 3-

---

[1] Morton and Hechenbleikner, THIS JOURNAL, **58**, 1024 (1936).

[2] Gilman and Wright, *ibid.*, **55**, 2893 (1933).

furoic acid was obtained. The obtention of the organo-metallic compound in that instance was ascribed to the extraordinary inertness of iodine in 3-iodofuran.

Continued evidence of the formation of a dicarboxylic acid from a monohalogen compound has been found in this work. The over-all equation for amylidene disodium used in calculating the yields of butylmalonic acid is

$$2C_5H_{11}Cl + 4Na \longrightarrow C_5H_{10}Na_2 + C_5H_{12} + 2NaCl \quad (1)$$

A possible mechanism by which amylidene disodium could be formed is by dismutation of amyl sodium as illustrated in equation (2). Opportunity was found to test this idea and adverse conclusions were drawn.

$$2C_5H_{11}Na \longrightarrow C_5H_{10}Na_2 + C_5H_{12} \quad (2)$$

In two series of experiments the intermediate sodium compounds were subjected to the action of heat, first at 60° and then at 80°. The products were carbonated and caproic and butylmalonic acids isolated. It was found that the yield of caproic acid progressively decreased with extended time at these temperatures, that a quantity of tarry acids appeared and continually increased with added severity of conditions, and that the amount of butylmalonic acid was unchanged. Amyl sodium was thus seen to be unstable thermally but amylidene disodium was not one of the primary decomposition products.

These facts permit a similar dismissal of any manner of thermal decomposition of the monosodium compound as a source of malonic acid. One such mechanism is shown in equation (3) which represents amyl sodium decomposing to sodium hydride and amylidene.

$$C_5H_{11}Na \longrightarrow NaH + C_4H_9CH< \quad (3)$$

The bivalent carbon atom would then add two atoms of sodium giving amylidene disodium. Carothers and Coffman[3] found good reasons for suggesting such a breakdown to explain their results with ethyl sodium. Our attempts to apply a parallel decomposition with amyl sodium have been without success as judged by the unchanged yield of the malonic acid. Negative tests for sodium hydride, reported in the previous paper on the action of sodium on diamyl mercury, while not conclusive by themselves, are nevertheless in full agreement with the view that equation (3) does not represent the decomposition of this compound.

The same authors have also pointed out that the hydrogen atoms in "sodium ethide" may be considered as being slightly acidic and capable of further replacement by sodium. An acidic nature of the hydrogen adjacent to sodium in amyl sodium was not revealed in our study of the feasibility of applying equation (2) to our results. It is possible, however, to derive a type of acidity from the presence of a carboxyl group and to consider that such a reactive hydrogen would be displaced by either sodium metal or the sodium in amyl sodium[4] after the manner set down in equation (4). Against this idea can be cited the fact that no increased yield of butyl-malonic acid was observed (a) when a large (over 100%) excess of sodium sand was used in the reaction; (b) when amyl sodium was formed in the presence of freshly prepared sodium caproate.

$$C_4H_9CH_2COONa \xrightarrow[NaC_5H_{11}]{Na\ or} C_4H_9CH(Na)COONa + H\ (or\ C_5H_{12}) \quad (4)$$

The observation of Bachmann and Clarke[5] that sodium acting on isoamyl bromide gave some pentadecane as well as the expected decane adds weight to the view that the disodium intermediate was formed prior to carbonation.

A reasonably safe conclusion can be drawn at this time that the malonic acids formed in the sodium condensations being reported in this series do not arise from any reaction of an intermediate alkyl sodium. Our data do not permit a differentiation between the plausible free radical-disproportionation path and the direct formation of an idene intermediate by splitting out of hydrogen chloride (Michael's mechanism).[6]

In addition to the discovery of a general method of interrupting the Wurtz synthesis, and the elimination of amyl sodium as a source of the malonic acid, a brief comment might be made on the surprising stability of amylidene disodium. A period of fourteen hours of heating at 80° left the amylidene disodium practically unaffected as contrasted with the 63% decomposition of amyl sodium under the same conditions.

Experiments

The reactions were carried out in a 3-necked 250-ml. flask provided with a mercury-sealed stirrer, dropping funnel, condenser, nitrogen inlet tube and thermometer.

[a] Ninety minutes required for addition of alkyl chloride, temperature 60–62°.

The sodium sand (from a stock quantity made by stirring 500 g. in hot kerosene) was placed in the flask with the desired solvent and the organic chloride added through the dropping funnel. Usually a little over an hour was required for addition. Stirring was continued for some period afterward, at least until no more heat was given off by the reaction. The temperature at any stage of the process was regulated by a bath or by the boiling point of the solvent. The color of the reaction mixtures usually changed from purplish-blue to green and red (on heating) during the reaction. Carbon dioxide was finally admitted (all colors disappeared) and the products separated in the same manner as described in the earlier paper.[7] Yields were calculated on the basis of the halide added. In Tables I and II (the numbering of the runs is for convenience in reference only) experiments in *n*-pentane (E. K. Co. practical grade) and in ligroin, respectively, are described. Attempts were made to isolate the products from pyrolysis of amyl sodium in experiments 9 to 15. Tarry acids insoluble in water and ligroin were found. The amount qualitatively increased with greater severity of the pyrolysis conditions. Only a poorly crystalline product

TABLE III

COMPARISON OF BUTYL IODIDE, BROMIDE AND CHLORIDE

Constant factors: alkyl chloride dissolved in 25 ml. of *n*-pentane; sodium sand in 75 ml. of same solvent; temperature 0–5° during addition of the alkyl halide; one hour required for addition of alkyl chloride except in number 18 in which the time was two hours; one hour of stirring at room temperature after addition of alkyl chloride was completed

[a] The sodium was first fused with 1.5 g. of mercury and then made into sand in the usual way. [b] Carbon dioxide was passed through the mixture during the addition. No oxalic acid was found among the products. [c] Pentane used as a solvent. Temperature rose to 20° during carbonation. [d] 10 ml. of solvent used. [e] 40 ml. of solvent used. Toward the end of the reaction the mass became so viscous that 50 ml. more ligroin was added. [f] *n*-Octane used as a solvent. [g] Only 30 ml. of solvent used with the sodium. [h] Half of the alkyl chloride added, and product carbonated after which the remainder was added, followed by a final carbonation.

Special attention is called to (a) the nearly complete agreement in respect to yields of reaction 7 and 8, although in the latter case the mixture stood thirteen hours before carbonation; (b) the constancy of the yields of butylmalonic acid which in 12 out of 16 runs varied between 13 and 17% in spite of wide fluctuations in time and temperature conditions to which the alkylidene disodium intermediate was subjected; (c) the surprising stability of the amylidene disodium compound which in fourteen hours' heating at 80° (run No. 15) was not appreciably decomposed; (d) the lack of thermal stability of the monosodium compound as exemplified by decreasing yield of caproic acid (to 10%) as the period of heating at 60° before carbonation was extended in reactions 9 and 10; (e) the greater thermal instability of the mono-sodium compound at the 80° level in reactions 11 to 15 where the yield of caproic acid fell to around 6%; (f) the general failure to observe any gain in butylmalonic acid in spite of a great loss of caproic acid (see reactions 9 to 15) thereby showing that the pyrolysis of sodium amyl did not lead to amylidene disodium; (g) the decidedly lower yield for both mono- and dicarboxylic acids when the temperature during addition of alkyl chloride to sodium was raised (reaction no. 16) to 62°.

In Tables III and IV the results with a number of other halides are given. The general method of separation of the mono- and the dicarboxylic acids was the same as described before.

Comparison of butyl iodide, bromide and chloride, Table III, showed that there was an increasing amount of interruption in the order named. This difference was not surprising in view of the common opinion of decreased activity of the halogen atoms in progressing from iodide to chloride. The butyl sodium formed in the initial phase can be assumed to react less readily with the least reactive halide and therefore can be isolated in larger amounts from the chloride reaction. The list in Table IV shows the results with a secondary, an aromatic and a tertiary chloride. In addition, experiments on two more primary chlorides are given. No attempt was made to discover the conditions which were best for each compound. A major difficulty was in getting the reaction started. The yield of benzoic acid was not in agreement with what might have been expected from the inactivity of the halogen atom in chlorobenzene (compare with *n*-hexyl chloride) which might suggest that an inactive halogen atom was not the only factor involved in isolation of intermediate products.

For the experiments with other alkali metals, Table V, potassium sand was prepared by shaking the metal in ligroin solution; lithium sand by stirring in hot kerosene. Potassium, the most active metal, reacted with such vigor that amyl chloride had to be added very slowly. Less than 2% of carboxylic acid was obtained. Since lithium is the least active of the alkali metals, a high yield could be expected. Lithium alkyl compounds have been shown already[8] to be isolable in benzene solution and capable of

---

[8] Ziegler and Colonius, *Ann.*, **479**, 135 (1930).

being used in the same manner as the Grignard reagent. The unfortunately low yields of carboxylic acids which we obtained upon carbonation are not due therefore to any absence of the intermediate lithium alkyl but to the formation of secondary products as already shown by Gilman and Van Ess.[9] The position of the alkyl sodium appears to be unique in that it lacks the reactivity necessary to complete the Wurtz reaction under these conditions, yet does not participate in the formation of secondary products with sodium caproate.

Data for a number of miscellaneous experiments are set down in Table VI. Many of these runs were made in an effort to locate some factor which would lead to increased yields of butylmalonic acid. Special mention can be made of (a) the effect of using over 100% excess of sodium sand—reaction No. 27—which resulted in a maximum yield of 57% of combined carboxylic acids; (b) the failure to obtain an improved yield of butylmalonic acid in No. 28 from the simultaneous presence of mercury, a test inspired by the higher yields of this acid in some of the experiments reported in the previous paper on the action of sodium on diamyl mercury; (c) the failure of the simultaneous presence of carbon dioxide to increase materially the yield of combined organic acids over what was obtained when the amyl chloride was first allowed to react until long after all evidence of reaction—judged by a temperature rise—had ceased; (d) the failure to note any marked increase in the yield of malonic acid in reaction No. 35 when amyl chloride was added to sodium in the presence of freshly prepared sodium caproate in order to test the validity of equation 4; (e) the continued constancy in the yields of butylmalonic acid in runs 27, 28, 29 and 35.

Conclusions

The Wurtz reaction can be interrupted at the intermediate organo-metallic stage if the alkyl halide is added to excess sodium at low or moderate temperatures. The reaction has been studied in some detail with *n*-amyl chloride and has been tested in a preliminary way with a number of other organic halides.

In the case of *n*-amyl chloride, caproic and butylmalonic acids were obtained upon carbonation. The yield of combined acids in one instance was as high as 56%.

The formation of the malonic acid by way of the monosodium compound has been shown to be unlikely.

Amylidene disodium is thermally more stable than amyl sodium.

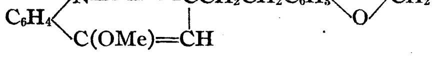
Researches on Quinazolines. XLIII. The Synthesis of a Quinazoline Derivative Structurally Analogous to Cusparine

BY DOMENICK PAPA[1] AND MARSTON TAYLOR BOGERT

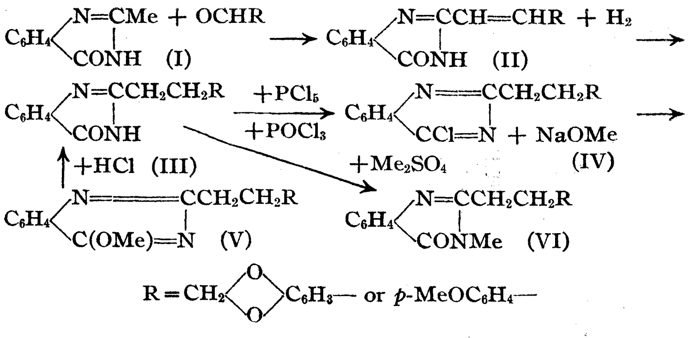
In a recent communication[2] from these Laboratories, there was described the synthesis of quinazoline derivatives akin structurally to the angostura alkaloids galipine and galipoline.[3]

The most important angostura alkaloid, however, is cusparine



The synthesis of its quinazoline analog is described in the following pages. The *p*-methoxyphenylethyl derivatives were also prepared, because they correspond, respectively to the galipoline and galipine analogs referred to above, but possess one less methoxyl group, and it seemed desirable therefore to include them in the series for pharmacological examination.

The steps involved in these syntheses were the following



Experimental

2-*p*-Methoxystyryl-4-quinazolone (II).—A mixture of 5 g. of 2-methyl-4-quinazolone (I) and 4.5 g. of *p*-anisaldehyde was heated for two hours at 170–175°. It liquefied after half an hour of heating and at the end of two hours

[3] Through an unfortunate error in proofreading, this alkaloid appears in that article as "galiopine."—M. T. B.

was semi-solid. When cold, it was pulverized, boiled with 10 cc. of 96% ethyl alcohol, to remove unchanged initial materials, and crystallized twice from glacial acetic acid in the presence of Norite. The product was a pale yellow crystalline solid, m. p. 284–285° (corr.); yield 80%. For analysis, it was dried for two hours at 110°.

Anal. Calcd. for $C_{17}H_{14}O_2N_2$: C, 73.34; H, 5.05. Found: C, 73.47; H, 4.97.

2 - (3′,4′ - Methylenedioxystyryl) - 4 - quinazolone (II) was prepared from 2-methyl-4-quinazolone (I) and piperonal, as described by Bogert and Beal,[4] except that the crude product was purified as recorded above, and then appeared as a crystalline solid of very pale yellowish cast, m. p. 316–317° (corr.) with decomposition; yield 64%. Bogert and Beal reported a m. p. of 305°. Dried at 110°, it was analyzed with the following results.

Anal. Calcd. for $C_{17}H_{12}O_3N_2$: C, 69.94; H, 4.15. Found: C, 70.11; H, 4.35.

2-(beta-*p*-Anisylethyl)-4-quinazolone (III), prepared by the same process as the next compound, formed colorless lustrous crystals, m. p. 213–214° (corr.); yield 90%. For analysis, it was dried to constant weight at 110°.

Anal. Calcd. for $C_{17}H_{16}O_2N_2$: C, 72.85; H, 5.76. Found: C, 72.73; H, 5.47.

2-(beta-3′,4′-Methylenedioxyphenylethyl)-4-quinazolone (III).—The styryl compound (II) was reduced catalytically by the process used by Marr and Bogert[2] for the reduction of 2-styryl-4-quinazolone, except that the crude product was washed first with water and then with 50% ethanol. From 4 g. of the styryl derivative (II), 500 cc. of 96% ethanol, and 150 g. of 3% sodium amalgam, there was obtained 3.49 g. (85%) of a colorless crude product, m. p. 238.5° (corr.), which was recrystallized by careful dilution of its hot alcoholic solution, and then melted at 239–240° (corr.). For analysis, it was dried to constant weight at 110°.

Anal. Calcd. for $C_{17}H_{14}O_3N_2$: C, 69.38; H, 4.78. Found: C, 69.40; H, 4.77.

2-(beta-*p*-Anisylethyl)-4-chloroquinazoline (IV).—In the main, the procedure followed was similar to that used by Marr and Bogert[2] for the production of 2-phenylethyl-4-chloroquinazoline. A mixture of 2 g. of the 4-quinazolone derivative (III), 1.4 g. of phosphorus pentachloride, and 25 cc. of phosphorus oxychloride, was refluxed for ten hours. The cooled solution was poured upon cracked ice, immediately extracted with ether, the ether extract washed with dilute sodium carbonate solution, then with water, dried over calcium chloride and the ether evaporated. There was thus obtained 0.75 g. of yellow crystals, m. p. 125–128° (corr.), containing halogen.

No analysis was attempted, because the instability of the product rendered it unlikely that an analytically pure compound could be obtained.

For successful results in this preparation, the following precautions must be observed: (a) the initial quinazolone must be pure, dry, and finely pulverized; (b) the phosphorus oxychloride must be distilled just before use and collected under carefully maintained anhydrous conditions (the product used in our experiments was colorless, transparent, and boiled at 107.4–107.7° (corr.)); (c) the apparatus should be washed thoroughly with water, alcohol, and ether, and dried for twelve hours at 110°; (d) the heating period of ten hours must be continuous; (e) the temperature must not be permitted to rise above 115° for any length of time, or considerable decomposition will occur; (f) the rate of evaporation of the ether influences the physical state of the residue, for too rapid evaporation tends to leave an oil which solidifies only with difficulty.

2 - (beta - 3′,4′ - Methylenedioxyphenylethyl) - 4 - chloroquinazoline (IV), prepared like the above *p*-anisyl derivative, was obtained as an orange oil, which refused to congeal; yield 0.85 g., from 2 g. of initial quinazolone (III); qualitative test for halogen, positive.

2 - (beta - *p* - Anisylethyl) - 4 - methoxyquinazoline (V), prepared as described for the next compound, gave 0.3 g. of colorless crystals, m. p. 84.5–85.5° (corr.), from 0.75 g. of the chloro derivative (IV).

Anal. Calcd. for $C_{18}H_{18}O_2N_2$: C, 73.47; H, 6.17. Found: C, 73.41; H, 5.93.

Refluxed for thirty minutes with concentrated hydrochloric acid, a clear solution resulted, from which 2-(beta-*p*-anisylethyl)-4-quinazolone (III) was precipitated by dilution, m. p. 209–212° (corr.). Recrystallized from absolute alcohol, the m. p. was raised to 212–213°. Mixed with a sample of the anisylethyl-4-quinazolone (III) (m. p. 213–214°, corr.), synthesized as noted above, the m. p. was 212–213.5° (corr.).

2 - (beta - 3′,4′ - Methylenedioxyphenylethyl) - 4 - methoxyquinazoline (V).—To a solution of 0.85 g. of the chloro compound (IV) in 15 cc. of absolute methanol, there was added a sodium methylate solution prepared from 0.14 g. of sodium and 10 cc. of absolute methanol. After standing for twenty-four hours in a stoppered flask, the solution was filtered and the filtrate diluted. Yellow crystals (0.6 g.) separated after eighteen hours. These were digested with Norite in absolute ethanol solution, the mixture filtered hot and the filtrate diluted carefully. An emulsion formed which, after cooling overnight and heating again, separated crystals. Washed with dilute ethanol and dried in a vacuum desiccator, they melted at 67–68° (corr.).

Anal. Calcd. for $C_{18}H_{16}O_3N_2$: C, 70.10; H, 5.25. Found: C, 70.04; H, 4.86.

Hydrolyzed by concentrated hydrochloric acid, the corresponding quinazolone (III) was obtained, m. p. 239–240° (corr.). Mixed with a sample of the synthetic quinazolone (III) (m. p. 239–240°, corr.), the m. p. was 238.5–239.5° (corr.).

2-(beta-*p*-Anisylethyl)-3-methyl-4-quinazolone (VI).—The anisylethyl-4-quinazolone (III) was dissolved in sodium hydroxide solution and treated with dimethyl sulfate. The crude product was crystallized from diluted alcohol and then formed small colorless needles, m. p. 118–118.5° (corr.), which were not hydrolyzed by digestion with concentrated hydrochloric acid.

Anal. Calcd. for $C_{18}H_{18}O_2N_2$: C, 73.47; H, 6.17. Found: C, 73.81; H, 6.10.

2 - (beta - 3′,4′ - Methylenedioxyphenylethyl) - 3 - methyl-4-quinazolone (VI), prepared similarly, crystallized in long, thin needles which melted sharply at 94–94.5°

---

[4] Bogert and Beal, THIS JOURNAL, **34**, 522 (1912).

(corr.), and were not hydrolyzed by digestion with concentrated hydrochloric acid.

Anal. Calcd. for $C_{18}H_{16}O_3N_2$: C, 70.10; H, 5.25. Found: C, 70.20; H, 5.17.

2,3-Dimethyl-4-quinazolone.—Incidentally this compound was also prepared from 2-methyl-4-quinazolone (I), by the same method as the two just reported above. It was obtained in thin colorless needles, m. p. 111–111.5° (corr.), which were not hydrolyzed when boiled with concentrated hydrochloric acid. Bogert and Seil[5] obtained it by the action of methylamine upon acetanthranil and gave its m. p. as 110°.

Summary

1. 2-Methyl-4-quinazolone has been condensed with *p*-anisaldehyde and with piperonal to the corresponding styryl derivatives, and the olefin bond of the latter has been saturated by catalytic hydrogenation.

2. These substituted 2-phenylethyl-4-quinazolones have been converted into the corresponding substituted 2-phenylethyl-4-chloro and 4-methoxy quinazolines, of which the 2-(beta-3′,4′-methylene dioxyphenylethyl)-4-methoxyquinazoline is the quinazoline analog of the angostura alkaloid cusparine.

3. The substituted 2-phenylethyl-3-methyl-4-quinazolones were also synthesized, to learn in what respects these N-methyl derivatives differed from their O-methyl isomers.

4. The pharmacological properties of these compounds have not yet been studied.

A Sensitive Manostat for Low Pressures and its Application to the Adsorption of Hydrogen and Deuterium on Copper

BY THEODORE SOLLER, SEYMORE GOLDWASSER AND RALPH A. BEEBE

In the course of experiments conducted in the Amherst[1] Laboratory of Chemistry on the rates of hydrogen and deuterium adsorption on copper at gas pressures in the region of 2 mm., it became apparent that rate data were needed under conditions of constant pressure. The most sensitive manostat described in the literature is that of Huntress and Hershberg[2] who claim control of pressure to ±0.15 mm. Because this amount of variation was prohibitive for work at 1 to 2 mm. total pressure, a new automatic manostat has been developed which regulates the pressure to better than ±0.005 mm. and is applicable to all pressures. Provision has also been made for the continuous reading of the volume of gas entering the system during the course of adsorption. With the new manostatic technique it has been possible to investigate in detail the relative rates of adsorption of the two hydrogen isotopes on copper at low pressures. At 0° we have found a marked difference in the rates of adsorption of hydrogen and deuterium under identical conditions. Moreover, the temperature inversion in the ratio H_2/D_2 adsorbed has again been observed. This inversion has been found previously by Beebe *et al.*[1] and more recently has been predicted by Pease and Wheeler[3] from a statistical mechanical approach to the problem.

A. The Manostat

The general plan of the control mechanism is as follows. A slight decrease in the pressure of the system causes the mirror of the differential manometer to be tilted downward in such a way as to throw a light beam onto a photo-electric cell. Working through an amplifier, this cell actuates the solenoid which opens the mercury valve, thereby admitting a small amount of gas to the system. The admission of this gas causes a slight increase of the pressure and the valve is closed *via* the mirror, the photo-electric cell, and the solenoid, thus completing the cycle.

The Differential Manometer.—A modified form of the mercury manometer described by Johnson and Harrison[4] was used. To eliminate the rather troublesome task of fusing the platinum strip into a glass roller rod, a 1.6 mm. steel rod was substituted. The platinum strip was then easily attached by spot welding. Three leveling screws supporting the whole float and mirror mechanism made the device more readily adjustable. The whole manometer was placed in a small water thermostat, control of which was necessary to ±0.1° to prevent undue change in the volume of the mercury supporting the glass float. Because a quick response to pressure change was essential, the dead-beat feature of the manometer of Johnson and Harrison was sacrificed by using a 10-mm. tube to connect the mer-

[4] Johnson and Harrison, *J. Sci. Instruments*, **6**, 305 (1929).

cury in the two arms of the instrument. This resulted in a slight surging back and forth after the admission of a gas increment but had no undesirable effect on the successful functioning of the control mechanism.

The Photo-electric Relay.—The photo-electric relay circuit is a modification of one suggested by F. H. Shepard.[5] Its advantages are the use of standard parts and operation directly from 110-volt, 60-cycle power circuit, no rectifier being necessary. The diagram of the circuit used is given in Fig. 1.

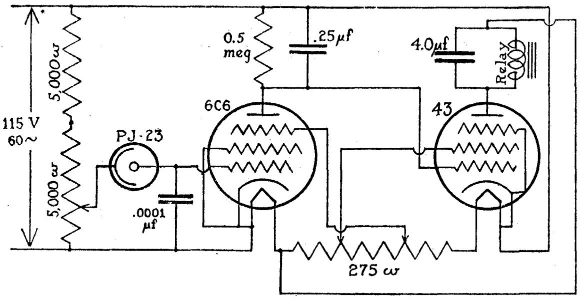

Fig. 1.—Diagram of photo-electric relay circuit.

Light from a straight-line filament lamp operating on 10 volts and 3.5 amperes falls on the mirror of the differential manometer, is reflected and brought to a focus at the PJ-23 photo-cell by a lens of one meter focal length. The sensitivity of the circuit is controlled by the position of the moving contact of the 5000 ohm potentiometer. The relay used in the output of the 43 tube is a Struthers Dunn ASBTS, operating on 15 m.a. half wave rectified current, having an A. C. core, No. 190 coil, and secondary contacts capable of carrying 10 amperes at 110 volts.

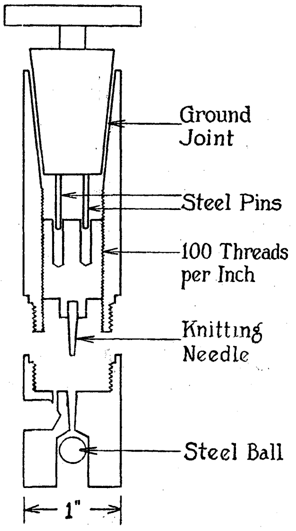

Fig. 2.—Adjustable leak.

The Adjustable Leak.—A rather large variation in rates of adsorption was anticipated during the different stages of the various processes to be studied. Moreover, it was found desirable for the effective functioning of the control mechanism that the rate of flow of the gas entering the system with the mercury valve open be of the same order of magnitude as the rate of removal of gas from the system by adsorption. The adjustable steel leak shown in Fig. 2 has met this requirement very satisfactorily. Because of the rigid construction of the glass apparatus, it was necessary that the leak be designed in such a way that neither the inlet nor the outlet glass tube should be moved during adjustment of the leak. For convenience in construction, the leak was made in two parts which fitted together at the joint J. This joint, which was in a fixed position while in use, was made vacuum tight with picene cement.

Gas Buret.—The gas buret, operated under reduced pressure for increased sensitivity, is maintained at constant pressure by an electrolysis device (see Fig. 3) built on the same principle as that of Taylor and Strother.[6] When the mercury touches the platinum tipped tungsten contact C, a 0.25 ampere current is allowed to flow between C and D; this current, acting through a simple relay, closes a switch which permits a 3 ampere current to flow through the solution of the electrolytic cell between the electrodes E and F. This relay system reduced difficulties from sparking at the contact C. A specially designed iron plate float with a platinum center helps to eliminate trouble from clinging of the mercury to the contact C, thus giving closer control of the pressure in the gas buret. The quantity of gas leaving the buret over any time interval is a linear function of the change in height of the mercury column. For the buret tube used, a change in height of 1 mm. represented 0.0132 cc. of gas at standard conditions when the buret pressure was 10 cm.

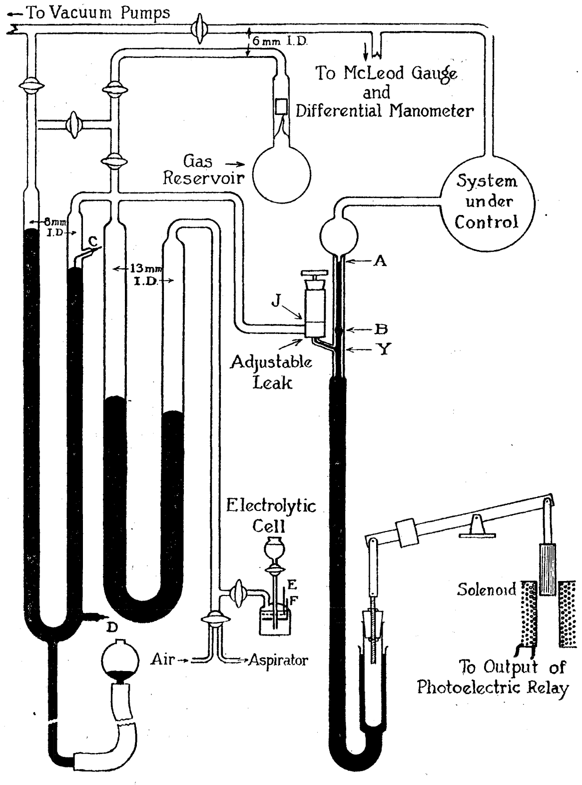

Fig. 3.

The Mercury Valve.—The mercury valve is so arranged that in its closed position the difference in height in mm. between the top of the mercury column A, Fig. 3, and the top of the ball valve in the metal adjustable leak slightly exceeds the gas pressure in mm. in the gas buret. This prevents any passage of gas when the mercury valve is closed. In the open position of the mercury valve, the mercury column stands, of course, slightly below the junc-

---

(5) F. H. Shepard, *Electronics*, **8**, 304 (1935).

(6) Taylor and Strother, THIS JOURNAL, **56**, 586 (1934).

tion Y. The vertical glass section just above the Y junction is of 3 mm. inside diameter to eliminate appreciable expansion or compression of the gas in the system under control because of changes in volume of the system during the opening or closing of the mercury valve. A small enlargement, B, in the bore of the tube serves to prevent trapping of a short mercury column above the incoming gas increment. It was found that the amount of each increment could conveniently be made as small as 0.008 cc. (at standard conditions).

The successful operation of the apparatus is illustrated in Fig. 4. Volumes of gas delivered from the buret to the system under control are plotted against time. In obtaining the data for curve 2, the system to be controlled was initially at 1.003 mm. pressure. Gas was allowed to leak out of the system through a very narrow glass capillary tube (not shown in Fig. 3) directly to the mercury diffusion pump; gas then entered the system through the mercury valve at a rate sufficient to maintain the pressure constant to ±0.005 mm. as was shown on a McLeod gage. The straight line obtained in curve 2 under these conditions is evidence that all parts of the apparatus were functioning properly. For curve 1, the gas leaked out through a still finer capillary at first, but at point A the path of the leak was changed to the coarser capillary used for curve 2. For curve 3, the gas was allowed to leak out of the system, the pressure in which was 1.325 mm. at the start, into an evacuated bulb (not shown in Fig. 3). Because the rate of leak out of the system decreased with time as the pressure in the initially evacuated bulb was built up, a corresponding decrease was obtained in the rate of leak into the system as is shown in Fig. 4. For adsorption measurements, the tube containing the adsorbent would correspond to the bulb and capillary attachment used for curve 3.

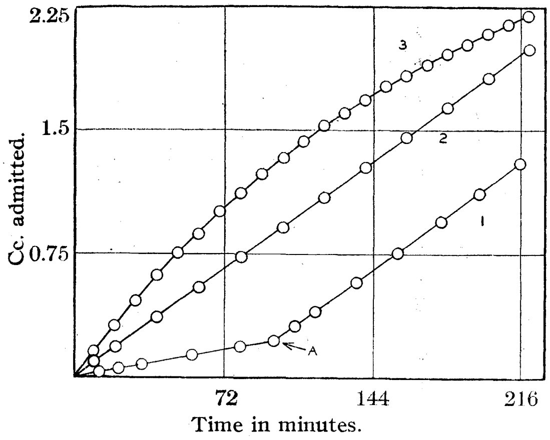

Fig. 4.

Owing to its differential principle, the manometer and consequently the manostat should operate satisfactorily at all pressures up to 760 mm. Obviously the percentage of variation in the pressure would be much less at higher pressures. Moreover, by drawing gas out of the system under control through the adjustable metal leak and mercury valve into an evacuated system, the manostat should be equally adaptable to control in a system in which gas is slowly being evolved or admitted from outside.

B. Adsorption Experiments

Apparatus.—The apparatus was that referred to and described above. All the measurements were made at 2.63 ± 0.005 mm. pressure.

Materials.—The copper powder supplied through the courtesy of the General Metals Powder Company was prepared in the same way as copper 3 described in the earlier work;[1] it came from a different batch, however. The copper was outgassed for fourteen to sixteen hours at 170° before each run.

The deuterium gas containing less than 0.5% of hydrogen was received from the Princeton Laboratory of Chemistry in October, 1935.

The sources of the hydrogen and helium have been described previously.[1]

Experimental Results

The relative rates of adsorption of hydrogen and deuterium at 0° are shown in Fig. 5. For example, the average rates from 0.20 cc. to 0.50 cc. absorbed bear the ratio: $H_2/D_2 = 5.5$. The rates which were investigated at the higher temperatures were too rapid to make the H_2/D_2 ratio significant.

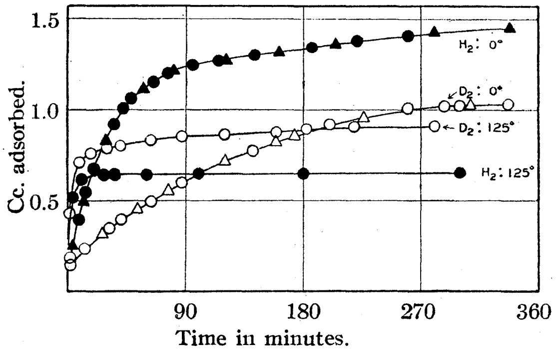

Fig. 5.—Adsorption of hydrogen and deuterium on 109 g. of copper powder.

The temperature inversion in the amounts of hydrogen and deuterium adsorbed is also apparent in Fig. 5, hydrogen being adsorbed in greater amount at 0° but in lesser quantity than deuterium at 125°. We estimate from these experiments at 0 and 125° together with experiments at 100° not shown, that the inversion temperature for this sample of copper was approximately 95°. This is to be compared with 60° previously observed on another copper sample.

The order of experiments was: H_2 at 0°, H_2 at 0°, H_2 at 100°, D_2 at 0°, D_2 at 100°, H_2 at 100°, D_2 at 125°, H_2 at 125°, D_2 at 0°, H_2 at 0°. In Fig. 5, points for 0° represented by circles are plotted from data taken at the beginning of the series, and those represented by triangles at the end of the series of rate measurements. The reproducibility of the data at 0° indicates the stability of the copper surface as well as the dependability of the manostatic technique throughout the whole series of measurements.

Discussion

The large difference in the rates of adsorption which we have observed appears to be in disagreement with the recent work of Melville and Rideal,[7] who have investigated the adsorption of hydrogen and of a 70% deuterium to 30% hydrogen mixture on copper at low pressures over the temperature range 71 to 171° and have found no difference in rates in the lower part of the temperature interval. The fact that we have found a threefold difference in rates for the two isotopes makes it seem probable that the results obtained by Melville and Rideal would have been different if they had used pure deuterium although the apparent discrepancy between their results and ours may conceivably be attributed to a difference in the nature of the copper surfaces studied.

Moreover, Melville and Rideal have not reported the temperature inversion of H_2/D_2 adsorbed which has been found in the Amherst laboratory by two different experimental methods. It seems probable that their failure to observe this phenomenon is due to the limited time interval over which the process was studied. For instance, referring to Fig. 3, p. 85, of their paper it would appear that the rate curve at 137° for the 70% deuterium mixture would actually cross the hydrogen curve, if extrapolated, instead of bending downward as shown. This would mean that although the rate for hydrogen was greater, more deuterium would be adsorbed at equilibrium at the higher temperatures.

Using the value 5.5 as the H_2/D_2 ratio of the average rates of adsorption on copper from the second to the forty-second minute at 0°, it is possible to show that the difference in activation energies is 0.75 kcal., making due allowance for the $\sqrt{2}$ collision factor. From this it may be inferred that the difference in zero point energies of hydrogen and deuterium in the activated state is 1.05 kcal. This result, which indicates that not all the zero point energy is contributed to the energy pool in the activating collision, is in accordance with the data of other investigators[7] (p. 77) for several homogeneous reactions.

The work of Pace and Taylor[8] as well as that of Kohlschütter[9] indicates that the rates of adsorption of hydrogen and deuterium on chromic oxide are identical at atmospheric pressure. Because our results make it clear that there is a marked difference in the rates for the two isotopes on copper at low pressures, it seems apparent that the adsorption of the two gases should be studied on both the adsorbents mentioned over a wide range of pressures. This series of measurements for copper adsorbent is now being undertaken making use of the constant pressure technique.

Our thanks are due to the Committee on Grants-in-Aid of the National Research Council for supplying funds for technical assistance in this work.

Summary

1. A device is described for the control of gas pressures to ±0.005 mm. and its applicability to the measurement of adsorption rates at low pressures is demonstrated.

2. At 0° and 2.63 mm. the relative rates of adsorption of hydrogen and deuterium on copper bear the ratio 3.35 to 1; and the difference in activation energies of adsorption for the two isotopes on copper at 0° is 0.48 kcal.

3. The temperature inversion in the ratio of adsorbabilities of hydrogen and deuterium on copper, which had been observed previously, has been confirmed using the new manostatic technique.

Photochemical Studies. XXIV. The Photochemical Chlorination of the Dichlorobenzenes

BY CHARLES F. FISK AND W. ALBERT NOYES, JR.

The photochemical chlorination of benzene and of its chlorine substitution products has been the subject of several previous investigations.[1] In the gas phase, the initial reaction proceeds by short chains and results largely in the addition of chlorine to the aromatic nucleus. Products soon condense on the walls and most of the reaction after the initial stages must take place in the solid or liquid phase. With prolonged photochemical chlorination both benzene and chlorobenzene give eventually C_6Cl_{12}.

The present study was undertaken to compare the rates of addition of chlorine to *o*-, *m*- and *p*-dichlorobenzene and to investigate particularly the mechanism of the latter by measuring the rate of pressure decrease as a function of several different variables. The extent of the chlorination and a value for the quantum yield have also been obtained. An explanation of the data is given.

I. Experimental

The preparation of the chlorine was similar to that previously used.[1c] The dichlorobenzenes were all C. P. products from the Eastman Kodak Company. The *p*-dichlorobenzene was subjected to several fractional crystallizations from its own liquid. The fraction chosen melted sharply at 52.2–52.3° (corr.). Finally this 1-g. sample was fractionally distilled in vacuum and stored behind a mercury trap so that it was not exposed to the air once it had been freed from volatile substances by evacuation. Somewhat less care was taken with the *o*- and *m*-dichlorobenzenes since they were investigated much less completely than the para compound. They were both fractionally distilled, the middle fraction being treated by vacuum distillation before use.

All other chemicals were of standard C. P. quality.

The reaction vessel was a cylindrical fused quartz cell attached to the main vacuum line, pressure gages, etc., by a quartz to Pyrex graded seal. The vessel was held in a fixed clamp on an optical bench so that its position could be duplicated.

The technique of filling the reaction vessels has already been described.[1] All pressure measurements were made with an all glass gage of the Bourdon type. For determining the rate of pressure change with time it became necessary to measure pressure changes of about 0.04 mm. with an accuracy of about 5% at a total pressure of around 40 mm. For this purpose the Bourdon gage was modified by making the primary pointer operate a lever swung on a glass axle and bearing to give a magnification of fifteen to thirty times that obtained with the unmodified gage. With good luck a sensitivity of 0.001 mm. pressure per 0.01 mm. motion (as measured by a filar micrometer) could be obtained. This gage was calibrated and used as a direct deflection instrument for rate measurements. Although the experiments were carried out at room temperature, this was sufficiently constant during a run so that when the gage was balanced at 40 mm. pressure the needle position was constant in time, since small temperature variations operated nearly equally on both sides of the gage. This modified gage was used in the study of the dependence of rate on light intensity. For other experiments the ordinary gage was used.

For measuring the outside pressure used to balance the gages when they served as null point instruments a dibutyl phthalate manometer was employed.

The light source was a water cooled capillary mercury arc similar to that described by Forbes and Harrison.[2] It was operated at atmospheric pressure on 35 volts and 5 amperes. The light was filtered by 3 mm. of greenish window glass plus 3 mm. or more of number 986 red purple Corex. A number 586 violet ultra filter was used for low intensities.[3] From the intensity distribution in the arc, the transmissions of the various glasses and the absorption coefficients of chlorine it is possible to show that approximately 97% of the radiation absorbed by the chlorine in these experiments was in the group of lines around 3660 Å.

Although parallel light is to be desired in experiments involving chain reactions, it was necessary to use a focused beam in order to obtain the desired intensity. However, a simple calculation showed that the effect due to divergence in these experiments is negligible. The arc lamp was clamped in such a way that its position was reproducible. The lens was mounted on the optical bench so that an image of the arc was produced in the center of the reaction vessel without any part of the beam hitting the walls. The light intensity was varied by changing the number of filters. The shape of the light beam always remained the same. Light intensities were measured by means of a photoelectric cell which could be placed in reproducible positions either in front or in back of the reaction vessel.

The *p*-dichlorobenzene was first admitted to the desired pressure, controlled by the temperature of the supply bulb, and the reaction vessel sealed off. The chlorine was then admitted by breaking a capillary magnetically. The ingoing chlorine undoubtedly concentrated the *p*-dichlorobenzene slightly in the reaction vessel, but this effect was minimized as much as possible by the geometry of the system. An hour was always permitted to elapse after

[3] The authors wish to express their appreciation to the Corning Glass Co. for furnishing these filters.

filling the cell for the attainment of equilibrium of mixing. The total pressure was measured and the chlorine pressure obtained by difference.

The arc lamp was started and a Wratten green filter interposed to prevent reaction. The ratio of intensity in front to that in back as determined by the photo-cell was used as a check on the optical system. The color filters to be used during the run were then placed in position and the zero deflection obtained by interposing a Wratten number 2 filter which cuts off quite sharply at 4000 Å.

The pressure was always found to remain constant for an hour before the actual run was started. After a definite time of irradiation, during which the variations in intensity were obtained by measurements behind the cell, a shutter was interposed and upon moving the photocell to the front of the reaction vessel the incident intensity was again noted. The pressure stayed constant, except for the Budde effect, after the light was cut off. This procedure will be called Technique I.

The magnitude of the quantum yield was obtained by comparing intensities as measured with the photo-cell with the decomposition produced in a uranyl sulfate–oxalic acid actinometer.[4] Corrections were applied for absorption and reflection by the windows, but a high accuracy for the absolute values of the quantum yields is not claimed.

Some early runs were made in all Pyrex reaction vessels made by sealing optically plane windows on the necks of Erlenmeyer flasks. Two identical cells, one containing the actinometer solution, were operated on opposite sides of the mercury arc in a thermostat. Color filters similar to those previously mentioned were used and pressure measurements were made in the manner already described. The over-all intensity was about one hundred times that used in the other technique. This less accurate method will be referred to as Technique II.

Since the vapor pressures of the *o*-, *m*- and *p*-dichlorobenzenes are low (approximately 1.05, 1.35 and 0.64 mm. at 20°, respectively), the rate measurements were much more difficult of execution than those for benzene and chlorobenzene. The total pressure change (assuming negligible vapor pressures for the addition products) is four times the initial pressure of the dichlorobenzene in a given run. The smoothness of the total pressure–time curves indicated definitely that this assumption is valid.

II. Results

(a) The Vapor Pressures of the Dichlorobenzenes.—In order to obtain the effect of pressure of dichlorobenzene on the reaction rate, it was necessary to measure the vapor pressures of the three substances at a series of temperatures. This was accomplished by the use of the pressure gages described in the previous section and while a high order of accuracy was not obtained the results were accurate enough for the purpose at hand. Since these vapor pressures do not seem to be given in the literature they are presented (interpolated to even temperatures) in Table I.

TABLE I

VAPOR PRESSURES OF THE DICHLOROBENZENES

Temp., °C.	Dichlorobenzene vapor pressure, mm. *p*-(solid)	*m*-(liquid)	*o*-(liquid)
0	0.07	0.30	0.25
5	.15	.47	.38
10	.25	.68	.55
15	.40	.96	.76
20	.64	1.35	1.05
24	.90	1.75	1.35

(b) The Dark Reaction.—The dark reaction had been found to be appreciable in the case of benzene and small, although negligible compared to the photochemical rate, in the case of chlorobenzene. Several bulbs were prepared containing chlorine at a pressure of 40 mm. and *p*-dichlorobenzene at a pressure of 0.7 mm. At various intervals over a period of months the chlorine was determined by standard procedure.[1] The results showed no disappearance of chlorine. Similarly no pressure decrease was observed due to dark reaction over periods of several days in the apparatus used for photolysis.

(c) The Budde Effect.—A Budde effect was always observed when the reaction mixture was irradiated. That this was due to the transformation of radiant energy into thermal energy was demonstrated by the fact that it was proportional to the light intensity but independent of the pressure of *p*-dichlorobenzene. The effects were of the order of hundredths of a millimeter.

(d) Effect of Impurities, etc.—The following seemed to have no influence on the results: (1) air or oxygen at pressures below 0.5 mm.; (2) mercury or mercury chlorides in small amounts (due to the presence of mercury vapor before the admission of the chlorine); (3) quite large variations in the treatment of the reaction vessel by flaming, baking out, etc. There may possibly be some effect due to the condition of the walls, but no definite statement in this connection is possible.

Some chlorine compounds of silicon may have been formed at the moment the reaction vessel was sealed off from the chlorine supply bulb. However, attempts to exaggerate this effect by longer heating, etc., produced no noticeable change in the results. There still remains the possibility that chlorine atoms may react with the walls to produce silicon compounds which would act as inhibitors.[5] However, this effect must have been reproducible from run to run if it exists at all.

(e) The Magnitude of the Absolute Quantum Yield.—By comparison of the uranyl sulfate–oxalic acid actinometer with the photoelectric cell it was found that 1 cm. deflection was equivalent to 5.9 × 10^{14} quanta per second. If the initial reaction leading to pressure change is the addition of one molecule of chlorine to one molecule of *p*-dichlorobenzene (see later discussion), then one-half of the initial rate of pressure change is equal to the rate of disappearance of chlorine by the addition reaction. In one run (number 13a) the following data were obtained: chlorine pressure, 31.2 mm.; *p*-dichlorobenzene pressure, 0.64 mm.; intensity, 7.45 cm. deflection; window transmission, 0.85; fraction of radiation absorbed by the chlorine, 0.441; volume of system, 45 cc.; quanta absorbed per sec., 1.65 × 10^{15}; molecules of Cl_2 disappearing per second, 6.44 × 10^{14}; quantum yield, 0.39.

(D_f is the intensity in front of the cell in arbitrary units.) The final pressure change is not exactly four times the pressure of the *p*-dichlorobenzene because some of the tubing was not included in the reaction zone and diffusion was slow enough to prevent all of the substance initially present from reacting. The difference is quite closely accounted for on this basis.

This value of the quantum yield may not be compared directly with values for benzene and chlorobenzene which were obtained at higher pressures. Rough estimates indicate that the value for *p*-dichlorobenzene is lower if anything than for the other two substances under comparable conditions.

(f) The Form of the Total Pressure–Time Curve.—In all some seventy different runs were made and it would be useless to present the data in detail. Table II shows the data obtained for one typical run with Technique I.

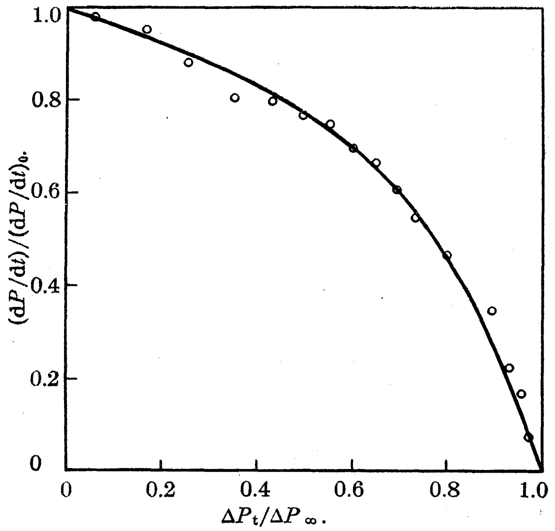

Fig. 1.—Behavior of rate at low light intensity.

Figure 1 shows a plot of $(dP/dt/(dP/dt)_0)$ against $\Delta P/\Delta P_\infty$ for the data in Table II (run 11). Figure 2 shows a similar plot for a run at very high light intensity using Technique II. The fact that the plot is curved at low light intensities would seem to signify that a steady state is not reached as regards all of the chemically stable intermediate addition products. At high intensities such a steady state seems to be reached. Little can be said concerning the mechanism of the reaction after the early stages because a mist is produced which settles out on the walls and a large fraction of the reaction must occur at the interface between the liquid or solid and the gas phase.

In benzene and chlorobenzene the amount of substitution occurring during the early stages of the reaction was small.[1] It was impossible to obtain an adequate proof of this point for *p*-dichlorobenzene due to the small amount of it which could be obtained in the vapor phase. However, the results indicated that this substance did behave in much the same way as the other two. It is assumed, therefore, in treating the rate data that the main initial reaction is one of addition. The next problem is to study the rate of the initial reaction as a function of the different variables using total pressure change as a measure of reaction rate.

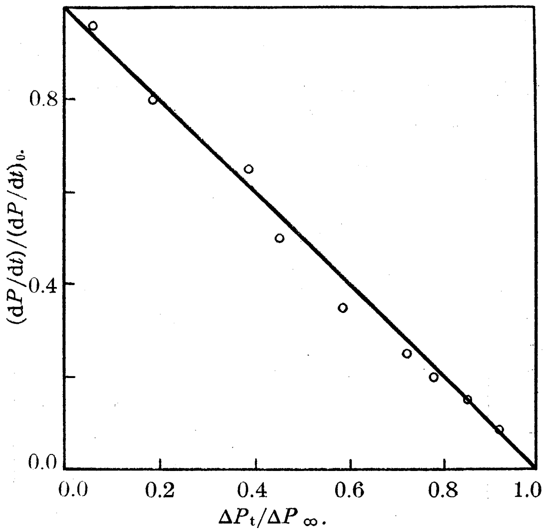

Fig. 2.—Behavior of rate at high light intensity.

(g) The Effect of Light Intensity on the Rate.—Table III presents data showing the effect of light intensity on the rate for the runs made at fairly low light intensities. It will be noted, however, that the intensity has been varied by a factor of nearly fifty. In the sixth column the intensity (expressed in cm. deflection) is multiplied by the fraction absorbed by the chlorine and in the seventh column the rate of pressure change in mm./min. is divided by the corresponding figure in column six. The values in the seventh column are reasonably constant, indicating that within experimental error the rate of pressure change is proportional to the light intensity when the intensity is fairly low.

In ascertaining whether the rate is proportional to a particular power of the light intensity for chain reactions, the number of quanta absorbed per cc. per second is the really important quantity. Thus variations in intensity from one part of the beam to another, the geometry of the beam and the volume of the reaction vessel must all be taken into account in making comparisons. As pointed out above the runs at very high light intensity were made with a different technique from those at low intensity and hence a direct comparison between the two sets of data is difficult. In Table IV the data obtained at high intensities are presented. The figure of 0.33 cc. of 0.1 *N* potassium permanganate per minute for the average intensity of the first group of runs corresponds to about ten times the highest number of quanta absorbed per cc. per second in Table III. It is seen that over the data in both tables the number of quanta absorbed per cc. per second has been varied by a factor of nearly 500.

TABLE III

EFFECT OF VARIATION IN INTENSITY AT LOW LIGHT INTENSITIES ON THE RATE OF ADDITION OF CHLORINE TO *p*-DICHLOROBENZENE

(Pressure *p*-dichlorobenzene, 0.64 mm. Volume, 45 cc.)

Run	$(dP/dt)_0$ mm./min. × 10^2	Intensity in front (cm. deflection) D_f	Chlorine pressure	Fraction absorbed, F_a	I_a ($= F_a \times D_f$)	$\frac{(dP/dt)_0}{I_a} \times 10^2$
11	8.66	10.20	32.6	0.455	4.65	1.86
13a	5.27	6.34	31.2	.441	2.80	1.88
13b	0.84	1.04			0.46	1.83
13c	2.64	2.79			1.23	2.14
13d	4.93	5.89			2.60	1.89
14	3.13	3.56	32.5	.454	1.62	1.93
17	12.22	12.50	44.2	.562	7.03	1.74
18a	11.18	11.50	43.8	.558	6.42	1.74
18b	3.75	3.92			2.19	1.71
19a	9.06	8.97	45.4	.573	5.14	1.76
19b	4.65	4.58			2.63	1.77
19c	1.09	1.06			0.61	1.78
19d	0.32	0.33			.19	1.68

(D_f is already corrected for window transmission.)

TABLE IV

EFFECT OF VARIATION IN INTENSITY AT HIGH INTENSITIES ON THE RATE OF ADDITION OF CHLORINE TO *p*-DICHLOROBENZENE

(Calculated to pressure of *p*-dichlorobenzene = 1 mm.)

Run no.	$(dP/dt)_0$ mm./min.	I_a (cc. 0.1 *N* $KMnO_4$ per min.)	$\frac{(dP/dt)_0}{I_a}$	$\frac{(dP/dt)_0}{I_a^{1/2}}$	$\frac{(dP/dt)_0}{I_a^{.65}}$
o-4	1.10	0.37	3.0	1.8	2.1
o-5	0.89	.28	3.2	1.7	2.0
o-28	1.20	.39	3.1	1.9	2.2
o-31	1.18	.28	4.2	2.2	2.7
Av.	1.09	.33	3.3	1.9	2.24
o-29	0.57	.09	6.3	1.9	2.7
o-30	.43	.11	3.9	1.3	1.8
o-32	.39	.06	6.5	1.6	2.4
o-33	.47	.08	5.9	1.7	2.4
Av.	.465	.085	5.5	1.6	2.26

It is seen that the proportionality to light intensity which is found within experimental error at low light intensities cannot be extrapolated to very high intensities. This will be taken up in the Discussion of Results. The quantum yield for the first four runs in Table IV averages about 0.08, while for the second group of runs it is 0.14.

(h) The Effect of Pressure of *p*-Dichlorobenzene on the Rate.—The effect of *p*-dichlorobenzene pressure on the rate was determined with runs made at intensities similar to those in Table III. The technique was Technique I previously described. Table V presents the results.

TABLE V

EFFECT OF *p*-DICHLOROBENZENE PRESSURE ON RATE

Run	$(dP/dt)_0$ mm./min. $\times 10^2$	Chlorine pressure, mm., P_1	p-$C_6H_4Cl_2$ pressure, mm., P_2	I_a	$\frac{(dP/dt)_0}{I_a}$	$\frac{(dPtd/)_0}{I_a \times P_2)}$
22	2.27	37.1	0.64	1.56	1.46	2.3
23	5.06	37.3	.30	5.98	0.85	2.8
24	6.89	36.4	.47	5.68	1.21	2.6
26	2.62	34.1	.22	4.39	0.60	2.7
27	4.84	28.1	.64	3.18	1.52	2.4
29	7.03	29.9	.91	3.14	2.24	2.5

The results in Table V indicate quite clearly that the rate is proportional to the pressure of *p*-dichlorobenzene within experimental error.

(i) Dependence of Rate on Chlorine Pressure.—Here again the same technique was used as for the runs in Table III. Table VI presents the results.

TABLE VI

EFFECT OF CHLORINE PRESSURE ON RATE

Pressure p-$C_6H_4Cl_2$, 0.64 mm.

Run	$(dP/dt)_0$ mm./min. $\times 10^2$	D_f deflection, cm.	%, absorbed	I_a	Chlorine pressure, mm.	$\frac{(dP/dt)_0}{I_a}$
27	4.84	13.9	22.9	3.18	28.1	1.52
30	3.06	12.9	13.9	1.80	16.1	1.70
31	1.16	11.5	6.5	0.75	7.1	1.55
32	3.51	10.0	23.9	2.39	29.2	1.47
11[a]	8.66	10.2	45.5	4.65	32.6	1.86
19[a]	9.06	8.97	57.3	5.14	45.4	1.76

[a] Runs 11 and 19 were made in a different quartz cell from the others, the length being twice as great as for the other runs.

(j) The Extents of Addition and Substitution.—Benzene and chlorobenzene could be chlorinated eventually to the cyclic compound C_6Cl_{12}. Chlorination of the dichlorobenzenes to the same final product should lead to the disappearance of 7 molecules of chlorine per molecule of dichlorobenzene present at the beginning of a run. That this seems to be the case is indicated by the data in Table VII. If the final product has a negligible vapor pressure, the total pressure should change by an amount equal to four times the initial pressure of *p*-dichlorobenzene. Final chlorine pressures were determined by titration.

TABLE VII

EXTENTS OF SUBSTITUTION AND ADDITION (*p*-DICHLOROBENZENE)

Run	p-$C_6H_4Cl_2$ pressure, mm., P_1	Change in total pressure, ΔP	$\Delta P/P_1$	Change in chlorine pressure, ΔP_2	$\Delta P_2/P_1$
o-26	0.98	2.89	2.95	4.87	5.0
o-25	.79	1.82	2.3	2.97	3.8
o-24	.99	3.69	3.7	6.87	6.9
o-23	.98	3.86	3.9	5.86	6.7
o-28	.91	3.28	3.6	5.10	5.6

(k) Comparison of the Ortho, Meta and Para Compounds under Similar Conditions.—The three dichlorobenzenes were compared as to reaction rate using technique similar to that for the data in Table III. Table VIII gives the data.

TABLE VIII

COMPARISON OF RATES OF CHLORINATION OF ORTHO, META AND PARA DICHLOROBENZENES

Run	Compound	$(dP/dt)_0$ mm./min. $\times 10^2$	Intensity in front (cm. deflection) D_f	Chlorine pressure, mm.	I_a	$\frac{(dP/dt)_0}{I_a} \times 10^2$
32	para	3.51	10.0	29.2	2.39	1.47
33	meta	4.85	11.2	32.1	2.91	1.66
34	meta	3.76	10.2	34.4	2.81	1.34
35	ortho	4.40	11.0	34.8	3.06	1.44
36	ortho	4.40	10.2	36.5	2.95	1.49

The three compounds do not exhibit differences in behavior greater than experimental error.

III. Discussion of Results

The following facts seem to stand out from the results of the experimental work: (1) the rate of pressure change in a system of chlorine and *p*-dichlorobenzene is proportional to the pressure of the latter and independent of the pressure of the former except in so far as the amount of radiation absorbed is dependent on this quantity; (2) at moderate light intensities the rate is proportional to the intensity within experimental error, but at very high intensities (and also in a larger vessel) the rate depends on some power of the light intensity between 0.5 and 1.0; (3) the rates for the ortho, meta and para compounds do not differ appreciably.

As happens so frequently in studies of kinetics of reactions, one mechanism cannot be selected as fitting the data better than any other on the basis of reaction rate studies alone. One which is adequate is represented by the following equations

$$\begin{array}{rcllr} Cl_2 + h\nu &=& 2Cl & & (1) \\ Cl + A &=& ACl & k_2 & (2) \\ ACl + Cl_2 &=& ACl_2 + Cl & k_3 & (3) \\ Cl + \text{walls} &=& \text{removed} & k_4 & (4) \\ Cl + Cl &=& Cl_2 & k_5 & (5) \end{array}$$

where A represents a molecule of dichlorobenzene. The rate of disappearance of chlorine is

$$-\mathrm{d}P_2/\mathrm{d}t = (k_2k_4/2k_5)P_1((1 + 8k_5I_a/k_4^2)^{1/2} - 1) \quad (6)$$

Equation (6) gives a dependence on a power of I_a between 1.0 and 0.5 at high intensities and reduces to

$$-\mathrm{d}P_2/\mathrm{d}t = 2k_2I_aP_1/k_4 \quad (7)$$

at low light intensities. (P_1 = pressure of $C_6H_4Cl_2$; P_2 = pressure of Cl_2; I_a = intensity absorbed in the proper units.)

The mechanism represented by equations (1) to (5) resembles in one respect those postulated for benzene and chlorobenzene in that the addition of a chlorine atom to the substance being chlorinated is postulated as the first step following absorption of radiation.

To account for the effect of intensity, the recombination of chlorine atoms (or some other unsaturated groups) must be allowed to proceed both on the walls and homogeneously in the gas phase. Since the rate of diffusion of atoms to the walls will depend on the pressure, decreasing as the pressure increases, whereas the homogeneous recombination will take place as the result of three-body collisions which increase in number with the pressure, the effect of total pressure on the rate of reaction may not be very marked over quite large changes in that quantity.[6] Nevertheless, one will expect wall recombination to be most important at low pressures and in vessels of small diameter, while three-body collision recombination will be most important at high pressures and in vessels of large diameter. The transition from preponderance of one to preponderance of the other may take place over a relatively short pressure interval.[7] An exact treatment would necessarily include both the rate of diffusion of atoms to the walls and the effect of total pressure (or more specifically of the partial pressures of all of the constituents of the gas phase) on the rate of recombination of chlorine atoms.

The results in Table VI show no pronounced effect of the total pressure (which will depend almost entirely on the chlorine pressure since the pressure of p-$C_6H_4Cl_2$ is always small). It seems necessary to conclude, therefore, that in a small vessel over the pressure range investigated the rate of diffusion to the walls is rapid. If one assumes that the concentration of chlorine atoms is not far from uniform throughout the reaction vessel, one finds the number of chlorine atoms hitting the walls per second to be

$$N_1 = 1.69 \times 10^{22}\, P_3 \quad (8)$$

where P_3 is the pressure of chlorine atoms in mm. and the area of the walls is 49 sq. cm. Turning to run 13a in Table III, one finds the rate of production of chlorine atoms to be

$$2 \times 6.34 \times 0.441 \times 5.9 \times 10^{14} = 3.30 \times 10^{15} \text{ per sec.} \quad (9)$$

If α is the fraction of the collisions with the walls which lead to removal of chlorine atoms, the postulation of a steady state leads to

$$P_3 = 1.95 \times 10^{-7}/\alpha \text{ mm.} \quad (10)$$

In a steady state the rates of reactions (2) and (3) are equal, the rate of removal of chlorine molecules by the formation of the addition product will be equal to the number of collisions between p-$C_6H_4Cl_2$ molecules and chlorine atoms multiplied by a steric factor, β, multiplied by the fraction of the collisions involving sufficient energy to produce reaction which may be written as exp $(-E/RT)$. If σ, the distance between centers at closest approach for these collisions, is taken as 6×10^{-8} cm., the total number of collisions per second in a volume of 25 cc. will be

$$z = 1.43 \times 10^{25}\, P_1P_3 \quad (11)$$

if P_1 and P_3 are expressed in millimeters.

The rate of change of chlorine pressure is one-half the rate of change of total pressure and multiplying by 3.26×10^{16} (the number of molecules per cc. at 1 mm. pressure at 25°) and by the volume gives the number of molecules of chlorine disappearing per second. Equating this to the effective number of collisions per second gives

$$\alpha/\beta = 4.33 \times 10^{3} \exp(-E/RT) \quad (12)$$

where β is the steric factor. In round numbers, therefore

$$E = 5000 - 1365 \log_{10} \alpha/\beta \quad (13)$$

If the proper collision radius has been chosen both α and β must be fractions and will probably not differ greatly from unity. The heat of activation of reaction (2) is thus of the order of magnitude of 5000 calories per mole. This may be compared to 6100 calories for the reaction $Cl + H_2 = HCl + H$.[8] If the reaction between chlorine and p-

---

[6] Jost and Jung, *Z. physik. Chem.*, **3B**, 92 (1929), find little change in the value of the reaction rate constant for the hydrogen-bromine reaction at pressures greater than thirty or forty mm.

[7] Rabinowitch and Wood, *Trans. Faraday Soc.*, **32**, 907 (1936).

[8] Rodebush and Klingelhoefer, THIS JOURNAL, **55**, 130 (1933).

dichlorobenzene could be studied at higher pressures comparable to those used in the hydrogen chlorine reaction, the lengths of the chains would probably become quite large.

A word might be said with regard to other possible mechanisms for the reaction. Equations (2) and (3) may not be combined into one equation involving Cl, A and Cl_2 without introducing a factor of the chlorine pressure in the final rate equation. This is contrary to the experimental evidence. The evidence for or against the molecule Cl_3 is not conclusive. At low light intensities the proper form of rate equation may be based on the following series of reactions

$$Cl_2 + h\nu = 2Cl \qquad (14)$$
$$Cl + Cl_2 = Cl_3 \qquad (15)$$
$$Cl_3 + A = ACl_2 + Cl \qquad (16)$$
$$Cl_3 + \text{walls} = 3/2Cl_2 \qquad (17)$$

With this mechanism the numerical factors will be changed somewhat due to differences in the masses of the molecules involved and in the collision radius, but the heat of activation of reaction (16) will be of the order of that given by equation (13).

Most of the other mechanisms tried gave equations disagreeing very definitely with the experimental data.

It should be reëmphasized that at high light intensities it is necessary to introduce a homogeneous recombination of atoms or radicals which is partly responsible for the stopping of chains.

Since the treatment of the rate data applies only to the addition reaction, under conditions such that the substitution reaction is small, it should be noted that the possible mechanisms bear some resemblance to those postulated by other authors to explain reactions of a similar type.[9]

Some mention of the relationship of the work described in the present article to the work on benzene and chlorobenzene may be made. Two runs were made in the present apparatus with benzene (Technique II). The rate for *p*-dichlorobenzene, corrected to the same pressure and intensity, was two-thirds to one-half that for benzene, indicating that the heat of activation for the reaction corresponding to (2) or (16) is lower for the latter substance.

At low light intensities the rate of chlorination of benzene was found to be proportional to the pressure of chlorine, or in other words to the intensity absorbed. At higher intensities and in vessels of fairly large volume so that the distance the chlorine atoms had to traverse to reach the walls was much larger than in the present experiments, the rate was found to be proportional approximately to the square root of the light intensity, the pressure of the chlorine and the pressure of the benzene. With chlorobenzene the incident intensity could not be varied conveniently with the apparatus used, but the volume of the apparatus was again large and the rate was again best represented by an expression involving the square root of the light intensity. As regards the effect of light intensity the agreement between the expressions for the three substances may be said to be complete. The differences center largely upon the effects of the chlorine pressure and of the pressure of the substance being chlorinated. The pressure of benzene was varied from about 1.6 mm. to about 12.5 mm., while that of chlorobenzene was varied from about 1.5 mm. to about 8.3 mm. In both cases the initial rate was found to be proportional to the pressure of the substance being chlorinated, thus agreeing with the work on the dichlorobenzenes.[10] The square root of the chlorobenzene pressure (or of some quantity proportional to the amount of uncompleted addition reaction) seemed to be involved in calculating constants for the course of runs beyond the initial stages.

For both benzene and chlorobenzene the chlorine pressure appeared in the final rate expression, thus disagreeing with the work on the dichlorobenzenes. This may possibly be due to the fact that when the pressure of the substance to be chlorinated is higher than in the present experiments reactions (2) and (3) follow each other so rapidly that their sum may be written as one step. It is probable also that in the case of chlorobenzene where the volume of the vessel was large and the intensity high, the total gas pressure (primarily dependent on the pressure of the chlorine) affected the rate of diffusion of atoms to the walls, thus making it necessary to introduce this quantity into the rate expression.

Thus while there are some superficial differences in the rate expressions obtained for these various substances, many aspects of the reactions

are similar and the mechanisms probably are not widely different.

Summary

1. The rates of photochemical chlorination of the three dichlorobenzenes have been investigated. Most of the measurements were made on the para compound, although little difference in behavior between the three was noted.
2. The rate of chlorination is proportional to the intensity at low intensities, but depends on some power of the intensity between 0.5 and 1.0 at higher intensities.
3. The rate is independent of the chlorine pressure, except in so far as this determines the light absorption, but is proportional to the pressure of the dichlorobenzene.
4. Various possible mechanisms of the reaction have been discussed and a brief comparison with the results for benzene and chlorobenzene has been made.

[Contribution from the Chemical Laboratory of the University of Texas]

The Determination of the Heat Capacities and the Heat Capacity Ratios of Gaseous Hydrogen Cyanide and of Hydrogen Sulfide[1]

By W. A. Felsing and G. W. Drake

Object of the Investigation.—The purpose of this investigation was the experimental determination of the heat capacities and of the heat capacity ratios at different temperatures of gaseous hydrogen cyanide and hydrogen sulfide. Heat capacity data for gaseous hydrogen cyanide were necessary for the thermodynamic treatment of the thermal decomposition data for monomethylamine obtained in this Laboratory.[2] Hydrogen cyanide is one of the products of this decomposition, and since published data for the heat capacities of this substance are meager and discordant it was decided to measure these needed quantities. It constitutes an integral part of the study of the methylamines as refrigerating fluids in the absorption type refrigerating units as carried out in this Laboratory.[3]

Since the apparatus was available and the heat capacity data for gaseous hydrogen sulfide are rather meager, this substance was included in this investigation.

Previous Investigations.—Bryant proposed,[4] on the basis of spectroscopic measurements, the following relation for gaseous hydrogen cyanide

$$C_p(\text{cal./mole})\ \text{HCN (g)} = 7.01 + 0.006600T - 0.000001641T^2$$

This relation is claimed to apply over the region 300–2000°K. with an accuracy of about 3%. Usherwood,[5] Partington and Carroll[6] and Bredig and Teichmann[7] have determined heat capacity ratios for gaseous hydrogen cyanide at different temperatures. The latter investigators also calculated values of C_p and C_v from their heat capacity ratios.

Eastman proposed a relation for gaseous hydrogen sulfide,[8] which he based upon a review of all existing data; for the region 300–600°K. he proposed

$$C_p\ (\text{cal./mole})\ H_2S\ (g) = 7.2 + 0.0036T$$

for which he claimed only a 5–10% accuracy. Bryant[4] proposed a relation based upon spectroscopic measurements

$$C_p(\text{cal./mole})\ H_2S\ (g) = 6.48 + 0.00558T + 0.000001204T^2$$

This relation is to apply over the range 300–2000°K. with an accuracy of about 2%. Partington and Shilling[9] give a résumé of all heat capacity ratios for gaseous hydrogen sulfide as determined through 1923. Recently Giauque and Blue[10] determined the heat capacities of solid and liquid hydrogen sulfide.

The Method of this Investigation.—The method selected for the experimental determination of the heat capacities was the closed system continuous flow method of

Scheel and Heuse,[11] with certain modifications suggested by Thayer and Stegeman[12] and by Haas and Stegeman.[13] Modifications dealing with calorimeter design, the heating unit, and the gas circulating pump as developed during this investigation are described in the appropriate sections following.

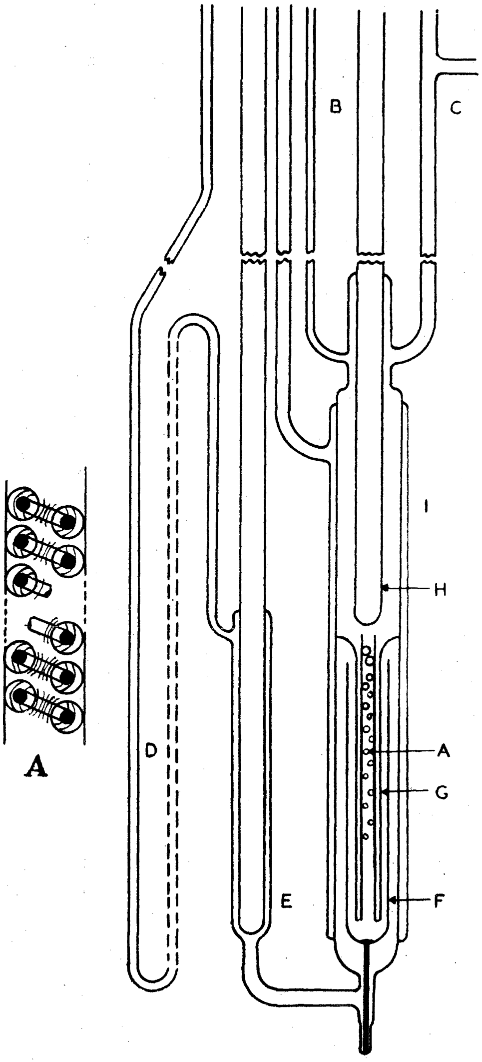

Fig. 1.

The Calorimeter.—The calorimeter is shown in Fig. 1. An enlarged section shows the heating unit design. This unit consisted of approximately 3.66 meters of No. 34 B. & S. bare manganin wire; it was wound smoothly in a lathe on 1.58 mm. diameter rod. A Pyrex rod spiral, which fitted loosely into the heater tube, was constructed; upon this the coiled heating wire was threaded. The glass spiral and its covering of coiled wire was then inserted into the heater tube; the coils fitted tightly against the walls and there was no open channel for the gas to travel through without coming in contact with the heating unit many times. The return wire from the lower end of the coil was brought through a small glass tube extending through the center of the glass spiral. Thus 3.66 meters of bare wire were placed into a tube 4.75 mm. in diameter and 7.6 cm. long.

The Thermoelement.—A 10-junction copper–constantan thermoelement, constructed with the usual precautions, was used to measure the temperature difference between the incoming and outgoing gas. In calibration, nine observations were made at each calibration point, the hot and cold junctions differing by about 3.5° as measured by calibrated Beckmann thermometers. The values of $\Delta E/\Delta t$ thus determined at a given point differed by only 2 parts in 2500 from the average.

The Circulating Pump.—The pump first used was of the type described by Scheel and Heuse,[11] by Thayer and Stegeman,[12] and by Haas and Stegeman.[13] But, since it was found impossible to prevent oscillation of the conventional mercury valves at higher rates of flow with the consequent irregularity of flow, a new design of pump was introduced. The details of this pump are shown in Fig. 2. Mercury valves were abandoned and replaced by ground glass ones, as shown at A and B of Fig. 2. The operating mechanism is shown at K; a crank was mounted on the face-plate of an ordinary speed reducer and the pin of the crank was carried on a threaded bar. This bar was supported at each end by brass blocks and the stroke was varied by turning the threaded bar; this changed, of course, the rate of flow of the gas.

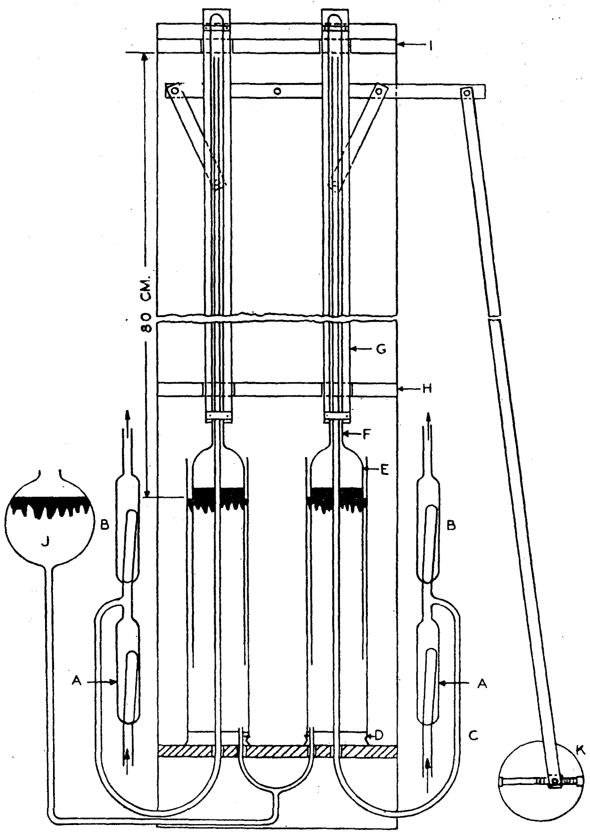

Fig. 2.

[12] Thayer and Stegeman, *J. Phys. Chem.*, **35**, 1505 (1931).

[13] Haas and Stegeman, *ibid.*, **36**, 2127 (1932).

The rate of flow was determined as usual by the calibrated bulb method provided, however, with automatic timing. In addition, a flow-meter, calibrated against the bulb, was inserted in the system and the pressure drop measured with a differential manometer filled with olive oil.

The Thermostat.—The thermostat containing the calorimeter consisted of a large Dewar flask (15 × 50 cm.). It was filled with liquid paraffin and was maintained constant at each temperature to within ±0.005°.

The Kundt Tube.—This apparatus does not differ in essentials from that described by Felsing and Jessen,[3c] except in the method of sound production. A General Radio (Type 213, 1000 cycle) audio oscillator produced the current which was sent through a General Radio filter section (Type 330E, 1000 cycle, 600 ohm impedance) and a General Radio band-pass filter (Type 534-B, 1000 cycle, 2000 ohms impedance). This current, impressed upon a telephone receiver in its special housing, produced a sound wave in the tube of such a nature that the minima could be detected easily. The listening tube was closed, the sound being transmitted to a thin aluminum disk fitted into an old-style telephone receiver. The tube was approximately 4 cm. in diameter and it was accurately thermostated.

The Preparation of the Gases.—Hydrogen cyanide was prepared from potassium cyanide and sulfuric acid as recommended by Gilman.[14] The gas was freed from spray, dried by passage over calcium chloride, and condensed by an ice–salt mixture. Repeated fractional distillation under reduced pressure yielded a pure product, which was stored in a reservoir under its own vapor pressure.

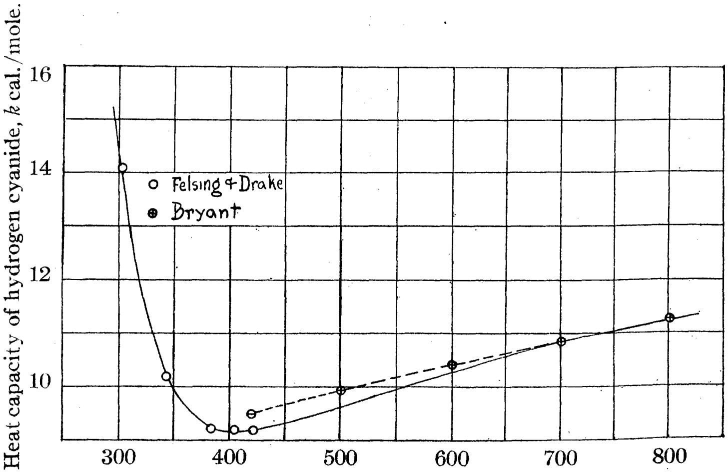

Fig. 3.—Temperature, deg. Kelvin.

Hydrogen sulfide was prepared from aluminum sulfide and water by the method of Keyes and Felsing.[15] The gas was dried by passage over aluminum sulfide.

The Heat Capacities.—The heat capacities for gaseous hydrogen cyanide were measured at 30, 70, 110, 130 and 148°; for hydrogen sulfide they were 30, 70 and 110°. The apparatus was calibrated carefully with pure air (moisture and carbon dioxide free) and the heat loss constant for the apparatus, at different rates of flow, was determined with the aid of the heat capacities listed for air in "I. C. T."[16] The loss determined for air at each temperature and given rate of flow was then assumed to be the loss for the two gases investigated under like conditions. This assumption seems justified for gases of about the same density. The following table presents the data obtained; each value listed is the average of six separate, closely agreeing determinations.

Table I

The Specific and Molecular Heat Capacities of Gaseous Hydrogen Cyanide and Hydrogen Sulfide

Temp., °C.	Heat input J./g./deg.	Heat loss J./g./deg.	Heat capacity Specific J./g.	Heat capacity Molecular cal./mole
		Hydrogen Cyanide		
30	2.697	0.513	2.185	14.107
70	2.147	.567	1.580	10.201
110	2.065	.637	1.428	9.219
130	2.085	.661	1.424	9.194
148	2.095	.667	1.422	9.181
		Hydrogen Sulfide		
30	1.475	0.513	0.962	7.838
70	1.540	.567	.973	7.928
110	1.640	.637	1.003	8.172

The values for the heat capacity for hydrogen cyanide were plotted against the temperature as shown in Fig. 3; on the same plot is included the equation by Bryant.[4] The very rapid change in heat capacity at and near room temperature is due most likely to the fact that the gas is associated, as is shown in the table of densities determined during this investigation. As the temperature rises, the gas density approaches normal; Ingold[17] stated that the density of this gas becomes normal above 170°, a fact substantiated by the density measurements listed below. These were made with great care, observing every precaution for high accuracy.

Accordingly, the continuous line, representing the most probable values, does not join the Bryant line until about 700°K. It is assumed that

Table II

The Densities of Gaseous Hydrogen Cyanide

Temp., °C.	Density (1 atm.) (g./cc.)	Obsd. density/ Calcd. density
30	0.0011615	1.07050
70	.0009880	1.03013
110	.0008735	1.01699

[16] "I. C. T.," Vol. V, p. 81.

[17] Ingold, *J. Chem. Soc.*, **129**, 26 (1926).

above that temperature the Bryant relation may yield values of the heat capacity. Since, however, the heat capacity changes so rapidly at or near 400°K. two relations were obtained: one for the region 280–400°K. and the other for the region 400–1000°K. These are given as follows

$$(280\text{–}400^\circ\text{K.}):\ C_p(\text{cal./mole})\ \text{HCN(g)} = 121.03 - 0.58130T + 0.00754T^2$$

$$(400\text{–}1000^\circ\text{K.}):\ C_p(\text{cal./mole})\ \text{HCN(g)} = 6.650 + 0.00675T - 0.000001125T^2$$

The relation best expressing the heat capacities of hydrogen sulfide over the temperature range investigated is

$$(273\text{–}450^\circ\text{K.}):\ C_p(\text{cal./mole})\ H_2S\text{(g)} = 12.157 - 0.02883T + 0.0000048125T^2$$

Since this relation contains rather large temperature coefficients it is not advisable to extrapolate it far past the temperature limits specified.

The Heat Capacity Ratios.—The γ values are presented in Table III; the values in the column marked "uncorrected" resulted from the relation

$$\gamma\ (\text{uncorr.}) = 1.403\ \frac{M}{28.96}\ \frac{l_2^2}{l_1^2}$$

while the values in the "corrected" column resulted from the application of the correction relation

$$\gamma\ \text{corr.} = \gamma\ (\text{uncorr.})\cdot\Phi$$

where $\Phi = 1 - {}^9/_{64}\ \pi\ \tau\ (1 - 6\tau^2)$, as suggested by Partington and Shilling[9] (p. 50). Here $\pi = p/p_c$ = actual pressure/critical pressure and $\tau = T_c/T$ = critical temperature/actual temperature. The critical data for hydrogen cyanide are those of Bredig and Teichmann,[7] while those for hydrogen sulfide are due to Pickering.[18]

TABLE III

VALUES OF C_p/C_v FOR HYDROGEN CYANIDE AND HYDROGEN SULFIDE

Gas	Temp., °C.	γ, uncorr.	γ, corr.
HCN	30	1.144	1.087
	50	1.252	1.201
	75	1.276	1.235
H_2S	10	1.349	1.322
	25	1.343	1.321
	50	1.330	1.313
	75	1.314	1.301

The increasing values of γ for hydrogen cyanide may be explained by the apparently greater complexity, as indicated by the density; if values had been extended to higher temperatures, the γ values would most likely have gone through a maximum as is shown by the results of Bredig and Teichmann (maximum at 140°).[7]

The Accuracy of the Determinations.—From a consideration of all sources of error, it is believed that the heat capacity data are accurate to within *one* per cent.; the accuracy of the heat capacity ratios is within 0.2%; and the density data for gaseous hydrogen cyanide are believed to be accurate to within 0.5%.

Summary

1. The heat capacities of gaseous hydrogen cyanide and of hydrogen sulfide have been determined over a limited temperature interval with an accuracy of approximately 1%. These have been expressed as functions of the temperature.

2. Improvements in measurement of the rate of flow in the construction of the heating unit, and in the gas circulating pump have been described.

3. The densities of gaseous hydrogen cyanide have been measured with an accuracy of approximately 0.5%.

4. The heat capacity ratios for hydrogen cyanide and sulfide have been measured over a temperature range with an accuracy of about 0.2%.

Non-Rotation of Molecules in a Number of Solids

BY S. A. MCNEIGHT AND C. P. SMYTH

This paper presents the negative results of investigation through dielectric constant measurements on a number of solids in which the size and shape of the molecule or the properties of the substance indicated the possibility of molecular rotation. The apparatus and method employed was essentially the same as that described in earlier papers.[1] The work on benzophenone was carried out by Dr. W. S. Walls.

Purification

Methylamine.—This was prepared by the action of a concentrated potassium hydroxide solution on Merck C. P. methylamine hydrochloride, dried by passing over fused potassium hydroxide, condensed by a carbon dioxide–acetone slush and fractionally distilled, the middle third being collected directly in the dielectric constant cell. Evaporation of the last third of the material at about 183°K. left no residue, m. p. 179.7°K.

Ethyl Ether.—The material used was part of a sample carefully purified for freezing point measurements.[2]

Acetone.—C. P. acetone was dried by standing over fused calcium chloride for some weeks with a subsequent fractional distillation from a fresh supply of calcium chloride; m. p. 178.2°K.; b. p. 329.3°K.

Benzophenone.—Material from the Florasinth Laboratories, Inc., was dissolved in a small amount of benzene and filtered. The benzene was distilled off and the residue fractionally crystallized ten times; m. p. 321.2°K. A portion of the original material was fractionally distilled under reduced pressure and a sample boiling from 457.6 to 458.1°K. was collected and measured. This material showed such dispersion of the dielectric constant that the sample purified by fractional crystallization was used for the measurements reported in Table I.

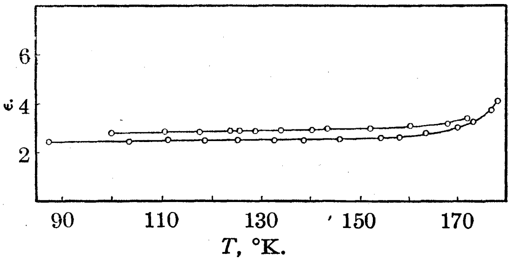

Fig. 1.—Temperature dependence of the dielectric constants (at 50 kc.) of acetone and methylamine; upper curve, acetone; lower curve, methylamine.

Succinic Acid.—C. P. succinic acid was recrystallized from water three times; m. p. 455.9°K. The material on which measurements were made probably contained appreciable amounts of succinic anhydride since melting was necessary in order to fill the condenser and a melting point determination made at the conclusion of the measurements gave 453.6°K.

Experimental Results

The dielectric constants ϵ and the specific conductances $k(\text{ohm}^{-1}\,\text{cm}^{-1})$ are given in Table I, the absolute temperatures being given in the first column and the frequencies in kilocycles across the top of each group of data. Unless otherwise indicated, the values were obtained with rising temperature. As the material in each case is frozen between the fixed plates of the measuring condenser, the value found for the dielectric constant does not change because of change in the number of molecules per cc. with temperature. For an approximate calculation of the polarization of the solid at any temperature, the density at the melting point is the one to be used. Many values of the dielectric constant at intermediate frequencies and temperatures have been omitted for the sake of brevity. As no appreciable dependence upon frequency was observed for ether, its dielectric constant values are given only at 5 kc. and its specific conductances, 0.02×10^{-9} for the solid and 0.04×10^{-9} for the liquid at 5 kc., are omitted.

Discussion of Results

As methyl alcohol has been found to show rotation with some difficulty above a transition point, methylamine, which has a melting point 4° higher, a dipole moment 1.23 instead of 1.68×10^{-18} and a molecule rather similar in shape and size, might also be expected to show molecular rotation. Figure 1 shows that the dielectric constant rises rapidly above 160°K., the rapidity increasing with increasing temperature and decreasing frequency. The first part of the rise appears like the curves for ice, in which the molecules evidently turn with difficulty, but the very steep rise as the melting point is approached and the great increase in conductance as compared to a maximum in the conductance curve shown by ice and by methyl alcohol show that this rise in dielectric constant is not due to the setting in of molecular rotation in the solid but is caused by impurities, which give rise

to traces of liquid and probably ionic displacements. The presence of these impurities is indicated by the fact that the melting point of the sample used was 0.9° lower than that found by Timmermans and Mattaar[3] and lacking in sharpness. The size, shape and dipole moment of the methylamine molecule are such that its rotation in the solid might occur at least as easily as that of the methyl alcohol molecule. As this begins to show limited rotation only 15.5° below its melting point, the rotation of the methylamine molecule might be expected to begin a few degrees below its melting point. However, the uncertainty in the effects of the various factors is more than enough to make possible the postponement of rotation in the solid until a temperature above the melting point is reached. Methylamine resembles ammonia, which shows no molecular rotation in the solid, much as methyl alcohol does water, which turns with difficulty in the solid. The absence of any rotation of the —NH_2 group in the molecule is like that in aniline, which shows no molecular or group rotation.[1]

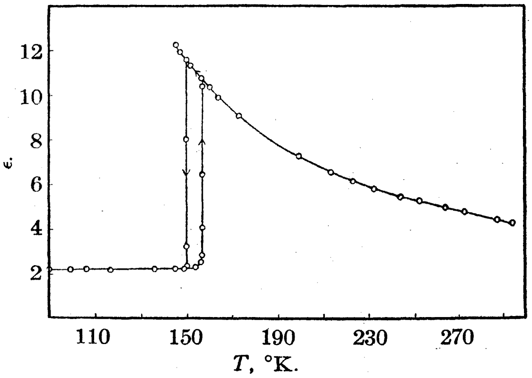

Fig. 2.—Temperature dependence of the dielectric constant (at 5 kc.) of ethyl ether.

It may be concluded from the low dielectric constant values found[4] for solid methyl chloride, bromide and iodide that there is no molecular rotation around any axis perpendicular to the carbon–halogen line, the dielectric constant giving no information as to rotation around the carbon–halogen line, in which the molecular dipole lies. Low dielectric constants found[4] for solid methylene chloride and chloroform show that these molecules do not rotate around any axes perpendicular to their one axis of symmetry. It is probable that all of these molecules are so located in their lattices as to block one another's rotations around axes perpendicular to those in which their dipoles lie, such rotation being presumably much more difficult than rotation of the methylamine molecule around the C–N line or of the methyl alcohol molecule around the C–O line.

The dielectric polarization of ethyl ether in solution and in the pure liquid state shows very little orienting force between the molecules.[5] As the freezing point is 7° lower than the melting point, a change from an unstable to a stable form apparently occurring in the solid, one would anticipate a considerable amount of molecular freedom in the solid. The dielectric constant–temperature curve in Fig. 2 shows clearly the different freezing and melting temperatures and shows equally clearly by its low and almost horizontal position below the freezing point the absence of molecular rotation in the solid. The curves for falling and rising temperature are coincident below the freezing point and show no sign of any transition, therein agreeing with the absence of discontinuity in the temperature–time curves run in this Laboratory.[2] The curve gives no sign of the behavior reported for liquid ether by Mazur,[6] whose measurements showed a rise in dielectric constant from 4.18 at 303.7°K. to a maximum of 12.39 at 167.7°K. followed by a decreasingly rapid decrease with further lowering of temperature, then a slight increase with only a small break downward on freezing. Mazur ascribed this phenomenon to the formation of two liquid phases by the ether, which was supposed to undergo a transition at 167.7°K., but Smits[7] has concluded that Mazur's results are due to the presence of impurities. The material measured in the present work appeared to be very pure, since the melting point was shown by temperature–time curves to be very sharp and in excellent agreement with the carefully determined value of Timmermans and Martin[8] as well as that of Skau.[9] The failure to find the abnormal behavior reported by Mazur for liquid ether parallels a similar failure in the case of nitrobenzene.[1] The specific volume 1.156[10] at 150°K. and the dielectric constant 2.20 from 89.9 to 106.2°K. give a polarization value 24.5, from which subtraction of the electronic

polarization 22.0[11] gives 2.5 for the atomic polarization in fair agreement with the value 3.3 obtained by Fuchs.

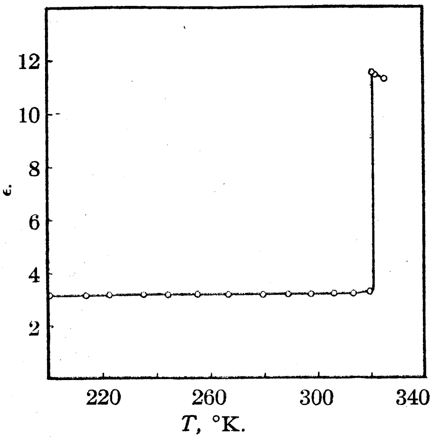

Fig. 3.—Temperature dependence of the dielectric constant (at 70 kc.) of benzophenone.

The considerable departure of the acetone molecule from a spherical or cylindrical shape would lead one to expect no rotation in the solid. This expectation is borne out by the dielectric constant values in Table I and Fig. 1, the rapid increase of both dielectric constant and conductance and their variation with frequency as the region of the melting point is approached being caused by impurities as in the case of methylamine. Special care was taken with the measurements in the neighborhood of 126°K., where a small hump had been found[12] in the specific heat–temperature curve but no irregularity was observed in the dielectric constant–temperature curve at any of the frequencies used. Pauling has suggested[13] that the small hump sometimes observed in specific heat–temperature curves is due to the setting in of rotation of a group within the molecules. Although the dielectric constant values show that the entire molecule does not rotate in the solid, they would not be affected appreciably by rotation of the methyl groups in the molecule, which may be the cause of the hump in the specific heat curve. Use is made of the density 0.9686 of solid acetone at its melting point given by "International Critical Tables" to calculate the polarization of the solid at 100°K. The value 22.7 thus obtained gives an atomic polarization value 7, which is almost certainly too high. The small but not negligible variation of dielectric constant with frequency and temperature even down to 100°K. shows that it has not quite settled down to the value which arises wholly from induced shifts of charge in the molecule.

Although benzophenone exists in an unstable monoclinic form as well as in a stable rhombic, the large size of its molecule and its great departure from spherical shape render molecular rotation even more improbable than in acetone. The absence of molecular rotation is established very clearly by the data in Table I and Fig. 3, which show a dielectric constant value independent of frequency and temperature for temperatures more than 20° below the melting point. The considerable rise on melting is due to the large dipole moment of the molecule.

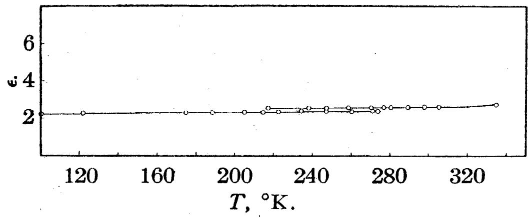

Fig. 4.—Temperature dependence of the dielectric constant (at 5 kc.) of succinic acid; lower curve after remelting and refreezing.

As the variation of the dielectric constant of succinic acid (Fig. 4) apparently was caused by impurities, the values at frequencies other than 5 kc. are omitted from Table I. It was necessary to melt the substance in order to fill the space between the condenser plates which undoubtedly produced appreciable quantities of succinic anhydride as shown by the somewhat lower melting point obtained on a second melting. To investigate the effect of increasing quantities of the anhydride, the dielectric constant–temperature curve for the refrozen sample was obtained but, aside from a decrease in the temperature at which variation with frequency became pronounced, little change was observed. The specific heat–temperature curve of succinic acid[14] shows a hump, with a heat effect of 41 cal. per mole at 272°K. The dielectric constant values give no indication of any effect as they vary slightly but steadily both on heating and cooling through this temperature. It would appear therefore that this effect cannot be due to rotation of the molecule or of any groups within the molecule since such rota-

tion would cause an increase of the dielectric constant at the temperature of its appearance. Unfortunately it proved impossible, due to the high conductance, to investigate the transition at 310°K. where a transition from a triclinic to a monoclinic form has been observed.[15]

Such variation of dielectric constant and conductance with frequency and temperature as has been found for these substances has been dismissed as not being significant of rotation. The ordinary direct current conductance rises with rising temperature as does that of a liquid and the alternating current conductance increases with increasing frequency.[16] The apparent capacity of a condenser and, hence, the value of the dielectric constant calculated from it, increases with decreasing frequency and resistance.[17] At very high frequencies and resistances the effect upon the apparent capacity is slight or negligible, but at the lower frequencies employed in these measurements and with the lower resistances in the region of the melting point, the effect is considerable. It is well illustrated by the dielectric constant values for liquid benzophenone (Table I), where there can be no question of a true anomalous dispersion. The value for the slightly supercooled liquid increases only 0.01 on lowering the frequency from 70 to 12 kc., but increases 0.50 on further lowering the frequency from 12 to 0.3 kc., more than half of the increase occurring between 0.7 and 0.3 kc. A temperature rise of 5° lowers the resistance and thus increases the effect slightly. As the conductivity of a material of low conductivity is tremendously affected by the presence of minute traces of ionic impurities, the effects under discussion have been attributed mainly to impurities rather than to the properties of the pure substances under examination. Although the effects are undoubtedly due primarily to the conductances of the materials examined, there remains a possibility, particularly in the case of methylamine, that an occasional molecule may have sufficient freedom of rotation to orient in the electric field or that a larger number of molecules executing small rotational oscillations in their lattices may each contribute very slightly to the dielectric constant through a distortion of the oscillation by the field.

Summary

The dielectric constants of solid methylamine, ethyl ether, acetone, benzophenone and succinic acid have been measured over a wide range of temperature and frequency to investigate the possibility of rotation of their molecules. Although the molecular shape of methylamine is such that rotation might well occur and although ether shows different freezing and melting points, benzophenone shows polymorphism, and acetone and succinic acid show humps in their specific heat–temperature curves, no molecular rotation has been found in these solids.

The low dielectric constants of solid methyl chloride, bromide and iodide, methylene chloride and chloroform are used to show that, in the solid state, their molecules cannot rotate around any axes perpendicular to the axis of molecular symmetry.

Molecular Rotation in Solid Arsine and Other Hydrides

BY C. P. SMYTH AND S. A. MCNEIGHT

This paper presents measurements of dielectric constant made in continuation of previous work[1,2] on the rotation or non-rotation of molecules in solid hydrides and discusses the results in relation to the properties of the other hydrides and the factors affecting rotation. The apparatus and technique employed were essentially the same as that described in earlier papers[1,3] from this Laboratory, the same bridge being used. However, because liquid hydrogen cyanide attacked the gold cylinders of the measuring cell normally used, a new condenser was made for this substance from tin tubes turned to such a size as to give a geometrical capacity of 10 micromicrofarads. When liquid hydrogen became available for the first time for the measurements on arsine, the brass block surrounding the glass cell containing the condenser was replaced by a similar block of lead in order to obtain greater heat capacity and slow down the rate of temperature change at very low temperature. For the measurement of these low temperatures the calibration of the platinum resistance thermometer used in the other measurements was extended by using the boiling point of hydrogen as an additional fixed point.

Preparation of Materials

Hydrogen Cyanide.—This material was prepared from potassium cyanide and sulfuric acid according to the directions given in "Organic Syntheses."[4] It was condensed at 0° and the middle portion distilled into the condenser cell; m. p. 259.2°K.

Hydrogen Selenide.—Hydrogen selenide was prepared in an oxygen-free apparatus by dropping freshly boiled, dilute hydrochloric acid upon aluminum selenide, which had been prepared by the ignition of an intimate mixture of powdered aluminum and selenium containing a 50% excess of selenium over that required by the formula Al_2Se_3. The gas was dried by passage over calcium chloride and phosphorus pentoxide and condensed by means of a slush of acetone and solid carbon dioxide, which froze it immediately to the solid, preventing possible decomposition in the liquid phase.

Arsine.—Arsine was generated in a system previously flushed out with oxygen-free hydrogen by dropping 30% sulfuric acid upon an alloy of 53% zinc and 47% arsenic according to the method used by Cohen.[5] It was dried by passage over calcium chloride and phosphorus pentoxide and condensed by a slush of acetone and solid carbon dioxide.

Experimental Results

The dielectric constants ϵ and the specific conductances k (ohm^{-1} cm.$^{-1}$) are given in Table I, the absolute temperatures being given in the first column and the frequencies in kilocycles across the top of each group of data. Many determinations at intermediate temperatures and frequencies are omitted for the sake of brevity, but more values than usual are included for arsine because of its peculiar behavior. All the values listed were obtained with rising temperature, but arsine was taken up and down several times between liquid air temperature and the melting point. The upper transition temperature and the melting point obtained were identical with those in Table I and the shape of the dielectric constant–temperature curve obtained for this region was the same as that in Fig. 3. As the liquid was refrozen each time, small differences naturally occurred in the absolute values of the dielectric constant. Consequently, none of these check values are given in Table I and most of the specific conductances, which did not change significantly above the lowest transition, are omitted. As the hydrogen selenide measurements, through an unfortunate chain of circumstances, are incomplete, only the dielectric constant values are given.

Discussion of Results

The first attempt to measure solid hydrogen cyanide by Dr. W. S. Walls in this Laboratory was unsuccessful because the interaction of the liquid cyanide with the gold condenser was sufficient to give high conductance on solidification. The first results obtained in the present investigation were uncertain for the same reason, but the results in Table I obtained with a tin condenser appear satisfactory. The melting point 259.2°K. obtained for this sample of hydrogen cyanide is in excellent agreement with the value 259.1°K. given by "International Critical Tables" and 259°K. found by Lewis and Schutz,[6] but its lack

of sharpness is indicative of the presence of impurities, which are presumably responsible for the rapid increase in the dielectric constant and conductance of the solid as the melting point is approached. The conductance becomes so high near the melting point that the dielectric constant can no longer be measured with any accuracy but a temperature–time curve shows the absence of any transition in this region. The dielectric constant–temperature curve in Fig. 1 shows no transition and gives no positive evidence of molecular rotation. The gradual rise with temperature below the region of the melting point is probably due to the effect of increasing conductance and the rapid rise in the region of the melting point together with increasing dependence upon frequency is due both to the rapid increase in conductance resulting from the formation of liquid and the presence of ions and to the direct effect of liquid of high dielectric constant and ions in raising the dielectric constant. The value[7] for liquid hydrogen cyanide 194.4 at 259.7°K., the highest found for any pure liquid, shows that the presence of appreciable quantities of liquid in the solid would raise the dielectric constant markedly and also shows that freedom of rotation in the solid would give a dielectric constant over 200 instead of between 2 and 3. Use of a density value 0.925 at 233°K.[8] and of the Grüneisen rule together with a dielectric constant value from Table I gives a molar polarization 9.2 for the solid at 100°K. Subtraction of the electronic polarization 6.3[9] gives 2.9 for the atomic polarization as compared to the zero value found in the more accurate measurements on the gas.[9] The rough value 2.9, as far as it is significant at all, probably indicates that the dielectric constant values even at 100°K. are a little high because of conductance. However, the results certainly do not preclude the possibility of the rotation of an occasional molecule in the lattice of the solid, particularly as the region of the melting point is approached, but make it apparent that it is at most only a very occasional molecule that might have the freedom necessary for rotation.

In view of the freedom of molecular rotation in solid hydrogen chloride, bromide and iodide,[1] one might anticipate rotation in solid hydrogen cyanide. However, the factors which tend to prevent rotation are obviously stronger in the latter substance. The linear triatomic molecule of hydrogen cyanide must depart farther from a spherical shape than do the molecules of hydrogen chloride, bromide and iodide, as the minimum value for the distance of the hydrogen from the nitrogen nucleus would seem to be about 1.34 Å.[10] as compared to an internuclear distance 1.28 Å. in hydrogen chloride and the maximum molecular diameter perpendicular to this axis in which the nuclei lie must be considerably smaller in the hydrogen cyanide molecule. The hydrogen cyanide lattice, which has not yet been subjected to x-ray analysis, would seem, therefore, to offer the possibility of a molecular arrangement such that any considerable turning of the molecules would cause them to overlap and prevent further turning and, consequently, give no chance for free rotation. This appears to be the case in the cubic lattice of the linear carbon dioxide molecule.[11] If molecular rotation is not prevented by overlapping, the potential energy barrier which the molecule has to pass in order to rotate through an angle of 360° should be high because of the large dipole moment[9] 2.93×10^{-18}, which is nearly three times as large as that of the hydrogen chloride molecule,[12] 1.03×10^{-18}. This potential energy barrier may well be so large that the thermal rotational energy of the molecules is too small below the melting point to make it possible for the molecules to pass, that is, to rotate. A possible third factor is the formation of a hydrogen bond between molecules, which gives abnormal properties to ammonia, water and hydrogen fluoride and hinders or prevents molecular rotation in the lattices of their solid forms. The first two factors, however, are quite sufficient to account for the non-rotation of the hydrogen cyanide molecule in the lattice of its solid form and Lewis and Schutz[6] conclude that the great abnormality of the liquid form is due not to hydrogen bond formation but to the high dipole moment of the molecule.

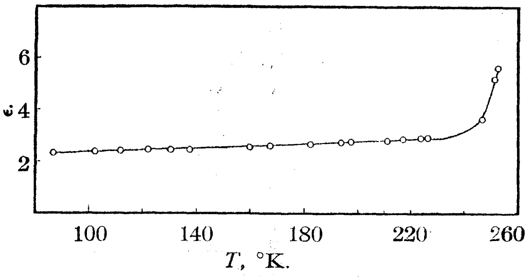

Fig. 1.—Temperature dependence of the dielectric constant (at 50 kc.) of hydrogen cyanide.

The x-ray photographs of potassium cyanide, which crystallizes in a cubic lattice, give no evidence of separate carbon and nitrogen positions, which is probably indicative of rotation of the cyanide ion in the lattice[11] (p. 364). The potential barrier to rotation of this ion should be much

smaller than that for the hydrogen cyanide molecule for the departure of the ion from sphericity must be less than that of the molecule, its dipole moment should be much smaller, and the factor of the possible hydrogen bond is absent. There is, therefore, no conflict between the interpretation of the x-ray photographs as showing rotation of the cyanide ion in the potassium cyanide lattice and the non-rotation here found for the hydrogen cyanide molecule in its lattice.

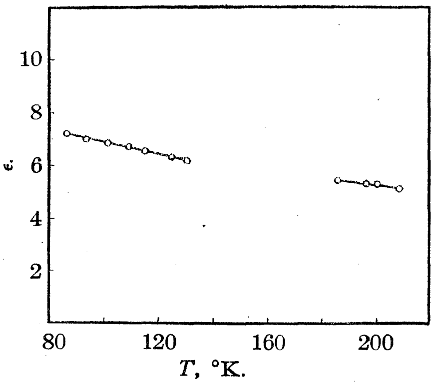

Fig. 2.—Temperature dependence of the dielectric constant (at 50 kc.) of hydrogen selenide.

The incomplete measurements on solid hydrogen selenide in Table I and Fig. 2 show by the high values of the dielectric constant and their increase with decreasing temperature as required by the Debye equation for polar molecules in the liquid and gaseous states that the molecules are able to rotate, probably with much the same freedom as in the liquid. The dielectric constant–temperature curve below 130.6°K. is sufficiently different from that above 186.0°K. to suggest a probable discontinuity somewhere between these two temperatures resulting from a transition like the upper transition found in hydrogen sulfide[2] and in hydrogen iodide.[1] Use of Natta's density value 2.456 for the cubic lattice at 103°K.[13] and the Grüneisen rule gives a density value of 2.33 at the melting point, which, combined with the dielectric constant value at 86.8°K., gives a molar polarization value 23.4. As the molar refraction for the H_α line is 11.95[14] and the atomic polarization must be small, this gives a value of about 12 for P_M, the polarization due to the dipole moment of the molecule. From this the apparent moment of the molecule is calculated to be 0.4×10^{-18}, little lower than the rough value $0.5\text{–}0.6 \times 10^{-18}$ which one would estimate from consideration of the moments of other hydrides. Naturally, this is not to be taken as a determination of the dipole moment of hydrogen selenide, but is to be regarded as evidence that the molecule has much the same freedom of rotation in its lattice down to liquid air temperature that it has in the liquid.

Although the melting point of the arsine used was 3.2° below that given in "International Critical Tables," melting occurred sharply, but because of some tendency toward decomposition, the sample was probably not of a high degree of purity. In considering the data for arsine in Table I and Fig. 3, it should be borne in mind that, because of its small dipole moment[15] 0.16×10^{-18}, the dielectric constant is small and increases but slowly with falling temperature. On this account, the scale used in Fig. 3 for the dielectric constant is much larger than that usually employed so that secondary effects having nothing to do with the fundamental factors involved may affect the shape of the curve. The drop of the dielectric constant during melting below the value for either the solid or the liquid has not been previously observed as far as the authors know, although a sharp rise above the value for either the solid or the liquid has been observed in some cases where two phases presumably existed below the melting point because of considerable quantities of impurity.[16] This drop and rise which occurs within a temperature range of only 0.3° is clearly shown by numerous values determined during the rising temperature run represented in Table I, but does not appear in either the cooling or the heating curve previously run through the melting point with the

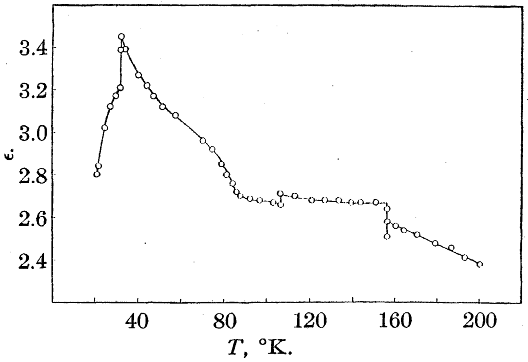

Fig. 3.—Temperature dependence of the dielectric constant (at 50 kc.) of arsine.

same sample. The upper transition point evident at 106.6°K. was checked accurately by a temperature–time curve. This transition appears similar to the slight upper transitions occurring in hydrogen bromide,[1] iodide,[1] sulfide[2] and, probably, in the selenide. As in these substances, the rate of change of the dielectric constant with temperature is much more rapid below it than above it. The two points of inflection between the two transitions probably arise from secondary effects of which we are unaware. A single unexplained point of inflection was found in the curves for hydrogen chloride, bromide and iodide, and in an unpublished curve for a sample of hydrogen sulfide slightly less pure than that for which a curve without inflection was published.

As incomplete cancellation of the effects of the inductance of the circuit causes small errors in the dielectric constant values, differences of 0.01 or 0.02 between values at different frequencies are meaningless. However, a pronounced anomalous dispersion is evident during the lower part of the transition which is incomplete at the lowest temperature reached. Although the material was maintained within 0.3° of this temperature for three hours, the rising temperature values in Table I agree well with those obtained during the relatively rapid initial cooling, showing that stable equilibrium existed throughout. The variation of the dielectric constant with frequency is greatest at 20.7°K., where the apparent conductance actually shows a maximum at 20 kc. Evidently at least some of the arsine molecules can rotate at 20.5°K. with a difficulty which decreases rapidly with rising temperature, the variation of the dielectric constant with frequency having disappeared at 30.9°K., where the transition is still incomplete. Above 31.8°K. the acquisition of rotational freedom occurs almost as sharply as does the entire process in hydrogen chloride at its one transition. Although the thermodynamic behavior of solid hydrogen[17] requires molecular rotation and the specific heat–heat temperature curve for methane[18] shows the setting in of rotation at 20.4°K., no molecule other than these has been found to rotate at so low a temperature as that here found for arsine.

Application of the Grüneisen rule to the density value[19] 1.96 found for arsine at 103°K. gives the density at the melting point, which is used with the values in Table I to calculate a molar polarization 16.0 at 20.5°K., 19.1 at 33.7° and 15.3 at 151.2°. The apparent dipole moment calculated for the molecule from the variation of polarization with temperature in the region between 33.7 and 80°K. is 0.15×10^{-18}, indistinguishable from the value 0.16×10^{-18} obtained for the gas,[15] which would seem to indicate freedom of molecular rotation in this region comparable to that in the liquid state.

In the three groups of hydrides of which ammonia, water and hydrogen fluoride are the first members, the smallest molecule does not rotate in the cases of solid ammonia[2] and hydrogen fluoride[20] and rotates only with great difficulty in ice, probably because of hydrogen bonds between the molecules or, possibly, merely because the smallest molecules with their large dipole moments are surrounded by the strongest fields of force. The larger molecules of these three groups of hydrides show rotation which extends to lower temperature the smaller the dipole moment, arsine being the molecule of smallest moment. In the next group of hydrides, methane, the first member, having zero dipole moment and no possibility of hydrogen bond formation, rotates down to very low temperature.[18] It is evident that the moment of inertia of the molecule does not have the dominant effect in determining rotation or non-rotation that has been attributed to it at times. Monosilane[21] requires a temperature 43° higher to bring about molecular rotation than does methane, but this may be due to stronger intermolecular forces rather than to the larger moment of inertia of the molecule.

Of these hydrides which have been considered, all have cubic lattices in the regions of free molecular rotation except hydrogen iodide, which is tetragonal, its *a*- and *c*- axes differing by only 8%, and possibly monosilane which has not been determined. Since free rotation gives spherical symmetry to a molecule, it is natural that molecules possessing it form lattices corresponding to an arrangement of close-packed spheres, which is roughly approximated by the molecular arrangement in a liquid. It is not surprising, therefore, that the dielectric behavior of solid arsine above its lower transition could be roughly approximated by extrapolation of the curve for the liquid. Indeed, from a molecular point of view these solid

hydrides with rotating molecules differ little from liquids.

Summary

The dielectric constants and specific conductances of solid hydrogen cyanide and hydrogen selenide have been measured from liquid air temperature to the regions of the melting point and those of arsine have been measured from liquid hydrogen temperature to the region of the boiling point over a frequency range from 0.5 to 50 kilocycles. No molecular rotation is found in solid hydrogen cyanide while the molecule rotates freely in the selenide even at liquid air temperature. The arsine molecule rotates freely down to 32.1°K. where a transition sets in, which is not complete at 20.5°K. and is accompanied by some anomalous dispersion. The molecules of the hydrides tend to rotate more readily the smaller their dipole moments.

Thermal Data. VI. The Heats of Combustion and Free Energies of Seven Organic Compounds Containing Nitrogen

BY HUGH M. HUFFMAN, EMORY L. ELLIS AND SIDNEY W. FOX

In the first paper[1] of this series we presented heat capacity data for the following seven compounds, *d*-alanine, *l*-asparagine (anhydrous), *l*-asparagine monohydrate, *l*-aspartic acid, *d*-glutamic acid, creatine and creatinine. These data were used to calculate the entropies of the compounds, which were further utilized in conjunction with the heats of combustion and certain other auxiliary data to calculate the standard free energies of formation of these compounds.

Due to the general unreliability of the older combustion data appearing in the literature, we have redetermined this quantity for each of the seven compounds mentioned above. In so doing we have kept constantly before us the necessity of establishing the purity and the physical state of the compounds as well as the need for calorimetry of high precision and accuracy.

These new combustion data have been used in conjunction with the entropies obtained by Huffman and Borsook[1] and certain other auxiliary data to calculate new and more reliable free energy data for these compounds.

Calorimetric Method

The method and apparatus used have been described in previous communications.[2] No essential changes in method or apparatus have been made. All of the combustions were made in a Parr bomb having a volume of 0.380 liter with an initial oxygen pressure of 30 atm. and with 1 ml. of water in the bomb. The platinum wire technique[2a] was used exclusively. During the course of this investigation our resistance thermometer developed a short circuit. After repair the thermometer characteristics were found to have changed but upon recalibration identical results for the energy equivalent of the calorimeter were found. Numerous calibrations of the calorimeter have been made, at irregular intervals throughout the course of this investigation, with Bureau of Standards benzoic acid, samples 39d and 39e, having for its isothermal heat of combustion at 25.0° the value 26,419 international joules per gram true mass. We have used oxygen from several cylinders supplied by the "Linde Air Products Company" and at cylinder pressures varying from 1950 to 450 pounds. The precision of our calibration data has remained the same as that previously reported, namely, an extreme deviation from the mean of slightly more than 0.01%. The precision error calculated from the formula recommended by Rossini[3] was 0.005%.

In several cases we have found it necessary to use oil as an auxiliary substance. The combustion value of this oil has been controlled by occasional combustions and the value found was 10,830 ± 3 cal. per gram weighed in air. When the mass of the oil is determined by difference after adding it directly to the sample in the crucible an additional uncertainty is introduced when the material is hygroscopic. To avoid this uncertainty as well as to permit the addition of small quantities, the following method was adopted. The oil was kept in a small hypodermic syringe and the amount added was determined from the mass difference in this syringe.

Units and Corrections

The unit of energy used throughout this paper is the defined conventional calorie which is derived from the international joule by multiplying by the factor 1.0004/4.185. The method of calculation, the corrections and the symbols used are the same as those given by Stiehler and Huffman.[2b] The molecular weights are based on the 1935 table of atomic weights. In applying the correction for true mass

we have used approximate densities obtained from the mass and volume of the pelleted material when other data were not available in the literature. All of the thermal data are given for the isothermal process at 25°.

In some cases the combustion was incomplete, leaving a small residue of carbon in the crucible. The mass of this carbon was determined from the mass of the crucible before and after ignition and corrected for. In no case did this correction exceed 0.003%. Some of the preparations left a residue of ash in the crucible. When this was appreciable it was corrected for by arbitrarily subtracting the weight of the ash from the weight of the sample. In the extreme case this correction was about 0.03%.

Purity and Dryness of the Materials Used

We have followed the general methods of Stiehler and Huffman[2b] to assure ourselves of the purity and dryness of the combustion samples. As mentioned above we have made routine ash determinations on each sample burned. We have also made suitable analyses such as nitrogen determinations, titrations and measurement of the optical rotation. We have attempted, furthermore, to define accurately the physical state of the compounds by photomicrographs of their crystalline condition (Fig. 1) as well as by a precise description of the method of preparation.

Preparation, Purification and Heats of Combustion of the Compounds

***d*-Alanine.**—Combustions were made on two commercial samples of this material which were purified in the following manner.

(a) A material from an unknown source was twice crystallized from water[4] by dissolving in hot water and allowing the solution to cool and deposit crystals.

(d) A Hoffmann–LaRoche product was twice crystallized from water in the above manner.

Nitrogen determinations[5] on sample (a) gave the theoretical results. The ash content of (a) was less than 0.01% and that of (d) undetectable. The specific rotation of (d) has been reported by Huffman and Borsook.[1]

This compound was very troublesome to burn as it had a decided tendency to jump out of the crucible when partially burned. We have tried all of the tricks at our command to overcome this unfortunate tendency, such as varying the crucible weight, using large amounts of oil, increasing the oxygen pressure, etc., but with little success. In all five preparations of *d*-alanine were used and the three values given in the table are the usable results from fifteen attempted combustions. *d*-Alanine appears to exist in at least two crystal modifications (see Fig. 1). Since our combustions are on a single type we cannot be sure that these are polymorphous forms.

l-Asparagine Hydrate

Material from four different commercial sources was utilized to prepare eleven combustion samples.

(a) Merck *l*-asparagine, which had been recrystallized several times for heat capacity measurements, was subjected to three additional crystallizations by dissolving in boiling water and allowing crystals to form as the solution cooled.

(b) A preparation from Hoffmann–LaRoche was used without further purification.

(c) A portion of (b) was once crystallized from water by cooling the hot solution.

(d) A portion of (b) was twice crystallized from water as in (c).

(e) Material from Pfanstiehl was twice crystallized from water.

(f) Material from Eastman was twice crystallized from water.

(g) A sample from Merck recently purchased (1936) for this research was twice crystallized from water.

(h) A portion of (a) was converted to the copper salt, which was purified by one crystallization from a large volume of water. The copper was precipitated with hydrogen sulfide and the regenerated asparagine was further purified by several crystallizations from water.

(i) A portion of (e) was recrystallized by dissolving in hot water and seeding heavily with *l*-asparagine which had been dehydrated at 100°.

(j) A portion of (e) which had been dehydrated at 100° was rehydrated by allowing to stand several days covered with water at room temperature.

(k) A part of (a) was twice more crystallized from water.

The nitrogen content of (a) was the theoretical. Measurements of the rotation of samples (a) and (b) in HCl solutions with the ratio (HCl/asparagine hydrate) equal to 12.3 gave values for $(\alpha)^{20}\mathrm{D}$ of 30.3 and 27.9, respectively. The ash content of all of the samples with the exception of (a), (h) and (k) was undetectable. In sample (h), the worst case, it was less than 0.01%.

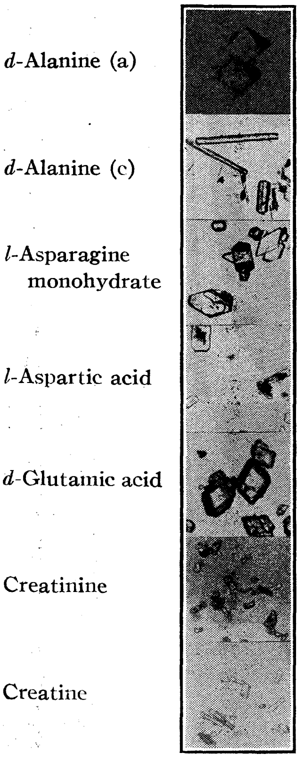

Fig. 1.

Numerous combustions on sample (a) dehydrated at 100° consistently gave results about five calories higher than the accepted value. For this reason preparations (h) and (k) were made. The result of one combustion on (k) agreed with those on (a) while the result of one combustion on (h) was about midway between those on (a) and the accepted value. Further attempts at purification were impossible because of lack of this material. When a new sample (g) was purchased from Merck it was found to yield values which agreed with the accepted result.

The combustions on anhydrous *l*-asparagine are further complicated by the fact that it appears to exist in two modi-

---

[4] Redistilled water for all of the purifications.

[5] All of the nitrogen determinations with the exception of that on creatine were by micro Kjeldahl.

fications.[5a] Several combustions on specimens of (a) and (b) which had been dehydrated in the vacuum oven at 65–70° gave results from 23 to 28 calories higher than those dehydrated at 100°. Furthermore, this difference tended to decrease with the heating time, indicating that the material was changing continuously into the stable form. As a test of this hypothesis we have included in the table the result of one combustion on a sample which had been heated for seventy-eight days at 65–70° followed by eighteen hours at 100°. This additional heating caused no change in the mass of the pellet but did cause the combustion value to drop about 28 calories (as determined by comparison with a sample whose history was identical except for treatment at 100°) to agree with that of other samples dehydrated at 100°. The removal of the water of hydration takes place so slowly at room temperature that we have not been able to obtain a completely anhydrous material in this manner. At elevated temperatures the fact that dehydration is accompanied by the transition to the stable form makes it impossible to obtain a reliable combustion value for the high temperature form. We believe, however, that it is probably about 30 calories higher than that of the stable modifications.

To see if this apparent dimorphism persisted in the hydrate two attempts were made to obtain a different crystal type, preparations (i) and (j). The results of the combustions of these two hydrated samples agreed perfectly with those on the hydrate obtained in the usual manner.

Where the hydrated asparagine has been burned the following method was resorted to. The crystalline material protected from contamination by dust particles was allowed to come to equilibrium in the air of the room. Pellets were made and also allowed to equilibrate with the air of the room before burning. At the time of burning, a pellet was also dehydrated at 100° and the amount of hydration determined. In the case of sample (i) the loss in mass corresponded to 99.68% hydrate, hence a suitable correction was applied for the amount of anhydrous material present. In the other cases the material was 100% hydrated within the error ±0.02% of the measurements. Due to the fact that it is impossible to be sure that the substance is free from adsorbed gases or water the mass determinations in this case are probably less reliable than in the other cases.

***l*-Aspartic Acid.**—Material from two commercial sources was treated in the following manner to make three combustion samples.

(a) An Eastman product which had been subjected to seven recrystallizations for use in heat capacity measurements[1] was recrystallized three more times from water by dissolving in hot water and allowing the solution to cool.

(b) A portion of (a) was subjected to two additional crystallizations from water in the same manner.

(c) Material obtained from Hoffmann–LaRoche was once crystallized from water.

The nitrogen content of (a) was found to be theoretical. The rotation of the original material of sample (a) has been given in a previous communication.[1] The ash content of each of the preparations was less than 0.01%.

In addition to the values given in the table combustions on samples of (b) and (c) which had been dried for several days at 100° gave values about 2.5 calories higher than the mean value reported. These pellets showed signs of decomposition and hence the results have been discarded.

***d*-Glutamic Acid.**—A commercial sample from Pfanstiehl and a preparation made from Ajinomoto by the method of Schmidt and Foster[6] were the starting materials for the preparation of five combustion samples.

(a) A large amount of *d*-glutamic acid had been prepared from Ajinomoto and carefully purified for heat capacity measurements.[1] A portion of this material was subjected to two fractional crystallizations from water by solution at 100° and subsequent rapid cooling to zero degrees. This material was discarded when found to contain glass from the sintered glass filters used.

(b) A sample of Pfanstiehl *d*-glutamic acid was subjected to five crystallizations under the same conditions as (a).

(c) The same original material as used in preparation (a) was three times crystallized from water by dissolving at 75° and subsequent cooling rapidly to zero degrees.

(d) A portion of sample (a) was once more crystallized from water by dissolving at 100° and rapidly cooling.

(e) A portion of sample (b) was dissolved in water at 60° and rapidly cooled.

The nitrogen content of samples (a), (b) and (c) was found to be theoretical. The ash content of all of the above samples was negligible. The optical rotation of the original material for (a) has been reported previously.[1]

In addition to the values given in the table, several combustions were made on material dried at 100°. These samples were discolored and the combustion values increased with the time of heating.

Creatine (Anhydrous).—Two commercial products were utilized to prepare three different combustion samples.

(a) Eastman creatine was twice crystallized from water by dissolving in boiling water and cooling the solution.

(b) Creatine from Hoffmann–LaRoche was twice crystallized from water as above.

(d) A portion of sample (a) was dissolved in boiling water and crystallization started by seeding with anhydrous creatine which had been dehydrated at 100°.

The nitrogen content was theoretical and the ash content negligible. It was necessary to use oil to initiate the combustion.

During the course of this investigation of anhydrous creatine we have again found evidence of dimorphism. As in the case of *l*-asparagine different values were obtained for the anhydrous material depending merely on its heat treatment. Thus creatine (samples (a) and (b)) which was crystallized in the usual manner and heated to 100° for dehydrating has a lower combustion value by about five calories than that which has been dehydrated at room temperature. We have included two values obtained on sample (d), dehydrated at room temperature, which agree with combustions on the other samples dehydrated at 100°. We are investigating this phenomenon further and will make a report in a future publication.

These phenomena in the case of *l*-asparagine and creatine serve again to emphasize the necessity for a positive definition of the physical state when reporting physical properties.

[5a] Since submitting this article for publication, the existence of the two polymorphic forms of anhydrous asparagine has been confirmed by x-ray pictures, which were taken for us by Mr. G. Albrecht working in Professor Pauling's laboratory.

(6) Schmidt and Foster, *J. Exptl. Biol. Med.*, **18**, 205 (1920–21).

Creatinine.—Materials from two commercial sources were utilized to prepare four combustion samples.

(a) A sample of Pfanstiehl creatinine purchased in 1931 and extensively purified for heat capacity measurements[1] was dissolved in water at 65° and precipitated with purified acetone according to the method of Edgar and Hinegardner.[7]

(b) A portion of the starting material in (a) was converted to the hydrochloride and neutralized with ammonia according to Edgar and Hinegardner's[7] methods (a) and (b). It was finally washed with ammonia and ethyl alcohol.

(c) A sample from Eastman was dissolved in water and precipitated with acetone as in (a).

(d) A sample of Pfanstiehl creatinine especially purchased for this research (1936) was dissolved in boiling water and immediately placed in an ice-bath to crystallize. The crystals were slightly greenish. This material was again dissolved in hot water and treated with norite. The crystals from the above were again dissolved in hot water and allowed to cool and crystallize.

Nitrogen determinations on (a) gave theoretical values. Sample (c) was found to have a high ash content 0.02–0.03% while that of samples (a) and (d) was negligible. In view of the uncertainty introduced into the combustion values of (c) by the high ash content we have reported the weights only to the nearest 0.1 mg. Sample (b) was discolored and gave low combustion values, hence it was discarded.

Since most of these compounds are more or less hygroscopic the following method was adopted for an accurate determination of the mass. The pelleted samples were kept in open weighing bottles during the desiccation process, after which they were stoppered immediately and kept over phosphorus pentoxide in a desiccator until time for their combustion. The bottle was then transferred to the balance case and allowed to equilibrate for a short time. The bottle plus pellet was weighed and the pellet transferred to the crucible and the empty bottle weighed. As a check on the weight thus obtained the weight was also determined by weighing the crucible plus the pellet.

When these materials were hygroscopic it was observed that the pellet usually gained weight rapidly when first exposed to the air, the rate falling off with time and approaching a steady state. There is of course the possibility that the reaction between the material and water may appreciably change the energy content of the sample. In the case of creatinine we have investigated this possibility by burning a sample in the bomb without having any water present. The sample was transferred as rapidly as possible to the bomb and then evacuated for some time before admitting oxygen which had been passed over drierite. This combustion when corrected in a suitable manner for the initial absence of water agreed exactly with the rest of the combustions in that series. There is some uncertainty in the corrections to be applied as we found that the oxygen still contained a small and unknown amount of water vapor. For this reason we have not included this value in the table but feel that it shows that creatinine values are not appreciably affected by sorbed water.

The use of oil as an auxiliary substance serves also to give at least partial protection against sorption of water. Our feeling is that any energy effect due to this phenomenon is well within the experimental error.

There is, furthermore, the possibility that oil may react with the materials in such a manner as to affect the energy content. In the cases where we have used oil we have either varied the amount of oil or have made combustions in which no oil was used. The results show that this effect if present is negligible.

The experimental results of the combustion on these seven compounds are given in Table I. We have utilized the experimental values to calculate certain other useful data. These appear in Table II along with some auxiliary data which have been used. Finally we have utilized these new values for ΔH_f^0 in conjunction with the entropy data of Huffman and Borsook[1] to calculate new and more reliable values for the free energies of formation. We have used the same values for the entropies of the elements and the heats of formation of water and carbon dioxide as were used by Stiehler and Huffman.[2b]

Discussion of the Results

As in the previous papers in this series we have chosen as our limits of error the extreme deviation from the mean of the experimental results in each case and have also allowed for an additional uncertainty of 10% in the Washburn correction. We have taken numerous precautions to assure ourselves of the purity, dryness and physical state of these compounds so that we feel that absolute errors due to these factors have been largely eliminated. We have not assigned any limits of error to the heats or free energies of formation of these compounds, due to uncertainties in the accuracy of certain of the auxiliary data required. We have included photomicrographs of the crystalline compounds which were burned. In the case where the original material was hydrated, the physical state of the anhydrous material must be defined by the method of dehydration.

All of these compounds have been burned by earlier workers. Wrede[8] has burned *d*-alanine, Fischer and Wrede[9] have burned *l*-aspartic acid and *d*-glutamic acid, Emory and Benedict[10] have burned all of the compounds except anhydrous *l*-asparagine. Stohmann and Langbein[11] have burned anhydrous *l*-asparagine and anhydrous creatine.

With the exception of Wrede[8] none of the above authors include sufficient data for correcting their values in terms of newer thermochemical standards. We have, however, made approximate

In a recent paper Zittle and Schmidt[12] report the heat of hydration of anhydrous *l*-asparagine as 2250 ± 200 calories. This compares favorably with the value of 2680 ± 330 calories as calculated from our combustion data on these two compounds. They do not state how the anhydrous material was obtained but it was very probably by treatment at 100° or above.

Summary

1. The experimental values of the heats of combustion at constant volume and at 25° of seven organic compounds are given.

2. From the experimental values the heat of combustion at constant pressure and the heat of formation have been calculated.

3. These new values for heats of formation have been used with existing entropy data to calculate more reliable free energy data.

Coördination Compounds of Platinous Halides with Unsaturated (Ethylene) Substances

BY M. S. KHARASCH AND T. A. ASHFORD[1]

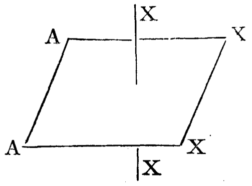
Introduction

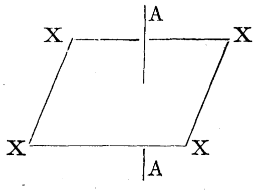
Platinum is an unusually versatile element. It has primary valences of two and four, and it forms two series of coördination compounds with both organic and inorganic substances. In these the metal exhibits the coördination numbers of four and six, respectively. Stereoisomers have been obtained in both series. Where the coördination number is six, the accepted view is that the valence bonds of the platinum atom are directed toward the corners of an octahedron; giving rise to the following two stereoisomeric configurations for compounds of the type PtX_4A_2.[2] Some compounds of the type PtX_2A_2 also exist in two stereoisomeric forms: *cis* and *trans*[2] (p. 338).

---

[1] This communication is an abstract of a dissertation submitted by T. A. Ashford in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Chicago.

[2] Werner, "Lehrbuch der Stereochemie," Gustave Fischer, Jena, 1904, p. 350.





Furthermore, Reihlen and Hühn[3] report that they have resolved into optical antipodes platinum compounds of coördination number four. It is still an unsettled question whether the configuration of these compounds is planar, tetrahedral or pyramidal.[4]

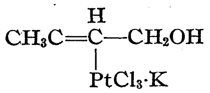
Several classes of coördination compounds of platinum, notably those with ammonia and with the amines, have been studied extensively. However, two important classes, namely, those with unsaturated substances and those with nitriles, have received scant attention because of the lack of satisfactory methods for preparing these complexes.

In the work reported in this paper a particularly simple general method has been developed for the preparation of organo-platinum complexes with unsaturated compounds. This method has been used to prepare a large number of compounds, the properties of which are herein described.

Previous Work

The literature contains references to complex salts of the type $K(Un\cdot PtX_3)$, in which Un is an unsaturated molecule containing an ethylene bond. The first compound of this series was obtained by Zeise,[5] who isolated a substance with the empirical formula $K(C_2H_4\cdot PtCl_3)\cdot H_2O$, from a reaction mixture of chloroplatinic acid and alcohol. Birnbaum[6] prepared similar compounds with propylene and amylene, and Chojnacki[7] obtained $K(C_2H_4\cdot PtBr_3)$, with platinic bromide.

Biilmann and his collaborators[8] have extended the work to unsaturated substances other than hydrocarbons, and they have prepared compounds with unsaturated alcohols, acids and aldehydes. Pfeiffer and Hoyer[9] have prepared similar substances from allyl alcohol, allyl acetate, crotyl alcohol and crotyl aldehyde. The latter workers consider that in these compounds the platinum atom is coördinately bound directly to the carbon atom by a single bond; they propose the following structure.



$$CH_3C{=}\overset{H}{\underset{PtCl_3\cdot K}{C}}{-}CH_2OH$$

This structure indicates that the compounds are derivatives of the metallic chloroplatinates, in which a chloride ion has been replaced by an unsaturated molecule. There is, however, no experimental evidence that the substances are monomolecular.

The series from which the compounds discussed above are derived is obviously $Un\cdot PtX_2$. As will be shown later, however, substances of this type are bimolecular and should be written $(Un\cdot PtX_2)_2$. Recently, Anderson[10] obtained $(C_2H_4PtCl_2)_2$ by refluxing ethyl alcohol with sodium chloroplatinate. This reaction is very complex, presumably involving at least four steps. Preliminary attempts to extend this method to other alcohols have not as yet proved successful.

General Method of Preparation

The most direct method for preparing a compound of the type $(Un\cdot PtCl_2)_2$ or $(Un\cdot PtBr_2)_2$ would be to combine a platinous halide with an unsaturated compound. However, attempts to apply this method have given unsatisfactory results. Platinous halides are very insoluble and inert substances; consequently platinic halides have been used.

The general method here described departs radically from that of Anderson since anhydrous platinic chloride or bromide in an anhydrous solvent is used instead of the metallic haloplatinates. It differs further in that the unsaturated compounds are used instead of the alcohols. The method is rapid as well as general. The reaction is complete in about an hour.

Although the reaction, as outlined above, and described in more detail in the experimental part, appears simple, it is probably more complex than might at first be supposed. Hydrogen halide is usually evolved during the reaction, and in some instances a small quantity of platinum separates. Halogenation of the unsaturated compound also has been demonstrated.

Physical and Chemical Properties

The coördination compounds $(Un\cdot PtCl_2)_2$ are well-defined crystalline substances. When heated

(10) Anderson, *J. Chem. Soc.*, 971 (1934).

in a melting-point tube they do not melt sharply, but darken over a range of several degrees. They vary widely in stability. The greatest difference has been observed between the compounds obtained from *trans*-dichloroethylene and from dipentene. The former decomposes in a few days; the latter appears unchanged even after standing in the air for ten months.

The compounds are in general soluble in acetone, chloroform and alcohol; they are less soluble in benzene, and difficultly soluble or insoluble in glacial acetic acid. Those of low molecular weight are soluble in sodium chloride solution, presumably forming compounds analogous to Zeise's salt

$$[(CH_3)_2C{=}CH_2{\cdot}PtCl_2]_2 + 2NaCl \longrightarrow 2Na(CH_3)_2C{=}CH_2{\cdot}PtCl_3$$

When treated with pyridine the substances decompose, liberating the olefin and forming the pyridine platinous chloride.

$$[Un{\cdot}PtCl_2]_2 + 4C_5H_5N \longrightarrow 2Un + 2(C_5H_5N)_2{\cdot}PtCl_2$$

Concentrated hydrochloric acid decomposes them.

$$Un{\cdot}PtCl_2]_2 + 4HCl \longrightarrow 2Un + 2H_2PtCl_4$$

Bromine also decomposes these substances, forming the platinum halides and the bromine addition product of the unsaturated compound.

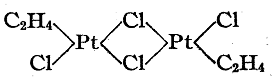
Molecular Weight

The coördination compounds of the series $(Un{\cdot}PtCl_2)_2$ are unstable at higher temperatures; consequently the ebullioscopic method for the determination of their molecular weights is inapplicable. For the same reason the Rast method cannot be used. With the exception of the compound obtained from isobutylene, these substances are also sparingly soluble in benzene. However, the depression of the freezing point of benzene by isobutylene platinous dichloride indicates that the substance is bimolecular, $[(CH_3)_2C{=}CH_2{\cdot}PtCl_2]_2$, and no doubt the other compounds of the same series are likewise.[11]

Structure of the Compounds of the Type $[(Un{\cdot}PtCl_2)]_2$

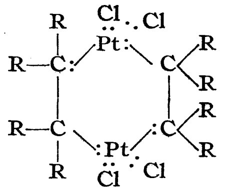
That these compounds are derivatives of platinous chloride seems fairly well established. Their analyses as well as their reactions with pyridine, with concentrated hydrochloric acid, and with bromine point to this conclusion. Furthermore, the compound prepared from dipentene and platinic chloride is the same as the one obtained by treating dipentene with platinous chloride in the presence of dry hydrogen chloride.

Anderson[10] has proposed for ethylene platinous chloride the formula

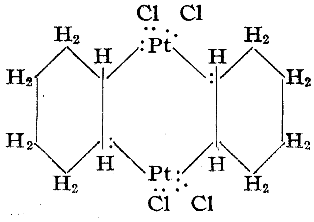


Against this formula, however, may be raised the serious objection that it makes a chlorine atom form two coördination bonds.

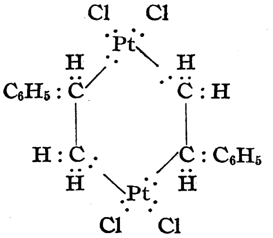
Consideration of the electron arrangement in the substance aids in deriving a structure. The general electronic configuration here proposed for all compounds of the type $(Un{\cdot}PtCl_2)_2$



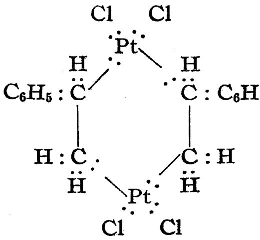
is specifically exemplified in the following formula for cyclohexene platinous chloride



When monosubstituted ethylenes are used, there is a possibility of structural isomerism. For instance, the compound derived from styrene might have either of the two structures shown by the formulas



and



It is interesting to note that each of these structural isomers contains two asymmetric carbon atoms, and can exist in three stereoisomeric forms. With more complex substituted ethylenes, the number of isomers becomes still greater. Further study of these substances is contemplated.

---

[11] Anderson[10] has estimated the molecular weight of ethylene platinous chloride by the Barger–Rast method, and his results point to a bimolecular form.

Applicability of the Method

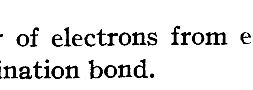
The method described above has been used to prepare coördination compounds from the following unsaturated substances: cyclohexene, dipentene, pinene, ethylene, isobutylene, styrene, stilbene and *trans*-dichloroethylene. No crystalline coördination compounds could be isolated from the following substances: allyl chloride, allyl bromide, allylbenzene, vinyl bromide, tridecene, isostilbene and *cis*-dichloroethylene. The latter substances react with the platinic chloride to give red solutions but no crystals separate. In all these cases red gums are obtained.

It is interesting that crystalline compounds have been isolated from *trans*-dichloroethylene and from *trans*-diphenylethylene, whereas all attempts to obtain crystalline substances from their *cis*-isomers have failed. It would be desirable to extend the work to other pairs of *cis–trans* stereoisomers, to determine how general this relation is. In this connection it should be noted that from cyclohexene, dipentene and pinene (which are *cis* compounds) crystalline substances have been isolated.

The method does not seem to be applicable to unsaturated acids and their esters. All attempts to prepare compounds with maleic anhydride, maleic and fumaric acids and their ethyl esters, and with cinnamic ester have failed. These substances do not appear to react at all with platinic chloride.

Coördination Compound of Platinic Chloride with Azobenzene

It might be expected that azo compounds which contain a double bond between two nitrogen atoms would form coördination compounds similar to those obtained from the olefins. However, the compound obtained from the interaction of platinic chloride and azobenzene has the empirical formula $(C_6H_5N{=}NC_6H_5)_2PtCl_4$. This compound is analogous to the coördination compounds of the type $(RCN)_2PtCl_4$ obtained from platinic chloride and nitriles. It appears that the azo group is equivalent to a nitrile group. For this compound the following formula is proposed



$$\begin{array}{c} \cdot\cdot\,\mathrm{Cl}\ \ \mathrm{Cl}\,\cdot\cdot \\ C_6H_5:\ddot{N}\ \ \ddot{N}:C_6H_5 \\ :\mathrm{Pt}: \\ C_6H_5:\ddot{N}\ \ \ddot{N}:C_6H_5 \\ \cdot\cdot\,\mathrm{Cl}\ \ \mathrm{Cl}\,\cdot\cdot \end{array}$$

Here one pair of electrons from each azo group forms a coördination bond.

Experimental Part

Preparation of Anhydrous Platinic Chloride.—Anhydrous platinic chloride is prepared by a modification of the method of Rosenheim and Löwenstamm.[12] Chloroplatinic acid is prepared by the usual method. The acid melts at about 60° and still contains six molecules of water of crystallization. The melted acid is poured into a porcelain boat and the boat with its contents is placed in a glass tube contained in an electric furnace. A slow current of dry chlorine is passed through the apparatus. The temperature is raised gradually to 275° in the course of two hours; it is kept there for one-half hour and then is allowed to fall gradually. When the apparatus has cooled to about 150°, the boat is removed and the contents are pulverized while hot in an agate mortar. The powdered substance is again placed in the furnace in an atmosphere of chlorine at 275° for one-half hour. It is then allowed to cool and is placed in a glass-stoppered bottle in a desiccator over concentrated sulfuric acid.

Anal. Calcd. for $PtCl_4$: Pt, 57.9. Found: Pt, 57.7.

Platinic chloride thus prepared is a very hygroscopic red-brown substance. It is slightly soluble in nitrobenzene, glacial acetic acid and alcohol, very slightly soluble in chloroform and ether, and insoluble in benzene and in toluene.

Preparation of Platinous Chloride.—Platinous chloride is prepared by a modification of the method of Berzelius.[13] Pure chloroplatinic acid is heated over a free flame to about 150°. The resulting solid is placed in a boat, and the boat with its contents is placed inside the furnace. The temperature is raised to 360–380° for about two hours, while a slow current of air is passed through the apparatus. The greenish solid is then pulverized and is again placed in the furnace at 360° for about one hour. After cooling, the solid is boiled with water containing a few drops of hydrochloric acid to remove any unchanged platinic chloride. The platinous chloride, which is insoluble, is washed twice by decantation and again placed in the furnace at 360° for one-half hour.

Anal. Calcd. for $PtCl_2$: Pt, 73.4. Found: Pt, 73.2.

Platinous chloride is a greenish-gray solid. It is insoluble in benzene, chloroform, glacial acetic acid and alcohol.

General Method of Preparation of Complexes

The most direct method for preparing a compound of the type $(Un{\cdot}PtCl_2)_2$ or $(Un{\cdot}PtBr_2)$ would be to combine a platinous halide with an unsaturated compound. However, attempts to apply this method have given unsatisfactory results. Platinous halides are very insoluble and inert substances; consequently platinic halides have been used.

To prepare the chlorides 0.5 g. of platinic chloride is suspended in 10 cc. of glacial acetic acid and 0.5 cc. (about 2–4 moles) of the unsaturated hydrocarbon is added (in the case of pinene 1 cc. is added). The mixture is warmed in the steam-bath for about ten minutes. During this period the platinic chloride goes into solution and the reaction is completed. Crystals of the chloride

---

[12] Rosenheim and Löwenstamm, *Z. anorg. Chem.*, **37**, 403 (1903).

[13] Berzelius, *Schweigger's J.*, **7**, 55 (1813).

separate out from the filtrate with or without cooling and these are collected and washed with additional portions of the solvent. In the case of *cyclohexene* 1 g. of the chloride is triturated with 0.25 g. (1 mole) of the hydrocarbon in 15 cc. of glacial acetic acid and after a few minutes 1 cc. (3 moles) more of the cyclohexene is added, considerable heat being evolved and the reaction going to completion.

In the case of *stilbene* 0.25 g. of the hydrocarbon also is first added and the mixture is heated on the steam-bath, the platinic chloride being completely dissolved in about fifteen minutes to form a red solution. After filtration an additional 0.5 g. (2 moles) of stilbene is added.

Platinic bromide can also be used in place of the chloride and it has the advantage of being more soluble in glacial acetic acid. In the case of *cyclohexene* 0.2 g. of the bromide is dissolved in 5 cc. of glacial acetic acid and 1 cc. of cyclohexene is added. In a few minutes the deep red solution becomes pale orange and long needles separate.

In the case of *styrene* 2 cc. of the hydrocarbon is added to 0.5 g. of the bromide in 10 cc. of glacial acetic acid.

Preparation of Ethylene Platinous Chloride ($(C_2H_4 \cdot PtCl_2)_2$).—About 1 g. of platinic chloride is suspended in about 25 cc. of anhydrous benzene. The suspension is kept at 70° for about one hour, while ethylene from a cylinder is bubbled through it. After standing at room temperature for twenty-four hours, the reaction mixture is again warmed to 70° and treated with ethylene. During these operations most of the platinic chloride goes into solution, and at the same time a considerable quantity of hydrogen chloride is evolved. The hot solution is filtered, and from the filtrate, upon cooling, orange crystals separate. They are crystallized from benzene.

This compound is identical with the one prepared by Anderson[10] by refluxing absolute alcohol with sodium chloroplatinate.

Preparation of Isobutylene Platinous Chloride $[(CH_3)_2C{=}CH_2 \cdot PtCl_2]_2$.—About 0.5 g. of platinic chloride is suspended in 10 cc. of glacial acetic acid and the mixture is warmed to 50°. Isobutylene, prepared by heating *t*-butyl alcohol with oxalic acid, is then bubbled through the suspension. In the course of a few minutes the platinic chloride dissolves, giving a red solution. The solution is filtered. As more isobutylene is bubbled through the filtrate orange crystals separate. The crystals are washed with glacial acetic acid.

Molecular Weight.—The solubility of this compound in benzene permits an accurate determination of its molecular weight. The compound is found to be bimolecular: solute, 0.1330, 0.2406, 0.2406 g.; solvent, 8.742, 8.742, 17.484 g.; average depression, 0.119, 0.223, 0.107°. Calcd. for $(C_4H_8 \cdot PtCl_2)_2$: mol. wt., 644.4. Found: mol. wt., 654, 633, 658.

Reaction of Stilbene Platinous Chloride with Pyridine.—About 0.2 g. of stilbene platinous chloride is dissolved in 2 cc. of chloroform and 10 drops of pyridine added. A yellowish precipitate, presumably pyridine platinous chloride, separates. About 25 cc. of petroleum ether is added, and the filtrate is evaporated to dryness. A crystalline substance melting at 125° is obtained. A mixture of this substance with stilbene also melts at 125°. The reaction evidently proceeds according to the equation

$$(C_6H_5CH{=}CHC_6H_5PtCl_2)_2 + 4C_5H_5N \longrightarrow 2C_6H_5CH{=}CHC_6H_5 + 2(C_5H_5N)_2PtCl_2$$

Reaction of Stilbene Platinous Chloride with Concentrated Hydrochloric Acid.—About 0.1 g. of stilbene platinous chloride is dissolved in 10 cc. of benzene, and 20 cc. of concentrated hydrochloric acid is added. After shaking for about one hour the mixture is allowed to stand overnight. The benzene layer becomes colorless, while the aqueous layer becomes orange. The benzene layer upon evaporation gives colorless crystals, melting at 125°. A mixture of these crystals with stilbene also melts at 125°. The aqueous layer upon evaporation at 100° gives platinous chloride.

Reaction of Stilbene Platinous Chloride with Bromine.—About 0.3 g. of stilbene platinous chloride is dissolved in 20 cc. of chloroform and an excess of bromine in carbon tetrachloride is added. The solution is then evaporated under reduced pressure. The red mass is extracted with petroleum ether, and the solution after filtering is evaporated to dryness. The solid that is obtained and also a mixture with stilbene dibromide melts at 237°. The residue from the extraction is soluble in water, consisting presumably of platinic chloride and platinic bromide.

Cis-Phenylethylene; Isostilbene.—This substance is prepared by hydrogenation of tolane in methyl alcohol solution in the presence of platinum catalyst, until the theoretical amount of hydrogen is absorbed. Upon evaporation of the solvent an oil is obtained. This oil is dissolved in light petroleum ether (b. p. 30–35°), and placed in acetone–carbon dioxide mixture to precipitate any unchanged tolane. The cold solution is then filtered and the filtrate is evaporated, leaving the pure substance in the form of an oil.

All attempts to prepare crystalline coördination compounds with isostilbene have failed. Nitrobenzene, benzene, chloroform and glacial acetic acid have been used as solvents, and the temperature as well as the time of heating have been varied. In all cases the platinic chloride goes into solution while hydrogen chloride is evolved. Under all conditions red gums have been obtained.

Preparation of Trans-Dichloroethylene Platinous Chloride, *trans*-$(C_2H_2Cl_2 \cdot PtCl_2)_2$.—About 0.5 g. of platinic chloride is suspended in 10 cc. of benzene, and 1 cc. of *trans*-dichloroethylene is added. The mixture is warmed to 40–50° for about three hours, during which most of the platinic chloride goes into solution and at the same time a considerable quantity of hydrogen chloride gas is evolved. The reaction mixture is then heated to the boiling point of benzene and filtered. From the filtrate amber crystals separate on cooling.

Cis-Dichloroethylene.—Several attempts to isolate a crystalline compound with *cis*-dichloroethylene have failed. As in the case of *cis*-diphenylethylene gums have been obtained.

Preparation of Di-azobenzene Platinic Chloride $(C_6H_5N{=}NC_6H_5)_2 \cdot PtCl_4$.—About 0.5 g. of platinic chloride is suspended in 10 cc. of glacial acetic acid, a gram of azobenzene added to the mixture and the whole warmed on a steam-bath. After about one hour the platinic chloride goes into solution and at the same time a brick-red solid separates. The compound is purified by washing successively with glacial acetic acid, benzene and petroleum ether.

Anal. Calcd. for $(C_6H_5N{=}NC_6H_5)_2 \cdot PtCl_4$: Pt, 27.84. Found: Pt, 27.5, 27.6.

Summary

1. It has been shown that anhydrous platinic halides react with ethylenic substances to give coördination compounds of the type $(Un \cdot PtX_2)_2$.

2. The behavior of these coördination compounds with various reagents has been described.

3. A ring formula has been proposed for the coördination compounds.

[Contribution from the Chemical Laboratory of Harvard University]

The Orientation of *p*-Methoxydiphenyl in the Friedel and Crafts Reaction

By L. F. Fieser and Charles K. Bradsher

In the course of certain synthetic work the occasion arose to investigate the condensation of *p*-methoxydiphenyl with succinic anhydride in the presence of aluminum chloride, and it was found that the reaction proceeds smoothly in nitrobenzene solution, giving a mixture of two isomers. As the higher melting keto acid forms a sparingly soluble sodium salt by means of which it can be removed from the mixture, a separation is easily accomplished. It was found that about two-thirds of the substitution occurs in the para position of the unsubstituted ring (I) and the remainder ortho to the methoxyl group (II). In establishing the structures the keto acids were first oxidized, best with permanganate in the case of I and with hypobromite for II, to the methoxydiphenyl carboxylic acids III and IV. The hydroxy acids obtained on demethylation corresponded in melting point to substances described in the patent literature, 4-hydroxy-4′-carboxydiphenyl having been obtained through the nitro derivative of the 4-carboxylic acid[1] and 3-carboxy-4-hydroxydiphenyl from the 4-hydroxy compound through the aldehyde[2] and by the Kolbe reaction.[3] In order to establish the structures completely exhaustive oxidations were conducted on the phenol III and the keto acid II. These yielded terephthalic acid and benzoic acid, respectively, in accordance with the formulation.

It was of interest to see whether the solvent in the Friedel and Crafts reaction plays any part in determining the ratio of homo- and hetero-nuclear substitution products, and as the condensation of *p*-methoxydiphenyl with succinic anhy-

---

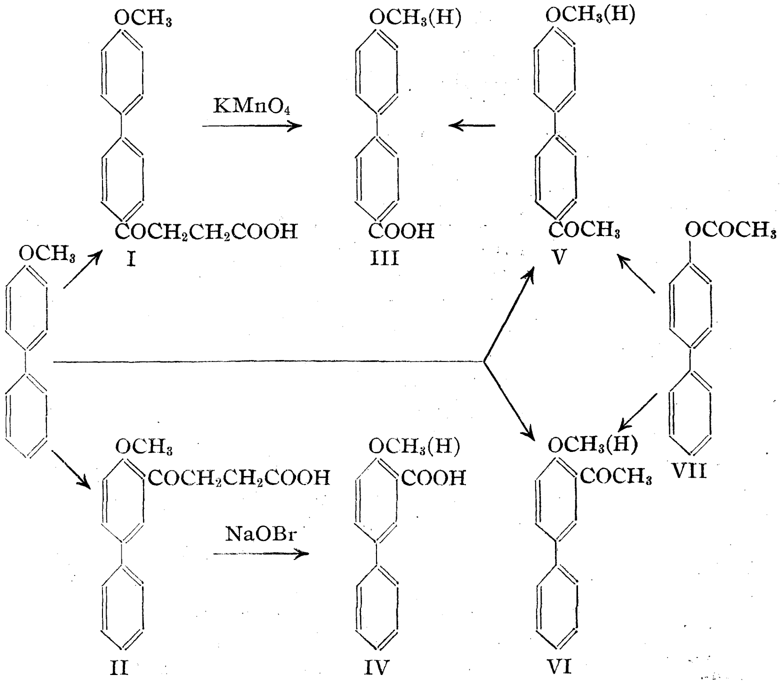
(2) American Patent 1,839,526.

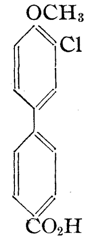
(3) American Patent 1,941,207.



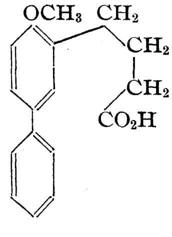
dride did not proceed satisfactorily in solvents other than nitrobenzene the reaction with acetyl chloride was investigated for this purpose. Two isomers were invariably obtained and there was no appreciable difference in the results using nitrobenzene, tetrachloroethane or carbon bisulfide. The isomer formed in larger amounts and having the higher melting point was found to be 4′-aceto-4-methoxydiphenyl (V) for it yielded III (ether) on oxidation with permanganate. In analogy with the above results the second product, isolated from the mother liquor as the semicarbazone, is very probably VI. With the two aceto compounds available it was of interest to investigate the Fries rearrangement of the acetate of *p*-hydroxydiphenyl (VII), for although Blicke and Weinkauff[4] studied the rearrangement of the benzoate they did not establish rigorously the structure of the sole reaction product isolated. In the present case it was found that the acetyl group migrates to both the *o*- and the *p*′-positions.

In general *p*-methoxydiphenyl resembles β-methoxynaphthalene in giving rise to Friedel and Crafts substitutions both ortho to the methoxyl group and at the most remote position of the second nucleus.

An additional observation worthy of note is that on oxidizing β-(4-methoxy-4′-xenoyl)-propionic acid (I) with sodium hypochlorite the product, separated from excess reagent as the sodium salt, was found to contain chlorine. The structure VIII was established by the preparation of the acid from the known[5] 3-chloro-4-methoxydiphenyl by condensation with acetyl chloride and permanganate oxidation. In this Friedel and Crafts reaction the unsubstituted ring alone appears to be attacked. The corresponding 3-bromo compounds also were prepared. Another interesting observation is that all attempts to cyclize the butyric acid derivative IX with sulfuric acid or through the acid chloride were unsuccessful. The ester of IX was also converted into the oxalyl derivative and submitted to the Bougault reaction with sulfuric acid, but a ring closure was not achieved. This evidently constitutes an additional case of the inhibitory influence on cyclizations often exerted by a *m*-methoxyl group.[6]



VIII



IX

Experimental Part

Condensation of *p*-Methoxydiphenyl with Succinic Anhydride.—A solution of 50 g. of the ether and 29.9 g. of succinic anhydride in 500 cc. of nitrobenzene was cooled in an ice-bath and 67.5 g. of aluminum chloride was added in small portions with stirring. The mixture was stirred cold for six hours and at room temperature for an equal period and then treated with ice and acid and the solvent removed with steam. The solid residue was dissolved in 1.5 liters of water containing 40 g. of sodium carbonate and after clarifying the hot solution with Norite and cooling to 0° the sodium salt of **β-(4-methoxy-4′-xenoyl)-propionic acid** (I) separated as a curdy precipitate. The collected salt was suspended in hot water and acidified, giving a light gray precipitate of the free acid, m. p. 192–195°, yield 18.9 g. (24.5%). Crystallized from acetic acid in which it

is moderately soluble, the acid forms colorless plates or needles melting at 200–201° with slight darkening in contact with the glass.

The mother liquor remaining after removal of the salt was treated at the boiling point with sodium chloride until nearly saturated, and on cooling the sodium salt of **β-(4-methoxy-3-xenoyl)-propionic acid** (II) separated in a crystalline condition. The free acid precipitated from a clarified solution was nearly pure, m. p. 147–148°, yield 46.5 g. (60%). It is much more soluble than the isomer and forms small needles from ether and a microcrystalline powder from alcohol, m. p. (camphor-like) 155°, clear.

Anal. Calcd. for $C_{17}H_{16}O_4$: C, 71.81; H, 5.67. Found: (I) C, 72.02; H, 5.63; (II) C, 72.05; H, 5.90.

The methyl ester of I, microcrystals from dilute acetic acid, has a camphor-like melting point, liquefaction beginning at 99° and the crystal skeleton disappearing at 110°. **The methyl ester of II** forms small plates from ether–petroleum ether, m. p. 48–49°.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.46; H, 6.09. Found: (I-ester) C, 72.31; H, 5.93; (II-ester) C, 72.12; H, 6.06.

Clemmensen Reduction.—The keto acids I and II were reduced in the form of the methyl esters (crude) by the ordinary Clemmensen procedure and the resulting acids were conveniently purified by salting out the sodium salts from the alkaline solutions. **γ-(4-Methoxy-4′-xenyl)-butyric acid,** obtained in a small-scale experiment in 20% yield, formed microcrystals from dilute alcohol, m. p. 148–149° with previous softening. **γ-(4-Methoxy-3-xenyl)-butyric acid** (IX) formed long, colorless needles from dilute alcohol, m. p. (camphor-like) 109°; yield 54–58%.

Anal. Calcd. for $C_{17}H_{18}O_3$: C, 75.56; H, 6.72. Found: (4′-isomer) C, 75.62; H, 6.64; (3-isomer) C, 75.69; H, 6.49.

The acid IX was either sulfonated or unattacked in attempted cyclizations with sulfuric acid of various strengths, and the acid chloride seemed either not to react or to yield polymeric products when treated with condensing agents. Polymerization seemed to occur also in the Bougault condensation of the oxalyl derivative of the ethyl ester, prepared and treated in the usual way.[7]

Oxidation to Methoxydiphenyl Carboxylic Acids.—The keto acid I (2.5 g.) was best oxidized in a solution of potassium hydroxide (2.5 g.) and water (200 cc.) with potassium permanganate (6.6 g.) at the temperature of the steam-bath. The precipitated dioxide was dissolved, after cooling, with sulfur dioxide and the solution was acidified and heated to coagulate the **4-methoxy-4′-carboxydiphenyl** (III) which separated; yield 1.5 g. This formed a microcrystalline powder from glacial acetic acid, m. p. 248–249°.

For the preparation of **3-carboxy-4-methoxydiphenyl** (IV) a solution of 5 g. of the keto acid II and 14 g. of sodium hydroxide in 200 cc. of water was treated at 10° with 14 g. of bromine. After twelve hours the solution was treated with sulfur dioxide, followed by hydrochloric acid. The precipitated acid was coagulated by digestion at the boiling point; yield 3 g. (75%). Distilled in vacuum and crystallized from ether the acid formed slightly yellow plates, m. p. 166–167°.

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.65; H, 5.31. Found: (III) C, 73.49; H, 5.66; (IV) C, 73.30; H, 5.59.

The methyl ester of III forms plates from methyl alcohol, m. p. 172–173°.

Demethylation.—The methoxy acids III and IV were refluxed with glacial acetic acid (20 cc. for a 3-g. lot) and 48% hydrobromic acid (6 cc.) for four hours and the solutions were concentrated and diluted to crystallization. **4-Hydroxy-4′-carboxydiphenyl** was crystallized from dioxane–cyclohexane, forming transparent (solvated) needles, m. p. (dry) 293–294°. **3-Carboxy-4-hydroxydiphenyl** formed needles from ether–cyclohexane, m. p. 212–213°.

Anal. Calcd. for $C_{13}H_{10}O_3$: C, 72.86; H, 4.71. Found: (4′-acid) C, 72.62; H, 5.05; (3-acid) C, 72.73; H, 5.08.

The 4′-methyl ester formed plates from alcohol, m. p. 224–225°; the **3-ester** crystallized from petroleum ether as prismatic needles, m. p. 93–94°.

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.65; H, 5.31. Found: (4′-ester) C, 73.97; H, 5.64; (3-ester) C, 73.67; H, 5.42.

Exhaustive Oxidation.—A hot solution of 0.9 g. of 4-hydroxy-4′-carboxydiphenyl and 3 g. of potassium hydroxide in 100 cc. of water was treated in the course of two hours with a solution of 5.75 g. of permanganate. The crude oxidation product was esterified and the ester (0.3 g.) distilled in vacuum and crystallized from methyl alcohol, giving flat needles of dimethyl terephthalate, m. p. 140–141°.

Anal. Calcd. for $C_{10}H_{10}O_4$: C, 61.82; H, 5.19. Found: C, 61.66; H, 5.52.

β-(4-Methoxy-3-xenoyl)-propionic acid on oxidation with excess alkaline permanganate gave benzoic acid, which was extracted with ether from the residue after evaporation, sublimed, and fully identified.

3-Chloro-4-methoxy-4′-carboxydiphenyl (VIII).—(a) β-(4-Methoxy-4′-xenoyl)-propionic acid (5 g.) was heated with 720 cc. of 2.5% sodium hypochlorite solution for several hours on the steam-bath and on nearly saturating the solution with sodium chloride and cooling, the sodium salt of the chlorinated acid separated. It was collected and washed with salt solution, and the free acid was liberated and crystallized from dilute acetic acid; small needles, m. p. 275–276°.

Anal. Calcd. for $C_{14}H_{11}O_3Cl$: C, 63.98; H, 4.23. Found: C, 63.96; H, 4.62.

The methyl ester formed cottony needles from methyl alcohol, m. p. 145–146°.

Anal. Calcd. for $C_{15}H_{13}O_3Cl$: C, 65.08; H, 4.74. Found: C, 65.30; H, 4.82.

(b) 3-Chloro-4-methoxydiphenyl (5 g.) was first converted with acetyl chloride (2 g.) and aluminum chloride (3.4 g.) in carbon bisulfide medium into **3-chloro-4-methoxy-4′-acetodiphenyl,** which was vacuum distilled and crystallized from alcohol; needles, m. p. 109–110°.

Anal. Calcd. for $C_{15}H_{13}O_2Cl$: C, 69.07; H, 5.03. Found: C, 69.17; H, 5.30.

The ketone (1 g.) was oxidized with potassium permanganate (1.21 g.) in a hot, stirred, alkaline medium, and the purified product (0.35 g.) and its methyl ester were com-

---

[7] Fieser and Hershberg, This Journal, **57**, 1851 (1935).

pared with the above samples and found to give no depressions in the melting points.

Bromo Compounds.—Using analogous methods the following compounds were prepared: **3-bromo-4-methoxy-4′-acetodiphenyl** (a), plates from methyl alcohol, m. p. 97–98°; **3-bromo-4-methoxy-4′-carboxydiphenyl** (b), needles from tetrachloroethane, m. p. 270–271°; methyl ester (c), long needles from alcohol, m. p. 148–149°.

Anal. Calcd. (a) C, 59.02; H, 4.30; (b) C, 54.72; H, 3.62; (c) C, 56.07; H, 4.08. Found: (a) C, 59.10; H, 4.63; (b) C, 54.66; H, 3.89; (c) C, 55.91; H, 3.95.

Condensation of *p*-Methoxydiphenyl with Acetyl Chloride.—The reaction of the ether (5 g.) and acetyl chloride (2.2 g.) in the presence of aluminum chloride (4 g.) was run in boiling carbon bisulfide, in tetrachloroethane at 0–20°, and in nitrobenzene at 0–20°. There was little difference in the total yield or the ratio of isomers in the three cases, although tetrachloroethane seemed to give slightly better results (65% yield) than the other solvents. A separation is easily accomplished with ether, which readily dissolves the low-melting isomer (VI) and leaves the other ketone (V) as a residue, and in each case the high-melting compound was found to comprise 65–75% of the total. This substance, **4-methoxy-4′-acetodiphenyl** (V), forms microcrystals from methyl alcohol, m. p. 153–154°. On oxidation with alkaline permanganate it gave an acid identical with III. **3-Aceto-4-methoxydiphenyl** (VI) was found in the ether mother liquor contaminated with unchanged *p*-methoxydiphenyl. It was easily separated from this substance and purified through the semicarbazone, which gives plates from alcohol. On hydrolysis with boiling 2 *N* hydrochloric acid the ketone was obtained and crystallized from dilute methyl alcohol; plates, m. p. 62–63°.

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.61; H, 6.24. Found: (V) C, 79.65; H, 6.34; (VI) C, 79.66; H, 6.43.

Fries Rearrangement.—4-Acetoxydiphenyl (5 g.) was intimately mixed with aluminum chloride (3.5 g.) and carbon disulfide (20 cc.) and heated to evaporate the solvent. The residue was heated in a bath at 140° for thirty minutes and then decomposed with dilute hydrochloric acid and extracted with ether. The rearranged material was extracted from the washed solution with dilute alkali and recovered as a solid by acidification. **4-Hydroxy-4′-acetodiphenyl,** the less soluble isomer, was obtained by crystallization of the crude material to constant melting point from benzene; small needles, m. p. 206–207° (0.2 g.). It gave on methylation a product identical with the ether V described above. The material recovered from the benzene mother liquor was taken up in alcohol (50 cc.) and treated with an aqueous solution of semicarbazide hydrochloride (1.1 g.) and sodium acetate (0.8 g.). On standing yellow crystals of a semicarbazone separated (0.95 g.; m. p. >270°) and this was hydrolyzed with boiling 2 *N* hydrochloric acid. After crystallizing the recovered ketone from petroleum ether **3-aceto-4-hydroxydiphenyl** was obtained as small prisms, m. p. 61–62°, and on methylation it formed an ether, m. p. 62–63°, which did not depress the melting point of 3-aceto-4-methoxydiphenyl.

Anal. Calcd. for $C_{14}H_{12}O_2$: C, 79.21; H, 5.71. Found: (4′-isomer) C, 79.37; H, 6.01; (3-isomer) C, 79.19; H, 5.83.

Summary

In the Friedel and Crafts reaction with succinic anhydride and with acetyl chloride 4-methoxydiphenyl is substituted in both the 3- and the 4′-positions and solvents have little influence on the ratio of the isomers produced. The Fries rearrangement of 4-acetoxydiphenyl also proceeds in these two directions.

The closing of a six-membered ring at the 2-position of diphenyl is inhibited by a *m*-methoxyl group at position 4.

The Condensation of Phenols with Ethanolamine and Formaldehyde

BY HERMAN ALEXANDER BRUSON

It has been known for some time that amines catalyze the condensation between phenols and formaldehyde to form resins. The mechanism of this reaction is still obscure.

When phenols are condensed with molecular equivalents each of formaldehyde and secondary amines, such as dimethylamine or piperidine, tertiary amines are formed.[1]

Décombe has shown that the products thus obtained are, without doubt, *o*-hydroxybenzylamino derivatives.[2]

Morpholine is particularly prone to form well-defined, crystalline hydroxybenzylmorpholines with a variety of monohydric or polyhydric phenols and formaldehyde.[3]

In a study of this reaction with other amines, it has now been found that β-aminoethanol can be combined with formaldehyde and phenols to yield hydroxybenzylaminoethanols. The condensation is, however, complicated by the formation of resinous materials which in some cases form the main product. It has been found possible, by intro-

ducing various orienting groups into the phenol nucleus and thereby decreasing the number of reactive available nuclear positions, to so arrest resin formation that the intermediate compounds can be isolated in pure crystalline form.

When phenol was mixed with a molecular equivalent quantity each of formaldehyde and ethanolamine, heat was evolved, and a sticky, sirupy mass was formed. After washing with water, this material formed a reddish, viscous, resinous material which was readily soluble in dilute hydrochloric acid or sodium hydroxide solution. It therefore contained an amino group and a free phenolic hydroxyl group. When heated to about 100°, it gradually hardened to a nitrogenous, pale reddish, resin which was still soluble in dilute acid, but which progressively became more and more insoluble as heating was continued. When two molecular equivalents of formaldehyde were used for the condensation, the product resinified faster to an infusible resin. At no stage was it possible to isolate therefrom any crystalline product.

The three isomeric cresols reacted in a similar manner to yield sticky, nitrogenous sirups or resins which could not be crystallized, nor could they be distilled, even in high vacuum, without decomposition.

However, the introduction of a phenyl group *ortho* to the phenolic hydroxyl group, led to the formation of a crystalline compound which could easily be separated from resinous by-products. *o*-Phenylphenol reacted with one mole equivalent each of formaldehyde and ethanolamine to yield a substance crystallizing in colorless needles melting at 116° and corresponding to the empirical formula $C_{15}H_{17}O_2N$. This compound was soluble in aqueous 10% sodium hydroxide solution or phosphoric acid solution, but was insoluble in sodium bicarbonate solution. From its empirical composition and chemical behavior, it would correspond to the probable formula $C_6H_5C_6H_3OHCH_2NHCH_2CH_2OH$ in which the entering group could be ortho or para to the phenolic hydroxyl group.

p-Phenylphenol, on the other hand, formed a crystalline compound containing less nitrogen than that called for by the above empirical formula. It was less soluble in acids or in sodium hydroxide solution and more soluble in alcohol than the *o*-phenyl compound. After repeated crystallizations from benzene, it melted at 102°. Assuming that it is not a mixture, its analysis approximates a possible formula $(C_6H_5C_6H_3OHCH_2)_2NCH_2CH_2OH$.

p-Cyclohexylphenol likewise formed a crystalline compound, m. p. 171°, which contained less nitrogen than that called for by a simple cyclohexylhydroxybenzylaminoethanol, and which approximates a possible structure analogous to the para-phenyl compound.

Well-defined crystalline reaction products were obtained from *p*-*t*-butylphenol, *p*-*t*-amylphenol, *p*-benzoylphenol, *p*-nitrophenol and 3-nitro-4-hydroxytoluene, the analysis and behavior of which indicated the presence of one $—CH_2NHCH_2CH_2OH$ group attached to the aromatic nucleus. In view of the blocking of the para positions in these phenols, the entering $—CH_2NHCH_2CH_2OH$ radical very probably enters the ortho position to the phenolic hydroxyl group. By using 2,4-dichlorophenol and 5-chloro-2-hydroxydiphenyl, which contain one very reactive free ortho position, the corresponding compounds containing the $—CH_2NHCH_2CH_2OH$ group undoubtedly ortho to the phenolic OH group, were obtained.

In the case of *o*-cyclohexylphenol, *p*-benzylphenol, *p*-$\alpha,\alpha,\gamma,\gamma$-tetramethylbutylphenol, *o*- and *p*-chlorophenols, oily, resinous materials were obtained. These products were soluble, however, for the most part in 10% phosphoric acid solution.

Resorcinol, upon treatment with one mole equivalent each of formaldehyde and ethanolamine, gave an amorphous water-insoluble powder which was soluble in dilute hydrochloric acid.

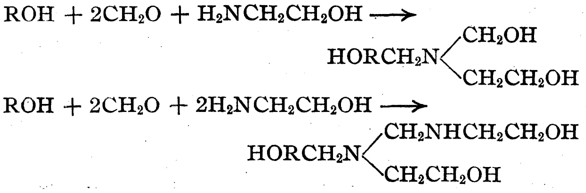
Attempts to introduce two hydroxyethyl aminomethyl groups into those phenols containing two free *ortho* positions to the hydroxyl group, led to the formation of viscous oils which could not be distilled without resinification.

The crystalline hydroxybenzylamino ethanols isolated, react further with formaldehyde to form resins. It is believed that the formaldehyde reacts with the imino group to form a methylol compound which is capable of further condensation with the components present. Various competing reactions may take place. These may be formulated as follows, where R is the phenolic nucleus

$$CH_2O + H_2NCH_2CH_2OH \longrightarrow HOCH_2NHCH_2CH_2OH \quad (A)$$

$$ROH + HOCH_2NHCH_2CH_2OH \longrightarrow HORCH_2NHCH_2CH_2OH \quad (B)$$

The formaldehyde and ethanolamine first combine with evolution of heat to form a methylol derivative (A), which then reacts with a mole of the phenol to form the hydroxyaralkylaminoethanol (B). This compound is usually the main product of the reaction, especially if care is taken to use only one molecular equivalent to each of the three components. If the phenol is suitably oriented, product (B) crystallizes out. However, side reactions also occur, especially if an excess of formaldehyde or of ethanolamine is present, so that a complex mixture of phenolic amino alcohols is formed, among which may be the following



$$ROH + 2CH_2O + H_2NCH_2CH_2OH \longrightarrow HORCH_2N\left\langle\begin{matrix}CH_2OH\\CH_2CH_2OH\end{matrix}\right.$$

$$ROH + 2CH_2O + 2H_2NCH_2CH_2OH \longrightarrow HORCH_2N\left\langle\begin{matrix}CH_2NHCH_2CH_2OH\\CH_2CH_2OH\end{matrix}\right.$$

These can, of course, again react with formaldehyde or with formaldehyde plus ethanolamine, and this can be kept up until all free molecular movement ceases and the end-product becomes a rigid, nitrogenous resin.

Experimental Part

Phenylhydroxybenzylaminoethanol.—(a) To a solution of 51 g. of *o*-phenylphenol (0.3 mol), 50 cc. of methanol, and 30 g. of aqueous 30% formaldehyde (0.3 mol), there was added, while shaking and cooling with tap water, 18.3 g. of β-aminoethanol. The clear, reddish solution was allowed to stand at room temperature (20–25°) for about sixty-five hours, during which time it solidified to a crystalline mass which contained a sticky, resinous material. The yield of the filtered, air-dried, crude crystalline product was 33 g. Upon recrystallization from 50 cc. of absolute ethyl alcohol, 19 g. of product were obtained in the form of colorless needles. The analytical sample melted at 116° (uncorr.) after three recrystallizations from alcohol.

Anal. Calcd. for $C_{15}H_{17}O_2N$: C, 74.03; H, 7.05; N, 5.76. Found: C, 73.72; H, 6.89; N, 5.51.

(b) The same product may be obtained in a much shorter time by the following procedure:

A solution of 60 g. of aqueous 30% formaldehyde (0.6 mole) was added slowly to 36.6 g. of β-aminoethanol (0.6 mole) while cooling and stirring the mixture. The clear solution was allowed to stand for about one hour until the odor of formaldehyde disappeared. It was then added to a solution of 102 g. of *o*-phenylphenol (0.6 mole) in 100 cc. of ethyl alcohol. The solution was boiled under reflux on a steam-bath for one and one-half hours, and allowed to stand overnight in an ice-box. The weight of colorless crystals obtained was 55 g. or 38%.

Condensation of *p*-Phenylphenol, Formaldehyde and Ethanolamine.—To a suspension of 34 g. of *p*-phenylphenol (0.2 mol) in 34 cc. of methanol, 12.2 g. of β-aminoethanol was added and the mixture warmed until it became clear. It was then cooled to 25° and 6 g. of powdered *p*-formaldehyde added. The mixture was shaken for about ten minutes, during which time the *p*-formaldehyde dissolved with heat evolution, the temperature reaching 40°. The clear solution thus obtained was then boiled for one hour under reflux on a steam-bath, cooled and poured slowly into 200 cc. of water with stirring. The white precipitate was filtered by suction, washed thoroughly with water and dried in the air. The somewhat yellowish powder thus obtained was recrystallized twice from benzene with chilling, using Norite to remove the yellow color, until a constant melting point of 102° was obtained; colorless crystals; very soluble in alcohol. Three separate preparations were analyzed in duplicate and averaged.

Anal. Calcd. for $C_{28}H_{27}O_3N$: C, 79.02; H, 6.40; N, 3.30. Found (1): C, 78.54; H, 6.98; N, 3.46. Found (2): C, 78.93; H, 6.92; N, 3.20. Found (3): C, 78.67; H, 6.88; N, 3.26.

***p*-Cyclohexylphenol, Formaldehyde, Ethanolamine Condensation.**—To a solution of 35.2 g. of *p*-cyclohexylphenol, 33 cc. of methanol and 12.2 g. of β-aminoethanol, there was added, with cooling and shaking, 20 g. of aqueous 30% formaldehyde solution. After standing at room temperature for one hour, the mixture was boiled for one and one-half hours under reflux on a steam-bath and placed in a refrigerator at 5° for several weeks. A small quantity (5 g.) of crystalline crusts separated, which were contaminated with a sticky sirup. The crystalline material was dried on porous tile and recrystallized from methanol to a constant melting point; colorless fine crystals, m. p. 170–171°. Four separate preparations were analyzed in duplicate and averaged.

Anal. Calcd. for $C_{15}H_{23}O_2N$: C, 72.23; H, 9.32; N, 5.62. $C_{28}H_{39}O_3N$: C, 76.83; H, 8.99; N, 3.20. Found (1): C, 76.27; H, 9.15; N, 3.21. Found (2): C, 76.71; H, 8.66; N, 3.26. Found (3): C, 76.94; H, 8.84; N, 3.27. Found (4): C, 76.38; H, 9.16; N, 3.38.

Chlorophenylphenol, Formaldehyde, Ethanolamine Condensation.—To a solution consisting of 20.5 g. of 5-chloro-2-hydroxydiphenyl, 27 cc. of methanol, and 10 g. of aqueous 30% formaldehyde, there was added, with cooling and shaking, 6.1 g. of ethanolamine. The mixture was then boiled under reflux for one and one-half hours on a steam-bath. The crystalline mass thus obtained was recrystallized from *n*-butanol. It separated in very fine colorless crystals, m. p. 182–183°; difficultly soluble in alcohol; readily soluble in 10% sodium hydroxide or hydrochloric acid solution.

Anal. Calcd. for $C_{15}H_{16}O_2NCl$: Cl, 12.77; N, 5.04. Found: Cl, 12.80; N, 4.81.

2-Hydroxy-3,5-dichlorobenzylaminoethanol.—To a solution of 16.3 g. of 2,4-dichlorophenol, 16 cc. of methanol, and 6.1 g. of ethanolamine, there was added 3 g. of *p*-formaldehyde. The mixture was shaken for fifteen minutes until the *p*-formaldehyde had dissolved, then boiled under reflux on the steam-bath. After about thirty minutes of boiling, a yellowish crystalline material began to separate. The mixture was cooled and filtered. The yellowish crystals (7 g.) were washed with a little methanol and recrystallized from *n*-butanol for analysis; colorless, fine white needles, m. p. 199–200°.

Anal. Calcd. for $C_9H_{11}O_2NCl_2$: Cl, 30.04; N, 5.93. Found: Cl, 29.80; N, 5.76.

2-Hydroxy-3-nitro-5-methylbenzylaminoethanol.—A mixture of 15.3 g. of 3-nitro-4-hydroxytoluene, 20 cc. of methanol, 6.1 g. of ethanolamine and 3 g. of *p*-formaldehyde, was boiled under reflux for one hour. The clear red solution was cooled and scratched to induce crystallization. The yellow crystals were washed with a little methanol and recrystallized from butanol; yellow needles, m. p. 205–206°.

Anal. Calcd. for $C_{10}H_{14}O_4N_2$: C, 53.07; H, 6.24; N, 12.38. Found: C, 53.26; H, 6.36; N, 12.61.

***p*-*t*-Butylhydroxybenzylaminoethanol.**—To a solution consisting of 30 g. of *p*-*t*-butylphenol, 30 cc. of methanol and 12.2 g. of ethanolamine, there was added, with cooling and shaking, 6 g. of *p*-formaldehyde. After shaking until all heat evolution had ceased, the clear solution obtained was boiled for one hour under reflux on a steam-bath, and then placed in a refrigerator at 5° for several days, during which time it solidified to a colorless, crystalline mass; yield of crude air-dried crystals was 19 g. After recrystallization from methanol by repeated boiling and chilling, 5 g. of the analytically pure, colorless, crystalline product, m. p. 127–128°, was isolated.

Anal. Calcd. for $C_{13}H_{21}O_2N$: C, 69.99; H, 9.49; N, 6.27. Found: C, 69.91; H, 9.63; N, 6.17.

The product dissolved readily in 10% sodium hydroxide solution, as well as in 10% hydrochloric acid.

***p*-*t*-Amylhydroxybenzylaminoethanol.**—To a solution of 49.2 g. of *p*-*t*-amylphenol, 50 cc. of methanol, and 30 g. of aqueous 30% formaldehyde solution, there was added 18.3 g. of ethanolamine, while cooling with tap water and shaking. The solution was then boiled under reflux on a steam-bath for one and one-half hours. The oily layer which separated on cooling was run off and chilled to 0° to induce crystallization. The crystals were dried on porous tile to remove sticky, resinous material, and recrystallized from methanol to a constant melting point of 114° (uncorr.).

Anal. Calcd. for $C_{14}H_{23}O_2N$: C, 70.87; H, 9.77; N, 5.90. Found: C, 70.54; H, 9.44; N, 5.72.

***p*-Nitrohydroxybenzylaminoethanol.**—A solution of 20 g. of 30% formaldehyde and 12.2 g. of ethanolamine was added to a solution of 27.8 g. of *p*-nitrophenol in 30 cc. of methanol. A clear red solution was obtained. After standing for seven days at room temperature, there was no evidence of reaction. The solution was therefore boiled for one and one-half hours under reflux on a steam-bath. Upon cooling, yellow crystals slowly separated. Upon recrystallization from ethyl alcohol to a constant melting point, the product formed yellow needles melting at 195–196° (uncorr.).

Anal. Calcd. for $C_9H_{12}O_4N_2$: C, 50.91; H, 5.75; N, 13.20. Found: C, 50.81; H, 5.77; N, 12.86.

***p*-Benzoylhydroxybenzylaminoethanol.**—To a solution of 19.8 g. of *p*-benzoylphenol in 25 cc. of methanol, there was added a previously prepared solution made by mixing 10 g. of aqueous 30% formaldehyde with 6.1 g. of ethanolamine, with cooling. The mixture was allowed to stand for two hours at room temperature, and was then heated under reflux on a steam-bath for one and one-half hours. The solution thus obtained was allowed to stand at 5° for several days. The crystals which separated were dried on tile, washed with a little alcohol and recrystallized from alcohol to a constant melting point of 188–189°.

Anal. Calcd. for $C_{16}H_{17}O_3N$: C, 70.81; H, 6.32; N, 5.16. Found: C, 70.47; H, 6.38; N, 5.05.

The product was soluble in dilute oxalic or lactic acid. The above analyses were carried out by Dr. C. W. Nash of the Röhm and Haas Company.

Summary

The condensation of formaldehyde and β-aminoethanol with various phenols was investigated. Crystalline compounds were obtained from equimolecular mixtures of formaldehyde and ethanolamine with *o*-phenylphenol, *p*-*t*-butylphenol, *p*-*t*-amylphenol, *p*-nitrophenol, *p*-benzoylphenol, 5-chloro-2-hydroxydiphenyl, 2,4-dichlorophenol and 3-nitro-4-hydroxytoluene. These appear to be substituted hydroxybenzylaminoethanols; *i. e.*, phenols containing one —$CH_2NHCH_2CH_2OH$ group attached to the aromatic nucleus.

p-Phenylphenol and *p*-cyclohexylphenol gave compounds containing less nitrogen per mole of the phenol, indicating the presence of two phenolic nuclei in the products.

Resins containing nitrogen were obtained from phenol, the three cresols and resorcinol.

The Reversibility of the Friedel-Crafts Reaction. Hydrogenation

BY L. L. ALEXANDER AND REYNOLD C. FUSON

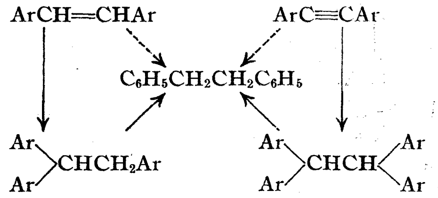
The addition of hydrogen to an ethylenic bond can be accomplished by use of benzene and aluminum chloride at room temperatures.[1] Under these conditions this reaction competes with the addition of benzene to the double bond. However, the latter process is reversible, whereas the former appears to be irreversible. This means that eventually the hydrogenation process will take place to the exclusion of the addition of benzene. Thus, in the case of stilbene the formation of dibenzyl, which is irreversible, must eventually supplant the reaction leading to the production of triphenylethane:[2]

$$(C_6H_5)_2CHCH_2C_6H_5 \overset{C_6H_6}{\rightleftarrows} C_6H_5CH{=}CHC_6H_5 \xrightarrow{H_2} C_6H_5CH_2CH_2C_6H_5$$

Another way of stating the proposition is to say that in aryl ethanes or ethylenes the aryl groups will be replaced by hydrogen atoms. Experiment has shown that this replacement is subject to certain limitations. The end-product under the conditions mentioned above is dibenzyl rather than ethane. Thus, with dibenzyl (or stilbene), ethylbenzene, styrene, 1,1-diphenylethane or 1,1-diphenylethylene, no replacement of aryl groups is observed.

From these facts emerges the following generalization. *The production of dibenzyl by the action of benzene and aluminum chloride is a general phenomenon for acetylene and ethylene derivatives in which each carbon atom bears at least one aryl group, and for similarly constituted tri- and tetraarylethanes.*

These four classes of compounds may in reality be reduced to two, since the ethylenic and acetylenic types are converted to the triarylethane and tetraarylethane types, respectively, under the conditions used. This is indicated in the following chart

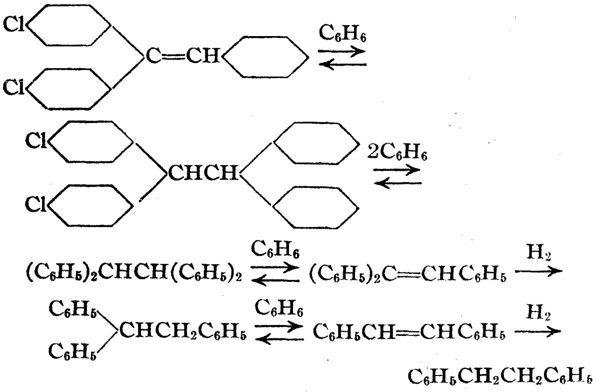


We have found, for example, that stilbene and *p*-bromostilbene give 1,1,2-triphenylethane when treated with benzene in the presence of a limited amount of aluminum chloride.

$$\left.\begin{array}{r} C_6H_5CH{=}CHC_6H_5 \\ BrC_6H_4CH{=}CHC_6H_5 \end{array}\right\} \rightarrow C_6H_5CH_2CH(C_6H_5)_2$$

It seems probable, therefore, that the transformation of these compounds into dibenzyl in the presence of large amounts of aluminum chloride involves the triphenylethane as an intermediate.

Similarly, triphenylethylene and 1,1-di-(*p*-chlorophenyl)-2-phenylethylene could be converted either to *sym*-tetraphenylethane or to dibenzyl, depending on the experimental conditions used. Thus, in the case of triphenylethylene the product is *sym*-tetraphenylethane *when 0.3 mole of aluminum chloride is used.* If four moles of aluminum chloride is employed, the chief product is dibenzyl. The same results were obtained with 1,1-di-(*p*-chlorophenyl)-2-phenylethylene. In the latter case, the mechanism must be the following



$$(C_6H_5)_2CHCH(C_6H_5)_2 \overset{C_6H_6}{\rightleftarrows} (C_6H_5)_2C{=}CHC_6H_5 \xrightarrow{H_2}$$

$$(C_6H_5)_2CHCH_2C_6H_5 \overset{C_6H_6}{\rightleftarrows} C_6H_5CH{=}CHC_6H_5 \xrightarrow{H_2} C_6H_5CH_2CH_2C_6H_5$$

These findings make possible a satisfactory interpretation of the fact that dibenzyl results when certain halogen derivatives of ethane, ethylene or acetylene are treated with benzene and aluminum chloride. It will be obvious that dibenzyl may

---

[1] Alexander, Jacoby and Fuson, THIS JOURNAL, **57**, 2208 (1935). It seems probable that a similar explanation might account for the formation of propylbenzene by the action of benzene and aluminum chloride on allyl chloride [Nenitzescu and Isacescu, *Ber.*, **66B**, 1100 (1933)].

[2] Neither the source of the hydrogen nor the mechanism by which it is added have as yet been discovered. It may be, for example, that the process consists of the addition of hydrogen chloride to the ethylenic bond, followed by replacement of the chlorine atom by a hydrogen atom.

be expected from such of these compounds as react to form derivatives in which each of the two carbon atoms bears a phenyl radical. According to the literature, dibenzyl has been obtained in greater or less amounts from a number of such halogen derivatives. The following are illustrative examples: ethylene chloride,[3] ethylene bromide,[3] acetylene dibromide,[4] 1,1,2-trichloroethane,[5] 1,1,2-tribromoethane,[4] 1-phenyl-2-chloroethane,[6] 1-phenyl-1,2-dibromoethane[7] and tolane dibromide.[8]

Experimental Part

***sym*-Tetraphenylethane from Tolane.**—A mixture of 1 g. of tolane, 60 cc. of benzene and 0.5 g. of aluminum chloride was saturated with dry hydrogen chloride, then tightly stoppered and shaken for six hours at room temperature. The color changed from green to brown. The decomposition was carried out in an ice–hydrochloric acid mixture, and the product obtained on removal of the benzene melted, after recrystallization from glacial acetic acid, at 207–208°. There was no depression of a mixed melting point with an authentic sample of *sym*-tetraphenylethane. The yield was 64% of the theoretical amount.

Dibenzyl from Tolane.—A mixture of 1 g. of tolane, 50 cc. of benzene and 4 g. of aluminum chloride was saturated with dry hydrogen chloride. The mixture was placed in a glass-stoppered bottle and shaken at room temperature for twenty hours. The decomposition and the washing of the reaction mixture were effected as described in the other experiments. The brown viscous product was distilled at 4 to 5 mm., and the fraction boiling up to 120° was collected. The distillate crystallized on standing, and melted at 50–51°. It was shown by the method of mixed melting points to be dibenzyl. The yield was 32% of the theoretical amount.

Dibenzyl also has been obtained as a result of the treatment of the following compounds in a manner which was entirely analogous to that described for the production of dibenzyl from tolane.

Starting material	Material, g.	Aluminum chloride, g.	Yield of dibenzyl, %
Triphenylethylene	5	10	28
1,1-Di-(*p*-chlorophenyl)-2-phenylethylene	5	10	27
1,1,2-Triphenylethane	5	10	57
s-Tetraphenylethane	2.5	5	54

1,1,2-Triphenylethane from Stilbene.—A solution of 10 g. of stilbene in 150 cc. of benzene was saturated with hydrogen chloride and shaken for eight hours with 2 g. of aluminum chloride. The decomposition was accomplished with a mixture of ice and hydrochloric acid. The red oil resulting was distilled under reduced pressure. A fraction distilling at 206–210° (12 mm.) was collected, and crystallized on standing. The melting point of the product, as well as the mixed melting point with 1,1,2-triphenylethane (prepared as indicated below), was 51–52.5°. The yield calculated on the basis of triphenylethane was 49% of the theoretical amount.

1,1,2-Triphenylethane from *p*-Bromostilbene.—From 5 g. of *p*-bromostilbene, 100 cc. of benzene, dry hydrogen chloride and 0.5 g. of aluminum chloride, 1,1,2-triphenylethane was prepared in a yield of 37% of the theoretical by a procedure exactly analogous to the conversion of stilbene into 1,1,2-triphenylethane described above.

Synthesis of 1,1,2-Triphenylethane.[9]—A solution of 2 g. of triphenylethylene in 100 cc. of dry ether was freed from oxygen by means of a stream of dry nitrogen gas. Three grams of finely powdered sodium was added, and the mixture was shaken for ten hours at room temperature. The solution was added slowly to 100 cc. of absolute alcohol, and a large part of the ether and alcohol removed. Upon the addition of water and extraction with ether, a liquid residue was obtained which crystallized readily on standing with methyl alcohol. After recrystallization from the same solvent, it melted at 52–53°. The yield was 83% of the theoretical amount.

Synthesis of Di-(*p*-chlorophenyl)-benzylcarbinol.—A Grignard reagent was prepared from 13 g. of magnesium, 63 g. of benzyl chloride and 200 cc. of dry ether. To this solution 85 g. of *p*,*p*′-dichlorobenzophenone was added, and the solution was stirred for two hours. It was then allowed to stand overnight. After decomposition in an ammonium chloride–ice mixture and separation and concentration of the ether solution, a straw-colored liquid remained. When recrystallized from petroleum ether (high-boiling), the product melted at 116–117°. The yield was 68%.

Anal. Calcd. for $C_{20}H_{16}OCl_2$: C, 69.85; H, 4.66. Found: C, 70.02; H, 4.76.

1,1-Di-(*p*-chlorophenyl)-2-phenylethylene.—Fifty grams of di-(*p*-chlorophenyl)-benzylcarbinol dissolved in 600 cc. of glacial acetic acid was heated to boiling as 50 cc. of concentrated sulfuric acid was slowly added. The mixture was heated under reflux for thirty minutes, and then poured into water. The organic material was extracted with ether and obtained in crystalline form by removal of the ether. After recrystallization from methyl alcohol, it melted at 116.5–117.5°; the mixed melting point with the original carbinol was 90–96°. The yield of the ethylenic compound was practically quantitative.

Anal. Calcd. for $C_{20}H_{14}Cl_2$: Cl, 21.87. Found: Cl, 21.80.

***sym*-Tetraphenylethane from Triphenylethylene.**—A solution of 5 g. of triphenylethylene in 150 cc. of benzene was saturated with dry hydrogen chloride and shaken with 1 g. of aluminum chloride for twenty hours. The resulting red solution was decomposed in ice and hydrochloric acid and, after removal of the benzene, the resulting product was treated with norite and crystallized from an acetic acid solution. The melting point was 206–208°, and a mixed melting point with an authentic sample of *sym*-tetraphenylethane showed no depression. The yield was 70% of the theoretical amount.

***sym*-Tetraphenylethane from 1,1-Di-(*p*-chlorophenyl)-2-phenylethylene.**—A yield of 55% of the calculated quan-

tity of tetraphenylethylene was obtained from 5 g. of the ethylene, 1 g. of aluminum chloride and 150 cc. of benzene which had been saturated with hydrogen chloride. The procedure was the same as that used for the conversion of triphenylethylene into *sym*-tetraphenylethane.

Dibenzyl from Tetraphenylethylene.—A solution of 7 g. of tetraphenylethylene in 150 cc. of dry benzene was saturated with dry hydrogen chloride and shaken in contact with 20 g. of aluminum chloride for three days. After decomposition and separation had been completed, the benzene was removed and the residue distilled under reduced pressure. A small amount of distillate was collected at 100–200° (8 mm.). This distillate crystallized from dilute alcohol and melted at 52–53°. It was shown by the method of mixed melting points to be dibenzyl. The residue from the distillation was unchanged tetraphenylethylene.

Summary

The production of dibenzyl by the action of benzene and aluminum chloride is a general phenomenon in the case of acetylene and ethylene derivatives in which each carbon atom bears at least one aryl group, and for similarly constituted tri- and tetraarylethanes. These transformations may be explained by assuming that hydrogen adds irreversibly to the ethylenic bond, whereas aromatic hydrocarbons add reversibly.

Acetylene Polymers and their Derivatives. XXVI. The Reaction of Halogen Ethers with Vinylacetylene

BY HARRY B. DYKSTRA

Isochloroprene (I) and chloroprene (II) are obtained by the addition of hydrogen chloride to

$$CH\equiv CCH{=}CH_2 + HCl \longrightarrow \underset{\text{(I)}}{CH_2{=}C{=}CHCH_2Cl} \longrightarrow \underset{\text{(II)}}{CH_2{=}CClCH{=}CH_2}$$

vinylacetylene.[1] The present paper is concerned with analogous compounds obtained by the addition of alpha chloroethers to vinylacetylene.

$$CH\equiv CCH{=}CH_2 + CH_3OCH_2Cl \longrightarrow \underset{\text{(III)}}{CH_3OCH_2CH{=}C{=}CHCH_2Cl} \longrightarrow \underset{\text{(IV)}}{CH_3OCH_2CH{=}CClCH{=}CH_2}$$

Methoxy-5-chloro-1-pentadiene-2,3 (III) and methoxy-5-chloro-3-pentadiene-1,3 (IV) are formed when vinylacetylene and chloromethyl methyl ether have reacted in ether solution containing bismuth chloride. The initial step appears to be 1,4-addition, for III is the principal product of the reaction. On treatment with hydrochloric acid and cuprous chloride, III rapidly rearranges to IV. The presence of IV in the original reaction mixture probably results from isomerization of III induced by the bismuth chloride.

The addition of alpha halogen ethers to vinylacetylene appears to be a general reaction. Compounds obtained in this manner are listed in Table I. The synthesis is a special application of the olefin–halogen ether reaction developed by Norman D. Scott.[2]

Proof of Structure of Methoxy-5-chloro-1-pentadiene-2,3 (III).—This compound is a colorless liquid having an ethereal odor. Other physical properties are recorded in Table I. Failure of III to react with alkaline mercuric iodide reagent indicates the absence of acetylenic hydrogen. It does not polymerize or react with maleic anhydride as it might be expected to do if it contained a 1,3-diene structure. Its chlorine atom is reactive, for on treatment with alcoholic silver nitrate it rapidly yields a copious precipitate of silver chloride. A substantially quantitative yield of silver chloride is obtained in twenty hours at 25°. On oxidation with potassium permanganate, III yields chloroacetic acid. These data are similar to those reported for isochloroprene[1] and indicate that III is methoxy-5-chloro-1-pentadiene-2,3.

Proof of Structure of Methoxy-5-chloro-3-pentadiene-1,3 (IV).—Physical and analytical data for this compound are given in Table I. It is a colorless liquid having weakly lachrymatory properties. It does not yield a derivative with alkaline mercuric iodide reagent, which shows that it is not a true acetylenic compound. Its chlorine atom must be attached to a carbon bearing a

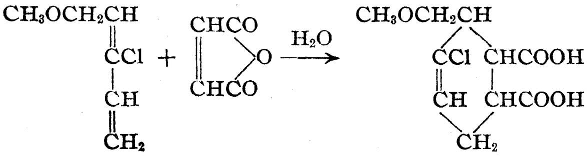
[a] Impure.

double bond, for it does not react appreciably with alcoholic silver nitrate. When heated with an equivalent amount of maleic anhydride, it forms a viscous mass from which a chloro acid can be obtained by extraction with hot water. This acid melts at 163–165° and has a neutral equivalent of 123.3 as compared with a calculated value of 124.3 for $C_{10}H_{13}O_5Cl$ (V)



(V)

The reaction with maleic anhydride shows that IV is a 1,3-diene.[3] The 1,3-diene structure is further evidenced by the ease with which IV polymerizes. On oxidation with alkaline potassium permanganate, IV yields carbon dioxide, oxalic acid and methoxyacetic acid. These data indicate that IV has one of the structures

$CH_3OCH_2CH{=}CHCCl{=}CH_2$ (A)
$CH_3OCH_2CH{=}CClCH{=}CH_2$ (B)

The formation of IV from III and the close analogy which these compounds bear to chloroprene and isochloroprene, respectively, strongly favor structure B for compound IV.

Polymerization of Methoxy-5-chloro-3-pentadiene-1,3 (IV).—On standing at room temperature in the presence of air and diffused light, IV polymerizes slowly to a soft, rubber-like resin. The rate of polymerization is accelerated by light, heat and the presence of certain catalysts, *e. g.*, benzoyl peroxide and maleic anhydride. Exposure of IV to ultraviolet light from a mercury arc causes 65% to polymerize in forty-eight hours. When IV is heated in contact with air at 80°, 72% polymerizes in ten hours. In the presence of 1% benzoyl peroxide, a 95% yield of polymer is obtained in five hours at 75°. A comparison of these data with those reported for isoprene[4] and for chloroprene[5] indicates that IV polymerizes about 115 times as fast as isoprene and one-sixth as fast as chloroprene.

Polymers of IV are for the most part light colored resins which are soluble in acetone, ethyl acetate and benzene. Polymers prepared at low temperatures are somewhat rubber-like; they are elastic and resilient but lack the snap and strength of polychloroprene. Similar polymers are obtained from the analogs of IV described in Table I.

Experimental Part

Preparation of Methoxy-5-chloro-1-pentadiene-2,3 (III) and Methoxy-5-chloro-3-pentadiene-1,3 (IV).—During the course of two hours, 156 g. of vinylacetylene and 241 g. of chloromethyl methyl ether were added to a well-stirred mixture of 100 g. of ether, 1 g. of pyrogallol (antioxidant), and 3 g. of bismuth chloride maintained at 5–15°. The stirring was continued at this temperature for nine hours with periodic additions of bismuth chloride until a total of 13 g. had been added. The reaction mixture was then washed with water, dried over magnesium sulfate and distilled under reduced pressure. This yielded 60 g. of impure IV boiling at 46° (10 mm.), 138 g. of III boiling at 60–61° (10 mm.), 21 g. of liquid boiling at 78–85° (2 mm.) (probably resulting from addition of two mols of chloro ether to one of vinylacetylene), and 38 g. of non-volatile resin. Compound IV was obtained in pure form from the fraction boiling at 46° (10 mm.) by shaking with sodium methylate and redistilling. This removed an impurity containing active chlorine.

The analogs of III and IV described in Table I were prepared in a similar manner using alpha-chloroethyl ethyl ether and alpha-chloroethyl butyl ether.

Isomerization of Methoxy-5-chloro-1-pentadiene-2,3 (III).—A mixture of 200 g. of III, 50 g. of ether, 10 g. of cuprous chloride, and 50 g. of 18% hydrochloric acid was stirred at 20–40° for two hours. The ether layer was separated, dried over magnesium sulfate, and distilled. This gave 162 g. of IV boiling at 46° (10 mm.) and corresponding in properties with that separated from the reaction of chloromethyl ether with vinylacetylene.

Reaction of Methoxy-5-chloro-3-pentadiene-1,3 (IV) with Maleic Anhydride.—Twenty-seven grams of IV, 20 g. of maleic anhydride and 30 g. of acetone were heated to-

gether at 50° for two hours. The acetone was then removed by distillation and the residue refluxed with water for two hours. The aqueous portion on evaporation yielded 15 g. of chloro acid. After two recrystallizations from hot water, the chloro acid melted at 163–165°. The acid had a neutral equivalent of 123.3 as compared with a calculated value of 124.3 for $C_{10}H_{13}O_5Cl$ (V).

Oxidation of Methoxy-5-chloro-3-pentadiene-1,3 (IV).—To a vigorously stirred mixture of 20 g. of IV, 80 g. of potassium carbonate and 200 g. of water, maintained at 10–25°, 165 g. of potassium permanganate was added during the course of six hours. The mixture was then decolorized with sulfur dioxide, acidified with sulfuric acid and extracted with ether. The ether extract yielded 0.8 g. of oxalic acid and 2 g. of crude methoxyacetic acid, b. p. 70–110° (25 mm.); n^{20}_D 1.4140. The oxalic acid was identified by its melting point (97–101°) and its transformation into oxal-*p*-toluidide (m. p. 266°). The methoxyacetic acid was characterized by conversion into its amide, which melted, after one crystallization from alcohol, at 92–94°, as compared with a recorded value of 92°.[6]

Oxidation of Methoxy-5-chloro-1-pentadiene-2,3 (III).—One hundred and sixty grams of potassium permanganate was added during the course of five hours to a well-stirred mixture of 20 g. of III and 200 g. of water. The mixture was then decolorized with sulfur dioxide, filtered, acidified with sulfuric acid (carbon dioxide evolved) and extracted with ether in the usual way. The ether extract yielded 0.3 g. of oxalic acid (identified by its m. p. of 99–101°, and its *p*-toluidide, m. p. 267–269°) and 6 g. of liquid boiling at 95–110° (25 mm.). On cooling, the liquid fraction deposited chloroacetic acid, m. p. 48–53°. The chloroacetic acid was further identified by conversion into its amide, which melted at 118–120° as compared with a recorded value of 119.5°.[7]

The author wishes to express his thanks to Dr. Wallace H. Carothers for his interest in this work and for his helpful suggestions.

Summary

The reaction between alpha chloro ethers and vinylacetylene is shown to be closely analogous to the addition of hydrogen chloride to vinylacetylene to form isochloroprene and chloroprene. The initial step appears to be 1,4 addition of the chloroethers  $(\mathrm{RO\overset{\overset{R'}{|}}{C}HCl})$ to vinylacetylene with the formation of products of the formula  $\mathrm{RO\overset{\overset{R'}{|}}{C}HCH{=}C{=}CHCH_2Cl}$. In the presence of cuprous chloride and hydrochloric acid these products readily isomerize to compounds of probable structure  $\mathrm{RO\overset{\overset{R'}{|}}{C}HCH{=}CClCH{=}CH_2}$. The latter compounds polymerize to form resins which are somewhat rubber-like.

The Synthesis of 4-Methyl-6-oxypyrimidine-5-acetic Acid and 4-Methyluracil-5-methylamine

BY WILLIAM T. CALDWELL AND WILLIAM M. ZIEGLER

The first structure[1] for vitamin B_1 proposed by Williams contained an ethyl group in the pyrimidine nucleus. Later, Windaus, Tschesche and Grewe[2] expressed the opinion that the existence of two methyl groups rather than that of a single ethyl group in the primidine nucleus was in better harmony with their experimental results. Cleavage of the vitamin by sulfite[3] formed an amino sulfonic acid from which a corresponding hydroxy acid was obtained in which the sulfonic acid group presumably would be attached to the pyrimidine nucleus in position 5, in accord with the hypothesis of the existence of two free methyl groups in the nucleus.

A search of the literature, however, failed to disclose to us a case in which a pyrimidine with sulfonic acid group in position 5 had been isolated, and although this was no proof that a substance of the latter type was not formed by the sulfite cleavage, it nevertheless led us to consider the synthesis of compounds containing an amino methyl group in position 5.

The formula proposed by Makino and Imai[4] expresses the same conclusion as to the likelihood of an amino methyl group in this position. We set about, accordingly, to synthesize a compound of the structure

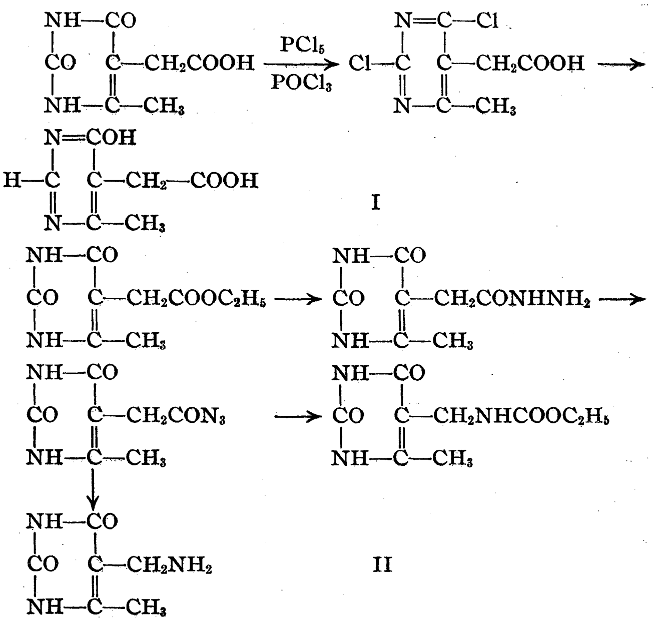
I

in the hope that it might prove to be identical with the compound $C_6H_{10}N_4$ isolated by Windaus as picrate. There has appeared quite recently, however, a report of further work by Williams[5] on the basis of which he proposes a new formula for vitamin B_1 from which it is quite clear that, although one amino group should be found in the side chain in position 5, the nuclear methyl group is in position 2 and not 4 as in the compound we hoped to prepare.

As a result of this new evidence, we have abandoned our original intention of preparing a compound represented by structure I, and are therefore reporting the synthesis of several new pyrimidine derivatives obtained as intermediates for the preparation of the diamine which we had thought might be identical with Windaus' $C_6H_{10}N_4$ but which Williams has shown now could be only an isomer thereof.

One plan of procedure involved the preparation of 4-methyl-6-oxypyrimidine-5-acetic acid from which, by means of the Curtius reaction which Johnson and Litzinger[6] had used successfully for an analogous reaction, we hoped to obtain a desired intermediate in good yield. Unfortunately, preliminary experiments gave little promise of satisfactory yields in our hands, so that we abandoned this path temporarily in the hope of securing more promising results by preparing first 4-methyluracil-5-methylamine. Although we have succeeded in preparing this compound, both as free base and as acetate, the yield is far from good. In fact, we have been unable to hydrolyze the urethan to the amine as yet; heating in a sealed tube at 130° for several hours produced a white, extremely insoluble compound but no amine. After a number of attempts to hydrolyze the urethan had yielded us only white solids that did not melt below 320° and which were insoluble in water or alcohol, we decided to attempt the direct conversion of the azide into the amine by the method described by Lindemann.[7] In this way we were able to obtain a small amount of the desired free base by liberating it from the acetate. This method appears to be more likely to give improved yields than the hydrolysis of the urethan.

The reactions that we shall describe are summarized by the following formulas



Experimental Part

2,6 - Dichloro - 4 - methylpyrimidine - 5 - acetic Acid.— This compound was prepared from the corresponding 4-methyluracil-5-acetic acid which was obtained readily by the method described by Johnson and Heyl.[8] Phosphorus oxychloride (460 g.) was poured upon 4-methyluracil-5-acetic acid (63 g.). Hydrogen chloride was evolved but the solid apparently did not go into solution. Phosphorus pentachloride (350 g.) was then added to the ice-cooled mixture, and then this was heated for six hours on a boiling water-bath. By the end of this time, practically all of the material appeared to have dissolved, forming a very dark brown solution. Phosphorus oxychloride (443 g.) was removed under diminished pressure on the steam-bath, leaving a dark, resinous residue. This was cooled in ice, treated with ether and ice in portions until all had either gone into solution or broken up into small particles so that the material could be poured from the flask. This aqueous suspension and ether extract (both very dark brown or black) upon filtration with suction left a small residue of tarry material upon the filter paper. After separating the ether layer from the aqueous one, and re-extracting the latter with ether, the ether extract (about 2000 cc. in all) was set aside and allowed to evaporate slowly in such a way that the temperature did not rise above 25°. After several days, dark colored crystals (21.4 g.) separated. They were insoluble in benzene and in petroleum ether, but soluble in absolute ether, from which they were recrystallized, separating as pale yellow crystals, melting at 156–157°.

Anal. Calcd. for $C_7H_6O_2N_2Cl_2$: Cl, 32.09. Found: Cl, 30.93.

4 - Methyl - 6 - oxypyrimidine - 5 - acetic Acid.—The above dichloro compound (11.8 g.) was reduced by the method of Gabriel and Colman.[9] The free acid, after liberation from its potassium salt with acetic acid, extraction with benzene and recrystallization from the latter, was obtained as snow-white crystals, melting at 147–149° and giving no Beilstein test; yield 3.5 g.

Anal. Calcd. for $C_7H_8O_3N_2$: N, 16.66. Found: N, 16.38.

4 - Methyluracil - 5 - carbethoxymethylamine.—The ethyl ester of 4-methyluracil-5-acetic acid (22 g.), m. p. 221–222°, was converted into the hydrazide in the usual way. From these white crystals that darkened slightly above 320° but did not melt by 375°, the azide was obtained easily and was converted into the urethan by heating with an excess of absolute alcohol. After the vigorous evolution of gas had ceased, the hot liquid was filtered from considerable insoluble white solid and concentrated. The urethan, which was soluble in water and in alcohol, was obtained as fine white crystals of m. p. 214–215° from absolute alcohol; yield, 12 g. of urethan from 20 g. of hydrazide.

Anal. Calcd. for $C_9H_{13}O_4N_3$: N, 18.50. Found: N, 18.48.

Our attempts to hydrolyze this urethan by heating with concentrated hydrochloric acid either at atmospheric pressure or in a sealed tube for a day at 130–140° failed to yield any of the desired 5-aminomethyl compound. The product was a white solid that did not melt or decompose by 320°, and which was insoluble in all organic solvents that we tried.

4-Methyluracil-5-methylamine.—In view of the unexpected difficulty encountered in the hydrolysis of the above urethan, we made use of Lindemann's method[7] for the conversion of an azide into an amine. By heating the azide with 50% acetic acid, the substance dissolved with evolution of gas. After a few minutes, white solid began to appear and was removed from time to time as the liquid was concentrated. This material was insoluble in water and did not melt below 310°. The filtrate was evaporated to dryness, the residue dissolved in water, filtered, and again concentrated. The white crystals obtained in this way, when dissolved in water, turned red litmus slowly, but distinctly, blue. With a drop of concentrated sulfuric acid the odor of acetic acid became easily perceptible, and the analysis also indicated that the product was the acetate of the amine. The yield from 12 g. of the azide was 2.8 g.

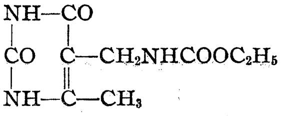
Anal. Calcd. for $C_6H_9O_2N_3 \cdot C_2H_4O_2$: N, 19.53. Found: N, 19.55.

The white salt turned to a very pale yellow material at 227–229°, but on further heating to 360° merely became progressively darker. On adding a solution of potassium hydroxide to a solution of the acetate there soon separated, upon scratching with glass, a finely crystalline white solid—fine needles under the microscope. After washing well with absolute alcohol, they were recrystallized from water in which they were easily soluble. The free base is a strong one, turning red litmus blue. On heating, it became brown by 335° but did not melt; yield 0.5 g.

Anal. Calcd. for $C_6H_9O_2N_3$: C, 46.45; H, 5.85; N, 27.09. Found: C, 46.50; H, 6.50; N, 27.27.

Summary

Several new pyrimidines, whose preparation was stimulated by the work of Williams and others on vitamin B, are reported. Attention is called to the difficulty met in the attempt to hydrolyze the urethan



to the amine

A New Method for the Separation of Yttrium from the Yttrium Earths

BY H. C. FOGG AND LEWIS HESS

The use of urea as a precipitant for aluminum in the presence of calcium, barium, magnesium, manganese, zinc, cobalt, nickel, iron, cadmium and copper was the subject of an investigation by Willard and Tang,[1] and its use as a precipitant for gallium in the quantitative determination of that element was studied by Willard and Fogg.[2] Since the decomposition of urea[3] results in the formation of ammonia at a slow and uniform rate throughout the homogeneous solution, it may advantageously be applied to the fractionation of the yttrium earths.

Method of Separation

The mixed earths, in the form of their oxides, are dissolved in nitric acid, and the solution is nearly neutralized with ammonia and diluted. Ammonium sulfate is added in amount just insufficient to cause precipitation, followed by one- to two-tenths of an equivalent of urea. The solution is heated with stirring to 90–95°, and

[3] E. A. Werner, *J. Chem. Soc.*, **113**, 84 (1918).

kept at this temperature for six to eight hours, during which time a precipitate gradually forms. This is filtered off, more urea is added, and the filtrate is again treated in the same manner, fractionation being continued until examination of the absorption spectrum indicates that the solution is nearly free of erbium.

Control of Fractionation

The materials subjected to fractionation were of two types, one a mixture of yttrium and erbium oxides containing very small amounts of the other yttrium earths, and the other a mixture of the hydroxides of the yttrium earths containing 2–3% of thorium. The separation was followed by means of the equivalent weight of the rare earth mixture, which was determined by conversion of oxide to sulfate.

Results of Fractionation

The results of two typical series of fractionations are given below.

TABLE I

FRACTIONATION OF YTTRIUM–ERBIUM MIXTURE

	At. wt.	% Er_2O_3	Weight, g.
Original material	134.6	58.0	100.6
Fraction 1	147.0	73.8	21.3
Fraction 3	141.3	66.5	11.3
Fraction 5	139.9	64.8	5.3
Fraction 7	135.9	59.7	8.2
Fraction 10[a]	107.8	24.0	18.7

[a] Represented the material remaining after the precipitation with urea, and was precipitated as oxalate.

TABLE II

FRACTIONATION OF MIXTURE CONTAINING THORIUM

	At. wt.	Equivalent % Er_2O_3,	Weight, g.
Original material	110.9	27.9	540.0
Fraction 2	131.9	54.6	18.3
Fraction 3	129.6	51.7	22.7
Fraction 5	120.1	39.6	49.7
Fraction 7	114.7	32.8	35.8
Fraction 9	107.2	23.2	31.7
Fraction 11[a]	98.2	11.8	211.3

[a] Represented the material remaining after the precipitation with urea, and was precipitated as oxalate.

The equivalent percentages in Tables II and III are computed upon the admittedly false assumption that the original material was a mixture of yttria and erbia only. The equivalent weight of fraction 1 of the series described in Table II was not determined as, due to its high thorium content, it was not soluble in hydrochloric acid. The thorium content of this fraction (as ThO_2) was found to be 36.4%. It was determined by the method of Carney and Campbell,[4] the solution of the sample being prepared by fusion with potassium pyrosulfate and extraction with water.

Several series of fractionations were carried out using a full equivalent of ammonium sulfate per equivalent of rare earth. This method was found to have no greater efficiency than the one recommended and to have a definite disadvantage, due to the limited solubility of yttrium sulfate. This made it necessary to use a dilute solution of the mixed nitrates with consequent increase in the volume and decrease in the quantity of material which could be handled conveniently. With the method described above, it was possible to use a relatively concentrated solution, say of the order of 5 to 6 per cent. Tables III and IV are representative of data obtained with the use of a full equivalent.

TABLE III

FRACTIONATION OF MATERIAL CONTAINING THORIUM

	At. wt.	Equivalent % Er	Weight, g.
Original material	112.8	30.3	101.1
Fraction 3	136.3	60.2	4.5
Fraction 5	125.4	46.3	5.8
Fraction 7	115.0	33.1	6.8
Fraction 9	108.5	24.9	6.7
Fraction 11	101.3	15.7	7.7
Fraction 13[a]	93.5	5.8	17.8

[a] Represented the material remaining after the precipitation with urea, and was precipitated as oxalate.

TABLE IV

FRACTIONATION OF YTTRIUM–ERBIUM MIXTURE

	At. wt.	% Er	Wt., g.
Original material	132.0	54.7	50.0
Fraction 1	144.7	70.9	3.9
Fraction 4	141.3	66.5	3.2
Fraction 7	136.8	60.8	2.9
Fraction 10	127.9	49.5	3.6
Fraction 14	110.9	27.9	1.2
Fraction 15[a]	101.7	16.2	3.8

[a] Represented the material remaining after the precipitation with urea, and was precipitated as oxalate.

Discussion

A comparison of the new method with those previously used may be of interest. The more important of the earlier methods include the fractional crystallization of the bromates,[5] the fractional decomposition of the nitrates by fusion,[6] and the fractional precipitation of the chromates,[7]

the basic nitrites,[8] the cobalticyanides[9] and the ferricyanides.[10] The bromate method is the standard one for the fractionation of the yttrium earths, but is not particularly effective for the preparation of pure yttrium. The new method compares favorably in efficiency with the nitrate fusion, chromate and basic nitrite methods. It appears to be superior to the ferricyanide and cobalticyanide methods. Grant and James[10] report a very high efficiency for the ferricyanide method, but no supporting data have been published.

Summary

A new method for the separation of yttrium from the yttrium earths has been proposed, and has been found to compare favorably in efficiency with the methods now in use.

The Activated Adsorption of Hydrogen and Carbon Monoxide on Zinc Oxide. The Effect of Water Vapor

BY ROBERT L. BURWELL, JR., AND HUGH S. TAYLOR

Poisons such as water vapor have been presumed to effect the retardation of catalytic processes by being adsorbed on the "active spots," thus blocking access of the reactants to such catalytically effective sections of the surface.[1] This access of reactants to catalytically effective sections of the surface consists according to Taylor[2] of an activated adsorption of the reactants on such regions of the surface. Reversible poisoning would accordingly result from an activated adsorption of the poison on the active sections of the surface, an adsorption possessed of energy relations such that the activation energy of desorption would be large compared with that of the other components of the system. In this fashion the activated adsorption of the reactants may be hindered.

Taylor and Sickman[3] and Taylor and Strother[4] investigated the activated adsorption of hydrogen on zinc oxide. The former investigators further reported that water vapor exerted an inhibitory influence on a catalytic action which they studied, the decomposition of propanol-2 on zinc oxide. It thus appeared of interest to study the effects of water vapor on the activated adsorption of hydrogen on zinc oxide.

Experimental

Rates of the activated adsorption of hydrogen on zinc oxide were determined by means of an apparatus and method similar to that described by Taylor and Strother.[4] The purified hydrogen could be saturated with water vapor at any desired temperature between 0° and room temperature by diverting it through a spiral bubbling column filled with distilled water and maintained at the desired temperature. Carbon monoxide was prepared by dropping formic acid on hot sulfuric acid. It was purified by passage over copper heated to 450°, soda lime, calcium chloride and phosphorus pentoxide. To supply water vapor to the adsorbent preliminary to rate runs, the apparatus was further provided with a buret of 410-cc. capacity. The zinc oxide was prepared from zinc oxalate as described by the above authors.

All gas volumes reported have been corrected to N. T. P. All the experiments described in this paper were performed on two samples of the same batch of zinc oxide. These samples were 3B, weight 16.5 g., and 3C, weight 22.7 g.

Before the start of these researches these adsorbents had been subjected to a series of determinations of the rates of activated adsorption, first of carbon monoxide and then of hydrogen. During the course of these adsorption measurements the activity of the surface had fallen slowly but steadily.

Results and Discussion

After a number of runs with hydrogen at 184 to 302°, it was observed that, at the completion of the adsorption, the preparations, notably 3B, had

---

[4] Taylor and Strother, *ibid.*, **56**, 586 (1934).

a distinctly grayish appearance. On evacuation at 400° the original color of the preparation reappeared. A dark gray condensate gradually appeared above the furnace level on the walls of the capillary tube leading from the catalyst bulb.

It appears that, by reduction, there is formed a certain quantity of metallic zinc which subsequently distils from the catalyst bulb during evacuation. Only a small portion of the adsorbed hydrogen reduces the zinc oxide. Thus in 32 runs on preparation 3C, over 334 cc. of hydrogen was adsorbed. One gram of zinc would have been formed if all of this had led to reduction; actually less than 0.05 g. appeared. The diminution of the activity of the zinc oxide preparation probably resulted from destruction of the more active spots by reduction.

For bulk zinc oxide a very small pressure of water vapor would thermodynamically render reduction impossible at these temperatures. Even at 419° this pressure is only 0.0033 mm.[5] There are two factors which may enter into the observed reduction: (a) thermodynamic considerations applying to bulk material will not apply to surface molecules of different energy characteristics; (b) water vapor is adsorbed so tenaciously as to reduce its vapor pressure below the critical level.

If the surface of the adsorbents be saturated with water vapor after the evacuation but before the start of the determination of the rate of hydrogen adsorption, then the catalyst remains white.

If hydrogen saturated with water at 17° be adsorbed on a freshly evacuated preparation, a fraction of the material at the top of the bulb near the supply tube remains white but that at the bottom turns gray. Thus, during run 51 on preparation 3B at 254°, gas pressure 360 mm., water vapor pressure 7.2 mm., the upper fifth of the zinc oxide remained white, while in run 52 under similar conditions, the upper seventh remained white.

The explanation of this phenomenon is clear. Water vapor is adsorbed so strongly by zinc oxide that the first sections of zinc oxide completely remove the water vapor from the entering gas. Those sections with adsorbed water vapor are protected from attack.

This phenomenon is closely related to one recorded by Russell and Ghering[6] in a study of the effect of oxygen poisoning upon the rate of the hydrogenation of ethylene on copper. There the oxygen was adsorbed tenaciously by the first sections of copper with which it came in contact and portions farther from the inlet tube were supplied only as the nearer portions approached saturation. As a result, progressive additions of oxygen reduced the rate of hydrogenation in a linear manner. As Russell and Ghering emphasize, such a linear relation is not an argument for a uniform surface. From the evidence presented by the present authors, it is clear that similar consideration would prevail in poisoning zinc oxide surfaces with water vapor. In spite of the non-uniformity of zinc oxide surfaces, the reduction of the rate of reaction would bear a linear relation to the quantity of water vapor introduced.

Effect of Water Vapor on the Rate of Activated Adsorption.—Experiments were performed which permit comparison of the rates of activated adsorption of hydrogen and carbon monoxide on zinc oxide surfaces previously saturated with water vapor with those obtained on the ordinarily evacuated catalyst. Adsorption measurements were made at 1 atm. pressure on preparation 3C.

As Taylor and Sickman[3] found, the first portions of water vapor are adsorbed on zinc oxide with great rapidity, the later portions more slowly. Thus, at 218°, preparation 3C, after evacuation for five hours at 410°, adsorbed 7.4 cc. (N. T. P.) of water vapor under 14.5 mm. pressure within two minutes. Another 7.4 cc. was adsorbed in an hour. The final pressure of water vapor was 6 mm.

Table I exhibits the effect of water vapor on the rate of activated adsorption of hydrogen and carbon monoxide on preparation 3C.

TABLE I

EFFECT OF WATER VAPOR ON THE RATE OF ADSORPTION OF HYDROGEN AND CARBON MONOXIDE ON PREPARATION 3C AT 218°

---

[5] G. B. Taylor and Starkweather, THIS JOURNAL, **52**, 2323 (1930). This paper deals thoroughly with the problem of reduction of zinc oxide by hydrogen.

[6] Russell and Ghering, *ibid.*, **57**, 2544 (1935).

Adsorption runs 58 and 65 on preparation 3C were performed on zinc oxide surfaces which had been saturated with water vapor in the manner just described. The other runs were made on freshly evacuated surfaces. The gases employed in runs 52, 54, 58, 59, 62, 64 and 65 were free from water vapor. The hydrogen employed in run 55 contained 4.5 mm. of water vapor and that in run 56, 14.5 mm.

It is observed that rates of adsorption of both hydrogen and carbon monoxide are markedly smaller on surfaces saturated with water vapor. On the other hand, partial pressures of water vapor up to 14.5 mm. may be introduced with hydrogen without sensibly affecting the rate of adsorption. At 218° the dead space in the catalyst bulb of preparation 3C amounts to about 20 cc. In run 56, this 20 cc. of gas contains 0.4 cc. (N. T. P.) of water vapor. In the light of earlier considerations this entire quantity would be adsorbed immediately but only by those portions of zinc oxide very near the inlet tube. Since about 7.4 cc. of water vapor can be absorbed with great tenacity, from 5 to 10% of the surface is in the condition of the whole surface in run 58, whereas the remainder of the surface is unaffected. Such variation is within the experimental error set by the reproducibility of the surface.

Similar results were obtained on preparation 3B in regard to the effect of water vapor on the rate of adsorption of hydrogen. At 254° and 0.5 atm. pressure, preliminary saturation of the surface with water vapor reduced the rate of adsorption by 75%.

Because, in the presence of nickel, deuterium exchanges very much more rapidly with benzene than does deuterium oxide, Horiuti and Polanyi[7] consider that the exchange does not proceed by dissociative adsorption succeeded by recombination of the fragments, unless equilibrium conditions on the surface are upset by a change from deuterium to deuterium oxide.

On the basis of common examples of poisoning and on the basis of the researches presented in the paper, the authors consider that water vapor in quantity may reduce reaction rates by reducing the rate of the activated adsorption of the reactants if such adsorption be rate determining, or by making unavailable a certain fraction of the catalytically effective surface if some succeeding step be rate determining. Thus the authors believe that the consideration whereby Horiuti and Polanyi reject the mechanism of exchange via dissociative adsorption is not valid.

Summary

1. Water vapor has been shown to minimize surface reduction of zinc oxide catalysts at lower temperatures.

2. Water vapor has been shown to be strongly adsorbed from gas mixtures containing this vapor by those fractions of zinc oxide surfaces to which the mixture of gases first has access.

3. Saturation of zinc oxide surfaces with water vapor has been shown markedly to inhibit the activated adsorption of hydrogen and carbon monoxide.

The Behavior of Iodine in Some Sensitized Decompositions of Gaseous Organic Compounds

BY R. FRANCIS FAULL AND G. K. ROLLEFSON

Introduction

It has been shown by Hinshelwood and others[1-3] that the decomposition rates of a number of organic substances are greatly increased by the addition of relatively small amounts of iodine. In discussing their results they have discarded chemical mechanisms for the action of iodine in favor of a hypothesis involving collisions between iodine and the organic molecules. Recently, while preparing to test these reactions for photosensitivity, we have discovered that under the same conditions as prevailed in Hinshelwood's work little or no free iodine can be detected by spectroscopic methods during the course of the reactions. This result leads to the conclusion that these reactions actually proceed by chemical mechan-

[2] Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems," Oxford Univ. Press, London, 1933, p. 225.

[3] Bairstow, *Trans. Faraday Soc.*, **29**, 1227 (1933).

isms and in this paper we wish to present evidence for three types of behavior.

Apparatus and Experimental Details

The apparatus consisted of a Pyrex reaction vessel of approximately 350-cc. capacity within an electric furnace. The reaction vessel was connected to an external vacuum system and to an iodine storage bulb, each through a heated glass valve.[4]

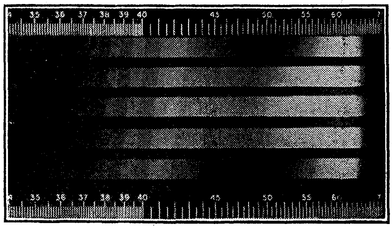

Plate I.—Propionaldehyde at 394°.

The glass valves eliminated troubles caused by ordinary grease stopcocks and were found to operate very satisfactorily in individual ovens, whereby the temperature could be maintained as high as 150°. The iodine storage bulb was immersed in a small oil-bath that could be heated to distil iodine into the reaction vessel. The pressure was measured by a click gage[5] and a mercury manometer. All connecting tubing was capillary glass, wound with resistance wire and electrically heated. The temperature was measured by a chromel–alumel thermocouple which was imbedded in a well extending into the center of the reaction vessel and could be regulated within one degree. The light source was a 500-watt tungsten projection lamp. By utilizing windows in the ends of the furnace the beam could be directed along a 15-cm. path through the reaction vessel into a Hilger E3 spectrograph.

The organic materials used were taken from the center fractions of redistillations of Eastman Kodak Co. stock and stored in three-liter bulbs connected to the vacuum line. The iodine was Merck reagent. In each experiment the iodine, at 1.5 cm. pressure, was introduced from the heated reservoir, the pressure measured and then the organic gas in question, at approximately 25 cm. pressure, was allowed to enter the reaction vessel.

Observations and Spectrograms

Acetaldehyde.—At 400° acetaldehyde removes the iodine color immediately upon entering the reaction vessel. The restoration of the color begins in about three minutes and is complete after five minutes. At 350° the reaction is slower, but at 300° the iodine color never completely disappears. All attempts to isolate an intermediate state failed because the iodine was liberated rapidly on cooling the reaction mixture. The reaction at 300° is photosensitive, the rate measured by pressure change being approximately doubled upon intense illumination with a 500-watt tungsten lamp.

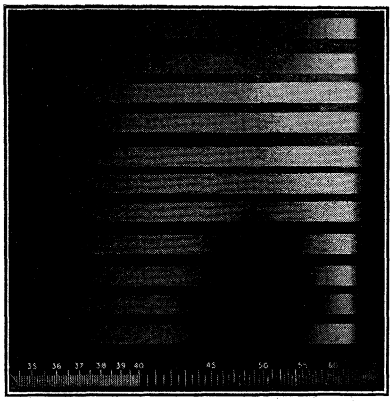
Propionaldehyde.—The same characteristics that are shown by acetaldehyde are exhibited by propionaldehyde (see Plate I). At 394° the color of the iodine disappears and returns within four minutes. At 340° the rate of reaction was increased by strong illumination as measured by pressure change.

Diethyl Ether.—At 440° the color of iodine disappears almost immediately and is completely restored after thirty or forty minutes.

Ethylene Oxide.—The behavior of ethylene oxide resembled closely that of acetaldehyde.

Methyl Alcohol.—At 470° methyl alcohol decolorized iodine within one minute. The color does not begin to return until after four hours have elapsed. The colorless reaction mixture can be removed without the liberation of iodine and can be shown to contain hydrogen iodide.

Methyl Formate.—At 460° methyl formate requires about fifteen minutes to decolorize the iodine (see Plate II). The color begins to return after three hours and is almost completely restored within five hours.



Methyl Formate at 460°.

Plate II.—Spectrograms of different stages of iodine sensitized decompositions. The exposures are ten seconds, with a 500-watt lamp as a light source. Elapsed times are given from the beginning of the reactions. Scale units are in hundreds of Ångströms.

Formaldehyde.—At 450° the color disappears immediately and begins to reappear in about two hours. It is completely restored after five hours.

Diethylamine.—Diethylamine shows no decolorization of iodine over a wide temperature range within which it decomposes.

Discussion

The substances investigated fall into three distinct classes. The first consists of acetaldehyde, propionaldehyde, diethyl ether and ethylene oxide. The characteristics shown by these may be listed as follows: (1) the color of iodine disappears and returns within a short time; (2) no hydrogen iodide can be isolated during the course of the reaction; (3) the iodine absorption band disappears completely on the spectrograms

---

(4) The glass valves were of a design supplied to one of us (G. K. R.) by Professor G. B. Kistiakowsky. They are similar to those which have been described by Bodenstein except that they have silver chloride on the valve seat which eliminates the necessity for grinding the movable parts very exactly.

(5) Smith and Taylor, This Journal, **46**, 1393 (1924).

in some experiments; and (4) the decomposition products are the same in both the sensitized and unsensitized reactions.

The second class includes methyl alcohol, methyl formate and formaldehyde. The principal characteristics exhibited by these are as follows: (1) the color disappears rapidly but does not return for a relatively long period of time although the temperature is much higher than in Class I; (2) hydrogen iodide is present and can be isolated during the reaction; (3) the iodine absorption band is never completely removed from the spectrograms; and (4) the products in the iodine sensitized decompositions, except formaldehyde, are different from those in the unsensitized reactions.

The third class, which includes diethylamine, shows no decolorization of the iodine, which may be due to the conditions being such that a high concentration of iodine exists at the steady state.

In both cases where the color of iodine disappears, the reaction is much too fast to be accounted for by a decomposition of the organic substance into hydrogen and a subsequent reaction between iodine and hydrogen.[6] The disappearance of the iodine therefore must be due to the formation of hydrogen iodide or an alkyl iodide.[7] On this basis the following equations for the first two classes may be proposed

CLASS I

$$(C_2H_5)_2O + I_2 = C_2H_5I + HI + CH_3CHO$$

$$RCHO + I_2 = RI + HI + CO$$

$$RI + HI = RH + I_2$$

CLASS II

$$CH_3OH + I_2 = 2HI + HCHO$$

$$HCHO + I_2 = 2HI + CO$$

$$2HI + CH_3OH = H_2O + CH_4 + I_2$$

$$2HI = H_2 + I_2$$

These equations account for the difference in the rate of reappearance of the iodine, because the reaction between an alkyl iodide and hydrogen iodide is rapid, whereas the decomposition of hydrogen iodide is slow.[6] A test of this is given by the rapid appearance of iodine color where methyl iodide is introduced into a reaction mixture containing hydrogen iodide at 365°. Methyl iodide itself does not begin to decompose appreciably until the temperature is well above 400°. A test reaction between hydrogen and iodine was found to be very slow at 450°, showing the absence of any catalytic effect in the apparatus. Therefore the essential difference between the two classes lies in the steps that produce iodine. Also the actual products present in the decomposition are accounted for by the equation.[8]

In any case it seems apparent that the sensitized decomposition takes place through definite chemical reactions rather than a collision activation process that was proposed by Hinshelwood.[1–3] In regard to Class I, it is known that acetaldehyde exists as an intermediate in the thermal decomposition of diethyl ether[9] and ethylene oxide,[10,11] and hence it is not unlikely that the sensitized decompositions go through an aldehyde stage. Even in Class II the formaldehyde intermediate has been reported in some of the thermal decompositions. In comparing the behavior of the two classes it appears that in Class II the course of reaction may go through a formaldehyde step rather than through any other aldehyde, the resulting slowness of the return of iodine color being due to the lack of formation of alkyl iodide from formaldehyde, as would have been the case if the decomposition had gone through any other aldehyde.

Our attention has been called to the work of Ogg [THIS JOURNAL, **56**, 526 (1934)] which makes it possible to calculate the rate of such a reaction as that between methyl iodide and hydrogen iodide under conditions such as prevail in the experiments referred to in this paper. According to the mechanism we have presented after the iodine color has disappeared the rate of decomposition of acetaldehyde is determined by the rate of the reaction between methyl iodide and hydrogen iodide. Using Ogg's equation for the rate as a function of temperature we calculate for one particular experiment at 420° [Hinshelwood, *Proc. Roy Soc.* (London) **A128**, 89 (1930)] a rate of 1.83×10^{-8} mol./cc./sec. whereas the observed rate was 3.47×10^{-8} mol./cc./sec. when the reaction was approximately forty per cent.

---

[6] Bodenstein, *Z. physik. Chem.*, **29**, 295 (1899).

[7] The possibility of an addition compound between the organic substances and iodine may be ruled out by the following consideration. The entropy change in an addition reaction is always negative and from the change in the residual iodine concentration with temperature we must consider that ΔH for the formation of an addition product as an intermediate is positive. Therefore if we calculate $\Delta F^\circ_T = \Delta H - T\Delta S$ we find that the free energy change is positive and the equilibrium constant is less than one, which means that such an equilibrium could not account for the disappearance of the iodine.

[8] Bairstow and Hinshelwood, *J. Chem. Soc.*, 1147 (1933).

[9] Newitt and Vernon, *Proc. Roy. Soc.* (London), **A135**, 307 (1932).

[10] Heckert and Mack, THIS JOURNAL, **51**, 2706 (1929).

[11] Fletcher, *ibid.*, **58**, 539 (1936).

complete. This is as close agreement as could be expected.

Summary

The iodine concentration during a sensitized decomposition of gaseous diethyl ether, acetaldehyde, propionaldehyde, ethylene oxide, methyl alcohol, methyl formate, formaldehyde and probably many others, is very low.

The decompositions proceed through definite chemical reactions rather than collision activation processes.

The Heat Capacity and Entropy of Barium Chloride Dihydrate from 15 to 300°K. The Heat of Solution of Barium Chloride Dihydrate. The Entropy of Barium Ion

BY OLIVER L. I. BROWN, WENDELL V. SMITH AND WENDELL M. LATIMER

The method of calculating the entropy of barium ion which has been used up to the present[1] involves directly the entropies of chloride, thallous and nitrate ions, and indirectly the entropies of silver, bromide and iodide ions. Since the entropy of chloride ion is known with greater precision than that of thallous and nitrate ions, a method of calculating barium ion directly from chloride ion has long been considered desirable. The recent careful work of Tippetts and Newton[2] on the thermodynamics of aqueous barium chloride solutions has now made such a calculation feasible. In the present paper we have determined the following properties of barium chloride dihydrate: (1) the entropy, (2) the heat of solution in water, and (3) the solubility in water. Combining these data we have calculated the entropy of barium ion in aqueous solution.

Material.—A C. P. grade of barium chloride was crystallized three times from redistilled water. It was then dried in a desiccator over partially dehydrated barium chloride dihydrate. Since the sample was found by analysis to have more than the theoretical amount of water, it was dried at 105°, then rehydrated in a desiccator containing water. After analysis showed that the sample had taken up more than the theoretical amount of water, the sample was again dried over partially dehydrated barium chloride dihydrate. This cycle was repeated once again before a sample containing the theoretical amount of water was obtained.

Heat Capacity Measurements.—The experimental method was that of Latimer and Greensfelder.[3] The apparatus was slightly modified from that used in previous work. The block employed to ensure a uniform temperature environment for the calorimeter was replaced by a new block, which was machined very carefully so as to provide better contact between the two halves of the block. The inner surface of the block was gold plated and polished, and reduced considerably the corrections necessary for heat interchange due to radiation. The approximate values of ΔT used in the measurements were: 1.2° up to 20°K., 2–3° up to 50°K., 3–6° up to 180°K, and 6–9° up to 300°K. In calculating the heat capacities one calorie was taken equal to 4.1833 int. joules, and the molecular weight of barium chloride diphydrate was taken as 244.317. Measurements were made on a sample of 192.845 g. (weight *in vacuo*). The results are given in Table I and shown as a function of temperature in Fig. 1.

Entropy of Barium Chloride Dihydrate.—The entropy was calculated by graphical integration of a plot of C_p against log T, combined with an extrapolation at low temperatures using the Debye specific heat equation. The calculation is summarized in Table II.

TABLE II

MOLAL ENTROPY OF BARIUM CHLORIDE DIHYDRATE

0–14.87°K.	Debye extrapolation	0.39
14.87–298.1°K.	Graphical from data	48.19 ± 0.1
	Entropy at 298.1°K.	48.58 E. U.

Heat of Solution of Barium Chloride Dihydrate.—The measurements of the heat of solution were made in a calorimeter which consisted of a vacuum-walled flask of about one-liter capacity fitted with a stirrer, resistance thermometer, and device for introducing a weighed quantity of salt into the water by breaking two gold foil seals. The resistance thermometer consisted of about 45 ohms of platinum wire and also served as a heater for determining the heat capacity of the calorimeter and contents. The values obtained for the heat of solution of one mole of barium chloride dihydrate in 400 moles of water at 298.1°K. were 4412 and 4427 cal. If we combine the average value, 4420 cal., with the known heat of dilution of barium chloride solutions at 298.1°K.[4,5] we obtain for the heat of solution at infinite dilution, $\Delta H^\circ = 3955$ cal./mole.

Free Energy and Entropy of Solution of Barium Chloride Dihydrate.—The solubility of barium chloride at 298.1°K. was determined by evaporating weighed portions of the saturated solution to dryness and weighing the anhydrous barium chloride, after heating to constant weight at 150°. Equilibrium in the saturated solution was approached from both sides by saturating at higher temperatures and at lower temperatures than 298.1°K. The solubility in moles of anhydrous salt per 1000 g. of water was found to be 1.788. The activity coefficient of barium chloride has been determined by Tippetts and Newton[2] from both e. m. f. measurements and vapor pressure measurements. Using their results we find for the saturated solution $\gamma = 0.4418$ and $a_1 = 0.9021$ (a_1 = activity of water). For the reaction

$$BaCl_2{\cdot}2H_2O(s) = Ba^{++} + 2Cl^- + 2H_2O(l) \quad \text{(hypothetical one molal solution)} \qquad (1)$$

$\Delta F^\circ = -1363.8 \log 4(\gamma m)^3 a_1^2 = -280$ cal. $\Delta H^\circ = 3955$ cal. $\Delta S^\circ = (\Delta H^\circ - \Delta F^\circ)/T = 14.20$ E. U.

Entropy of Barium Ion.—The entropy of chloride ion is 13.5 E .U.[1] The entropy of water calculated from the spectroscopic value for the perfect gas[6] and the entropy of condensation of the perfect gas to liquid water[7] is 16.77 E. U. The entropy of barium ion is given by the expression

$$S^\circ_{Ba^{++}} = S_{BaCl_2\cdot 2H_2O} + \Delta S^\circ - 2S^\circ_{Cl^-} - 2S_{H_2O} = 48.58 + 14.20 - 27.0 - 33.54 = 2.2 \text{ E. U.}$$

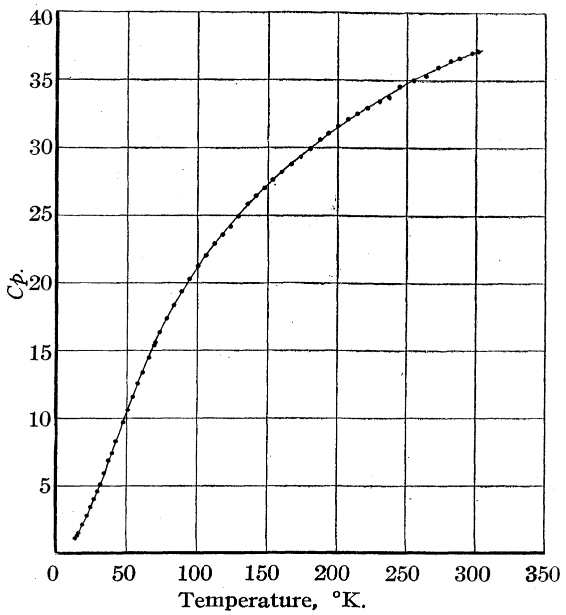

Fig. 1.—Molal heat capacity of barium chloride dihydrate.

Summary

The heat capacity of barium chloride dihydrate has been measured from 15 to 300°K., and the entropy of the salt determined by graphical integration. The solubility and heat of solution of barium chloride dihydrate in water has been determined at 298.1°K. Combining these data with other data already available, the entropy of barium ion has been determined.

Kinetic and Equilibrium Measurements of the Reaction $2Fe^{+++} + 2I^- = 2Fe^{++} + I_2$

BY ALLEN V. HERSHEY AND WILLIAM C. BRAY

The reaction

$$2Fe^{+++} + 2I^- \rightleftharpoons 2Fe^{++} + I_2 \qquad (1)$$

furnishes an example in which the rates of both the forward and reverse reactions may be measured conveniently, and in which the kinetic results may be checked by comparison between values of the equilibrium quotient

$$K = (Fe^{++})^2(I_2)/(Fe^{+++})^2(I^-)^2 \qquad (2)$$

based on measurements of rate, electromotive force and equilibrium concentrations. Wagner[1] in 1924 suggested the complete rate law

$$\frac{d(Fe^{++})}{dt} = \frac{k_1(Fe^{+++})(I^-)^2}{1 + (Fe^{++})/(Fe^{+++})\epsilon_4} - \frac{k_4(Fe^{++})(I_2)}{1 + (Fe^{+++})\epsilon_4/(Fe^{++})} \qquad (3)$$

which corresponds to a single path with two rate determining steps. Application of the condition that $d(Fe^{++})/dt$ is equal to zero at equlibrium leads to the relation $K = k_1\epsilon_4/k_4$. A check of equation 3 is thus furnished by the calculation of K from experimental values of k_1, k_4 and ϵ_4, provided all measurements are made at the same temperature and the same ionic strength.

Wagner's evidence for the rate law of the forward reaction

$$\frac{d(Fe^{++})}{dt} = \frac{k_1(Fe^{+++})(I^-)^2}{1 + (Fe^{++})/(Fe^{+++})\epsilon_4} \qquad (3a)$$

comprised the early work of Schukarew[2] showing that the initial rate depends on the third order reaction $Fe^{+++} + 2I^- \longrightarrow$, the retarding effect of ferrous ion, and the identity of this rate law with that demonstrated by Wagner himself for the analogous reaction between ferricyanide ion and iodide ion. He gives one pair of values of k_1 and ϵ_4 at 15° and a single ionic strength. As evidence that the first step of the reverse reaction is $Fe^{++} + I_2 \longrightarrow$, Wagner refers to the results of Banerji and Dhar.[3a] However, we were not able to calculate values of k_4 in conventional units from the published data.[3] Additional experimental work was therefore necessary before the above mentioned test could be applied to equation 3.

Our measurements were made at 25° in dilute acid solutions having an ionic strength of 0.09, and are in agreement with a rate law of the form

$$\frac{d(Fe^{++})}{dt} = \frac{k_1(Fe^{+++})(I^-)^2}{1 + (Fe^{++})/(Fe^{+++})[\epsilon_4 + \epsilon_6(I^-)]} - \frac{k_4(Fe^{++})(I_2) + k_6(Fe^{++})(I_3^-)}{1 + (Fe^{+++})[\epsilon_4 + \epsilon_6(I^-)]/(Fe^{++})}\ \mathrm{I}$$
$$+ \frac{k_1'(Fe^{+++})(I^-)}{1 + (Fe^{++})(H^+)/(Fe^{+++})\epsilon'} - \frac{k_4'(Fe^{++})(I_2)/(H^+)(I^-)}{1 + (Fe^{+++})\epsilon'/(Fe^{++})(H^+)}\ \mathrm{II} \qquad (4)$$

The two parts, I and II, correspond to two paths, each with two rate determining steps. If the terms containing ϵ_6 and k_6 are omitted, I is the rate law suggested by Wagner. II is dominant only at low concentrations of iodide ion. Setting $d(Fe^{++})/dt$ equal to zero in equation 4 gives the relations

$$k_1\epsilon_4/k_4 = K_{I_3^-}k_1\epsilon_6/k_6 = k_1'\epsilon'/k_4' = K \qquad (5)$$

where $K_{I_3^-}$ is the equilibrium quotient of the reaction $I_3^- = I_2 + I^-$.

Equation 4 was constructed by combining into one rate law the results of rate measurements on both sides of equilibrium. The two positive terms of the rate law were derived from an analysis of the data for the forward reaction between ferric ion and iodide ion, and the sum of the numerators of the negative terms was in agreement with the data for the reverse reaction between ferrous ion and iodine. The denominators of the negative terms were included in the rate law to make it consistent with the equilibrium law, 2. They did not exceed unity by an amount significant in comparison with the experimental errors. Equations 5 were checked by comparison with the results of equilibrium determinations.

The specific rates and equilibrium quotients of ferric reactions vary rapidly with changing ionic strength. According to the Debye–Hückel theory, the relationship between any equilibrium quotient, K, the ionic strength, μ, and the charge of each ion, z, may be expressed in the form

$$\log_{10}(K/K^0) = -(\Delta z^2)f(\gamma)$$

where $f(\gamma)$ is a function of the activity coefficients of the ions, and at 25° approaches the limit $-0.5\ \mu^{1/2}$ as $\mu^{1/2}$ approaches zero.

Randall[4] has shown that, when Δz^2 is not zero, the $-(1/\Delta z^2)\log K/K^0$ curve in a $\mu^{1/2}$ diagram may be represented by the log γ curve for some one of the strong electrolytes. Bray and Hershey[5a] adopted this method of plotting in their study of certain equilibria involving ferric ion, and their values of $f(\gamma)$ have been used in this investigation. Thus at $\mu = 0.09, f(\gamma) = -0.097$; in reaction 1, $\Delta z^2 = -12$, $\log (K/K^0) = -12\,(0.097)$, and $K/K^0 = 0.0685$.

In applying these ideas to the specific rates in equation 4 the value $\Delta z^2 = -12$ must be distributed among the specific rates in each part of the rate law. The following values are based upon the Brönsted rule and equation 5.

	k_1	ϵ_4	k_4	ϵ_6	k_6	k_1'	ϵ'	k_4'
Δz^2	-10	-2	0	-6	-4	-6	-4	$+2$

In each case $f(\gamma)$ was assumed to be -0.097 at $\mu = 0.09$.

Allowance was made for the formation of the complex ferric iodide ion, FeI^{++}, by comparing two sets of calculations, the first based on the complete ionization of ferric iodide, the second on the assumption that, at $\mu = 0.09$, $K_{FeI^{++}} = (FeI^{++})/(Fe^{+++})(I^-) = 20$.

$$Fe^{+++} + I^- = FeI^{++} \quad \Delta z^2 = -6 \tag{6}$$

The corresponding value of $K_{FeI^{++}}$ at $\mu = 0$ is 75.

Corrections for the hydrolysis of ferric ion were based on the results of Bray and Hershey.[5a]

$$Fe^{+++} + H_2O = FeOH^{++} + H^+ \quad \Delta z^2 = -4 \tag{7}$$

$K^0_{FeOH^{++}} = 60(10^{-4})$. At $\mu = 0.09$, $K_{FeOH^{++}} = 24.6(10^{-4})$. The hydrolysis ranged from 10 to 30% and was controlled by the addition of nitric acid. We believe that the hydrolysis corrections are at least approximately correct since the values of the hydrolysis quotients[5a] were determined from a study of equilibria involving ferric ion. The calculation of ferric ion concentrations is the reverse step, and may be accepted as an empirical method even if the values of $K_{FeOH^{++}}$ are incorrect.[5b]

The concentrations of triiodide ion were calculated by means of the equilibrium constant $K_{I_3^-} = (I_2)(I^-)/(I_3^-) = 0.00141$[6]

$$I_3^- = I_2 + I^- \quad \Delta z^2 = 0 \tag{8}$$

Similarly, in one group of experiments in which bromide ion was present, the concentrations of I_2Br^- were calculated by means of the constant $K_{I_2Br^-} = 0.08$.[7]

The standard potentials used in calculating the equilibrium constant of reaction 1 were

$$Fe^{+++} + E^- = Fe^{++} \quad \Delta z^2 = -5 \quad E^0 = 0.772^{5a} \tag{9}$$

and

$${}^1/_2\,I_2 + E^- = I^- \quad \Delta z^2 = 1 \quad E^0 = 0.534 \tag{10}$$

To determine the latter value, the correction recommended by Randall and Young[8] was applied to the value, 0.5357, chosen by Lewis and Randall.[9]

The solubility product of silver iodide

$$AgI = Ag^+ + I^- \quad \Delta z^2 = +2$$
$$K^0_{AgI} = (9.0 \pm 0.5)(10^{-17}) \tag{11}$$

was calculated by combining the standard iodine potential (equation 10) with the results of Jones and Kaplan[6] for the reaction

$$Ag + {}^1/_2 I_2(s) = AgI \quad E^0_{298} = 0.6845$$

and the silver electrode potential[5a]

$$Ag^+ + E^- = Ag \quad E^0_{298} = 0.7985$$

The solubility product of silver bromide

$$AgBr = Ag^+ + Br^- \quad K^0_{AgBr} = (5.3 \pm 0.3)(10^{-13}) \tag{12}$$

was determined by combining the silver electrode potential with the silver bromide electrode potential

$$AgBr + E^- = Ag + Br^- \quad E^0_{298} = 0.0723 \pm 0.0002$$

The latter was obtained by plotting in a $\mu^{1/2}$ diagram the results of Lewis and Storch[10] for the reaction $AgBr + {}^1/_2H_2 = Ag + H^+ + Br^-$. This potential is in agreement with the value 0.072 ± 0.001 obtained by combining the measurements of Afanasiev[11] for the reaction $AgCl + Br^- = AgBr + Cl^-$ with the silver chloride potential of Randall and Young.[8]

On account of the great tendency of ferric ion to form addition compounds, the presence of chloride and sulfate ions is to be avoided, but ferric nitrate may be assumed to be completely ionized. The ionic strength was controlled by the addition of potassium nitrate. C. P. chemicals were used without further purification. Ferrous

(5) (b) In our previous calculations (Ref. 5a) we assumed that the hydrolysis of $FeOH^{++}$ is negligible in comparison with that of Fe^{+++}. If this assumption is in error our values of $K_{FeOH^{++}}$ are too large. Also, methods which are based on the determination of hydrogen ion concentrations should yield higher values of $K_{FeOH^{++}}$ than we obtained. This may explain the higher results of Brönsted and Volqvartz, *Z. physik. Chem.*, **134,** 127, 133 (1928), which we unwittingly overlooked in 1934. Their value of $K^0_{FeOH^{++}}$ at 15° is nearly the same as ours at 25°.

nitrate solutions were prepared by mixing barium nitrate and ferrous sulfate solutions in equivalent amounts and filtering off the precipitated barium sulfate. Atmospheric oxidation of the ferrous salt was closely watched, and fresh solutions were prepared when the ferric iron content exceeded 3% of the total iron. To diminish the oxygen concentration the solutions and reaction systems were shaken with carbon dioxide. Although the effect of the diffuse daylight of the laboratory on the rates was found to be negligible, the precaution was taken to shield the reaction vessels from light in the rate measurements with iodine and ferrous salts and in the equilibrium determinations. All concentrations were measured in moles per liter, and time intervals in minutes.

Rate Measurements of the Reaction between Ferric Ion and Iodide Ion

Sasaki[12] and Kiss and Bossányi[13] have studied the reaction in low ferrous ion concentration. To

[12] Sasaki, *Z. anorg. allgem Chem.*, **137**, 181, 291 (1924).

[13] Kiss and Bossányi, *ibid.*, **191**, 289 (1930).

measure the initial rate they added starch and a small known quantity of sodium thiosulfate to the reaction system, and observed the interval of time from the start of the reaction to the appearance of the blue color of starch–iodine. Ferric ion reacts directly with thiosulfate ion, however, and the method is subject to error. Increasing the quantity of the thiosulfate increases the amount lost by direct reaction with ferric ion, but there is then a greater average concentration of ferrous ion and the reaction between ferric ion and iodide ion is retarded. The two effects cancel and the rate appears to be independent of the quantity of thiosulfate used. The specific rate in low ferrous ion concentration was redetermined, therefore, by a more direct method.

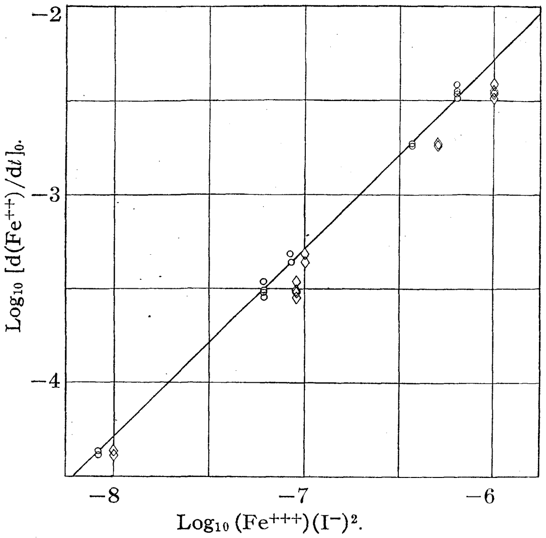

Fig. 1.—Rate measurements in low (Fe^{++}), Expts. 1 to 14: ○, concentrations based on $K_{\text{FeI}^{++}} = (\text{FeI}^{++})/(\text{Fe}^{+++})(\text{I}^-) = 20$; ◇, concentrations based on $K_{\text{FeI}^{++}} = 0$.

Control experiments showed that when iodine is in excess it can be titrated with sodium thiosulfate in the presence of ferric ion without loss of accuracy. Ten-cc. samples of the reaction system were quenched in about 0.075 *M* FeSO_4, and the iodine was titrated without delay. The effectiveness of the quenching was indicated by the slowness with which the blue color reappeared after the starch end-point had been reached.

The results are summarized in Table I. The initial concentrations of ferric nitrate, potassium iodide, nitric acid and ferrous nitrate, composing the reaction systems, are listed in the second, third, fourth and fifth columns. The initial concentrations of ferric ion, iodide ion and hydrogen ion, corrected for the complex ion, FeI^{++}, by means of $K_{\text{FeI}^{++}} = 20$, are listed in the sixth, seventh and eighth columns.

The "observed" initial rates listed in the ninth column were determined from the experimental data by the following method. An approximate rate law was formulated, and values of the rate were calculated at convenient values of (Fe^{++}), the concentration of ferrous ion. For each experiment the reciprocal of the rate, $dt/d(\text{Fe}^{++})$ was plotted against (Fe^{++}). By graphically integrating $[dt/d(\text{Fe}^{++})]d(\text{Fe}^{++})$ from the initial value of (Fe^{++}), time intervals were determined, and compared with those found experimentally. The rate law was modified and the calculations repeated until these two sets of time intervals were brought into agreement. This procedure made certain that the initial rate chosen in each experiment is consistent with the rates during the experiment. The points in Figs. 1 to 4 below correspond to these observed initial rates.

The method of calculating the initial rates listed in the last column is explained at the end of the section.

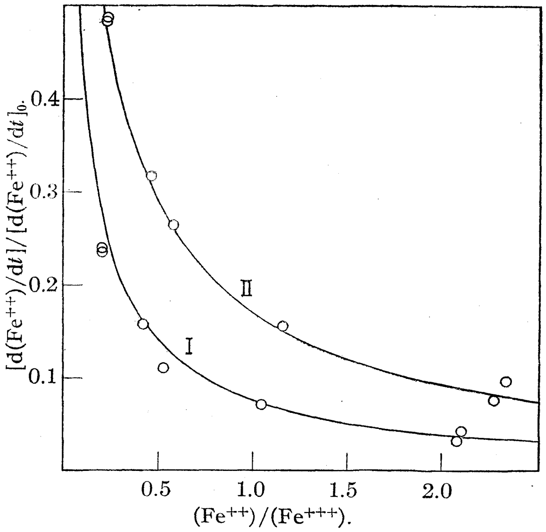

Fig. 2.—The retarding effect of ferrous ion. Curve I, 0.003 *M* KI, Expts; 21, 22, 29, 31, 33, 35 and 41; Curve II, 0.01 *M* KI; Expts. 17, 18, 28, 30, 32, 34 and 40.

The rate is proportional to the concentration product $(\text{Fe}^{+++})(\text{I}^-)^2$ when the concentration of ferrous ion is small and that of iodide ion is not less than about 0.003 molal. This is shown in Fig. 1, where, for the experiments with zero initial ferrous salt, the logarithm of the initial rate is plotted against $\log(\text{Fe}^{+++})(\text{I}^-)^2$. The results obtained without correcting for FeI^{++} are also included in Fig. 1 (but not in Figs. 2, 3 and 4 below). The two values of the specific rate, k_1, determined from the two sets of data are listed at the end of the section.

The retarding effect of ferrous ion is shown in Figs. 2 and 3, where the ratio of the initial rate in each experiment to the rate at zero concentration of ferrous ion, $[d(Fe^{++})/dt]_0$, is plotted against the ratio $(Fe^{++})/(Fe^{+++})$. If equation 3a were the correct rate law, a single curve would be obtained starting at unity on the ordinate axis and approaching zero at high values of $(Fe^{++})/(Fe^{+++})$. The incompleteness of this rate law is therefore shown at once by the existence of two curves in Fig. 2 when the concentration of potassium iodide is varied from 0.01 to 0.003 *M* KI; and in Fig. 3 when, at a much lower iodide concentration, the concentration of hydrogen ion is varied from approximately 0.005 to 0.01 *M* H^+.

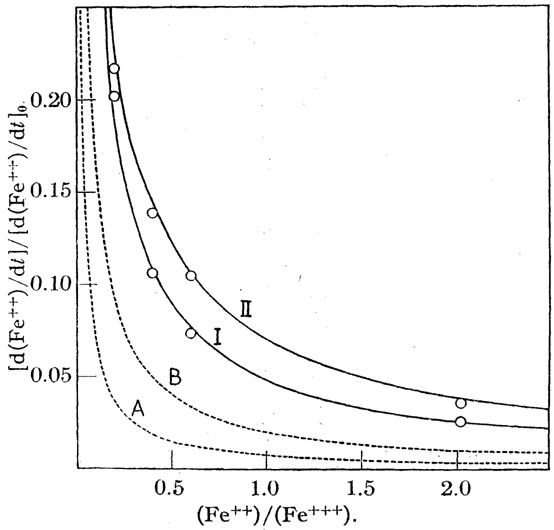

Fig. 3.—The retarding effect of ferrous ion at 0.0005 *M* KI. Curve I, approximately 0.01 *M* H^+; Expts. 27, 37, 39 and 44; Curve II, approximately 0.005 *M* H^+; Expts. 26, 36, 38 and 43.

In Fig. 2, as $(Fe^{++})/(Fe^{+++})$ is increased, the ordinate becomes nearly proportional to (I^-), indicating a rate law of the form

$$\frac{d(Fe^{++})}{dt} = \frac{k_1(Fe^{+++})(I^-)^2}{1 + (Fe^{++})/(Fe^{+++})(I^-)\epsilon_6} \tag{13a}$$

However, when this equation and the data in Fig. 2 are used to calculate the curve for 0.0005 *M* KI, Curve A in Fig. 3 is obtained, and the ratio $[d(Fe^{++})/dt]/[d(Fe^{++})/dt]_0$ is much too small. Some of the discrepancy may be removed by introducing another constant, ϵ_4, in equation 13a

$$\frac{d(Fe^{++})}{dt} = \frac{k_1(Fe^{+++})(I^-)^2}{1 + (Fe^{++})/(Fe^{+++})[\epsilon_4 + \epsilon_6(I^-)]} \tag{13b}$$

which raises Curve A to Curve B. The retarding action of hydrogen ion at low (I^-) and high $(Fe^{++})/(Fe^{+++})$, as shown in Fig. 3, suggests the presence of an additional term in the rate law which is important only at low (I^-), and is therefore of less than the second degree in (I^-)

$$\frac{d(Fe^{++})}{dt} = \frac{k_1'(Fe^{+++})(I^-)}{1 + (Fe^{++})(H^+)/(Fe^{+++})\epsilon'} \tag{13c}$$

The effect of changing (I^-) at constant (Fe^{++}) is shown in Fig. 4. Curves B and B′ are based on equation 13b. At low iodide concentration B is much lower than Curves I and II, and B′ is lower than III; which again shows the need for an added term, such as 13c, in the rate law. Were this added term of the form

$$\frac{d(Fe^{++})}{dt} = \frac{k_1'(Fe^{+++})(I^-)}{(H^+)[1 + (Fe^{++})/(Fe^{+++})\epsilon']}$$

Curve B would have been raised to C, instead of to II, by halving the concentration of hydrogen ion. Were it of the form

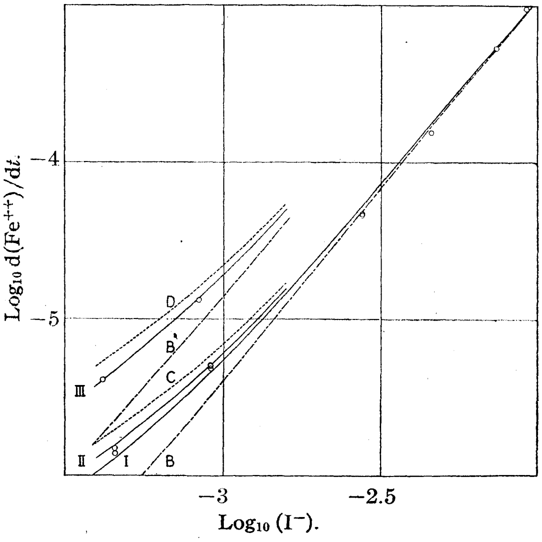

Fig. 4.—Rate measurements at 0.001 *M* Fe^{++}, Expts. 15 to 27: Curve I, 0.0062 *M* $Fe(NO_3)_3$, approximately 0.01 *M* H^+; Curve II, 0.0074 *M* $Fe(NO_3)_3$, approximately 0.005 *M* H^+; Curve III, 0.0148 *M* $Fe(NO_3)_3$, approximately 0.005 *M* H^+.

$$\frac{d(Fe^{++})}{dt} = \frac{k_1'(Fe^{+++})^2(I^-)}{1 + (H^+)(Fe^{++})/\epsilon'}$$

Curve B′ would have been raised to D, instead of to III, by doubling the concentration of ferric ion.

Our experimental data on the rate of interaction of ferric ion and iodide ion are therefore in agreement with the rate law

$$\frac{d(\mathrm{Fe}^{++})}{dt} = \frac{k_1(\mathrm{Fe}^{+++})(\mathrm{I}^-)^2}{1 + (\mathrm{Fe}^{++})/(\mathrm{Fe}^{+++})[\epsilon_4 + \epsilon_6(\mathrm{I}^-)]} + \frac{k_1'(\mathrm{Fe}^{+++})(\mathrm{I}^-)}{1 + (\mathrm{Fe}^{++})(\mathrm{H}^+)/(\mathrm{Fe}^{+++})\epsilon'} \qquad (13)$$

Equation 13 is the sum of 13b and 13c and consists of the positive terms of equation 4. The solid curves in Figs. 1 to 4 and the initial rates in the last column of Table I were calculated by means of equation 13 and the specific rates listed below for $K_{\mathrm{FeI}^{++}} = 20$. When no correction for FeI^{++} was applied, satisfactory agreement between observed and calculated data was also obtained with the same rate law, but with different specific rates.

The values of the specific rates at $\mu = 0.09$ are

	k_1	ϵ_4	ϵ_6	k_1'	ϵ'
$K_{\mathrm{FeI}^{++}} = 20$	5200 ± 500	0.018 ± 0.002	20 ± 1	0.70 ± 0.05	1/(700 ± 50)
$K_{\mathrm{FeI}^{++}} = 0$	3800	.02	17	.55	1/600

Rate Measurements of the Reaction between Ferrous Ion and Iodine

In Homogeneous Solutions at 25°.—Solutions of iodine and ferrous nitrate were mixed and the subsequent changes in the concentration of total iodine, $(\Sigma \mathrm{I}_2)$, were determined by titration against sodium thiosulfate. Since the time required for analysis was negligible in comparison with the time intervals between analyses, no quenching was necessary. The initial concentrations of the substances affecting the rate, corrected for the complex ion, FeI^{++}, are listed in Table II. The ferric iron concentration, $(\Sigma \mathrm{Fe}^{+++})$, was determined iodimetrically. On account of the atmospheric oxidation of some of the ferrous salt, the hydrogen ion concentration is less than that corresponding to the amount of nitric acid added to the reaction system. The iodine solution contained a trace of iodide, which was determined by the permanganate method.[14]

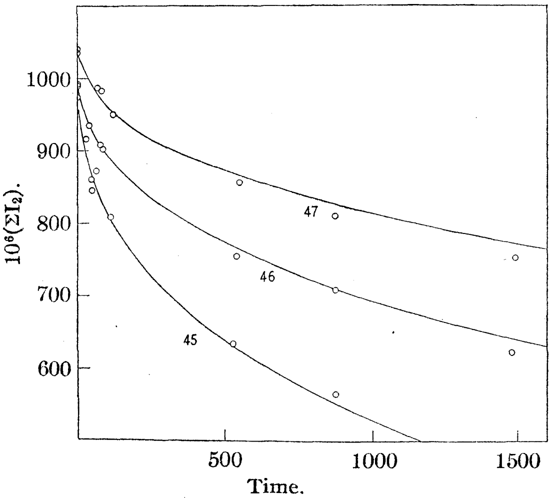

Fig. 5.—The reaction between ferrous ion and iodide ion at 0.005 M $\mathrm{HNO_3}$: Expt. 45, 0.025 M $\mathrm{Fe(NO_3)_2}$; Expt. 46, 0.01 M $\mathrm{Fe(NO_3)_2}$; Expt. 47, 0.005 M $\mathrm{Fe(NO_3)_2}$.

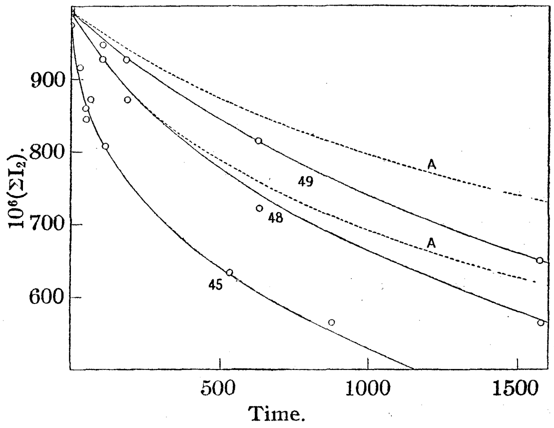

Fig. 6.—The retarding effect of iodide ion at 0.025 M $\mathrm{Fe(NO_3)_2}$ and 0.005 M $\mathrm{HNO_3}$. Initial concentrations of iodide: Expt. 45, $60(10^{-6})$ M; Expt. 48, 0.0005 M; Expt. 49, 0.001 M.

The experimental results are represented by points in Figs. 5 to 8, where the total iodine concentration is plotted against the time in minutes.

In the analysis of these results, various rate laws were tested by a method similar to that described in the preceding section. The reciprocal of the rate, $-dt/d(\Sigma \mathrm{I}_2)$, was calculated at convenient values of $(\Sigma \mathrm{I}_2)$ by means of the assumed rate law, and plotted against $(\Sigma \mathrm{I}_2)$. The time interval to any selected value of $(\Sigma \mathrm{I}_2)$ was calcu-

---

[14] Bray and MacKay, THIS JOURNAL, **32**, 1193 (1910).

lated by graphical integration of $-[dt/d(\Sigma I_2)]$ $d(\Sigma I_2)$ from the initial value of (ΣI_2).

In experiments 45 to 51 ferrous nitrate was present in sufficient excess to make the proportionate change in the concentration of ferrous ion during each experiment small in comparison with that of iodine or iodide ion. The results of experiments 45 to 47, which differ only in the concentration of ferrous ion, are given in Fig. 5. At any selected concentration of total iodine the time intervals are inversely proportional to the concentration of ferrous ion. The rate is therefore directly proportional to the concentration of this ion.

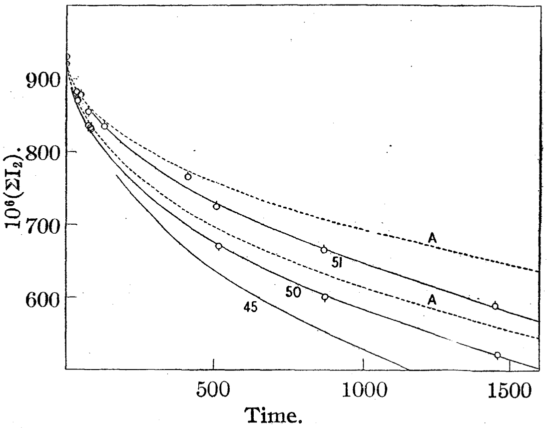

Fig. 7.—The retarding effect of hydrogen ion at 0.025 *M* $Fe(NO_3)_2$: concentrations of HNO_3: Expt. 45, 0.005 *M;* Expt. 50, 0.01 *M;* Expt. 51, 0.02 *M*.

The retarding action of iodide ion is illustrated in Fig. 6, where in three experiments the initial concentration of iodide is varied from a small value in 45 to 0.001 molal in 49. Similarly the retarding action of hydrogen ion is shown in Fig. 7, where the concentration of hydrogen ion is varied from approximately 0.005 molal in 45 to 0.02 molal in 51.

These results indicate a rate law of the form

$$\frac{-d(Fe^{++})}{dt} = \frac{-2d(\Sigma I_2)}{dt} = \frac{k_4'(Fe^{++})(I_2)}{(H^+)(I^-)} \quad (14a)$$

This rate law is in agreement with the results of experiment 45. However, when it is used to calculate the results of the other experiments in Figs. 6 and 7, the curves labeled A are obtained; and the agreement is not satisfactory. The actual rate is greater than that given by equation 14a and the discrepancy increases rapidly as the product $(H^+)(I^-)$ is increased. The discrepancy may be removed, in these experiments, by including in the rate law an added term, which is independent of $(H^+)(I^-)$

$$-d(Fe^{++})/dt = k_4(Fe^{++})(I_2) \quad (14b)$$

That there is a third term in the rate law

$$-d(Fe^{++})/dt = k_6(Fe^{++})(I_3^-) \quad (14c)$$

is indicated by the results of experiment 52, Fig. 8, in which the concentration of triiodide ion was much greater than in the other experiments. Were the rate given by the sum of equations 14a and 14b alone, the measurements would have been represented by Curve B.

Our experimental data on the rate of interaction of ferrous ion and iodine are therefore in agreement with the rate law

$$-d(Fe^{++})/dt = k_4(Fe^{++})(I_2) + k_6(Fe^{++})(I_3^-) + k_4'(Fe^{++})(I_2)/(H^+)(I^-) \quad (14)$$

Equation 14 is the sum of 14a, 14b and 14c, and consists of the numerators of the negative terms of equation 4. The solid curves in Figs. 5 to 8 were calculated by means of equation 4, the specific rates listed below and the specific rates listed at the end of the preceding section. In evaluating k_6 it is necessary to allow for the rate of reaction between ferric ion and iodide ion, which was relatively large only in experiment 52. The magnitude of this effect is illustrated in Fig. 8 by the difference between Curve C, based on equation 14, and the actual data. The values of the specific rates obtained when the complex ion FeI^{++} was neglected were not changed when the correction was applied.

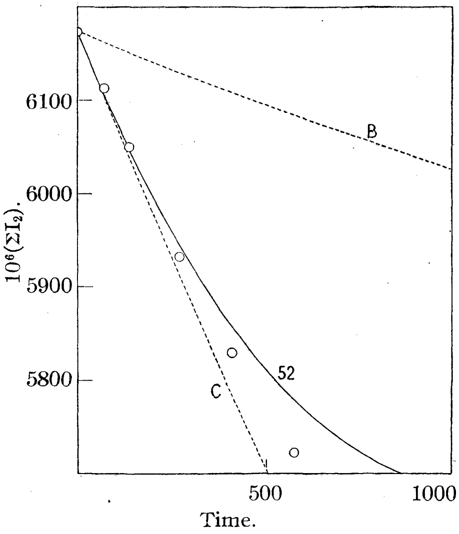

Fig. 8.—The reaction between ferrous ion and triiodide ion at 0.02 *M* HNO_3.

The values of the specific rates at $\mu = 0.09$ are

$$k_4 = 0.009 \pm 0.001$$
$$k_6 = 0.0145 \pm 0.001$$
$$k_4' = (10.0 \pm 0.5)(10^{-8})$$

Rate Measurements in the Presence of Silver Iodide, Silver Bromide and Bromide Ion.—Rate measurements were made also at very low concentrations of iodide ion, maintained by a buffer of silver iodide and silver bromide in a solution containing bromide ion. The ratio $(I^-)/(Br^-)$, which is constant when the system is in equilibrium, is equal to $K_{AgI}/K_{AgBr} = 1.7(10^{-4})$ (*cf.* equations 11 and 12). The ionic strength was 0.055 in these experiments.

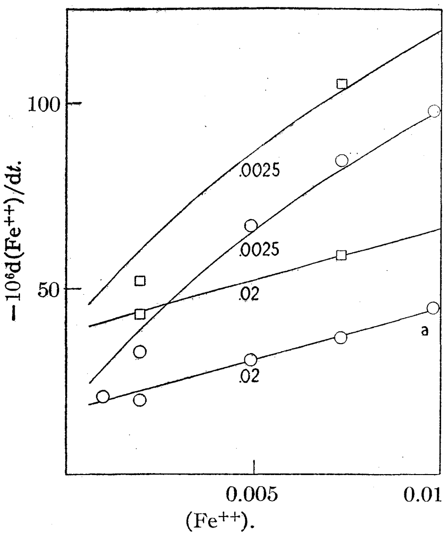

Fig. 9.—Variation of initial rates with the concentration of ferrous ion: ○, 0.005; □, 0.01 mole per liter of AgI and of AgBr; 0.0006 M I_2; 0.01 M Br^-; 0.02 and 0.0025 M H^+; stirring rate, 2000 r. p. m.

An equimolal mixture of the silver halides was precipitated in the reaction vessel before each experiment by adding the calculated amount of a known silver nitrate solution to a solution containing hydrogen ion, potassium ion, iodide ion and bromide ion. After the addition of the ferrous salt solution the reaction was started by adding to the mixture a measured volume of nearly saturated iodine solution (at 25°). The precipitate was kept from settling by vigorously stirring the reaction mixture at a rate of 2000 revolutions per minute, except when otherwise stated. This stirring rate was found to be high enough to bring the reaction rate to within a few per cent. of its maximum value (*cf.* Fig. 11). The results were reproducible when a definite procedure was followed, but they depended on the order in which the reagents were mixed, and are therefore not presented in detail.

The concentration of iodine during the course of the reaction was determined by extraction with carbon tetrachloride and titration with sodium thiosulfate. Since carbon tetrachloride is emulsified by the silver halide precipitate, the latter was first filtered out rapidly on a loosely packed asbestos filter. Some iodine was volatilized in this procedure, and control experiments were made to determine the loss.

(ΣI_2) or $(I_2) + (I_2Br^-)$ could be expressed as a function of the time, t, to within the precision of analysis, by the empirical equation

$$\log [(\Sigma I_2) - \alpha] = -\beta t + \gamma \qquad (15)$$

where α, β and γ were constant during an experiment, but varied from experiment to experiment.

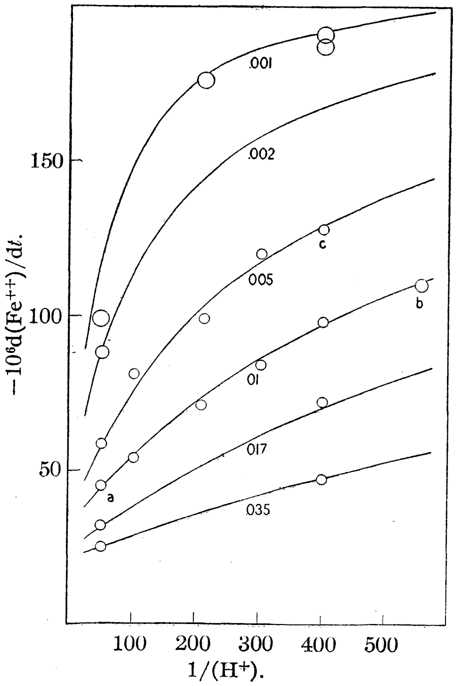

Fig. 10.—Initial rates at various concentrations of hydrogen ion and bromide ion: 0.005 mole per liter of AgI and of AgBr; 0.0006 M I_2; 0.0098 M Fe^{++}; 0.001 to 0.035 M Br^-.

Differentiation of equation 15 gave the rate at any time during the experiment.

$$-d(\Sigma I_2)/dt = -\tfrac{1}{2}d(Fe^{++})/dt = \beta[(\Sigma I_2) - \alpha] \qquad (16)$$

By substituting $t = 0$ in equation 15, the initial value of $(\Sigma I_2) - \alpha$ was calculated, and the initial rate was obtained by substituting this value in equation 16.

The results are presented graphically in Figs. 9, 10 and 11, where the ordinates are the initial rates, reduced to the same iodine concentration, 0.0006 M I_2.

The experimental results can be explained only by assuming two simultaneous reactions, one a homogeneous reaction whose rate is retarded by hydrogen ion and iodide ion (*cf.* equation 14a), and the other a reaction at the surface of the silver halides. As the homogeneous reaction is slow at 0.02 M H^+, the observed rates in the experiments at this concentration, shown in Fig. 9, are due mainly to the heterogeneous reaction. A two-fold increase in the surface, which should double the rate of the heterogeneous reaction, increased the observed rate by the same amount at the two concentrations of hydrogen ion. This result suggests that the rate of the heterogeneous reaction was not altered by an eight-fold change in the concentration of hydrogen ion. A study of all the data supported this result, and led to the additional conclusions that the rate of the heterogeneous reaction was approximately proportional to the concentration of iodine, increased slightly when the concentration of ferrous ion was increased from 0.001 to 0.01 molal, and decreased slightly when the concentration of bromide ion was increased.

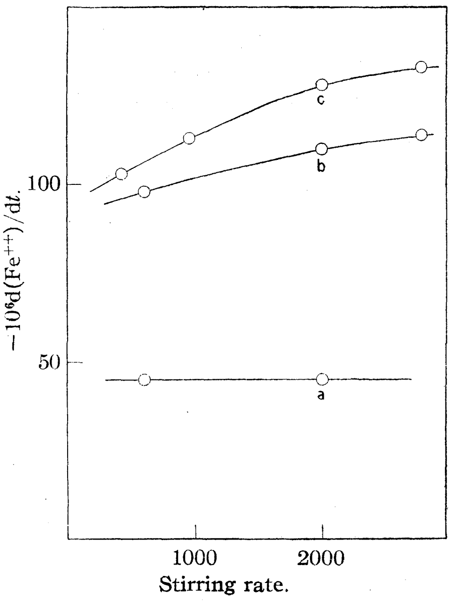

Fig. 11.—Effect of varying the stirring rate in Experiments a, b and c, Fig. 10.

The retarding effects of hydrogen ion and bromide ion (and therefore iodide ion) are illustrated by the data in Fig. 10—and especially by those at low concentrations of hydrogen ion and bromide ion, where the observed rate is due mainly to the homogeneous reaction. When a consistent set of corrections for the heterogeneous reaction were applied to the observed rates, the homogeneous reaction was found to obey rate law 14a at the lowest rates. With increasing values of the quotient $(Fe^{++})/(H^+)(Br^-)$, it approached a value independent of the concentrations of ferrous ion, hydrogen ion and bromide ion. The rates of the homogeneous reaction could therefore be represented by the equation

$$\frac{-d(Fe^{++})}{dt} = \frac{-2d(\Sigma I_2)}{dt} = \frac{k_4'(Fe^{++})(I_2)/(H^+)(I^-)}{1 + \sigma(Fe^{++})/(H^+)(I^-)} \quad (17)$$

The curves in Figs. 9 and 10 represent the sum of the rates calculated by means of this equation and the assumed rates of the heterogeneous reaction. The concentration of iodide ion was assumed to have its equilibrium value, $1.7(10^{-4})$ (Br^-). The corresponding values of σ and k_4' are $28(10^{-8})$ and $8(10^{-8})$ at $\mu = 0.055$.

This value of k_4' corresponds to $8.5(10^{-8})$ at $\mu = 0.09$ and is to be compared with the more accurate value, $10(10^{-8})$, obtained at higher concentrations of iodide ion. The difference could have been eliminated by a small decrease in the corrections for the heterogeneous reaction.

The differential equation, 17, signifies that there are two rate determining steps in series, the first of which is the hydrolysis of iodine. This will become dominant only at high velocities. Thus when the quotient $(Fe^{++})/(H^+)(I^-)$ is increased the equation approaches the limit

$$-d(I_2)/dt = (k_4'/2\sigma)(I_2)$$

$k_4'/2\sigma$ is equal to 0.14, which is of the same order of magnitude as 0.25, the specific rate derived by Abel[15] for the hydrolysis of iodine at 25°. However, this agreement may not be significant, as Liebhafsky[16] has concluded that the specific rate of the iodine hydrolysis has a much higher value. Such a value would require σ to be much smaller than $28(10^{-8})$, and the denominator in 17 would then not be large enough to account for the observed retardations at high reaction rates.

Some or all of the departure of the homogeneous rate from direct proportionality to $(Fe^{++})(I_2)/(H^+)(Br^-)$ may be explained in another way if the steady state concentration of iodide ion is

---

[15] Abel, *Z. physik. Chem.*, **136**, 161 (1928).

[16] Liebhafsky, *ibid.*, **A155**, 289 (1931); THIS JOURNAL, **56**, 2372 (1934). *Cf.* Skrabal, *Z. Elektrochem.*, **42**, 244 (1936).

assumed to have exceeded its equilibrium concentration by an amount which increased rapidly with increasing speed of reaction. This assumption receives some support from the decrease in rate observed when the stirring rate was decreased in experiments b and c, Fig. 11. In order to test this explanation the total reaction rate was assumed to be equal to $\kappa[(I^-) - 1.7(10^{-4})\ (Br^-)]$, where κ is a constant of proportionality. Steady state concentrations of iodide ion were calculated by means of this relation and substituted for (I^-) in equation 14a. Comparison of these rates with the data showed that the homogeneous rate could be represented approximately by equation 14a

$$-2d(\Sigma I_2)/dt = k_4'(Fe^{++})(I_2)/(H^+)(I^-) \quad (14a)$$

if the corrections for the heterogeneous reaction were much larger than before, and if κ and k_4' were equal to 250 and $6(10^{-8})$.

TABLE III

MEASUREMENTS OF THE EQUILIBRIUM $2Fe^{+++} + 2I^- = 2Fe^{++} + I_2$ AT 25°

Expt.	53	54	55
	Initial Concentrations		
KI	0.01916	0.00766	0.0100

HNO_3	.02	.02	.0191
KNO_3	....	.042	....
	Final Concentrations		
$10^6(\Sigma I_2)$	4845 ± 10	2140 ± 7	5360 ± 30
$10^6(\Sigma Fe^{+++})$	598 ± 5	752 ± 7	1530 ± 20
(Fe^{++})	0.00962	0.00436	0.0235
(ΣI^-)	.00950	.00334	.01060
μ	.0715	.087	.108
	Results Based on $K^0_{FeI^{++}} = 75$		
(I^-)	0.00558	0.00205	0.00611
$10^6(I_2)$	977	873	1010
$10^6(Fe^{+++})$	478	646	1240
K	12,800 ± 600	9500 ± 1000	9700 ± 1000
	Results Based on $K^0_{FeI^{++}} = 0$		
(I^-)	0.00563	0.00206	0.00623
$10^6(I_2)$	970	870	990
$10^6(Fe^{+++})$	530	670	1365
K	10,100 ± 600	8700 ± 1000	7600 ± 1000

In spite of the uncertainties with regard to the magnitude of the corrections for the heterogeneous reaction, the specific rate of the iodine hydrolysis and the amount of supersaturation of iodide ion, the rate measurements at very low concentrations of iodide ion confirm the presence in the rate law of the term represented by equation 14a, and the order of magnitude of the specific rate, $k_4' = 10^{-7}$.

Equilibrium Determinations

After dilute solutions of ferric nitrate and potassium iodide had been allowed to react for nine days, the concentration of iodine was determined by titration with sodium thiosulfate, and the ferric iron concentration was determined iodimetrically. Equilibrium was approached also from the reverse side by allowing ferrous nitrate and iodine to react.

The results are summarized in Table III. The amounts of potassium iodide, ferric nitrate, nitric acid and potassium nitrate composing the reaction systems are listed in the second to fifth rows. The total iodine, (ΣI_2), and the total ferric iron concentration, (ΣFe^{+++}), obtained by analysis at equilibrium, are given in the sixth and seventh rows. In experiments 53 and 54, the total iodide ion concentration, $(\Sigma I^-) = (FeI^{++}) + (I_3^-) + (I^-)$, can be calculated from the data by subtracting either (Fe^{++}) or $2(\Sigma I_2)$ from the concentration of potassium iodide initially added, and the values of (ΣI^-) given in the ninth row of Table III are the averages of these two values. In the remaining rows are given the ionic strengths, and values of the equilibrium quotient, K, calculated with and without correction for the complex ion FeI^{++}.

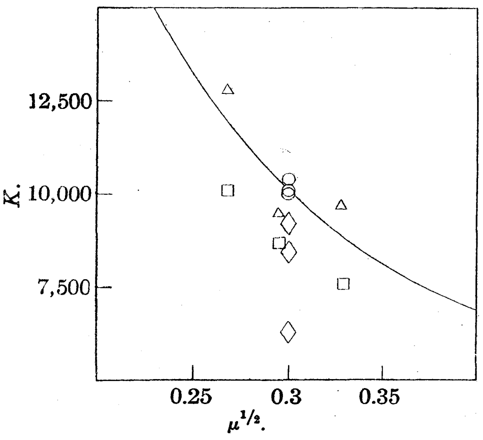

Fig. 12.—$2Fe^{+++} + 2I^- = 2Fe^{++} + I_2$; equilibrium quotients: △, □, from analysis at equilibrium, Table III, assuming $K^0_{FeI^{++}} = 75$ and zero, respectively; ○, ◇, from rate measurements assuming $K^0_{FeI^{++}} = 75$ and zero, respectively; the curve is based on the standard potentials of the ferric–ferrous and iodine–iodide electrodes.

Combination of the standard potentials of the ferric–ferrous and iodine–iodide electrodes, equations 9 and 10, with the solubility of iodine, 0.00132 mole per liter, gives the value of the equilibrium constant, $K^0 = 148{,}000 \pm 2000$ at 25°. This result and the corresponding values of the equilibrium quotients at various ionic strengths, calculated by the method outlined in the introduction, are independent of any assumption regarding the stability of FeI^{++}. At $\mu = 0.09$, $K = 10{,}100$.

The equilibrium quotients at $\mu = 0.09$, calculated from the experimentally determined specific rates by means of equations 5, are

	$K = k_1\epsilon_4/k_4$	$K = K_{I_3^-}k_1\epsilon_6/k_6$	$K = k_1'\epsilon'/k_4'$
$K_{FeI^{++}} = 20$	10,400	10,100	10,000
$K_{FeI^{++}} = 0$	8,450	6,300	9,200

The various values for the equilibrium quotients are compared in Fig. 12. The agreement between the equilibrium quotients calculated from kinetic data, and those determined from measurements of equilibrium concentrations, is fairly close even when no correction for the complex ion FeI^{++} is applied. These "experimental" results are brought into much better agreement with each other, and with the "theoretical" results, represented by the curve in Fig. 12, by correcting for the complex ion, FeI^{++}. This improved agreement may not deserve much weight, since it is the chief basis for the choice of $K_{FeI^{++}} = 20 \pm 5$ at $\mu = 0.09$ and $K^0_{FeI^{++}} = 75 \pm 25$. Regardless of the value of $K_{FeI^{++}}$, however, the results of the various determinations of the equilibrium quotient of reaction 1 confirm the complete rate law, equation 4.

Intermediate Compounds

The rate law expressed by equation 4 signifies that ferric ion may react with either two or one iodide ions in the first rate determining steps of the forward reaction, and that ferrous ion may react with iodine, triiodide ion or hypoiodous acid in the first steps of the reverse reaction. Many reactions are known in which hypoiodous acid is the reactive oxidizing agent in aqueous iodine solutions, and very few in which the iodine itself reacts directly with the reducing agent. This is probably the first example of the direct action of triiodide ion as an oxidizing agent.

To explain part I of the rate law, Wagner[1] advocated intermediate formation of I_2^-, which may be regarded as an addition compound of atomic iodine and iodide ion. Strong supporting evidence is furnished by his more detailed study of the analogous reaction between ferricyanide ion and iodide ion. His theory is a necessary consequence of the assumption that ferrous ion is formed in the rate determining reaction

$$Fe^{+++} + 2I^- \longrightarrow Fe^{++} + I_2^-$$

since there is then only one unit change in the valence of the iron. The same theory may also be used to explain the kinetic results of Yost and Zabaro[17] for the reaction between trivalent titanium and iodine. The rate determining step is then $TiOH^{++} + I_2 \longrightarrow I_2^- + TiO^{++} + H^+$. It seems to be impossible in this case for the titanium to increase its valence by more than one unit. The analogous theory for part II of our rate law requires the formation of IOH^-, an addition compound of atomic iodine and hydroxide ion. If this substance exists at all, it is probably in equilibrium with I_2^-

$$IOH^- + I^- + H^+ = I_2^- + H_2O$$

and therefore is not likely to play a significant role at high concentrations of hydrogen and iodide ions.

The following systems of reactions are in agreement with the rate law:

I

$$Fe^{+++} + I^- \overset{K_2}{Z} FeI^{++}$$

$$FeI^{++} + I^- \underset{k_2}{\overset{^1/_2k_1/K_2}{\rightleftarrows}} Fe^{++} + I_2^-$$

$$\left\{\begin{array}{l} I_2^- + Fe^{+++} \underset{^1/_2k_4}{\overset{k_3}{\rightleftarrows}} Fe^{++} + I_2 \\ I_2^- + FeI^{++} \underset{^1/_2k_6}{\overset{k_5/k_2}{\rightleftarrows}} Fe^{++} + I_3 \end{array}\right.$$

II

$$Fe^{+++} + I^- \overset{K_2}{Z} FeI^{++}$$

$$FeI^{++} + H_2O \underset{k_2'}{\overset{^1/_2k_1'/K_2}{\rightleftarrows}} Fe^{++} + IOH^- + H^+$$

$$IOH^- + Fe^{+++} \underset{^1/_2k_4'/K_3}{\overset{k_3'}{\rightleftarrows}} Fe^{++} + IOH$$

$$IOH + I^- + H^+ \overset{1/K_3}{Z} I_2 + H_2O$$

$$\epsilon_4 = k_3/k_2$$
$$\epsilon_6 = k_5/k_2$$
$$\epsilon' = k_3'/k_2'$$

Each arrow designates a rate determining reaction, and the symbol[18] Z denotes that equilibrium is established relatively rapidly. In deriving the

---

(17) Yost and Zabaro, THIS JOURNAL, **48**, 1181 (1926).

(18) Skrabal, *Z. Elektrochem.*, **40**, 235 (1934).

rate law, the concentrations of I_2^- and IOH^- are assumed to be so small that the rate of change of their concentrations may be set equal to zero.

It has usually been assumed that hypohalous acid is reduced to halide in one step, which requires the valence of the element oxidized to increase by two units. For this reason, our preliminary results at low concentrations of iodide and hydrogen ions were cited by Bray and Gorin[19] as one of several items of evidence for the formation of a +4 iron compound as an intermediate.

The following systems of reactions, which involve tetravalent iron compounds as intermediates, are also in agreement with the rate law:

I

$$Fe^{+++} + I^- \overset{K_2}{Z} FeI^{++}$$

$$FeI^{++} + I^- \underset{k_2}{\overset{^1/_2k_1/K_2}{\rightleftarrows}} FeI_2^+$$

$$FeI_2^+ + Fe^{+++} \overset{K_1}{Z} Fe^{++} + FeI_2^{++}$$

$$\left\{\begin{array}{l} FeI_2^{++} \quad \underset{^1/_2k_4}{\overset{k_3}{\rightleftarrows}} Fe^{++} + I_2 \\ FeI_2^{++} + I^- \underset{^1/_2k_6}{\overset{k_5}{\rightleftarrows}} Fe^{++} + I_3^- \end{array}\right.$$

II

$$Fe^{+++} + I^- \overset{K_2}{Z} FeI^{++}$$

$$FeI^{++} + H_2O \underset{k_2'}{\overset{^1/_2k_1'/K_2}{\rightleftarrows}} FeI(OH)^+ + H^+$$

$$FeI(OH)^+ + Fe^{+++} \overset{K_1'}{Z} Fe^{++} + FeI(OH)^{++}$$

$$FeI(OH)^{++} \underset{^1/_2k_4'/K_3}{\overset{k_3'}{\rightleftarrows}} Fe^{++} + IOH$$

$$IOH + I^- + H^+ \overset{1/K_3}{Z} I_2 + H_2O$$

$$\epsilon_4 = k_3K_1/k_2$$
$$\epsilon_6 = k_5K_1/k_2$$
$$\epsilon' = k_3'K_1'/k_2'$$

An ultimate choice between the two theories will depend upon the results of future investigations of other halogen–halide and other ferric–ferrous reactions. At the present time there is definite supporting evidence for the existence of I_2^- as an intermediate, some less definite evidence for tetravalent iron, and no other evidence for IOH^-. The available evidence thus favors Wagner's theory for part I of the rate law, and the tetravalent iron theory for part II.

Summary

Rate measurements at 25° and at an ionic strength of 0.09 in aqueous solutions containing H^+, Fe^{+++}, Fe^{++}, I^-, I_2, K^+ and NO_3^- were found to be in agreement with the rate law

$$\frac{d(Fe^{++})}{dt} = \frac{k_1(Fe^{+++})(I^-)^2}{1 + (Fe^{++})/(Fe^{+++})[\epsilon_4 + \epsilon_6(I^-)]} - \frac{k_4(Fe^{++})(I_2) + k_6(Fe^{++})(I_3^-)}{1 + (Fe^{+++})[\epsilon_4 + \epsilon_6(I^-)]/(Fe^{++})} \quad \text{I}$$

$$+ \frac{k_1'(Fe^{+++})(I^-)}{1 + (Fe^{++})(H^+)/(Fe^{+++})\epsilon'} - \frac{k_4'(Fe^{++})(I_2)/(H^+)(I^-)}{1 + (Fe^{+++})\epsilon'/(Fe^{++})(H^+)} \quad \text{II}$$

The two parts, I and II, correspond to two paths, each with two rate determining steps. The intermediate compounds involved are either derivatives of zero valent iodine, I_2^- and IOH^-, or derivatives of tetravalent iron, FeI_2^{++} and $FeI(OH)^{++}$. I_2^- and a rate law similar to I were suggested by Wagner in 1924.

Rate measurements of the reaction between ferrous ion and iodine in the presence of silver iodide, silver bromide and bromide ion confirmed the $k_4'(Fe^{++})(I_2)/(H^+)(I^-)$ term of the rate law. The homogeneous reaction was accompanied by reaction between ferrous ion and iodine at the surface of the silver halides.

The equilibrium quotient was calculated from the specific rates by means of the following relations

$$\frac{(Fe^{++})^2(I_2)}{(Fe^{+++})^2(I^-)^2} = K = \frac{\epsilon_4k_1}{k_4} = \frac{K_{I_3^-}\epsilon_6k_1}{k_6} = \frac{\epsilon'k_1'}{k_4'}$$

where $K_{I_3^-}$ is the equilibrium quotient of the reaction, $I^-_3 = I_2 + I^-$.

The quotient, K, was determined in the range $\mu = 0.07$ to 0.11 by analyzing equilibrium solutions. The value at $\mu = 0.09$ was also calculated from the value of $K°$ at $\mu = 0$ based on the standard potentials of the ferric–ferrous and iodine–iodide electrodes.

The several values of K at $\mu = 0.09$ were in fair agreement when ferric iodide was assumed to be completely ionized, and became almost identical when $K_{FeI^{++}} = (FeI^{++})/(Fe^{+++})(I^-)$ was assumed to be 20 ± 5 at $\mu = 0.09$ which corresponds to 75 ± 25 at $\mu = 0$. Corrections for the hydrolysis of ferric ion, and extrapolations to zero ionic strength were made by the method outlined by Bray and Hershey; changing the method of extrapolation would change the results at $\mu = 0$, but would not affect the conclusions at $\mu = 0.09$.

The following values of the specific rates and of the equilibrium quotient were chosen:

---

[19] Bray and Gorin, THIS JOURNAL, **54**, 2124 (1932).

	k_1	ϵ_4	ϵ_6	k_4	k_6
At $\mu = 0.09$	5200 ± 500	0.018 ± 0.002	20 ± 1	0.009 ± 0.001	0.0145 ± 0.001
At $\mu = 0$	48,500	0.028	75	0.009	0.035

	k_1'	ϵ'	k_4'	K
At $\mu = 0.09$	0.70 ± 0.05	$1/(700 \pm 50)$	$(10.0 \pm 0.5)(10^{-8})$	$10{,}000 \pm 1000$
At $\mu = 0$	2.7	1/290	$6.4\,(10^{-8})$	$148{,}000 \pm 20{,}000$

Concentrations are expressed in moles per liter and time intervals in minutes.

The Use of Certain Amines for Distinguishing Geometrically Isomeric Aldoximes and their Acyl Derivatives

BY CHARLES R. HAUSER AND EARL JORDAN

A pair of geometrically isomeric aldoximes was originally distinguished by Hantzsch[1] by the reactions of their acetyl derivatives with cold sodium carbonate solution; with this reagent the derivative prepared from the β-aldoxime gave mainly nitrile,[2] whereas the one obtained from the α-isomer was unaffected. In an extensive investigation of this field, Brady and co-workers have found that three acetyl-β-aldoximes,[3] similar to their α-isomers, are unaffected by cold sodium carbonate.[4] These three acetyl-β-aldoximes, however, are readily decomposed by 2 N sodium hydroxide to give nitrile, but, as was shown recently, this reagent decomposes acetyl-β-aldoximes to form oxime in addition to nitrile, the relative yields of these products being dependent upon the temperature of the reaction.[5] The use of sodium hydroxide for distinguishing acylaldoximes is further complicated by the fact that certain acetyl-α-aldoximes are decomposed by hot alkali to give some nitrile (or corresponding acid) in addition to oxime;[5] moreover, certain carbethoxy-α-aldoximes, with this reagent, give even more nitrile than oxime.[6]

Obviously, it would be desirable to find a reagent or a combination of reagents which would react with acyl-β-aldoximes to give only nitrile, but which would either not react with the corresponding α-isomers, or form only aldoxime; pyridine, especially when used in connection with n-butylamine, apparently meets these requirements.

In a previous paper[7] it has been shown that the acetyl-β-3,4-methylenedioxybenzaldoxime is readily decomposed by pyridine to form only nitrile, whereas the corresponding α-isomer is stable in pyridine solution even at 100°. These isomers are distinguished, also, by their reactions with n-butylamine;[8] with this reagent the α-isomer dissolves without noticeable rise of temperature to give only the corresponding aldoxime, but the β-isomer reacts vigorously with this amine to form both β-aldoxime[9] and nitrile, the yield of the latter being almost quantitative when n-butylamine[8] is added, in one cubic centimeter portions, to a gram sample of the acetyl-β-aldoxime.

These reactions have now been carried out with a series of representative acetyl-α- and acetyl-β-aldoximes. In Table I are given the yields of

---

(1) Hantzsch, *Ber.*, **24**, 21 (1891).

(2) Recently, it has been found that at least certain acetyl-β-aldoximes with sodium carbonate give small amounts of aldoxime in addition to nitrile. See Hauser and Jordan, THIS JOURNAL, **57**, 2450 (1935).

(3) Acetyl-3,4-dimethoxy-5-bromobenzaldoxime, Wentworth and Brady, *J. Chem. Soc.*, **117**, 1045 (1920); acetyl-3,4-dimethoxybenzaldoxime, Brady and Dunn, *ibid.*, **123**, 1800 (1923); acetyl-2-methoxycinnamaldoxime, Brady and Grayson, *ibid.*, **125**, 1419 (1924). See also Brady, *Science Progress*, **29**, 485 (1935).

(4) Whether or not these particular acetyl-β-aldoximes would give nitrile with hot sodium carbonate apparently has not been determined.

(5) Nevertheless, it is possible to distinguish geometrically isomeric acetyl-aldoximes by means of alkali, since, at the same temperature, the β-isomers give much higher yields of nitrile than the corresponding α-isomers; at 30°, the latter generally give only traces of nitrile or corresponding acid. See especially the reference in Note 2.

(7) See Hauser and Jordan, *ibid.*, **58**, 1419 (1936).

(8) Piperidine and diethylamine react in a similar manner; see ref. 7.

(9) It should be pointed out that when the acetyl-β-aldoxime was added in small portions to n-butylamine kept at room temperature or below, mainly β-oxime was obtained, but when the reaction was carried out at the boiling point of the amine (78°), only nitrile could be isolated; see ref. 7.

Table I

Percentage Yields of Products from the Acetyl Derivatives of Substituted Benzaldoximes with Pyridine

nitrile and recovered acetyl-α-aldoxime from the reactions with pyridine, and in Table II, those of nitrile and α-aldoxime from the reactions with *n*-butylamine. The reactions with pyridine were carried out at room temperatures unless otherwise stated; in these cases the yields of products presumably are not affected by a variation of temperature from 0 to 100°. The reactions with *n*-butylamine were carried out by adding the amine, which was at room temperature, to the acetyl-aldoximes as indicated in Table II. In the case of the acetyl-β-aldoximes, the mixtures became hot immediately, producing high yields of nitrile, no aldoxime being found. On the other hand, the α-isomers merely dissolved in the amine without noticeable rise of temperature, giving only α-aldoxime.[10] It should be pointed out that the products of these reactions are readily isolated from the amine solutions; the addition of crushed ice precipitates nitrile, unchanged acetyl-α-aldoxime, or part of the α-oxime, the remainder of the latter being obtained from the filtrate in the usual manner.

These reactions with pyridine and *n*-butylamine may thus be used to distinguish the pairs of geometrically isomeric acetyl-aldoximes listed in Tables I and II; in the cases in which only one geometrical isomer has been studied, their reactions with amines indicate that they have the α- or *syn*-configuration.[11] Since these acetyl derivatives are readily prepared from the corresponding aldoximes, the latter also may be distinguished by this method, but whether or not this method is applicable in all cases remains to be determined by experiment. On this basis α-aldoximes[12] would be those whose acetyl derivatives are stable in pyridine, but react with

---

(10) It should be mentioned that even when acetyl-α-3,4-methylenedioxybenzaldoxime was added to *n*-butylamine at 97–100°, only oxime was obtained; see ref. 7.

(11) Contrary to the older view, α-aldoximes are now considered to have the "*syn*" configuration, and the β-aldoximes, the "*anti*" configuration. For references see Hauser and Jordan.[2]

[a] The melting points of these products were raised by recrystallization to those reported in the literature.

TABLE IV

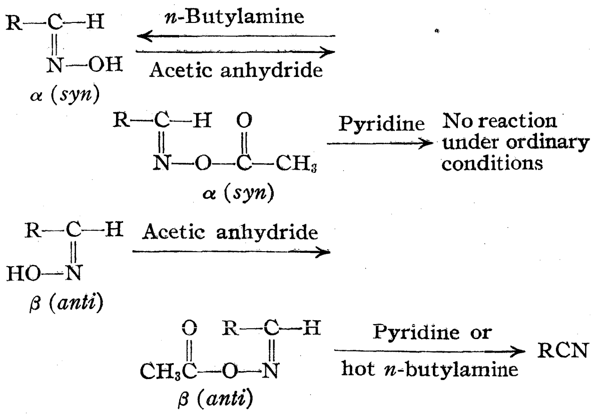
PERCENTAGE YIELDS OF PRODUCTS OBTAINED BY ADDING 5 CC. OF *n*-BUTYLAMINE IN 1-CC. PORTIONS TO 1–2 G. SAMPLES OF CARBANILINO DERIVATIVES OF SUBSTITUTED BENZALDOXIMES

Substituent	Isomer	Corresponding oxime Yield, %	Corresponding oxime M. p., °C. Crude prod.[a]	Corresponding oxime Literature m. p., °C.	Nitrile Yield, %	Nitrile M. p., °C. Crude prod.[a]	Nitrile Literature m. p., °C.
3,4-Methylenedioxy-	α[b,c]	81	109–110	110			
3,4-Methylenedioxy-	β				90	94–95	94–95
3-Nitro-	α[c]	89	120–121	123			
3-Nitro-	β				99	110–112	117–118

[a] The melting points of these products were raised by recrystallization to those reported in the literature. [b] In this case the carbanilino derivative was added to boiling *n*-butylamine. [c] N-Phenyl-N′-*n*-butylurea was obtained in a yield of 98%.

n-butylamine to regenerate the original aldoxime, whereas the β-aldoximes[12] would be those whose acetyl derivatives are decomposed by pyridine or by hot *n*-butylamine to form the corresponding nitrile. Although pure acetyl-aldoximes have generally been used in this work, similar results have been obtained when α-, and β-3,4-methylenedioxybenzaldoximes were treated with acetic anhydride, and, without isolating the acetyl derivatives, the mixtures treated with pyridine or *n*-butylamine.

Using the newer configurations[11] for aldoximes and their acetyl derivatives, these reactions may be represented as follows



$$\underset{\alpha\ (syn)}{\mathrm{R{-}CH{=}N{-}OH}} \underset{\text{Acetic anhydride}}{\overset{n\text{-Butylamine}}{\rightleftarrows}} \underset{\alpha\ (syn)}{\mathrm{R{-}CH{=}N{-}O{-}CO{-}CH_3}} \xrightarrow{\text{Pyridine}} \text{No reaction under ordinary conditions}$$

$$\underset{\beta\ (anti)}{\mathrm{R{-}CH{=}N{-}OH}} \xrightarrow{\text{Acetic anhydride}} \underset{\beta\ (anti)}{\mathrm{CH_3CO{-}O{-}N{=}CH{-}R}} \xrightarrow[\text{hot } n\text{-butylamine}]{\text{Pyridine or}} \mathrm{RCN}$$

This method may be used also for distinguishing certain other acyl-aldoximes. It has been found that carbanilino-β-3-nitro- and carbanilino-β-3,4-methylenedioxybenzaldoximes react with pyridine to give only nitrile whereas the corresponding α-isomers are stable in pyridine solution. Moreover, when *n*-butylamine is added to the β-isomers vigorous reactions occur giving high yields of nitrile, whereas the corresponding α-isomers with this amine give only α-aldoxime. The yields of these products are given in Tables III and IV. It should be pointed out that from the α-isomers with *n*-butylamine high yields of N-phenyl-N′-*n*-butylurea were obtained.

For comparison with these results the yields of products obtained from the reactions of the carbanilino-aldoximes with alkali are given in Table V. It can be seen that, similar to the acetyl-β-aldoximes, these carbanilino-β-aldoximes with alkali give both nitrile and β-aldoxime, although the yield of the latter from the 3-nitro derivative at 25–30° is very small. Alcoholic alkali was used in these cases since these carbanilino derivatives are relatively insoluble in cold aqueous alkali. The reactions with the carbanilino-α-aldoximes give the corresponding oxime as previously reported by others.[13]

It has been shown also that the carbethoxy and benzoyl derivatives of α-aldoximes are stable in pyridine, but are decomposed readily by *n*-butylamine to regenerate the original aldoxime. The yields of recovered acyl-aldoxime and of α-aldoxime obtained in these cases are given in Tables VI and VII.

PERCENTAGE YIELDS OF PRODUCTS FROM BENZOYL DERIVATIVES OF SUBSTITUTED α-BENZALDOXIMES WITH *n*-BUTYLAMINE AND PYRIDINE

Substituent	Amine	Temp., °C.	Oxime Yield, %	Oxime M. p., °C. Crude prod.[a]	Oxime Literature m. p., °C.	Recovered derivatives Yield, %	Recovered derivatives M. p., °C. Crude prod.[a]	Recovered derivatives Literature m. p., °C.
3-Nitro-	*n*-Butylamine	25–30	98	119–120	123			
3-Nitro-	Pyridine	97–100				99	162–163	164
3,4-Methylenedioxy-	*n*-Butylamine	25–30	90	109–110	110			
3,4-Methylenedioxy-	Pyridine	97–100				99	167–168	168

[a] The melting points of these products were raised by recrystallization to those reported in the literature.

These results are of especial significance in connection with the configuration of the carbethoxy-aldoximes which have been isolated in only one geometrical form. Certain of these compounds, although prepared from the corresponding α-aldoximes, were originally assigned the β-configuration by Brady and McHugh,[14] because with hot alkali, nitrile or the corresponding acid was obtained. Recently, however, it has been shown that these carbethoxy-aldoximes react with alkali to give both nitrile and α-aldoximes,[6] the yields of the latter predominating in most cases at 30° or below. Since the aldoximes obtained had been assigned previously the α-configuration as determined by the reactions of their acetyl derivatives with alkali, it was concluded that these carbethoxy derivatives should likewise be assigned the α-configuration; this conclusion is now supported by the fact that, like the acetyl-α-aldoximes, these carbethoxy derivatives are stable in pyridine solution, but are readily decomposed by *n*-butylamine to give the corresponding α-aldoxime.

In conclusion, it should be pointed out that, although the method for distinguishing geometri-

---

(14) Brady and McHugh, *J. Chem. Soc.*, **123**, 1190 (1923). These workers assigned the α-configuration to certain other carbethoxy-aldoximes because with alkali the original aldoxime was obtained. At the time of their work the effect of temperature on the relative yields of nitrile and oxime produced by these reactions was presumably not known; see ref. 6.

cally isomeric acyl-aldoximes described in this paper is very satisfactory for the compounds studied, it is possible that certain types of acyl-α-aldoximes, as well as their β-isomers, might be decomposed by pyridine or *n*-butylamine to give nitrile, especially if there is present in these compounds an activated aldehydic hydrogen atom, or groups that would hinder the aminolysis[7] to aldoxime. Even in these cases, however, it should be possible to distinguish the α- and β-isomers, since the latter would probably form nitrile more readily.[15]

Experimental

Preparation of Acyl-aldoximes.—The acetyl-α- and acetyl-β-aldoximes were prepared according to methods previously described.[2]

The carbanilino-α- and carbanilino-β-aldoximes were prepared by treating the corresponding aldoximes in ether solution with phenyl isocyanate according to the methods described by Brady and others.[13] Crystals of the β-derivatives formed almost immediately; these were purified by recrystallization from alcohol and water. Crystals of the α-derivatives formed on standing several hours; these were purified by boiling them in alcohol solution for an hour, followed by recrystallization from alcohol and water as described by Brady and co-workers.[13] The melting points of these derivatives agreed with those reported by the earlier workers.

The carbethoxy-α-aldoximes[14] and benzoyl-α-aldoximes[16] were prepared from α-aldoximes according to methods previously described.

Reactions of Acyl-aldoximes with Pyridine and *n*-Butylamine.—These amines (4–6 cc.) were added, in 1-cc. portions, to 1–2 g. samples of the acyl-aldoximes. The reactions of *n*-butylamine with the acetyl-β- and carbanilino-β-aldoximes were vigorous, generating considerable heat; in the other reactions the acyl-aldoximes dissolved without appreciable rise of temperature. After standing several hours, crushed ice was added to the amine solutions, and the products isolated as described previously for the case of the acetyl-3,4-methylenedioxybenzaldoximes.[7] In the reactions of *n*-butylamine with the carbanilino-α-aldoximes a solid was obtained which was insoluble in alkali; it melted at 130°, and was shown to be identical with N-phenyl-N′-*n*-butylurea[17] synthesized from phenyl isocyanate and *n*-butylamine.

In order to show that α- and β-3,4-methylenedioxybenzaldoximes may be distinguished without isolating the corresponding acetyl derivatives, 1-g. samples of these aldoximes were dissolved in minimum quantities of acetic anhydride (about 1 cc.) at room temperature and the solutions cooled in an ice-bath. The mixtures were then treated with approximately 6 cc. of pyridine or *n*-butylamine; when the latter was added the mixture became very hot. After standing for an hour, ice water was added and the products isolated in the usual manner. The yields of products obtained were as follows: from the β-aldoxime with pyridine, 97% nitrile, and with *n*-butylamine, 84% nitrile; from the α-aldoxime with pyridine, 80% of the corresponding acetyl-α-aldoxime, and with *n*-butylamine, 72% of the original α-aldoxime.

Reactions of Carbanilino-aldoximes with 2 *N* Sodium Hydroxide.—These reactions were carried out and the products isolated as described previously for the reactions of the acetyl-aldoximes with alkali.[2] In the reactions with the carbanilino-α-aldoximes, diphenylurea was obtained as previously reported.[13]

Summary

A method for distinguishing geometrically isomeric aldoximes and their acyl derivatives is described; it is based on the reactions of the latter with pyridine and *n*-butylamine.

Acetyl-β- and carbanilino-β-aldoximes are decomposed by pyridine to form nitrile, while the corresponding α-isomers are stable in pyridine solution.

Acetyl-β- and carbanilino-β-aldoximes react vigorously with *n*-butylamine, the hot mixture giving mainly nitrile, whereas the corresponding α-isomers dissolve in *n*-butylamine without noticeable rise of temperature, giving aldoxime.

α- and β-aldoximes are readily converted into their corresponding acetyl derivatives; consequently, the method may be used to distinguish geometrically isomeric aldoximes.

The carbethoxy and benzoyl derivatives of α-aldoximes are stable in pyridine solution, but are decomposed by *n*-butylamine to regenerate the original aldoxime.

DURHAM, N. C.

---

[15] It might be mentioned in this connection that often it is not possible to isolate the β-isomers, especially when the β-aldoximes are treated with the acylating agent in a basic medium; however, the presence of the β-isomers is indicated by the formation of nitrile directly; see ref. 6.

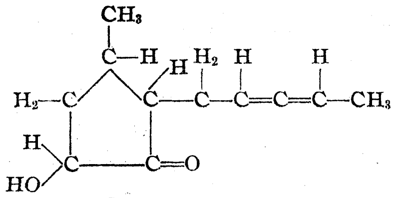
Constituents of Pyrethrum Flowers. VI. The Structure of Pyrethrolone[1,2]

BY F. B. LAFORGE AND H. L. HALLER

Pyrethrolone, the cyclic ketonic alcoholic component common to the two insecticidal constituents of pyrethrum flowers, has been assigned formula I by Staudinger and Ruzicka.[3]

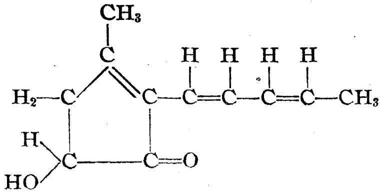


I

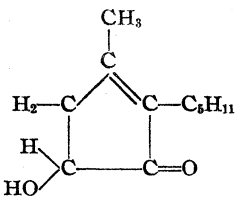
The semicarbazone of pyrethrolone is obtained by saponification of the semicarbazones of either of the pyrethrins or mixtures of their semicarbazones.

In a previous communication[4] it has been shown that the semicarbazone of pyrethrolone should be represented by the empirical formula $C_{12}H_{17}O_2N_3$, and that of tetrahydropyrethrolone, which has a saturated side chain, by $C_{12}H_{21}O_2N_3$. It follows that pyrethrolone corresponds to formula $C_{11}H_{14}O_2$ and tetrahydropyrethrolone to $C_{11}H_{18}O_2$. These formulas, which have been verified by numerous analyses, have two less hydrogen atoms than formula I and its tetrahydro derivative.[5]

This fact calls for a revision of formula I, and it is suggested that pyrethrolone be assigned formula II and tetrahydropyrethrolone formula III.



II



III

In formula II a two-fold revision has been made. An additional double bond is placed in the 2,3-position in the nucleus, and following a later suggestion of Ruzicka and Pfeiffer the cumulated double-bond system has been replaced by a system of conjugated double bonds.[6,7]

Tetrahydropyrethrolone, having a saturated side chain, is better suited for study of the nuclear reactions than is pyrethrolone. It is best prepared by hydrogenation of pyrethrolone semicarbazone and subsequent hydrolysis of the hydrogenated compound.

When tetrahydropyrethrolone, prepared by hydrolysis of its semicarbazone (m. p. 196°), is again treated with semicarbazide, a mixture of semicarbazones that can be separated into two fractions is obtained. The larger part is the original semicarbazone melting at 196°, the other an isomer melting at 168°.[8] This observation has been verified by us. When the semicarbazone of tetrahydropyrethrolone is hydrolyzed with potassium bisulfate solution at 100°, all the tetrahydropyrethrolone is obtained in the form which gives the semicarbazone melting at 168–170°.

The difference between the two tetrahydropyrethrolones derived from these semicarbazones, as suggested by Staudinger and Ruzicka,[8] is due merely to optical inactivation at the carbon atom to which the hydroxyl group is attached, the racemic compound being the one that yields the semicarbazone melting at 170°. This is true because the free ketone is optically inactive and for reasons that will immediately follow.

Preparations of pyrethrolone obtained from the semicarbazones are also without doubt mixtures containing more or less of the inactive form.

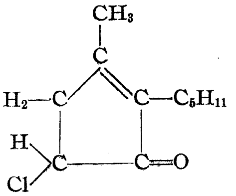
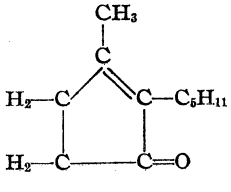
(7) With the suggested change in the nucleus, a reinterpretation of the results of the oxidation and ozonization experiments of Staudinger and Ruzicka from which the arrangement of the double bonds in the side chain of formula 1 was deduced might indicate that the conjugated system so common in natural products is not excluded. We wish to state emphatically, however, that at present no positive evidence for either the conjugated or the cumulated system is available. This phase of the investigation is now in progress.

(8) Staudinger and Ruzicka, *Helv. Chim. Acta*, **7**, 226 (1924).

The hydroxyl group in tetrahydropyrethrolone is readily replaced by chlorine, and the resulting chloro derivative of formula IV yields on reduction an optically inactive ketone of structure V, which gives a semicarbazone that melts at 176°.



IV

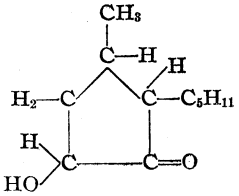


V

Structure V is the one that on the basis of degradation and synthesis has been assigned to dihydrojasmone,[6,9] the semicarbazone of which also melts at 176°. Through the courtesy of Dr. W. Treff, of Heine and Co., Leipzig, Germany, we have obtained a sample of authentic dihydrojasmone semicarbazone. It melted at 176° and a mixture of it with our tetrahydropyrethrone semicarbazone likewise at 176°. The two compounds are therefore identical. The optically inactive tetrahydropyrethrolone, the semicarbazone of which melts at 170°, also yields a chloro compound which on reduction gives the same compound of formula V as that obtained from active tetrahydropyrethrolone. Its semicarbazone also melts at 176°, and a mixture of it with the corresponding derivative obtained from the active substance likewise melts at 176°. The *p*-nitrophenylhydrazone melts at 107°. The two substances are therefore identical, and the proof is established that both active and inactive tetrahydropyrethrolone are to be represented by formula III.

With the assumption that tetrahydropyrethrolone corresponds to formula III, its characteristic reactions are readily explained. In agreement with the recorded observation, it should yield caproic acid on oxidation. The location of the double bond where only carbon-to-carbon linkages are present would render it difficult to hydrogenate, which is also in agreement with experience. Formula III, in fact, not only satisfies all the recorded properties of tetrahydropyrethrolone, but in addition it explains all the recorded divergences from the expected.

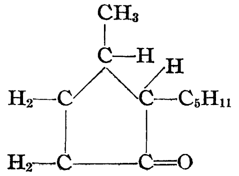
The formula VI, which has been proposed by Staudinger and Ruzicka[3] for tetrahydropyrethrolone, has the same nucleus as formula I, but it has a saturated side chain. From analogy with compounds having the same nucleus, a compound of that structure would be expected to yield 1-amyl-2-methylglutaric acid upon mild oxidation with permanganate. The experiment, however, gave a negative result.[10]



VI

The formation of malonic acid, which has been regarded as a degradation product of the side chain in the oxidation of pyrethrolone (of formula I), may possibly be as an oxidation product of the nucleus (of formula II), and hence could not be regarded as proof of the grouping —$CHCH_2CH$— in the side chain.

Although the ethers and acetates of cyclopentanolones of known structure are stable on hydrogenation, pyrethrolone and its methyl ether and acetate are in part hydrogenated to the completely saturated compound of formula VII.[11,12]



VII

This compound was also prepared synthetically by Staudinger and Ruzicka, and its identity established with the reduction product of pyrethrolone. (The compound of formula V was an intermediate product in this synthesis.)

It is possible that the presence of a double bond, situated as in formulas II and III, might induce a cleavage such as is observed with the pyrethrolone derivatives, with the formation of hexahydropyrethrone of formula VII. The hydrogenation of the pyrethrolone derivatives does not, however, proceed simply or with quantitative yields.

It was in this phase of their investigations that the discontinuity in the reasoning of Staudinger and Ruzicka occurred.

Pyrethrolone and also tetrahydropyrethrolone

(12) This compound has been called "tetrahydropyrethrone" by Staudinger and Ruzicka. In view of the introduction of a double bond in the nucleus of the revised formulas it should be designated as hexahydropyrethrone.

have been found to be very sensitive compounds. Both, although nearly insoluble in water, are probably hygroscopic, and for this reason it is unusually difficult to obtain satisfactory analytical results. It was only when the samples for the combustions were weighed out immediately after distillation that values close to the theoretical for carbon and hydrogen were obtained. Subsequent analyses always showed a decreasing carbon content. When samples were redistilled after standing for a few days, a vigorous evolution of vapor preceded the distillation. This property, not referred to in the literature, may have contributed to the faulty analyses reported. It does not, however, appear to be shared by the enolic forms of pyrethrolone and tetrahydropyrethrolone or by the acetates and ethers.

Experimental

Pyrethrolone.—Staudinger and Ruzicka prepared pyrethrolone by shaking its semicarbazone for a long time in the cold with a concentrated solution of potassium bisulfate in the presence of benzene. The method has been changed slightly, because at a temperature near 0° the salt crystallized out and the benzene solidified. Instead of benzene, peroxide-free ether has been employed as the solvent and the operation carried out during the cool season in a room with open window. Many experiments were performed with quantities of semicarbazone ranging from 5 to 15 g., about 75 g. of potassium bisulfate dissolved in 150 cc. of water, and about 150 cc. of ether. The air in the container was displaced by carbon dioxide. The time required for practically complete decomposition ranged from one to three weeks, depending on the quantity of semicarbazone used. The ether solution was separated, washed, and dried, and the solvent evaporated. The yields of crude product were always somewhat less than quantitative, and a small amount of insoluble solid material always remained. It was necessary to avoid contact of the ether with rubber, as otherwise sulfur was dissolved which was impossible to remove.

The colorless crude product was distilled at about 0.25 mm. and passed over between 130 and 135°. The distillate should be protected as much as possible from contact with air, if satisfactory analytical results are to be obtained. The samples for combustion were therefore weighed out immediately after distillation. Even when all possible care was taken, the figures obtained are not all that could be desired. Results obtained on samples weighed even an hour after distillation showed a decrease in carbon and an increase in hydrogen content, and weighed portions were observed to gain in weight visibly on the balance. When preparations that had been in contact with air a few days were redistilled, a vigorous evolution of vapor preceded the distillation, and the distilled product when again immediately analyzed gave results very close to the calculated. There is also a slight loss in distillation, due perhaps to oxidation or polymerization.

Anal. (freshly distilled material) Calcd. for $C_{11}H_{14}O_2$: C, 74.15; H, 7.87; for $C_{11}H_{16}O_2$: C, 73.33; H, 8.89. Found: C, 73.94, 73.77, 73.36, 73.33; H, 8.34, 8.35, 8.31, 8.13.

Tetrahydropyrethrolone.—The free ketone alcohol was always prepared from the corresponding semicarbazone[4] by hydrolysis with potassium bisulfate under exactly the same conditions as described above. The time required for complete reaction was shorter than for pyrethrolone.

Tetrahydropyrethrolone closely resembles the unhydrogenated compound in its physical properties. The two compounds are both hygroscopic and require the same precautions in handling. It boils at about 120–125° and 0.25 mm.

The following results were obtained with material analyzed immediately after distillation:

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.53; H, 9.98; for $C_{11}H_{20}O_2$: C, 71.74; H, 10.88. Found: C, 72.19, 71.90, 72.00, 71.75; H, 10.05, 10.15, 10.05, 10.05.

The compound gives a pale yellow coloration with tetranitromethane. In ethyl alcohol $[\alpha]^{20}_{D} +11.9°$, $c = 7$; $l = 1$ dm. Staudinger and Ruzicka[8] report a levo rotation ($-11.3°$).

Racemic Tetrahydropyrethrolone and its Semicarbazone.—When the semicarbazone is prepared from distilled tetrahydropyrethrolone, two compounds are obtained. For the most part the mixture consists of the original semicarbazone melting at 196°. The remainder is the semicarbazone of the racemic compound melting at 170°. One gram of distilled tetrahydropyrethrolone was dissolved in 10 cc. of 95% alcohol and 3 cc. of pyridine, and 0.6 g. of semicarbazide hydrochloride in a few drops of water was added to the solution. After standing for two days the 0.6 g. of separated crystalline material was removed by filtration. It melted at 196°. Water was added to the filtrate, and the precipitated material was separated. It melted at 180–185°. It was recrystallized from ethyl acetate and yielded 0.3 g. of the material melting at 196°. The residue obtained on complete evaporation of the solvent was recrystallized from ethyl acetate with addition of benzene. It melted at 170°. The yield was 0.2 g. The total yield of the main product was thus about 66% of the theoretical.

When the semicarbazone of tetrahydropyrethrolone (m. p. 196°) is hydrolyzed with bisulfate solution at 100°, all the resulting tetrahydropyrethrolone is converted into the inactive form, the semicarbazone of which melts at 170°. Two and a half grams of tetrahydropyrethrolone semicarbazone (m. p. 196°) was shaken at 100° with a solution of 15 g. of potassium bisulfate in 30 cc. of water and 15 cc. of toluene. After three hours the toluene solution was diluted with ether, separated from the aqueous solution, washed, dried, and the solvents removed. The residue distilled at about 120° and 0.2 mm. The yield of pure substance was 1.4 g. The compound is optically inactive. A 6.8% solution in ethyl alcohol showed no detectable rotation in a 1-dm. tube. The semicarbazone was prepared and found to melt at 170°.

Tetrahydropyrethrolone Methyl Ether.—Two grams of tetrahydropyrethrolone semicarbazone in 20 cc. of methanol containing 1 cc. of concentrated sulfuric acid was boiled under reflux for two and one-half hours. The solution was poured into 200 cc. of water, and the separated oil was extracted with petroleum ether. Some solid material insoluble in petroleum ether was removed by filtration. Although not further examined, it was probably the semicarbazone of tetrahydropyrethrolone methyl ether. The petroleum ether solution was washed with water and dried. After removal of the solvent the residual oil was distilled and boiled at 82° and 0.35 mm. The yield of distilled product was 0.6 g.

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.47; H, 10.20; CH_3O, 15.82. For $C_{12}H_{22}O_2$: C, 72.72; H, 11.11. Found: C, 73.00, 73.16, 73.25; H, 10.01, 10.27, 10.06; CH_3O, 16.1.

3,5-Dinitrobenzoyl Ester of Pyrethrolone.—Four-tenths of a gram of pyrethrolone was dissolved in 8 cc. of benzene and 2 cc. of quinoline, and 0.7 g. of 3,5-dinitrobenzoyl chloride was added in small portions. The solution was heated under reflux on the steam-bath for one hour, and then poured into ice water and extracted with ether. The ether solution was washed with water and carbonate solution, and the residue left on evaporation of the solvent was combined with the small quantity of solid material that had separated during extraction and was recrystallized from methanol. The yield was about 0.5 g. It melted at 145°.

Anal. Calcd. for $C_{18}H_{16}O_7N_2$: C, 58.06; H, 4.28; for $C_{18}H_{18}O_7N_2$: C, 57.76; H, 4.81. Found: C, 57.86, 57.85; H, 4.24, 4.48.

5-Chlorotetrahydropyrethrone (Formula IV) from Active Tetrahydropyrethrolone.—One gram of tetrahydropyrethrolone was cooled to 0°, and 1 cc. of thionyl chloride was added in small portions. Reaction took place readily with gas evolution. After the main reaction had subsided, an additional 0.5 cc. of thionyl chloride was added and the reaction allowed to proceed about fifteen minutes at room temperature. The excess of thionyl chloride was removed by distillation at about 15 mm., and the chloro derivative was then distilled at 0.6 mm. Practically all passed over at 97–100°. The yield was 0.9 g.

Anal. Calcd. for $C_{11}H_{17}OCl$: C, 65.84; H, 8.47. Found: C, 65.19, 65.16; H, 8.52, 8.59.

Tetrahydropyrethrone (Dihydrojasmone), Formula V.—Two grams of zinc dust was added in small portions to a solution of 0.8 g. of 5-chlorotetrahydropyrethrone in 5 cc. of acetic acid. The solution warmed up spontaneously, and the reaction was completed by heating for one hour on the steam-bath. Water was then added and the aqueous suspension decanted. The separated oil was extracted with ether and the ethereal solution freed from acetic acid by washing with water and sodium carbonate solution. The solvent was then removed and the remaining liquid distilled at 15 mm. The temperature was not recorded owing to the small quantity of material handled. The yield of tetrahydropyrethrone was 0.7 g. It has a pleasant odor and $n^{28}\text{D}$ 1.476. It is optically inactive. A 7% solution in alcohol showed no rotation in a 1-dm. tube.

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.46; H, 10.84. Found: C, 78.92, 78.92; H, 11.16, 10.80.

The semicarbazone was obtained in quantitative yield from 0.1 g. of material and 0.15 g. of semicarbazide hydrochloride in pyridine–alcohol solution. It melted at 176°. The melting point was unchanged after recrystallization from benzene.

5-Chlorotetrahydropyrethrone and Tetrahydropyrethrone (Dihydrojasmone) from Inactive Tetrahydropyrethrolone.—The preparation of the chloro compound and its reduction to dihydrojasmone were repeated to show that no migration of the double bond had occurred in the inactivation of tetrahydropyrethrolone. One and six-tenths grams of the inactive tetrahydropyrethrolone was converted into the chloro derivative by the procedure described above and yielded 1.4 g. of distilled product.

Anal. Calcd. for $C_{11}H_{17}OCl$: Cl, 17.70. Found: Cl, 17.90, 17.93.

One and three-tenths grams of the chloro compound yielded, on reduction with zinc and acetic acid, 1.1 g. of tetrahydropyrethrone, $n^{28}\text{D}$ 1.476. The semicarbazone melted at 176°, and when mixed with an equal quantity of the same compound obtained from active tetrahydropyrethrolone or with authentic dihydrojasmone semicarbazone the melting point was also 176°. The *p*-nitrophenylhydrazone was prepared by dissolving equal quantities of the ketone and *p*-nitrophenylhydrazine hydrochloride in methanolic solution. After recrystallization it melted at 106–107°. Ruzicka and Pfeiffer record the melting point of the *p*-nitrophenylhydrazone of dihydrojasmone as 111.[6] The *p*-nitrophenylhydrazone of the compound of formula VII is reported to melt at 88°.[13]

Summary

The formula I for pyrethrolone proposed by Staudinger and Ruzicka has been revised by placing an additional double bond within the cyclopentane nucleus in the 2,3-position and by changing the cumulated double-bond system in the side chain to a system of conjugated double bonds. The same revision of the nucleus is also made in the formula for tetrahydropyrethrolone. These changes are in agreement with the analytical results found for pyrethrolone and its derivatives.

The new formulas II and III for pyrethrolone and tetrahydropyrethrolone are substantiated by the conversion of the latter compound into a chloro derivative, which on reduction yields dihydrojasmone of the established structure V.

Open Chain Derivatives of *d*-Mannose

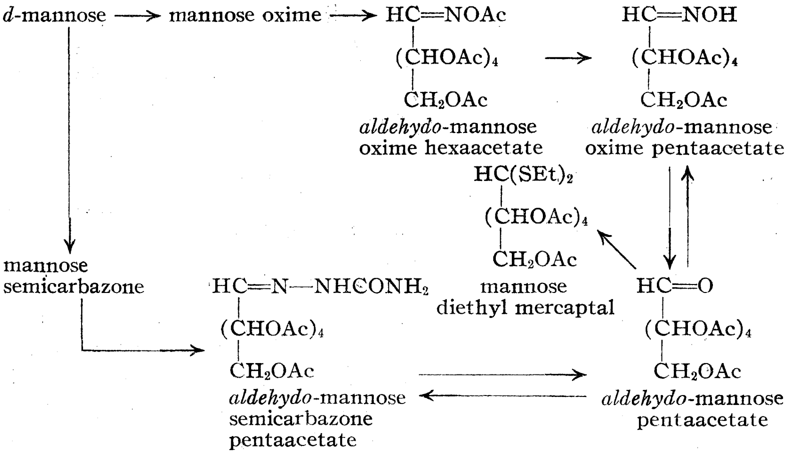
BY M. L. WOLFROM AND L. W. GEORGES

Application of the controlled hydrolysis, with mercuric chloride and cadmium carbonate, to acetylated sugar mercaptals[1] having the *cis*-configuration on carbon atoms two and three, such as mannose, rhamnose and α-glucoheptose, has led to impure sirupy products instead of the desired crystalline *aldehydo*-sugar acetates. The new synthesis of *aldehydo*-sugar acetates reported from this Laboratory[2] offered a different method of approach which has now been applied to *d*-mannose. The desired *aldehydo*-mannose pentaacetate was not obtained in crystalline form but a sirupy product was secured which was less impure than that produced by de-mercaptalation. This sirup was characterized by a number of crystalline derivatives, of an open chain structure, which are of interest and which can be produced by direct acetylation methods.

Deulofeu and co-workers[3] have shown that the low temperature acetylation of mannose oxime gives the open chain or *aldehydo*-mannose oxime hexaacetate in good yield. The assignment of an open chain structure to this compound was based upon its transformation to the acetylated nitrile on heating, a reaction characteristic of the open chain aldose oxime hexaacetates.[4] In the work herein reported, the O-acetyl of the oxime group has been selectively hydrolyzed and the resulting crystalline oxime pentaacetate has been deoximated with nitrous acid to produce the *aldehydo*-mannose pentaacetate as a sirup. This sirup was characterized by two crystalline derivatives, mannose diethyl mercaptal pentaacetate and *aldehydo*-mannose semicarbazone pentaacetate. The formation of these two carbonyl derivatives without loss of acetyl groups indicated that the sirup was essentially the *aldehydo*-pentaacetate. Mild acetylation of mannose semicarbazone formed the same crystalline semicarbazone pentaacetate as was obtained by the reaction between the deoximated product and semicarbazide. Removal of the semicarbazide group from this substance with nitrous acid yielded a sirupy pentaacetate which could be oximated to produce a crystalline *aldehydo*-mannose oxime pentaacetate identical with that obtained from the selective hydrolysis of the oxime hexaacetate of Deulofeu and co-workers. The relationships between these compounds are shown in Fig. 1. It would appear from these results and from those of Deulofeu and co-workers, that *d*-mannose shows a pronounced tendency to react in its open chain form.

Fig. 1

Interrelationships in the *aldehydo*-mannose series



Experimental

Preparation of *Aldehydo-d*-mannose Oxime Hexaacetate.—This substance was prepared by the low temperature acetylation of mannose oxime as described by Deulofeu and co-workers,[3] except that mechanical stirring was employed and the reaction was satisfactorily completed in twelve hours at 2° instead of in eight days at 0°; m. p. 91–92°; $(\alpha)^{25}_D$ $-8.5°$ (c, 4; $CHCl_3$). Deulofeu and co-workers record the constants: m. p. 94°; $(\alpha)^{20}_D$ $-8.3°$ ($CHCl_3$).

***Aldehydo-d*-mannose Oxime Pentaacetate.**—*Aldehydo-d*-mannose oxime hexaacetate (7.5 g.) and 6.5 g. of oxalic acid dihydrate were dissolved in 80 cc. of warm methanol and the solution refluxed for thirty minutes. The solvent

[4] M. L. Wolfrom and A. Thompson, THIS JOURNAL, **53**, 625 (1931).

was removed under reduced pressure and the crystalline residue was washed with several 50-cc. portions of cold water to remove the oxalic acid; yield 4.9 g.; m. p. 119–122°; $(\alpha)_D$ +14° ($CHCl_3$). Pure material was obtained by digestion with ether followed by recrystallization from the minimum amount of hot ethanol by the addition of water; m. p. 122–123°; $(\alpha)^{29}_D$ +15° (*c*, 4; $CHCl_3$).

Anal. Calcd. for $C_6H_8O_6N(COCH_3)_5$: N, 3.45; acetyl, 12.35 cc. of 0.1 *N* NaOH per 100 mg. Found: N, 3.53; acetyl (Freudenberg[5] method), 12.3 cc.

Further acetylation of this substance under mild conditions produced *aldehydo-d*-mannose oxime hexaacetate. The pentaacetate (4.4 g.) was dissolved at 0° in a previously cooled solution of acetic anhydride (13 cc.) and pyridine (26 cc.) and maintained at 0° for one hour. The product was obtained in crystalline form by pouring into 300 cc. of ice and water; yield 3.8 g.; m. p. 89–90°. Pure material was obtained by recrystallization from a small amount of hot ethanol by the addition of water; yield 2.5 g.; m. p. 91–92°; $(\alpha)^{29}_D$ −8.4° (*c*, 4; $CHCl_3$).

De-oximation of *Aldehydo-d*-mannose Oxime Pentaacetate.—*Aldehydo-d*-mannose oxime pentaacetate (1.6 g.) was de-oximated with nitrous acid as described by Wolfrom, Georges and Soltzberg[2] for the corresponding glucose compound. The sirup (1.2 g.) obtained after chloroform removal resisted crystallization and was purified by precipitation from acetone solution by the addition of petroleum ether. The product reduced Fehling's solution and gave a Schiff free aldehyde test.

Anal. Calcd. for $C_6H_7O_6(COCH_3)_5$: acetyl, 12.8 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 12.24 cc.

That the sirup was moderately pure *aldehydo-d*-mannose pentaacetate was proved by the preparation of two crystalline derivatives. Treatment of the sirup with ethyl mercaptan and zinc chloride according to the procedure of Wolfrom and Thompson[6] yielded crystalline mannose diethyl mercaptal pentaacetate; m. p. 51–52° (unchanged on admixture with the product obtained on acetylation of mannose diethyl mercaptal);[7] $(\alpha)^{25}_D$ +32° (*c*, 4; $CHCl_3$). Pirie records the constants: m. p. 51–52°; $(\alpha)^{17}_D$ +31° ($CHCl_3$).

***Aldehydo-d*-mannose Semicarbazone Pentaacetate.**—An amount of 2.4 g. of the sirupy *aldehydo-d*-mannose pentaacetate, obtained by the de-oximation procedure, was dissolved in 35 cc. of hot water, the solution cooled rapidly to room temperature and treated with a solid mixture of semicarbazide hydrochloride (0.95 g.) and potassium acetate (1.5 g.). The semicarbazone separated in crystalline form; yield 1.3 g., m. p. 173–175° (dec.); $(\alpha)^{23}_D$ +9.4° (*c*, 2.5; $CHCl_3$). Pure material was obtained on recrystallization from hot water; m. p. 177–178° (dec.); $(\alpha)^{25}_D$ +9.2° (*c*, 2.5; $CHCl_3$).

Anal. Calcd. for $C_7H_{10}O_6N_3(COCH_3)_5$: N, 9.40; acetyl, 11.2 cc. of 0.1 *N* NaOH per 100 mg. Found: N, 9.12; acetyl, 11.3 cc.

Aldehydo-d-mannose semicarbazone pentaacetate was also obtained in good yield by the direct acetylation of mannose semicarbazone.[8] An amount of 6 g. of mannose semicarbazone was added to a solution of pyridine (36 cc.) and acetic anhydride (18 cc.) and the mixture shaken mechanically at room temperature for four hours. The semicarbazone dissolved and the solution was kept at ice box temperature for twelve hours and was then poured into 800 cc. of ice and water. The crystalline product that separated was removed by filtration and washed with cold water; yield 5 g.; m. p. 176–179° (dec.); $(\alpha)^{23}_D$ +8.9° (*c*, 2; $CHCl_3$). Pure material was obtained on one recrystallization from hot water; m. p. 178–180° (dec.) (m. p. unchanged on admixture with product from the de-oximation); $(\alpha)^{21}_D$ +9.3° (*c*, 2.5; $CHCl_3$).

Splitting of *Aldehydo-d*-mannose Semicarbazone Pentaacetate with Nitrous Acid.—*Aldehydo-d*-mannose semicarbazone pentaacetate (3.2 g.) obtained from the acetylation of mannose semicarbazone was dissolved in 40 cc. of hot ethanol and a warm solution of 10 g. of sodium nitrite in 200 cc. of hot water added. The solution was then placed in a water-bath maintained at 70° and treated with hydrochloric acid and additional sodium nitrite as described by Wolfrom, Georges and Soltzberg[2] for the de-oximation of *aldehydo*-glucose oxime pentaacetate. The sirup so obtained was dissolved in 30 cc. of hot water, cooled to room temperature and treated with a solid mixture of hydroxylamine hydrochloride (0.6 g.) and potassium acetate (1.2 g.). Crystals formed after several hours; m. p. 118–120°. These were recrystallized from hot ethanol by the addition of water; m. p. 121–123° (m. p. unchanged on admixture with the previously described preparations of *aldehydo*-mannose oxime pentaacetate); $(\alpha)^{21}_D$ $+13 \pm 1°$ (*c*, 2.3; $CHCl_3$). The isolation of this product from the oximated sirup indicated that the sirup was essentially *aldehydo-d*-mannose pentaacetate.

Summary

1. *Aldehydo-d*-mannose semicarbazone pentaacetate and *aldehydo-d*-mannose oxime pentaacetate have been synthesized in crystalline condition. Proof is furnished for the structure of these compounds.

2. Mild acetylation of *d*-mannose semicarbazone produces *aldehydo-d*-mannose semicarbazone pentaacetate in good yield.

3. Nitrous acid treatment of either *aldehydo-d*-mannose semicarbazone pentaacetate or *aldehydo-d*-mannose oxime pentaacetate produces *aldehydo-d*-mannose pentaacetate as a sirup characterized by several crystalline derivatives.

Semicarbazone and Oxime Acetates of Maltose and Cellobiose. *Aldehydo*-Cellobiose Octaacetate

BY M. L. WOLFROM AND S. SOLTZBERG

In previous work reported from this Laboratory we have shown that on acetylation of a sugar oxime or semicarbazone, either acetylated ring structures, or the acetylated open chain structure, or a mixture of both, is obtained. If an open chain structure is produced, methods have been devised for removing the nitrogen residue and obtaining the *aldehydo*-acetate.[1] In the case of the acetylated oximes, the open chain or *aldehydo* forms are readily detected by acetylated nitrile formation on heating and by the selective hydrolysis of the O-acetyl on the oxime group. These criteria are not applicable to the acetylated semicarbazones. With a hexose, a ring structure may be assumed if the product is a tetraacetate. If the substance is a semicarbazone pentaacetate of the ring structure, then the fifth acetyl group is attached to nitrogen and may be distinguished by the difference between the total acetyl and O-acetyl analyses.[2] The total acetyl value is determined by the method of Freudenberg and Harder[3] and the O-acetyl is determined by the Kunz[4] procedure, using phenolsulfonphthalein indicator.

In the work herein reported, the above-described procedures have been extended to maltose and cellobiose. Acetylation of the hitherto unknown crystalline maltose semicarbazone produced a crystalline octaacetate of the ring type. The rotations of these ring forms of acetylated sugar oximes and semicarbazones are very similar to those of the β-forms of the completely acetylated cyclic sugars and we have consequently distinguished them by the prefix β.[5] Acetylation of either the hydrated or anhydrous form of cellobiose semicarbazone likewise yielded the ring octaacetate as the sole crystalline product isolated. Mild acetylation produced the ring heptaacetate.

Cellobiose heptaacetate was oximated and acetylated with the production of the ring or β-cellobiose oxime nonaacetate. We would predict that this should be identical with the product isolated by Zemplén[6] as a by-product in the formation of cellobionic acid nitrile octaacetate.

Zemplén called his product cellobiose *anti*-oxime octaacetate although his published analytical values are in closer agreement with a nonaacetate. His recorded constants are: melting point, 165°; $(\alpha)_D -7°$ (chloroform). Those obtained by us for our compound are: melting point, 195–195.5°; $(\alpha)_D -8.5°$ (chloroform). The β-isomer would be expected to form in Zemplén's experiments by analogy with the behavior of glucose and galactose oximes under the vigorous nitrile forming conditions.[7] The low melting point recorded by Zemplén might be accounted for by the presence of some of the acetylated nitrile, which is frequently very difficult to separate.

When cellobiose oxime was acetylated at low temperatures an amorphous product was obtained which was essentially the *aldehydo*-cellobiose oxime nonaacetate. This fact was established by the formation of cellobionic acid nitrile octaacetate on heating and by its transformation in good yield into a crystalline oxime octaacetate. The latter was deoximated with nitrous acid to yield *aldehydo*-cellobiose octaacetate in the form of an analytically pure, colorless, amorphous powder that resisted crystallization. The substance was nitrogen-free and regenerated the crystalline oxime octaacetate on oximation.

At this point we wish to call attention to the differences in behavior of cellobiose semicarbazone, oxime and heptaacetate as compared to the glucose[1] semicarbazone, oxime and tetraacetate, the latter being analogous to the cellobiose heptaacetate. Thus, cellobiose semicarbazone yielded only the ring form on acetylation, while glucose semicarbazone gave predominantly the open chain form. Cellobiose oxime, on the other hand, produced the open chain acetate, while glucose oxime under the same conditions gave the ring

form. Cellobiose heptaacetate, after oximation and acetylation, yielded the ring form, whereas glucose tetraacetate after the same treatment gave the *aldehydo* form. Thus the introduction of a glucose molecule in the fourth position completely reversed the behavior of the active glucose function with respect to the acetylation of the oximes and semicarbazones under the conditions employed.

Experimental

Maltose Semicarbazone.—Semicarbazide hydrochloride (9 g.) was rubbed to a paste with 6 g. of fused potassium acetate and heated on the water-bath with 75 cc. of absolute ethanol to extract the semicarbazide, the solution being filtered to remove potassium chloride. The warm ethanol extract was added to a warm solution of 25 g. of maltose in 50 cc. of water and the mixture allowed to cool to room temperature. The proportions of ethanol and water should be such that no sirupy phase forms at this point. Crystalline material appeared on standing. After several days, this material was removed by filtration; yield 12.5 g. Pure material was obtained by dissolving in a minimum of hot water and adding ethanol; m. p. 213° (dec.); $[\alpha]^{25}\text{D}$ +80° (*c*, 3.5; H_2O), initial value, changing slowly in the dextro direction. The substance crystallized in the anhydrous condition.

Anal. Calcd. for $C_{13}H_{25}O_{11}N_3$: N, 10.53. Found: N, 10.45.

β-Maltose Semicarbazone Octaacetate.—Powdered maltose semicarbazone (12 g.) and 96 cc. of pyridine were heated in a bath maintained at 60–65° and 48 cc. of acetic anhydride added. The reaction mixture was stirred mechanically for seven hours at this temperature to effect solution of the semicarbazone and was then allowed to stand overnight at room temperature. The solution was then poured into ice and water, a small amount of amorphous material removed by filtration and the filtrate extracted with chloroform. The chloroform extract was washed successively with 5% hydrochloric acid, sodium bicarbonate solution, and water dried, and the solvent removed under reduced pressure. The residue was crystallized from ethanol; yield 8.3 g.; m. p. 206–208° (dec.); $(\alpha)^{25}\text{D}$ +61° ($CHCl_3$). Pure material was obtained on further recrystallization from ethanol; m. p. 209–210° (dec.); $(\alpha)^{26}\text{D}$ +61° (*c*, 3; $CHCl_3$). The analytical data indicated that the compound was a maltose semicarbazone octaacetate with one N-acetyl group.

Anal. Calcd. for $C_{13}H_{17}O_4N_2(OCOCH_3)_7(NCOCH_3)$: total acetyl, 10.9 cc. of 0.1 *N* NaOH per 100 mg.; O-acetyl, 9.5 cc. Found: total acetyl, 11.0 cc.; O-acetyl, 9.5 cc.

β-Cellobiose Semicarbazone Heptaacetate.—Cellobiose semicarbazone dihydrate[8] (6.2 g.) was acetylated at room temperature with pyridine (48 cc.) and acetic anhydride (24 cc.) for eighteen hours with mechanical stirring. The reaction mixture was then poured into 150 cc. of ice and water and on standing at ice box temperature for several hours the liquid set to a semi-solid mass of crystals; yield 5.8 g.; m. p. 205–207°; $(\alpha)^{25}\text{D}$ −20° ($CHCl_3$). A further small amount of material (0.8 g.) of lower purity could be obtained by chloroform extraction of the mother liquor. Pure material was obtained on recrystallization from ethanol; m. p. 207–208°; $(\alpha)^{27}\text{D}$ −21° (*c*, 3; $CHCl_3$).

Anal. Calcd. for $C_{13}H_{18}O_4N_3(OCOCH_3)_7$: total acetyl, 10.1 cc. of 0.1 *N* NaOH per 100 mg.; O-acetyl, 10.1 cc. Found: total acetyl, 10.1 cc.; O-acetyl, 9.8 cc.

β-Cellobiose Semicarbazone Octaacetate.—Further acetylation of β-cellobiose semicarbazone heptaacetate (0.5 g.) with pyridine (3 cc.) and acetic anhydride (1 cc.) for two days at 40° produced β-cellobiose semicarbazone octaacetate; m. p. 238–240° (dec.). This could also be prepared directly from cellobiose semicarbazone dihydrate (6 g.) according to the previously described acetylation procedure except that after the semicarbazone had dissolved in the acetylating mixture, the solution was kept at 40° for two days. No product was obtained on pouring into water but on extraction with chloroform in the usual manner, a crystalline product was obtained on the addition of ether to the concentrated chloroform solution; yield 3.1 g.; m. p. 215–220° (dec.). Pure material was obtained after several recrystallizations from ethanol; m. p. 240–241° (dec.); $(\alpha)^{25}\text{D}$ −26.5° (*c*, 3; $CHCl_3$). Acetylation of anhydrous semicarbazone with the same reagents maintained at 70–75° until solution was complete, produced the same octaacetate.

Anal. Calcd. for $C_{13}H_{17}O_4N_2(OCOCH_3)_7(NCOCH_3)$: N, 5.71; total acetyl, 10.9 cc. of 0.1 *N* NaOH per 100 mg.; O-acetyl, 9.5 cc. Found: N, 5.80; total acetyl, 10.8 cc.; O-acetyl, 9.5 cc.

β-Cellobiose Oxime Nonaacetate.—Cellobiose heptaacetate (10 g.)[9] was refluxed with two equivalents of free hydroxylamine in 35 cc. of ethanol on a water-bath for two hours. The sirup obtained on solvent removal was acetylated for two hours in an ice–salt bath with pyridine (50 cc.) and acetic anhydride (25 cc.). On pouring into water, a crystalline product (8 g.) was obtained which consisted essentially of a mixture of α-cellobiose octaacetate and the oxime nonaacetate. This mixture was heated with sufficient ethyl acetate to make a thin paste, filtered rapidly, and the residue washed with several portions of hot 95% ethanol. The crystals that separated from the filtrate were likewise filtered and washed with alcohol. The filtrate and washings were combined, concentrated to dryness, and the residue crystallized from a small amount of hot ethanol; yield 2.5 g.; m. p. 187–188°; $(\alpha)\text{D}$ +0.5° ($CHCl_3$). Pure material was obtained on repeated crystallization from 95% ethanol; m. p. 195–195.5°; $(\alpha)^{27}\text{D}$ −8.5° (*c*, 2.5; $CHCl_3$).

Anal. Calcd. for $C_{12}H_{14}O_3(OCOCH_3)_8(NCOCH_3)$: total acetyl, 12.25 cc. of 0.1 *N* NaOH per 100 mg.; O-acetyl, 10.9 cc. Found: total acetyl, 12.1 cc.; O-acetyl, 11.0 cc.

Unchanged material was recovered on heating the compound to incipient decomposition and also on refluxing for thirty minutes with a methanol solution of oxalic acid dihydrate. This behavior, together with the analytical data, shows that the compound was the oxime nonaacetate of cellobiose with one acetyl group attached to nitrogen. β-Glucose oxime hexaacetate also resists the hydrolytic ac-

[9] E. Fischer and G. Zemplén, *Ber.*, **43**, 2536 (1910).

tion of a methanol solution of oxalic acid and can be recovered unchanged under the above conditions.

Aldehydo-Cellobiose Oxime Octaacetate.—Cellobiose oxime (3 g.)[10] was acetylated with pyridine (24 cc.) and acetic anhydride (12 cc.) by stirring at 0° for two hours, followed by forty hours of standing at ice box temperature. The sirup ($(\alpha)_D$ +36°, $CHCl_3$) that was precipitated by pouring into ice and water was combined (total, 4.6 g.) with the sirupy material ($(\alpha)_D$ +35°, $CHCl_3$) obtained by chloroform extraction of the mother liquor and precipitated several times from benzene by means of heptane; $(\alpha)_D$ +37°, $CHCl_3$. The material resisted crystallization but produced crystalline cellobionic acid nitrile octaacetate when heated in the solid state to incipient decomposition.

The acetylated product obtained from 12 g. of cellobiose oxime as described above, was refluxed for thirty minutes with a solution of 13 g. of oxalic acid dihydrate in 160 cc. of methanol. The material obtained after solvent removal was dissolved in water, extracted with chloroform, the extract washed with an aqueous solution of sodium bicarbonate, dried, and the solvent removed. The residue was obtained crystalline from ether; yield 10.4 g.; m. p. 150–151°. Pure material was obtained by dissolving in chloroform and adding ether; m. p. 154–155°; $(\alpha)^{28}_D$ +30° (*c*, 3; $CHCl_3$).

Anal. Calcd. for $C_{12}H_{15}O_3N(OCOCH_3)_8$: total acetyl, 11.5 cc. of 0.1 *N* NaOH per 100 mg.; O-acetyl, 11.5 cc. Found: total acetyl, 11.6 cc.; O-acetyl, 11.6 cc.

De-oximation of *Aldehydo*-Cellobiose Oxime Octaacetate.—*Aldehydo*-cellobiose oxime octaacetate (2 g.) was dissolved in 60 cc. of glacial acetic acid and a solution of 20 g. of sodium nitrite in 60 cc. of water was dropped in during one hour with slow stirring. The stirring was continued for an additional hour with the rate greatly increased during the last ten minutes. The reaction mixture was poured into ice and water, extracted with chloroform, the extract washed with an aqueous solution of sodium bicarbonate, dried, and the solvent removed under reduced pressure. The product so obtained was purified three times by precipitation from methanol by the addition of water; $(\alpha)_D$ +17.1° (*c*, 3.6; alcohol-free $CHCl_3$). This procedure was repeated four more times; $(\alpha)_D$ +17.7° (*c*, 3.4; $CHCl_3$). The substance was obtained as a snow-white, amorphous solid that resisted crystallization but was nitrogen-free. It reduced Fehling's solution and reacted with hydroxylamine to produce the original crystalline *aldehydo*-cellobiose oxime octaacetate.

Anal. Calcd. for $C_{12}H_{14}O_{11}(COCH_3)_8$: acetyl, 11.8 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 12.1 cc.

Summary

1. Maltose semicarbazone has been synthesized. This compound on acetylation yields a crystalline octaacetate of ring structure.

2. Mild acetylation of cellobiose semicarbazone produces crystalline cellobiose semicarbazone heptaacetate. Evidence is presented to show that it is the ring form. More vigorous acetylation yields the crystalline octaacetate which also has the ring form.

3. A crystalline cellobiose oxime nonaacetate has been synthesized and evidence is presented to show that it has a ring structure.

4. *Aldehydo*-Cellobiose oxime octaacetate has been synthesized in crystalline form from cellobiose oxime. Evidence is presented to show that it has the true oxime structure.

5. Cellobiose oxime octaacetate has been de-oximated to give an amorphous *aldehydo*-cellobiose octaacetate which re-forms the original oxime on treatment with hydroxylamine.

Pyridinium Vanadate

By S. Katzoff and R. Roseman

In the course of some work on vanadium, crystals were obtained which we have identified as a new compound, of formula $(C_5H_6N)_3V_5O_{14}\cdot H_2O$.

Preparation

1. The compound can be prepared by double decomposition between ammonium metavanadate and pyridine hydrochloride. A 7% water solution of the metavanadate is prepared by saturating at the boiling point (filtering, if necessary), and to the cooled solution is added one-fifth of its volume of a cool 2:1 mixture of pyridine and concentrated hydrochloric acid. Addition of an equal volume of alcohol, and cooling, result in nearly complete precipitation of the crystalline compound.[1] The precipitate is collected on a Büchner funnel and washed with a pyridine–water mixture (1:1), 95% alcohol and, finally, ether.

---

[1] The cool solution sometimes remains supersaturated for remarkably long times, but crystallization is readily initiated by the usual methods.

2. The compound can also be prepared directly from vanadium pentoxide and pyridine, with the aid of hydrogen peroxide. To 1 part by weight of vanadium pentoxide powder (prepared by gently warming ammonium metavanadate) is added 3 parts of pyridine, 1 part of water, and then 2 parts of 30% hydrogen peroxide in small portions, not allowing the temperature of the mixture to rise above 50° at any time. Crystals of the compound soon appear,[1] and the conversion is essentially complete after several hours. The function of the hydrogen peroxide is, presumably, to help dissolve the vanadium pentoxide, giving a solution containing pervanadate ions which, either by subsequent decomposition of the peroxide group or simply by maintaining equilibrium with the vanadate ions, leads to the desired compound.

3. The compound is purified by recrystallization, which is easily carried out since there is a large variation of the solubility in water with temperature. The procedure is to dissolve the material in 3 times its weight of hot water (80°) containing a little pyridine, filter through a quantitative paper, and cool.[1] Rapid performance of the operations is desirable, since hydrolysis occurs at the high temperature, with precipitation of vanadic acid. The crystalline product is collected, washed, and dried on a Büchner funnel, as previously described.

Analysis

The compound was analyzed for vanadium and pyridine.

1. Vanadium was determined by direct ignition of a sample (in a platinum crucible) to vanadium pentoxide. Treatment of the residue with a little nitric acid and reignition did not, in general, result in a change in weight.

2. Pyridine was determined by the following method. A sample (0.5 to 1 g.) is dissolved in 25 cc. of water in a 50-cc. Kjeldahl flask, and 3 cc. of 6 *N* sodium hydroxide is added. The solution is then distilled, using a trap, into a slight excess of standard hydrochloric acid (0.25 *N*), the distillation being carried nearly to dryness. The excess hydrochloric acid is titrated with standard sodium hydroxide (0.25 *N*), using methyl orange or brom phenol blue as indicator.[2]

Following the methods outlined above, the ratio of pyridine to vanadium in the compound was found to be 3:5. For the water content, we depend on an accurate determination of the vanadium. Determinations of the V_2O_5 content of our best products gave values between 61.55 and 61.75%. This corresponds satisfactorily to the compound of simple formula $(C_5H_6N)_3V_5O_{14}\cdot H_2O$, the theoretical V_2O_5 content of which is 61.71%.

Properties

The compound has an orange color, which appears of a lighter or a darker shade according as the crystals are small or large. The density is 2.04, as determined with a pycnometer, using pyridine as the immersion liquid. The crystals are monoclinic, generally appearing as parallelepipeds, sometimes with truncated edges or corners. Pyridine, ether, alcohol, benzene, and acetone do not dissolve the compound appreciably. Water dissolves it, giving an orange solution which reacts acid to litmus. Molten phenol was also found to dissolve it.

When exposed to the atmosphere, the compound slowly loses its volatile constituents. For example, a sample kept on a watch glass in the laboratory for one month lost 5% of its weight. Analysis showed that the percentage of vanadium pentoxide had correspondingly risen, proving that no vanadium had been lost. On the other hand, a sample kept in a glass-stoppered container did not change its composition over a period of two weeks.

Some excellent crystals, of a deep orange color, and perfectly transparent, were prepared by using the previously described recrystallization technique without, however, rapid cooling of the filtrate. The crystallography is being studied by Dr. J. D. H. Donnay, of this University, in collaboration with Dr. J. Mélon, of the University of Liége.

We are greatly indebted to Mr. Jerome Strauss, Vice President of the Vanadium Corporation of America, for the generosity with which he supplied us with pure vanadium compounds for our work.

BALTIMORE, MARYLAND RECEIVED JULY 17, 1936

---

(2) Care must be taken to choose the end-point color according to the concentration of pyridine hydrochloride in the solution. The *p*H corresponding to this concentration is calculated, and the end-point color is obtained from a previously prepared set of color standards made up in potassium acid phthalate–hydrochloric acid buffers [Clark and Lubs, *J. Biol. Chem.*, **25**, 479 (1916)].

Our method of analysis was checked by showing, first, that the titration method for pyridine gives accurate results over a wide range of concentrations, and, second, that essentially all of the pyridine is recovered in the distillation. The accuracy of the method is about 1%.

The Kinetics of the Reaction between Ferric and Stannous Perchlorates in Acid Solution

BY M. H. GORIN

The present investigation was undertaken to study the reduction of ferric salts by stannous salts in solutions in which it is reasonably certain no complex ions exist; perchlorates were therefore used. Sufficient perchloric acid was added to suppress the formation of colloidal ferric hydroxide.

The kinetics of the comparatively rapid reaction between ferric and stannous chlorides has been much investigated.[1] A rather complete discussion of these researches and new experimental material has been given by the author in a thesis.[2] It is sufficient to state here that the rate-determining step is not a third order reaction involving two ferric and one stannous ions, as is generally supposed, but a second order reaction between unpolymerized chloride complexes of ferric iron and stannous tin. Timofeew[1c] first proved that the reaction is second order and the author[2] and Robertson and Law[1d] independently demonstrated the influence of chloride ion.

It was expected that the reaction rate would be very much smaller with perchlorates than with chlorides, since the repulsive forces between the highly charged and positive ferric and stannous ions are very great and those between the lower valent or neutral chloride complexes (as $FeCl_3$ and $SnCl^+$ or $SnCl_3^-$) are small or negligible. Actually the rate was found to be smaller by a factor of 10^5 to 10^6 under comparable conditions. Moreover, no evidence was found that ferric ion itself reacts directly with stannous ion in a range of temperature from 55 to 70° and of hydrogen-ion concentrations from 0.02 to 1 *M*.

The rate-determining step for the reduction of the ferric salt was concluded to be

$$Fe(OH)_2^+ + Sn^{++} \longrightarrow \qquad (1)$$

The actual kinetics are complicated by the fact that the reactions involved in the hydrolysis equilibrium, $H_2O + FeOH^{++} \rightleftarrows Fe(OH)_2^+ + H^+$, are often not rapid compared to reaction 1; and by the fact that in most of the solutions an appreciable proportion of the ferric iron was present in the form of hydrolysis products. It was found that the presence of colloidal ferric hydroxide increased the rate; this complication was avoided by the addition of perchloric acid in amounts sufficient to suppress its formation.

Materials.—A solution of *ferrous perchlorate* was prepared by the addition of equivalent amounts of a barium perchlorate solution to a ferrous sulfate solution; the mixture was held at a temperature of 100° for several hours in the absence of air in order to coagulate the precipitate of barium sulfate. The clear resulting solution was pipetted off after cooling.

A solution of *stannous perchlorate*, free from excess acid, was prepared by a method formerly employed by Noyes and Toabe.[3]

Experimental Method.—The reaction was started in all experiments by adding a small volume of a concentrated solution of stannous perchlorate to a solution containing the other reactants. The progress of the reaction was followed by the method used by all previous investigators: stannous ion was rapidly destroyed by quenching the sample with mercuric chloride solution, and the extent to which the reaction had progressed was determined by an analysis for the ferrous ion produced.

The reaction mixture, exclusive of stannous perchlorate, contained ferric perchlorate and perchloric acid. It was made up by adding the desired amounts of ferrous perchlorate and perchloric acid solution and an excess of hydrogen peroxide to the desired volume of water in a volumetric flask. The reaction mixture was then transferred to the apparatus employed and allowed to remain at the temperature of the run for a period of at least one day in order to ensure complete decomposition of the excess hydrogen peroxide and attainment of equilibrium.

The apparatus shown in Fig. 1 was employed to enable the withdrawal of samples in the complete absence of air and to eliminate the loss of water by evaporation.

The concentration of ferrous ion in the sample was determined by titration with 0.01 *N* potassium dichromate, using diphenylamine[4] as the indicator.

Experimental Results.—If $Fe(OH)_2^+$ is at equilibrium with ferric and hydrogen ions, the rate law corresponding to equation 1 is

$$d(Fe^{++})/dt = 2k_3K_1K_2(Fe^{+++})(Sn^{++})/(H^+)^2 \qquad (2)$$

where

$$K_1 = (Fe(OH)^{++})(H^+)/(Fe^{+++}) \qquad (3)$$

and

$$K_2 = (Fe(OH)_2^+)(H^+)/(Fe(OH)^{++}) \qquad (4)$$

and k_3 is the specific rate of reaction 1.

At the moment of starting, the system must be at equilibrium and therefore the initial rate will be given by equation 2. It was found that the experiments fell into two groups: (1) in those with *ferric perchlorate in excess* the results can be accurately extrapolated to obtain the initial rate; (2) in those with *stannous perchlorate in excess* the rate drops off so quickly from the initial value that no accurate extrapolation can be made.

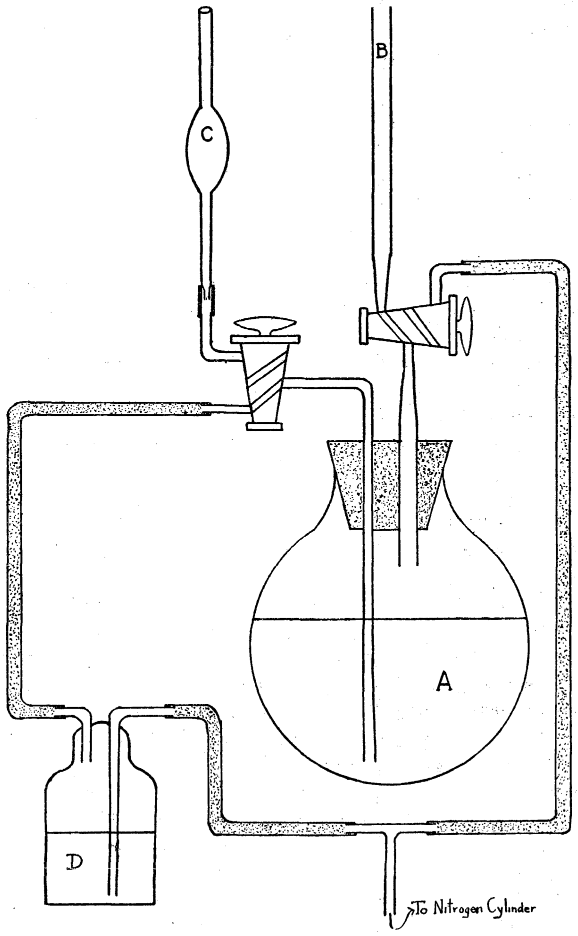

Fig. 1.—Apparatus for rate measurements at 70°: A, reaction vessel in thermostat; B, condenser; C, sampling pipet; D, pressure regulator containing mercury.

Ferric Ion in Excess at 70°.—In Fig. 2, the quantity, $\log (a - x)/(2b - x)$, is plotted against time for the first few experimental points in 6 runs, nos. 1–6. The initial slope, as estimated for each run, is shown by the solid straight lines in Fig. 2. If a, b and c are the initial concentrations of ferric perchlorate, stannous perchlorate and perchloric acid, respectively, x, the concentration of ferrous ion produced at the time, t, and S the slope of the lines drawn in Fig. 2, it follows that

$$(\mathrm{d}x/\mathrm{d}t)_{\text{initial}} = 2.303S(2b)a/(a - 2b)$$

and that

$$2k_3K_1K_2 = \frac{4.606aS[c + (\mathrm{FeOH}^{++})_i + 2(\mathrm{Fe(OH)_2}^{+})_i]^2}{(a - 2b)[a - (\mathrm{FeOH}^{++})_i - (\mathrm{Fe(OH)_2}^{+})_i]} \tag{5}$$

The values of K_1 and K_2 are not well known. Bray and Hershey[5] corrected several equilibria involving ferric ion for hydrolysis by considering the first step only. Although they assumed the second step in the hydrolysis to be negligible, their method is a satisfactory empirical one for correcting ferric ion but not hydrogen-ion concentration. It will be shown later that essentially the same results for ferric ion could have been obtained by including the second step and using a smaller value for K_1. The values given in Table I for K_1 and K_1K_2 were calculated from the values, 0.0250 and 35.2×10^{-4}, respectively, at zero ionic strength by assuming the activity function given by Bray and Hershey.[5] K_1K_2 was obtained from the kinetic data to be described later and K_1 was assumed to have one-quarter of the value obtained by extrapolating the results of Bray and Hershey[5] to 70°.

The values of $2k_3K_1K_2$ calculated from initial rates are given in Table I.

Table I

Evidence for Equation 2 Based on Initial Rates Measured at 70° with Ferric Perchlorate in Excess

6	.0104	9.7	.00090	.00183	.00383	.0446	.0500

It is seen from Table I that equation 2 represents the initial rate of the reaction quite well over an 8-fold variation in ferric ion, a 3-fold variation in stannous ion and 6-fold variation in the square of hydrogen ion. For the expected and observed

---

[5] Bray and Hershey, This Journal, **56**, 1889 (1934).

variation of the specific rate, $2k_3K_1K_2$, with ionic strength, see Fig. 7.

In Fig. 3, runs 1–6 are plotted for the entire course of the reaction. Since the main reaction at 70° is

$$3H_2O + 2Fe^{+++} + Sn^{++} \longrightarrow H_2SnO_3 + 2H^+ + 2Fe^{++} \qquad (6)$$

hydrogen ion is produced during the reaction. Therefore the quantity $(c + 2x)/c \log (a - x)/(2b - x)$ is plotted against t rather than the quantity $\log (a - x)/(2b - x)$. The dotted lines in Fig. 3 are the lines that would result if equation 2 were followed over the entire course of the reaction. It is seen that in runs 1 and 3 the dotted line is followed within the experimental error over the entire extent of the reaction. In the other runs the curves slowly deviate from the dotted line and then go through an inflection point and appear to again approach a line whose slope is equal to the slope of the dotted line. The deviation on the positive side of the dotted line at the beginning of the runs is probably due to the fact that the first product is $Sn(OH)_2^{++}$ rather than stannic acid and therefore the calculated hydrogen-ion concentrations in this region are too high; as the run proceeds, $Sn(OH)_2^{++}$ hydrolyzes to stannic acid and toward the end of the reaction the calculated hydrogen-ion concentrations are correct.

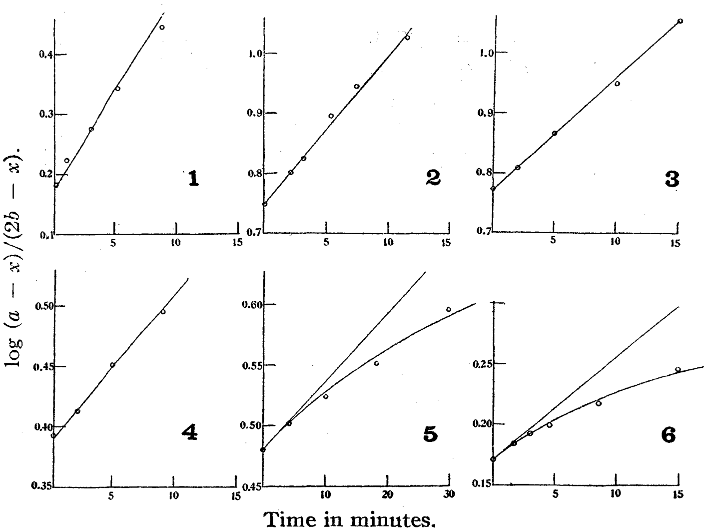

Fig. 2.—Determination of initial rates at 70° in Expts. 1–6: $a - x$ $b - x/2$ are the concentrations in moles per liter of ferric perchlorate and stannous perchlorate at time t.

The appearance of the inflection points in Fig. 3 confirms the theory that the concentration of $Fe(OH)_2^+$ falls below its equilibrium value and then as stannous ion decreases in concentration $Fe(OH)_2^+$ again begins to build up toward equilibrium.

Stannous Ion in Excess at 70°.—In these experiments the rate drops off very quickly from the initial value demanded by equation 2. The results for the entire course of the reaction are plotted in Fig. 4 in the same way as those in Fig. 2; the dotted line represents the initial rate demanded by equation 2. It is seen that the curves very rapidly deviate from the dotted line and appear to approach a straight line. This would correspond to the differential equation

$$\frac{d(Fe^{++})}{dt} = \psi\ (\Sigma Fe^{iii})(Sn^{++}) = \frac{\psi}{2}(a - x)(2b - x) \qquad (7)$$

in the region of the straight line. The quantity, ψ, is of course only a constant within each run and is itself a function of stannous and hydrogen-ion concentrations.

The differential equation

$$\frac{d(Fe^{++})}{dt} = \frac{2k_3K_1K_2(Fe^{+++})(Sn^{++})}{(H^+)^2\,[1 + \chi(Sn^{++})]} \qquad (8)$$

will be applied to the results, where χ of course is a constant. From equations 7, 8, 3 and 4 we obtain the result

$$\chi = \frac{[(2k_3K_1K_2/\psi) - (H^+)[(H^+) + K_1] - K_1K_2]}{(H^+)[(H^+) + K_1](Sn^{++})} \qquad (9)$$

The value of $2k_3K_1K_2$ is taken from the graph in Fig. 7; ψ is calculated from the slopes of the lines in Fig. 4, $\psi = 4.6S/(2b - a)$; χ is calculated for the two points, indicated in each run by the symbols ① and ②. The calculations are presented in Table II.

It is demonstrated in Table II that equation 8 represents the rate quite well for these experiments, which cover a 10-fold variation in (Sn^{++}) and a 20-fold variation in $(H^+)^2$. The variation of χ with ionic strength will be discussed later.

Experimental Results at 55°.—In Fig. 5 the rate measurements at 55° are plotted. In runs 17, 18 and 19 no perchloric acid was added to the reaction mixture and therefore the initial rates could not be used, since small amounts of colloidal ferric hydroxide were present. For this reason the last half of these runs only is presented. In runs 13 and 14 the initial rates were estimated

Equation 8 was applied to the latter part of the reaction in the same way as at 70°. The calculations are presented in Table IV; $(\bar{H}^+)$ is the average value of (H^+) in the region through which the points in Fig. 5 fall on a straight line and

TABLE IV

DETERMINATION OF χ AT 55°

Run	$\mu^{1/2}$	K_1	$K_1K_2 \times 10^4$	$2k_3K_1K_2$	$(\bar{H}^+)$	$(\overline{Sn}^{++})$	ψ	χ
18[a]	1.13	0.0039	1.05	0.00180	0.0270	0.0184	0.952	59
14	1.13	.0039	1.05	.00180	1.01	.0121	.00104	61
13	0.54	.0041	1.20	.00150	0.125	.0090	.0504	77
19[a]	0.50	.0041	1.21	.00150	.0258	.0194	.735	93

[a] Runs 18 and 19 are identical except that the reaction mixture in run 18 contained, in addition to 0.0332 M $Fe(ClO_4)_3$ and 0.0323 M $Sn(ClO_4)_2$, 1 M NH_4ClO_4.

$(\overline{\mathrm{Sn}}^{++})$ is defined similarly. The value of $2k_3K_1K_2$ used is taken from Fig. 7. In runs 18 and 19, (H^+) was small and no precipitation of H_2SnO_3 was observed. It was found that one rather than two hydrogen ions were formed per ferric ion produced in these two runs.

Table IV demonstrates that the experimental results at 55° are in good agreement with equation 8 over a 1400-fold change in $(\mathrm{H}^+)^2$.

Interpretation of Results.—The following scheme for the mechanism of the reaction satisfies the experimental results.

Comparatively rapid equilibrium	$\mathrm{Fe^{+++}\cdot 6H_2O} \overset{K_1}{\rightleftharpoons} \mathrm{FeOH^{++}\cdot 5H_2O + H^+} \quad (9)$
Rapid equilibrium	$\mathrm{H_2O} \overset{K_{\mathrm{H_2O}}}{\rightleftharpoons} \mathrm{H^+ + OH^-} \quad (10)$
Slow equilibrium	$\mathrm{OH^- + FeOH^{++}\cdot 5H_2O} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{Fe(OH)_2{}^+\cdot 4H_2O + H_2O} \quad (11)$
Slow follow reaction	$\mathrm{Sn^{++} + Fe(OH)_2{}^+\cdot 4H_2O} \xrightarrow{k_3} \mathrm{Fe^{++}\cdot 4H_2O + Sn(OH)_2{}^+} \quad (12)$
Rapid follow reaction	$\mathrm{Fe^{+++}\cdot 6H_2O + Sn(OH)_2{}^+ = Fe^{++}\cdot 4H_2O + Sn(OH)_2{}^{++}} \quad (13)$
Main reaction at 55° and low (H^+) is (9) + (10) + (11) + (12) + (13)	$\mathrm{2Fe^{+++}\cdot 6H_2O + Sn^{++} = 2Fe^{++}\cdot 4H_2O + Sn(OH)_2{}^{++} + H_2O + 2H^+} \quad (14)$
Slow follow reaction	$\mathrm{Sn(OH)_2{}^{++} + H_2O = H_2SnO_3 + 2H^+} \quad (15)$
Main reaction at 70° under all conditions and at 55° at high hydrogen-ion concentration, (14) + (15)	$\mathrm{2Fe^{+++}\cdot 6H_2O + Sn^{++} = 2Fe^{++}\cdot 4H_2O + H_2SnO_3 + 4H^+} \quad (16)$

In the most general case the concentration of $\mathrm{Fe(OH)_2{}^+}$ is not negligible and therefore it is not possible to postulate a steady state between reactions 11 and 12. Therefore the following pair of differential equations results

$$\mathrm{d(Fe(OH)_2{}^+)/d}t = k_1(\mathrm{FeOH^{++}})(\mathrm{OH^-}) - (\mathrm{Fe(OH)_2{}^+})\,[k_2 + k_3(\mathrm{Sn^{++}})]$$

$$\mathrm{d(Fe^{++})/d}t = 2k_3(\mathrm{Fe(OH)_2{}^+})(\mathrm{Sn^{++}})$$

or

$$\mathrm{d(Fe(OH)_2{}^+)/d}t = k_1K_1K_{\mathrm{H_2O}}(\mathrm{Fe^{+++}})/(\mathrm{H^+})^2 - (\mathrm{Fe(OH)_2{}^+})\,[k_2 + k_3(\mathrm{Sn^{++}})] \tag{17}$$

$$\mathrm{d(Fe^{++})/d}t = 2k_3(\mathrm{Fe(OH)_2{}^+})(\mathrm{Sn^{++}}) \tag{18}$$

If, however, $\mathrm{Fe(OH)_2{}^+}$ is at equilibrium with $\mathrm{FeOH^{++}}$ and hydrogen ion, as is the case at the start of the reaction, equations 17 and 18 become equation 2

$$\mathrm{d(Fe^{++})/d}t = 2k_3K_1K_2(\mathrm{Fe^{+++}})(\mathrm{Sn^{++}})/(\mathrm{H^+})^2$$

since

$$k_1K_{\mathrm{H_2O}}/k_1 = K_2 = (\mathrm{Fe(OH)_2{}^+})(\mathrm{H^+})/(\mathrm{FeOH^{++}}) \tag{19}$$

In the experiments with stannous ion in excess $\mathrm{Fe(OH)_2{}^+}$ is changing very rapidly while the first 15 or 20% of the reaction occurs. After this initial period, the rate appears to follow the differential equation 8. This indicates that the concentration of $\mathrm{Fe(OH)_2{}^+}$ must be approaching some kind of "steady state." The ordinary steady state postulate, $\mathrm{d(Fe(OH)_2{}^+)/d}t = 0$ for two compensating reactions involving an intermediate, would involve appreciable error in some of the experiments, since it is evident that a considerable portion of the ferric salt is present in the form of $\mathrm{Fe(OH)_2{}^+}$ even at the "steady state stage" of the reaction. It was discovered that another steady state condition could be postulated which involves very much less error. This postulate is that

$$\mathrm{d(Fe^{++})/{-d}(Fe(OH)_2{}^+)} = 0$$

and leads to the equation

$$\frac{-\mathrm{d(Fe(OH)_2{}^+)}}{\mathrm{d}t} = \frac{1}{2}\,\frac{(\mathrm{Fe(OH)_2{}^+})}{(\Sigma\mathrm{Fe^{iii}})}\,\frac{\mathrm{d(Fe^{++})}}{\mathrm{d}t} = \frac{1}{2}\,\alpha\,\frac{\mathrm{d(Fe^{++})}}{\mathrm{d}t} \tag{20}$$

Applying equation 20 to equations 17 and 18, we obtain

$$(\mathrm{Fe(OH)_2{}^+}) = \frac{K_1K_2(\mathrm{Fe^{+++}})}{(\mathrm{H^+})^2[1 + (1 + \alpha)(k_3/k_2)(\mathrm{Sn^{++}})]} \tag{21}$$

and

$$\frac{\mathrm{d(Fe^{++})}}{\mathrm{d}t} = \frac{2k_3K_1K_2(\mathrm{Fe^{+++}})(\mathrm{Sn^{++}})}{(\mathrm{H^+})^2\,[1 + (1 + \alpha)(k_3/k_2)(\mathrm{Sn^{++}})]} \tag{22}$$

Equation 22 is identical with equation 8 and therefore $\chi = (1 + \alpha)\ (k_3/k_2)$. Knowing χ we can easily calculate α from equation 21 and therefore k_3/k_2.

$$\alpha = \frac{(\mathrm{Fe(OH)_2{}^+})}{(\Sigma\mathrm{Fe^{iii}})} = \frac{K_1K_2}{K_1K_2 + (\mathrm{H^+})(\mathrm{H^+} + K_1)[1 + \chi\,\mathrm{Sn^{++}}]} \tag{23}$$

These calculations are given in Table V for the experiments at 70° (see Table II) with stannous in excess.

It is seen that the maximum correction in Table V is about 15%. This is probably smaller than the experimental error (small errors in ψ are greatly magnified in χ). However, it is of inter-

Table V

est to consider this analysis and to point out its great accuracy as demonstrated by the constancy of α over the whole "steady state region" of each run.

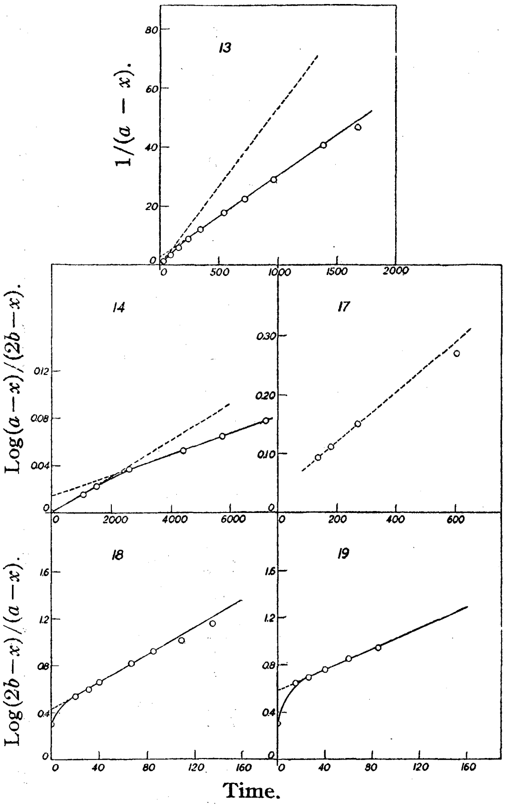

Fig. 5.—Rate measurements at 55°, Expts. 13–19.

Calculation of $\mathbf{K_1K_2}$.—In the initial part of the experiments with stannous perchlorate in excess the concentration of $Fe(OH)_2^+$ is changing much more rapidly than that of ferric ion and therefore the concentration of ferric ion may be assumed to be constant in this region. If this assumption is made equations 17 and 18 may be integrated, and the following result

$$(y - y_0) = \bar{A}t - {}^1/_2x - 2.303(\mathrm{d}t/\mathrm{d}x)^0A^0(2b)\log(2b)(2b - x) \qquad (24)$$

and

$$y = y_0(\mathrm{d}x/\mathrm{d}t)(\mathrm{d}t/\mathrm{d}x)^0\,(2b)/(2b - x) \qquad (25)$$

where $y = (\mathrm{Fe(OH)_2^+})$ and $x = (\mathrm{Fe^{++}})$ at time equals t, y_0 is initial value of y

$$A_0 = \frac{k_1K_{\mathrm{H_2O}}K_1(\mathrm{Fe^{+++}})}{(\mathrm{H^+})^2} = \frac{2k_3K_1K_2}{2(k_3/k_2)}\,\frac{(\mathrm{Fe^{+++}})}{(\mathrm{H^+})^2}$$

at $t = 0$ and $\bar{A} = A^0(a - x)/a$. If x, t and $(\mathrm{d}x/\mathrm{d}t)$ are known, y_0 may be calculated, since $2k_3K_1K_2$, k_3/k_2 and therefore $(\mathrm{d}x/\mathrm{d}t)_0$ are known.

In Fig. 6 x is plotted against t for the first three experimental points in two runs, nos. 7 and 9. A smooth curve was drawn from the origin, using the initial slope calculated from equation 2 (or 5) as a guide. Three points were chosen on the smooth curve, and $(\mathrm{d}x/\mathrm{d}t)$ was determined at each point by estimating the tangent to the curve. The points chosen are marked by the symbol +; the experimental point by the symbol 0 and the estimated tangents by the dotted lines.

It is seen that equations 24 and 25 do not involve K_1 and K_2 directly, but of course these constants are involved in calculating the initial rate, $(\mathrm{d}x/\mathrm{d}t)_0$. However, it is to be noted that the experimental value of $2k_3K_1K_2$ depends upon the choice of K_1 and K_2. Actually, it was found that the value of y_0 from equations 24 and 25 was very slightly dependent upon the choice of K_1 and K_2 and therefore the resulting value of $2k_3K_1K_2$. The calculations presented in Table VI were made using the values of K_1 and K_1K_2 assumed in Table I and of course the resulting value of $2k_3K_1K_2$ from Fig. 7 ($K_1^0 = 0.025$ $K_1^0K_2^0 = 35.2 \times 10^{-4}$).

The constancy of y_0 for the three points in each run in Table VI demonstrates that equations 24 and 25 are good representations of the initial portion of the reaction. Furthermore, the values of y_0 are in good agreement with those calculated and therefore it is demonstrated that the value of K_1K_2 chosen is the experimental value within the experimental error.

Actually of course the value of K_1K_2 assumed in Table I was the experimental value found from equations 24 and 25, but a complete logical presentation of the calculations was avoided in order to save space.

Variation with Ionic Strength and Temperature Coefficients.—By combining the Debye–Hückel theory and the Brönsted theory the following relationships result, as $\mu^{1/2} \longrightarrow 0$

$$\log_{10} K_1 = \log_{10} K_1^0 - 2.0\mu^{1/2} \qquad (26a)$$
$$\log_{10} K_1K_2 = \log_{10} K_1^0K_2^0 - 3.0\mu^{1/2} \qquad (26b)$$
$$\log_{10} 2k_3K_1K_2 = \log_{10} 2k_3^0K_1^0K_2^0 - 1.0\mu^{1/2} \qquad (26c)$$
$$\log_{10} (k_2/k_3) = \log_{10} (k_3^0/k_2^0) + 2.0\mu^{1/2} \qquad (26d)$$

However, all of the experimental results are in a region of ionic strength where equations 26 cannot be expected to apply. Instead the method of Randall[6] was used. Applying this method, it follows

$$-{}^1/_4 \log K_1 = -{}^1/_4 \log K_1^0 + f(\gamma) \quad (27a)$$
$$-{}^1/_6 \log K_1K_2 = -{}^1/_6 \log K_1^0K_2^0 + f(\gamma) \quad (27b)$$
$$-{}^1/_2 \log 2k_3K_1K_2 = -{}^1/_2 \log 2k_3^0K_1^0K_2^0 + f(\gamma) \quad (27c)$$
$${}^1/_4 \log (k_3/k_2) = {}^1/_4 \log (k_1^0/k_2^0) + f(\gamma) \quad (27d)$$

where $f(\gamma)$ may be represented by some one of the family of log γ curves for single electrolytes. For K_1 and K_1K_2 the same $f(\gamma)$ was used as that given by Bray and Hershey[5] in Table I, page 1890.

In Fig. 7 the quantities $^1/_2$ log $2k_3K_1K_2$ at 70°, and $^1/_2$ log $2k_3K_1K_2 + 0.7$ at 55°, are plotted against $\mu^{1/2}$. The curve that seemed to fit best is one somewhere between the curve chosen by Bray and Hershey[5] for ferric equilibria and the curve for hydrochloric acid. It can be said that all the points except the one at the lowest ionic strength fit the curve within the experimental error. The 20% deviation of this point from the curve might be attributed to small amounts of colloidal ferric hydroxide.

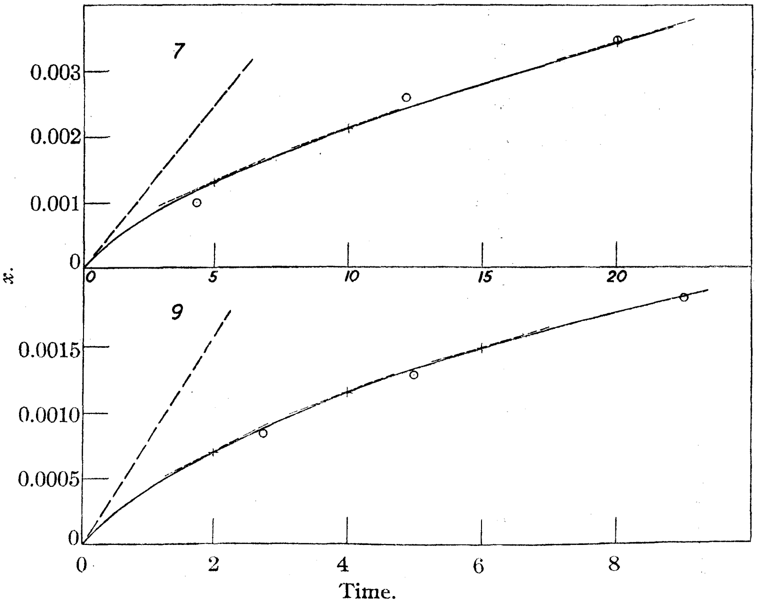

Fig. 6.—Determination of equilibrium concentration of $Fe(OH)_2^+$ in two experiments, nos. 7 and 9.

In Fig. 8, $-{}^1/_4$ log k_3/k_2 at 70° and $-{}^1/_4$ log $k_3/k_2 - 0.087$ at 55°, are plotted against $\mu^{1/2}$. The curve is the same one used in Fig. 7 and is purposely drawn through the points at the higher ionic strengths. The failure of the three points at the lowest ionic strength to reach the curve can be attributed to inaccuracies in the ionic strength functions used, since small errors in K_1K_2, K_1, and especially in $2k_3K_1K_2$, will cause larger errors in k_3/k_2.

Using the extrapolations in Figs. 7 and 8 the following values are obtained for $2k_3^0K_1^0K_2^0$ and k_3^0/k_2^0 at 70 and 55°.

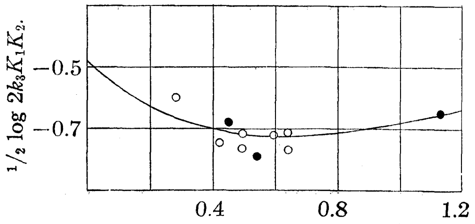
$2k_3^0K_1^0K_2^0$ at 70° is 0.0660 and at 55° is 0.00262, therefore ΔH = 48,600 calories; k_3^0/k_2^0 at 70° = 58 and at 55° = 25.7, ΔH = 12,300 calories.

The quantities in bold figures in Table VII can

---

(6) See Refs. 5 and 6(a), Randall and Vietti, THIS JOURNAL, **50**, 926 (1928); (b) Randall, *J. Chem. Educ.*, **8**, 1062 (1931); (c) unpublished results.

be calculated without knowing ΔH for K_1K_2 and K_1; those in italics depend upon the choice of ΔH for K_1K_2 and K_1, 2 × 12,650 and 12,650, respectively.



Square root of the ionic strength.

Fig. 7.—Variation of $2k_3K_1K_2$ with ionic strength: ○, at 70°; ●, at 55°, $^1/_2 \log (2k_3K_1K_2) + 0.7$.

The values assumed for ΔH_{K_1} and $\Delta H_{K_1K_2}$ depend upon the following: Bray and Hershey[5] would have obtained essentially the same result if they had used a smaller value of K_1 and taken the second step of the hydrolysis into consideration. There are two reasons for this: the first is that the equilibria they were considering did not involve hydrogen ion, and the second that K_1 decreases more rapidly than K_2 with ionic strength. The kinetic value which was obtained at 70° for K_1K_2 was extrapolated to 25° by using Bray and Hershey's value[5] for ΔH_{K_1}, 12,650, and assuming that $\Delta H_{K_1K_2} = 2\Delta H_{K_1}$. It was found that the value obtained for K_1K_2 at 25°, 13.0×10^{-6}, taken together with a value for K_1, one-quarter of that used by Bray and Hershey,[5] will give approximately the same results as those obtained by Bray and Hershey.[5]

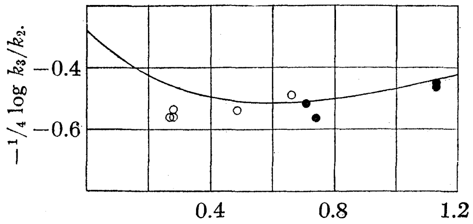
Discussion of Results.—It is considered by the author that the following have been definitely established in perchlorate solutions: (1) the rate determining step for the reduction of the ferric salt is

$$Fe(OH)_2{}^+ \cdot 4H_2O + Sn^{++} \longrightarrow$$

and (2) the mechanism for the reactions involved in the equilibrium

$$FeOH^{++} + H_2O \rightleftarrows Fe(OH)_2{}^+ + H^+$$

is the one given by equation 11. All alternative formulations to the two above that were tried failed to explain one or more portions of the experimental data.



Square root of the ionic strength.

Fig. 8.—Variation of k_3/k_2 with ionic strength at 70°: ○, at 70°; ●, at 55°, $-^1/_4 \log (k_3/k_2) - 0.087$.

The most plausible explanation of the failure of ferric and stannous ions to react directly is that ions of like and multiple charges cannot approach each other closely enough to cause reaction unless their relative kinetic energy is very high. This minimum kinetic energy is estimated to be, at the very least, 15,000 calories. If it is assumed that the ordinary chemical heat of activation for ferric plus stannous is the same as for $Fe(OH)_2{}^+$ plus stannous, then the ratio of the rates at 70° will be less than

$$e^{-15,000/(343 \times 1.986)} = 3 \times 10^{-10}$$

The products of the rate determining step, equation 1, were assumed in equation 12 to be 2-valent iron and 3-valent tin, rather than 1-valent iron and 4-valent tin. There is no evidence for the existence of univalent iron and Ball[7] and co-workers have recently published evidence for the existence of trivalent tin as an intermediate.

The mechanism of the reactions involved in the hydrolysis of $FeOH^{++} \cdot 5H_2O$ was demonstrated to be

$$FeOH^{++} \cdot 5H_2O + OH^- \underset{k_2}{\overset{k_1}{\rightleftarrows}} Fe(OH)_2{}^+ \cdot 4H_2O + H_2O$$

the replacement of water by hydroxide ion and the replacement of hydroxide ion by water. This replacement mechanism is analogous to the theory of Olson[8] for organic substitution reactions. It differs from the one generally assumed for the hydrolysis of hydrated metallic ions

$$FeOH^{++} \cdot 5H_2O \longrightarrow Fe(OH)_2{}^+ \cdot 4H_2O + H^+$$

a simple splitting off and addition of a proton.

In conclusion I wish to express my gratitude to Professor William C. Bray for his advice and suggestions during the progress of the work.

Summary

Rate measurements are presented for the reaction between ferric and stannous perchlorates in solutions containing perchloric acid at 70 and 55°. The rate is much slower than when chloride ion is present.

There is no evidence for a direct reaction between ferric ion and stannous ion. The failure of the two ions to react at an appreciable rate is attributed to the high repulsive forces between these polyvalent, positive ions.

The experimental results are in agreement with the theory that the rate determining step for the reduction of the ferric salt is

$$Fe(OH)_2^+ + Sn^{++} \xrightarrow{k_3} \qquad (1)$$

When the hydrolysis equilibria

$$Fe^{+++} + H_2O \overset{K_1}{\rightleftarrows} FeOH^{++} + H^+ \qquad (3)$$

and

$$FeOH^{++} + H_2O \overset{K_2}{\rightleftarrows} Fe(OH)_2^+ + H^+ \qquad (4)$$

are maintained the rate law is

$$d(Fe^{++})/dt = 2k_3K_1K_2(Fe^{+++})(Sn^{++})/(H^+)^2 \qquad (2)$$

This law represents the initial rate in all experiments and applies throughout when the concentration of ferric ion is high compared to that of stannous ion. The specific rate, $2k_3K_1K_2$, is 660 $\times 10^{-4}$ at 70° and 26.2 $\times 10^{-4}$ at 55°.

A study of the deviations from equation 2 led to the conclusions that reaction 4 is not rapid compared to Reaction 1 and that the mechanism of reaction 4 is

$$\text{Rapid equil. } H_2O \overset{K_{H_2O}}{\rightleftarrows} H^+ + OH^-$$

$$\text{Slow equil. } OH^- + Fe(OH)_2^{++}\cdot 5H_2O \underset{k_2}{\overset{k_1}{\rightleftarrows}} Fe(OH)_2^{+}\cdot 4H_2O + H_2O$$

The study resulted in the determination of the product, K_1K_2, at 70° and the ratio, k_3/k_2 at 70° and 55°. Combination with the value of the specific rate, $2k_3K_1K_2$, gave the following values at 70°: $K_1K_2 = 35.2 \times 10^{-4}$, $k_3 = 9.4$ and $k_2 = 0.162$.

While neither of the hydrolysis quotients, K_1 nor K_2, has been determined directly, values of each have been chosen which are consistent with the above results and with available data for the hydrolysis of ferric ion. The resulting values of the various equilibrium quotients and specific rates at 70 and 55° are listed in Table VII. Concentrations are expressed in moles per liter and time intervals in minutes.

The Activation of Specific Bonds in Complex Molecules at Catalytic Surfaces. II. The Carbon–Hydrogen and Carbon–Carbon Bonds in Ethane and Ethane-*d*

BY KIYOSHI MORIKAWA,[1] W. S. BENEDICT AND HUGH S. TAYLOR

The activation of the carbon–hydrogen and carbon–carbon bonds in ethane at nickel catalyst surfaces can be studied with the aid of deuterium since two reactions may be examined: (a) the exchange reaction which may be generalized as $C_2H_xD_y + D_2 = C_2H_{x-1}D_{y+1} + HD$ in which $x + y = 6$ and y may have any integral values from 0 to 5; and (b) the methane producing reaction $C_2H_6 + H_2 = 2CH_4$. The former reaction involves the C–H bond, the latter the C–C bond. Deuterium permits these reactions to be studied when they are occurring simultaneously on a given catalyst under given conditions of temperature and pressure. During the course of this work, also, investigation was made of the kinetics of methane formation from ethane and hydrogen, the data providing interesting aspects of the mechanism of activation of the ethane at nickel surfaces.

Experimental Details

Materials.—Electrolytic hydrogen and deuterium from the electrolysis of ordinary and heavy water ($d^{25}_{25} = 1.1079$) were employed. Ethane was produced catalytically from ethylene and hydrogen over a nickel catalyst at room temperature. It was purified by combustion of the excess hydrogen over copper–copper oxide, followed by fractional distillation to remove nitrogen and methane present.

---

(1) Visiting research fellow of the South Manchuria Railway Co., Dairen, Japan.

The comparison of exchange reaction and methane formation was conducted by a dynamic method in which the gas mixtures $C_2H_6 + D_2(H_2)$ were slowly passed backward and forward over a nickel catalyst supported on kieselguhr. Vapor baths were employed for temperature control. The catalyst was similar to that described in Part I of this series,[2] and was protected against mercury vapor by two traps at −78°. The kinetic studies were made in a static system.

Analytical Procedure.—The progress of the exchange reaction was again followed by infra-red absorption measurements of the C–H and C–D bonds as already described.[2,3] The formation of methane was followed by combustion of the hydrogen over copper–copper oxide at 300°. From the data thus obtained, the volume of hydrogen consumed in the reaction could be checked against the increase in hydrocarbon volume. This double check was occasionally further confirmed by fractional extraction of methane from ethane at liquid air temperature. The accuracy attainable may be illustrated by expt. 27. In this experiment 19.6 cc. of C_2H_6 and 20.4 cc. of H_2 were treated for one hour in contact with 2.0 g. of nickel catalyst at 184° to give a final volume of 39.7 and 26.2 cc. of residual hydrocarbon. Calculating from the hydrogen decrease 13.8 cc. of CH_4 was formed. From the hydrocarbon increase 13.2 cc. was formed. Fractionation of the residual hydrocarbon gave >12.1 cc. of methane and <14.1 cc. of ethane, the latter certainly still containing some dissolved methane. It was found that methane dissolved readily in and was persistently retained by the condensed higher hydrocarbon. The larger the methane content the easier and more accurate was the fractionation.

Experimental Results

Comparison of Exchange Reaction and Methane Formation.—The data of Tables I and II represent the measurements made by the dynamic method to effect this comparison, the same nickel catalyst, 2.5 g., being used for both sets of data.

TABLE I

THE REACTION $C_2H_6 + H_2 = 2CH_4$

Expt.	C_2H_6, cc.	H_2, cc.	Temp., °C.	Time, hrs.	Conversion % C_2H_6 reacted
4	20.9	21.0	110	1	0
11	25.9	28.5	157	3	11.9
9	24.8	26.4	172	1	19.3
10	22.9	25.4	184	1	92
5	21.8	22.5	184	1	73.2
2	22.4	22.5	302	1	100

These results show that the exchange reaction becomes, under the given conditions, quite marked already at 110° whereas methane formation only becomes appreciable around 150° and is fast at 180°. There is therefore about 60° difference in temperature, on this catalyst, between comparable activations of the C–H and C–C bonds in ethane. The data of Table II also suggested the following method of preparation of C_2D_6.

TABLE II

THE EXCHANGE REACTION $C_2H_xD_y + D_2 = C_2H_{x-1}D_{y+1} + HD$

Expt.	C_2H_6, cc.	D_2, cc.	Temp., °C.	Time, hrs.	C–D Bond % equilibrium
12	22.1	44.4	25	22	0
13	21.4	43.1	110	2.5	33
8	25.6	52.3	138	2.5	100
7	22.7	41.5	302		0[a]

[a] This experiment was conducted in presence of Cu–CuO at 302° to show that the hydrogen removal during analysis did not effect exchange.

Preparation of Ethane-*d*$_6$.—Two grams of nickel catalyst was reduced at 450° for five and a half hours and then evacuated for two hours. At 0°, 22.2 cc. of C_2H_4 and 50.4 cc. of D_2 were introduced to the catalyst and when hydrogenation was complete the temperature was raised to 138° and there maintained for two and a half hours. The hydrogen–deuterium was then removed by combustion at 275° and next the partially deuterized ethane was subjected to the same procedure, each time with twice its volume of pure deuterium, for seven successive treatments. If the equilibrium constant is approximately 1 and the equilibrium is established in each treatment the final ethane should have been ~99% C–D. This was actually found to be the case by infra-red measurements. The recovered C_2D_6 had a volume of 22 cc. and the methane formed throughout the experiment was 0.27 cc. The C_2D_6 had a negligible vapor pressure at liquid air temperatures. We shall report elsewhere some of the physical properties of this product.

The Kinetics of the Reaction $C_2H_6 + H_2 = 2CH_4$.—The data of Table III record the results of static experiments on 1 g. of nickel catalyst at 172 and 184° in a reaction space of 125 cc. with 3 cc. dead space for the dry ice traps. The experiments were so conducted that, at each stage, the hydrogen, removed by combustion for analytical purposes, was replaced by an equal volume of hydrogen and the next stage followed. The data are all recorded as pressures of gas in mm. at a constant volume of 88 cc. corrected to 25°.

Comparison of expts. 2a and 3 indicates that the activity of the catalyst is constant and that the trend upward in conversion per hour as the re-

action proceeds is real and is to be ascribed to the reasonable assumption that hydrogen is strongly adsorbed but the hydrocarbons only weakly. As the hydrogen is consumed more of the surface becomes accessible to activated adsorption of the hydrocarbons. This conclusion is supported by the following data with varying ratios of hydrogen to ethane. The concordance between the data of the two columns +ΔH.C. and $-\Delta H_2$ save in expt. 1a indicates also the absence of any side reactions, which is not true with other ratios of reactants (*vide infra*). The apparent activation energy of the reactants calculated from the data at the two temperatures gives $E_{\text{app.}} \sim 43$ kcal.

In Table IV are recorded experiments with $1C_2H_6 + 0.5\ H_2$, $1C_2H_6 + 2H_2$ and $1C_2H_6 + 0.69H_2$.

All the experiments recorded in this Table IV were done successively on one catalyst. The comparison of expts. 1 and 2 with a gas ratio of $2C_2H_6{:}1H_2$ with expts. 2 and 3 of Table III where the ratio is 1:1 indicates that increase of hydrogen ratio severely reduces the reaction rate. Calculations from the data 2a and 3a of Table III and 1 and 2 of Table IV and from the data of expts. 5, 6, 7 of this latter table would indicate an effect of hydrogen proportional to $\sim P_{H_2}{}^{-2.5}$. We shall discuss this later. Comparison of expts. 1 and 2 of Table IV with the subsequent experiments of this table at other ratios indicates that during expts. 1 and 2 the nickel catalyst suffered a considerable degree of poisoning leading to abnormally low conversions in expts. 3–7. A critical analysis of the data of the table reveals that the poisoning is due to carbon deposition. In addition to the reaction forming methane (1) $C_2H_6 + H_2 = 2CH_4$ there are occurring simultaneously reactions which may be represented by the over-all equations (2) $2C_2H_6 = C + 3CH_4$ and (3) $C + 2H_2 = CH_4$. These conclusions may be reached especially from a comparison of the columns recording initial and final pressures, *i. e.*, ΔP_{total} and those recording increase of hydrocarbon +ΔH.C. and decrease of hydrogen pressure $-\Delta H_2$. Thus, in expt. 1a of Table IV, the recovered gas exceeds the amount introduced by 33.9 mm. and the increase in hydrocarbon is 122.4 mm. The increase of hydrocarbon due to reaction (1) with hydrogen is not less than 88.6 mm., which leaves 122.4 − 88.6 =

TABLE V

DECOMPOSITION OF ETHANE ON NICKEL AT 218°

Expt.	Initial $P_{C_2H_6}$, mm.	Time, hrs.	Final pressure, mm. Total	+ΔP	H.C.	+ΔH.C.	+H_2	CH_4	C_2H_6	CO_2 from combustion of C_2H_6 fraction
1a	169.4	10.3	186.2	16.8	184.9	15.5	1.3	50.7	136.2	260.5
b	159.7	57	184.6	24.9	183.4	23.7	1.3	76.4	108.5	205.3

33.8 mm. increase coming from reaction (2). This corresponds to a decomposition according to (2) of 67.6 mm. ethane, and therefore to carbon deposition on the surface equivalent to ~33.8 mm. In expt. 2a the recovered gas is less than the initial by 28.5 mm. Of the hydrogen consumed some 57 mm. must have reacted in the main with the previously deposited carbon to give 28.5 mm. methane. This leaves only 5.2 mm. hydrogen to react with an equivalent of ethane to give a further 10.4 mm. methane. This would give a total increase of hydrocarbon of 28.5 + 5.2 = 33.7 mm. to be compared with the observed hydrocarbon increase of 33.6 mm. Expt. 2b appears to repeat 1 since the carbon laid on the surface in expt. 1a was more than 90% consumed by hydrogen in 2a. Similar variations in the nature of the important reaction with change in the carbon–hydrogen ratio of the reaction mixture and change in carbon content of the surface may be traced through the results of expts. 2b–7. It emerges that, in a catalyst heavily charged with carbon, reaction (3) between carbon and hydrogen occurs preferentially to reaction (1). A certain amount of the carbon, however, appears to be laid down in such a form that subsequent reaction does not readily occur. Also, the activity of the catalyst falls steadily due to the deposition of the carbon.

The experiments presented in Table V are concerned with the decomposition of ethane alone on the same nickel catalyst at 218°. The catalyst after evacuation was washed with ethane at 218° for one and a half hours and then evacuated for one hour further. The three final columns of the table give the data obtained by a fractional separation of the hydrocarbon product and a combustion of the ethane fraction to carbon dioxide as a check on its composition.

The fact that the methane formed is, in each case, equal to three times the increase in pressure due to reaction or equal to three times the increase in hydrocarbon plus twice that of the hydrogen, is indicative of the over-all reaction (2) $2C_2H_6 = C + 3CH_4$. The methane yields from the fractionation of the product further confirm this view. The carbon deposited on the catalyst by reason of this reaction can be removed in part by reaction with hydrogen as indicated in the two experiments of Table VI.

TABLE VI

INTERACTION OF HYDROGEN WITH CARBON DEPOSITED ON NICKEL AT 218°

Expt.	P_{H_2}, mm.	Time, hrs.	Recovered gas, mm.	−ΔP	+ΔH.C.	−ΔH_2	CH_4 by fractionation
1a	416.1	4.5	356.0	60.1	57.1	117.2	56.7
b	421.0	14.0	414.4	6.6	6.0	12.6	..

Since −ΔH_2 is twice (−ΔP) or twice (+ΔH.C.) it follows that the hydrocarbon formed is all methane. This was confirmed in the first case by fractionation. The total methane produced amounts to 63.1 mm. equivalent to 42 mm. of C_2H_6. Some carbon is left on the catalyst and a subsequent measurement of reaction rate with $1C_2H_6{:}1H_2$ gave very low activity, *i. e.*, 0.9% per hour at 184°.

The Activation Energy of the Reactions of Ethane with Hydrogen and Deuterium to Form Methane and Methane-*d*.—To check the apparently high activation energy deduced from the data of Table III and to obtain comparison between the rates of reaction of hydrogen and deuterium with ethane the data of Table VII were obtained on a new catalyst containing 2 g. of nickel. Again the static method was employed and the experiments with deuterium were interposed between two experiments with hydrogen under comparable conditions.

TABLE VII

REACTION OF ETHANE WITH HYDROGEN AND WITH DEUTERIUM TO FORM METHANE

Expt.	Initial volumes, cc. C_2H_6	H_2	D_2	Temp., °C.	Time, hrs.	Conversion % C_2H_6
28	20.0	20.0		184	1.0	53.7
29	20.1	20.1		172	2.5	28.3
30	20.3		19.4	172	2.5	16.7
31	20.3	19.7		172	2.5	23.9
32	20.3	20.4		157	10.0	21.2
33	20.3		20.9	157	10.0	10.3
34	20.3	21.4		157	10.3	17.5

A slow deterioration of the catalyst with successive experiments does not obscure the obvious result that reaction with deuterium is slower than that with hydrogen. Nor is it serious enough to prevent the conclusion that the activation energy has the high value previously indicated. The data at 157 and 172° in this table indicate an observed activation energy of ∼42 kcal. The relative rates of the hydrogen and deuterium reactions at the two temperatures 157 and 172° can be accounted for on the basis of a difference in activation energies of ∼450 cal.

General Discussion

From these studies of reactivity of ethane–hydrogen mixtures on nickel in the temperature range 157–300°, we conclude that, in the presence of excess hydrogen, the ethane undergoes a dissociative adsorption to methyls which are converted quantitatively with adsorbed hydrogen to methane. With deficiency of hydrogen the activated adsorption of ethane continues beyond the stage of formation of adsorbed methyls at the surface and the dissociative adsorption proceeds via CH_2 and CH to C with simultaneous formation of adsorbed atomic hydrogen. Reaction of this latter with adjacent methyls produces methane which then evaporates. In this temperature range the dissociative process to C appears to be practically complete, carbon and methane being the products formed in overwhelmingly preponderant amount. A small amount of hydrogen escapes from the surface as such. Some of the carbon formed goes over into a form in which it is no longer capable of undergoing the reverse reactions of the dissociative processes discussed and acts as a permanent poison to the catalyst. The bulk of the carbon formed in this temperature range is however recoverable by reaction with hydrogen as methane. All these observations are in best agreement with the calculated equilibrium data in such systems. In the system $2C + 3H_2 = C_2H_6$ this is quite remarkably true since we compute that at 227° partial pressures $P_{C_2H_6} = 0.46$, $P_{H_2} = 0.54$ atm. are in equilibrium with carbon with a total pressure of 1 atm. In contrast to this in the system $C + 2H_2 = CH_4$ at atmospheric pressure the equilibrium partial pressure at 255° is $P_{H_2} = 0.03$ atm. The necessity for excess hydrogen in the ethane system is thus evident, while with the methane system minimal pressures of hydrogen prevent carbon formation. In the system $C_2H_6 = C + 3CH_4$ the equilibrium partial pressure at 184° is $P_{C_2H_6} = 0.6 \times 10^{-4}$ atm., and in the system $C_2H_6 + H_2 = 2CH_4$ at the same temperature $P_{C_2H_6} = 2 \times 10^{-4}$ atm.

The occurrence of the exchange reaction to yield deutero-ethanes in a temperature range where dissociative adsorption to yield methyls is unimportant indicates that the dissociative adsorption of ethane to yield ethyl and hydrogen atom is a process of lower activation energy than that of adsorption to yield methyls. The reverse of the ethane–ethyl–hydrogen dissociative process is the final stage in the formation of ethane from ethylene and hydrogen on such catalysts in the low temperature range. In our previous study of the methanes we found an activation energy of 19 kcal. for the dissociative adsorption to methyl and hydrogen. We expect that the corresponding process for ethane might be less than this value.

The high apparent activation energy of the reaction of ethane with hydrogen to yield methane, ∼43 kcal., is worthy of note especially since the temperature range in which the reaction occurs is not considerably higher than that in which the exchange reaction occurs. We compare this result with the case of methane and deuterium in which $E \sim 28$ kcal. In both cases the retarding influence of hydrogen contributes to the high value. From the earlier work we assess its contribution at ∼9 kcal. The simplest explanation of the high activation energy in the present work appears to be that it is associated with a somewhat higher energy of activated adsorption involving dissociation of the C–C bond. Sterically we would expect this to be higher than that involving the C–H bond. Further, of the surface free from hydrogen, available to ethane adsorption, a fraction will be occupied by ethane adsorbed by a mechanism involving the C–H dissociation. Such adsorption will cause an increase in the observed activation energy of the ethane–hydrogen reaction as does hydrogen. If we ascribe the difference between the two observed activation energies in the ethane and methane reactions, $43 - 28 = 15$ kcal., to such an effect, we arrive at the reasonable values for the activation energies of dissociative adsorption of ethane, for the C–C bond ∼ 19 kcal., and for the C–H bond ∼ 15 kcal. Qualitatively such results are entirely consonant with all our data.

One final point for discussion involves the abnormal inhibitory action of hydrogen ($\propto P_{H_2}^{-2.5}$) which we deduce from the data of Tables III and IV. Such a high power of the hydrogen pressure cannot be explained on the basis of pressure influence on surface occupied by hydrogen molecules. It may, however, be explained as due to the increasing deposition of carbon with decrease in hydrogen concentration and the preferential occurrence of the reaction between hydrogen and the deposited carbon rather than that between ethane and hydrogen. As we have already observed, our experimental data abundantly confirm this preferential reaction and thus account for the abnormal effect of hydrogen concentration. One alternative possibility is that activation involving the C–C bond requires at least two adjacent elementary spaces of catalyst and that this condition at high hydrogen coverage of the surface might be inversely proportional to a higher power of the hydrogen concentration. Further studies in the general field of hydrocarbon–hydrogen reactions are planned to test these points of view.

Summary

1. The exchange reaction between ethane and deuterium on a nickel catalyst takes place in a lower temperature range, 100–130°, than that required for the interaction to yield methane, 160–300°.

2. The formation of methane by this reaction has been studied kinetically. The surface reaction is inhibited by hydrogen.

3. At low hydrogen concentrations side reactions occur representable by the equations $2C_2H_6 = C + 3CH_4$ and $C + 2H_2 = CH_4$ and these may become the predominant reactions.

4. The activation energy of the reaction on nickel between ethane and hydrogen to form methane is $\sim$43 kcal. The reaction with deuterium is somewhat slower with an activation energy $\sim$0.5 kcal. higher.

5. An interpretation of these data in terms of a dissociative activated adsorption of ethane is given, leading to the conclusion that the activation energy of dissociative adsorption at the C–C bond is greater than that of the C–H bond.

6. A method of preparation of ethane-d_6 has been described.

Studies in the Urea Series. XIII.[1] Alkyl-nitroureas and Alkyl-nitrobiurets

BY TENNEY L. DAVIS AND NICHOLAS D. CONSTAN

Experiments reported in the tenth paper of this series led to the conclusion that "only those alkylguanidines which contain an unsubstituted amino group form nitro-compounds by direct nitration, the nitro group entering the non-alkylated amino group." A similar generalization is evidently not valid for the alkylureas, for Degner and von Pechmann[2] have reported that N-nitro-N-methylurea is produced by the nitration of methylurea with ethyl nitrate and concentrated sulfuric acid. Thiele and Lachmann[3] on the other hand reported somewhat earlier that ethylurea yields N-nitro-N′-ethylurea by a similar procedure. We have wished to verify this difference between methyl- and ethylurea and to determine in general the behavior of the alkylureas on nitration—and have carried the study farther to the nitration of two ω-substituted biurets and to the preparation from one of the resulting nitro compounds of certain ω,ω,ω'-trisubstituted biurets.

The nitrate of methylurea on treatment with concd. sulfuric acid yields N-nitro-N-methylurea in which the nitro and methyl groups are both attached to the same nitrogen atom, as is demonstrated by the fact that it yields methylnitramine and urea when treated with ammonia. The nitrates of ethyl-, *n*-propyl- and *n*-butylurea on treatment with concd. sulfuric acid yield alkylnitroureas in which the nitro group and the alkyl group are attached to different nitrogen atoms. Unlike methylurea they behave in the same manner as the corresponding alkylguanidines. The structure of the N-nitro-N′-alkylureas is demonstrated by the facts that with ammonia water they yield the alkylureas and with aniline the N-phenyl-N′-alkylureas. As would be expected they dearrange somewhat less readily than nitro-

[3] Thiele and Lachmann, *Ann.*, **288**, 285 (1895).

urea itself. With cupric salts and pyridine they form colored complex compounds which are soluble in chloroform and may be extracted from aqueous solution by means of that solvent.

The nitrates of N,N-dimethyl-, N,N-diethyl- and N,N-di-*n*-butylurea on treatment with concd. sulfuric acid yield the corresponding dialkylnitramines. No nitrourea derivatives could be found. In one experiment in which N,N-diethylurea nitrate was treated with acetic anhydride, diethylnitramine was produced and a portion of the diethylurea was recovered. The N,N-dialkylureas differ then in their behavior on nitration from N,N-dimethylguanidine, which yields N,N-dimethyl-N′-nitroguanidine.

N,N′-dimethyl- and N,N′-diethylurea could not be nitrated.

ω-Methyl- and ω,ω-dimethylbiuret on nitration with mixed acid yield, respectively, ω-methyl-ω′-nitrobiuret and ω,ω-dimethyl-ω′-nitrobiuret, in which the nitro group has entered the otherwise unsubstituted amino group at the remote end of the molecule. The position of the nitro group is proved by the fact that the nitro compounds react with ammonia to reproduce the original un-nitrated alkylbiurets. A consideration of the facts already known about the urea dearrangement[4] leads to the conclusions (1) that ω-methyl-ω-nitrobiuret would dearrange to form methylnitramine and dicyanic acid and with ammonia water would yield unsubstituted biuret, (2) that ω-methyl-α-nitrobiuret would dearrange to form nitroamide, cyanic acid and methyl isocyanate, and with ammonia water would yield urea and methylurea and (3) that ω-methyl-ω′-nitrobiuret would dearrange to form nitroamide and methyldicyanic acid, and with ammonia water would yield ω-methylbiuret.

$$CH_3NHCONHCONHNO_2 \longrightarrow NH_2NO_2 + CH_3NHCONCO$$

$$CH_3NHCONCO + NH_3 \longrightarrow CH_3NHCONHCONH_2$$

ω,ω-Dimethyl-ω′-nitrobiuret similarly would yield dimethyl-dicyanic acid by dearrangement, and ω,ω-dimethylbiuret by reaction with ammonia. The probable presence of dimethyl-dicyanic acid is further confirmed by the reaction of ω,ω-dimethyl-ω′-nitrobiuret with primary amines.

$$(CH_3)_2NCONCO + RNH_2 \longrightarrow (CH_3)_2NCONHCONHR$$

In this way we have prepared ω,ω,ω′-trimethylbiuret, ω,ω-dimethyl-ω′-*n*-amylbiuret, and ω,ω-dimethyl-ω′-phenylbiuret. None of these tri-substituted biurets gave the biuret test with cupric salts and sodium hydroxide.

Experiments

N-Nitro-N-methylurea.—Twenty-two grams of dry methylurea nitrate, m. p. 125–126°, was added gradually and with stirring to 35 cc. of concd. c. p. sulfuric acid (sp. gr. 1.84) while the temperature was maintained below −15°. The homogeneous mixture was drowned in 120 cc. of ice-water, and the precipitate, washed, dried in a desiccator, and recrystallized from petroleum ether, yielded 8 g. (41.7%) of N-nitro-N-methylurea, m. p. 156–158° with decomposition. The material yielded methylnitramine and urea by interaction with warm ammonia water. Its properties were the same as those reported by Degner and von Pechmann[2] for the N-nitro-N-methylurea prepared by the nitration of methylurea with ethyl nitrate in concd. sulfuric acid solution, and were different from those of the N-nitro-N′-methylurea, m. p. 105–106°, which the same workers prepared by the action of diazomethane on nitrourea.

N-Nitro-N′-ethylurea.—Forty grams of ethylurea nitrate, treated in a similar manner with 60 cc. of concd. sulfuric acid and drowned in 200 cc. of ice-water, yielded 17 g. (49.3%) of N-nitro-N′-ethylurea, pearl-white flakes from petroleum ether, not hygroscopic, m. p. 133–134°. Thiele and Lachmann[3] reported m. p. about 130–131°. The material yielded ethylurea by interaction with warm ammonia water.

N-Nitro-N′-*n*-propylurea.—Fifteen grams of *n*-propylurea nitrate, treated in a similar manner with 23 cc. of concd. sulfuric acid and drowned in 100 cc. of ice-water, yielded 8 g. (60%) of N-nitro-N′-*n*-propylurea, crystals from petroleum ether, m. p. 96°.

Anal. Calcd. for $C_4H_9O_3N_3$: N, 28.5. Found: N, 28.7, 28.6.

The structure of the N-nitro-N′-*n*-propylurea was proved by the fact that it reacted with aniline in warm water to yield N-phenyl-N′-*n*-propylurea, m. p. 116–117°, identified by mixed melting point with a sample prepared by the combination of phenyl iosocyanate with *n*-propylamine in benzene solution. Oliveri-Mandalà and Noto[5] reported the melting point of N-phenyl-N′-*n*-propylurea as 114–116°.

***n*-Butylurea Nitrate.**—Twenty-five grams of *n*-butylurea was made into a paste with 25 cc. of water, 20 cc. of nitric acid (sp. gr. 1.42) was added, and the solution was cooled in a freezing mixture of ice and salt. The crystals which separated, after drying in a vacuum desiccator, melted at 62–65°. They were found to be appreciably soluble in benzene; recrystallized from that solvent they yielded the pure substance, m. p. 70–71°, 33 g. (85.5%).

Anal. Calcd. for $C_5H_{13}O_4N_3$: N, 23.5. Found: N, 23.2, 23.3.

N-Nitro-N′-*n*-butylurea.—Thirty grams of *n*-butylurea nitrate, treated with 45 cc. of concd. sulfuric acid and drowned in 150 cc. of ice-water, yielded 18 g. (66.5%) of N-nitro-N′-*n*-butylurea, m. p. 80–81°, pearl-white fluffy leaflets from petroleum ether.

Anal. Calcd. for $C_5H_{11}O_3N_3$: N, 26.1. Found: N, 26.0, 25.9.

The behavior of N-nitro-N′-*n*-butylurea with ammonia and with aniline is typical of the behavior of the N-nitro-N′-alkylureas in general. It reacts less vigorously with these reagents than does nitrourea. The effect of the alkyl group is to reduce the ease of the dearrangement.

Two grams of N-nitro-N′-*n*-butylurea treated with 60 cc. of strong ammonia water gave no evidence of any reaction, and the viscous liquid which remained after spontaneous evaporation was strongly acid to litmus and gave a blue color with a solution of diphenylamine in concd. sulfuric acid. In another experiment, the materials were warmed; a vigorous evolution of nitrous oxide took place, and the evaporation of the liquid on the water-bath gave a residue of *n*-butylurea which, even without purification, failed to give a test for the nitro group with the diphenylamine reagent.

Three grams of N-nitro-N′-*n*-butylurea was treated with a slight excess of aniline dissolved in water. There was no evidence of reaction at room temperature. On spontaneous evaporation of the liquid, aniline separated first and afterward unchanged N-nitro-N′-*n*-butylurea. When a similar mixture was warmed gently it became milky from innumerable small bubbles of nitrous oxide. On continued boiling of the mixture, gassing ceased, and acicular crystals began to separate from the boiling liquid. These on recrystallization from benzene yielded pure N-phenyl-N′-*n*-butylurea, m. p. 129–130°, identified by analysis and by mixed melting point with a sample prepared by the combination of phenyl isocyanate with *n*-butylamine in benzene solution.

Anal. Calcd. for $C_{11}H_{16}ON_2$: N, 14.6. Found: N, 14.8, 14.3.

***n*-Amylurea nitrate**, m. p. 75°, was prepared in the same way as the nitrate of *n*-butylurea.

Anal. Calcd. for $C_6H_{15}O_4N_3$: N, 21.8. Found: N, 21.9, 22.0.

N-Nitro-N′-*n*-amylurea.—Twelve grams of *n*-amylurea nitrate, treated with 16 cc. of concd. sulfuric acid and drowned in 80 cc. of ice-water, yielded an oil which on chilling solidified to crystals. These, dried and recrystallized from ether, gave 6 g. (67%) of N-nitro-N′-*n*-amylurea, m. p. 62°.

Anal. Calcd. for $C_6H_{13}O_3N_3$: N, 24.6. Found: N, 24.6, 24.7.

By reaction with aniline in warm water N-nitro-N′-*n*-amylurea yielded N-phenyl-N′-*n*-amylurea, m. p. 92°, identified by analysis and by mixed melting point with a sample prepared by the combination of phenyl isocyanate with *n*-amylamine in benzene solution.

Anal. Calcd. for $C_{12}H_{18}ON_2$: N, 13.6. Found: N, 13.5.

N,N-Dimethylurea nitrate was prepared by the same method as the nitrate of butylurea, 86.8% yield, crystals from benzene, m. p. 103–104°.

Anal. Calcd. for $C_3H_9O_4N_3$: N, 27.8. Found: N, 28.0, 28.2.

Ten grams of N,N-dimethylurea nitrate was treated with 15 cc. of concd. sulfuric acid and drowned in 75 cc. of of ice-water, as described, but no precipitate appeared. The liquid was extracted repeatedly with small portions of ether, and the ether extract, evaporated and cooled to a low temperature, gave stout needle crystals of dimethylnitramine, m. p. 79°. Franchimont[6] obtained the same material by the action of strong nitric acid on the nitrate of N,N-dimethylurea.

N,N-Diethylurea nitrate was prepared by the same method as the other nitrates, 77% yield, crystals from benzene, m. p. 118°.

Anal. Calcd. for $C_5H_{13}O_4N_3$: N, 23.5. Found: N, 23.7, 23.5.

Twelve grams of N,N-diethylurea nitrate was treated with 16 cc. of concd. sulfuric acid and drowned in 80 cc. of ice-water, the liquid was extracted with ether, and the ethereal extract on distillation in vacuum yielded a small amount of diethylnitramine boiling as reported at 93° at 16 mm. pressure.[7] In another experiment the sulfuric acid solution of N,N-diethylurea nitrate was diluted with ether before it was poured into water, but no nitrodiethylurea was obtained. In another, acetic anhydride was used instead of sulfuric acid; some diethylnitramine was produced and a portion of the N,N-diethylurea nitrate was recovered unchanged.

N,N-Di-*n*-propylurea nitrate was procured in excellent yield by the same method as the other nitrates, m. p. 165°.

Anal. Calcd. for $C_7H_{17}O_4N_3$: N, 20.3. Found: N, 20.5, 20.4.

On treatment with sulfuric acid, water and ether in the same manner as the other nitrates, it yielded a small quantity of di-*n*-propylnitramine boiling as reported at 76–79° at 10 mm. pressure.[8]

Action of Sulfuric Acid on the Nitrates of N,N′-Dialkylureas.—Ten grams of finely powdered dry N,N′-dimethylurea nitrate was added gradually to 15 cc. of concd. sulfuric acid while the mixture was kept at a temperature below −15°. When the liquid was poured into 75 cc. of ice-water, no precipitate appeared. Ether and benzene extracts of the acid solution gave no residues when they were evaporated. The solution was treated with barium carbonate in excess, filtered, and evaporated to dryness at a temperature below 55°. Ether, petroleum ether, and benzene extracts of the residue gave no products which showed a positive test with the diphenylamine reagent.

An experiment with the nitrate of N,N′-diethylurea gave a similar result.

In another experiment with N,N′-dimethylurea nitrate, the sulfuric acid solution was diluted with ether instead of with water. The ether removed most of the sulfuric acid. In order to determine whether any cyanic acid from the dearrangement of the N,N′-dimethylurea was present, the residue from the ether was treated with benzylamine in the expectation that the cyanic acid, if present, would combine with that material to form benzyl- or dibenzylurea, but only benzylamine sulfate, nitrate and N,N′-dimethylurea were identified in the mixture.

[8] Thomas, *ibid.*, **9**, 79 (1890).

ω-Methyl-ω′-nitrobiuret.—Four grams of finely powdered dry ω-methylbiuret[9] was added gradually and with stirring to a mixture, below −15°, of 12 cc. of concd. sulfuric acid (1.84) and 3 cc. of nitric acid (1.42). On drowning the clear liquid in 25 cc. of ice-water, the ω-methyl-ω′-nitrobiuret precipitated as an almost impalpable powder. Washed with ice-water and dried in vacuum, this yielded without recrystallization 2.9 g. (52%) of product which did not melt but decomposed at 99–100°.

Anal. Calcd. for $C_3H_6O_4N_4$: N, 34.5. Found: N, 34.5, 34.6.

ω-Methyl-ω′-nitrobiuret did not yield a chloroform soluble copper pyridine complex. Warmed with ammonia water, it yielded ω-methylbiuret, identified by mixed melting point with a known sample.

ω,ω-Dimethyl-ω′-nitrobiuret.—Ten grams of ω,ω-dimethylbiuret, nitrated with a mixture of 18.5 cc. of concd. sulfuric acid (1.84) and 4.5 cc. of nitric acid (1.42) and drowned in 100 cc. of ice-water, gave 9.8 g. (73%) of ω,ω-dimethyl-ω′-nitrobiuret, m. p. 114–115°, with decomposition.

Anal. Calcd. for $C_4H_8O_4N_4$: N, 31.8. Found: N, 31.7, 31.4.

ω,ω-Dimethyl-ω′-nitrobiuret, warmed with ammonia water, yielded ω,ω-dimethylbiuret, identified by mixed melting point with a known sample. It did not form a chloroform soluble copper pyridine complex.

ω,ω-Dimethyl-ω′-phenylbiuret.—Two grams of ω,ω-dimethyl-ω′-nitrobiuret was treated with a slight excess of aniline in aqueous solution. Gassing set in at once. The material was warmed until gassing ceased and evaporated to dryness on the water-bath. The product was purified by recrystallization from methyl alcohol and by sublimation in vacuum. At ordinary pressure it sublimed without melting at about 225°.

Anal. Calcd. for $C_{10}H_{13}O_2N_3$: N, 20.3. Found: N, 20.6.

ω,ω,ω′-Trimethylbiuret, prepared in similar manner from ω,ω-dimethyl-ω′-nitrobiuret and methylamine, melted at 154°, small crystals from chloroform.

Anal. Calcd. for $C_5H_{11}O_2N_3$: N, 29.0. Found: N, 29.2, 29.3.

ω,ω-Dimethyl-ω′-*n*-amylbiuret, prepared in similar manner from ω,ω-dimethyl-ω′-nitrobiuret and *n*-amylamine, melted at 149°, small crystals from chloroform.

Anal. Calcd. for $C_9H_{19}O_2N_3$: N, 20.9. Found: N, 21.1.

Very few substituted biurets containing substituents in both the ω- and the ω′-positions are described in the literature. Experimentation along this line is being continued.

Summary

The nitration of alkylureas has been studied by the method of treating the urea nitrates with concentrated sulfuric acid.

Ethyl-, *n*-propyl- and *n*-butylurea, like the corresponding guanidines, nitrate in the nonalkylated amino group.

Methylurea, unlike methylguanidine, nitrates on the nitrogen atom which is attached to the methyl.

Dialkylureas in which the two alkyl groups are attached to the same nitrogen atom yield dialkylnitramines.

Dialkylureas in which the two alkyl groups are attached to different nitrogen atoms could not be nitrated.

ω-Methyl- and ω,ω-dimethylbiuret with mixed acid take on a nitro group in the non-alkylated amino group at the remote end of the molecule.

Three ω,ω,ω′-trisubstituted biurets are described.

Studies of Crystalline Vitamin B_1. XIV. Sulfite Cleavage. IV. The Thiazole Half

BY EDWIN R. BUCHMAN

The vitamin B_1 molecule is split by sulfite[1] yielding 4-methyl 5-(β-hydroxyethyl) thiazole[2] as basic cleavage product. The synthesis of this substance from brominated acetopropyl alcohol and thioformamide was announced[3] over a year ago. Subsequently H. T. Clarke and S. Gurin prepared[2] the compound in connection with their establishment of the presence of the thiazole nucleus in the vitamin. Recently the following improved method has been developed.

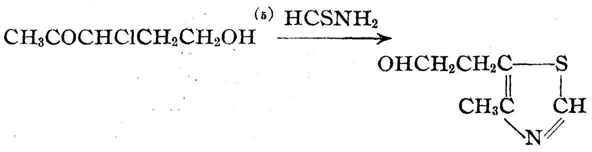
[3] E. R. Buchman and R. R. Williams, Paper read before the Organic Division of the American Chemical Society at the New York meeting, April, 1935.

[4] I. L. Knunyantz, G. V. Chelintzev and E. D. Osetrova, *Compt. rend. acad. sci.* (U. R. S. S.), [N. S.], **1**, 312 (1934); *C. A.*, **28**, 4382 (1934).



The yield of thiazole varies from 8 to 12 g. per 100 g. of ethyl acetoacetate used as starting material.

The similarity between the vitamin and the methiodide of the basic cleavage product has been pointed out.[6] Although the resemblance does not extend to the sulfite cleavage,[1] it was found that the characteristic color test which the vitamin gives with diazotized sulfanilic acid is a property of quaternary salts of the hydroxy thiazole.

Experimental

Brominated Acetopropyl Alcohol and Thioformamide.[7]—Thirty-one grams of γ-acetopropyl alcohol[4] was dissolved in 150 cc. of water and stirred while 48 g. of bromine was added slowly at room temperature over a period of two hours. The aqueous layer was decanted from a small amount of oil, extracted with ether and the ethereal solution dried over sodium sulfate. After removal of the solvent *in vacuo*, the crude bromo compound (unstable even at room temperature), weighing 30 g., was added directly to 13 g. of crude thioformamide[8] dissolved in 10 cc. of ethanol. A spontaneous reaction took place during which the temperature was kept below 60° by external cooling. The reaction mixture, after standing overnight at room temperature, was heated for one hour on the steam-bath, taken up in water and washed with ether. Excess alkali was added and the liberated thiazole extracted with ether, dried over sodium sulfate and fractionated. The yield was 7.1 g.; b. p. 110–112° (3 mm.).

Anal.[9] Calcd. for C_6H_9NSO: C, 50.30; H, 6.34. Found: C, 49.96; H, 6.29.

The presence in the product of a small amount of the isomer, 4-(γ-hydroxypropyl) thiazole, may be inferred from the unsharp melting points of crude derivatives. These, on recrystallization, were found to be identical with corresponding material[6a] from the vitamin: picrolonate, m. p. 184° d.; picrate, from ethanol, m. p. 163°; *p*-nitrobenzoate, from methanol, m. p. and mixed m. p. 124°.[10]

α-Chloro-α-acetobutyrolactone.—Sixty-four grams of α-acetobutyrolactone[4] was placed in a flask equipped with a mechanical stirrer and 68 g. of sulfuryl chloride added over a period of one and one-half hours. The reaction was accompanied by spontaneous warming and a steady evolution of hydrogen chloride and sulfur dioxide. The product was washed with water, taken up in ether and dried over calcium chloride. Fractionation yielded 67.5 g. (83% of the theoretical); b. p. 84–86° at 3 mm.; d^{24}_{4} 1.325.

Anal. Calcd. for $C_6H_7O_3Cl$: C, 44.30; H, 4.35. Found: C, 44.19; H, 4.39.

γ-Chloro-γ-acetopropyl Alcohol.—Eighty-one grams of the chloro lactone, 80 cc. of water and 15 cc. of concentrated hydrochloric acid were mixed and heated under reflux at 100° for seventy-five minutes. During this time carbon dioxide was evolved and complete solution took place. The reaction mixture was extracted several times with small portions of ether and the ethereal solution dried over sodium sulfate and distilled. The portion boiling at 85–110° at 3 mm. was collected; yield 50 g. or 73%; d^{25}_{4} 1.221.

Anal. Calcd. for $C_5H_9O_2Cl$: Cl, 25.97. Found: Cl, 27.26.

The stability of the chloro alcohol is in marked contrast to the behavior of the corresponding bromo compound.

4-Methyl 5-(β-Hydroxyethyl) Thiazole.—Nine and one-half grams of chloroacetopropyl alcohol, 6.7 g. of crude thioformamide and 3 cc. of ethanol were mixed and allowed to stand in a stoppered vessel for three days at room temperature. During this time an additional 3.0 g. of thioformamide was added. The product was isolated as described above. On distillation at 2 mm. there was obtained a 4.9-g. fraction (corresponding to a 50% yield) boiling at 93–95°; d^{24}_{4} 1.196.

Anal. Calcd. for C_6H_9NSO: C, 50.30; H, 6.34; N, 9.79. Found: C, 50.27; H, 6.31; N, 9.52.

The sharp melting points of even crude derivatives attest the high purity of the product.

The thiazole was also prepared by brominating the acetobutyrolactone in aqueous suspension, hydrolyzing the bromo lactone with 10% hydrobromic acid and condensing the resulting γ-bromo-γ-acetopropyl alcohol with thioformamide as before. The yields however are only about one-half of those obtained through the chloro lactone.

The thiazole methiodide,[6a] m. p. 89°, when treated with sulfite[1] did not cleave appreciably but with alkali and diazotized sulfanilic acid[11] gave the red color characteristic of the vitamin under these conditions. The azo test is not given by the hydroxythiazole itself nor is it a general reaction of quaternary thiazolium salts. Acetopropyl alcohol gave a strong positive test.

4-Methyl 5-(β-Chloroethyl) Thiazole.[6a]—Two grams of the hydroxythiazole was heated with 25 cc. of concentrated hydrochloric acid for three hours in a sealed tube at 145°. After evaporation of excess acid, the free base was liberated with alkali and isolated by distillation; yield 1.5 g. The compound has a characteristic odor and is stable[12] at room temperature: b. p. 74–75° (3 mm.) d^{25}_{4} 1.233. *Anal.* Calcd. for C_6H_8NSCl: C, 44.56; H, 4.99; N, 8.67. Found: C, 44.40; H, 5.06; N, 8.60. Picrate[2] m. p. 139–140°; chloroplatinate m. p. 215–218° d.; methiodide m. p. 165°.

The author wishes to acknowledge the kind cooperation of Drs. R. R. Williams and E. E. Reid.

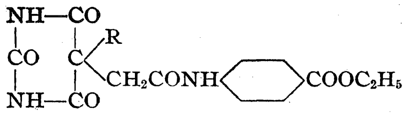
Alkylacetanilidobarbituric Acids. II. *p*-Carbethoxy Derivatives

BY JOHN A. TIMM AND JOHN B. HOWARD[1]

In many instances the simultaneous administration of either mixtures or addition products of hypnotic and antipyretic substances produces an analgesic effect.[2] Further, compounds have been synthesized in which groups tending to exhibit hypnotic properties and others, antipyretic properties are present within the same molecules. Hepner and Frenkenberg[2] have prepared 5,5-dialkyl derivatives of 1-phenyl-3-methylbarbituric acid. Dox and Yoder[3] have synthesized derivatives of two dialkylbarbituric acids (5-ethyl-5-propyl- and 5-isoamyl-5-propylbarbituric acids) with diethylamine, ethylaniline, acetanilide, and phenacetin, respectively, attached to the γ-carbon atom of the propyl group. Timm[4] prepared a series of 5-alkyl-5-acetanilidobarbituric acids. This work has now been extended to include a series of 5-alkyl-5-*p*-carbethoxyacetanilidobarbituric acids of the type



These compounds may be considered as derivatives of ethyl *p*-aminobenzoate, the local anesthetic.

Experimental Part

Barbituric Acids Containing the *p*-Carbethoxyacetanilido Group.—The method used in the synthesis of these compounds was identical with that used for the corresponding acetanilido derivatives[4] except that ethyl *p*-chloroacetaminobenzoate[5] was substituted for chloroacetanilide. The products were recrystallized from 90% ethyl alcohol except in the cases of the allyl and the isopropyl derivatives in which cases absolute alcohol was used to avoid the formation of hydrates. All melt with decomposition at temperatures above 225°.

TABLE I

Barbituric acid, 5-*p*-carbethoxyacetanilido-	Yield, %	N Analysis, %		
		Calcd.	Found	
5-Ethyl-	40	11.63	11.54	11.60
5-Isopropyl-	9	11.20	11.22	11.24
5-*n*-Butyl-	13	10.79	10.78	10.81
5-Isobutyl-	25	10.79	10.73	10.77
5-Isoamyl-	43	10.42	10.41	10.43
5-Allyl-	20	11.25	11.18	11.22

Summary

The following 5-*p*-carbethoxyacetanilidobarbituric acids have been prepared: 5-ethyl-, 5-isopropyl-, 5-*n*-butyl-, 5-isobutyl-, 5-isoamyl- and 5-allyl-.

The Reaction of Butylacetylene with Hydrogen Bromide[1]

BY CHARLES A. YOUNG, R. R. VOGT AND J. A. NIEUWLAND

Although it is a problem of much interest, relatively little attention has been directed toward the addition of hydrogen bromide to acetylene compounds. Bauer[2] obtained vinyl bromide and ethylene dibromide from acetylene and hydrogen bromide in the presence of gaseous oxidizing agents. Using catalysts such as mercuric bromide on asbestos, Wibaut[3] obtained from acetylene and hydrogen bromide a mixture of ethylidene dibromide and ethylene dibromide, the latter compound being formed in the larger amount. Réboul[4] found that aqueous hydrogen bromide and methylacetylene reacted to form 2,2-dibromopropane and a small amount of 2-bromopropene.

During the course of the investigation in this Laboratory, there appeared two papers which furnished further data on the addition of hydrogen bromide to acetylene compounds. Harris and Smith[5] found that in the presence of perbenzoic acid hydrogen bromide added to 10-undecynoic acid to yield the 11-bromo acid, while in the absence of peroxides the 10-bromo acid was formed. Only one molecule of hydrogen bromide was added. On adding hydrogen bromide to methylacetylene Kharasch, McNab and McNab[6] obtained 1,2-dibromopropane in the presence of ascaridole, and 2,2-dibromopropane in the absence of peroxides. No monobromopropenes were obtained. The results of these two papers agree with certain portions of the present communication.

The existence of peroxides in many acetylene derivatives has been demonstrated by Young, Vogt and Nieuwland.[7] In view of the importance in the field of olefins of the peroxide effect discovered by Kharasch and Mayo,[8] it has been deemed advisable to study carefully the influence of peroxides on the addition of hydrogen bromide to some convenient member of the acetylene series. For this purpose butylacetylene has been chosen.

When hydrogen bromide is passed into butylacetylene containing an appreciable amount of peroxides, there is formed a mixture of 1-bromo-1-hexene and 1,2-dibromohexane in quantities depending on the conditions of the experiment. At 0° the hydrogen bromide is absorbed very rapidly and at the end of an hour only a small amount of unreacted butylacetylene remains. The product of the reaction is 1-bromo-1-hexene, together with a small amount of 1,2-dibromohexane. If the reaction is carried out for a longer period of time, greater amounts of 1,2-dibromohexane are formed. There is no formation of 2-bromo-1-hexene in the presence of peroxides.

The reaction of hydrogen bromide with butylacetylene in the absence of peroxides occurs at a very much slower rate. In order to accelerate the addition the reaction was carried out at 15°. In one experiment using hydroquinone as the inhibitor and toluene as a solvent, less than one-half of the butylacetylene reacted in six hours, and the products of the reaction consisted of about one-sixth 2-bromo-1-hexene and about five-sixths 1-bromo-1-hexene. Since the hydrogen bromide was not completely free from oxygen, the 1-bromo-1-hexene was probably produced by the formation of a trace of peroxide in the reaction mixture.

It has been found that ferrous salts rapidly destroy the peroxides which are formed in butylacetylene. Consequently, in attempting to add hydrogen bromide to butylacetylene in the absence of peroxides, both hydroquinone and ferrous bromide were finally used as inhibitors. No solvent was used, and the reaction was carried out at 15°. At the end of twelve hours about one-half of the butylacetylene had not yet reacted, and the remainder of the butylacetylene had been converted to 2-bromo-1-hexene and 2,2-dibromohexane, together with a small quantity of 1-bromo-1-hexene.

The addition of hydrogen bromide to butylacetylene in the presence and in the absence of peroxides has therefore been shown to be similar

to the additions of hydrogen bromide which numerous workers have obtained with olefins having a terminal double bond. However, the results with butylacetylene are particularly interesting because the peroxide effect is shown in the addition of both one and two molecules of hydrogen bromide.

In order to obtain further information concerning the manner in which the dibromohexanes were formed, hydrogen bromide was added to 1-bromo-1-hexene and to 2-bromo-1-hexene, both in the presence and in the absence of peroxides. With 1-bromo-1-hexene containing a small amount of peroxide, hydrogen bromide reacted rapidly at 10°, giving at the end of one and one-half hours a 75% yield of 1,2-dibromohexane. No 1,1-dibromohexane was formed. Using hydroquinone and ferrous bromide as inhibitors, hydrogen bromide was passed for one hundred and twenty hours into 1-bromo-1-hexene at room temperature. The only reaction product was a small quantity of 1,2-dibromohexane. It is evident that the "normal" addition to form 1,1-dibromohexane occurs very slowly, if at all, under the conditions used.

In the presence of peroxides hydrogen bromide reacted readily with 2-bromo-1-hexene at 25°, most of the olefin being converted to 1,2-dibromohexane in four hours. No 2,2-dibromohexane was formed. On the other hand, the addition of hydrogen bromide to 2-bromo-1-hexene in the absence of peroxides, using hydroquinone and ferrous bromide as inhibitors, was considerably slower. At a temperature of 23° about two-thirds of the olefin had reacted at the end of nine hours. The product was mainly 2,2-dibromohexane, but a small amount of 1,2-dibromohexane was also formed.

Experimental

Butylacetylene.—The butylacetylene, b. p. 70.5–70.7°, corr., (747 mm.), was prepared from sodium acetylide and butyl bromide in liquid ammonia by a modification of the method described by Lebeau and Picon.[9]

Detection of Peroxides.—In all cases where peroxides were used, they were formed by the unsaturated compounds themselves. The peroxides were estimated colorimetrically, using as the reagent an acidified solution of ferrous ammonium sulfate and ammonium thiocyanate in absolute methyl alcohol. Details of this method are to be published elsewhere.

Addition to Butylacetylene in the Presence of Peroxides.—Two typical experiments will be reported. The reactions were carried out in all experiments in a 500-cc. three-necked flask equipped with an efficient mechanical stirrer, an inlet tube and a reflux condenser. In all cases the products of the reactions were washed with aqueous sodium carbonate and then with water. The products were dried with anhydrous sodium sulfate or with calcium chloride.

In one experiment 1.5 moles of dry hydrogen bromide was passed rapidly into 82 g. (1 mole) of butylacetylene containing a fairly good quantity of peroxides (about 0.8 mole %). The reaction flask was cooled with an ice-bath. At the end of one hour the reaction was stopped. Upon distillation of the reaction mixture through an efficient column there were obtained 5 g. of unreacted butylacetylene, 120 g. of 1-bromo-1-hexene and 3 g. of 1,2-dibromohexane.

In another experiment 2 moles of hydrogen bromide was passed for three hours into 82 g. of butylacetylene containing a fair amount (about 0.6 mole %) of peroxides. The reaction flask was cooled with an ice-bath. From the reaction mixture there were obtained 85 g. of 1-bromo-1-hexene and 91 g. of 1,2-dibromohexane.

Addition to Butylacetylene in the Absence of Peroxides.—Two moles of hydrogen bromide was added to a solution of 102 g. of peroxide-free butylacetylene in 138 g. of toluene to which had been added 0.5 g. of hydroquinone. The toluene facilitated somewhat the absorption of the hydrogen bromide. The reaction flask was maintained at 17°. At the end of six hours the reaction was stopped, and the product washed and dried in the usual manner. Upon distillation of the product there were obtained 67 g. of unreacted butylacetylene, 8 g. of 2-bromo-1-hexene and 38 g. of 1-bromo-1-hexene.

Using 0.25 g. of hydroquinone and 0.5 g. of ferrous bromide as inhibitors, 4 moles of hydrogen bromide was passed into 156 g. of peroxide-free butylacetylene without any solvent. The temperature was kept at 15°, and the reaction continued for twelve hours. There were obtained on distilling the reaction product 42 g. of butylacetylene, 135 g. of 2-bromo-1-hexene, 6 g. of 1-bromo-1-hexene and 39 g. of 2,2-dibromohexane.

Addition to 1-Bromo-1-hexene.—One-half mole of hydrogen bromide was passed during a period of one and one-half hours into 54 g. ($^1/_3$ mole) of 1-bromo-1-hexene containing a trace of peroxides. The reaction temperature was 10°. On distilling the reaction product there were obtained 11 g. of unreacted 1-bromo-1-hexene and 60 g. of 1,2-dibromohexane.

A solution of 138 g. of peroxide-free 1-bromo-1-hexene, 78 g. of benzene, 0.5 g. of hydroquinone and 1 g. of ferrous bromide was kept saturated with hydrogen bromide for one hundred twenty hours at room temperature. Three moles of hydrogen bromide was used. After removing the benzene from the reaction product, there were obtained 120 g. of unreacted 1-bromo-1-hexene and 5 g. of 1,2-dibromohexane. The distillation curve gave no indication of 1,1-dibromohexane.

Addition to 2-Bromo-1-hexene.—In the presence of a small quantity of peroxide 0.4 mole of hydrogen bromide was passed into a solution of 32.6 g. (0.2 mole) of 2-bromo-1-hexene in 39 g. of benzene. The solution was kept at 25°. The reaction was continued for four hours. The

---

[9] Lebeau and Picon, *Compt. rend.*, **156**, 1077 (1913); Picon, *ibid.*, **158**, 1346 (1914); *ibid.*, **169**, 32 (1919).

reaction product consisted of 3.5 g. of 2-bromo-1-hexene and 41 g. of 1,2-dibromohexane.

One-half mole of hydrogen bromide was passed for nine hours into a solution of 32.6 g. of peroxide-free 2-bromo-1-hexene in 39 g. of benzene; 0.2 g. each of hydroquinone and ferrous bromide were used to inhibit peroxide formation. The temperature of the reaction was 23°. The reaction product contained 10 g. of unreacted 2-bromo-1-hexene, 24 g. of 2,2-dibromohexane and 4 g. of 1,2-dibromohexane.

Identification of Products.—The properties of 2-bromo-1-hexene, b. p. 132.5–133.5° (740 mm.), n^{19}_{D} 1.4555, d_{20} 1.1960, agree closely with those reported by Bourguel:[10] b. p. 134° (760 mm.), n^{19}_{D} 1.455, d_{19} 1.203.

The 1-bromo-1-hexene had the properties: b. p. 139–141° (751 mm.), n^{20}_{D} 1.4596, d_{21} 1.1998. Bachman[11] reported for this compound: b. p. 138–140° (747 mm.), n^{20}_{D} 1.4584, d^{20}_{20} 1.1910. The slight discrepancy in these physical constants may be caused by a difference in the ratio of *cis-trans* isomers obtained in the two cases. The 1-bromo-1-hexene was analyzed for bromine by the method of Chablay, as modified by Vaughn and Nieuwland:[12] calcd. for $C_6H_{11}Br$, 49.0; found, Br, 49.1.

The properties of the 1,2-dibromohexane, b. p. 89–90° (18 mm.), n^{20}_{D} 1.5023, d_{21} 1.5767, agree well with those reported by Schmitt and Boord:[13] b. p. 89–90° (18 mm.), n^{20}_{D} 1.5024, d_{20} 1.5774.

The 2,2-dibromohexane has not been reported previously. The following physical constants were obtained: b. p. 83.5–84.0° (24 mm.), n^{22}_{D} 1.4930, calcd. MR_D 45.45, found MR_D 45.57, d_{22} 1.5463. *Anal.*:[12] calcd. for $C_6H_{12}Br_2$: Br, 65.5; found: Br, 65.4. The identity of the 2,2-dibromohexane was established by hydrolyzing it to 2-hexanone. This was accomplished by refluxing with silver sulfate in 10% sulfuric acid. The 2-hexanone boiled at 126.1° (747 mm.), reported b. p. 126.0–126.5° (760 mm.),[14] and the semicarbazone melted at 118°, reported m. p. 118°.[15]

Summary

1. The addition of hydrogen bromide to butylacetylene in the presence of peroxides derived from butylacetylene yielded 1-bromo-1-hexene and 1,2-dibromohexane.

2. In the absence of peroxides hydrogen bromide yielded mainly 2-bromo-1-hexene and 2,2-dibromohexane.

3. The addition of hydrogen bromide was much more rapid in the presence of peroxides than in their absence.

4. The addition of hydrogen bromide to 1-bromo-1-hexene in the presence of peroxides formed only 1,2-dibromohexane, while in the absence of peroxides scarcely any reaction occurred under the conditions used. No 1,1-dibromohexane was formed in either case.

5. In the presence of peroxides 2-bromo-1-hexene yielded with hydrogen bromide only 1,2-dibromohexane; under peroxide-free conditions the chief product was 2,2-dibromohexane, the other product being 1,2-dibromohexane.

Extensions of the Leuckart Synthesis of Amines

By A. W. Ingersoll, J. H. Brown, C. K. Kim, W. D. Beauchamp and Garland Jennings

The conversion of certain ketones (and aldehydes) to the corresponding amines by heating with excess ammonium formate was described by Leuckart[1] as early as 1885. The mechanism of the reaction has been discussed by Wallach,[2c] but is not definitely known. The equation

$$\begin{aligned} &R—CO—R' + 2HCO_2NH_4 \longrightarrow \\ &\qquad R—CH(NHCHO)R' + 2H_2O + NH_3 + CO_2 \end{aligned}$$

appears to summarize the primary reaction, although formamide is doubtless an intermediate and may be used instead of ammonium formate. The amine is formed by subsequent hydrolysis of the formyl derivative.

Although Leuckart's method has been applied by Wallach[2] to a number of alicyclic and terpenoid ketones, and appears to be rather general, it has found little use by others. Possibly the obvious advantages of economy and simplicity have appeared to be outweighed by the unsatisfactory procedures that have so far been suggested. Leuckart himself, and also Wallach, ordinarily heated the reagents in a sealed tube at 210–240°. In some instances, however, Wallach[2b,2c] and others[3] have shown that the primary reaction

occurs, though rather slowly, upon refluxing the reagents at atmospheric pressure. In a recent example Read and Johnston[3c] have reported only a 20–25% conversion of carvomenthone to carvomenthylamines after forty-eight hours of refluxing at 130°. Thus neither the sealed tube process nor the refluxing process is attractive and the method is also known to yield the corresponding secondary and tertiary amines as by-products.

Since other work in this Laboratory required large quantities of a variety of asymmetric amines, which are conveniently derived from ketones, it was sought to improve Leuckart's method with a view to adapt it to large scale laboratory use and, if possible, to extend its scope. As the result of several years of experience a simple procedure has been worked out which, when applied to some twenty ketones of various types, has given the corresponding primary amines in yields usually ranging from 60 to 85% of the theoretical and in amounts as large as several hundred grams per run. It has been found that the proportion of secondary and tertiary amine produced is so small as to cause no difficulties. In most cases a uniform procedure can be followed, with slight modifications for special cases. A number of amines have been prepared by this method for which no other method of synthesis appears feasible.

In preliminary experiments with the refluxing procedure it soon appeared that formamide rather than ammonium formate must be made the effective reagent. Thus when the process was tried with acetophenone and initially solid ammonium formate, as suggested by Freylon,[3a] it was found that the mixture boiled freely at 150–160° but remained in two layers; no appreciable reaction occurred in ten hours. On the other hand, when water was allowed to distil during the process or when formamide was used initially, the mixture soon became homogeneous and the reaction occurred in a few hours at 150 to 190°. The improved procedure involves, therefore, essentially a slow distillation, with occasional return of any ketone that may distil; both processes may be combined by the use of an automatic separator. The general procedure is described in the Experimental part.

Scope of the Method.—The improved method has been studied thus far principally in instances in which the main concern was the suitability of the amine for other work. In its usual form the method appears best adapted to the conversion of stable, water-insoluble ketones boiling at about 120° or higher. These include the higher aliphatic ketones, acetophenone and its numerous analogs, and certain terpenoid ketones. For such ketones the yields are consistently good and the method is definitely superior in economy and convenience to the familiar methods involving the formation and reduction of ketoximes.

Of even greater interest is the fact that the method can be used successfully in instances in which the reduction of an oxime is inadmissible. Thus it was found that when *p*-chloroacetophenoneoxime was reduced in the usual way with sodium and alcohol or with sodium amalgam and acetic acid, about half of the resulting mixture of amines was α-phenylethylamine, formed by the removal of nuclear halogen. On the other hand, the improved Leuckart method gave a high yield of pure α-*p*-chlorophenylethylamine. In the same way *p*-bromoacetophenone and even *m*-nitroacetophenone were readily converted to the corresponding amines.

When applied to benzalacetone or to carvone the method yielded chiefly a neutral resin and only small amounts of the corresponding amines. From present experience the method is believed to be unsuitable for application to α,β-unsaturated ketones, but otherwise appears widely applicable.

Most of the amines that were prepared have not been described previously. For these the principal constants, derivatives and analyses are given in the accompanying table. It is hoped to describe the new amines more fully in later papers. There are also included in the table yield data on these amines and on a few other representative amines. In most cases the stated yields are the average of two or more runs and make no allowance for recovered ketone.

Experimental

General Procedure.—A satisfactory ammonium formate–formamide reagent, sufficient for one mole of ketone, is made most economically as follows. In a 1-liter round-bottomed flask is placed 215 g. (4 mole-equivalents of ammonia) of commercial ammonium carbonate–carbamate. The flask is fitted with a cork bearing a thermometer that extends nearly to the bottom, a small separatory funnel, and a wide bent tube attached for distillation to a short, wide condenser. There is then added cautiously 215–230 g. (4.1 moles) of commercial 85–90% formic acid. When the reaction moderates the mixture is heated cautiously and then slowly distilled until the temperature is about 165°. The same amount of reagent can

be obtained by distilling 250 g. of commercial solid ammonium formate instead of the reagents mentioned, but this offers no advantage.

To the reagent described above the ketone is added and the heating continued with a small flame. The reaction occurs fairly rapidly in the range 160–185° and may be accompanied by mild foaming. Water, ammonia, carbon dioxide and more or less ketone distil. The distillate is conveniently collected in a separatory funnel. The mixture gradually becomes homogeneous as the proportion of formamide increases. The distilled ketone, if any, is separated from time to time and returned to the reaction mixture. Alternatively, when rather volatile ketones are used, the reaction may be run in a flask fitted with a simple automatic separator so arranged as to return the (upper) ketone layer and discharge the aqueous layer.

When distillation of water practically ceases and the temperature reaches 175–185°, the temperature is maintained in this range for three to ten hours longer. In most cases three to four hours is sufficient; a longer time was found necessary only for "hindered" ketones such as camphor and fenchone. The end of the reaction is fairly clearly marked when the deposition of ammonium carbonate in the condenser nearly ceases. The rate of reaction increases somewhat with temperature, but above about 185° a faint odor of cyanide becomes apparent and the mixture tends to change from straw-color to dark brown The heating may be interrupted and resumed at any time.

When the reaction is complete the mixture is cooled and stirred thoroughly with twice its volume of water. The aqueous layer is separated and may be used for the recovery of formamide by distilling to 165°. Recovered formamide should be used only with the same ketone. The formyl derivative of the amine, mixed with unused ketone, may or may not solidify. It can be purified by vacuum distillation or crystallization, but this is not necessary. The crude, water-insoluble material is refluxed with about 100 cc. of concentrated hydrochloric acid for each mole of ketone used. Water may be added, if necessary, to keep the amine hydrochloride in solution. Hydrolysis is usually complete in thirty to fifty minutes, as shown by the solution of all but a small amount of inert material, consisting of unchanged ketone and condensation products. This is extracted with small portions of benzene and discarded or saved for recovery of the ketone. The latter may sometimes be recovered conveniently by steam distillation of the acid mixture. When the ketone is resinified by the action of hot acid, it may best be steam-distilled previously to hydrolysis. The corresponding formyl derivative of the amine is usually much less volatile, but may also distil with steam.

The amine is obtained from the aqueous acid solution by a method appropriate to its physical properties. When sufficiently volatile it is best purified by liberation with alkali and distillation with steam. The small amounts of secondary and tertiary amines present are thereby almost completely left behind. The distilled amine is extracted with benzene, dried, and redistilled as usual. When the amine is not very volatile it may often be obtained directly from the acid solution by fractional crystallization of the hydrochloride or may be purified in other ways.

Notes and Modifications.—The above procedure was not satisfactory with camphor because the sublimate rapidly clogged the apparatus. This difficulty was readily overcome by adding to the camphor about one-half its weight of nitrobenzene. The latter is unaffected by heating with formamide and serves to liquefy the camphor in both the reaction mixture and the distillate. The nitrobenzene and unchanged camphor are removed by steam distillation following the hydrolysis of the amine.

A similar procedure was fairly successful when applied to pinacolone. The nitrobenzene in this case appeared to diminish the distillation of the rather volatile ketone (b. p. 106°) and also served to extract it from the aqueous portion of the distillate. However, the general procedure described above is not regarded as suitable for the more volatile and water-soluble ketones. With such ketones it would appear better to start with substantially pure formamide and carry out the reaction entirely by refluxing. The small amount of water formed in the reaction causes no difficulty. In comparative experiments upon acetophenone and fenchone the yield was 4–6% better with pure formamide (4 moles) than with the usual reagent. With cheap ketones, however, the use of formamide is not justified, because of the extra cost.

In a series of experiments with acetophenone the percentage yields of amine were 53, 62, 72 and 72, respectively, when the molar ratios of reagent to ketone were 3.0, 3.5, 4.0 and 5.0. In experiments with 2:1 and 4:1 ratios of pure formamide the yields were 23 and 78%, respectively.

Runs were made with from 0.1 mole to 4.0 moles of ketone without important variations in yield. There is no apparent reason why the scale may not be as large as desired.

Summary

1. The Leuckart synthesis of amines from ketones has been improved and adapted to large scale use. A general procedure is described.

2. Eight new amines have been prepared and described.

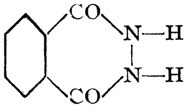
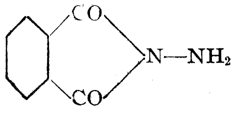
The Methyl and Phenyl Derivatives of the Nitrophthalhydrazides

BY C. N. ZELLNER AND GREGG DOUGHERTY

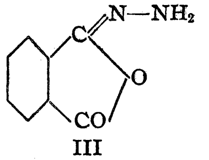
The brilliant chemiluminescence of some of the phthalhydrazide derivatives has created an interest in the chemistry and structure of these compounds. Of the three structures which have been proposed for phthalhydrazide



I



II



III

I and II have received the most serious consideration. The work of Radulescu and Georgescu,[1] Moyer,[2] and Rowe and Peters[3] on the various methylated and acetylated phthalhydrazides has indicated that structure I or a tautomeric modification of it is preferable to structure II. These workers confined their efforts to phthalhydrazide which was not substituted in the benzene ring.

It is obvious that, if the hydrazide structure I is correct, the presence of a substituent in the aromatic nucleus would make possible the existence of various isomeric non-nuclear alkyl or aryl derivatives not capable of existence on the basis of the aminophthalimide formula II. Also the study of a nuclear substituted hydrazide should give some indication of the normal tautomeric condition of the molecule. In order to test these points the present work with the nitrophthalhydrazides was undertaken.

The reaction of 3-nitrophthalic anhydride with methylhydrazine acetate gave two isomeric monoethyl derivatives which were produced in almost equal proportions, one melting at 305°, and the other at 273°. Both were readily acetylated, the two monomethyl monoacetyl derivatives melting at 211 and 144°, respectively. (All melting points have been corrected.) The existence of two *n*-methyl compounds is easily accounted for on the basis of the hydrazide structure

---

[1] Radulescu and Georgescu, *Bull. soc. chim.*, **37**, 881 (1925).

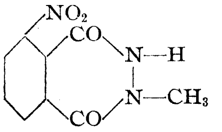
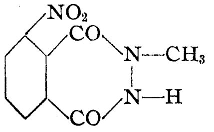
[3] Rowe and Peters, *J. Chem. Soc.*, 1331 (1933).

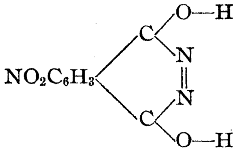


and

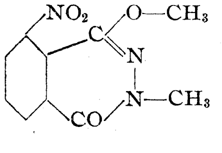


It is not yet possible to say which of the structures should be assigned to which isomer. On the basis of Mihailescu's aminophthalimide structure II,[4] this type of isomerism would not be possible.

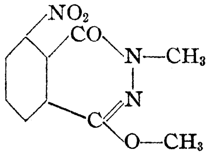
The same two *n*-methyl-3-nitrophthalhydrazides were obtained by treating 3-nitrophthalhydrazide with dimethyl sulfate in alkaline solution. This is an indication that the double enolic form, *i. e.*,



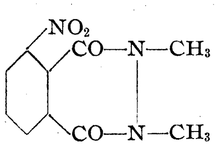
does not occur to any extent at least in alkaline solution, otherwise an *o*-methyl derivative would have been obtained. With excess dimethyl sulfate two dimethylnitrophthalhydrazides were obtained, melting at 207 and 138–139°, respectively. The derivative of m. p. 207° was also prepared by reaction of the higher melting *n*-methyl-3-nitrophthalhydrazide with dimethyl sulfate in alkaline solution, whereas the lower melting dimethyl derivative was obtained from the lower melting mono-methyl compound. Again, the existence of the isomeric dimethyl derivatives is evidence against Mihailescu's formula. The fact that the two were obtained by the methods outlined indicates strongly that they are *n*-methyl *o*-methyl derivatives



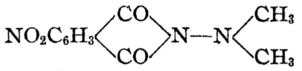
and



This was further substantiated by the preparation of a third dimethyl derivative from 3-nitrophthalic anhydride and symmetrical dimethyl hydrazine. In this case there is little doubt but that both methyl groups are attached to nitrogen:

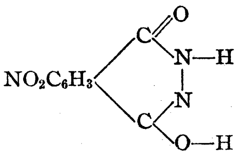


A fourth dimethyl derivative was obtained from the anhydride and unsymmetrical dimethyl hydrazine to which the aminophthalimide structure,

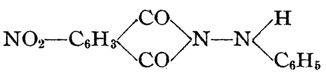


must be assigned. The remaining structurally possible dimethyl derivative in which both methyl groups are attached to oxygen is apparently not formed by any of the ordinary methods of methylation.

Since in the alkylation of 3-nitrophthalhydrazide in alkaline solution, the first methyl group goes to the nitrogen and the second to oxygen, it appears that the lactam–lactim form of the compound, is present and most reactive under the conditions. This conclusion, also arrived at by Rowe and Peters,[3] is important when considering the mechanism of the oxy-luminescence of phthalhydrazide derivatives, always carried out in alkaline solution.



Using 4-nitrophthalic anhydride and the hydrazide, a set of monomethyl and dimethyl derivatives was prepared similar to those obtained from the 3-nitro compounds. These are described in the experimental part. The reaction between phenylhydrazine and the 3 and 4-nitrophthalic anhydrides was studied. In this case only one of the two possible *n*-phenylhydrazides was formed in sufficient quantity to permit isolation and purification. A second compound was formed of the anilinophthalimide type, so that methylhydrazine and phenylhydrazine do not behave in quite the same way in this reaction. The anilinophthalimide type is insoluble in alkalies which differentiates it sharply from the *n*-phenyl derivatives of the nitrophthalhydrazides.



Experimental

α-3-Nitro-N-methyl Phthalhydrazide.—9.6 g. (0.05 mole) of 3-nitrophthalic anhydride was dissolved in 50 cc. of acetic acid. To the hot solution, a 20-cc. aqueous solution of 7.2 g. (0.05 mole) of mono-methylhydrazine sulfate and 6.8 g. of sodium acetate crystals, was added. The reaction mixture was heated to boiling, using an air condenser, until all the acetic acid was driven off. The residue was washed in portions of warm water and the two isomers were fractionally recrystallized from alcohol, until constant melting points were obtained. The more insoluble isomer melted at 305° (cor.).

4-Nitro-N-dimethylamino Phthalimide.—M. p. 202° (cor.). A mixed melting point determination with the preceding compound showed a large depression.

4-Nitro-anilino Phthalimide.—Prepared by refluxing 4-nitrophthalic anhydride and phenylhydrazine in HOAc for two and a half hours. On cooling, the crystals were filtered and treated with sodium carbonate solution. The insoluble product, recrystallized from alcohol several times, melted at 182° (cor.).

Anal. Calcd. for $C_{14}H_9O_4N_3$: C, 59.31; H, 3.21. Found: C, 59.54; H, 3.26.

4-Nitro-N-phenyl Phthalhydrazide.—Was obtained on acidifying the above sodium carbonate solution. After three recrystallizations from alcohol, it melted at 253° (cor.).

Anal. Calcd. for $C_{14}H_9O_4N_3$: C, 59.31; H, 3.21. Found: C, 59.24; H, 3.33; C, 59.38; H, 3.33.

Its acetyl derivative melted at 186° (cor.).

Anal. Calcd. for $C_{16}H_{11}O_5N_3$: C, 59.08; H, 3.38. Found: C, 58.81; H, 3.31.

3-Nitroanilino Phthalimide.—From 3-nitrophthalic anhydride and phenylhydrazine, after washing in dilute sodium hydroxide solution, and recrystallization from alcohol: m. p. 198–199° (cor.).

Anal. Calcd. for $C_{14}H_9O_4N_3$: C, 59.31; H, 3.21. Found: C, 59.39; H, 3.18.

Summary

Evidence has been obtained in favor of the hydrazide structure as opposed to the amino–imide structure for substituted phthalhydrazides. It has been shown that in the methylation of the nitrophthalhydrazides in alkaline solution, the compounds behave as if they possessed the lactam–lactim structure.

The preparation of various methylated and phenylated nitrophthalhydrazides has been described and some of their properties noted.

PRINCETON, N. J. RECEIVED JULY 15, 1936

NOTES

New Types of Racemization Reactions

By Ernst Bergmann and Alfred Bondi

To the number of racemization reactions which obviously are of fundamental importance for our knowledge of the stability of spacial configurations, three new types have recently been added: (a) the racemization of methylalkyliodomethanes by interaction with iodide ions,[1] (b) the racemization of 2-bromohexane during its conversion into the Grignard compound,[2] and (c) the racemization occurring during the interaction between active ethyl propylmethylacetate and phenylmagnesium bromide.[3] Only the first of these three types has so far a theoretical and experimental treatment.

For case (b) one would perhaps be inclined to assume that racemization is due to electrolytic dissociation of the Grignard compound. But this assumption seems inadmissible, since negative carbonium ions seem to be sufficiently stable,[4] while positive ions of carbon are unstable.[5] Therefore one has probably to conclude that the racemization belongs to type (a): the bromide is racemized by bromide ions, which are formed by the ordinary equilibrium reaction $2RMgBr \rightleftharpoons R_2Mg + MgBr_2$. The case, therefore, is analogous to the racemization of phenylmethylchloromethane by interaction with magnesium or sodium metal.[1,6]

For case (c) the following suggestion has been advanced by Bergmann and Hartrott.[3] The ester does not undergo racemization—it is unstable only in alkaline solution[7]—but the carbinol is subjected to an equilibrium $(Me)(Pr\text{-}\alpha)CH\text{-}C(OH)Ph_2 \rightleftharpoons H_2O + (Me)(Pr\text{-}\alpha)C{=}CPh_2$, whereby the asymmetry is destroyed. It is well known that diphenylalkylcarbinols are easily dehydrated. If this explanation is correct, ethyl propylmethylacetate should give optically active carbinols with simple aliphatic alkylmagnesium halides, since compounds like (2-pentyl)-diethylcarbinol, $(Me)(Pr\text{-}\alpha)CHC(OH)Et_2$, do not lose water so easily. The conclusion has been confirmed by experiment. Into a solution of ethylmagnesium bromide (from 2.5 g. of magnesium and 11 g. of ethyl bromide), active methyl propylmethylacetate (4 g., rotation in acetone, $l = 1$, $c = 2.70$, α_D $-0.19°$; hence $[\alpha]_D$ $-7.04°$) was introduced. The rather violent reaction was completed by boiling for thirty minutes, then the mixture was decomposed with ice and ammonium chloride and the ethereal layer dried with anhydrous sodium sulfate and evaporated. The (2-pentyl)-diethylcarbinol boiled at 92–93° (32 mm.); yield 2.9 g. Calcd. for $C_{10}H_{22}O$: C, 75.9; H, 14.0. Found: C, 75.8, 75.4; H, 14.4, 14.1. Rotation in acetone: $l = 1$, $c = 2.80$, α^{22}_D $-0.365°$; hence $[\alpha]^{22}_D$ $-13.04°$.

The Preparation of Pure Apocodeine and its Hydrochloride

By Karl Folkers

Early preparations of apocodeine were complex mixtures.[1] Knorr obtained "pseudoapocodeine"[2] by melting codeine with oxalic acid, and later he showed[3] that his apocodeine was identical with the monomethylation product of apomorphine; although this latter product had been reported earlier by Pschorr,[4] but with widely different physical properties. Later methods[5] of making apocodeine from codeine with zinc and sodium chlorides still introduced apomorphine impurities, which necessitated the use of a troublesome perchlorate, chromate or phosphate salt for purification.

Nevertheless, a certain confusion exists in the

(2) Knorr and Roth, *Ber.*, **40**, 3355 (1907). The name pseudoapocodeine was introduced by Knorr as he believed pseudocodeine to be an intermediate in the transformation of the morphine nucleus to the aporphine nucleus. Apocodeine is the generally accepted name, and it suggests the same relationship to codeine that apomorphine has to morphine.

literature[6] concerning the chemical properties of pure apocodeine.

The herein described method is an improvement of the Knorr reaction, and a confirmation of Knorr's properties of apocodeine with ethanol of crystallization. The pure anhydrous base and hydrochloride have not been described previously.

Apocodeine.—Twenty grams of anhydrous codeine and 60 g. of anhydrous oxalic acid,[7] were heated for one and one-half hours at 150–155° bath temperature with very slow stirring. The melt was cooled and diluted with 250 ml. of water. After complete solution, it was further diluted to 600 ml. in a separatory funnel, shaken with 300 ml. of ether, and the bases precipitated with addition of concentrated ammonia solution. Too slow operation caused troublesome crystallization of ammonium oxalate. The ether layer was separated, filtered and distilled *in vacuo*. A residue of 5.8 g. remained, which was dissolved in 15 ml. of absolute ethanol. Nearly pure apocodeine with a molecule of ethanol crystallized on standing at 10°; yield 2.7–2.8 g. (12.8%). One crystallization gave pure white products of m. p. 104.5–106.5° with gas evolution $[\alpha]^{23}\text{D}$ −90.0, *C*, 0.533, abs. ethanol, $l = 1$. Further crystallization did not change the melting point or optical rotation.

Anal. Calcd. for $C_{18}H_{19}O_2N{\cdot}C_2H_5OH$: C, 73.35; H, 7.70; C_2H_5OH, 14.06. Found: C, 72.99, 73.01; H, 7.57, 7.76; C_2H_5OH, 13.76.

The base was best purified by recrystallization from absolute ethanol. The use of the hydriodide as Knorr suggested resulted in partial oxidation. The crystals showed no ready tendency to oxidize, unless they were finely pulverized. The ethanol was lost very slowly at 25° (2 mm.), but readily at 78° (2 mm.). The anhydrous base showed m. p. 122.5–124.5°.

Anal. Calcd. for $C_{18}H_{19}O_2N$: C, 76.82; H, 6.81. Found: C, 76.63, 76.80; H, 7.02, 7.06.

As Knorr described, there were ether and water insoluble bases present. It was found, however, that nearly all the apocodeine was extracted by the ether. In one experiment very little more was obtained by redissolving the insoluble bases with acid, reprecipitating, extracting etc. A third repetition of this process yielded no more apocodeine. Thus it was not necessary to bring all the precipitated bases into ether solution as Knorr described. In fact, the moderate insolubility of pseudocodeine[8] and the amorphous products in ether make the first extraction one of considerable purification.

Apocodeine Hydrochloride.—To a solution of the base in absolute ethanol was added the calculated amount of dry hydrogen chloride in absolute ethanol and, while hot, absolute ether was added until crystallization started. The yield of pure white salt was quantitative; m. p. softening started at 140°, dec. at 260–263°; $[\alpha]^{22}\text{D}$ −41.3 to 43.3°; *c*, 0.508; H_2O, $l = 1$. Recrystallization from 95% ethanol and ether did not alter the physical constants. The salt was practically anhydrous.

Anal. Calcd. for $C_{18}H_{19}O_2N{\cdot}HCl$: C, 68.00; H, 6.35. Found: C, 68.26, 67.92; H, 6.35, 6.22.

The Thermal Decomposition of Acetone

BY JOHN R. HUFFMAN[1]

The present experiments were undertaken to discover whether the unimolecular rate constant for the thermal decomposition of acetone fell off at low pressures and in such a case to apply the theories of Rice and Ramsperger and of Kassel.[2] Recently Winkler and Hinshelwood[3] working at 875°K. and pressures down to 2.5 mm. reported that this decrease of rate constant started at 100 mm.

Acetone was decomposed in a 200-cc. silica bulb in a furnace automatically controlled to

[3] Winkler and Hinshelwood, *Proc. Roy. Soc.* (London), **A149**, 340 (1935).

±0.2°. Pressures were read either on a mercury or a bromonaphthalene–mercury manometer. Experimental errors were smoothed out by a process of graphical differentiation and re-integration.[4] To correct for dead space (1.7%) the rate constants were calculated by the method suggested by Allen.[5] These constants fell off during a run due to the second step in the decomposition and consequently were extrapolated to zero time. The results, corrected slightly to 826°K., are presented in Table I.

A second series of runs was made to determine the temperature effect of the high pressure reaction. This is expressed by the equation

$$\ln k_\infty = 34.52 - 68120/RT$$

and is shown in Table II.

TABLE II

T, °K.	817	826	836	845.5	854
$k_\infty \times 10^4$	5.85	9.3	15.41	24.18	34.88

A plot of *k versus* P_0 (k_∞ = 0.001125 at 826°K.) establishes 100 mm. as the pressure where the reaction commences to fall off, checking the results of previous workers. A plot of $1/k$ versus $1/P_0$ indicates a break at 40 mm. pressure suggesting a second mode of activation.

Application of Hinshelwood's simple theory gives 22 active degrees of freedom. Using O. K. Rice's classical theory, 8 degrees of freedom and a molecular diameter of 28.3×10^{-8} cm. appear to be the best values to use. Kassel's quantum theory gives curves that fit the experimental results the best. The most reasonable values in this case appear to be 8 degrees of freedom, 22 quanta, and a diameter of 45×10^{-8} cm. This gives a frequency in the infra-red and a vibrational specific heat contribution of 12 cal./g. The results of Winkler and Hinshelwood at 875°K. are satisfied by 8 degrees of freedom, 22 quanta and 35×10^{-8} cm. Table III gives a comparison of the experimental and calculated results.

5	.426	.439	.344	.320

[a] From the work of Winkler and Hinshelwood.

It was impossible to obtain a fit of theory to experiment throughout the whole pressure range. The calculated results fit within the experimental error from about 50 mm. pressure down. The rate constant falls off with decreasing pressure rather abruptly in comparison with other unimolecular reactions in such a manner as to indicate a free radical chain mechanism as proposed by F. O. Rice and Herzfeld.[6] This is further substantiated by the recent publication of A. O. Allen.[7]

Semiquinones of Neutral Red and Safranines

BY LEONOR MICHAELIS

Many derivatives of phenazine have been shown to form semiquinones on partial reduction, all of green color in compounds containing only benzene and no naphthalene rings. The separation of the two steps of reduction is more distinct as the acidity of the solvent increases. The degree of acidity at which a distinct separation of the steps becomes easily recognizable varies from dye to dye. So far, no semiquinone has been observed in a number of those phenazine or phenazonium compounds containing amino groups as side chains. However, even in these compounds a semiquinone will be demonstrated by the following experiment, in which the conditions of reduction are slightly changed. One simply has to work in extremely acid solution. The experiment can be performed with neutral red, phenosafranine or the commercial "safranine."

Dissolve a small amount of the dye in concentrated hydrochloric acid. The color will be, according to the dye, blue to green. Dilute with water just enough to make it blue, with a shade of violet. Add some particles of solid chromous chloride and stir. The color will change first to an intense green, then to the almost colorless condition of the leuco dye. On reoxidizing, say by adding a crystal of potassium persulfate, the twofold change of color will be reversed. Zinc dust may also be used as reductant.

Since the color of the oxidized form of the dye in utmost acid solution (especially in concentrated sulfuric acid) itself is green, the acidity has to be lowered just to such an extent as to make it blue-violet before adding the reductant. Otherwise there is no visible change on reducing the dye to the semiquinone state.

Polymolecular Films

BY WILLIAM D. HARKINS AND ROBERT J. MYERS

Surface films which spread over water are supposed to be monomolecular. However, Harkins and Morgan[1] were able to produce solid, partly crystalline films with a mean thickness much greater than this. Thus to a spreading substance whose organic molecules contain a polar group (stearic acid, etc.) they added a thickening or non-polar substance (phenanthrene). In the present work polymolecular liquid films were produced by thickening the films with a liquid paraffin oil (nujol) of low volatility.

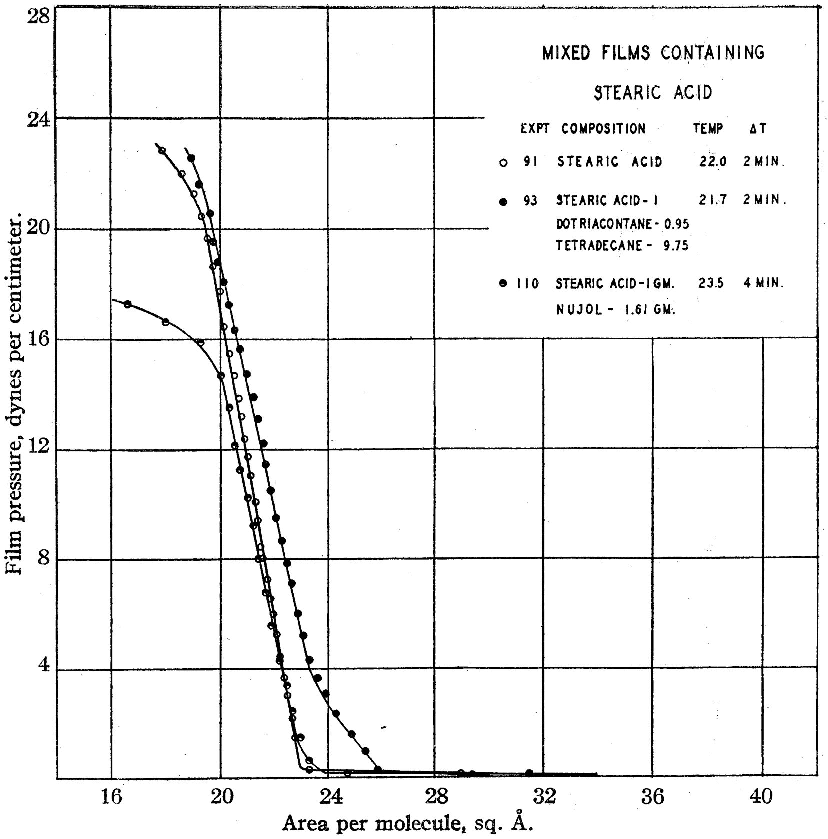

Fig. 1.—Poly- and mono-molecular films with stearic acid.

1. Condensed Films.—Films of pure stearic acid form condensed films on 0.01 N hydrochloric acid at room temperature except at pressures below about 0.2 dyne per cm. The addition of 1.61 g. of nujol to 1 g. of stearic acid in the film forming substances does not seem to increase the area of the condensed film (Fig. 1, expts. 91 and 110), but only weakens it at high pressures.

The areas given in the figures of this paper represent the area per molecule of the more polar constituent (stearic acid, etc.).

2. Expanded Films of Oleic Acid.—The effects are, however, markedly different in cases in which the acid when alone forms an "expanded" film, as in the case of oleic acid (Fig. 2). Here the mixed film contains 1.66 parts by weight of the paraffin oil to 1 part of oleic acid. The effect of the paraffin oil is very great, since it raises the surface pressure greatly at large areas, and decreases it very markedly at low areas. At 36.4 sq. Å. per molecule of oleic acid the pressures are the same for the pure acid and the mixture.

3. Expanded Films of Myristic Acid.—At 22.8° films of pure myristic acid exhibit a kink in the curve at an area of 25.45 sq. Å. and a pressure of 17.25 dynes per cm. The addition of 1.67 parts

---

[1] Harkins and Morgan, *Proc. Nat. Acad. Sci.*, **11**, 631 (1925).

by weight of nujol to 1 part of myristic acid removes the kink and increases the film pressure at any given area. The increase is particularly great at the lower pressures (larger areas). With a greater proportion of nujol (9.08 parts) the phenomenon encountered with oleic acid is found, that is, the paraffin oil increases the pressure at large molecular areas and decreases it at the lower areas. The decrease in surface pressure at the lower areas becomes much more marked as the amount of paraffin oil is increased (expt. 104, Fig. 3).

4. Films of Pentadecylic Acid (Fig. 4).—The addition of 1.5 g. of the paraffin oil to 1 g. of pentadecylic acid increases the film pressure very greatly, both above and below the kink in the curve. However, at about 20 sq. Å. per molecule the two sets of curves cross. The curve for experiment 97 indicates that the tetradecane has evaporated.

5. Surface Potentials of Polymolecular Films.—Figure 5 exhibits interesting relations and shows that there is a kink in the potential area curves of both the pure acid and the mixture.

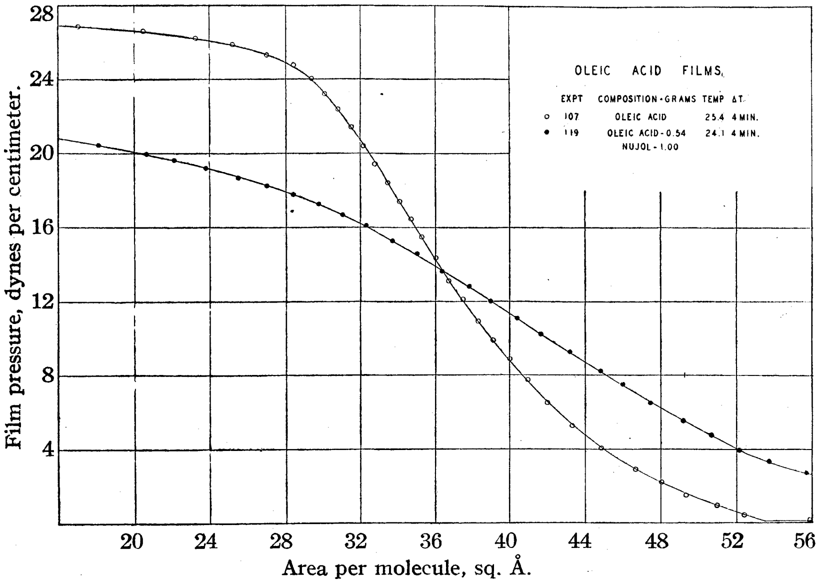

Fig. 2.—Poly- and mono-molecular films with oleic acid.

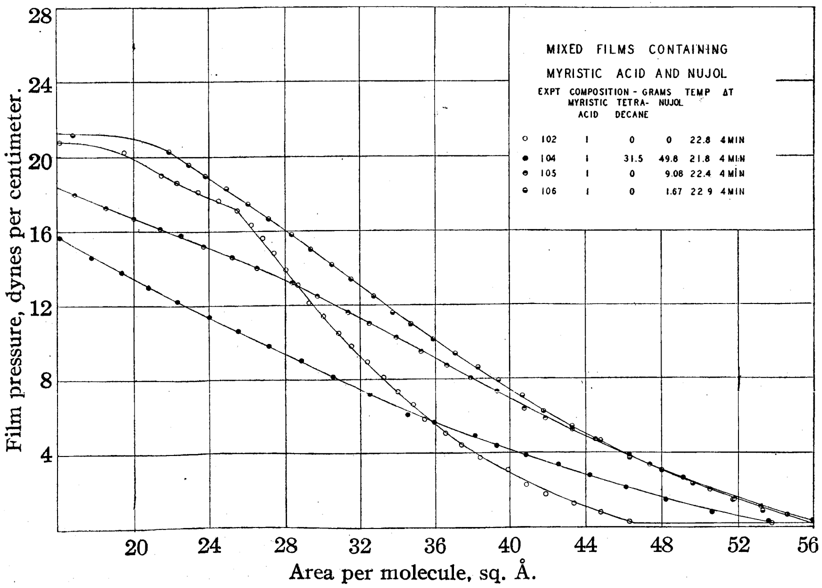

Fig. 3.—Poly- and mono-molecular films with myristic acid.

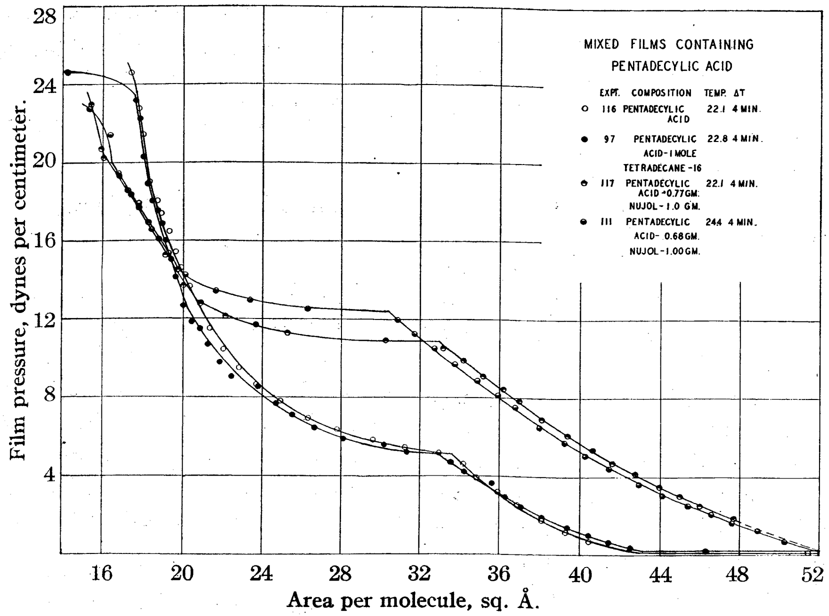

Fig. 4.—Poly- and mono-molecular films with pentadecylic acid.

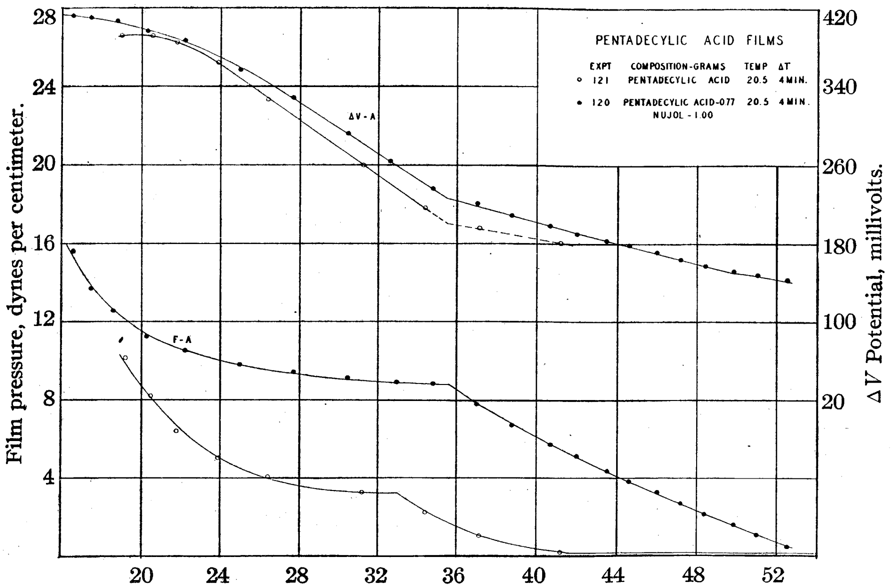

Fig. 5.—Surface potentials and areas of poly- and mono-molecular films of pentadecylic acid.

Polymolecular films exhibit many interesting relations, and many of these are under investigation in this Laboratory. At constant pressure many polymolecular, as well as monomolecular, films shrink with time. This shrinkage is very marked with pentadecylic acid at areas just below and pressures just above that of the kink in the curve.

Micro Determination of Active Hydrogen with Deuterium Oxide

By Roger J. Williams

The usual methods of determining active hydrogen involving the use of a Grignard reagent, cannot be applied to highly water soluble materials which do not dissolve in ethers or other organic solvents.

We early suggested[1] the determination of active hydrogen by dissolving the unknown in deuterium oxide followed by a determination of the changed density of the water distilled off. Others[2,3] have independently made use of the principle.

An experimentally simple embodiment of the same principle has now occurred to us which consists merely in dissolving the substance to be analyzed in deuterium oxide, evaporating to dryness and determining the increase in weight due to the replacement of active hydrogen by deuterium. This method has been applied to two known substances and the results are given in the following table. Other experimental work along similar lines which need not be detailed here has convinced us of the applicability of the method. The substances in small weighing bottles were simply dissolved in 0.25 ml. of 99.5% deuterium oxide and then carefully evaporated and dried to constant weight in vacuum desiccators, and weighed again.

Substance analyzed	Hydroxyproline			Urea		
Sample, mg.	8.386			5.749		
After treatment, mg.	8.592			6.121		
Incr. after subtr. 5 γ blank	0.201			0.367		
Calcd. increases	2H	3H	4H	3H	4H	5H
	0.128	0.192	0.256	0.297	0.383	0.479

The theoretical increases were calculated on the basis of complete replacement by deuterium. This assumption would introduce practically no error in the first determination and a very slight error in the second. A small increase in weight, about 5 γ, is noted when a glass weighing bottle itself is treated with heavy water.

The method need not be limited to water soluble substances since interchange should occur in ether or pyridine solution. In case of compounds which do not dry readily, appropriate means will have to be taken to bring the material to the same degree of dryness before and after treatment with deuterium oxide. Since the principle is so simple and the manipulation involves nothing beyond drying and weighing, it appears that no serious difficulty should be involved in applying the method. We hope other investigators to whom this type of work is less incidental, will perfect and extend the method which has been experimented with in our laboratory only in a preliminary way.

Some Bismuth Derivatives of Diphenyl

BY DAVID E. WORRALL

Since the number of known organic compounds of bismuth is meager, previous work on diphenyl derivatives of the arsenic group has been extended to include this element.[1] Arylation was accomplished through the organo magnesium compound, for the Wurtz–Fittig method employing sodium, used so successfully with other members of the group, failed with bismuth.

Experimental

Tri-biphenylbismuth.—One hundred grams of *p*-bromodiphenyl was changed into the magnesium compound according to the directions of Bent.[2] After dilution with several volumes of ether, 36 g. of powdered bismuth chloride was added directly (in small lots) with shaking and the mixture allowed to stand overnight. The ether was removed by decantation, after which the residue was decomposed as usual. A small amount of dilute acid was added to remove basic salts. The black precipitate was then filtered, dried and extracted successively with hot alcohol and chloroform. A small amount of dibiphenyl separated from the chloroform extract on cooling, after which the filtrate was concentrated to a small volume. On the addition of an equal volume of alcohol a crystalline product formed; yield approximately 43 g.

Anal. Calcd. for $C_{36}H_{27}Bi$: C, 64.7; H, 4.0. Found: C, 65.0; H, 4.3.

It is insoluble in alcohol, but dissolves readily in chloroform, separating in the form of tiny flat needles that melt at 182–183°.

Tri-biphenylbismuth Dichloride.—To the above substance dissolved in carbon tetrachloride was added chlorine dissolved in the same solvent; yield nearly quantitative. The product was recrystallized from chloroform–alcohol mixture, from which it separated as small plates melting with decomposition at 198–200°, if heated slowly.

Anal. Calcd. for $C_{36}H_{27}BiCl_2$: Cl, 9.6. Found: Cl, 9.5.

The dibromide prepared in a similar manner formed pale yellow plates that melted indefinitely with decomposition when heated.

Anal. Calcd. for $C_{36}H_{37}BrBr_2$: Br, 19.3. Found: Br, 19.1.

Both halides dissolved in fuming nitric acid, forming nitro derivatives that deflagrated if heated quickly.

Di-biphenylbismuth Chloride.—This was prepared by the method of Challenger[3] using bismuth chloride with the

triarylbismuth derivative in dry ether. A bright yellow powder rapidly separated out. It melted indefinitely when heated and probably contained some dichloride.

Anal. Calcd. for $C_{24}H_{18}BiCl$: Cl, 6.5. Found: Cl, 7.0.

Tri-biphenylbismuth Dinitrate.—Alcoholic silver nitrate solution was added to an equivalent amount of tri-biphenylbismuth dichloride suspended in a large volume of acetone. On concentrating the filtrate after removal of insoluble material, small plates were obtained that decomposed at approximately 162°, but deflagrated if heated quickly.

Chile Seed

BY W. A. BUSH

The seeds of the Chile pepper (sometimes called pimento) obtained from the pods of the Southern Pacific Coast cultural variety of *Capsicum Annuum* have received little mention in the literature from the point of view of their composition.

A representative sample of a quantity of sixteen tons of dried seeds accumulated during a year from pods mostly of Californian origin gave results differing somewhat from those obtained by Ebert and Bailey[1] from Southeastern seed.

Yields from the seed by drying and extraction were: oil, 26.10%; moisture, 6.25%; dried extracted meal, 67.65%. Analysis of the meal, free from oil and moisture, shows: protein (N × 6.25), 28.92%; fiber, 29.10%; ash, 5.61%; N-free extract (carbohydrates), 36.37%. The constants of the oil, obtained by hot pressing (100°) and then filtering are

Specific gravity, 24.5°/25°	0.918
Refractive index at 25°	1.4738
Color (2.54 cm. column, Lovibond)	100 yellow—46 red
Acid number	2.18
Iodine number, Hanus	133.5
Acetyl number	7.0
Saponification number	192.0
Unsaponifiable matter	1.7%
Melting pt. of separated fatty acids	21.2°

The resemblance to tomato seed oil is striking.[2] However, the presence of colored veins on the outer edges of the seeds imparts to the oil the deep color noted above and a characteristic burning taste and paprika-like aroma.

COMMUNICATIONS TO THE EDITOR

MUREXIDE AND LEUCOMUREXIDE

Sir:

The recent publication of Kuhn and Lyman [*Ber.*, **69**, 1547 (1936)] concerning the oxidation–reduction potential of murexide prompts this report of results obtained in this field.

Preparation of Murexide.—The uncertainty in the preparation of murexide emphasized by previous writers including Kuhn and Lyman (who obtained only a 2% yield) has been removed by employing glacial acetic acid as the reaction medium. Furthermore, recrystallization has been effected without heating, by salting out at room temperature. Thus, 16.1 g. of finely powdered alloxantine suspended in 1600 cc. of boiling glacial acetic acid and treated with 80 g. of ammonium acetate with continued boiling for 1–2 minutes gave, on cooling, filtering, washing with acetic acid, alcohol and ether, and drying at 100°, 14.0 g. (calcd. 14.2 g.) of crude murexide. One gram of this dissolved in 900 cc. of water at 30° gave, on salting out the filtered solution with 60 g. of ammonium chloride, filtering, washing with 60% methanol and then with absolute methanol, and drying at 110°, about 75% of beautiful, reddish-brown crystals possessing a green reflex, which, on titration with sodium hydrosulfite, were found to be pure murexide.

Reduction of Murexide.—Leucomurexide has not been described previously, although postulated by Labes and Freisburger [*Arch. exptl. Path. Pharmakol.*, **156**, 226 (1930)] as well as by Kuhn and Lyman. One gram of pure murexide dissolved in 900 cc. of water at 30° was treated with a filtered solution of one g. of sodium hydrosulfite in a mixture of 20 cc. of water and 10 cc. of ammonia. In a few moments complete decolorization occurred. Salting out with 60 g. of ammonium chloride gave on filtering, washing with 60% methanol and finally with absolute methanol, and drying at 110°, 0.98 g. (98%) of a buff-colored microcrystalline powder which turned pink in the air. It contained the theoretical percentage of nitrogen for ammonium dihydropurpurate. Since its composition is identical with uramil (its molecular formula is simply twice that of uramil), a distinguishing test was sought. This was found in the action of potassium ferricyanide, which immediately converts leucomurexide to murexide, while uramil yields colorless oxidation products. Aeration of a dilute suspension of leucomurexide in water quickly regenerates murexide, 70% (by titration) having been obtained in one experiment after thirty minutes of aeration.

RHEOPEXY IN BENTONITE

Sir:

Recently during the course of an investigation in the thixotropic properties of the clay mineral bentonite, gels showing pronounced rheopectic properties were observed. These gels are of particular interest inasmuch as Freundlich and Juliusburger in the original article describing rheopexy [*Trans. Faraday Soc.*, **31**, 920 (1935)] state that they were unable to find any evidence of rheopexy in bentonite.

The discovery of rheopexy in bentonite may be attributed to a new technique of fractionation which the authors have developed and described at the thirteenth Colloid Symposium at St. Louis, Mo., in June of 1936. Natural bentonite is dispersed in distilled water and then run through a high speed continuously fed centrifuge of the Sharples type. At various distances up the centrifuge bowl different particle size fractions of bentonite are removed and then refractionated. The finest fractions are a beautiful perfectly transparent golden-yellow color and completely amicronic while the coarser fractions are more opaque. There is a large percentage of amicronic particles present in the Wyoming Bentonite being used. By such a method of preparation the authors are establishing the influence of particle size upon thixotropy and rheopexy in bentonite.

Specifically 10 cc. of a very fine fraction (1.3% bentonite) was placed in a test-tube 1 cm. in diameter and 1 drop of saturated potassium chloride added. The setting time at 23° when the tube was kept perfectly still was twenty-five minutes, whereas slight tapping of the tube on a pad of rubber reduced the setting time to fifteen seconds. Additional potassium chloride makes it so stiff that it cannot be liquefied. Such a gel is perfectly transparent. In addition these fine bentonite fractions show pronounced streaking upon being stirred. This streaking phenomenon is greatly increased after electrodialysis. Altogether the bentonite fractions prepared in this manner act very similarly to the vanadium pentoxide system described by Juliusburger and Pirquet [*Trans. Faraday Soc.*, **32**, 445 (1936)].

From a consideration of the properties of a 1.3% bentonite gel in comparison to those gels of 10–20% concentration described by Freundlich, Schmidt and Lindau [*Kolloidchem. Beih.*, **36**, 43 (1932)], one is forced to the conclusion that particle size is of paramount influence in this case of thixotropy. In fact we have found evidences of gel structure at concentrations as low as 0.01% by wt. in the low colloidal range. It may be stated, however, that if hydrogen bentonite produced by electrodialysis is ever allowed to dry, it fails to exhibit thixotropy in low concentrations. This property can still be observed providing the material is never allowed to dry.

EXCHANGE BETWEEN SODIUM IODIDE AND ETHYL IODIDE*

Sir:

It was reported a few months ago in these columns [Hull, Schiflett and Lind, THIS JOURNAL,

---

* This work was supported in part by the Fluid Research Fund of the Graduate School.

58, 535 (1936)] that while there is no exchange between radioactive iodine and ethyl iodide when heated together for fifteen minutes at 87°, as determined by the subsequent measurement of the activities of the two substances, yet in alcoholic solution at 100° a ready exchange takes place between sodium iodide and ethyl iodide. Further experiments on this latter reaction have shown the existence of a marked temperature effect.

The general procedure in these experiments has been as follows: A solution of 50 micro-moles of iodine in a liter of iodobenzene is irradiated with the neutrons from a Rn–Be source for a period of one and one-half hours or longer. After removal of the neutron source, the iodine is extracted and precipitated as silver iodide, which is then transformed into dry sodium radio-iodide. This is dissolved in 1–2 cc. of ethyl alcohol and mixed with 100 micro-moles of inactive ethyl iodide. This mixture is heated to the desired temperature for a stated interval of time and then quickly cooled. (In the one experiment carried out below room temperature both solutions were cooled before being mixed.) The two iodides are separated by shaking the solution with excess ether and water, and are transformed into silver iodide for measurement. The activity of each precipitate is measured by means of a tube counter. The results obtained in a series of experiments at different temperatures are given in tabular form.

Temp., °C.	Time, min.	Exchange
100	5	Complete
100	1	Complete
80	5	Complete
29	5	Partial
29	1	None
24	5	None
19	5	None

The authors are grateful to Dr. K. W. Stenstrom of the University Hospital for the gift of 150 millicuries of radon, and to Dr. J. H. Williams of the Department of Physics for the use of a low resistance amplifier [of the type described by Neher and Harper, *Phys. Rev.*, **49**, 940 (1936)], without which it would not have been possible to carry on this work during the recent hot weather.

THE PHOTOCHEMICAL DECOMPOSITION OF METHANE

Sir:

Methane at atmospheric pressure is photochemically decomposed when irradiated with the light which is transmitted by a thin fluorite window from a hydrogen discharge tube. The effective radiation would appear to lie near the limit of transmission of fluorite. Although no direct measurements of quantum yield have been made, a crude estimate based on a comparison with the rate of the ozone synthesis in the same cell indicates a value of the order of unity.

Among the products we have identified hydrogen and unsaturated hydrocarbons (probably ethylene) in the approximate molecular ratio of 4:1. Higher saturated hydrocarbons may also be produced but have not been detected. The large ratio of hydrogen to unsaturation in the products indicates that the decomposition

$$CH_4 + h\nu \longrightarrow CH_2 + H_2$$
$$2CH_2 \longrightarrow C_2H_4$$

cannot be the only process involved.

NEW SYNTHESIS OF GLYCOFURANOSIDES

Sir:

In the last decade considerable progress in sugar chemistry had been made from the study of the glycopyranosides. Further developments can likely be expected from a greater than our present knowledge of the glycofuranosides, or, as E. Fischer originally named them, γ-glycosides. The physical, chemical and biological properties, the conversion into the pyranosides under certain conditions, and the chemical structure in general, of these γ-glycosides should be thoroughly investigated. To be sure, such studies have already been made in the past, in a few isolated instances. However, a review of the literature reveals that only five or six γ-glycosides are known in pure crystalline form obtained mostly in small yields by cumbersome methods. The majority of the γ-glycosides described in the literature were prepared by the original method of E. Fischer [*Ber.*, **28**, 1145 (1895); **47**, 1980 (1914)] yielding only sirupy mixtures that could not be separated. Obviously, a general method which leads to well-defined, crystalline products, would constitute the first step toward a more extensive study of this class of sugar derivatives. We believe that we have found such a method. It represents a modification of a previous general procedure of one of us [Pacsu, *ibid.*, **58,** 509 (1925); Pacsu and Ticharich, *ibid.*, **62,** 3008 (1929)] by which the α-alkylpyranosides were prepared from the sugar mercaptals and mercuric chloride in the *boiling* solutions of the different alcohols. Taking, *e. g.*, galactosediethylmercaptal and ethanol, the reaction can be expressed by the following summary equation

$$C_6H_{12}O_5{\cdot}(SC_2H_5)_2 + 2HgCl_2 + C_2H_5OH = 2HCl + 2C_2H_5S{\cdot}HgCl + C_6H_{11}O_5{\cdot}OC_2H_5$$

This method was shown to yield almost pure (up to 92%) α-alkylpyranosides accompanied only by a slight quantity of the β-isomers. Now we have found that if the same reaction be carried out *at low temperature*, and the hydrochloric acid formed be neutralized at the moment of its development, an excellent yield of crystalline β-ethylgalactofuranoside can be obtained. The substance had m. p. 84.5–86° and $[\alpha]^{25}\text{D}$ −100.1° in water solution. Schlubach and Meisenheimer [*ibid.*, **67,** 429 (1934)] reported m. p. 86° (corr.) and $[\alpha]^{20}\text{D}$ −97.2° for the same compound obtained by a lengthy synthesis from the β-pentaacetate of galactofuranose of Hudson and Johnson. So far it has not been possible to find any isomer in the mother liquor. The same furanoside was obtained when dibenzylmercaptal had been used as starting material. For the instantaneous neutralization of the hydrochloric acid we have found the use of an excess of yellow mercuric oxide to be most excellent. It keeps the reaction mixture neutral during the whole process, and it provides for a desirable excess of the mercuric chloride up to the end of the reaction. For the removal of the mercuric chloride from the solution we have found that pyridine can be used most successfully. It seems very likely that these modifications can also be used with advantage in the procedures developed for the preparation of the open-chain methylated (Levene, 1926) and acetylated (Wolfrom, 1929) aldoses.

Since the formation of glycopyranosides by the original method has proved to be of general validity, we believe that by this modified procedure it will be possible to prepare the hitherto unknown or only difficultly available furanosides of the carbohydrates. It is our purpose to prepare by this method the alkylfuranosides and -thiofuranosides of the aldoses and ketoses from their mercaptals and acetonylated mercaptals. In the forthcoming first paper of this series of investigations conducted in this Laboratory, a detailed description of the procedure will be given.

NEW BOOKS

Colorimetric Methods of Analysis, Including Some Turbidimetric and Nephelometric Methods. Vol. I. Inorganic. By FOSTER DEE SNELL and CORNELIA T. SNELL. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1936. 766 pp. Illustrated.

In this second edition of Dr. Snell's treatise a much more comprehensive treatment of the field of colorimetry has been made. The book has been divided. This first volume covers general colorimetry and inorganic determinations; a second will deal with organic, biological and miscellaneous methods.

In its general plan and scope the book closely resembles Yoe's "Photometric Analysis." It differs in that nephelometric methods are treated with the colorimetric ones instead of in a separate volume and in that the bibliography occurs in footnotes instead of as a separate section at the end of the book. It contains, of course, methods and references which have appeared in the seven years since the publication of Yoe's book.

In the first nine chapters the general methods of colorimetry are discussed and the multitudinous forms of apparatus which have been devised for the measurement of color and of turbidity are illustrated and explained. Fifty-four chapters are then devoted to different methods for the determination of seventy-four elements or simple inorganic compounds. The last four chapters deal with the colorimetric determination of hydrogen ions. As many as ten or twelve methods are given for some elements. The treatment is well balanced in that the more important methods are given more space while other methods of less value are dismissed with a reference and a brief description.

The book, however, is by no means simply a reference list but rather an excellent working text. In general, after an introductory discussion of each method, the preparation of samples is detailed. This should be one of the most attractive features of the book to the practical worker. Next directions for making up reagents are given and then details of the analytical procedure. Finally there are directions for preparing standards suitable for the method.

Although the treatment is comprehensive rather than critical, this text represents a distinct contribution to the literature of analytical chemistry. It is a reference book which should be on the shelves of every chemist who has occasion to take advantage of the ease and rapidity of colorimetric methods.

CHARLES H. GREENE

Protoplasm. By WILLIAM SEIFRIZ, Ph.D., Professor of Botany, University of Pennsylvania. McGraw-Hill Book Co., Inc., 330 West 42d Street, New York, N. Y., 1936. x + 584 pp. 179 figs. 15.5 × 23.5 cm. Price, $6.00.

This is a delightful volume, a storehouse of information, and should be on the desk of every biologist, biochemist and biophysicist. If only all chemists teaching general chemistry, organic chemistry and especially physical chemistry would read this book they would gain a clear insight into the role which chemistry plays in the phenomena of life.

The author is Professor of Botany in the University of Pennsylvania but the book reads almost as though it were written by a physical chemist. It is a far cry from the "plant physiology" of a generation ago to this discussion of "protoplasm," the ultimate living matter of all cells. The author is to be congratulated on his accomplishment in bringing together in a unified whole so many interesting and diverse series of information.

Of the twenty-seven chapters only five may be said to be primarily biological and even these contain much chemistry and physics. The first chapter deals with "The Living Substance." This is followed with "The Cell"; "Model Making," "Micrurgy" (micromanipulation within living cells) and "Tissue Culture." The last chapter "The Origin of Living Matter" sums up the volume and presents a philosophical consideration of how life possibly came to be.

The other 22 chapters are fundamentally chemical and deal with "The Colloidal State," "Emulsions," "Hydrophilic Sols and Gels," "Surface Tension," "Adsorption," "Osmosis," "Imbibition," "Viscosity," "Elasticity," "The Structure of Protoplasm and Organic Colloidal Matter," "Permeability," "Acidity," "Electrophysiology," "Electrokinetics," "Radiant Energy," "The Role of Water," "Salts," "Carbohydrates," "Fats," "Proteins," and "Regulatory Substances," but into the chemistry and physics of these chapters is woven the experience of years of reading and teaching biological principles so that they are a mine of information uniting abstract chemical and physical laws with cell behavior.

As is to be expected in the first edition of a volume of this size there are some unfortunate typographical errors, some omissions and some inaccuracies. Furthermore, it is perhaps too much to hope that everyone will agree with the author in his interpretation of certain biological processes, certainly the reviewer does not agree in all points, but any and all shortcomings of the book are easily condoned in the light of the magnificent accomplishment which the author has achieved.

A few of the more serious errors are here noted, not as criticisms but to assist prospective purchasers: p. 56, "microvolts" is incorrectly used for millivolts; p. 82, glutathione is stated to be a dipeptide, it is a tripeptide, glutamyl-cysteinyl-glycine; p. 82, amino acids are not the "hydration" products of proteins, rather the products of hydrolysis; pp. 92, 94 and 118, the Tyndall phenomenon is discussed and statements made that it is perhaps the most characteristic property of colloids. Since the Tyndall phenomenon depends upon the refraction of light from an interface it is evident that a solid immersed in a liquid, both having the same index of refraction, will show no Tyndall phenomenon. The absence of "optical properties" in certain protein sols is well known and does not mitigate against their being truly colloidally dispersed. On p. 93 the author states that the word peptization is derived from "peptone, itself a peptizing agent." This is incorrect. Graham coined the word "peptization" and states that it "may be looked upon as analogous to the solution of insoluble organic colloids witnessed in animal digestion. . . . Liquid silicic acid may be represented as the 'peptone' of gelatinous silicic acid—etc." Accordingly "peptization" is derived from pepsin and the process is likened to enzymatic action. On p. 144 there is an erroneous statement as to the osmotic pressure developed by an 0.1 molar sucrose solution. On p. 153 the reference in the text to Fig. 91 should be to Fig. 92. On p. 174 Traube's rule is stated with no indication that it depends upon the nature of the interface and that it is reversed for a polar substance, *e. g.*, SiO_2, in water. On p. 175 there is an unfortunate error in the formula of the Freundlich adsorption isotherm. On p. 199 in the discussion of the osmotic pressure of the blood and body fluids, no mention is made of colloid osmotic pressure and the role it plays in urine secretion. On p. 287 the unfortunate statement is made that a low surface tension means a "loose arrangement of surface molecules and therefore a more permeable membrane." On p. 361 the apparatus figured is that of Freundlich and Rona, not that of Kruyt. On p. 418 metabolic water is stated to arise in part from the "polymerization" of compounds. On p. 429 is given a list of the elements found in protoplasm and the statement that the first 10 are essential. In the first ten sodium is included and iron is omitted! On p. 431 the term "phosphoproteins" is used for the correct "nucleoproteins." On p. 431 in a discussion of the being an integral part of the chlorophyll molecule. That it is present in chlorophyll is noted in another connection on a later page. This type of "omission" occurs in a number of places in the book, thus in discussing vitamin C on p. 514 no mention is made of ascorbic acid although ascorbic acid comes in later in another connection on p. 519. On p. 432 a typographical error gives the sulfhydryl group the formula, SH_2 and on the same page the unfortunate statement occurs that the sulfur bacteria "use sulfur instead of carbon in the synthesis of higher foods"; of course what the author meant was that elemental sulfur was used by the sulfur bacteria as an *energy* source and that by the oxidation of the sulfur they secured energy for the synthesis of carbon compounds. Likewise on p. 432 the cystine discussion is ambiguous. On p. 451 pernicious anemia is confused with nutritional anemia. On p. 477 Sørensen is stated to have found the molecular weight of egg albumin by the freezing point method to be 14,000. This is incorrect. By direct osmotic pressure measurements he found (*Compt. rend. trav. Lab. Carlsberg*, Vol. 12) a mol. function of magnesium in plants no mention is made of its wt. for egg albumin of 34,000. On p. 514 "night blindness," an hereditary affliction, is confused with lack of Vitamin A. On. p. 508 Northrup instead of Sumner is credited with the crystalline enzyme urease.

Apparently the author (in common with most biologists and chemists) is confused (p. 478) with Svedberg's use of the term "molecular weight" as it applies to proteins. It is unfortunate that Svedberg has used this term instead of the more exact (from the chemists' viewpoint) term of "particle weight." Svedberg's "molecular weights" are used in the physical sense and defines "a molecule as a unit which will acquire from thermal vibrations an average of $^1/_2\ kT$ ergs of energy for each of three translational degrees of freedom, neglecting quantum restrictions. The size and weights of these molecules may change with temperature, rate of sheer, and other factors" (personal communication from Prof. J. W. Williams).

Svedberg's use of the term does not necessarily connote that the "molecule" is the smallest unit of that primary substance that can be obtained. Consequently he speaks of the "decomposition" of molecules and later the reversal of the "decomposition" process so that the original "molecular weight" was regained. Obviously this cannot be accomplished if the term "molecular" were used in the older chemical sense.

Again I recommend this volume to all biologists, physicists and chemists who are interested in the phenomena of life in its manifold manifestations.

ROSS AIKEN GORTNER

Handbuch der biologischen Arbeitsmethoden. Edited by EMIL ABDERHALDEN. Abt. IV, Angewandte chemische und physikalische Methoden, Teil 1, Heft 9. (**Handbook of Biological Methods.** Section IV. Applied Chemical and Physical Methods. Part I, Vol. 9.) Fermentforschung. Urban and Schwarzenberg, Friedrichstrasse 105 B, Berlin N 24, Germany, 1935. 245 pp. 17.5 × 25.5 cm. Price, RM. 13.50.

This volume is of interest to those devoted to research in enzyme chemistry and related fields. It gives a comprehensive review of the following subjects:

In the first two articles the method of carrying out the Abderhalden reaction with immersion refractometer according to the method described by Pregl–de Crinis, is given. The estimation of protective enzymes by the use of the interferometer is described by Paul Hirsch.

The preparation of crystalline pepsin, trypsin and chymotrypsin is presented by John H. Northrop and M. Kunitz. The crystalline pepsin is prepared from the amorphous commercial product and is obtained (after recrystallization) in colorless microscopic crystals. The trypsin is obtained from pancreas and finally the chymotrypsin from the pancreas of cattle through the intermediate preparation of crystalline chymotrypsinogen.

The ketonaldehydmutase, an enzyme having the property of converting the alpha-keto aldehydes into alpha-hydroxy acids, is described by Carl Neuberg and E. Simon. This enzyme is widely distributed in nature and functions in the metabolism of living organisms. The most important reaction of this kind is the conversion of methyl glyoxal into lactic acid. The various derivatives of methyl glyoxal such as phenyl glyoxal and methyl glyoxal acetic acid react similarly. The article gives a comprehensive treatment of these reactions.

Emulsin is described by Karl Tauböck. The enzyme preparation consists mainly of β-*d*-glucosidase. It cleaves the β-*d*-glucosides both natural and synthetic, but not the *l*-glucosides. It has been observed that some preparations also cleave various galactosides or mannosides, but the question as to whether this is due to some other enzyme such as alpha-*d*-galactosidase or alpha-*d*-mannosidase, or the β-glucosidase alone has not been determined. This subject is under investigation at the present time.

The method of studying dehydrogenases is presented by Torsten Thunberg in great detail. A complete bibliography is given with each article.

G. BRAUN
C. N. FREY

Die Allotropie der chemischen Elemente und die Ergebnisse der Röntgenographie. (The Allotropy of the Chemical Elements and the Results of X-Ray Analysis.) By M. C. NEUBURGER. Verlag von Ferdinand Enke, Stuttgart W, Germany, 1936. 106 pp. 32 figs. 16 × 24 cm. Price, RM. 9.30; RM. 8.20, for subscribers.

This is Number 30 of a series of monographs on chemistry and chemical technology. The author has written a number of works on crystal chemistry and x-ray diffraction. Each year he writes the annual summary of lattice constants for the *Zeitschrift für Kristallographie.*

The possible allotropic forms and crystal structures of 69 elements, 23 of which actually have several modifications, are discussed. In addition, there is an introduction in which the criteria for distinguishing allotropic forms are discussed. There are chapters on the influence of foreign atoms on allotropy; the relations between allotropy, crystal structure and atomic properties; and transformation mechanisms and the kinetics of allotropic changes.

Crystal structure is chosen as the most unambiguous criterion of allotropic change and x-ray data as the most direct evidence. Although the author is in a position to write authoritatively and his judgment is generally good, a number of criticisms must be made.

In a book of this nature we should expect to find a short review of the literature for each element, giving all important ideas which have been put forth with references. The author should weigh these facts critically and sum up his conclusions distinguishing between what is thoroughly established and what is merely probable and mention possibilities which have not been verified. Neuburger's book falls below this standard. He ignores considerable data, good and bad, and often gives only his conclusions without specifically indicating their source or their relative probability. To get a good idea of the status of work on a given element it is still necessary to consult the original literature.

The author fails completely to mention the fact that cobalt is hexagonal at high temperatures, which has been verified by a number of authors and never disputed. On phosphorus, he ignores the fact that a number of contradictory x-ray patterns have been reported. He mentions the work of Frost [*J. Russ. Phys.-Chem. Soc.*, **62,** 2235 (1930)] which shows that red and violet phosphorus have different structures without giving credit or listing the reference. The best work on the transformation point of iron [by Wells, Ackley and Mehl (1935)] is not mentioned; perhaps it is too recent for inclusion.

The references, instead of being conveniently listed under each element, are placed at the end of the volume. The first 920 of them are alphabetically arranged according to author, but 82 more follow (not the most recent ones) in irregular order. The reference numbers are hard to find since they are not conspicuously printed and separate lines are not given to each reference. A great deal of space could have been saved by omitting data such as lattice constants which are conveniently found elsewhere. A few good tables would advantageously take the place of much of the discussion.

On the whole, the book bears evidence of hasty preparation. However, it is the first book on this subject and provides a summary, usually well chosen, of data to be found only by a search of the literature. It should be a useful reference work.

RALPH HULTGREN
ALDEN B. GRENINGER

Organic Chemistry. By ROBIN CHARLES BURRELL, Ph.D., Associate Professor of Agricultural Chemistry, The Ohio State University. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York, N. Y., 1936. xii + 336 pp. 34 figs. 14 × 20.5 cm. Price, $2.75.

A more specific title for this textbook would be more appropriate in view of its rather extensive discussion of the biologically important substances and its more restricted treatment of some of the other subjects, such as methods of synthesis which are less pertinent to its purpose. The text is especially designed for a semester course in organic chemistry for students of home economics, agriculture and biological sciences. The choice of subject matter was largely based upon the consensus of the opinions of a number of authorities on nutrition.

The fundamental concepts and the most important types of compounds are adequately discussed. The aliphatic and the aromatic hydrocarbons are presented in the same chapter. About one-half of the book is devoted to the treatment of substances of direct biochemical importance—lipides, carbohydrates, proteins and their components, and miscellaneous natural substances. A concise account of the digestion and assimilation of each of the three important classes of food substances is also included.

The book is quite accurate and up-to-date; however, the following errors ought to be noted: "ethyl nitrile" for C_2H_5CN (p. 115); the boiling point of lactic acid is given as 122°C. (p. 154); the consideration of alcoholic fermentation as "a type of biological oxidation" (p. 176); and the formulas for hydroxyproline (p. 216) and nicotine (p. 281). The classification of the types of isomers that is given (p. 45) and the likening of esters to salts (p. 111) are not in accord with modern concepts.

The book is well organized and written in a clear and concise manner. It is well suited for the purpose for which it was intended.

The Entropy of Deuterium Oxide and the Third Law of Thermodynamics. Heat Capacity of Deuterium Oxide from 15 to 298°K. The Melting Point and Heat of Fusion

BY EARL A. LONG[1] AND J. D. KEMP

Aside from its usual thermodynamic utility, the entropy of deuterium oxide is of considerable interest in connection with the entropy discrepancy in ordinary water, first pointed out by Giauque and Ashley,[2] in which the calorimetric entropy does not agree with entropies calculated from the band spectrum and from reaction data. Explanations of this discrepancy have been discussed by Giauque and Ashley, and more recently by Pauling.[3]

In order to test these explanations, Giauque and Stout[4] have carried out a calorimetric investigation on ordinary water.

Since the substitution of deuterium for hydrogen in the water molecule does not appreciably change the internuclear distances, and probably has little effect on the nature of the bond forces, it seemed that an experimental investigation of the entropy of deuterium oxide would be valuable in any discussion of the entropy discrepancy in water. A calorimetric entropy value for heavy water should provide an additional test to distinguish between the theory of molecular rotation and the Pauling theory of random bond orientation, as has been pointed out by Giauque and Stout.[4]

Apparatus.—The measurements were made with the same copper calorimeter and auxiliary apparatus used by Giauque and Stout in their investigation of ordinary water. Although we did not have a sufficient quantity of pure heavy water to fill the calorimeter as completely as desired, the precision of the measurements was not seriously affected, and we feel that the use of the same calorimeter and temperature standard for hydrogen and deuterium oxide should lead to more accurate comparisons between the two isotopic forms.

The details of the apparatus and the method of making the measurements and calculations have been described previously.[5]

Purification of Deuterium Oxide.—The sample was taken from a preparation kindly supplied to us by Prof. H. L. Johnston. It had a density of 1.10781, corresponding to a deuterium content of 99.92 atomic per cent.,[6] if we compare our density with the maximum density of 1.1079 given by Taylor and Selwood.[7] The remaining 0.08 atomic per cent. of hydrogen does not affect our measurements, since the isotopes should of course form a perfect solution, and the thermal quantities are of nearly the same magnitude.

The heavy water container was broken in an

[6] We are informed by Prof. Johnston that the sample contains not more than 0.01% above the normal concentration of the heavier oxygen isotopes, on the basis of the electrolytic separation coefficient 1.008 for the concentration of O^{18} by electrolysis with iron electrodes, determined by Johnston [*ibid.*, **57**, 484 (1935)].

[7] Taylor and Selwood, *ibid.*, **56**, 998 (1934).

atmosphere of pure helium, and the water was distilled at low pressures through a series of three bulbs, in order to eliminate a small amount of alkali in the original sample. After each distillation the solid was cooled with liquid air and the system was evacuated to a pressure of 10^{-5} mm. in order to get rid of traces of dissolved gas. The water was then transferred through a small german silver tube into the copper calorimeter. The calorimeter was filled with helium gas at one atmosphere pressure, the german silver tube was pulled out, and the very small opening was sealed with Wood's metal.

In order to determine the amount of liquid-soluble, solid-insoluble impurity, a series of short heat capacity runs was made in the temperature region just below the melting point. From the observed premelting effect in these runs, we estimate the soluble impurity to be less than 0.003 of one mole per cent. This is of course exclusive of the 0.08 atomic per cent. hydrogen content of the sample, as the presence of another isotopic form would not cause premelting.

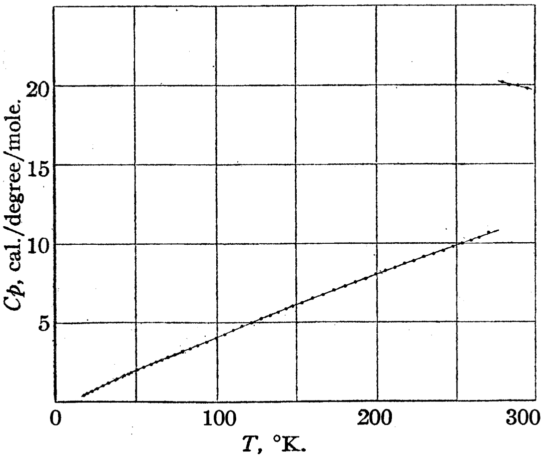

Fig. 1.—Heat capacity of deuterium oxide.

The Heat Capacity of Deuterium Oxide

The results of the heat capacity measurements are given in Table I, and are shown graphically in Fig. 1.

In the calculations, one 15° calorie was taken as equal to 4.1832 international joules. The calorimeter contained 32.708 g. of deuterium oxide. For the calculation of the molecular weight we used the value 2.01471 given by Aston[8] for the atomic weight of deuterium, and the factor 1.00025 for conversion from the physical to the chemical scale.

We took no special precautions in cooling the sample, as the first series of measurements showed no evidence of bad thermal equilibrium. For ordinary water, Giauque and Stout[4] observed slow attainment of thermal equilibrium in the region from 85 to 100°K. However, their experiments on different rates of cooling showed no appreciable effect on the heat capacities. If, as Giauque and Stout suggest, this lag in equilibrium is caused by the initial stages of excitation of new degrees of freedom connected with the motion of the hydrogen atoms, it is not surprising that the phenomenon does not appear in deuterium oxide, when one considers the great difference between the masses of hydrogen and deuterium.

In Table II are listed values of the heat capacity at even temperatures, as read from a smooth curve through the data. These values are compared with those of Brown, Barnes and Maass,[9] who measured the total change in heat content from various initial temperatures to 25°, and have derived from these data values for the specific heats. In making this comparison we have used 20.0284 as the molecular weight.

We have also included in Table II values for the ratio of the molal heat capacities D_2O/H_2O over the whole temperature region, calculated from our data and those of Giauque and Stout.[4] For the heat capacity of liquid H_2O, the values given in the "International Critical Tables"[10] were used.

The Melting Point and Heat of Fusion.—The melting point was determined with various percentages of the D_2O melted. In each measurement the temperature was observed for several hours after heat input, until readings on the sensitive resistance thermometer indicated that thermal equilibrium had been attained. From these measurements, the melting point was selected as 276.92 ± 0.05°K. (3.82°C.), after taking into account the slight freezing point depression due to the 0.003 mole per cent. of soluble impurity present.

Table III summarizes the measurements of the melting point by various observers.

The heat of fusion was determined by the usual procedure of starting heat input at a temperature slightly below the melting point and heating to a temperature a little above. In this case, due to the fact that the less dense ice floated on top of the melted material, it was necessary to heat to almost 11° above the melting point in order to obtain sufficiently rapid thermal equi-

librium after energy input. This necessitated a larger $\int C_p dT$ correction, which, however, could be applied with high accuracy.

The measurements are summarized in Table IV. Column two gives the heat input per mole, corrected for all experimental factors, but not including the $\int C_p dT$ correction, given in column three. A small correction for premelting is also included in the $\int C_p dT$ correction to the total energy. The last column gives the molal heat of fusion. We have also included in Table IV values for the heat of fusion given by other workers. These include the value of Bartholomé and Clusius, a direct determination with an ice calorimeter; that of Jacobs, an extrapolated value from heat of fusion measurements on equilibrium mixtures of light and heavy water; and indirect determinations by La Mer and Baker, and by Brown, Barnes and Maass.

In this connection it is of interest to point out that the heat of fusion of H_2O measured by Giauque and Stout[4] in the same calorimeter agreed with the accepted value within 0.1%.

The Entropy of Deuterium Oxide.—The entropy between 18 and 273.10°K. was obtained by graphical integration of our measured heat capacities. The entropy between 0 and 18°K. was calculated from the Debye equation, using $\theta = 185$.

The only direct value for the heat of vaporization of D_2O is that of Bartholomé and Clusius,[14] who determined the heat of sublimation at 0° using an ice calorimeter. They give 630.9 calories per gram as the mean of three determinations, with an average deviation of 0.4 cal./gram. Converting this to a molal basis, using our molecular weight (20.0284), we obtain 12,636 cal./mole as the heat of sublimation at 0°. The vapor pressure of D_2O at 0° is given by Bartholomé and Clusius as 3.65 ± 0.05 mm. The entropy correction to the ideal gas state should be negligible at this low pressure.

A summary of the entropy calculation at 273.10°K. is given in Table V.

TABLE V

ENTROPY OF DEUTERIUM OXIDE AT 273.10°K.

Table VI summarizes the calculation of the entropy of *liquid* deuterium oxide at 298.10°K.

TABLE VI

CALORIMETRIC ENTROPY OF LIQUID DEUTERIUM OXIDE AT 298.10°K.

0–18°K., Debye function, $\theta = 185$	0.135
18–276.92°K., graphical	10.247
Fusion at 276.92°K., $\frac{1501}{276.92}$	5.420
276.92–298.10°K., graphical	1.472
Calorimetric entropy of liquid D_2O at 298.10°K.	17.27 ± 0.05 E. U.

For use in thermodynamical calculations, 0.806 E. U. should be added to the value in Table VI, giving 18.08 E. U., on the basis of Pauling's theory, discussed in a later section.

The Entropy from Spectroscopic Data.—The entropy was calculated from the well-known equation

$$S = 3/2\, R \ln M + 4R \ln T + R/2 \ln I_A I_B I_C - R \ln \sigma + 265.35 + S_{\text{vibrational}}$$

The vibrational fundamentals $\nu_1 = 2784$ cm.$^{-1}$, $\nu_2 = 2666$ cm.$^{-1}$, $\nu_3 = 1179$ cm.$^{-1}$ given by Barker and Sleator[17] and Rank, Larsen and Bordner[18] were used in the calculation of the vibrational entropy. At 273.10°K., this amounts to only 0.02 E. U.

As there exist no experimental values for the moments of inertia of deuterium oxide, a calculation of these was made from the corresponding moments of inertia for hydrogen oxide in the

---

(14) Bartholomé and Clusius, *Z. physik. Chem.*, **B28**, 167 (1935).

(15) La Mer and Baker, THIS JOURNAL, **56**, 2641 (1934).

(16) Jacobs, *Trans. Faraday Soc.*, **31**, 813 (1935).

(18) Rank, Larsen and Bordner, *ibid.*, **2**, 464 (1934).

ground state (non-rigid molecule) given by Freudenberg and Mecke.[19]

In this calculation, it was assumed that the root mean square distance between the D atoms in D_2O was the same as the root mean square distance between the H atoms in H_2O; it was also assumed that the root mean square distance between the O atom and the line connecting the D atoms was the same as the corresponding distance between the O atom and the line connecting the H atoms. Thus

$$I_{A_{D_2O}} = \left[\frac{\dfrac{2DO}{2D + O}}{\dfrac{2HO}{2H + O}}\right] I_{A_{H_2O}} \qquad (1)$$

$$I_{B_{D_2O}} = \frac{D}{H} \times I_{B_{H_2O}} \qquad (2)$$

$I_{C_{D_2O}}$ was calculated assuming that the distance between the D and O atoms in D_2O was the same as the distance between the H and O atoms in H_2O, and that this distance r is determined by the expression

$$I_{C_{H_2O}} = 2Hr^2\left(1 - \frac{1}{9}\cos^2\frac{\alpha}{2}\right)$$

The valence angle α is determined by

$$\tan\frac{\alpha}{2} = \frac{2}{3} \times \sqrt{2\frac{I_{B_{H_2O}}}{I_{A_{H_2O}}}}$$

Then

$$I_{C_{D_2O}} = \frac{D\left(1 - \dfrac{2}{10}\cos^2\dfrac{\alpha}{2}\right)}{H\left(1 - \dfrac{1}{9}\cos^2\dfrac{\alpha}{2}\right)} I_{C_{H_2O}}$$

The following values were obtained for the moments of inertia of deuterium oxide (in g.-cm.^{2}):

$$I_A = 1.790 \times 10^{-40} \qquad I_B = 3.812 \times 10^{-40}$$
$$I_C = 5.752 \times 10^{-40}$$

Then, at 273.10°K. and one atmosphere pressure

$$S_{D_2O} = \frac{3}{2} R \ln 20.0284 + 4 R \ln 273.10 + \frac{R}{2} \ln (1.790 \times 10^{-40} \times 3.812 \times 10^{-40} \times 5.752 \times 10^{-40}) - R \ln 2 + 265.35 + 0.02 = 46.66 \text{ E. U.}$$

in accordance with the usual custom of neglecting entropy due to nuclear spin. At 298.1°K. and one atmosphere, the spectroscopic entropy for D_2O is 47.46 E. U.

A comparison of this spectroscopic value with the calorimetric entropy given in Table V shows a difference of 0.77 E. U. A corresponding discrepancy of 0.82 E. U. at 298.1°K. was found by Giauque and Stout[4] in the case of hydrogen oxide.

Two explanations of the hydrogen oxide discrepancy have been made. Giauque and Ashley[2] offered an explanation which assumed that the ortho and para states in gaseous water persisted in the solid state at low temperatures. This theory, as pointed out by Giauque and Stout,[4] leads to a calculated discrepancy of $1/3\ R \ln 2 = 0.459$ E. U. for deuterium oxide, as compared to a calculated discrepancy of 1.033 E. U. for hydrogen oxide.

Pauling[3] has offered an alternative explanation which ascribes the discrepancy to the random orientation of the hydrogen bonds in the crystal. His theory leads to a calculated discrepancy of $R \ln 6/4 = 0.806$ E. U. This discrepancy, in Pauling's explanation, is identical for both forms of water.

In the case of hydrogen oxide, Giauque and Stout[4] have pointed out that while the discrepancy is quantitatively explained by Pauling's theory, the ortho–para explanation is not absolutely excluded, as a partial attainment of equilibrium between ortho and para forms would lead to a discrepancy somewhat lower than 1.033 E. U. The ortho–para explanation becomes still more improbable for the discrepancy in deuterium oxide, as it predicts a discrepancy of about 0.31 E. U. lower than its measured value. Thus, the agreement between our experimental discrepancy and that calculated by Pauling, together with the similar agreement found by Giauque and Stout for hydrogen oxide, gives strong support to the Pauling theory of random bond orientation.

We are indebted to Professor H. L. Johnston, who suggested the problem to one of us (E. A. L.) and kindly loaned us the pure deuterium oxide used in this investigation, and to Professor W. F. Giauque for the use of the vacuum calorimeter, and for many helpful conversations.

Summary

The heat capacity of solid and liquid deuterium oxide has been determined over their respective ranges from 15 to 298°K.

The melting point has been found to be 276.92°K. The heat of fusion of deuterium oxide is 1501 cal./mole.

The calorimetric entropy of liquid deuterium oxide at 298.1°K. is 17.27 E. U. The value which should be used in thermodynamic calculations is 0.806 E. U. higher, or 1808 E. U., on the basis of Pauling's theory.

---

[19] Freudenberg and Mecke, *Z. Physik*, **81**, 465 (1933).

Using our measured heat capacities and the heat of sublimation of deuterium oxide given by Bartholomé and Clusius, we find the calorimetric entropy for $D_2O_{(g)}$ to be 45.89 E. U. at 273.10°K. and one atmosphere pressure. The entropy from spectroscopic data is 46.66 E. U., giving a discrepancy of 0.77 E. U. between the calorimetric and spectroscopic values. This is in good agreement with the theoretical discrepancy 0.806 calculated by Pauling from the assumption of random orientation of the hydrogen bonds in the crystal. This agreement, along with the similar agreement for hydrogen oxide found by Giauque and Stout, is evidence for the correctness of Pauling's theory.

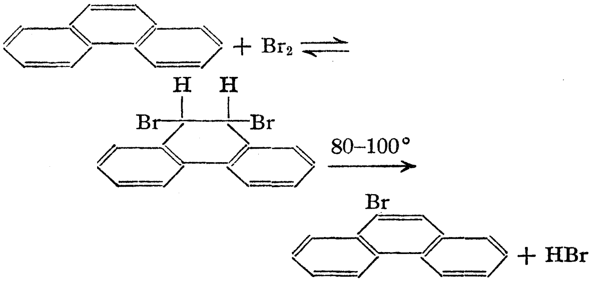
A Study of the Phenanthrene–Bromine Addition Reaction

BY CHARLES C. PRICE

Although it has been recognized since the discovery of phenanthrene[1] that the hydrocarbon forms a crystalline dibromide sufficiently stable to be isolated, the interesting reaction has received but little attention and the dibromide has been studied only as an incidental intermediate in the preparation of 9-bromophenanthrene,[2] loss of hydrogen bromide occurring when the substance is gently heated.



Since the reaction affords a model for the widely considered hypothesis that aromatic substitutions in general involve an addition–elimination mechanism, it was thought that a study of the kinetics of both of the above reactions in the presence and absence of halogenation catalysts might cast some light on the broad problem of substitution. That dibromides can be isolated from phenanthrene and anthracene but not from the other common aromatic hydrocarbons is no indication that these substances are different in kind from the others. It probably is merely a consequence of the greater reactivity of the central nucleus of the tricyclic hydrocarbons and of the stabilization of the dihydrobenzenoid nucleus of the addition product by the terminal, aromatic rings.

It was soon found in preliminary experiments that the reaction between phenanthrene and bromine in non-aqueous solvents is reversible, and that the position of the equilibrium and the rate of its establishment are both measurable by analytical methods. Consequently a study was made of the rate and equilibrium of the first reaction, the original problem being reserved for future investigation.

Analysis for bromine by titration was first tried and found to give approximate but unsatisfactory results, and the final measurements were made by colorimetric analysis for bromine with a Keuffel and Esser spectrophotometer. This proved to be a convenient and reliable method of attack. The experimental deviation of ±5% in the equilibrium constants determined by this method represents an error of only ±0.5% in the determination of the bromine concentration.

The phenanthrene used was a sample from coal tar (Gesellschaft für Teerverwertung) further purified by treatment with maleic anhydride,[3] distillation, and crystallization, m. p. 98.2–98.8°, corr. Pure bromine was prepared according to the directions of Scott,[4] dried over resublimed phosphorus pentoxide, and distilled. The purification of the carbon tetrachloride used as solvent was most satisfactorily accomplished by washing commercial material three times with one-tenth volume of concentrated potassium hydroxide in 50% alcohol at 60°, three times with water, three times with one-tenth volume of concentrated sulfuric acid at 25°, thorough washing with water, a

preliminary drying over calcium chloride, and distillation from phosphorus pentoxide, b. p. 76–76.5°. The use of sodium as a final drying agent, recommended by several investigators,[5] gave a product containing a slight amount of bromine-absorbing impurity (0.004–0.006%), determined by the decrease in the absorption coefficient with increasing dilution.

The rate as well as the equilibrium for the addition of bromine to phenanthrene follow quite as would be expected from the equation of the reaction

$$C_{14}H_{10} + Br_2 \underset{k_1}{\overset{k_2}{\rightleftharpoons}} C_{14}H_{10}Br_2$$

The equilibrium constant K is defined as follows:

$$K = \frac{[C_{14}H_{10}Br_2]}{[C_{14}H_{10}][Br_2]} = \frac{k_2}{k_1}$$

where k_1 and k_2 represent the rate constants for the reactions as indicated.

The rate constant for the bimolecular forward reaction, k_2, is calculated from the expression for a bimolecular forward reaction corrected for a monomolecular back reaction

$$dx/dt = k_2(a - x)(b - x) - k_1x$$

Substitution for k_1 of its value as determined from the expression for the equilibrium constant, $k_1 = k_2/K$, and integration lead to the following expression for k_2.

$$k_2 = \frac{2.303}{t\sqrt{-q}}\left[\log\frac{2x - (a + b + 1/K) - \sqrt{-q}}{2x - (a + b + 1/K) + \sqrt{-q}} - \log\frac{-(a + b + 1/K) - \sqrt{-q}}{-(a + b + 1/K) + \sqrt{-q}}\right]$$

where $a = [Br_2]_{i\,(\text{initial})}$, $b = [C_{14}H_{10}]_i$, $x = [Br_2]_i - [Br_2]_{t\,(\text{at time t})}$, and $-q = (a+b+1/K)^2 - 4ab$.

The experimentally determined values for these constants at 15.7, 25.0 and 39.0° are shown in Tables I and II. On plotting log K at these three temperatures against $1/T$, the points are observed to fall accurately on a straight line. The rate constants are all calculated from the starting time. In the determination of the rate constants for expts. 1–6 the light of the spectrophotometer was on during the entire course of the reaction, the rate constants increasing steadily due to catalysis by the light. In the remaining experiments the light was on for only about thirty seconds of every five minutes, and this seemed to have no appreciable effect on the rate of the reaction, the rate constants showing no systematic deviation either with the concentration or amount

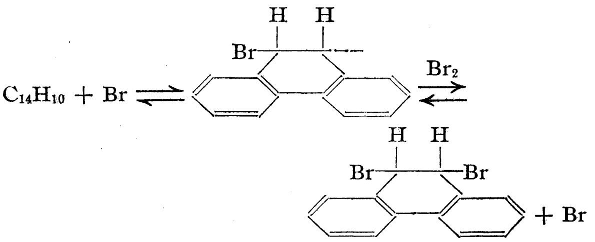
of reaction. Table III summarizes the equilibrium data, including ΔF, ΔH and ΔS, for the addition of bromine to phenanthrene. The limits indicated are calculated from the average deviation of the equilibrium constants.

The inhibitory effect of oxygen noted by Bauer and Daniels[6] in a study of the addition of bromine to cinnamic acid was not noticeable in this reaction (expt. 19). Benzoyl peroxide also had no effect on either the rate or the equilibrium, nor did the antioxidant β-naphthol. It was discovered, however, that such antioxidants as diphenylamine, hydroquinone, tetrabromohydroquinone and tetrabromocatechol are very effective inhibitors of the reaction, even in relatively small amounts. It appears significant that the distinctive feature of these inhibitors is the fact that they may readily donate *atoms* of hydrogen and revert to stable compounds, namely, tetraphenylhydrazine or a quinone.

These facts all find ready explanation on the basis of a chain mechanism for the addition of bromine to phenanthrene, propagated by bromine atoms and free radicals as follows



a type of mechanism which has been proposed by several investigators studying photochemical bromination reactions.[7] It is suggested that the inhibitor functions by interaction with the bromine atoms, yielding hydrogen bromide and either tetraphenylhydrazine or a quinone. Lauer,[8] in a recent series of papers on the bromination of various aromatic hydrocarbons does not seem to consider fully the possibility of a chain mechanism in the deduction of his conclusions.

This inhibitory effect not only indicates that the reaction proceeds through a chain mechanism but makes possible an estimation of the length of the chain, a determination which usually is made only through a photochemical study of quantum yield. If, for instance, the concentration of the inhibitor is one-tenth that of the phenanthrene, it may be assumed that the chain length is approximately ten, since the chances are ten to one in favor of a bromine atom colliding with a molecule of phenanthrene, thus propagating the chain rather than hitting a molecule of inhibitor and interrupting the chain. Multiplication of the ratio of phenanthrene to inhibitor by the ratio of the uninhibited rate to inhibited rate will then give the length of the chain in the case of the uninhibited reaction. The validity of the above assumption regarding the chain length of the inhibited reaction depends chiefly on two conditions, namely, the equality of the activation energy for the reactions between bromine atoms and phenanthrene or inhibitor, and the equivalence of the steric factors involved in these two reactions. The assumption implies that the fraction of effective collisions between bromine atoms and molecules of inhibitor is the same as that for the collisions between bromine atoms and phenanthrene. The quantitative identity of the results using diphenylamine, tetrabromocatechol, and tetrabromohydroquinone seems to substantiate the validity of the assumption, and to indicate the probability that all of the above collisions result in reaction, since if either a steric effect or activation energy were a factor it would not be expected to be the same in each case.

It should be pointed out that in the determinations of the chain length by this method, the inhibitor was added in quantity sufficient so that the ordinary chain-stopping process could be neglected as compared with the interruption of the chain by the inhibitor. The results of the experiments at 25° are shown in Table IV. In each case the experiment with less inhibitor gave a lower value for the chain length, possibly due to decrease in inhibitor concentration by reaction with bromine atoms, an effect which would natu-

TABLE IV

EFFECT OF VARIOUS INHIBITORS ON THE RATE OF ADDITION OF BROMINE TO PHENANTHRENE AT 25 AND 36°

Inhibitor	$[C_{14}H_{10}]$/ [Inhib.]	k	Chain length
Diphenylamine	38.8	0.18	2500[a]

rally be increasingly noticeable with decreasing concentration of inhibitor. For this reason the higher values are perhaps the more nearly correct.

It is necessary to reconcile the interpretation of the results in terms of a chain mechanism with the observed second order kinetics. In studies of photochemical brominations,[5,7] which apparently proceed by chain reactions, the initiating reaction is the photochemical dissociation of bromine molecules to atoms, the experimentally determined rates being proportional to the first power of the bromine concentration alone. That the rate in the present case is dependent also upon the concentration of phenanthrene can be accounted for by assuming that the chain initiating reaction is

$$C_{14}H_{10} + Br_2 \longrightarrow C_{14}H_{10}Br + Br$$

It is further necessary to assume that the length of the chain remains sensibly constant during the course of the reaction. A calculation of the variation of this factor with changing concentrations of the reactants was made on the basis of the following mechanism, the same as that proposed by Berthoud and by Wachholtz[7] for the addition of bromine to ethylenic double bonds, except that in the present case the chain-initiating reaction is not the photochemical dissociation of bromine.

$$\begin{array}{lll}
(1) & C_{14}H_{10} + Br_2 \longrightarrow C_{14}H_{10}Br + Br & k_1 \\
(2) & C_{14}H_{10} + Br \longrightarrow C_{14}H_{10}Br & k_2 \\
(3) & C_{14}H_{10}Br + Br_2 \longrightarrow C_{14}H_{10}Br_2 + Br & k_3 \\
(4) & C_{14}H_{10}Br + Br \longrightarrow C_{14}H_{10}Br_2 \text{ (or } C_{14}H_{10} + Br_2) & k_4 \\
(5) & C_{14}H_{10}Br \longrightarrow C_{14}H_{10} + Br & k_5 \\
(6) & C_{14}H_{10}Br_2 + Br \longrightarrow C_{14}H_{10}Br + Br_2 & k_6 \\
(7) & C_{14}H_{10}Br_2 + Br_2 \longrightarrow C_{14}H_{10}Br + Br_3 \text{ (or } Br + Br_2) & k_7
\end{array}$$

Reaction 7 is included since a solution of phenanthrene dibromide alone is quite stable and its dissociation proceeds only on the addition of a small amount of bromine.

If now the chain length, α, is placed equal to the ratio of the chain-propagating reactions to the chain-interrupting reactions

$$\alpha = \frac{k_2[C_{14}H_{10}][Br] + k_3[C_{14}H_{10}Br][Br_2]}{k_4[C_{14}H_{10}Br][Br]}$$

it is necessary only to obtain the concentrations of the intermediates, $C_{14}H_{10}Br$ and Br, in terms of the reactants by setting up and solving the equations of the steady state in order to obtain an expression for the chain length in terms of definitely determinable quantities. Making the one simplifying assumption that $k_6[C_{14}H_{10}Br_2]$ is negligible as compared with $k_2[C_{14}H_{10}]$, since the rate of the forward reactions must be greater than the back reactions due to the position of the equilibrium and since the concentration of the dibromide is at most equal to that of the phenanthrene at the dilution in question, the following expression can be derived:

$$\alpha^2 = 3\,\frac{k_2k_3}{k_1k_4} + \frac{k_2k_5}{k_1k_4}\,\frac{1}{[Br_2]} + \frac{k_2k_3^2}{k_1k_4}\left(\frac{[Br_2]}{k_3[Br_2] + k_5}\right)$$

A two- or three-fold change in bromine concentration, as was the case in the measurements, should have but little effect on α^2, even less on α itself.

A probable reason for the lack of temperature coefficient was indicated by the results of determinations of the chain length at 36°. At this temperature the chain-initiating reaction should have approximately twice the rate at 25°, but compensating for this factor it was found that the chain length had decreased from about 2000 to 1000. The results of these experiments are shown in Table IV.

One other very interesting phenomenon discovered in the course of the work was the phenanthrene-induced bromination of dioxane, and the observations offer further support for the proposed mechanism for the initiation of the bromine–phenanthrene reaction. A solution of bromine in dioxane was found to be completely stable at room temperature or slightly above, but the addition of phenanthrene causes a rapid absorption of bromine, not only by addition to phenanthrene ($^1/_3$) but by bromination of the dioxane ($^2/_3$). The phenomenon has not been thoroughly investigated but the results suggest the following mechanism:

$$\begin{array}{rl}
C_{14}H_{10} + Br_2 & \longrightarrow C_{14}H_{10}Br + Br \\
C_{14}H_{10}Br + Br_2 & \longrightarrow C_{14}H_{10}Br_2 + Br \\
C_4H_8O_2{\cdot}Br_2 + 2Br & \longrightarrow C_4H_6Br_2O_2 + 2HBr \\
 & \qquad\quad \big\downarrow H_2O \\
 & \qquad 2CH_2OH{\cdot}CHO + 2HBr
\end{array}$$

This accounts for the observed ratio of hydrogen bromide produced to bromine absorbed. A positive Fehling's test showed the presence of an aldehyde. The reaction is to be studied further.

The author wishes to express his grateful appreciation to Professor Louis F. Fieser both for proposing the problem and for inspiration to its successful completion. Acknowledgment is also due Dr. Paul D. Bartlett for much helpful advice and criticism.

Summary

1. The rate and equilibrium for the addition of bromine to phenanthrene have been measured.
2. Evidence for a chain mechanism has been presented, as well as a method for the determination of its length.

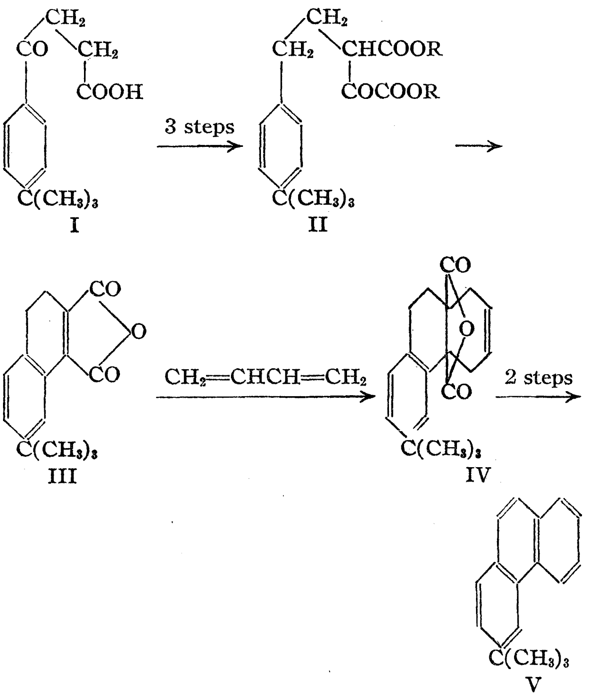
The Effect of Substituents on the Phenanthrene–Bromine Addition Reaction

BY LOUIS F. FIESER AND CHARLES C. PRICE

Following the observation[1] that the addition of bromine to phenanthrene proceeds to a measurable equilibrium at a conveniently measurable rate, it became of interest to investigate the effect of substituent groups in the terminal rings on the free energy and rate of the reaction. It seemed desirable to study compounds having substituents belonging to the three types distinguished by the nature of the directive influence which they exert on aromatic substitutions, and attention was directed first to 2- and 3-substituted phenanthrene derivatives since these are more readily available than the 1- and 4-isomers. As representative compounds with meta-directing groups the 2- and 3-carboxylic esters of phenanthrene were selected and found satisfactory. Halogen atoms constitute a special class of substituent since they retard substitution in the benzene ring like meta groups yet direct to the ortho–para positions, but of the compounds desired only 3-chlorophenanthrene[2] had been described at the time our work was undertaken. The 2- and 3-halophenanthrenes, however, were conveniently obtained from the acetyl compounds[3] through the oximes, acetylamines and amines, a method which has been reported by Bachmann and Boatner[4] in a preliminary communication published since the completion of our work.

It was a more difficult matter to find suitable 2- and 3-phenanthrene derivatives having ortho–para directing groups of the type that facilitate aromatic substitutions. A too powerfully directing group would lead to substitution in the terminal nucleus rather than 9,10-addition, and this apparently is the case with the methoxy- and acetylamino-phenanthrenes for they rapidly absorb more than one mole of bromine irreversibly in carbon tetrachloride solution. The same observation was made with 3-ethylphenanthrene, and it is possible that in this case the principal reaction is a side-chain substitution. The phenanthryldimethyl carbinols were investigated but they proved to be too unstable. Finally the tertiary butyl compounds were synthesized and found entirely satisfactory for the purpose. 3-*ter.*-Butylphenanthrene (V) was obtained by the synthetic method of Fieser and Hershberg[5] starting with the keto acid I resulting from the condensation of *ter.*-butylbenzene with succinic anhydride.



The structure was established by conversion to *p*-*ter.*-butylbenzoic acid and terephthalic acid. The addition of butadiene to III and the remaining steps all proceeded very satisfactorily, affording

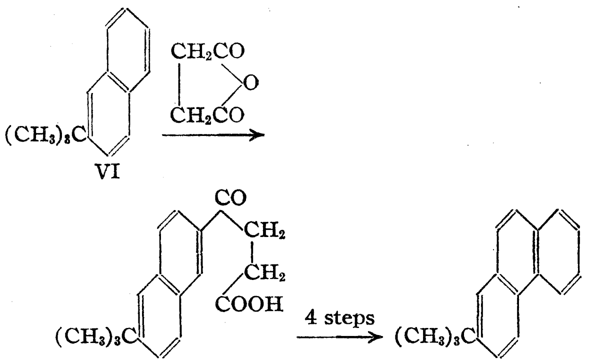
3-*ter.*-Butylphenanthrene	467	191*	7–11	5–7	3640	12,900	31.1

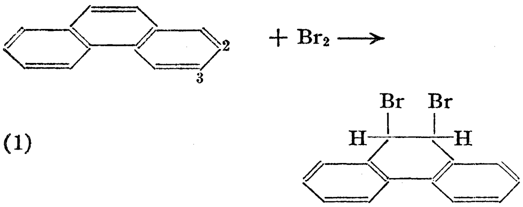
(* 37.4°.)

an easily purified hydrocarbon. The synthesis of the 2-isomer was patterned after Haworth's syntheses and based upon his observation[6] that in nitrobenzene solution succinic anhydride condenses with β-methyl- and β-isopropyl-naphthalene in the 6-position. β-*ter.*-Butylnaphthalene was found to react in the same way, giving the keto acid VII. On reduction, cyclization and conversion to an aromatic hydrocarbon, the product was found to be a phenanthrene derivative isomeric with 3-*ter.*-butylphenanthrene and yielding on oxidation an ortho quinone with the substituent still intact, hence a *ter.*-butyl-9,10-phenanthrenequinone. Theoretically VI could give rise to 2-, 3- or 9-*ter.*-butylphenanthrene, and since the last two structures are eliminated the substance obtained is the 2-isomer and the keto acid (VII) has the structure shown.



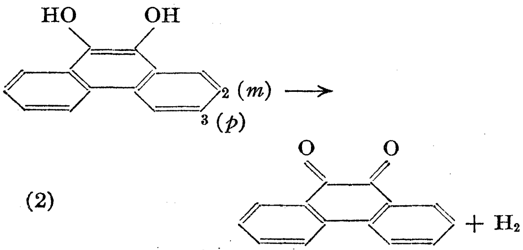
VI VII VIII

The bromine-addition reaction was studied in carbon tetrachloride solution by the method employed for phenanthrene[1] and the results are summarized in Table I. On comparing the equilibrium constants at 25 and 36° with the values for phenanthrene it is seen that the constants at the two temperatures are roughly parallel for the pairs of isomers except in the case of the two alkyl compounds. It is quite interesting that halogen substituents fall into line with the typically meta-directing carboxylate groups in decreasing the free energy of the bromine-addition, while an alkyl group has just the opposite effect. This relationship is exactly that found for the effect of groups of these three types on the oxido-reduction potentials of quinone-hydroquinone systems,[7] and it is of interest to compare the reactions:



(1)

$-\Delta F_{25°}$ = 3220 cal.



(2)

$-\Delta F_{25°}$ = 21,736 cal.[8]

As applied to the oxidation of a hydroquinone (Reaction 2), a rule previously stated[7] in terms of potentials may be phrased as follows: groups which facilitate substitution in the benzene ring increase the free energy of oxidation, while those which retard benzene-substitution, including meta-directing groups and halogen atoms, have the opposite influence. It is clear from the present re-

(6) Haworth, Letsky and Mavin, *J. Chem. Soc.*, 1784 (1932).

(7) Fieser and Fieser, THIS JOURNAL, **57**, 491 (1935).

(8) From the normal potential in 95% alcoholic solution, Fieser, *ibid.*, **51**, 3101 (1929).

sults that the rule applies equally well to Reaction 1. In each case the reaction involves the conversion of the central, benzenoid ring into a dihydrobenzenoid nucleus, and substituents in a terminal ring exert similar influences in the two processes. The free energy change in the bromine-addition is much less than in the oxidation, but a substituent has nearly the same proportionate influence in each case, as can be seen from the comparisons given in Table II. Although the effect of a 3-*ter*.-butyl group on the free energy of oxidation is not known, it can be inferred from other data[7,8] that such a group probably would increase the free energy change to about twice the extent that a bromine atom decreases it. This again corresponds to the findings regarding Reaction 1.

TABLE II

EFFECT OF SUBSTITUENTS IN CALORIES ON $-\Delta F$

Substituent	Reaction 1	Reaction 2
3-Bromo	230 (7.1%)	1292 (5.9%)
3-Carbomethoxy	340 (10.0%)	2677 (12.3%)

With regard to the effect of the position of the substituent in the phenanthrene nucleus, it has been observed[8] in the case of Reaction 2 that the effect of a group in either the positive or negative direction is greater when it is situated in the 3-position para to the 10-hydroxyl group than when it is located at the meta position 2. The present results are hardly extensive enough to show whether or not this is true also of Reaction 1. With the halogen compounds the differences in the values of $-\Delta F$ for the isomers are too slight to be significant. The ester groups are invariably more effective in the 3-position, and the differences are quite noticeable. Considering the free energy changes at 25°, the same relationship holds for the *ter*.-butyl group, but in this case there is a curious reversal at the higher temperature and more data will be required to establish the analogy.

Comparing the rate constants for the bromine-addition to the substituted phenanthrenes (Table I), it may be said that there is no striking deviation from the behavior of phenanthrene, and no significant difference between isomers, except in the case of the halogen compounds. A halogen atom at either the 2- or 3-position definitely retards the addition reaction, and there is a decided difference between the isomers. The rate constants for 2-bromo- and 2-chlorophenanthrene are only about one-fortieth as great as the constants for the 3-isomers. Considering that the 2-position is meta to one of the unsaturated carbon atoms concerned in the addition reaction while a 3-substituent occupies a para position with respect to this group, it may be said that halogen is somewhat inhibitory to the addition of bromine in any event but that it exerts a pronounced and specific inhibiting influence when in the meta (2-) position. This suggests a possible explanation of the peculiar fact that halogen atoms stabilize the benzene ring like the common meta-directing groups but nevertheless direct substituents into the ortho–para positions. In the present study halogen is classed with the meta-type groups with respect to its effect on the equilibrium (stabilizing effect) but is found to differ from other groups in specifically decreasing the rate of a reaction at a center with respect to which it occupies the meta position.

Experimental Part[9]

The phenanthroic esters were prepared according to Mosettig and van de Kamp[3] and the melting points were as follows: 2-methyl 95–96°, 2-ethyl 72.5–73.5°, 3-methyl 93.5–94.5°, 3-ethyl 55–56°. Incidentally, 3-acetophenanthrene on purification through the picrate was found to melt at 73.5–74.5°; picrate, m. p. 123–125°. In the hypochlorite oxidation of the acetophenanthrenes the time of reaction was shortened greatly by providing vigorous mechanical stirring. 3-Ethylphenanthrene[3] was purified through the picrate, m. p. 120–122°, and distilled. The halophenanthrenes employed had the following melting points: 2-chloro 86.5–87.5°, 2-bromo 97–98°, 3-chloro 82–83°, 3-bromo 82–83°. In view of the announcement of Bachmann and Boatner[4] the preparations and analyses will be omitted, but it may be noted that 2-acetophenanthrene-oxime (m. p. 193–195°, crystallized with excess hydroxylamine) and the 3-isomer were obtained in 83–95% yield, rearranged with phosphorus pentachloride in dry ether and converted to the phenanthrylamine hydrochlorides in about 70% yield. The Sandmeyer reaction proceeded best (45% yield) when the diazonium salt was added to the boiling cuprous halide solution.

2-Phenanthryldimethyl carbinol was prepared by adding a solution of 2-acetophenanthrene in benzene to an ethereal solution of methylmagnesium iodide and refluxing. On allowing a solution of the crude product (80% yield) in petroleum ether to evaporate at room temperature the substance was deposited as long silky needles, m. p. 90–92°, dec., and as cubes, m. p. 97–99°, dec.

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.44; H, 6.95. Found: (needles) C, 86.66; H, 6.85; (cubes) C, 86.12; H, 6.94.

3-Phenanthryldimethyl carbinol was obtained, after purification through the picrate, as an oil which crystallized from petroleum ether in a bath of solid carbon dioxide and alcohol but melted again at room temperature. The

picrate separated from methyl alcohol as bright orange crystals, m. p. 107–110°, dec.

Anal. Calcd. for $C_{17}H_{16}O \cdot C_6H_3O_7N_3$: C, 59.32; H, 4.13. Found: C, 59.50; H, 4.11.

On recrystallization from alcohol the melting point rose eventually to 160–163°, dec., and apparently dehydration had occurred giving 3-isopropenylphenanthrene picrate (calcd. C, 61.7; H, 3.8. Found: C, 62.5; H, 3.7).

Synthesis of 3-*ter*.-Butylphenanthrene

β-(*p-ter*.-Butylbenzoyl)-propionic Acid (I).—*ter*.-Butylbenzene (17 g.) was added slowly to a mixture of succinic anhydride (13 g.), aluminum chloride (36 g.), and carbon bisulfide (100 cc.), and after refluxing for one hour the mixture was cooled and decomposed with ice and hydrochloric acid. After removing the solvent with steam the product solidified (20 g.) and on crystallization from 50% acetic acid it was obtained as colorless crystals, m. p. 121–122°; yield 16.5 g. (55%). The substance crystallizes from dilute alcohol as lustrous plates and from benzene–ligroin as large cubes; both forms melt at 121–122°.

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.75; H, 7.73. Found: C, 71.46; H, 7.30.

The acid was converted by oxidation with potassium hypochlorite into *p-ter*.-butylbenzoic acid, m. p. 165–166°, corr., and this with dilute nitric acid gave terephthalic acid, identified as the dimethyl ester, m. p. 140.5–141°, corr., by comparison with an authentic sample.

γ-(*p-ter*.-Butylphenyl)-butyric acid was obtained in 72% yield from the keto acid by Martin's modification[10] of the Clemmensen method as already reported.[10] After refluxing for fifteen hours the product was collected and dried in ether and distilled, b. p. 164–167° (5 mm.), m. p. 57–60°. Recrystallized from petroleum ether the acid formed small crystals, m. p. 59.5–60.5°.

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.30; H, 9.17. Found: C, 76.30; H, 9.04.

The **ethyl ester** was conveniently prepared by distilling off the toluene at the end of the reduction, extracting with ether, esterifying the crude acid with absolute alcohol and hydrogen chloride, and distilling the ester. It was obtained as a colorless liquid, b. p. 145–147° (5 mm.), in 70% yield.

Anal. Calcd. for $C_{16}H_{24}O_2$: C, 77.41; H, 9.68. Found: C, 77.38; H, 10.19.

7-*ter*.-Butyl-Δ¹-dihydronaphthalene-1,2-dicarboxylic Anhydride (III).—Ethyl γ-(*p-ter*.-butylphenyl)-butyrate (63 g.) was condensed with ethyl oxalate in the presence of sodium ethylate by the procedure of Fieser and Hershberg[5a] and the crude oxalyl derivative (II), obtained as a light reddish oil after removal of the ether at diminished pressure, was cyclized by stirring a mixture of the oil with twenty parts by volume of 80% sulfuric acid at room temperature, heating the deep red solution to 60° and maintaining this temperature for ten minutes. The anhydride separated as a yellow solid which was collected after cooling on a sintered glass funnel and washed with fresh acid and with water. The yield of microcrystalline material was 55 g. (85%). Crystallized from benzene–ligroin the anhydride formed nearly colorless, flat needles, m. p. 143–145°.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.97; H, 6.28. Found: C, 75.36; H, 6.28.

The sulfuric acid liquor on standing deposited a second substance (0.8 g.) which after two crystallizations formed faintly yellow needles, m. p. 174–175°. The substance has the same composition as the chief reaction product (found: C, 75.19, 75.19; H, 6.33, 6.25) and it may arise from a small amount of an isomer present in the starting material.

7-*ter*.-Butylnaphthalene-1,2-dicarboxylic anhydride was obtained in good yield by heating the dihydro compound with the calculated amount of sulfur at 330–340° for one hour and distilling the product. Long, pale yellow needles, m. p. 146.5–147.5°, were obtained from benzene–ligroin.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.56; H, 5.55. Found: C, 75.71; H, 5.70.

6-*ter*.-Butyl-1,4,9,10,11,12-hexahydrophenanthrene-11,12-dicarboxylic anhydride (IV) was obtained by heating a mixture of 12.2 g. of the anhydride and 31.8 g. of butadiene at 150° for thirty-six hours. On distillation at 1 mm. pressure (bath at 240–260°) there was obtained 12.8 g. of colorless material which fluoresced bright blue in ultraviolet light. Crystallized from benzene–ligroin it formed stout, colorless needles, m. p. 85.5–86.5°; yield 10 g. (68%).

Anal. Calcd. for $C_{20}H_{22}O_3$: C, 77.36; H, 7.16. Found: C, 77.43; H, 7.20.

3-*ter*.-Butylphenanthrene.—The diene addition product (5 g.) was heated with 10 g. each of potassium hydroxide and water in the manner described,[5b] and after driving off the water the bath temperature was brought to 330–360°, when 2.5 g. (about 65%) of hydrocarbon collected as a colorless distillate (oil). A portion of the distillate (2.2 g.) was heated under nitrogen with 4 g. of selenium, added in portions, for thirty-six hours and the product was extracted with petroleum ether and vacuum distilled from a small bit of sodium. The pale yellow distillate soon solidified, m. p. 49–52°, yield 1.5 g. The hydrocarbon crystallized from alcohol as colorless, centimeter-long, prismatic needles fluorescing bright blue in ultraviolet light, m. p. 54–55°.

Anal. Calcd. for $C_{18}H_{18}$: C, 92.24; H, 7.76. Found: C, 92.30, 92.00; H, 7.55, 7.99.

The **picrate**, once recrystallized from alcohol, formed orange needles, m. p. 142–143°.

Anal. Calcd. for $C_{18}H_{18} \cdot C_6H_3O_7N_3$: C, 62.17; H, 4.58. Found: C, 61.79; H, 4.26.

The **quinone** was obtained by heating the hydrocarbon with chromic anhydride in acetic acid solution at 80–90° for one hour, the product separating as bright orange needles on cooling (77% yield). Recrystallized from alcohol it formed slender orange needles, m. p. 186–187°.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.78; H, 6.10. Found: C, 81.51; H, 6.15.

Synthesis of 2-*ter*.-Butylphenanthrene

β-*ter*.-Butylnaphthalene.—A mixture of 330 g. of naphthalene and 251 g. of *ter*.-butyl chloride was warmed at

---

[10] Martin, THIS JOURNAL, **58**, 1438 (1936).

50–60° until the solid had dissolved and 10 g. of aluminum chloride was added in small portions with stirring in about one and one-half hours. The reaction was largely over when about half of the aluminum chloride had been added. After a further half-hour of stirring the material was washed and dried in benzene and distilled. About 100 g. of naphthalene came over up to 140° (12 mm.) and the main product distilled at 119–135° (6 mm.). Redistillation gave 140 g. (30%) of β-*ter.*-butylnaphthalene as a colorless oil, b. p. 127–131° (9 mm.), picrate, m. p. 99.5–100.5°. The picrate of the hydrocarbon obtained by other methods is reported to melt at 102–103°[11] and at 96°.[12]

Di-*ter.*-**butylnaphthalenes.**—The combined higher-boiling fractions from the above preparation on redistillation gave 100 g. of a fraction boiling at 150–170° (10 mm.) and promptly solidifying. This apparently consisted largely of a mixture of the two di-*ter.*-butylnaphthalenes described by Gump,[13] and in a preliminary examination it was found that the higher-melting isomer can be isolated easily by two crystallizations from methyl alcohol: thick, lustrous plates, m. p. 146–147°. As this isomer does not form a picrate in alcoholic solution whereas the lower-melting hydrocarbon does, the latter can be isolated easily from the mother liquor or from the original mixture as the picrate. This picrate was obtained as beautiful orange needles, m. p. 155.5–156.5°, but it was not analyzed successfully. The hydrocarbon regenerated from the purified picrate formed fine cottony needles from alcohol; it melted unsharply at 86–90° but had the expected composition.

Anal. Calcd. for $C_{18}H_{24}$: C, 89.93; H, 10.07. Found: (146–147°) C, 90.14; H, 10.39; (86–90°) C, 90.17; H, 9.92.

A quinone was obtained by refluxing a solution of the higher-melting hydrocarbon in glacial acetic acid with chromic anhydride for twenty minutes. It was purified with Norite in ether solution and crystallized from alcohol; slender, bright yellow needles, m. p. 83.5–84.5°.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.22. Found: C, 79.98; H, 8.15.

β-(**6-*ter.*-Butylnaphthoyl-2)-propionic acid (VII)** was prepared by adding with stirring 140 g. of β-*ter.*-butylnaphthalene and 66 g. of succinic anhydride to a solution of 226 g. of aluminum chloride in 1.5 liters of nitrobenzene at 0°. After eight hours at 0° and one day at room temperature ice and hydrochloric acid were added and the solvent removed with steam. The dark brown mass remaining after decanting the aqueous liquor was treated with a small quantity of ether, as this dissolved a dark oil and left a fairly clean solid (92 g.). This was dissolved in glacial acetic acid and the solution was diluted with hot water until cloudy and treated with a liberal quantity of Norite. The filtered solution deposited glistening, colorless needles, m. p. 148–150°; total yield, 80 g. (37%).

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.07; H, 7.04. Found: C, 76.02; H, 7.11.

γ-(**6-*ter.*-Butylnaphthyl-2)-butyric Acid.**—The above keto acid was largely unchanged when submitted to reduction by the usual Clemmensen method or with added toluene (thirty hours) but, as already noted,[10] the reaction proceeded smoothly by Martin's method using toluene and a small amount of acetic acid, yield crude 78%. A portion of the acid was purified through the methyl ester, b. p. 185–187° (6 mm.), and after saponification crystallized from petroleum ether. It separated as long, slender needles which soon changed in part at least into short, stout needles. Apparently neither form was obtained as a pure individual, for the melting points were unsharp and varied from 87 to 95°.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.94; H, 8.22. Found: C, 79.86; H, 8.36.

7-*ter.*-Butyl-1-keto-1,2,3,4-tetrahydrophenanthrene.—The above acid (20 g.) was warmed gently with purified thionyl chloride and the mixture was then heated on the steam-bath and the excess reagent removed by water pump suction. The acid chloride was dissolved in 150 cc. of carbon bisulfide and treated at 0° with 14.7 g. of aluminum chloride. The mixture was allowed to come to room temperature, refluxed for fifteen minutes, and worked up as usual. After distillation the product (12 g., 65%) remained as a pale yellow, viscous oil, and it was characterized as the picrate, which formed yellow needles from alcohol, m. p. 107–108°.

Anal. Calcd. for $C_{18}H_{20}O\cdot C_6H_3O_7N_3$: C, 59.85; H, 4.82. Found: C, 59.75; H, 5.01.

2-*ter.*-Butylphenanthrene.—The cyclic ketone (3.6 g.) was reduced by refluxing for fifteen hours with 17 g. of amalgamated zinc, 35 cc. of constant boiling hydrochloric acid, and 4 cc. of toluene, and the crude product was heated at 320–350° with 9 g. of selenium, added in portions, for sixty hours. The resulting hydrocarbon was extracted with petroleum ether, distilled in vacuum from a small piece of sodium, and the solid distillate (1.5 g.) crystallized twice from alcohol (0.85 g.). The hydrocarbon formed colorless, pearly plates, m. p. 99–100°, showing a brilliant purple fluorescence in ultraviolet light.

Anal. Calcd. for $C_{18}H_{18}$: C, 92.24; H, 7.76. Found: C, 92.38; H, 7.71.

The **picrate** forms orange needles, m. p. 130–131°.

Anal. Calcd. for $C_{18}H_{18}\cdot C_6H_3O_7N_3$: C, 62.17; H, 4.58. Found: C, 62.29; H, 4.47.

The **quinone**, purified through the bisulfite addition product and crystallized from alcohol, formed bright orange needles, m. p. 129–130°.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.78; H, 6.10. Found: C, 81.62; H, 6.34.

Summary

Carboxylic ester groups and halogen atoms in the 2- and 3-positions of phenanthrene decrease the free energy of the 9,10-addition of bromine, while the *ter.*-butyl group has the opposite effect. The results parallel those obtained in the study of the free energy of oxidation of 9,10-phenanthrenehydroquinones and there is a correlation between the observed effects of the groups and their influence in retarding or facilitating sub-

Studies of the Reducing Action of Mercury. III. Hydrogen Peroxide Formation and the Copper-Catalyzed Autoxidation of Quinquivalent Molybdenum and Other Strong Reductants in Acid Solution

BY W. M. MURRAY, JR., AND N. HOWELL FURMAN

The first paper[1] of this series dealt with the formation of hydrogen peroxide when mercury and dilute hydrochloric acid are shaken in the presence of air. The second article[2] discussed the use of the mercury reductor in a new method for the determination of molybdenum and mention was made of the catalytic action of copper on the autoxidation of quinquivalent molybdenum.

It will be the object of this work to give data which show more clearly just what takes place in the mercury reductor when heavy metal ions are present and how it is possible to use the mercury reductor as an analytical tool even though the formation of hydrogen peroxide in the reductor is possible. Also, the question of the autoxidation of quinquivalent molybdenum solutions and the copper catalysis of this and of the analogous autoxidations of stannous, titanous and uranous solutions will be discussed more fully.

Hydrogen Peroxide in the Mercury Reductor.—Some of the work on the action of metallic mercury as a reducing agent was done by Schaffhaütl[3] and Carnegie,[4] although neither of these investigators undertook the subject from a quantitative standpoint. Later Borar[5] studied the stoichiometry of the reaction between mercury and potassium permanganate, potassium dichromate, ferric chloride and cupric sulfate.

McCay and Anderson[6] proposed the mercury reductor for use in the quantitative determination of ferric salts, and later they[7] studied the reduction of vanadic acid solutions by mercury. Finally, McCay[8] worked on the reduction of antimonic acid solutions by mercury as a quantitative method for determining antimony.

At present, then, mercury reduction has been proposed as a quantitative and efficient method for the determination of iron, vanadium, antimony and molybdenum. The reduction by mercury of solutions of these elements is always carried out in the presence of hydrochloric acid. It appears rather paradoxical that mercury can be used for the quantitative reduction of the above substances when we recall that mercury and hydrochloric acid will react rapidly with oxygen to form large amounts of hydrogen peroxide. The explanation of this seems to be largely a matter of competing rates, except in the case of antimony.

Solutions of iron, molybdenum, and vanadium salts are known to be good catalysts for the decomposition of hydrogen peroxide. It is then evident that if we shake a mixture of mercury and hydrochloric acid in the presence of oxygen and add small amounts of iron, vanadium or molybdenum salts to the mixture, the hydrogen peroxide should be decomposed catalytically by the heavy metal ions present. There would in such a case be two competing reactions: (a) the formation of hydrogen peroxide in the reaction between mercury, hydrochloric acid, and oxygen; (b) the catalytic decomposition of the hydrogen peroxide by the heavy metal ion. If reaction (a) is faster than reaction (b) we will be able to detect hydrogen peroxide in the mixture, but if step (a) is the slow one, then all the peroxide will be decomposed and will not be evident in the solution. However, the rate of reaction (b) will depend to some extent on the concentration of the heavy metal ion and the rate of its reduction by mercury since the decomposition of hydrogen peroxide by these ions is very probably an alternate oxidation and reduc-

tion of the ion as shown in the study of Haber and Weiss.[9]

To test these conclusions in a series of experiments, 25-ml. portions of mercury and 50 ml. of *N* hydrochloric acid were shaken with oxygen supplied from a buret for 150 minutes. The apparatus and technique were the same as in the previous study.[1]

In one pair of experiments 111 ml. of oxygen was consumed without any addition and 118 ml. when 5 mg. of vanadium was added as vanadic acid. A second pair gave 105 ml. without addition and 136 ml. with the addition of 0.5 mg. of iron as ferric chloride, while a third pair used 116 ml. of oxygen without addition and 163 ml. with the addition of 80 mg. of iron as ferric chloride. The effect of vanadium is negligible or very slight, while the iron perceptibly catalyzes the reaction.

The point of interest is the substances found in the solutions which contained iron and vanadium. In the cases where iron was present in amounts less than 0.005 g., hydrogen peroxide was detected with titanium sulfate, and the iron was found to be largely in the ferric state. In those cases where vanadium was present in amounts less than 0.005 g., the solution was of a deep red color which indicates the presence of pervanadic acid and hydrogen peroxide rather than the reduced vanadyl solution which is blue in color.

No experiments along this line were performed with molybdenum in the mercury reductor, for the quinquivalent molybdenum interferes with most of the color reactions given by hydrogen peroxide. However, it is assumed by analogy that molybdenum would behave quite similarly to iron and vanadium.

The case of antimony is different. McCay[8] found it necessary to carry out the reduction of antimony in an atmosphere of carbon dioxide, and this at once eliminates any interference from the hydrogen peroxide reaction. We have carried out experiments which show that even if very large samples (0.3 g.) of antimonic acid in 2 *N* hydrochloric acid are shaken with mercury in the presence of air, hydrogen peroxide is formed rapidly in large amounts.

Conclusions.—From the foregoing it is to be concluded that large samples (*ca.* 0.1 g.) of iron, vanadium or molybdenum decompose hydrogen peroxide as fast as it is formed in the mercury reductor and the mercury keeps these metal ions in the reduced state. However, when only very small samples (*ca* 0.005 g.) of these substances are taken, the mercury reduction method will not be reliable unless all oxygen is excluded. This means then that the mercury reductor would not be a practical tool for micro-analytical methods unless used in the absence of oxygen. This is in accord with the work of C. F. Fryling and F. V. Tooley,[10] who have found that the silver reductor yields large quantities of hydrogen peroxide when microsamples of iron are employed.

We determined the molybdenum in the Bureau of Standards Calcium Molybdate, which is certified to contain 35.3% of molybdenum by the accepted Jones reductor method and by gravimetric technique. Using samples varying between 0.4 and 1.0 g. we obtained, by the mercury reduction method, respectively, 34.65, 34.80, 34.43, 33.90 and 33.74%, with an average of 34.3%. Iron and titanium were removed prior to the reduction of the solution by mercury.[11] We detected copper in the solution at this point. Electrolytic and colorimetric estimations of the copper gave 0.05, 0.06, 0.04, 0.06 and 0.07%, average 0.05%. The presence of copper is not mentioned on the certificate of analysis.

We believe that this error in the value for molybdenum is caused by the copper which is in the solution at the time it is reduced by mercury. When the quinquivalent molybdenum solution from the mercury reductor is filtered in the presence of air, the traces of cuprous ion present are oxidized by the air and hydrogen peroxide is formed. The hydrogen peroxide then oxidizes some of the quinquivalent molybdenum, which causes the results to be low.

The formation of the hydrogen peroxide in the reaction between cuprous solutions and molecular oxygen has been studied many times since the original observation of Traube.[12] Our idea is then that we have a cyclic reaction in which hydrogen peroxide oxidizes the quinquivalent molybdenum. It will be shown presently that under certain conditions quinquivalent molybdenum is able to reduce cupric ions to the cuprous state and this makes it possible for the cycle to continue, oxidizing more quinquivalent molybdenum in each step. Such a cycle might be pictured as follows:

---

[9] Haber and Weiss, *Proc. Roy. Soc.* (London), **147A**, 332 (1934).

[10] Fryling and Tooley, THIS JOURNAL, **58**, 826 (1936).

[11] The standard procedure of double precipitation by ammonia was used according to Lundell, Hoffman and Bright, "Chemical Analysis of Iron and Steel," John Wiley & Sons, Inc., New York, 1932.

[12] Traube, *Ber.*, **15**, 659 (1882).

$$Cu^2 + Mo^5 = Cu^1 + Mo^6 \qquad (1)$$
$$2H^+ + 2Cu^1 + O_2 = 2Cu^2 + H_2O_2 \qquad (2)$$
$$2H^+ + 2Mo^5 + H_2O_2 = 2Mo^6 + 2H_2O \qquad (3)$$

With such a cyclic mechanism in mind, we have studied many conditions under which the autoxidation of the molybdenum solutions is apparently catalyzed by copper and all of the results of these experiments seem to verify the mechanism which we have postulated.

Experimental Studies on the Copper-Catalyzed Autoxidation of Quinquivalent Molybdenum Solutions.—First, in order to show that it is actually copper which causes the error in the determination of molybdenum by mercury reduction, we studied the effect of traces of copper sulfate on the determination of molybdenum in a standard ammonium molybdate solution. The ammonium molybdate solution was standardized by the silver molybdate method.[13] Copper was added in the form of a very dilute cupric sulfate solution. Total volume of solution at time of shaking was 30 ml. Hydrochloric acid concentration at time of shaking was 3 *N*.

TABLE I

EFFECT OF COPPER ON THE DETERMINATION OF MOLYBDENUM IN A STANDARD MOLYBDATE SOLUTION BY THE MERCURY REDUCTION METHOD

Copper added, mg.	0	0	0.1	0.4	0.7	1.1
Error, mg.	−0.2	+0.1	− .7	−1.1	−1.4	−1.7

If the mechanism for the autoxidation of the quinquivalent molybdenum is as indicated in equations (1), (2) and (3) the oxidation by air must take place while the solution is being filtered. This being the case, the volume of solution which passes through the funnel should have some effect on the amount of molybdenum oxidized. This was studied by taking equal samples of the ammonium molybdate solution and adding the same amount of cupric sulfate to each, then diluting the samples with 3 *N* hydrochloric acid to varying volumes before shaking with mercury. The results of this volume effect on the amount of molybdenum oxidized are shown in Table II.

TABLE II

DEPENDENCE OF COPPER AUTOXIDATION EFFECT ON VOLUME OF THE SOLUTION AT THE TIME OF FILTRATION

Copper added, g.	Total volume at time of filtering, ml.	Molybdenum Found, g.	Molybdenum Taken, g.	Error, mg.
....	30	0.2495	0.2494	+0.1
0.0005	30	.2483	.2494	−1.1
....	80	.2496	.2494	+0.2
.0005	80	.2463	.2494	−3.1
....	140	.2492	.2494	−0.2
.0005	140	.2450	.2494	−4.4

In all the experiments of Table II the copper was present at the time of reduction of the molybdenum with mercury. In order to study more fully the actual effect of the copper, we prepared a large quantity of quinquivalent molybdenum by reducing a concentrated molybdic acid solution with mercury. This reduced solution was then diluted with water and acid to yield a solution which was 0.1 *M* in molybdenum content and 2 *N* in hydrochloric acid. The solution was stored in a closed buret system under carbon dioxide and its normality with respect to the Mo^5—Mo^6 change was checked each day. Samples of this quinquivalent molybdenum solution were run into flasks, varying amounts of cuprous or cupric solutions added, then air bubbled through the mixture for a given length of time. In this way it was possible to change the copper and acid concentrations readily and also vary the time of contact of the solution with air.

The data of Table III were taken from a series of experiments run in this way, the rate of air bubbling being relatively constant throughout. These experiments prove definitely that copper is acting as a catalyst for the autoxidation of the quinquivalent molybdenum for here we are only bubbling air through a mixture of quinquivalent molybdenum and traces of copper. The HCl concentration was 1 *N* in all cases, total volume of solution being 150 ml.

TABLE III

EFFECT OF CUPRIC AND CUPROUS IONS UPON THE OXIDATION OF QUINQUIVALENT MOLYBDENUM SOLUTIONS BY AIR

Time of air bubbling, min.	Copper added, mg.	Error, mg.
15	...	+0.1
15	0.5 Cu^{++}	−1.1
15	1.0 Cu^{++}	−2.6

If the cyclic mechanism which we have postulated for the copper-catalyzed autoxidation of quinquivalent molybdenum is to be feasible, it must be shown that the first step as indicated by

---

[13] McCay, THIS JOURNAL, **56**, 2548 (1934).

equation (1) is possible. This step involves the formation of cuprous ions from the reaction between cupric ions and quinquivalent molybdenum and is the starting point of the cycle. The graph of Fig. 1 shows the potentials of the two systems Mo^6/Mo^5 and Cu^2/Cu^1 plotted against acidity. The data for the copper system were taken from the work of Carter and Lea[14] and the data for the molybdenum system from the work of Foerster, Fricke and Hausswald.[15] These curves are for the equivalent mixtures of Mo^6/Mo^5 and Cu^2/Cu^1. If we consider the potentials of pure cupric solutions and pure quinquivalent molybdenum solutions, we must take into account the logarithmic concentration term in the equation

$$E = E_0 + \frac{0.059}{n} \log \frac{(\mathrm{Ox})}{(\mathrm{Red})} \qquad (4)$$

If we consider the ratio of (Ox)/(Red) as being of the order of $^1/_{1000}$ in the case of quinquivalent molybdenum and $^{1000}/_1$ in the case of cupric solution, then the concentration term will lower the molybdenum potential by 0.17 volt and raise the copper potential by 0.17 volt. This will then place the molybdenum potential more than 0.2 volt below that of the copper system. Under these conditions, quinquivalent molybdenum would readily reduce cupric ions in 1 N hydrochloric acid. However, this could not proceed for very long, for the molybdenum potential is rising and the copper potential dropping as the reaction proceeds.

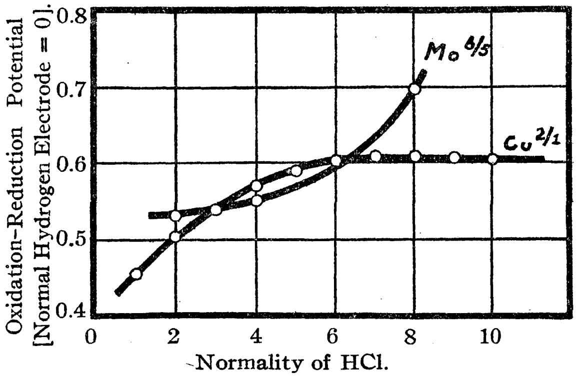

Fig 1.—Graphs of oxidation-reduction potentials of $Mo^{6/5}$ (25°) and Cu $^{2/1}$ (18°) systems as functions of acidity.

A portion of a freshly prepared quinquivalent molybdenum solution was mixed with a solution of cupric sulfate and the mixture adjusted to 1 N concentration of hydrochloric acid. A few ml. of potassium thiocyanate solution was then added. The mixture turned dark red in color due to the formation of the complex between the thiocyanate ion and quinquivalent molybdenum, but a heavy white precipitate was formed at the same time. This precipitate was filtered off and proved to be cuprous thiocyanate. This is therefore experimental proof that quinquivalent molybdenum can reduce cupric ions to the cuprous state in 1 N hydrochloric acid.

It is further evident from Fig. 1 that at an acid concentration of about 5 N the potential of the equilibrium mixture of Mo^6/Mo^5 is always below that of the Cu^2/Cu^1 system. This would suggest that in 5 N hydrochloric acid quinquivalent molybdenum should be rapidly and continuously autoxidized in the presence of traces of copper, since at this acidity the molybdenum will keep more of the copper reduced. The results of such an experiment are given in Table IV.

TABLE IV

Conclusions.—The data presented seem to verify our ideas of a cyclic autoxidation mechanism for quinquivalent molybdenum in which cuprous ions play the important role of first reacting with atmospheric oxygen to yield hydrogen peroxide. Such a reaction accounts for the difficulties in the determination of molybdenum by the mercury reduction method when small amounts of copper are present. Although it was not easily possible to detect hydrogen peroxide as an intermediate in this case, several instances are discussed in the next section which are quite analogous to this and in which hydrogen peroxide is readily detected.

Copper-Catalyzed Autoxidation of Reducing Substances in Acid Solution.—The autoxidation of cuprous ions in hydrochloric acid solution has been studied by Wieland and Franke,[16] Filson and Walton,[17] and others. Hydrogen peroxide is formed in this reaction in large amounts and no salt has been found so far which speeds up the autoxidation of the cuprous ion. Wieland

[17] Filson and Walton, *J. Phys. Chem.*, **36**, 740 (1932).

and Franke point out the fact that it is only in acid solution that hydrogen peroxide is formed during the autoxidation of the cuprous ion.

With these facts in view, we think that it may be said that the copper-catalyzed autoxidation of reducing substances in acid solutions possibly proceeds in most cases by a cyclic mechanism similar to that which we have postulated for the autoxidation of quinquivalent molybdenum.

Filson and Walton[17] and Haring and Walton[18] found copper salts to be excellent catalysts in the autoxidation of stannous chloride solutions and even detected hydrogen peroxide in the non-catalyzed reaction. The equations which they gave for the catalyzed reaction were

$$2CuCl_2 + SnCl_2 = 2CuCl + SnCl_4 \qquad (4)$$

$$4CuCl + 4HCl + O_2 = 4CuCl_2 + 2H_2O \qquad (5)$$

It is possible that equation (5) involves hydrogen peroxide as an intermediate according to our reasoning.

The copper-catalyzed autoxidation of ascorbic acid has been studied by Barron, De Meio and Klemperer[19] who found that in acid solution the reaction is dependent both on *p*H and copper concentration. They write a mechanism which is analogous to that postulated here and which includes hydrogen peroxide as an intermediate.

Luther and Michie[20] found that the rate of autoxidation of quadrivalent uranium solutions containing small amounts of sulfuric acid was increased markedly by the addition of traces of copper. This reaction was not thoroughly studied but it appears to be another case in which the cyclic mechanism involving hydrogen peroxide would apply.

We have studied qualitatively the effect of small amounts of copper on the rate of autoxidation of titanous chloride solutions which contained hydrochloric acid. The rate was increased greatly by the addition of cupric sulfate and when the red color of the titanous salt had disappeared, the solution rapidly became yellow, which was indicative of the presence of hydrogen peroxide.

Conclusions.—In all the cases cited a reducing agent capable of reducing cupric ions to the cuprous state has been employed. In this way a system is set up in which cuprous ions are available for autoxidation and with an excess of oxygen the cycle may proceed until either all the reducing agent has been oxidized or its potential has been raised so high that it can no longer furnish cuprous ions. From these facts and the instances in which hydrogen peroxide has been actually detected in such reactions, we think it probable that in general a cyclic reaction such as indicated in equations (1), (2) and (3) is the mechanism. This is not to be confused with the frequently studied chain reactions such as the sulfite oxidation which take place in nearly neutral or alkaline solution.

Summary

1. The mercury reductor gives satisfactory results when used for the determination of iron, vanadium and molybdenum on a macro scale, for these ions catalytically decompose any hydrogen peroxide formed. It could be used for microdeterminations only when oxygen was rigorously excluded. In the macro-determination of antimony, oxygen must be excluded because the hydrogen peroxide that is formed is not decomposed catalytically by the antimonite.

2. Quinquivalent molybdenum is rapidly autoxidized when small amounts of copper are present as catalyst. A mechanism for this reaction has been postulated which involves hydrogen peroxide as intermediate.

3. It is believed that the cyclic mechanism postulated will apply to most copper-catalyzed autoxidations which take place in acid solution as, for example, those of titanous, stannous and uranous ions.

Thermodynamic Properties of Fused Salt Solution. IX. Lithium Chloride in Silver Chloride

BY EDWARD J. SALSTROM, THEODORE J. KEW AND THOMAS M. POWELL

The following is a continuation of the general program of investigating fused salts and their solutions.

The apparatus and details of procedure have been described previously.[1]

The silver chloride and lithium chloride used in the cells were of the highest purity obtainable commercially. A pure silver wire inserted through a glass tube in the bottom of the cell container served as the negative electrode. The positive electrode was created by bubbling chlorine gas over a treated graphite rod. This treatment consisted of heating the graphite rod at 600° for twenty-four hours in chlorine gas at several atmospheres pressure. Just before using the rod as an electrode it was heated to a bright yellow heat to free it from all volatile products. The chlorine gas for the electrode was obtained by electrolysis of fused lead chloride of highest purity. The fused chlorides of silver and lithium in the cells and of lead in the chlorine generator were freed from all traces of moisture and oxides by bubbling dry hydrogen chloride gas through the filled containers for not less than an hour.

Other investigators, notably Lorenz and coworkers,[2] Hildebrand and Ruhle,[3] and Wachter and Hildebrand,[4] have worked with the chlorine electrode in fused salts. With the exception of the latter work, all previous attempts involved polarization methods and hence uncertainties.

As in previous studies these cells involved thermoelectric effects of from four to seven millivolts due to the temperature gradient existing at each electrode. The results of the e. m. f. measurements upon the cells plus these thermal corrections are given in Table I, and are shown graphically in Fig. 1. The mean deviation of the points from the straight lines drawn through them is less than 0.2 millivolt, while the maximum deviation is about three times this value.

To obtain the relations of free energy to composition at 500 and 600°, the data in Table I were plotted on a large scale and the e. m. f. values at these temperatures determined. These values of the e. m. f. are given under **E** in Table II, together

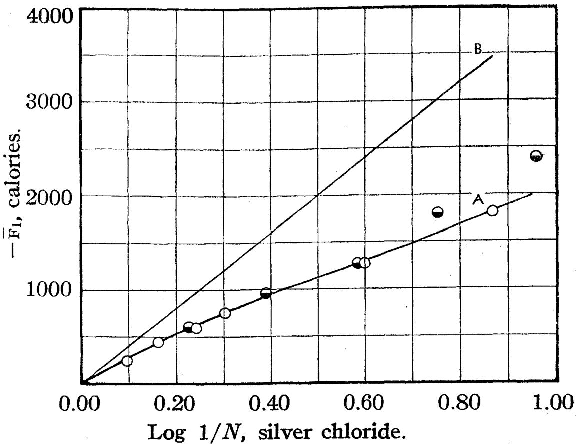

Fig. 2.—Change in free energy of silver chloride at 600° upon dilution with lithium chloride. Curve A shows the observed values, while B is that for a perfect solution. The shaded circles show the values previously obtained for the silver bromide–lithium bromide system.

Table II contains these calculated values while Fig. 2, curve A shows the partial molal free energy $-\bar{F}_1$, at 600° plotted against log $1/N_1$, where N_1 is the mole fraction of silver chloride. Curve B is that of a perfect solution where $a_1 = N_1$. Assumptions of no ionization or of complete ionization of both salts make no difference in the curve predicted by Raoult's law since in either case $a_1 = N_1$ and curve B results. There is then a marked positive deviation of the results from ideal behavior *i. e.*, in the direction of unmixing. This is in close agreement with the values previously obtained for the dilution of silver bromide by lithium bromide, shown in Fig. 2 by shaded circles except in the case of the highest concentration of added lithium chloride[1] (p. 4650).

A previous treatment of the deviations from ideality of solutions of silver bromide with alkali bromides[5] based upon Hildebrand's definition of regular solutions[6] thus holds equally well for this system. The excess of the partial molal free energy, $\bar{F}_1$, over the ideal, $\bar{F}_1^i$, given by $\bar{F}_1 - \bar{F}_1^i = RT \ln \gamma_1$, fits fairly well the relation, $\bar{F}_1 - \bar{F}_1^i = bN_2^2$, where N_2 is the mole fraction of lithium chloride, and the value of b in calories is 2100 compared to 1880 for the silver bromide-lithium bromide system. That b is practically independent of temperature is shown readily in Table III.

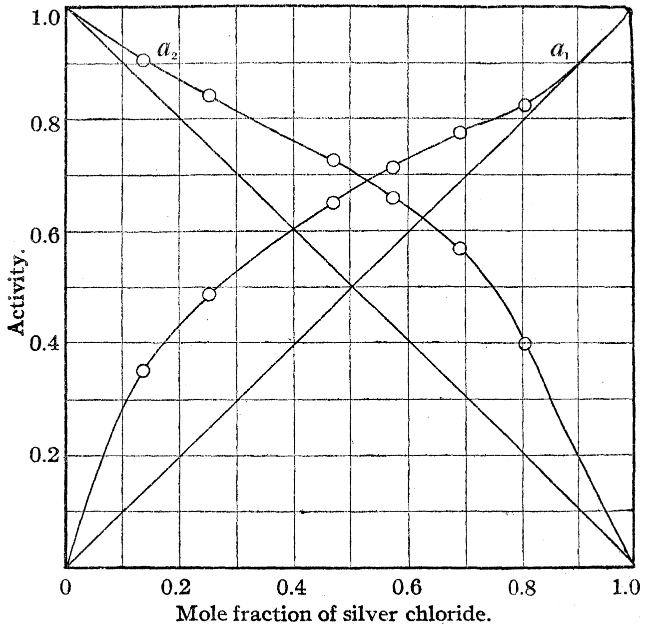

Fig. 3.—Relations of the activities of silver chloride, a_1, and lithium chloride, a_2, to their compositions at 600°.

TABLE III

N_1	1.000	0.804	0.690	0.573	0.469	0.252	0.136
$RT \ln \gamma_1$ at 500°	0	140	210	360	590	1140	1630
$RT \ln \gamma_1$ at 600°	0	140	200	380	560	1140	1650
bN_2^2	0	80	200	380	670	1170	1560

From this it may be concluded that the partial molal entropy is the same as it would be in an ideal solution, *i. e.*, $\bar{S}_1 = R \ln N_1$, indicating that the randomness of arrangement is the same in both cases. The bond between lithium and chloride ions may thus as before be regarded as being completely polar, while that between silver and chloride ions as tending to tighten into a non-polar bond, this tendency being hindered most by the presence of a small ion such as lithium, without in any case altering the simple cubic lattice arrangement which may probably be assumed to persist into the liquid state.

The activities and activity coefficients of the solute, lithium chloride, have been obtained by integrating graphically the equation given by the Duhem relationship

$$\log a_2/N_2 = -\int_0^{N_2} N_1/N_2 \; d \log a_1/N_1$$

In performing this integration the difficulty is encountered that N_1/N_2 rapidly approaches infinity as $\log a_1/N_1$ approaches zero. However, no change in the ratio between any two values of a_2/N_2 will be produced regardless of what method of extrapolation may be used. It thus becomes more convenient to calculate the activity of the solute by choosing the standard state of lithium chloride as the pure salt rather than the customary standard of infinite dilution. The partial molal free energy of lithium chloride was also obtained from its activity by use of the equation, $\bar{F}_2 = RT \ln a_2$. These values are given in Table IV while Fig. 3 shows the activities of silver chloride and lithium chloride plotted against the mole fraction of silver chloride at 600°.

TABLE IV

Summary

E. m. f. measurements of the cells, Ag (s), Ag Cl in LiCl (l), Cl_2 (g), have been made at mole fractions of silver chloride varying between 1.000 and 0.136 from temperatures of 500 to 635°.

Calculations of the activity, activity coefficient, free energy of formation and of dilution, entropy, and heat of formation of silver chloride have been made at 500 and 600°.

The activity, activity coefficient, and partial molal free energy of lithium chloride have been evaluated from the Duhem relationships.

A marked positive deviation of the activities of the salts in the solutions from ideality was found and has been discussed briefly.

The Surface Tension of Aqueous Solutions of Dipolar Ions

BY J. R. PAPPENHEIMER, M. P. LEPIE AND JEFFRIES WYMAN, JR.

I. Problem

It is a commonplace that the surface tension of aqueous solutions of practically all organic compounds is less than that of water, though a curious exception is afforded by certain sugars.[1,2] It was long ago pointed out by Traube[3] that the lowering of surface tension associated with a given molar concentration of the solute increases in a regular way with the number of carbon atoms in the members of a homologous series. On the other hand, the surface tension of solutions of inorganic salts, and indeed of most strong inorganic electrolytes, is greater than that of the solvent. This means of course, in accordance with Gibbs' theorem, that these ions, in contrast to the organic compounds, are negatively adsorbed at the liquid surface.[4]

Now there is a class of organic molecules, most familiarly represented by the amino acids, which exist in solution preponderantly as dipolar ions, or zwitter ions.[5] These dipolar ions are exceptional above all for their extremely large electric moments, which are the basis of much of their behavior. Although they bear no net charge they have affinities with strong electrolytes. In regard to their structure and phenomena associated with solubility, they are susceptible to treatment in accordance with the concepts of the Debye–Hückel theory for strong electrolytes, with some modifications.[6,7] Thus their partial free energy in dilute solution may be shown to be proportional to the first power, and not the square root, of the ionic strength of the medium, as for ordinary ions.[6,7] Clearly these dipolar ions are of interest in the matter of surface tension. This is especially true of the aliphatic amino acids, which, as organic compounds, belong to a well-defined homologous series, while at the same time they are ions of an exceptional class, owing to their zero net charge and extremely large electric moments. By suitable choice from members of this group it is possible on the one hand to try the effect of varying the electric moment without altering the molecule in any other way, as for example when we pass from an α- to a β-form, or on the other hand, keeping the moment constant, to alter the length of the hydrocarbon chain.

There appear to be but two studies in the literature dealing with this question. Jones and Lewis,[8] by means of Sugden's bubble pressure method, showed that the surface tension of aqueous solutions of glycine was somewhat greater than that of pure water and that the surface tension passed through a slight maximum between a *p*H of 4 and 7. Unfortunately their results are only presented in the form of a small scale graph. Errera and Milliau[9] also report that the surface tension of glycine solutions is slightly greater (about 1%) than that of water, but they say that solutions of leucine, alanine, aspartic acid and asparagine are indistinguishable from water. They give no figures. The present paper contains the results of measurements of the surface tension of aqueous solutions of seven amino acids of varying size and moment, and of one other substance, glycine betaine, which is known to be a zwitter ion.

II. Materials and Methods

The amino acids were all obtained from the Laboratory of Physical Chemistry of the Harvard Medical School and all had been purified by recrystallization before measurements were made. Recrystallization of α-aminocaproic acid and β-alanine was especially necessary in order to obtain reproducible results. The betaine was the same preparation, several times recrystallized, which was previously studied by Edsall and Wyman.[10] The importance of careful purification of materials in these studies is very great, since

[3] Traube, *Ann.*, **265**, 27 (1891).

[4] Onsager and Samara, *J. Chem. Phys.*, **2**, 528 (1934), have recently developed a theory first put forward by Wagner, *Physik. Z.*, **25**, 474 (1924), to account for this behavior. In its bare outline the theory is based on the Gibbs adsorption theorem and on the unequal distribution of ions between the interior and the surface of the liquid, calculated, in accordance with Debye's treatment of strong electrolytes, taking account of ionic atmospheres and image charges at the air–liquid interface, from the difference of potential energy between an ion at the surface and one in the interior. Whether or not it is correct in detail, this theory accounts for the increase of surface tension and points to a general method of attack on the problem of the surface tension of strong electrolytes.

minute traces of surface active impurities may have appreciable effects.

After a preliminary trial with Sugden's method it was decided to use the drop weight method as being simpler and giving more reproducible results.[11] The surface tension of the solutions was calculated from the weights of the drops of solution and of water falling from a given tip by means of the equation

$$\gamma = \frac{w}{w_0}\frac{\psi_0}{\psi}\gamma_0$$

in which γ denotes surface tension, w the weight of a single drop, ψ the corresponding correction factor as given by Harkins and Brown, and the subscript $_0$ refers to water. The surface tension of water was taken as 71.97 at 25°. For any particular case the value of ψ is determined by the ratio of the radius of the tip to the cube root of the volume of the drop, and in order to determine ψ it is therefore necessary to know the density of the liquid. The densities used in the calculation of the values of the surface tension given below were taken directly from the data given by Wyman and McMeekin[12] in the case of glycine and α-aminobutyric acid and were calculated from the partial molal volumes in the other cases—for betaine from the volume given by Edsall and Wyman;[10] otherwise from the figures of Cohn, McMeekin, Edsall and Blanchard.[13] In calculating the density of the solutions of ϵ-aminocaproic acid studied over a wide range of *p*H no attempt was made to distinguish between the isoelectric material and its salts since it was apparent that the effect of this on the values of the surface tension would be less than the experimental error. Indeed the tips were so chosen that ψ was relatively insensitive, and consequently varied but little between pure water and the most concentrated solution—the greatest variation was from 0.6022 to 0.6033, in the case of α-aminobutyric acid.

Three different tips were used, one of monel metal, one of Pyrex, and one of fused quartz. The radii of these were 0.4701 ± 0.0003, 0.476 ± 0.002 and 0.4770 ± 0.0003 cm., respectively. The monel metal and quartz tips were turned or ground so as to be of accurately circular cross section; the Pyrex tip was made from a selected piece of Pyrex rod and was less exact; yet on the whole it gave the best results and was used in the majority of the determinations. The fact that it was less round than the others did not appear to affect the consistency of the results and any possible error in the calculation of the surface tension arising from uncertainty as to the proper value to use for the radius in reckoning the values of ψ was negligible. The monel metal tip was difficult to clean and there was often trouble in getting the liquids to wet the face of the tip. It was found that this tip did better if the face was electrolytically coated with a light deposit of platinum black. It proved difficult to grind the face of the quartz tip sufficiently rough to provide for good wetting without chipping the edges. This problem of ensuring that the drops, particularly the first one, completely wet the tip proved to be the most troublesome feature of the manipulations, more so than that of adjusting the rate of drop formation.

The measurements were all made at 25° and the apparatus containing the liquid was always placed in the thermostat at least fifteen minutes before the first drop was formed in order to make sure of temperature equilibrium.

All hydrogen-ion concentrations were determined with a glass electrode, in connection with a circuit similar to that described by DuBridge and Brown,[14] making use of a type F. P. 54 General Electric tube. The electrode was calibrated with standard buffers before or after measurements.

III. Results

The results obtained on six isoelectric amino acids and on isoelectric betaine, are given below in Table I and are shown graphically in Fig. 1. Except in one case, each point is based on several determinations which agree to about 0.1% or better. It may be seen from Fig. 1 that in every case the relation between surface tension and concentration is linear within the limits of error. At their worst the experimental points depart from the straight lines by slightly more than 0.1%.

Glycine, α-alanine, β-alanine, and β-aminobutyric acids all behave like inorganic salts in that the surface tension of their solutions is greater than that of water. The effect however is less pronounced than in the case of most of the latter substances. Thus even for glycine the increment

TABLE I

SURFACE TENSION OF SOLUTIONS OF ISOELECTRIC MATERIALS AT 25°

Concentrations are expressed in moles per liter. Values of $\Delta\gamma/\Delta c$, the increment of surface tension per mole of solute, reckoned from the straight lines in Fig. 1, are given in parentheses after the name of each compound. The surface tension of water is 71.97

Glycine[a] ($\Delta\gamma/\Delta c = +0.92$)

c	0.502	1.035	1.185	1.360	1.517
γ	72.43	72.86	73.14	73.15	73.47

α-Alanine[b] ($\Delta\gamma/\Delta c = +0.58$)

c	0.50	1.00	1.39
γ	72.27	72.54	72.79

α-Aminobutyric acid[b] ($\Delta\gamma/\Delta c = -0.41$)

c	0.38	0.845	1.185	1.245
γ	71.80	71.63	71.49	71.43

α-Aminocaproic acid[b,c] ($\Delta\gamma/\Delta c = -23$)

c	0.025	0.051
γ	71.23	70.90

Betaine[b] ($\Delta\gamma/\Delta c = -0.14$)

c	0.44	0.88
γ	71.95	71.79

β-Alanine[b] ($\Delta\gamma/\Delta c = +0.77$)

c	0.237	0.475	0.949	1.390
γ	72.19	72.36	72.62	72.99

β-Aminobutyric acid[b] ($\Delta\gamma/\Delta c = +0.05$)

c	0.5	1.0	1.5
γ	72.03	72.04	72.04

ε-Aminocaproic acid[b] ($\Delta\gamma/\Delta c = -0.25$)

c	0.545	0.763	1.09
γ	71.88	71.80	71.66

[a] Measurements with monel metal tip. [b] Measurements with Pyrex tip. [c] Measurements with quartz tip.

of surface tension per mole of solute[15] is but 0.97 as compared with a value of 1.64 for sodium chloride or a value of 3.04 for magnesium chloride, a uni-divalent salt; for β-aminobutyric acid it is but 0.05.

If we compare the four α-amino acids, or the two β-acids, studied, it is clear that increasing the length of the carbon chain when the electric moment is kept constant has the effect of depressing the molar increment of surface tension, as in the case of other homologous series; and the data on the α-acids indicate that the depressing effect of each additional carbon atom increases geometrically, at least approximately so, with the number of atoms introduced, as has been observed in other series more extensively studied.[16] In this connection the behavior of betaine is of interest. Betaine ($(CH_3)_3{}^+NCH_2COO^-$) differs from glycine owing to the substitution of three methyl groups for the three hydrogens attached to the positively charged nitrogen atom. It therefore contains three more CH_2 groups than glycine, and since its electric moment is known to be very nearly if not quite the same as that of α-amino acids,[10] it might be supposed that it would behave like α-aminovaleric acid. Although we have not determined the surface tension–concentration curve for this amino acid, it is safe to predict that it lies between curves of α-aminobutyric and α-aminocaproic acids. Actually the curve for betaine lies well above that for α-aminobutyric acid. The implication of this is that a CH_2 group which is itself a part of the structure of a changed group contributes quite differently to the properties of the molecule than one which belongs to a hydrocarbon residue.

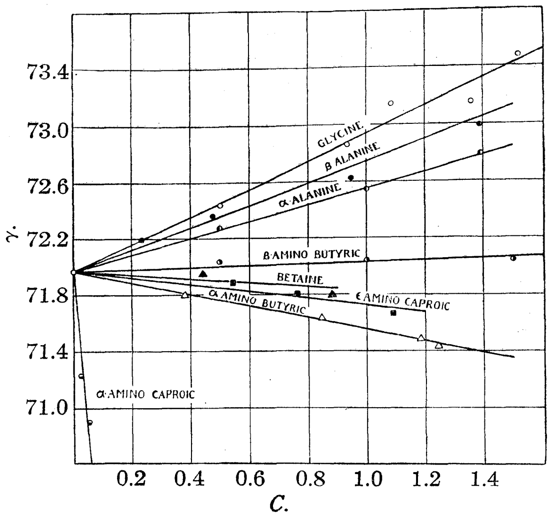

Fig. 1.—Graph of data in Table I.

The effect of increasing the dipole moment without otherwise altering a molecule is to increase the molar increment of surface tension,

---

(15) In what follows this quantity is referred to as the molar increment of surface tension, for brevity.

(16) Szgszkowski's data [*Z. physik. Chem.*, **64**, 385 (1908)] on normal fatty acids show that in dilute solutions, where the surface tension may be regarded as linear in the concentration, the molar surface tension increments decrease geometrically with the number of CH_2 groups in the molecule, the ratio for the series being about 3.4. This is equivalent to the statement that the differences, taken as positive, between the molar surface tension increments of successive members of the series increase in the same ratio, 3.4. In the case of the α-amino acids the molar surface tension increments themselves change from positive to negative values so that we must consider the differences. Data for one member of the series, α-aminovaleric acid, are lacking, which leaves only three differences to be considered. These may be fitted moderately well by assuming a ratio of 3.8. If we use a value of 0.30 instead of the observed value of 0.34 for the first difference, we may calculate expected values of the molar surface tension increments as +0.92, +0.62, −0.52, −21.4. These are in fairly good agreement with the values given in Table I.

that is, to rotate the curve counter-clockwise and make the substance behave more like an inorganic salt. This may be seen by comparing the curves for α- and β-alanine, α- and β-aminobutyric acid, or, better still, α- and ε-aminocaproic acid.

In Table II and Fig. 2 are given data showing the change of surface tension with *p*H for a solution of ε-aminocaproic acid containing 0.2431 mole per liter. Figure 2 also contains, in the upper portion, a graph of the titration data obtained incidentally in the course of these measurements. The full curve, with which the experimental points are in fairly good agreement, is calculated from the two *pK* values of 4.43 and 10.75 given for this amino acid by Edsall and Blanchard.[17]

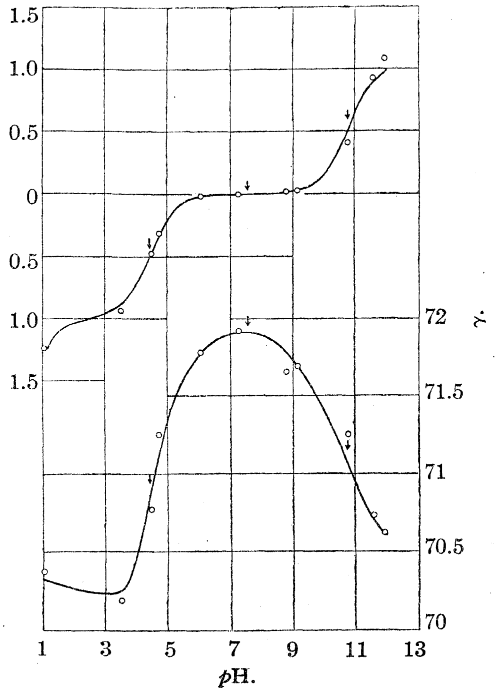

Fig. 2.—Lower curve: Surface tension of a 0.2431 molar solution of ε-aminocaproic acid as a function of *p*H. Upper curve: Titration of ε-aminocaproic acid (0.2431 molar). The ordinates give moles of acid or base per mole amino acid. The smooth curve is based on *pK* values of 4.43 and 10.75. The isoelectric point (7.59) and the *pK* values are indicated by arrows.

TABLE II

SURFACE TENSION OF ε-AMINOCAPROIC ACID SOLUTIONS AS A FUNCTION OF *p*H AT 25°

The total concentration of amino acid is 0.2431 mole per liter throughout. In column 1 the amount of acid or base present is expressed in terms of moles per mole of amino acid.

Amount of acid (−) or base (+)	*p*H	γ
−1.234	1.05	70.38
−0.944	3.52	70.19
− .474	4.50	70.77
− .308	4.74	71.24
− .021	6.07	71.78
0	7.26	71.92
+ .019	8.80	71.65
+ .020	9.16	71.69
+ .405	10.80	71.25
+ .925	11.58	70.73
+1.091	11.90	70.62

The data extend over somewhat more than the full titration range and show that the surface tension is a maximum at or close to the isoelectric point (*p*H = 7.59). There is a marked drop of surface tension with addition of acid or base amounting to about 2.4% when the isolectric material is converted completely into the hydrochloride, and a drop of about 1.7% when it is converted to the sodium salt. This is in general agreement with the results of Jones and Lewis[8] on glycine. As nearly as can be judged from their small scale graph there is roughly a 1% decrease in the surface tension of a 1.5 molar solution when the isoelectric amino acid is converted into the hydrochloride or sodium salt.[18]

This phenomenon is of interest since it shows the effect of the dipole moment as contrasted with the single charge of the anion or cation on the molar increment of surface tension. The increment is greater for the dipolar ion than for the simple ion, the more so for ε-aminocaproic acid where the moment is large than for glycine where it is relatively much smaller. In fact it appears from the figures given above, rough as they are in the case of glycine, that the increase in the surface tension increment of a 1 molar solution due to converting the cation or anion into the dipolar ion is about six times as great for ε-aminocaproic acid as for glycine. It is worth bearing in mind here the great size of the moments involved. Thus the moment of glycine has been estimated as in the neighborhood of 15×10^{-18} e. s. u. That of the caproic acid is much larger.[5]

---

(17) Edsall and Blanchard, THIS JOURNAL, **55**, 2337 (1933).

(18) Jones and Lewis [*Biochem. J.*, **26**, 632 (1932)] have shown that the surface tension of dispersions of lecithin in water, though less than that of water, is a maximum at *p*H = 2.8. This is close to the estimated isoelectric point of lecithin, which presumably exists as a dipolar ion. The surface tension of solutions of proteins and peptones is less than that of water, but there is disagreement among observers as to whether it is a maximum or a minimum at the isoelectric point. See Johnston, *ibid.*, **21**, 1314 (1927); Botazzi, in Alexander, "Colloid Chemistry," D. Van Nostrand Co., New York, 1919, Chap. VII; Berczeller, *Biochem. Z.*, **53**, 215 (1913); Errera and Milliau;[9] Loebel, *J. Phys. Chem.*, **32**, 763 (1928); Artom, *Arch. Sci. Biol.* (Ital.), **14**, 327 (1930).

It is striking that the molar increment of surface tension of the hydrochloride or sodium salt of ε-aminocaproic acid is very much less negative than that of isoelectric α-aminocaproic acid and therefore *a fortiori* presumably less negative than that of its salts. This is an illustration of the fact pointed out by Cohn[5] on the basis of a systematic study of solubilities that the effect of a CH_2 group situated between polar groups (whether or not they bear a free charge) is different from that of one located in a hydrocarbon residue in the molecule.

As a result of the application of a new and exceedingly accurate method of measuring surface tension Jones and Ray[19] report a very curious phenomenon shown by aqueous solutions of inorganic salts. The surface tension–concentration curves, which are linear at ordinary concentrations, do not continue straight back to the ordinate axis, but dip down so as to show negative surface tension increments when the solutions are very dilute. It would be of importance in any theoretical interpretation of surface tension to know whether or not dipolar ions behave in the same way, and it is hoped in the future to study the problem by this more accurate method.

Summary

Measurements of the surface tension of aqueous solutions of seven amino acids of differing size and moment and of glycine betaine have been made with the drop weight method. In the case of four of the amino acids the surface tension is greater than that of water; in the other cases it is less. In these dipolar ions there appears to be an antagonism between the effect of the electric moment which tends to increase the surface tension, and the size and number of organic groups in the molecule which tend to lower it. The effect of converting an amino acid into its hydrochloride or its sodium salt is to lower the surface tension of the solution.

The Electromotive Force of the Cell Zn-Hg (2 phase) | $ZnSO_4$ (m) $PbSO_4$ (s) | Pb-Hg (2 phase) and its Temperature Coefficient at 25° and Concentrations from 0.05 to 1.5 Molal[1]

BY JACOB KIELLAND[2]

Determinations of the e. m. f. of the cell

$$\text{Zn-Hg (2 phase)} \mid ZnSO_4\ (m)\ PbSO_4\ (s) \mid \text{Pb-Hg (2 phase)} \quad (1)$$

corresponding to the chemical reaction

$$\text{Zn (satd. amalg.)} + PbSO_4\ (s) = ZnSO_4\ (m) + \text{Pb (satd. amalg.)} \quad (2)$$

have been reported by Bray[3] at 25° for molalities from 0.0005 to 3.5, and by Cowperthwaite and La Mer[4] at 0, 12.5, 25, 37.5 and 50° for molalities from 0.0005 to 0.01, also 0.02 and 0.05 molal at 0, 25 and 50°.

In the present paper are given some e. m. f. measurements on cell (1) for the molalities 0.0512, 0.150, 0.510 and 1.501 at the temperatures 15, 25 and 35°.

Experimental Part

Preparation of Materials.—Lead sulfate of definite crystalline form was prepared from *pro analysi* reagents in the way recommended by Bray[3] and stored under doubly distilled water until needed. Zinc sulfate stock solution was made up from Kahlbaum "zur analyse" reagents and doubly distilled water, and analyzed by the zinc ammonium phosphate method as well as by weighing in the form of zinc sulfate after evaporation and heating on addition of some drops of sulfuric acid.

Four per cent. lead amalgam and 4% zinc amalgam were made up with *pro analysi* metals and redistilled mercury as described by Cowperthwaite and La Mer,[4] filtered hot through capillary tubings and stored under a slight excess pressure of purified nitrogen.

Tank nitrogen was purified from oxygen by the wet combustion method described by Van Brunt,[5] using a nitrogen lift pump to circulate the ammonia–ammonium carbonate solution over the copper wire gauze filling of the absorption tower.

Experimental Method.—The cell was similar to that used by Cowperthwaite and La Mer,[4] with

the exception that the electrodes were inserted at the top, using well ground glass joints. The solutions and the cell were freed from oxygen by running purified nitrogen through the whole system for four hours. The method of filling the cell with amalgams and solutions, and sealing off with mercury, was essentially the same as used by Cowperthwaite and La Mer.

The cleaning of cells and electrodes was effected by washing with concentrated sulfuric acid, distilled water, and then with a weak alcoholic solution of potassium hydroxide. They were then rinsed ten times with doubly distilled water, steamed out for an hour and subsequently dried at 110°.

Constant e. m. f. was ordinarily obtained one to four hours after the cell was prepared, and was controlled by readings after fifteen to twenty hours. It was found that a constant potential was far more rapidly obtained by passing from higher to lower temperatures than *vice versa.*

Apparatus.—The measurements were carried out with an Otto Wolff Potentiometer 5881 and a Hartmann and Braun Reflecting Galvanometer No. 1528. A Weston element calibrated by "Polytechnisches Reichsanstalt" served as the standard cell. The regulation of the thermostat temperature was maintained to a precision of ±0.02° by means of mercury regulators.

Results

The observed values of e. m. f. ($E_{\text{obsd.}}$) and of $E^{0\prime}$, computed from the equation

$$E^{0\prime} = E_{\text{obsd.}} + (\nu RT/nF) \ln m \qquad (3)$$

are given in Table I. The corrections necessary owing to the solubility of lead sulfate at the concentrations stated in the present paper, are less than 0.01 mv., and are therefore not taken into account.

TABLE I

OBSERVED E. M. F. AND COMPUTED VALUES OF $E^{0\prime}$

Molality, m	$E_{\text{obsd.}}$	$(\nu RT/nF)$ ln m	$E^{0\prime}$
Temperature 15°			
0.0512	0.53425	−0.07378	0.46047

.510	.49285	− .01787	.47498
1.501	.47800	+ .01078	.48878

The values of the mean practical[6] stoichiometric activity coefficient for zinc sulfate, given by the equation

$$\ln \gamma_{\pm} = \frac{E^0 - E_{\text{obsd.}}}{\nu RT/nF} - \ln m = \frac{E^0 - E^{0\prime}}{\nu RT/nF} \qquad (4)$$

are collected in Table II, using the best values for E^0 obtained by Cowperthwaite and La Mer.[4]

TABLE II

MEAN PRACTICAL STOICHIOMETRIC ACTIVITY COEFFICIENTS OF ZINC SULFATE

Molality, m	$t = 15°$ ($E^0 = 0.4215_5$)	$t = 25°$ ($E^0 = 0.41086$)	$t = 35°$ ($E^0 = 0.3992$)
0.0512	0.209	0.202	0.190
.150	.128	.123	.113
.510	.0667	.0631	.0569
1.501	.0392	.0372	.0342

Discussion

The agreement between the values presented here and those given by the measurements of Cowperthwaite and La Mer[4] up to 0.05 molal is very good.

The activity coefficients given previously by Bray[3] are all higher than those found by Cowperthwaite and La Mer and by the present author. This discrepancy can be traced back to Bray's measurements in the most dilute concentration range.[7] Using Cowperthwaite and La Mer's $E^0_{298.1} = 0.41086$, which hitherto is the most reliable value given for the normal potential of the cell (1), the activity coefficients given by Bray were recalculated. The results are shown in Table III.

TABLE III

MEAN PRACTICAL STOICHIOMETRIC ACTIVITY COEFFICIENTS OF ZINC SULFATE AT 25°, RECALCULATED FROM BRAY'S MEASUREMENTS

m	0.005	0.01	0.02	0.05		
$\gamma_{\pm}$	0.477	0.387	0.298	0.202

$\gamma_{\pm}$	0.162	0.148	0.104	0.0837	0.0634	0.0491
m	1.0	1.5	2.0	2.5	3.0	3.5
$\gamma_{\pm}$	0.0439	0.0368	0.0354	0.0368	0.0409	0.0476

---

(6) *Cf.* practical and rational activity coefficients by E. A. Guggenheim, *Phil. Mag.*, **19**, 588 (1935).

(7) The uncertainty of Bray's extrapolation was already pointed out by Gronwall, La Mer and Sandved [*Physik. Z.*, **29**, 390 (1928)], who found a somewhat different value, with "a" = 4.0 Å. Cowperthwaite and La Mer's "a" = 3.64 is however the most reliable, since cryoscopic measurements also give "a" = 3.6. Bray's measurements at the highest dilutions consequently should not be taken into account.

These recalculated coefficients are in good agreement with Cowperthwaite and La Mer's at concentrations 0.005 to 0.05 *m*, and with the author's at 0.05 to 1.5 *m*. Log $\gamma_{\pm}$ *vs.* $\sqrt{m}$ are shown in Fig. 1.

It would be of great interest to obtain values of the partial molal heat of dilution of zinc sulfate at concentrations here studied, on account of the difference between the calorimetric values given by Lange and collaborators[8] and the results of La Mer and Cowperthwaite, obtained by application of the Gibbs–Helmholtz equation.[9] But as $\overline{L}_2$ in the case of zinc sulfate depends about equally upon the precision with which $(E^{0\prime} - E^0)$ and $\mathrm{d}(E^{0\prime} - E^0)/\mathrm{d}T$ can be determined, it is obvious that more than the three temperatures investigated in the present paper, are necessary to obtain values of $\overline{L}_2$ which are sufficiently accurate[10] to be compared with those determined calorimetrically. The final answer to the questions must therefore await a more extended investigation.[11]

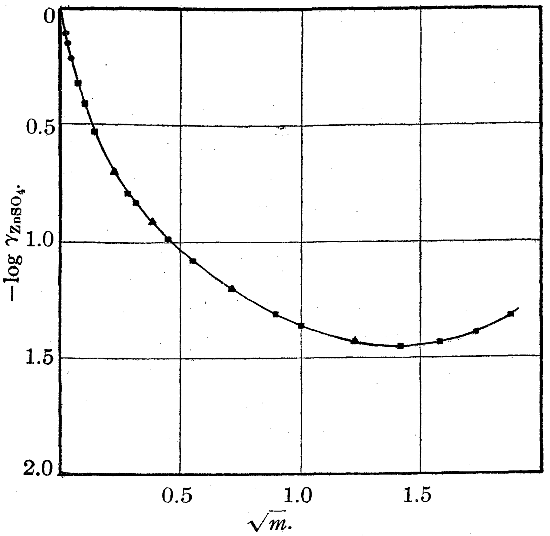

Fig. 1.—Mean stoichiometric activity coefficients of zinc sulfate at 25°: ●, Measurements of Cowperthwaite and La Mer; ■, Bray; ▲, Kielland.

Acknowledgments.—The author is indebted to "Norsk Hydro-Elektrisk Kvælstofaktieselskab," Oslo, to "Norges Tekniske Höiskole, Institutt for Uorganisk Kjemi," Trondheim, and especially to Docent K. Sandved, in whose laboratory this work has been done.

Summary

The electromotive force of the cell Zn (satd. amalgam) | $ZnSO_4(m)$, $PbSO_4(s)$ | Pb (satd. amalgam) has been measured at 15, 25 and 35° for concentrations of zinc sulfate of 0.0512, 0.150, 0.510 and 1.501 molal. The activity coefficients of zinc sulfate are given for these concentrations and temperatures.

OSLO, NORWAY RECEIVED JUNE 2, 1936

[10] The partial molal heat of dilution varies considerably with the temperature, according to some unpublished calculations of $\overline{C}_p - \overline{C}_p^0$ for zinc sulfate at concentrations studied; hence it is necessary to make use of a sufficient number of temperatures.

[11] According to a communication from Professor La Mer, W. H. Wood, working with Dr. Cowperthwaite, has been reinvestigating the e. m. f. of the cell at 5° temperature intervals from 0 to 50° from high dilution to one molal; the results have not yet been published.

Studies in the Phenanthrene Series. XIII. 9,10-Dihydrophenanthrene and Amino Alcohols Derived from It[1,2]

BY ALFRED BURGER AND ERICH MOSETTIG

The important investigations of Schroeter and his co-workers[3] have shown that phenanthrene yields by catalytic hydrogenation (elevated temperature and pressure) and by reduction with sodium and amyl alcohol, three well-defined hydrogenation products, namely, 9,10-dihydrophenanthrene, 1,2,3,4-tetrahydrophenanthrene and 1,2,3,4,5,6,7,8-octahydrophenanthrene, in amounts which depend upon the mode of reduction. These investigators determined the structure of the hydrocarbons beyond any doubt by synthetic methods, thus ridding the literature of the great confusion prevailing in the series of hydrogenated phenanthrenes up to that time. While the octahydro[4] and tetrahydro compounds may be isolated quite conveniently from the

reaction mixture and purified easily, the isolation and purification of the dihydro compound offers considerable difficulty. Neither the known reductive methods nor the synthetic method[3] is practicable for the preparation of 9,10-dihydrophenanthrene, which was needed in large amounts for systematic chemical and pharmacological investigations.

Through the extensive studies of Adkins and his collaborators on catalytic hydrogenation,[5] the great practical value of the "chromite" catalyst has been demonstrated. Copper–chromium oxide (or copper–chromium–barium oxide) proves to be particularly useful in cases where only partial or selective hydrogenation is desired. It has been known for a long time that the 9,10-double bond in phenanthrene is characteristically different from the other double bonds in this ring system. It behaves, to some extent, like an olefinic double bond (bromination, nitration), and it could be expected, therefore, that by employing the chromite catalyst in the reduction of phenanthrene, only or chiefly the 9,10-double bond would be attacked, leaving the benzenoid double bonds of the terminal nuclei intact. This expectation is fully realized; phenanthrene, reduced at 220° under a pressure of 2000–3000 lb./sq. in. (136–204 atm.), using copper–chromium–barium oxide as catalyst, yields practically pure 9,10-dihydrophenanthrene in very satisfactory amounts (up to 80%). The rate of reduction is apparently dependent to some extent upon the age of the catalyst. Phenanthrene can be recovered easily in the form of the picrate, and no higher hydrogenated phenanthrenes can be found in the reaction mixture. Efforts to bring the reduction to completion by varying experimental conditions were without success.

We found that anthracene, which is well known to be more reactive on the meso-positions than phenanthrene, is reduced under similar conditions, using chromite catalyst, at a decidedly lower temperature (160°) and in a considerably shorter time, yielding 9,10-dihydroanthracene only. The hydrogenation of anthracene at room temperature and atmospheric pressure, using noble catalysts, has been investigated carefully by Fries and Schilling.[6] The reduction of phenanthrene under similar conditions has not been reported, as far as we know. Phenanthrene, purified by the method of Cohen and Cormier,[7] distilled over sodium, treated with maleic anhydride,[8] recrystallized and resublimed, resists catalytic reduction under ordinary conditions (platinum oxide in glacial acetic acid). Synthetic phenanthrene, prepared by Pschorr's method, however (or as we later found, phenanthrene purified through the stages, 9-bromophenanthrene ⟶ 9-cyanophenanthrene ⟶ 9-phenanthroic acid ⟶ phenanthrene), absorbs hydrogen readily under those conditions.[9] We are now engaged in reinvestigating the course of the catalytic reduction of phenanthrene and of partially hydrogenated phenanthrenes under various conditions, a study that seems to be of interest as a complement to the investigation of Fries and Schilling[6] on the course of the reduction of anthracene. It may also be of importance in connection with the 1,4-dihydrophenanthrene (from the lithium addition product) of Schlenk and Bergmann,[10] for the structure of which, in our opinion, sufficient proof has not been offered.

The Friedel–Crafts reaction on 9,10-dihydrophenanthrene, employing acetyl and propionyl chlorides, proceeds smoothly in nitrobenzene solution as well as in carbon disulfide, giving in very satisfactory yields the expected ketones. It should be recalled that the same reaction on phenanthrene itself can be carried out successfully only in nitrobenzene solution, while in carbon disulfide chiefly oily and uncharacterizable products are obtained.[11] The formation of these is undoubtedly due to the interference of the 9,10-double bond.[12] Another remarkable difference between phenanthrene and 9,10-dihydrophenanthrene lies in their power to direct substituents. Whereas with phenanthrene in the Friedel–Crafts reaction, the acetyl or propionyl group enters mainly the 3-position, substitution in position-2 being a minor side reaction,[12,13] in 9,10-dihydrophenanthrene these groups are directed solely into the 2-position. Dihydrophenanthrene behaves in this respect as a diphenyl rather than as phenanthrene. The

[a] Obtained in poor yield by Friedel–Crafts reaction with chloroacetyl chloride.

[b] As a by-product in the exchange of the bromine with tetrahydroisoquinoline a red resin is formed, which on treatment with dilute alkali, yields 9,10-dihydrophenanthrene-2-carboxylic acid. Compare Mosettig and Robinson, THIS JOURNAL, **57**, 2188 (1935), footnote g.

In addition, the methyl ester of the carboxylic acid obtained by oxidation of the acetyl derivative with sodium hypochlorite was dehydrogenated with selenium, whereby 2-phenanthroic acid was formed.[14]

From the 2-acetyl- and 2-propionyl-9,10-dihydrophenanthrenes, amino alcohols of the type —$\mathrm{CHOHCH_2NR_2}$ and —$\mathrm{CHOHCH(CH_3)NR_2}$ were synthesized, *via* the bromo ketones and amino ketones, in a manner described previously in communications of this series. The pharmacological study of these compounds in comparison with their non-hydrogenated analogs, is expected to give some information concerning the influence of saturation of the 9,10-double bond on the physiological effectiveness in this series.

Experimental

Preparation of 9,10-Dihydrophenanthrene.[15]—One hundred and twenty grams of phenanthrene in 260 cc. of absolute alcohol with 10 g. of chromite catalyst was heated to 220° and kept at this temperature for eight to ten hours under a hydrogen pressure of 2000–3200 lb./sq. in. (136–218 atm.). Phenanthrene was removed from the reaction mixture as the picrate; the crude dihydrophenanthrene was purified by vacuum distillation (b. p. at 60 mm., 212–213°, yield 78–84%). This product was used for further reactions. By freezing it (5° overnight) and treating it with methyl alcohol at the same temperature, a pure dihydrophenanthrene was obtained. It is advantageous to use freshly prepared catalyst, since it was observed that with a catalyst that had been stored for about a year, the reduction proceeded considerably slower, and more catalyst had to be added to attain the same results.

2-Acetyl- and 2-Propionyl-9,10-dihydrophenanthrene.—A cold solution of 2 moles of aluminum chloride in 800 cc. of dry nitrobenzene was added gradually to an ice-cold solution of 1 mole of dihydrophenanthrene and 1.2 moles of acetyl or propionyl chloride, respectively, in 360 cc. of nitrobenzene. The mixture was allowed to stand at room temperature overnight, poured onto ice and hydrochloric acid and worked up in the customary way. The crude ketones were distilled in an oil pump vacuum and purified through the semicarbazones or oximes.

Structural Proofs.—Three grams of the acetyl compound was heated for four hours, with an excess of dilute sodium hypochlorite solution at 70°; yield of carboxylic acid, 1.9 g. One gram of the oily methyl ester (prepared from the acid with diazomethane) was heated with 2 g. of selenium in a sealed tube to 280–300° for twenty hours. The reaction product was treated with ether, and the ethereal solution was extracted with cold dilute potassium hydroxide solution. The acid obtained was identified as 2-phenanthroic acid by direct comparison with an authentic specimen of this acid (mixed melting point of acids and methyl esters).

One gram of the acetyl compound in 10 cc. of warm glacial acetic acid was treated with a solution of 1.2 g. of chromic acid in 2 cc. of water. After a few minutes the quinone crystallized out and was purified by high vacuum sublimation, m. p. 223–224° (dec.). The mixed melting point with an authentic sample of 2-acetyl-9,10-phenanthrene quinone showed no depression.

The propionyl-9,10-dihydrophenanthrene was oxidized in the same manner. The orange-red quinone was sublimed in a high vacuum; m. p. 215–217° (dec.).

Anal. Calcd. for $C_{17}H_{12}O_3$: C, 77.24; H, 4.58. Found: C, 77.25; H, 4.81.

The mixed melting point with 2-propionyl-9,10-phenanthrene quinone of the same m. p. (obtained by chromic acid oxidation of 2-propionylphenanthrene)[13] showed no depression.

Preparation of Amino Alcohols.—The bromination of the ketones was carried out in absolute ether (cooling with cold water). The yield of the bromoacetyl compound was 55%, that of the bromopropionyldihydrophenanthrene, 84%. The exchange of the bromine atom with the amino groups was effected by allowing the reactants to stand in benzene solution overnight. The hydrochlorides of the amino ketones (in two cases the perchlorates) were readily hydrogenated in 90% alcohol or methyl alcohol solutions, using a platinum oxide catalyst. The amino alcohols were acetylated in pyridine solution with acetic anhydride.

Summary

A convenient large scale method for the preparation of 9,10-dihydrophenanthrene by catalytic reduction of phenanthrene at elevated temperature and pressure, using chromite catalyst, is described.

By the Friedel–Crafts reaction, 2-acetyl- and 2-propionyl-9,10-dihydrophenanthrenes are obtained in good yields.

From the acetyl and propionyl derivatives amino alcohols of the type $\mathrm{C_{14}H_{11}CHOHCH_2NR_2}$ and $\mathrm{C_{14}H_{11}CHOHCH(CH_3)NR_2}$ ($\mathrm{NR_2}$ being the dimethylamino-, the diethylamino, the piperidino and the 1,2,3,4-tetrahydroisoquinolino group) have been synthesized for pharmacological studies.

UNIVERSITY, VIRGINIA

RECEIVED AUGUST 12, 1936

---

[14] The cleavage of the ester groups in this process is remarkable. Similar observations with selenium dehydrogenation of esters have been made recently also by Ruzicka [*Helv. Chim. Acta*, **19**, 419 (1936)].

The Synthesis of Acetylenic Ketones from Acetylenic Grignard Reagents[1]

BY J. W. KROEGER AND J. A. NIEUWLAND[2]

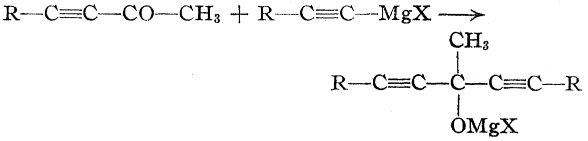
In connection with some of the work carried on in this Laboratory[3] it was found necessary to prepare acetylenic ketones of the type $R{-}C\equiv C{-}CO{-}CH_3$. The principal method reported in the literature consists in treating the sodium salt of an acetylenic hydrocarbon with an acyl halide.[4] This method was found to be unsatisfactory from the point of view both of yields and quality of products since traces of halogen were always present in the resulting ketone. This report concerns an entirely successful solution of the problem involving the use of acetylenic Grignard reagents.

A number of compounds have been reported to react with Grignard reagents to form ketones.[5] Of these, acetonitrile, acetamide, acetyl chloride and acetic anhydride were investigated. The first two compounds were found to be inert toward acetylenic Grignard reagents while, of the latter two, acetic anhydride gave the best results.

The ketone which is formed in accordance with the reaction

$$R{-}C\equiv C{-}MgX + (CH_3{-}CO)_2O \longrightarrow R{-}C\equiv C{-}CO{-}CH_3 + CH_3{-}CO{-}OMgX$$

may react further, as follows



$$R{-}C\equiv C{-}CO{-}CH_3 + R{-}C\equiv C{-}MgX \longrightarrow R{-}C\equiv C{-}\underset{OMgX}{\overset{CH_3}{C}}{-}C\equiv C{-}R$$

The usual method of avoiding this last reaction is to ensure the presence of a large excess of acetic anhydride by slow addition *to* it of the Grignard reagent. Better results, however, were obtained by cooling the Grignard reagent to at least $-25°$ and then adding the acetic anhydride.

For purposes of comparison alkynylmagnesium chlorides, bromides and iodides were investigated and of the three the chlorides were found most suitable. While the bromides and iodides invariably gave considerable amounts of carbinol and higher boiling polymeric material, the reaction product from an alkynylmagnesium chloride and acetic anhydride usually contained only the desired ketone and a small amount of unreacted alkyne. Occasionally the iodide yielded some iodine-containing material which exploded violently on heating.

Acetylenemagnesium chlorides are apparently rather insoluble in ether. Within the concentration range used, that is, 0.5 to 1.0 mole per liter, the bromides and iodides were always completely soluble whereas the preparation of an acetylenemagnesium chloride always resulted in the formation of a heavy, white precipitate. This was found to be mainly undissolved Grignard reagent.

Acetylenic Grignard reagents apparently are much more stable as well as less reactive than the Grignard reagents from the corresponding saturated hydrocarbons. Arylacetylenemagnesium halides occupy an intermediate position. Indications of this stability may be found in the facts that no reaction was obtained with acetonitrile or acetamide under the ordinary conditions of refluxing the ether solution. In addition, oxygen reacts only to a negligible extent with alkynylmagnesium halides at $-25°$. In spite of this fact, however, the reactions described below were always performed in an atmosphere of nitrogen as recommended by Gilman and Hewlett.[6]

Experimental

Reagents.—The alkylacetylenes were prepared by a modified Picon synthesis.[7] Phenylacetylene was prepared from ethylbenzene as suggested by Friedel and Balsohn.[8] The acetyl chloride, acetic anhydride and methyl iodide were redistilled shortly before use. Ethyl bromide was obtained from the Eastman Kodak Company. The ethyl chloride was supplied through the kindness of E. I. du Pont de Nemours and Company. Anhydrous ether was stored over phosphorus pentoxide and small quantities were distilled off when needed.

Analysis of Grignard Reagents.—The acetylenemagnesium chlorides prepared as described below always con-

tained considerable amounts of powdery, white, insoluble material which was analyzed as follows.

Three half-mole samples of ethylmagnesium chloride were prepared in ether, each having a volume of 250 ml. A 2-ml. sample of each was dropped into 50 ml. of ice cold, 0.1 *N* hydrochloric acid and back-titrated with 0.1 *N* sodium hydroxide. All three samples corresponded to 0.50 ± 0.02 mole of Grignard reagent.

One-half mole each of amyl-, butyl- and phenylacetylene, respectively, was dropped into the prepared Grignard reagents and the solutions were refluxed until no more ethane was evolved. The contents of each flask was then diluted with anhydrous ether to a volume of 500 ml. and 2-ml. samples were taken while the material in the flasks was being stirred vigorously. This last precaution was to ensure, as nearly as possible, representative samples. Titration of the samples showed that all three flasks contained 0.50 ± 0.01 mole of basic magnesium.

The solid material in each of the three samples was allowed to settle and the supernatant liquid was decanted under nitrogen. The solid was washed twice with 200-ml. portions of anhydrous ether which were then added to the original liquid. The three ether solutions were then diluted to 1000 ml. and 5-ml. samples were taken. They represented 0.20, 0.17 and 0.09 mole of amyl-, butyl-, and phenylacetylenylmagnesium chlorides, respectively.

Although these results give only a rough estimate of the solubilities of the acetylenemagnesium chlorides, they show definitely that the solid material is not magnesium chloride etherate, as it was first supposed, but that it consists largely, if not entirely, of active Grignard reagent.

At similar concentrations the acetylenemagnesium bromides and iodides were completely soluble.

Preparation of Acetylenic Grignard Reagents.—Methyl iodide, ethyl bromide or ethyl chloride was converted to the Grignard reagent in the usual manner. Ethyl chloride was diluted with twice its volume of ether and then added to the metallic magnesium. The preparations were carried out in nitrogen[6] and with mechanical stirring.

The calculated quantity of an acetylenic hydrocarbon was dissolved in ether and added to the prepared Grignard after which the solution was refluxed until no more ethane was evolved. In the case of quarter-mole runs, this required a half-hour for phenylacetylene and about two hours for the alkylacetylenes. Finally the apparatus was again flushed out with nitrogen. The volume of the solution at this point was about 500 ml.

Reaction of Hexynylmagnesium Bromide with Acetonitrile.—One-fourth mole of acetonitrile was added to 0.25 mole of hexynylmagnesium bromide, which was prepared from 21 g. of hexyne-1, and the solution was refluxed for eight hours. After hydrolysis with dilute acid in the usual way and drying, fractionation gave only hexyne-1, b. p. 70–71° (19.5 g.). Similarly, 20 g. of phenylacetylene was recovered from a quarter-mole run of phenylethynylmagnesium bromide.

Reaction of Heptynylmagnesium Bromide with Acetamide.—One mole of heptynylmagnesium bromide was prepared from 96 g. of heptyne-1. To this was added 0.33 mole of acetamide (20 g.) dissolved in warm ether. The acetamide had been previously fused to free it from water. A slight reaction was apparent and the solution was refluxed for four hours. Only heptyne-1 was recovered, b. p. 99–101° (90 g.).

Addition of Grignard Reagent to Acetic Anhydride.—One-half mole of hexynylmagnesium bromide in ether was slowly dropped into one mole of acetic anhydride cooled in an ice–salt mixture. The addition required three hours. Stirring was continued for two hours, then the product was hydrolyzed with ice water and steam distilled. From the steam distillate 20 g. of 3-octyne-2-one, b. p. 90–95° (30 mm.) was obtained. Fractionation of the tarry residue in the steam distillation flask gave 8 g. of *bis*-hexynylmethylcarbinol, b. p. 125–130° (5 mm.).

Phenylethynylmagnesium bromide (0.25 mole) when treated similarly gave 3 g. of 4-phenyl-3-butyne-2-one, b. p. 105–108° (5 mm.), and 30 g. of a yellow-brown powder, m. p. 108–111°. This material was extracted with hot alcohol and the extract diluted with an equal volume of water. The material so obtained was recrystallized six times from aqueous alcohol finally giving fine, white needles of *bis*-phenylethynylmethylcarbinol,[9] m. p. 111.5–112.0°.

Reaction of Hexynylmagnesium Chloride with Acetic Anhydride.—One-fourth mole of hexynylmagnesium chloride was prepared in the usual manner and cooled to −30° in a bath of liquid ammonia. One-half mole of acetic anhydride in ether was added at such a rate that the temperature of the mixture remained below −25°, vigorous stirring being maintained. The addition required two and one-half hours. Stirring was continued for two hours at −30° and then for two hours at −5° in an ice–salt bath. After hydrolysis with ice-water and drying, fractionation gave 8 g. of hexyne-1 and 18 g. of 3-octyne-2-one, b. p. 76–77° (15 mm.). This represents a 58% over-all yield or a 98% yield based on the amount of acetylene reacted.

Under similar conditions, 0.25 mole of heptynylmagnesium chloride gave 22 g. of 3-nonyne-2-one, b. p. 86–87° (13 mm.) and 10 g. of heptyne-1. In contrast to the practically quantitative yields from alkynes, only 40–45% yields of 4-phenyl-3-butyne-2-one were obtained. Considerable amounts of carbinol were always formed in this case.

Alkynylmagnesium bromides and iodides, when treated as outlined above, gave 10 to 20% yields of ketones.

When acetyl chloride was substituted for acetic anhydride, the yields varied from 8 to 15% in the case of bromides and chlorides while the iodides gave nothing but a viscous tar which exploded on attempted vacuum distillation and gave off iodine vapor.

The Action of Oxygen on Hexynylmagnesium Bromide.—The inertness of acetylenic Grignard reagents is well illustrated by the following experiment.

During eight hours dry oxygen was bubbled rapidly through a solution of hexynylmagnesium bromide (0.25 mole) cooled to −30°. A 5-ml. sample was then hydrolyzed with dilute hydrochloric acid and the organic layer allowed to evaporate. A slight film of oil remained which had a faint odor of caproic acid.

While the Grignard reagent was still in the liquid ammonia bath, 0.25 mole of acetic anhydride was added and the product was worked up as usual. Fractionation gave 5 g. of 3-octyne-2-one and 16 g. of *bis*-hexynylmethylcarbinol, b. p. 123–125° (2 mm.).

Acknowledgment.—We are indebted to Mr. G. M. Wolf for carrying out several of these preparations.

Summary

1. Acetylenic ketones of the type R—C$\equiv$C—CO—CH_3 have been prepared from acetylenic Grignard reagents.

2. Alkynylmagnesium chlorides, when cooled to −25° and treated with acetic anhydride, gave almost quantitative yields of acetylenic ketones.

Sedimentation and Electrophoresis of the Tobacco-Mosaic Virus Protein

By Inga-Britta Eriksson-Quensel and The Svedberg

The isolation by W. M. Stanley[1] of a crystalline protein showing the properties of the tobacco-mosaic virus has attracted much attention both in physiological and chemical circles. Stanley's substance is really the first example of a chemically well-defined virus, all previous preparations having been defined by means of biological tests only.

A quantity of the crystalline virus protein was kindly put at our disposal by Dr. Stanley for the purpose of an ultracentrifugal study. In view of the vivid discussion centering around the question whether a virus is a living being with the faculty of propagation or a high-molecular compound with the property of multiplication by autocatalysis a determination of the molecular weight and the degree of homogeneity of this virus protein seemed of great interest. Preliminary measurements by Dr. Stanley of the diffusion and osmotic pressure gave molecular weight values of the order of millions.

The object of our ultracentrifugal study was to determine by means of sedimentation velocity runs the sedimentation constant, and by sedimentation equilibrium runs the molecular weight as well as the dependence of the sedimentation constant on *p*H, *i. e.*, the *p*H stability region. Further we wanted to subject the material to a homogeneity test with regard to molecular weight by means of velocity scale runs and, should the virus protein prove inhomogeneous, to determine the distribution curve.

Previous work on proteins in this Laboratory has demonstrated the great sensitivity of the isoelectric point against chemical differences in the protein molecule. Thus the measurements carried out by K. O. Pedersen[2,3] on respiratory proteins have shown that the isoelectric point varies from species to species although the molecular weight is the same. For example the isoelectric point of the hemocyanin from Helix pomatia is 5.05 while that from Helix nemoralis is 4.63, both proteins possessing near the isoelectric point the molecular weight 6,400,000. On the other hand, the blood pigment of a certain species often contains several components all of which have the same isoelectric point and the same mobility in an electric field. For example, at *p*H 8.2 the hemocyanin of Helix pomatia has three well-defined components of molecular weight 6,400,000, 3,200,000, and 800,000, all of which are identical in electrophoretic respect. Subjected to a centrifugal field this particular protein system, therefore, is resolved into three components, while exposed to an electric field it moves with a single boundary. In view of this fact it was desirable to carry out a series of electrophoresis determinations on the virus protein.

[3] *Cf.* T. Svedberg, *J. Biol. Chem.*, **103**, 311 (1933).

Treatment of the Material. Specific Volume

Two grams of the protein was sent us in the form of crystals covered with half-saturated ammonium sulfate solution. It was recrystallized twice according to Stanley's method[1] taking care not to raise the *p*H above 8 when dissolving the crystals. The recrystallization was easy to perform.

The specific volume of the protein was determined pycnometrically at *p*H 6.8 and 8.5. The value 0.646 was obtained. It differs considerably from the ordinary value for proteins, this being 0.75.

Sedimentation Constant, *p*H Stability Range

Sedimentation velocity determinations were carried out before recrystallization, after one recrystallization, and after two recrystallizations. The light absorption method was generally used. The refractive index method was applied in some runs on the twice recrystallized material.

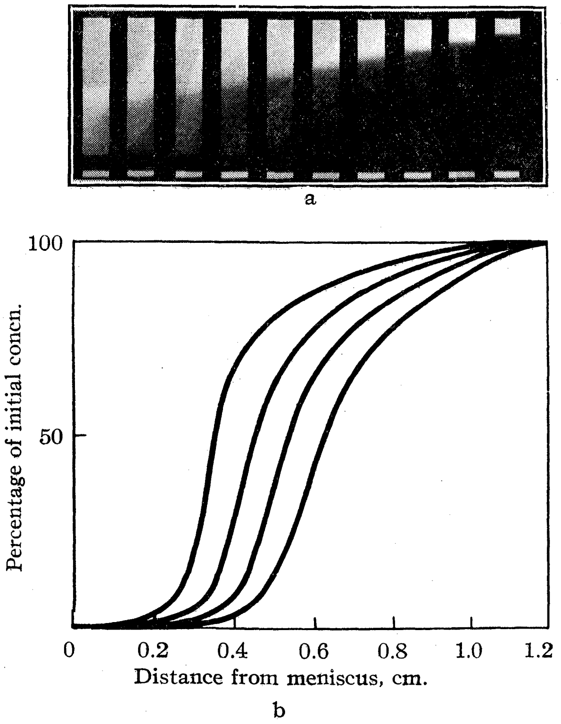

Fig. 1, a and b.—Sedimentation pictures (a), obtained by means of the light absorption method, and concentration curves (b) for the tobacco-mosaic virus protein at *p*H 6.8; centrifugal force 15,000 times gravity; time between the exposures 5 minutes. The blurring of the boundary and the change in shape of the curves with time of sedimentation indicate polydispersity.

Light Absorption Method.—In the ultracentrifuge the material appeared very polydisperse as compared with a well-defined high-molecular protein such as the hemocyanin from Helix pomatia (Figs. 1, 2, and 3). The recrystallizations seemed to have no effect on the degree of inhomogeneity. The sedimentation at different *p*H was studied. Below *p*H 3.8 the solubility was too small for determination. In the *p*H range 4.6–5.5 the particles were aggregated and went down to the bottom of the cell at very low speed. No change in sedimentation picture took place between *p*H 6 and 11.5. The sedimentation constant dropped slightly toward the alkaline side of the region, the mean value being 235 for the *p*H range 6–8 and 205 for the *p*H range 8–11.5. However, if a substance is inhomogeneous and does not consist of one or more well-defined components the sedimentation constant obtained with this method must be regarded as a mean value for all the different sized particles.

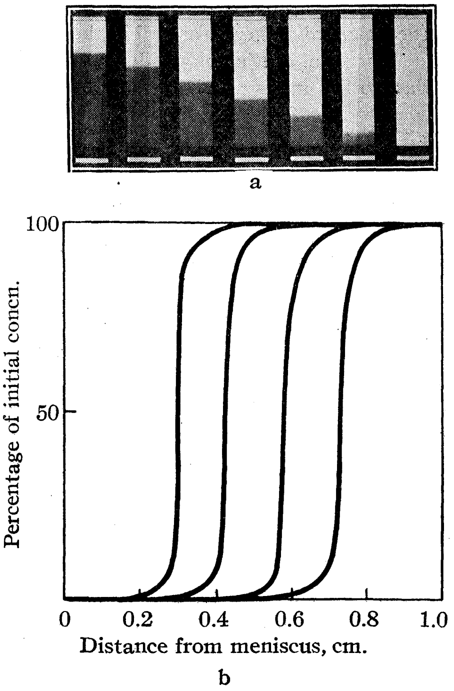

Fig. 2, a and b.—Sedimentation pictures (a) obtained by means of the absorption method, and concentration curves (b) for the hemocyanin from Helix pomatia at *p*H 5.5, ($M = 6{,}400{,}000$, $s = 98.9$); centrifugal force 45,000 times gravity, time between exposures 5 minutes. The sharpness of the boundary and steepness of the curves demonstrate the high degree of molecular homogeneity of this protein compared with that of the virus protein.

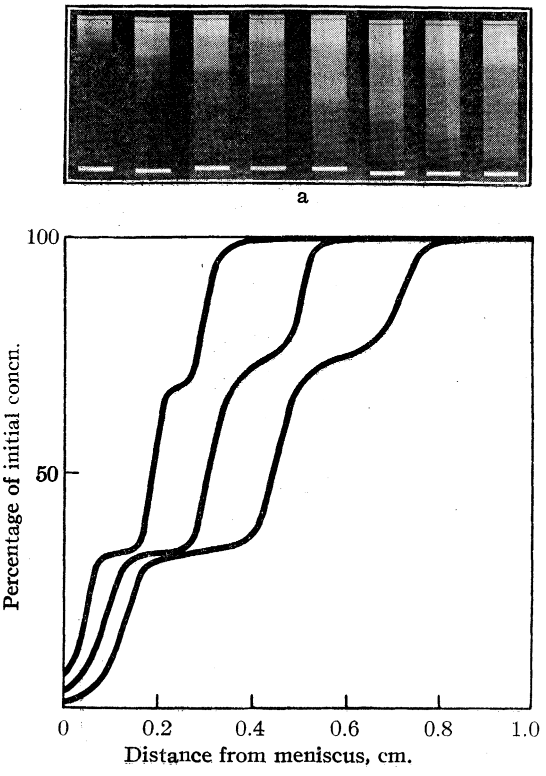
Refractive Index Method.—An example of a typical run on the virus protein with this method is given in Fig. 4. The concentration gradient curve has a rather sharp peak, due to a comparatively homogeneous part of the material. The sedimentation constants given refer to this homogeneous portion. The results of the measurements are summarized in Table I. The run at *p*H 9.5 shows a lower value than those at more neutral *p*H. The same is the case with the determination at *p*H 5.0 of the solution stored at 8.5, which means that the effect of a higher *p*H is not reversible.

Distribution Curve

The distribution of particle size[4-6] or molecular weight can be calculated easily from runs made by the refractive index method, provided the relation between rate of sedimentation and molecular weight is known. Because of the exceedingly low diffusion the spreading of the boundary is entirely due to molecular inhomogeneity. The scale runs give directly the concentration gradient as a function of distance from center of rotation. One of the most convenient types of distribution curve is the one where the percentage gradient dp/dM is given as a function of molecular weight. The area delimited by two ordinate lines, the abscissa axis and the distribution curve, represents the percentage of material having molecular weight in the interval in question. In the following we have assumed the dissymmetry constant to be independent of molecular weight and equal to 1.3, which is the value found for other high-molecular proteins.



a

b

Fig. 3, a and b.—Sedimentation pictures (a) obtained by means of the absorption method and concentration curves (b) for the hemocyanin from Helix pomatia at *p*H 8.2, molecular weight of components 6,400,000 ($s = 98.9$), 3,200,000 ($s = 62.0$) and 800,000 ($s = 16.0$); centrifugal force 60,000 times gravity; time between exposures 5 minutes. Each of these components is homogeneous with regard to molecular weight.

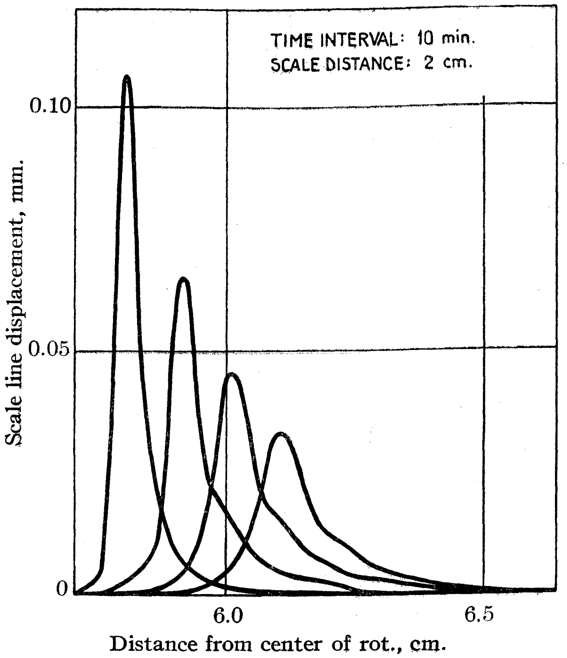


Fig. 4.—Sedimentation diagram, obtained by means of the refractive index method from the tobacco-mosaic virus at *p*H 9.5; centrifugal force 10,000 times gravity; time between exposures 10 minutes.

In Fig. 5 are given the distribution curves calculated from a run at *p*H 9.5. The agreement between the curves from different times of sedimentation is very good.

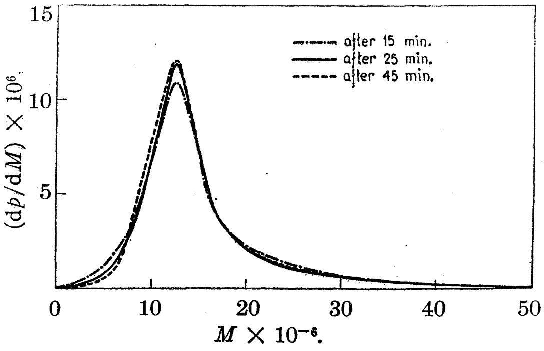

Fig. 5.—Molecular weight distribution curves calculated from the run shown in Fig. 4.

The result of runs at different *p*H is given in Fig. 6. A departure from neutrality (curve B, *p*H 6.8) causes a decrease in homogeneity both in the direction of higher alkalinity (curves C, *p*H 8.3 and D, *p*H 9.5) and higher acidity (curve A, *p*H 6.0). Not only the *p*H itself but also the time during which the solution is kept at a certain *p*H are of great importance. Thus curve E, *p*H 5.0 where the solution had been kept at *p*H 8.5 for two weeks represents a less homogeneous system than curve D, *p*H 9.5, where the solution was run immediately after the dissolution of the crystals. Recrystallization of material E did not bring it back to curve B, or thereabout, but on the contrary increased the inhomogeneity still more (curve F, *p*H 6.8).

Molecular Weight by Sedimentation Equilibrium Measurements.—Two sedimentation equilibrium determinations were carried out in order to obtain the molecular weight of the protein. In one of the experiments the solution was run for seventeen days with a height of column of 1.5 millimeters, in the other twenty-three days with 3 mm. height of solution. On account of the extremely low diffusion and the inhomogeneity of material, the results are very uncertain. The value obtained is, however, of the same order of magnitude as that calculated from the sedimentation constant under the assumption of f/f_0 = 1.3 as found for other high molecular proteins.

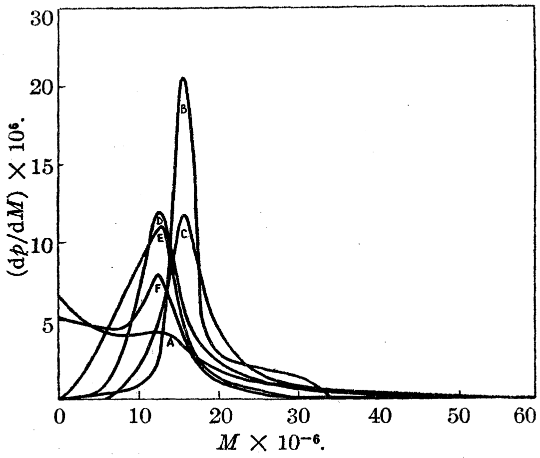

Fig. 6.—Molecular weight distribution curves for the tobacco-mosaic virus protein in solution of different *p*H.

Isoelectric Point and Mobility Gradient.—The isoelectric point was determined according to the very accurate method of Tiselius.[7,8]

In spite of its inhomogeneity with regard to molecular weight the protein shows a very uniform migration in the electrical field (Fig. 7). The results of the electrophoretic measurements are summarized in Table II. Figure 8 gives the *p*H–mobility curve. The isolectric point is situated at *p*H 3.49 and the slope of the *p*H–mobility curve (d*u*/d*p*H is 12.3 × 10^{-5}.

Discussion of Results

The material of tobacco-mosaic virus protein studied by us has proved to be inhomogeneous with regard to molecular weight. Assuming the dissymmetry constant to be the same as for other high molecular proteins about 65% of the material falls in the molecular weight interval 15–20 millions at a *p*H of 6.8. Raising or lowering the *p*H increases the polydispersity. Even mere recrystallization may give rise to a more inhomogeneous system.

---

(7) A. Tiselius, *Nova Acta Reg. Soc. Scient. Upsaliensis*, IV, 7, No. 4 (1930).

(8) Also described by K. O. Pedersen, *Kolloid-Z.*, **63**, 268 (1930).

It would seem, therefore, that any modifications in the process of isolation of the virus protein involving less drastic modes of operation (*p*H not higher than 7) than have hitherto been used, might render a product more homogeneous with regard to molecular weight. To judge from our data it is not impossible that the virus protein is quite homogeneous in its native state.

The fact that standing at *p*H 8.5 causes an irreversible change in the distribution curve not to be remedied by recrystallization, shows that a chemical change has taken place. The lack of homogeneity with regard to molecular weight, therefore, in all probability corresponds to a chemical inhomogeneity. On the other hand, this lack of chemical definition could not be very pronounced since the electrophoresis measurements did not reveal any inhomogeneity at all.

Our findings speak decidedly against the theory of the virus being a sort of bacteria. Even if we assume, for the sake of argument, that the particles of our distribution curves were living organisms in different stages of development and capable of orienting themselves and aggregating to "crystals," it would be extremely difficult to imagine these organisms to change their size with *p*H as found by us. The almost perfect homogeneity with regard to electrophoretic mobility indicates a chemical likeness hardly to be expected to obtain in the surface layer of organisms in different stages of development. The most likely interpretation of the facts revealed by us seems to be that the virus is a chemically well-defined protein, probably homogeneous with regard to molecular weight (17 millions) in the plant. It is very sensitive to deviations from neutral *p*H and is thus rendered inhomogeneous.

We are indebted to Dr. Stanley for his kindness in sending us this material and to The Rockefeller Foundation and the Foundation "Therese and Johan Anderssons Minne" for financial aid.

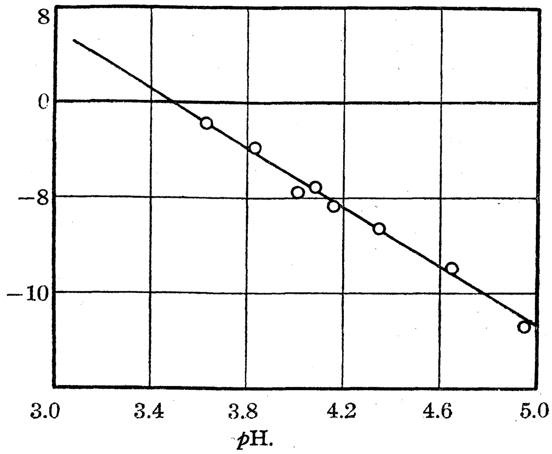

Fig. 8.—The *p*H–mobility curve for the tobacco-mosaic virus protein.

Summary

1. The tobacco-mosaic virus protein has been subjected to an ultracentrifugal and electrophoretic study.

2. Sedimentation velocity runs by the light absorption and the refractive index or scale method have revealed a considerable inhomogeneity with regard to molecular weight.

3. From the scale runs distribution curves were calculated. The position of the maxima and the dispersion changes with *p*H. At 6.8 about 65% of the material has molecular weight between 15 and 20 millions, provided the dissymmetry constant is the same as for other high molecular proteins.

4. It does not seem improbable that the virus protein might be homogeneous with regard to molecular weight in its native state.

5. Sedimentation equilibrium runs indicate a mean molecular weight of the same order.

6. Electrophoretic determinations showed the virus protein to be chemically well-defined and practically homogeneous.

The Solubility of Cobaltous Iodate in the Presence of Sodium Chloride, Sodium Iodate and Cobaltous Sulfate

BY H. M. TRIMBLE

The solubilities of the various hydrates of cobaltous iodate have been investigated carefully by Meusser.[1] The dihydrate is the stable form at and near room temperature; hence it was used in this study.

Preparation of Materials

Cobaltous iodate dihydrate is readily prepared by the reaction of any soluble cobaltous salt with any soluble iodate in aqueous solution. If the reagents are mixed in the cold this salt separates slowly, forming a close knit and hard mass of tiny crystals which can be removed from the precipitation vessel and purified only with difficulty. When the hot solutions are mixed with rapid stirring a more highly hydrated form, probably the tetrahydrate, separates along with the dihydrate, both forming larger crystals. Upon agitating the mixture with the mother liquor for some days, however, conversion to the dihydrate is complete, and good crystals are formed. Cementing together of the crystals is thus avoidable. This method was employed in preparing cobaltous iodate, using the best obtainable cobaltous nitrate and sodium iodate. The product was washed thoroughly and dried to constant weight at 50°. Repeated analyses established its exact composition and its purity.

The sodium chloride was a special product marked "for analysis" and was not further purified. Sodium iodate was prepared in this Laboratory, and several times recrystallized. Cobaltous sulfate was also recrystallized for use, starting with a commercial C. P. product. Redistilled water was used in the preparation of the salts and in preparing the solutions for saturation.

Experimental Methods and Results

Cobaltous iodate dihydrate dissolves very slowly; consequently saturated solutions are produced only after extended agitation. Contrary to the usual behavior of salts, too, saturation is approached from a condition of supersaturation much more slowly than from undersaturation. In three experiments in which solutions previously saturated at 60° were agitated with crystals of the dihydrate at 30° saturation had not yet been reached after a week. This persistence of metastable equilibrium was so great that solutions showed no separation of solute, even when allowed to stand for weeks at temperatures somewhat below that at which they had been saturated. Equilibrium was therefore always approached from below in these experiments, and times of seventy-five and one hundred and twenty hours were allowed in every case. A number of experiments with pure water and with solutions of various added salts showed that saturation was reached in the shorter time in every case.

All solutions were saturated at 30°. Their preparation and analysis were carried out in duplicate—many of them in triplicate. Solutions of sodium chloride, sodium iodate and cobaltous sulfate, respectively, were made up in suitable concentrations and analyzed and their densities were determined. Chloride concentrations were determined by the Volhard method. Sulfate was determined in the cobaltous sulfate solutions by the usual gravimetric method. Iodate was determined in all cases by iodometric titration. Potassium iodate was used in standardizing the thiosulfate solutions. After saturation, excess cobaltous iodate was filtered off, using a quantitative filter paper designed for the filtration of very fine precipitates. Then followed the iodometric titration of the iodate present in the saturated solutions. Carefully calibrated apparatus was used in all the determinations. The densities of the saturated solutions were determined in every case.

In the solutions in which sodium iodate was the added salt titration gave total iodate. Other samples of these solutions were treated with an excess of hydrochloric acid and boiled to destroy the iodate present and to remove the chlorine liberated by the reaction. Cobalt was then precipitated from the solutions as hydroxide by rendering them slightly alkaline with sodium hydroxide. After filtering and washing this precipitate, it was dissolved in hydrochloric acid and the cobalt was determined by the perborate method. From this determination the concentration of cobaltous iodate in each of the saturated solutions was calculated. The concentration of sodium iodate was found by difference. It was possible, also, to calculate the concentrations of these salts by the method, given below, which was used in those cases where sodium chloride and cobaltous sulfate were the added salts. This method of calculation gave results which agreed well with those from the direct analyses.

---

[1] Meusser, *Ber.*, **34**, 2440 (1901).

For the solutions with sodium chloride and cobaltous sulfate as added salts, titration gave directly the concentration of cobaltous iodate. Subtracting the weight of this salt present in each liter of solution from the weight of that volume of solution gave the weight of the solution of the added salt which entered into it. It was then a simple matter to calculate the weight of added salt and of water per liter. Calculation of the molalities of the salts present gave the data of Table I.

The Allotropic Forms of Diphenylsulfone and the Determination of their Transition Point

BY VLADIMIR J. MIKESKA, NICHOLAS T. FARINACCI AND MARSTON TAYLOR BOGERT

In the course of an examination of certain still residues remaining from the preparation of phenol by the fusion of sodium benzene sulfonate with sodium hydroxide, we separated a crystalline solid, in a yield of over 30%, whose chemical properties and analysis coincided with those of diphenylsulfone. The formation of this compound as a by-product in the manufacture of phenol by the process stated has been known for years. The only puzzling thing about our product was its melting point. The literature on this subject is confusing, some investigators giving the figure as 124°, others as 128°.

It seemed of interest, therefore, to ascertain if possible the reason for this discrepancy, and our study of the problem disclosed the following facts. (1) Diphenylsulfone exists in two reciprocally convertible allotropic forms, one melting at 124° and the other at 128°. (2) The transition temperature for the two is in the neighborhood of 75°. When crystallization is induced (no matter how) above this temperature, the product always melts (if pure) at 128°; if induced below this, it melts at 124°.

Otto[1] obtained both forms, but concluded that the 124° form, because of its lower m. p., was probably impure.

Remsen and Saunders[2] gave 124° as the correct m. p. for the sulfone. Because they were unable by recrystallization to raise this m. p. to the

[1] Otto, *Ann.*, **136**, 160 (1865).

[2] Remsen and Saunders, *Am. Chem. J.*, **17**, 364 (1895).

128° reported by Otto, they at first doubted the identity of the two products, but analysis and comparison of other properties convinced them that their product was also the diphenylsulfone.

In the light of the results of our own experiments, it seems most likely that Otto carried out his final crystallization above 75°, and Remsen and Saunders carried out theirs below that temperature.

The sulfone can be supercooled to 72°. Hence crystallization can be induced at any temperature between 72 and 124°. If the sulfone is fused and then cooled rapidly, as is the usual case, it yields the 128° form, because under these conditions it solidifies above 75°. But when the fused sulfone is cooled slowly, it supercools below the transition point before it congeals, and the 124° form is produced. It is therefore possible to change the m. p. of the sulfone at will, by fusing and then inducing crystallization above or below the transition point.

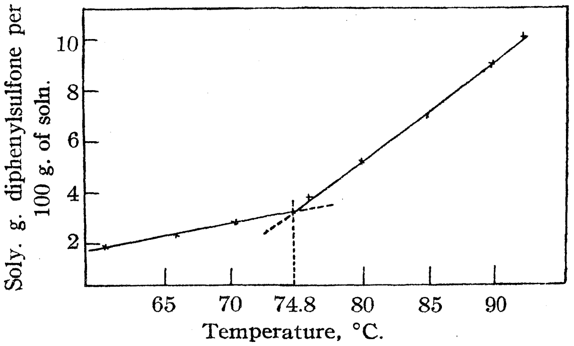

Fig. 1.—Allotropic forms of diphenylsulfone. The intersection of the three lines shows the transition point: α-form, m. p. 124°, stable below 74.8°, β-form, m. p. 128°, stable above 74.8°.

The method of inducing crystallization does not appear to make any difference. Cooling of the molten material was only one of several methods used. Seeding was another one. If the molten sulfone were seeded above 75° with either the 124 or the 128° form, it congealed immediately to the 128° form.

When the sulfone was crystallized from hot solvents under ordinary conditions, the 124° form generally resulted, because the crystals did not begin to separate until the solution had cooled below 75°. In these experiments, the solvents used were water, methyl and ethyl alcohols, ether, acetone, acetic acid, ligroin and chloroform. In every case, the 124° form was obtained, irrespective of whether the solute had been the 124 or the 128° form.

When the temperature of the solution was maintained above 75°, so that crystallization had to take place above this transition point, the 128° form resulted. Alcohol and acetic acid were the solvents employed. From the former, at 75 and at 78° the 128° type separated, at 66 and at 70° the 124° type. From acetic acid at 100°, the 128° type separated. When 50 g. of the 128° form, suspended in 600 cc. of 95% ethanol, was stirred for eight hours at 30°, it was transformed into the 124° form, a rearrangement which indicates that the lower-melting is the stabler form at the lower temperatures.

Another method used to induce crystallization at a desired temperature was to employ a mixture of two solvents, such as water and alcohol, in one of which (alcohol) it dissolved freely and in the other but slightly. An alcoholic solution of the sulfone saturated at the requisite temperature was treated with water heated to the same temperature. Crystallization ensued immediately at this temperature. When this mixing occurred above 75°, the 128° form was obtained, when below this the 124° form.

That the 124° form is not an impure 128° form was proved by the fact that no amount of purification enabled us to change the lower to the higher melting form.

The assumption that the 124° is a hydrated form of the 128° type is also untenable, for no water was evolved when the 124° form was heated, and the analysis of the two evidenced the identity of their composition, and both types could be obtained from water–alcohol mixtures. Further, as already noted, the 128° form could be changed to the 124° under strictly anhydrous conditions, *i. e.*, by fusing it and allowing it to crystallize slowly below 75°.

The transformation of the solid forms into each other seems to be slow. When the 128° form was kept at 66° for twenty-four hours, there was no evidence of its having changed; but when the 124° form was maintained at 100° for the same length of time it was partly converted into the 128° form. The higher velocity of transformation at the latter temperature may account for this partial transformation. The fact that the 124° type is obtained by metathesis in solution at low temperatures indicates that it is the stable form below the transition point.

A more precise determination of the transition point seemed to us desirable. The thermometric method was unsatisfactory, because of the slowness of the change of one solid form into the other, and also because there occurs appreciable sublimation of the sulfone above about 80°. We fell back, therefore, upon the solubility method, which was applied as follows.

A three-necked 500-cc. flask, containing a saturated solution of the sulfone in 45% aqueous acetic acid in contact with a large excess of the solid, was heated in a four-liter water-bath provided with a coil of perforated copper pipe. The water in the bath was kept in motion by air bubbles forced through pin-holes in this pipe, while the contents of the flask were agitated by a motor-driven glass stirrer. With the flask contents and bath liquid in vigorous agitation, the temperature of the solution in the flask was raised to 90°, and was then allowed to fall slowly, samples being removed at 76, 70.5, 66, and 60.5°. After this, the temperature was gradually raised again and samples taken at 80, 85, 90, and 92.5°. This procedure was adopted in order to ensure saturation and to facilitate the attainment of equilibrium. The samples were blown out of the flask by air pressure, through a preheated tube containing a plug of cotton wool to filter out any crystals, into tared bottles. The weights of liquid and solid were determined by evaporation to dryness, and the solubilities calculated on the basis of grams of solid per 100 g. of solvent. Eight determinations were made, with temperatures so chosen as to bring the transition point about halfway between the extremes. The graph shows these experimental results, with the transition point at 74.8°.

Summary

1. Diphenylsulfone exists in two reciprocally convertible allotropic forms, one melting at 128°, and the other at 124°.

2. The conditions are explained under which one form can be changed into the other, the transition temperature being about 74.8°.

3. Some of the confusion in the literature on this subject is thus explained.

The Condensation of 2-Butanone with Aldehydes of the Type RR'CHCHO[1,2]

BY S. G. POWELL AND MAYNARD M. BALDWIN

It has been shown that certain straight-chain aldehydes react with 2-butanone under the influence of alkaline condensing agents to form ketols of the type $RCHOHCH(CH_3)COCH_3$.[3] On the other hand, Thoms and Kahre found that with isobutyraldehyde the ketol $(CH_3)_2CHCHOHCH_2COC_2H_5$ was obtained.[4] It seemed therefore desirable to investigate the behavior of other aldehydes of the type RR'CHCHO.

2-Butanone was treated with methylethylacetaldehyde, diethylacetaldehyde, and ethyl-*n*-butylacetaldehyde in the presence of dilute potassium hydroxide. In each case the resulting ketol was dehydrated to the unsaturated ketone; this was reduced to the saturated secondary alcohol and this in turn oxidized to a mixture of acids as described in previous papers.[3c,3d,5] The water-insoluble acids obtained were then investigated and in each case the acid of the type RCH_2COOH (where the aldehyde in each instance is designated as RCHO) was found and in no case could the acid of the type RCOOH be identified, showing that the secondary alcohols were of the type $RCH_2CH_2CHOHC_2H_5$ and not $RCH_2CH(CH_3)COCH_3$, and that these aldehydes, like isobutyraldehyde, had reacted with the methyl group of the 2-butanone. The identity of the acids was established by a comparison of their piperazonium salts with those prepared from known samples of the acids which might be formed. Of the acids required for purposes of comparison β-ethylenanthic and γ-ethylcaprylic acids could not be found described in the literature and their preparation is given in detail. The other acids were

either purchased or prepared by standard methods.

Experimental Part

Methylethylacetaldehyde.—This was prepared by the dehydrogenation of *s*-butylcarbinol with a copper–chromium–barium oxide catalyst.[6] The *s*-butylcarbinol was made by the fractionation of the technical product obtained from the Eastman Kodak Company. The fraction boiling at 127–128° was used and its purity was tested by preparing the 3,5-dinitrobenzoate and comparing it with that of pure *s*-butylcarbinol and with that of isoamyl alcohol, the most likely impurity.

Diethylacetaldehyde.—One portion of this was prepared by the method of Darzens[7] from diethyl ketone and ethyl chloroacetate. The other portion was prepared from ethylmagnesium bromide and ethyl ethoxyacetate.[8]

Ethyl-*n*-butylacetaldehyde.—This was purchased from the Carbide and Carbon Chemicals Corporation under the name of "octyl aldehyde." The material was dried and distilled and the fraction boiling at 161–162° retained for use.

The Saturated Alcohols.—In Table I are listed some of the properties of the saturated secondary alcohols obtained by reducing the unsaturated ketones formed when the ketols were dehydrated.

Table I

	Alcohol	B. p., °C.	Mm.	n_D	d_4
1	6-Methyl-3-octanol	81–83	15	1.4372 (28°)	0.8320 (28°)
2	6-Ethyl-3-octanol	90–92	20	1.4371 (24°)	.8396 (24.5°)
3	6-Ethyl-3-decanol	119–120	18	1.4435 (28°)	.8364 (28°)

	Analyses			
	Calcd.		Found	
	C	H	C	H
1	74.92	13.98	75.02	13.55
2	75.87	14.02	75.37	13.76
3	77.33	14.07	76.99	13.67

β-Ethylenanthic Acid.—Ethyl-*n*-butylacetaldehyde was reduced to 2-ethyl-1-hexanol and this was converted into the bromide by treatment with phosphorus tribromide. The crude bromide was treated with sodium cyanide and the nitrile hydrolyzed in the usual manner with sodium hydroxide. The acid boiled at 135° (25 mm.) and at 236° (760 mm.).

Anal. Calcd. for $C_9H_{18}O_2$: C, 68.29; H, 11.47. Found: C, 68.41; H, 11.79.

2-Ethyl-1-hexanol.—The reduction of the ethyl-*n*-butylacetaldehyde was carried according to the method described for the preparation of 1-heptanol[9] using iron and acetic acid, and also by the use of sodium and moist ether. While the second method was inferior to the first in the matter of yield it was superior to it from the standpoint of convenience and time consumption. A solution of 5 g. of magnesium sulfate in 600 cc. of water, 500 cc. of ether, and 64 g. (0.5 mole) of the aldehyde were placed in a two-liter flask fitted with a condenser and dropping funnel. Sixty grams of sodium was then added in small portions through the condenser and at the same time acetic acid was added from the dropping funnel at such a rate that a slight precipitate of magnesium hydroxide was always present; yield 45%.

γ-Ethylcaprylic Acid.—This was prepared in the usual manner from 2-ethyl-1-bromohexane and ethyl malonate. The acid boiled at 253–256° (760 mm.).

Anal. Calcd. for $C_{10}H_{20}O_2$: C, 69.70; H, 11.71. Found: C, 69.67; H, 11.66.

The Piperazonium Salts.—The method of Pollard, Adelson, and Bain[10] was used for the preparation of these salts. Table II gives the properties of the piperazonium salts of the acids actually found among the water-insoluble oxidation products of the saturated alcohols. Although γ-ethylcaprylic acid was not among these, it is included in the table because it is a hitherto unknown acid.

Table II

Piperazonium salt of	M. p., °C.	Neut. equiv. Calcd.	Neut. equiv. Found	Nitrogen, % Calcd.	Nitrogen, % Found
β-Methylvaleric acid	129	318.2	316.2	8.79	8.85

The Addition of Sodium Bisulfite to Alkylene Oxides

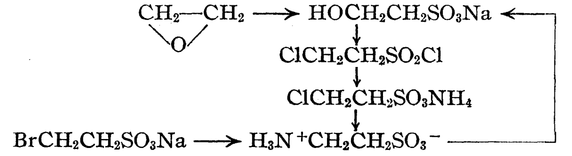
BY WALTER M. LAUER AND ARCHIE HILL

The addition of sodium or potassium bisulfite to an alkylene oxide has generally been assumed[1-5] to yield the corresponding salt of a β-hydroxysulfonic acid, even though the structure of addition compounds of this type has not been rigorously established. The work of Fromm, Kapeller and Taubmann[6] has introduced an element of doubt, however, since they have reported that the sodium bisulfite addition product obtained from epichlorhydrin,  $ClCH_2CH{-}CH_2$ (O bridging), after boiling with aqueous sodium hydroxide and subsequent treatment with hydrochloric acid, gave a positive test for sulfur dioxide. They regarded this as evidence for a C–O–S linkage and it therefore became of interest to attempt to decide between the two structures

$RCH(OH)CH_2SO_3Na$ (I) $RCH(OH)CH_2OSO_2Na$ (II)

for the product obtained by the action of sodium bisulfite on an alkylene oxide.

The following series of reactions, which demonstrates the correctness of the β-hydroxysulfonic acid structure (I), was carried out.



The taurine obtained in this manner from the bisulfite addition compound of ethylene oxide was identical with that obtained from sodium β-bromoethanesulfonate by the method of Marvel, Bailey and Sparberg[7] and the completion of the cycle of transformations by conversion of the taurine to the original addition compound makes a structural rearrangement improbable.

Since the alkali metal salts of β-hydroxysulfonates are water soluble and not infrequently difficult to free of inorganic sulfites, it is conceivable that the presence of sulfur dioxide upon acid treatment of the addition compound of Fromm, Kapeller and Taubmann can be accounted for in this way.

Experimental

Sodium β-Hydroxyethanesulfonate.—Ethylene oxide was passed into a concentrated solution of sodium bisulfite contained in a 500-cc. three-necked round-bottomed flask fitted with a mechanical stirrer and a reflux condenser. The ethylene oxide was absorbed rapidly with the evolution of heat. The bisulfite addition compound was obtained by evaporating the solution to dryness and extracting the solid residue repeatedly with 95% alcohol. Colorless crystalline sodium β-hydroxyethanesulfonate (m. p. 192–194°) separated from the alcoholic extract in approximately 60% yield.

Anal. Calcd. for $C_2H_5O_4SNa$: Na, 15.52. Found: Na, 15.68, 15.53.

Acetylation in a manner similar to that used in the case of the bisulfite addition compound of formaldehyde,[8] followed by crystallization from alcohol, yielded the acetyl derivative.

Anal. Calcd. for $C_4H_7O_5SNa$: Na, 12.10. Found: Na, 11.82, 11.98.

Potassium β-hydroxyethanesulfonate (m. p. 191–193°) was prepared in a manner similar to that described for the sodium compound. It was easier to obtain in pure form than the sodium salt.

Anal. Calcd. for $C_2H_5O_4SK$: K, 23.80. Found: K, 23.82, 23.94.

The acetylated product melted at 258–260°.

Anal. Calcd. for $C_4H_7O_5SK$: K, 18.95. Found: K, 19.08, 18.75.

The myristoyl derivative of the sodium β-hydroxyethanesulfonate, prepared by means of myristoyl chloride, was obtained in the form of a white powder which was rather difficult to purify. A mixture of benzene and water formed an emulsion when shaken with some of this material.

Anal. Calcd. for $C_{16}H_{31}O_5SNa$: Na, 6.44. Found: Na, 6.76.

β-Chloroethanesulfonyl Chloride.—The directions of Kolbe,[9] with slight modifications, served for the conversion of either the sodium or potassium β-hydroxysulfonate to β-chloroethanesulfonyl chloride. After the initial vigorous reaction with excess phosphorus pentachloride, the reaction mixture was refluxed gently for two to three hours. The reaction mixture was then poured onto ice. The oily layer was next fractionated; b. p. 13 mm. 86–88° (198–204° at 760 mm.). Twenty grams of the sodium bisulfite addition product and 57 g. of phosphorus pentachloride

yielded 14 g. of β-chloroethanesulfonyl chloride. Hydrolysis yielded β-chloroethanesulfonic acid.[10]

Ammonium β-Chloroethanesulfonate.—The viscous β-chloroethanesulfonic acid was treated with concd. ammonium hydroxide and the solution evaporated to dryness under reduced pressure. The residue was crystallized from alcohol.

Anal. Calcd. for $C_2H_8O_3ClNS$: C, 14.86; H, 4.99. Found: C, 15.18; H, 5.25.

Taurine was prepared by heating ammonium β-chloroethanesulfonate for twelve hours in a sealed tube at 105° with an excess of concd. ammonium hydroxide. Upon cooling, taurine separated out. It was recrystallized several times from water and was identical with a sample of taurine prepared by the method of Marvel, Bailey and Sparberg.[7] Identity was established by means of crystallographic examination.[11]

Potassium β-Hydroxyethanesulfonate from Taurine.—Acetic acid was added slowly to a hot aqueous solution containing taurine and potassium nitrite. After no further gas evolution, addition of acetic acid was discontinued and the solution was evaporated to dryness. The solid residue was extracted with hot alcohol. The alcohol extract yielded crystalline potassium β-hydroxyethanesulfonate; m. p. 189–191°.

Anal. Calcd. for $C_2H_5O_4SK$: K, 23.80. Found: K, 23.84.

A crystallographic examination showed this product to be identical with the one obtained by the addition of potassium bisulfite to ethylene oxide. Attempts to convert sodium β-bromoethanesulfonate to sodium β-hydroxyethanesulfonate by means of silver oxide led to products which were unsuited for crystallographic comparison.

Summary

The addition compound obtained by the action of sodium or potassium bisulfite on ethylene oxide has been shown to possess the β-hydroxysulfonic acid structure, a result which was generally accepted, but not demonstrated previously.

The Reaction of Haloamines with Ketenes

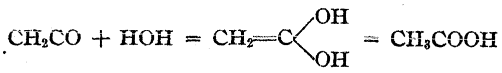
BY GEORGE H. COLEMAN, ROLF L. PETERSON AND GILBERT E. GOHEEN

Previous work in this Laboratory has shown that in the addition of nitrogen trichloride to unsaturated compounds[1] a chlorine atom in nitrogen trichloride behaves as though it were electropositive with respect to the NCl_2 group. By analogy it might be assumed that the halogens in other haloamines such as monochloroamine, monobromoamine, dibromoamine and the alkylchloroamines would show a similar behavior. The reactions of these compounds with reducing agents support this assumption. Attempts to bring about addition reactions of some of the haloamines other than nitrogen trichloride with unsaturated hydrocarbons have not been thus far successful. Monochloroamine reacts with Grignard reagents[2] to form primary amines and ammonia. With many of these reagents the percentage of amine formed is much greater than the percentage of ammonia. Such a result does not seem to be consistent with the assumption that in all reactions the NH_2 group in monochloroamine is electronegative with respect to the chlorine.

In the present work a study was made of the reactions of monochloroamine, dibromoamine, nitrogen trichloride and dimethylchloroamine with ketene and diphenylketene. The suitability of ketenes for this work depends on the fact that they are very reactive substances which add diverse molecules in a definite manner, as illustrated in the following well-known examples

$$CH_2CO + HOH = CH_3COOH$$
$$CH_2CO + RNH_2 = CH_3CONHR$$
$$CH_2CO + HCl = CH_3COCl$$

The activity of this class of compounds may be due to addition to the carbonyl group first and then rearrangement of the resulting enol form as postulated by Staudinger,[3] *e. g.*



$$CH_2CO + HOH = CH_2{=}C\begin{matrix}\diagup OH \\ \diagdown OH\end{matrix} = CH_3COOH$$

Regardless of the mechanism, however, by which the addition takes place, the final product is such that the electropositive portion of the adding molecule is found attached to the carbon farthest

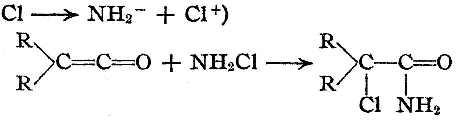
from the oxygen and the electronegative portion to the carbon to which the oxygen is united.

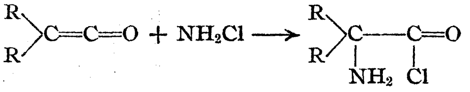
Applying these considerations to the question of the character of the halogen atoms in haloamines the following possibilities can be formulated for the reaction of monochloroamine with ketenes

($NH_2Cl \longrightarrow NH_2^- + Cl^+$)



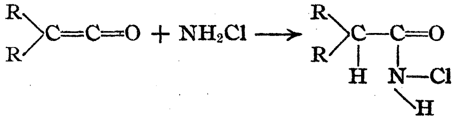
(1)

($NH_2Cl \longrightarrow NH_2^+ + Cl^-$)



(2)

($NH_2Cl \longrightarrow NHCl^- + H^+$)

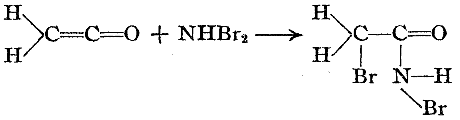


(3)

Diphenylketene was found to react with monochloroamine to form diphenylchloroacetamide according to equation (1). No evidence of the formation of other addition products was observed although the yield of diphenylchloroacetamide isolated was only 51% of the theoretical. With unsubstituted ketene (CH_2CO) N-chloroacetamide was formed in 70–75% yields, the reaction apparently occurring according to equation (3). The fact that the reaction with diphenylketene proceeds differently than that with ketene is not necessarily surprising, considering the electronegative character of the phenyl groups relative to hydrogen (Kharasch).[4]

Dibromoamine and ketene formed monobromoacetamide, a result most readily explained by assuming the reaction

($NHBr_2 \longrightarrow NHBr^- + Br^+$)



(4)

The replacement of the bromine on nitrogen by hydrogen is probably due to the presence of hydrobromic acid in the reaction mixture. If dibromoamine added to ketene in any other manner, acetamide or glycine would be the final product under the experimental conditions. It also seems quite improbable that the bromine on carbon could be due to direct bromination.

A nearly quantitative yield of N,N-dimethyldiphenylchloroacetamide was formed in the reaction of dimethylchloroamine with diphenylketene. In the light of previous work this product was to be expected.

With ketene and dimethylchloroamine a liquid product was obtained which after distillation had a chlorine and nitrogen content corresponding to that of N,N-dimethylchloroacetamide.

Nitrogen trichloride reacted with ketene to give as a final product monochloroacetamide in about 14% yields. This is in agreement with the assumption of relatively electropositive chlorine atoms in nitrogen trichloride. Boismenu[5] states that N,N-dichloroacetamide is unstable above 0°, decomposing with the liberation of chlorine. This instability may account in part for the low yield. The substitution of hydrogen for the chlorine on nitrogen is again doubtless due to the formation of hydrochloric acid in the reaction mixture.

The reaction of nitrogen trichloride with diphenylketene has been reported previously.[6] The results were interpreted as indicating the formation of N,N-dichlorodiphenylchloroacetamide which was transformed to benzophenoneimide hydrochloride. This reaction was repeated under different experimental conditions and a product isolated which was unstable at room temperature and contained chlorine attached to nitrogen. Its chlorine content corresponded to that of N,N-dichlorodiphenylchloroacetamide.

Experimental

Preparation of Haloamines.—The methods used in the preparation and analysis of monochloroamine,[2c,7] dibromoamine,[7] dimethylchloroamine[8] and nitrogen trichloride[9] were essentially those which have been described previously.

Preparation of Diphenylketene.—Diphenylketene was prepared as described by Schroeter.[10] The method has been investigated more recently by Ritter and Wiedeman.[11] It consists in the oxidation of benzil monohydrazone in benzene solution with yellow mercuric oxide. The azibenzil which is formed loses nitrogen on heating and rearranges to the ketene. The observations of Ritter and Wiedeman with respect to the freshness and character of the mercuric oxide to be used were substantiated. It was noticed that the tendency to form the side product bisbenzalketazine increased whenever the concentration of

the azibenzil solution was too great or whenever the solution was allowed to stand for some time. This was accompanied by premature slow evolution of nitrogen. The formation of the side product was avoided by using 8–9 cc. of dry benzene per gram of benzil monohydrazone, keeping the temperature at 23–24° during the oxidation and working up the reaction mixture without extended delay. In a typical run using 90 g. of powdered benzil monohydrazone there was obtained 44 g. of diphenylketene, b. p. 120–124° (1 mm.). This was 56% of the theoretical yield.

Preparation of Ketene.—Ketene was prepared by the method described by Hurd.[12] It was collected by bubbling the gases from the condenser into anhydrous ether cooled to −60°. The concentration was determined by adding aliquot portions to 3.5 *N* alkali and titrating the excess alkali with standard acid. The ethereal solutions were used at once.

The general method of carrying out the reactions with the haloamines is typified in the procedures described for the reactions of monochloroamine with ketene and diphenylketene. The essential results of the seven reactions studied are given in Table I. The products, with the exception of the two noted in the table, were identified by comparison with authentic samples.

Monochloroamine with Ketene.—Two hundred and twenty cubic centimeters of an ethereal solution containing 0.12 mole of monochloroamine was cooled to −60° and added to 225 cc. of an ethereal solution containing 0.162 mole of ketene also at −60°. The solutions were not exposed to moist air, the addition of the monochloroamine solution being effected through a vacuum jacketed glass tube. A white turbidity appeared at once. The reaction mixture was kept at −60° for three hours and then allowed to warm to room temperature and filtered. The white precipitate weighed 2.60 g. The filtrate was partially evaporated and a second crop of white crystals weighing 4.56 g. obtained. By complete evaporation of the solvent a third portion was obtained which after purification weighed 1.06 g. The total product weighed 8.22 g. It was recrystallized by dissolving in warm ether and cooling the solution to about −60°. Shiny white plates were formed, m. p. 111–112°.

Monochloroamine with Diphenylketene.—This reaction was carried out in a manner similar to that used with ketene. An ethereal solution of 0.13 mole of monochloroamine was added at −65° to an ethereal solution of 0.106 mole of diphenylketene. As the monochloroamine was added the orange color of the ketene solution faded and a white precipitate formed which proved to be ammonium chloride. The mixture was kept at −60° for thirty minutes, then allowed to warm to room temperature and kept at this temperature for eight hours. It was then filtered and the solvent evaporated at room temperature or below under reduced pressure. The residue was recrystallized from toluene. The total weight of material obtained melting above 105° was 13.4 g. (51% of the theoretical yield). After further recrystallization the product melted at 116.5–117°.

Summary

The haloamines monochloroamine, dibromoamine, nitrogen trichloride, and dimethylchloroamine react with ketene and diphenylketene to form amides or halogen substituted amides.

Molecular Size Distribution in Linear Condensation Polymers[1]

BY PAUL J. FLORY

Introduction

All synthetic polymers and most natural ones are recognized to be non-homogeneous substances consisting of mixtures of chemically similar molecules which are distributed in size about an average, some of them being much smaller and some much larger than this average. By various methods, more or less approximate estimates of the average molecular weights of such materials can be made, but as yet information concerning the distribution of molecules amongst the various sizes is exceedingly meager. An adequate understanding of the fundamental nature of polymeric substances requires comprehension of the molecular size distributions as well as the empirical compositions and average molecular weights.

Methods have been developed for the experimental determination of molecular size distributions in polymers by using the Svedberg ultracentrifuge,[2] but they have so far been applied only to a limited extent. Theoretical calculation of the molecular size distribution is possible if the kinetic mechanism of the polymerization process is sufficiently well understood. Such calculations have been attempted for vinyl polymerizations by Chalmers,[3] by Dostal and Mark,[4] and more recently by Schulz.[5]

The present paper offers a theoretical analysis of the molecular size distribution in linear condensation polymers formed by the inter-molecular reaction of bifunctional compounds. The polyesters prepared by Carothers and co-workers[6] provide excellent examples of this type of polymer. They are of two kinds, those formed from hydroxy acids

$$\text{HO—R—COOH} \xrightarrow{-\text{H}_2\text{O}} \text{H(O—R—CO)}_x\text{OH}$$

and those formed from glycols and dibasic acids

$$\text{HO—R—OH} + \text{HOCO—R}'\text{—COOH} \xrightarrow{-\text{H}_2\text{O}} \text{H(O—R—O—CO—R}'\text{—CO)}_x\text{OH}$$

In general, polymerizations[7] of the first type above may be formulated as

$$\text{(i)} \qquad x\ \text{A—B} \longrightarrow \text{A—B (A—B)}_{x-2}\text{A—B}$$

where A and B represent functional groups and AB, or BA, the product of their reaction with one another. A simple molecule such as water may or may not be released in this process. If, as in the second example above, there are two kinds of reactants, A—A and B—B, three varieties of molecules may be formed in the polymeric mixture, *viz.*,

(iia) If x, the total number of reactant molecules combined in the polymer molecule, is an even integer

$$x/2\ \text{A—A} + x/2\ \text{B—B} \longrightarrow \text{A—A (B—BA—A)}_{(x-2)/2}\text{B—B}$$

(iib) If x is odd, either

$$\left(\frac{x+1}{2}\right)\text{A—A} + \left(\frac{x-1}{2}\right)\text{B—B} \longrightarrow \text{A—A(B—BA—A)}_{(x-3)/2}\text{B—BA—A}$$

or

$$\left(\frac{x-1}{2}\right)\text{A—A} + \left(\frac{x+1}{2}\right)\text{B—B} \longrightarrow \text{B—BA—A(B—BA—A)}_{(x-3)/2}\text{B—B}$$

Another case which might be considered is that in which the functional groups are all alike, but this may be taken as a special case of (i) in which A = B.

It is characteristic of all of these polymerizations that they involve the coupling of two bifunctional compounds to form a bifunctional compound of higher molecular weight, which in turn is capable of polymerizing with other molecules. Here the reactions: monomer with monomer, monomer with polymer, and polymer with polymer all involve the same chemical process. These condensation polymerizations are not to be confused with polymerizations proceeding by a chain mechanism, for example, vinyl polymerizations,[8] or

---

[1] A preliminary account of part of this work was included in a paper presented by Dr. Wallace H. Carothers before the Faraday Society Symposium, September, 1935 [*Trans. Faraday Soc.*, **32**, 39 (1936)].

the polymerization of formaldehyde catalyzed by formic acid.[9]

The treatment which follows rests upon the fundamental assumption that the reactivity of a functional group, A or B, is independent of the size of the molecule to which it is attached. If the functional groups are separated by more than three atoms in the chain, this assumption is probably not seriously in error; if only one or two atoms separate the functional groups in the monomer, then the reactivities of monomer and dimer may differ greatly although the difference between dimer and trimer will be much less, between trimer and tetramer still less, etc.[10] If the reverse reaction, polymer degradation, occurs appreciably, it is necessary to append the assumption of equal reactivity of all links, AB, with respect to the reverse reaction, *e. g.*, hydrolysis in the case of polyesters. It is also assumed that the formation of cyclic compounds (as well as other side reactions) does not occur to an appreciable extent.[11] The errors arising from the assumptions will in general be most significant in the range of low molecular weights; for polymers of high average molecular weight, where the distribution is broad and the low molecular weight portion is small, deviation from the calculated results should not be large.

Theoretical Treatment and Discussion

Type (i) polymers and type (ii) polymers formed from equivalents of A—A and B—B molecules can be subjected to the same treatment and so will be considered simultaneously. The special and more complicated problem of the size distribution relations in type (ii) polymers formed from non-equivalents of A—A and B—B molecules will be relegated to a separate later section.

Definitions.—A reactant molecule or its radical will be defined as a "segment" and the term "x-mer" will denote a polymer composed of x segments, *e. g.*, a hexamer is a polymer composed of six segments.[12]

The following notation will be used:

n_0 = total number of segments = total number of A (or B) groups.

N = number of unreacted A (or B) groups which remain after the reaction has been in progress for a time, t.

$N_0 - N$ = number of reacted A (or B) groups.

(If desired, the N's may be expressed in moles without altering any of the equations which follow.)

p, the extent of reaction, = fraction of the total number of A (or B) groups which have reacted at time t

$$p = (N_0 - N)/N_0 \qquad (1)$$

Fundamental Distribution Functions.—In order to derive the distribution functions, let us determine the probability, Π_x, that a particular segment selected at random is part of an x-mer. Picture a large group of partially polymerized segments laid end to end, thus

$$\text{etc.}\ \underset{b_{-3}}{\underline{\qquad}}\ \ \underset{b_{-2}}{\underline{\qquad}}\ \ \underset{b_{-1}}{\overset{\text{S}}{\underline{\qquad}}}\ \ \underset{b_{1}}{\underline{\qquad}}\ \ \underset{b_{2}}{\underline{\qquad}}\ \ \underset{b_{3}}{\underline{\qquad}}\ \text{etc.}$$

the b's designating the linkages, or potential linkages, between the segments. Since all unreacted functional groups are assumed to be equally reactive, the probability that reaction has occurred to link the segments at any particular b is p and the probability that no linkage exists is $1-p$. There are x possible configurations, such as for example that consisting of linkages at $b_1, b_2 \ldots b_{x-1}$ and unreacted functional groups at b_{-1} and b_x, which fulfill the condition that the segment S be part of an x-mer. Since each of these consists of $x-1$ linkages and two unreacted potential linkages, the probability of the existence of each particular configuration is $p^{x-1}(1-p)^2$. The probability that any of the x configurations exists is[13]

$$\Pi_x = xp^{x-1}(1-p)^2 \qquad (2)$$

---

[9] Carruthers and Norrish, *Trans. Faraday Soc.*, **32**, 195 (1936).

[10] Factors which cause change in reaction rate during the course of the reaction do not invalidate this assumption if the rates of reaction of a monomer, a dimer, etc., are all affected equally. Thus, the increase in viscosity of the medium as the reaction progresses might slow down the reaction, but if the rate of reaction of each molecular species is slowed down proportionately the equality of the reactivities of all functional groups at any one time remains undisturbed.

[11] That the extent of ring formation in bifunctional esterifications involving unit lengths beyond 7 is exceedingly small has been shown experimentally in many papers published from this Laboratory—*e. g.*, Carothers and Hill, THIS JOURNAL, **54**, 1561 (1932). More recently something in the nature of quantitative data on this point has become available in a paper by Stoll and Rouve [*Helv. Chim. Acta*, **18**, 1087 (1935)]. By a long (and somewhat doubtful) extrapolation one can, for example, calculate that pure hydroxydecanoic acid would furnish only 0.0005% of monomeric lactone at complete esterification, while higher hydroxy acids might give as much as 0.2% of lactone.

[12] In condensations of type (i) a segment is identical with a "structural unit" as previously defined by Carothers [THIS JOURNAL, **51**, 2548 (1929); *ibid.*, **55**, 5023 (1933)], but in type (ii) condensations a segment is one A—A or one B—B group whereas the structural unit is A—AB—B. For type (ii) polymers the above definition of an x-mer does not agree with the previous definition according to which an x-mer contains x *structural units*. The above definitions have been adopted for the sake of simplifying the following analysis.

[13] Kuhn, *Ber.*, **63**, 1503 (1930), has derived the same equation for the molecular size distribution in a degraded cellulose formed by the hydrolysis of infinitely large cellulose molecules, assuming that all linkages are equally hydrolyzable. That the two distributions should be identical is obvious when one considers the equivalence of the formation of polymer molecules through random formation of linkages and through random breaking of linkages already formed. In a further study of the problem of cellulose degradation, Klages, *Z. physik. Chem.*, **A159**, 357 (1932), and Kuhn, *ibid.*, **A159**, 368 (1932), have taken into account the finite size of the cellulose molecule prior to its degradation, and they have deemed it necessary to consider different rates for mid-chain hydrolysis and for hydrolysis of the terminal unit. These added complications lead to results which differ from those for bifunctional condensations.

Schulz's[5] equation for the weight fraction distribution in vinyl

As a consequence of the definition of Π_x

$$\Pi_x = \frac{\text{Total number of segments which exist as components of } x\text{-mers}}{\text{Total number of segments } (= N_0)}$$

If in the condensation process no molecule such as water is eliminated, the molecular weight will be exactly proportional to the number of segments in the molecule, and Π_x will be exactly equal to the weight fraction of x-mers. If a molecule is eliminated in the condensation, the deviation from this proportionality (due to the excess weight of the unreacted terminal functional groups) will be negligible except for the very low molecular weight polymers. Hence, Π_x will be regarded hereinafter as the weight fraction.[14]

The number of x-mer molecules is given by

$$N_x = \frac{N_0\Pi_x}{x} = N_0p^{x-1}(1-p)^2 \qquad (3)$$

Since there is an average of one A (or B) group per molecule, the total number of molecules $N = N_0(1-p)$ (see (1)). Therefore, letting P_x be the mole fraction of x-mers

$$P_x = N_x/N = p^{x-1}(1-p) \qquad (4)$$

In order to locate the x value which gives a maximum in Π_x, let

$$\partial\Pi_x/\partial x = (1-p)^2\,(p^{x-1} + xp^{x-1}\ln p) = 0$$

Solutions are, $x = \infty$ (minimum), and

$$x_{\text{max.}} = -1/\ln p \qquad (5)$$

which for values of p near unity becomes

$$x_{\text{max.}} \cong 1/(1-p) = N_0/N = \text{average value of } x \qquad (5b)$$

At the maximum

$$\Pi_{\text{max.}} = -\frac{(1-p)^2}{\ln p}\,e^{-(1+\ln p)} \qquad (6)$$

which, on introducing approximations valid when p is near unity, becomes

$$\Pi_{\text{max.}} = (1-p)/e \qquad (6b)$$

Differentiating P_x with respect to x and equating to zero

$$\frac{\partial P_x}{\partial x} = p^{x-1}(1-p)\ln p = 0$$

Since $x = \infty$ is the only solution, P_x possesses no maximum with respect to x.

The values of p which will give respectively the maximum amount and the maximum number of a particular x-mer may be obtained as follows

$$\partial\Pi_x/\partial p = xp^{x-2}(1-p)(x-1-px-p) = 0$$

for which solutions are $p = 0$, 1 or

$$p_{\text{max.}} = (x-1)/(x+1) \qquad (7)$$

Similarly

$$\frac{\partial P_x}{\partial p} = p^{x-2}(x-px-1) = 0$$

$$p_{\text{max.}} = (x-1)/x \qquad (8)$$

Discussion and Graphs.—The weight fraction distribution function (2) and the mole fraction distribution function (4) are represented graphically in Figs. 1 and 2 and in Figs. 3 and 4, respectively, for the several values of p indicated above each curve. From the curves in Figs. 1 and 2 one can determine the relative quantities (by weight) of each molecular species; the curves in Figs. 3 and 4 give the relative numbers of molecules of each species. For the smaller values of p the weight fraction curve possesses a sharp maximum, but as p approaches unity, this maximum becomes lower, shifted to larger values of x, and broader in the sense that there are more species present in approximately the maximum amount.[15]

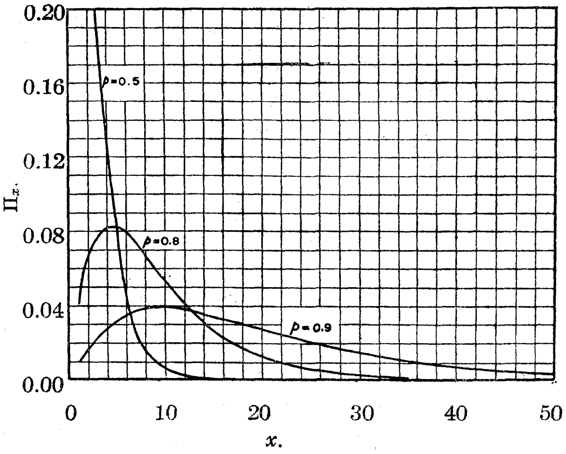

Fig. 1.—Weight fraction distributions for moderate extents of reaction (p). One square = 0.02 weight fraction.

---

polymers is essentially the same as (2) also, although it is based on an entirely different set of conditions. His equation for the weight fraction of x-mer expressed in the symbols used in this paper is $xp^x\,(\ln p)^2$ where $1-p$ $(1-\alpha$ in Schulz's terminology) is the ratio of the velocity of chain termination to the velocity of chain propagation. Inasmuch as Schulz was interested only in large x values, he replaced $1-x$ with x in the exponential. The constant term, $(\ln p)^2$, was evaluated by integration, a method which is approximate when applied to a mixture of molecules which vary in size in a stepwise manner. Had direct summation been used, this term would have been $(1-p)^2$ as in (2). However, for values of p near unity $(1-p)^2 = (\ln p)^2$.

(14) In type (ii) polymers it will be recalled that we have one type of x-mer when x is even and two when x is odd. When x is even the considerations of the preceding paragraph apply at once. When x is odd the numbers of the two types of x-mers are equal as a consequence of the assumption of equal reactivity of all A and of all B groups. It follows from this that if we take Π_x when x is odd to include both kinds of x-mers combined, then Π_x can be taken as the approximate weight fraction of x-mers in type (ii) as well as in (i) without further assumptions.

(15) It can be shown that the curves in Figs. 2 and 4 may be used for larger values of p by altering the coördinate scale according to the following rule: if p be increased so that $1-p$ is decreased n-fold, then the ordinate must be divided by n and the abscissa multiplied by n. Thus, the $p = 0.98$ curve may be used for $p = 0.998$ if the Π_x, or P_x values be divided by ten and the x values multiplied by ten. This procedure is approximate, but the error is insignificant if p is $\geqq 0.95$ and $x \geqq 20$.

The x-mer which is present in greater amount than any other, specified by the maximum in the Π_x curve, is given by (5) or (5b), and the quantity of this species is given by (6) or (6b). $x_{\text{max.}}$ coincides approximately with the average value of x (number-average, *cf. seq.*). It can be shown that for values of $p < 0.5$, monomer is in excess (by weight) of any other species; for $p > 0.5$, $x_{\text{max.}} \geqq 2$. As is shown by the above analysis, there is no maximum in the P_x curve for any value of p (see Figs. 3 and 4), and so *there are always more molecules of monomer than of any other single species.*

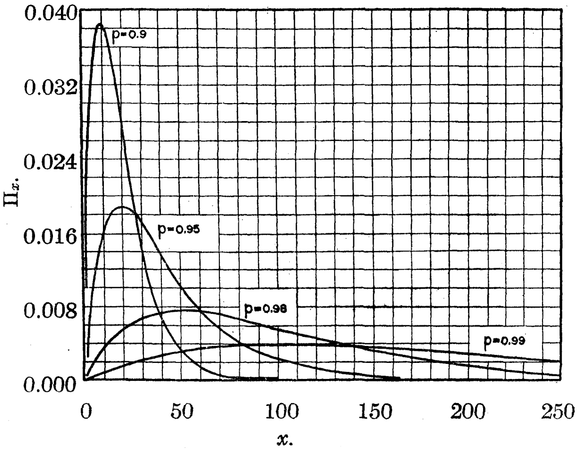

Fig. 2.—Weight fraction distributions for large extents of reaction. One square = 0.02 weight fraction.

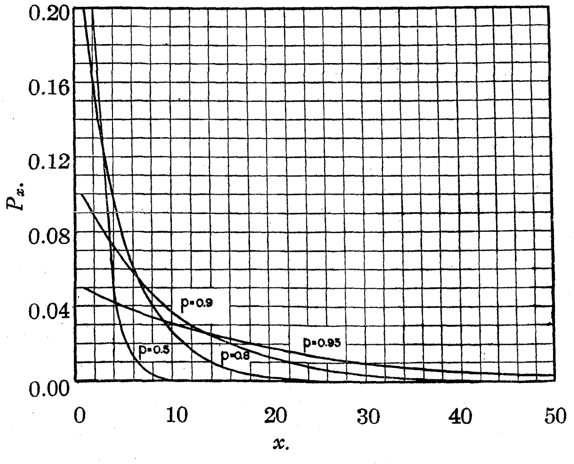

Fig. 3.—Mole fraction distributions for moderate extents of reaction (p). One square = 0.02 mole fraction.

In Fig. 5 the weight fraction is plotted against p for several values of x. As the reaction progresses, the amount of a particular x-mer builds up to a maximum located according to (7) at $p = (x - 1)/(x + 1)$ and then falls away to approach zero as p approaches unity. As x is increased, the maximum is lowered and shifted to higher p values. The mole fraction of a particular x-mer increases in a similar (but not identical) way as the reaction progresses, reaches a maximum (equation (8)) and then decreases to zero as p approaches unity.

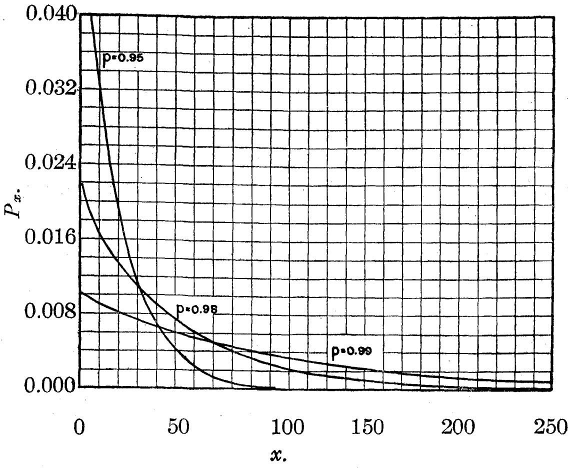

Fig. 4.—Mole fraction distributions for large extents of reaction. One square = 0.02 mole fraction.

The sum of the weight fractions of all constituents, of necessity always equal to unity, is approximately equal to the area under one of the curves in Figs. 1 and 2 from $x = 1$ to $x = \infty$, since[16]

$$\sum_{x=1}^{x=\infty} \Pi_x \cong \int \Pi_x \, dx$$

Similarly, the weight fraction of all constituents between $x = x_1$ and $x = x_2$ is approximately equal to the area under the curve from $x = x_1$ to

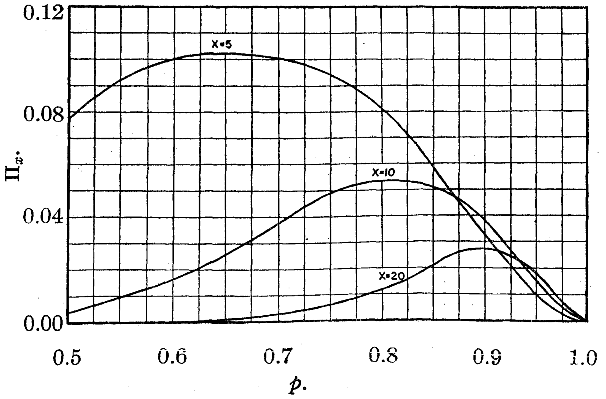

Fig. 5.—Weight fraction of x-mer *vs.* extent of reaction.

---

(16) The failure of this area to equal unity exactly arises because of the treatment of a discontinuous phenomenon as a continuous one; that is, only integral values of x have physical meaning, whereas the integration is carried out continuously over all values of x. When p is sufficiently large, however, the integral (or the area under the curve) differs inappreciably from unity.

$x = x_2$, and so the total weight fraction of these constituents can be evaluated graphically. This may be done in Figs. 1 and 2 by counting the squares under the curve between these limits and multiplying by 0.02. Similar considerations apply to the mole fraction graphs. This procedure is approximate, but for broad distributions ($p \geqq 0.90$) it may be used without significant error. For such distributions nearly three-fourths of the material (by weight) consists of molecules for which $x > x_{\text{max.}} \cong$ average x.

Molecular Weight Averages.—Lansing and Kraemer[2c] have discussed three different kinds of average molecular weights which are amenable to physical measurement. These are defined by the equations

$$M_n = \Sigma M_x N_x / \Sigma N_x \qquad (9)$$
$$M_w = \Sigma M_x^2 N_x / \Sigma M_x N_x \qquad (10)$$
$$M_z = \Sigma M_x^3 N_x / \Sigma M_x^2 N_x \qquad (11)$$

where M_x is the molecular weight of an x-mer molecule and N_x is the number of x-mers. The "number-average" molecular weight, M_n, may be obtained by ordinary physical or chemical methods (end group determination, osmotic pressure measurement, etc.); the "weight-average" molecular weight, M_w, and the "Z-average" molecular weight, M_z, can be evaluated from sedimentation equilibrium measurements in the ultracentrifuge. M_w may also be determined by means of Staudinger's[17] viscosity method (*cf. seq.*) in cases where this method is capable of yielding valid results.

These molecular weight averages may be evaluated in terms of p by substituting equation (3) for N_x, and xM_0 for M_x, the molecular weight of an x-mer molecule, where M_0 is the molecular weight of one segment.[18] These substitutions lead to the equations

$$M_n = M_0 \Sigma x p^{x-1}(1 - p)^2 / \Sigma p^{x-1}(1 - p)^2$$
$$M_w = M_0 \Sigma x^2 p^{x-1}(1 - p)^2 / \Sigma x p^{x-1}(1 - p)^2$$
$$M_z = M_0 \Sigma x^3 p^{x-1}(1 - p)^2 / \Sigma x^2 p^{x-1}(1 - p)^2$$

It can be shown that the values of the summations are as follows

$$\Sigma p^{x-1}(1 - p)^2 = 1 - p$$
$$\Sigma x p^{x-1}(1 - p)^2 = 1$$
$$\Sigma x^2 p^{x-1}(1 - p)^2 = (1 + p)/(1 - p)$$
$$\Sigma x^3 p^{x-1}(1 - p)^2 = (1 + 4p + p^2)/(1 - p)^2$$

Substituting these values in the equations for M_n, M_w and M_z

$$M_n = M_0/(1 - p) \qquad (12)$$
$$M_w = M_0(1 + p)/(1 - p) \qquad (13)$$
$$M_z = M_0(1 + 4p + p^2)/(1 - p^2) \qquad (14)$$

Also

$$M_n{:}M_w{:}M_z = 1{:}(1 + p){:}(1 + 4p + p^2)/(1 + p) \qquad (15)$$

The divergence among the three average molecular weights is a measure of the non-homogeneity of the polymer, and from it Lansing and Kraemer[2c] derive their "non-uniformity coefficient." The three averages are all equal when $p = 0$. As the polymerization proceeds and p increases, M_w becomes progressively greater than M_n, and M_z becomes greater than M_w. When p is close to unity, *i. e.*, when the average molecular weight is high, the ratio (15) becomes approximately

$$M_n{:}\,M_w{:}\,M_z = 1{:}2{:}3 \qquad (15b)$$

It will be well to emphasize the bearing of these results on Staudinger's method for determining molecular weights of linear polymers from the viscosities of their dilute solutions. He has advocated the use of the following relation for the determination of the average molecular weight of linear polymeric substances

$$KM_n = \left(\frac{\eta_r - 1}{c}\right)_{(c \rightarrow 0)}$$

where η_r is the relative viscosity, c is the concentration, and K is the Staudinger constant. Without taking into account different averages, Staudinger has used the common number-average molecular weight in the above equation. Kraemer and Lansing[19] have shown that the weight-average molecular weight, M_w, should be used in this equation instead of M_n. Therefore, only in cases where the ratio M_w/M_n is constant can it also be presumed that $[(1 - \eta_r)/c]_{(c \to 0)}$ will be proportional to M_n. As shown above, this ratio does become very nearly constant (equal to two) for high molecular weight polymers of the type considered here. Hence, though the Staudinger equation may be applicable to high molecular weight polymers of this type, when the molecular weight is low (when $p < 0.9$ and $M_n/M_0 < 10$), the use of this equation is no longer permissible. In its stead, one should use the equation

$$\left(\frac{\eta_r - 1}{c}\right)_{(c \rightarrow 0)} = K'M_w = K'(1 + p)M_n$$

where $K' = {}^1\!/_2K$. It would be interesting to trace experimentally the deviation from the

---

[17] Staudinger, "Die hochmolekularen organischen Verbindungen," J. Springer, Berlin, 1932.

[18] M_x may not equal xM_0 exactly inasmuch as the molecular weight of terminal groups (H and —OH in the case of polyesters) is neglected. However, for large molecules the discrepancy will be very small. If two kinds of segments are present (case (ii)), then M_0 must be taken as the mean molecular weight of the segments.

[19] Kraemer and Lansing, *J. Phys. Chem.*, **39**, 153 (1935); see also Kern, *Ber.*, **68**, 1439 (1935), and the work of Schulz[5] on vinyl polymers.

Staudinger equation in the range of low molecular weights.

Type (ii) Polymers Prepared from Nonequivalent Amounts of the Reactants.—As was described in the introduction, three kinds of molecules may be formed in type (ii) polymerizations: molecules composed of an even number of segments ("*even*" x-mers), molecules composed of an odd number of segments and terminated by A groups ("*odd*-A" x-mers), and molecules containing an odd number of segments and terminated by B groups ("*odd*-B" x-mers). When an excess of one reactant, arbitrarily chosen here as the reactant designated by B—B, is used, separate functions must be derived for each of the three kinds of molecules. The following modified terminology will be used.

N'_0 = number of A groups = twice number of A—A segments.

N''_0 = number of B groups = twice number of B—B segments.

N' and N'' are the numbers of the respective unreacted functional groups.

$N''_0 - N'_0 = N'' - N' = n$ = excess of B—B segments.

p = probability that an A group has reacted = $(N'_0 - N')/N'_0$

q = probability that a B group has reacted

$$= \frac{N''_0 - N''}{N''_0} = \frac{N'_0 - N'}{N''_0} = rp$$

where $r = N'_0/N''_0$.

In analogy to the method of derivation used formerly, a single segment S is selected at random from the sequence of segments

$$\begin{array}{c} \mathrm{S} \\ \text{—BA—AB—BA—AB—BA—AB—etc.} \\ b_3 \quad b_2 \quad b_1 \quad b_1 \quad b_2 \quad b_3 \end{array}$$

and the probability that it is a component of an x-mer is determined by adding the probabilities of each configuration which will meet this requirement. Because of the different varieties of polymers (see (iia) and (iib)) and the non-interchangeability of A—A and B—B when the latter are in excess, it will be necessary to use superscripts and subscripts to designate the various Π_x's, N_x's and P_x's which arise.

First, molecules for which x is an even integer will be considered. If the segment S selected at random happens to be an A—A, the probability that there is linkage at b_1 is p, at b_2 it is q, at b_3 it is p, etc., alternately. A similar rule applies to b_{-n}, and so we have p for the probability of linkage where n is odd (either + or −) and q where n is even. For each of the x configurations which will include S in the *even* x-mer, there will be $x/2$ links where n is odd, $(x/2)-1$ links where n is even, and one of the terminal groups will be A and the other B. The probability that any given A—A segment is a component of an *even* x-mer is, therefore

$$\begin{aligned} \Pi_x(even) &= xp^{x/2}q^{(x/2)-1}(1-p)(1-q) \\ &= xp^{x-1}\,r^{(x/2)-1}(1-p)(1-rp) \quad (16) \end{aligned}$$

If a B—B group had been selected as the segment S, the same considerations would apply with p and q interchanged. That is, if A's and B's were interchanged in the chain of segments pictured above then S would become a B—B segment, q would be the probability of linkage at b_n when n is odd, and p would be the probability when n is even. By interchanging p and q in (16) the probability, $\Pi''_x(even)$, that any given B—B segment is a part of an *even* x-mer is obtained.

$$\Pi''_0(even) = xp^{x-1}\,r^{x/2}(1-p)(1-rp) = r\Pi'_x(even) \quad (17)$$

The total number of segments in *even* x-mers = $xN_x(even)$ =

$$(N'_0/2)\Pi'_x(even) + (N''_0/2)\,\Pi''_x(even)$$

Substituting (16) and (17) and recalling that $rN''_0 = N'_0$

$$N_x(even) = \frac{N'_0\Pi'_x(even)}{x} = N'p^{x-1}\,r^{x/2}\,[(1-p)(1-rp)r^{-1}] \quad (18)$$

For the fraction of the total number of *both* kinds of segments which are contained in *even* x-mers

$$\Pi_x(even) = \frac{xN_x(even)}{1/2\,(N'_0 + N''_0)}$$

Substituting $N'_0 + N''_0 = N'_0(1+r)/r$ and (18) in the above

$$\Pi_x(even) = xp^{x-1}\,r^{x/2}\,\frac{2(1-p)(1-rp)}{1+r} \quad (19)$$

$\Pi_x(even)$ is the approximate weight fraction of an *even* x-mer (21).

For the mole fraction of *even* x-mer

$$P_x(even) = \frac{N_x}{\text{Total no. of molecules}} = \frac{N_x}{1/2(N' + N'')}$$

$$N' = (1-p)N'_0$$

$$N'' = (1/r - p)N'_0$$

From (18), therefore

$$P_x(even) = p^{x-1}\,r^{x/2}\left[\frac{2(1-p)(1-rp)}{(1+1/r-2p)r}\right] \quad (20)$$

When x is odd the number of links is even and the two terminal groups are either both A's or both B's (see (iib)). First, let us find the probability, $\Pi'_x(odd\text{-A})$, that an A—A segment such as S is a component of an *odd* x-mer having A groups at its ends. Each of the $(x+1)/2$ configurations fulfilling this requirement contains

$(x - 1)/2$ links at b_n's where n is odd and $(x - 1)/2$ links where n is even. Therefore

$$\Pi_x'(odd\text{-A}) = \left(\frac{x+1}{2}\right)(pq)^{(x-1)/2}(1-p)^2$$
$$= \left(\frac{x+1}{2}\right)p^{x-1}\,r^{(x-1)/2}(1-p)^2 \qquad (21)$$

There are $(x - 1)/2$ configurations containing the A—A segment, S, which give *odd* x-mers having B end groups. For each of these there are $(x + 1)/2$ links where n is odd and $(x - 3)/2$ where n is even. Consequently

$$\Pi_x'(odd\text{-B}) = \frac{x-1}{2}\,p^{x-1}\,r^{(x-3)/2}(1-rp)^2 \qquad (22)$$

To find the corresponding probabilities that a B—B segment is a component of an *odd* x-mer, A is interchanged with B and p with q, as was done above. When A and B are interchanged in configurations giving *odd*-A terminated x-mers, *odd*-B terminated x-mers result. By interchanging p and q in (21) one gets the probability, Π_x'' (*odd*-B), that any given B—B segment is contained in an *odd* x-mer terminated with B groups.

$$\Pi_x''(odd\text{-B}) = \frac{x+1}{2}\,p^{x-1}\,r^{(x-1)/2}(1-rp)^2 \qquad (23)$$

Similarly by interchanging p and q in $\Pi_x'(odd\text{-B})$ one gets

$$\Pi_x''(odd\text{-A}) = \frac{(x-1)}{2}\,p^{x-1}\,r^{(x+1)/2}(1-p)^2 \qquad (24)$$

The total number of segments contained in *odd* x-mers terminated with A groups is given by $xN_x(odd\text{-A}) = {}^1/_2\ N_0'\ \Pi_x'(odd\text{-A}) + {}^1/_2\ N_0''\ \Pi''$ (*odd*-A). Replacing N_0'' by N_0'/r and introducing (21) and (24)

$$N_x(odd\text{-A}) = N'\,p^{x-1}\,r^{x/2}\,[1/2(1-p)^2\,r^{-1/2}] \qquad (25)$$

Similarly

$$N_x(odd\text{-B}) = N'\,p^{x-1}\,r^{x/2}\,[1/2\,(1-rp)^2\,r^{-3/2}] \qquad (26)$$

The corresponding Π_x's are

$$\Pi_x(odd\text{-A}) = \frac{xN_x(odd\text{-A})}{1/2(N' + N'')}$$
$$= xp^{x-1}\,r^{x/2}\left[\frac{(1-p)^2\,r^{-1/2}}{1+r}\right] \qquad (27)$$

and

$$\Pi_x(odd\text{-B}) = xp^{x-1}\,r^{x/2}\left[\frac{(1-rp)^2}{1+r}\,r^{-1/2}\right] \qquad (28)$$

The mole fractions $P_x(odd\text{-A})$ and $P_x(odd\text{-B})$ can be derived from (25) and (26) in the same way that (20) was obtained from (18).

$$P_x(odd\text{-A}) = p^{x-1}\,r^{x/2}\left[\frac{(1-p)^2\,r^{-1/2}}{1+1/r-2p}\right] \qquad (29)$$

and

$$P_x(odd\text{-B}) = p^{x-1}\,r^{x/2}\left[\frac{(1-rp)^2\,r^{-3/2}}{1+1/r-2p}\right] \qquad (30)$$

Overlooking for the moment that x cannot assume the same integers in both *even* and *odd* functions, (19), (27) and (28) lead to the ratio

$$\Pi_x(even):\Pi_x(odd\text{-A}):\Pi_x(odd\text{-B}) =$$
$$2(1-p)(1-rp):(1-p)^2r^{1/2}:(1-rp)^2\,r^{-1/2} \qquad (31)$$

which is independent of x. The corresponding ratios for the N_x's and P_x's are identical with the above ratio.

Substituting $p = 1$ in the above equations to obtain distributions at completion of the reaction

$$\Pi_x(even) = \Pi_x(odd\text{-A}) = 0$$
$$P_x(even) = P_x(odd\text{-A}) = 0$$
$$\Pi_x(odd\text{-B}) = xr^{x/2}(1-r^2)r^{-1/2}/(1+r) \qquad (28b)$$
$$P_x(odd\text{-B}) = r^{x/2}(1-r)r^{-1/2} \qquad (30b)$$

The complete absence of *even* and *odd*-A molecules is a consequence of the reaction of all A groups.

To summarize the above equations, (18), (19) and (20) give, respectively, the numbers, the weight fractions and the mole fractions of *even* molecules. The corresponding quantities for *odd*-A molecules are given by (25), (27) and (29), and for *odd*-B molecules by (26), (28) and (30). The distributions at completion of the reaction ($p = 1$) are given by (28b) and (30b).

The weight fraction distribution functions are plotted in Fig. 6 for $r = 0.80$ (25% excess of B—B molecules) at the three stages of the reaction, $p = 0.85$, 0.95 and 1.00. All three curves for a given pair of r and p values are similar in the sense that, as shown by (30), for all x values the ratio of the three Π_x's is the same. Consequently, all three maxima come at the same molecular size (x value). In Fig. 7 the weight-fraction of x-mer (*odd*-B only, since all other types are absent) is plotted against x at complete reaction (equation (28b)) for several values of r. The method of area summation given above can be applied in these figures also.

For any value of r there are present initially ($p = 0$) only *odd*-A (A—A) and *odd*-B (B—B) molecules, and even molecules are absent entirely. If the numbers of the two kinds of segments are equal ($r = 1$), the amount of *even* polymer will increase steadily (starting from zero) as the reaction progresses, until the amounts of *even* and *odd* (*odd*-A plus *odd*-B) molecules become practically equal. With an excess of B—B segments present, the amount of *even* polymer increases until a maximum is reached and then decreases steadily, returning to zero when $p = 1$. At this maximum the amount of *even* polymer may or may not be greater than the amount of *odd*-B polymer, but for all values of p the amount of *even* polymer is less than the amount of BOTH kinds of *odd* polymer. The amount of *odd*-A polymer is always less than the amount of *odd*-B polymer and the ratio of the former to the latter becomes less as p increases. These characteristics are illustrated in Fig. 6.

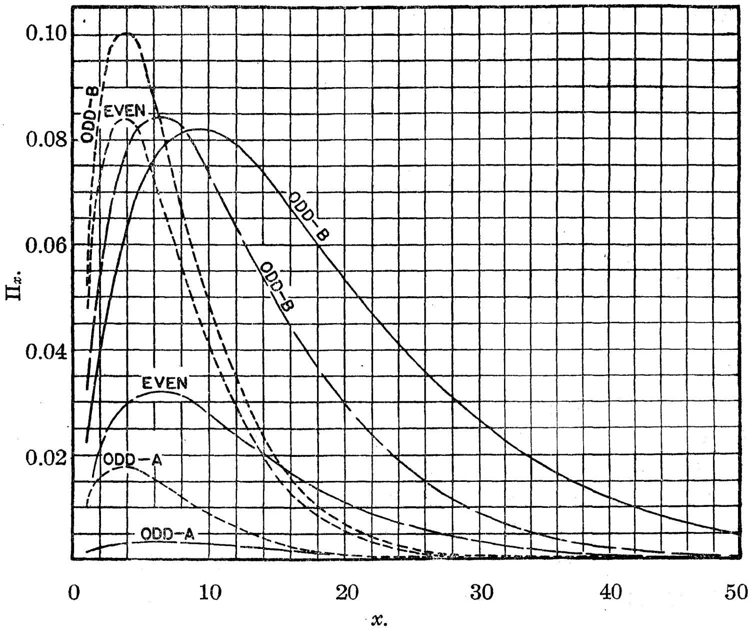

Fig. 6.—Weight fraction distribution curves for a 25% excess of B groups (r = 0.80). When p = 0.85 - - - -, p = 0.95 ——— and p = 1.00 ———. Curves labeled "even" are for *even* molecules, *i. e.*, those having an even number of segments; those labeled "odd-A" are for *odd* molecules having A groups as termini, and those labeled "odd-B" are for *odd*, B terminated molecules. The even curves apply for even integers only, the odd curves for odd integers only. One square = 0.005 weight fraction.

When equivalents of the reactants are used, the number-average molecular weight is

$$M_n = \frac{M_0(N_0' + N_0'')}{N' + N''} = M_0(1 + r)/(1 + r - 2rp) \quad (32)$$

where M_0[20] is the average molecular weight of one segment. When $r = 1$ this equation reduces to (12). At completion of the reaction when $p = 1$

$$M_n = M_0\,(1 + r)/(1 - r) \quad (32b)$$

This equation shows the effect of an excess of one reactant in limiting the maximum molecular weight which can be reached.

The type of distribution of molecules obtained when an excess of one reactant is used closely simulates the distribution in polymers formed from exact equivalents. (Compare curves in Figs. 6 and 7 with those in Figs. 1 and 2.) The dependence of weight fraction, or mole fraction, on x is of the same type; the principal difference lies in the replacement of p by $r^{1/2}p$. It can be shown that if $r^{1/2}p$ for one polymer equals $r^{1/2}p$ for another polymer, then their average molecular weights will be nearly the same (except when $r^{1/2}p$ is much less than unity), the maxima in their Π_x *vs.* x curves will occur at the same x value, and the distribution curves will vary with x in a similar way. The two distributions will differ only in the ratio of the quantities of the three kinds of molecules, *even*, *odd*-A and *odd*-B (2:1:1 for r = 1). Thus, for example, for a particular even value of x there will be fewer *even* x-mers contained in a polymer for which $r = r_1$ than in another polymer of the same average molecular weight (*i. e.*, the same $r^{1/2}p$ value) but for which $r = r_2 > r_1$; but the amount of *odd* (x + 1)-mers in the former polymer will be greater by a corresponding amount (unless M_n is very low). Unless the method of examination of the two polymers is sufficiently precise to differentiate consecutive members in the sequence of sizes, the two distributions will appear to be identical if $r^{1/2}p$ of one equals $r^{1/2}p$ for the other.

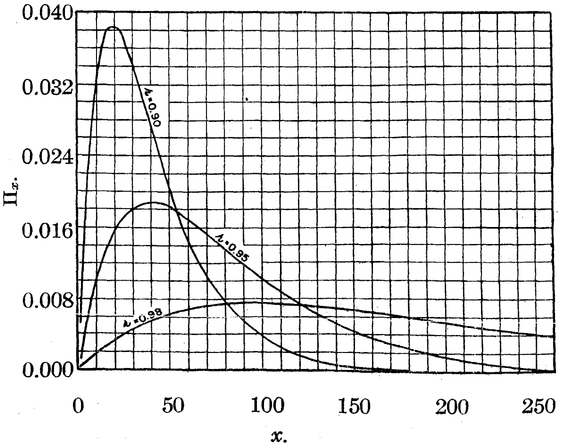

Fig. 7.—Weight fractions at completion of the reaction (p=1) for several values of r. Only odd integral values of x are significant. One square = 0.01 weight fraction.

---

[20] In this case, $M_0 = \dfrac{M_0'N_0' + M_0''N_0''}{N_0' + N_0''}$ where M_0' and M_0'' are the respective molecular weights of the two segments as contained within a polymer molecule.

The distribution functions possess maxima characteristics similar to those previously discussed for "$r = 1$" polymers. In fact, the same equations may be used for locating the $x_{\text{max.}}$ value for Π_x by replacing p with $r^{1/2}p$. Exact equations for M_w and M_z, corresponding to equations (13) and (14), are cumbersome; for all practical purposes it is permissible merely to replace p with $r^{1/2}p$ in (13) and (14), respectively. It follows that here also the ratio of $M_n:M_w:M_z$ approaches 1:2:3 for high molecular weights. Thus, sedimentation equilibrium measurements in the ultracentrifuge would not distinguish the two types of polymers.

The author wishes to acknowledge his gratitude to Dr. Wallace H. Carothers for his valuable advice and keen interest in this work. The author is also indebted to Dr. E. O. Kraemer for reading and criticizing the manuscript.

Summary

1. Equations expressing the weight fraction, number, and mole fraction of each molecular species in a linear condensation polymer have been derived on the basis of simple and not improbable assumptions. The characteristics of these functions have been demonstrated and discussed.

2. The number-average, weight-average and Z-average molecular weights of Lansing and Kraemer are shown to be in the ratio 1:2:3 for the high molecular weight polymers. The bearing of this result on Staudinger's method for determining molecular weights has been discussed.

3. The special case of polymers prepared by the condensation of non-equivalents of two bifunctional reactants (A—A + B—B) has been analyzed and shown to conform to a distribution similar to the above. Other special cases can be subjected to a similar analysis.

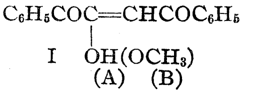
Further Studies on 1,4-Diphenyl-1,2,4-butanetrione Enol, Including Alkylation and Benzoylation

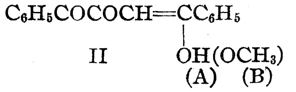
BY ROBERT E. LUTZ AND ALFRED H. STUART

Two methyl ethers have been obtained from the enol. One of these, dibenzoylmethoxyethylene I(B), the structure of which is certain, was made directly by the action of diazomethane.[1b] The other, a structural isomer II(B) or III(B), was obtained by the action of methanol and acid on the enol or various of its derivatives and was believed to have the open chain structure II(B) because it gave methyl benzoate on ozonization;[1b] however, the alternative cyclic structure III(B),[2] which was not considered at that time, also would account for this result.



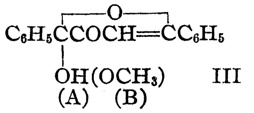
I

$C_6H_5COC(OH(OCH_3))=CHCOC_6H_5$ (A) (B)



II

$C_6H_5COCOCH=CC_6H_5(OH(OCH_3))$ (A) (B)



III

$C_6H_5C(OH(OCH_3))COCH=CC_6H_5$ (A) (B)

The ease of formation of the isomeric ether by catalytic etherification does not distinguish between the two formulations II(B) and III(B) since there is analogy for the reaction in both open chain and cyclic types (*cf.* hydroxynaphthoquinone[3] and the sugars). The quinoxaline reaction, however, which is specific for α-diketones, has been used.[2a]

o-Phenylenediamine reacts readily with the enol to give a quinoxaline (IV) which is bright orange in color in contrast with other quinoxalines of this series. Oxidation of this product by means of chromic acid gives the carboxy and

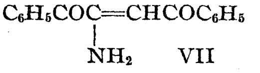
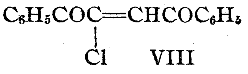
hydroxy quinoxalines V and VI.[4] The structure of IV seems to be established adequately by these reactions; however, the color is not accounted for.

Dibenzoylmethoxyethylene I(B), the structurally isomeric ether, and dibenzoylamino and chloroethylenes (VII and VIII) do not react under ordinary conditions with *o*-phenylenediamine. However, under more drastic conditions, namely, long continued refluxing with the reagents, dibenzoylmethoxyethylene gives IV with elimination of the methoxyl group, a reaction involving either the conjugated system or hydrolysis first to the reactive enol (the ether is known to be hydrolyzed or ammonolyzed easily).[1b] Dibenzoylaminoethylene VII under these conditions reacts very slowly giving IV, but the isomeric ether II or III(B) and also the *trans* chloro compound VIII, are stable.



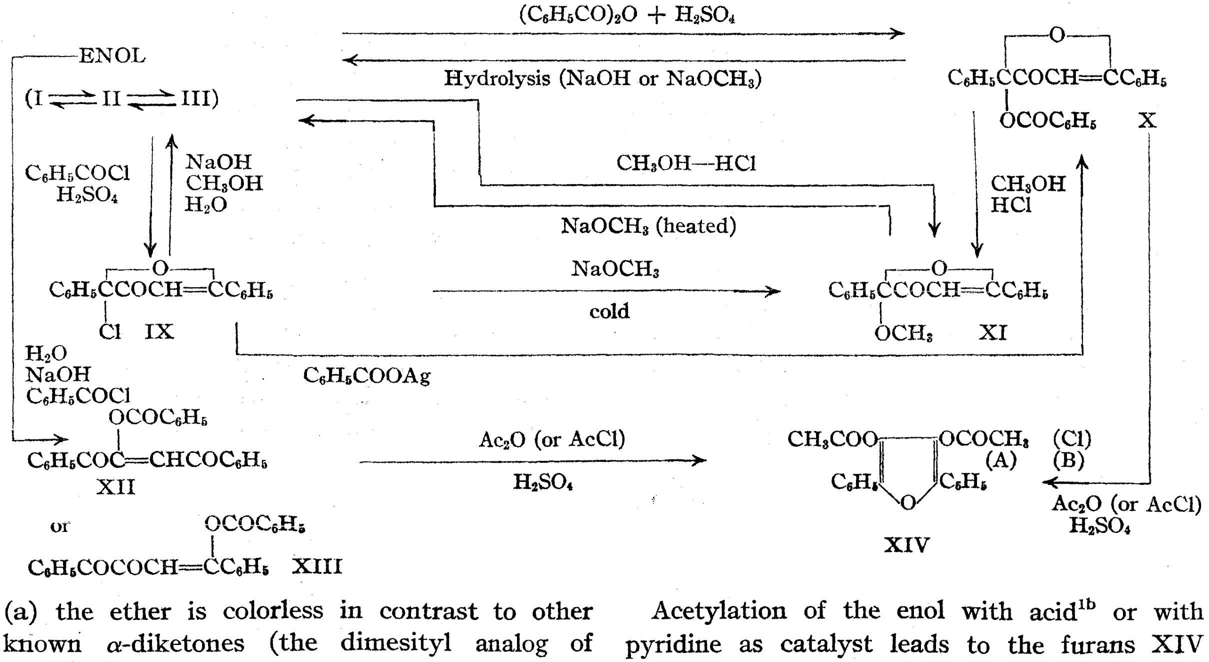
$C_6H_5C(NH_2){=}CHCOC_6H_5$ VII



$C_6H_5C(Cl){=}CHCOC_6H_5$ VIII

In regard to the bearing of these facts on the structure of the isomeric ether, the α-diketone formula II(B) seems to be excluded by the failure to react with *o*-phenylenediamine even under drastic conditions, and the cyclic formula III(B) is therefore the correct one. Other properties[1] of the ether support this conclusion: (a) the ether is colorless in contrast to other known α-diketones (the dimesityl analog of II(B) is bright yellow);[5] (b) it is not easily reduced by sodium hydrosulfite or zinc and acetic acid under ordinary conditions as would be expected of an α-diketone; (c) it does not react with acetyl chloride or acetic anhydride and sulfuric acid under ordinary conditions (as does dibenzoylmethoxyethylene I(B) and as presumably would an ether of formula II(B); and (d) it is only slowly hydrolyzed with alkali whereas the true enol ether, dibenzoylmethoxyethylene, and the two analogous 2- and 4-methoxynaphthoquinones[3] are hydrolyzed very rapidly under these conditions.

The chloro compound obtained by the action of thionyl chloride on either the enol or its methyl ether I(B) was previously assumed to be C_6H_5CO-$COCH{=}C(Cl)C_6H_5$.[1e] This compound must have the cyclic structure IX, however, in view of the following facts: (a) it is colorless; (b) it reacts readily with *o*-phenylenediamine to give the quinoxaline IV; (c) the chlorine is reactive as shown by the ease with which it is eliminated in the quinoxaline reaction and also in methanolysis to the cyclic ether III(B); and (d) the chlorine is replaceable readily by methoxyl by means of cold sodium methylate, giving the cyclic ether III(B) under conditions wherein the open chain enol ether I(B) is hydrolyzed directly to the enol.



Acetylation of the enol with acid[1b] or with pyridine as catalyst leads to the furans XIV (A and B). Studies on the enol salts, however, led to intractable products.

The action of benzoyl chloride and sulfuric

---

(4) We are indebted to Dr. A. H. Blatt for furnishing samples of V and VI for purposes of identification.

(5) Lutz and Wood, unpublished results.

acid on the enol gave the cyclic chloro compound IX instead of the expected furan of the type XIV(B). Benzoic anhydride and sulfuric acid likewise failed to give the benzoyl analog of the furan XIV(A), but instead gave a cyclic benzoate X the structure of which follows from its synthesis from the cyclic chloro compound IX by means of silver benzoate, and from its failure to react with *o*-phenylenediamine, in contrast with the open chain enol benzoate XII which reacts readily. The cyclic benzoate (X) is very reactive as would be expected; methanolic hydrogen chloride converts it into the cyclic methyl ether XI, sodium methylate hydrolyzes it quickly to the enol, and acetic anhydride or acetyl chloride with sulfuric acid converts it into the diacetoxy or acetoxychlorofurans XIV (A) or (B).

Benzoylation of the sodium salt of the enol in aqueous alkaline medium gives yields as high as 50% of the enol benzoate. The nature of this product is evident from the ease of hydrolysis to the enol and benzoic acid by means of cold alkali. Of the two possible formulas, XII and XIII, the former is the more likely, particularly in view of the absence of color. It reacts readily with *o*-phenylenediamine giving the quinoxaline IV, with methanolic hydrogen chloride to give the cyclic ether XI, and with acetic anhydride or acetyl chloride and sulfuric acid to give the diacetoxy and acetoxychlorofurans XIV(A) or (B). The ease of replacement of benzoyl by acetyl shows that neither this reaction nor the analogous conversion to a β-benzoyloxyfuran could be used to distinguish between the two structures XII and XIII. Preliminary reduction experiments with this end in view have not been successful.

There was produced consistently in the benzoylation of the sodium enolate in isopropyl ether as solvent smaller yields (30% or less) of the enol benzoate XII together with 20–25% yields of a product derived from the carbon benzoyl compound. The studies of the latter series are not yet completed and will be the subject of a later paper.

We have evidence that the true open chain enol methyl ether II(B), which we have not yet been able to isolate and characterize, is formed in considerable amount during methylation of the enol with diazomethane. Both forms of the enol react similarly, even in petroleum ether, solvent conditions under which they appear to be reasonably stable. The yields of dibenzoylmethoxyethylene I(B) average 30–50%. The oily product at the beginning contains no unchanged enol as shown by the absence of the very characteristic red ferric chloride test. However, in the course of handling the crude mixtures in order to isolate the dibenzoylmethoxyethylene, free enol is regenerated, gives a strong ferric chloride test, and has been isolated in one instance. The quinoxaline test on these oils gave amounts of IV corresponding to total yields of about 15–30% (neither the ethers I(B) nor III(B) react under these conditions). These facts indicate the presence of an unstable enol derivative which is readily hydrolyzed to the enol and which appears to be the open chain ether II(B). This hypothesis is not unreasonable in view of the fact that the analog has since been isolated in the dimesityl series.[5] Further evidence for the presence of this compound in approximately the amounts indicated above was obtained by ozonizing the crude product after separation of the dibenzoylmethoxyethylene and isolating methyl benzoate in a yield of 20%. The cyclic ether III(B), if present, would have given this result, but it could hardly have been formed as a result of methylation of III with diazomethane; furthermore, it crystallizes easily, has never been isolated in this type of methylation, and could not possibly have been present in amounts sufficient to account for the above result. It seems to be established, therefore, that the ether II(B) as well as I(B) is formed in the methylation of the enol with diazomethane, and that the enol reacts partly in the sense of formula II(A) as well as I and III(A).[6]

The foregoing facts necessitate reconsideration of the structural relations of the two solid forms of the enol. Both isomers react readily and similarly with one equivalent of bromine, and with ferric chloride, in ethanol at −10–15°, and with diazomethane in petroleum ether, solvent conditions under which the two forms alone appear to be fairly stable. It is not certain, however, that they are both true enols in view of the great mobility of the equilibrium and probable catalytic effect of the reagents, and

---

[6] In this connection it is noteworthy that since phenylglyoxylic acid was not found in significant amounts in the above ozonization of II(B), the discussion of results in the first paper (end of p. 1781, ref. 1b) is valid even though the methyl ether then under consideration (formula VIII of that paper) was really the cyclic compound III(B).

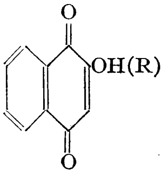
since a cyclic compound such as III(A) might react with bromine in much the same sense as the enol. The hypothesis that the two forms are *cis–trans* enols[1b] is unlikely, particularly in view of the fact that on methylation with diazomethane they give the same mixtures of the two structural and not stereoisomeric methyl ethers. The properties of the yellow form are in accord with an assumption of chelation between I(A) (*trans*) and II(A), with the possibility of actual existence of both isomers minimized or eliminated (through resonance). The colorless form can hardly be the triketone or the enol II(A) in view of the absence of color. The cyclic formulation III(A) for this isomer is the most reasonable one since, coupled with the assumption of chelation in the yellow form, it explains adequately why the two isomers always give the same results on methylation with diazomethane.

The formation of the cyclic ether III(B) upon alkylation of the sodium salt with dimethyl sulfate (reported in an earlier paper[1b]) was found to result not from direct alkylation but from hydrolysis of the sodium salt and catalytic etherification of the resulting enol through the action of alcohol and the acid generated by hydrolysis of dimethyl sulfate. In inert solvents the sodium salt does not react either with dimethyl sulfate or methyl iodide. In aqueous media, the alkylation was too slow to compete with hydrolysis of the reagent.

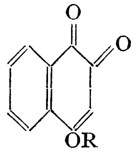
Alkylation was more conveniently studied using the silver salt and alkyl halides. With methyl iodide a 70% yield of the carbon–alkyl compound resulted, the gross structure of which was shown by hydrolytic fission to phenylglyoxylic acid and propiophenone. The oxygen–alkyl compound I(A) was formed also in approximately 10% yield. The new carbon–alkyl compound apparently has the cyclic structure  $C_6H_5C(OH)COC(CH_3){=}CC_6H_5$ (O bridging the two C atoms), XV (*cf.* ref. 2b), and will be considered in a later paper.

Ethylation of the silver salt with ethyl iodide gave a mixture from which were obtained yields of carbon- and oxygen–alkyl compounds of 50 and 20%, respectively. The carbon–alkyl compound (new) was identified by hydrolytic fission to phenylglyoxylic acid and butyrophenone. Propyl iodide also gave a carbon–alkyl product (45% yield, identified by hydrolytic fission); however, in this case we were unable to isolate a crystalline oxygen–alkyl compound from the residual oils.

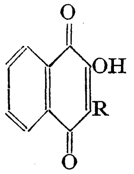
From the above results it would appear that there is nothing strikingly abnormal in the mode of alkylation in this series, contrary to the inference previously drawn from preliminary experiments.[1b] The yield of carbon–alkyl product, however, is relatively very high as compared with that in the alkylation of the α-diketones[7] and hydroxynaphthoquinone.[3]



XVI



XVII



XVIII

The analogy between the enol I(A) and hydroxynaphthoquinone XVI deserves emphasis. Both have the 1,2,4-triketone-enol system terminated by aromatic groups and both are rather strongly acidic. In both cases the silver salt is easily alkylated in contrast with the sodium salt. Hydroxynaphthoquinone gives mixtures of the two oxygen ethers XVI and XVII but does not give carbon–alkyl compounds (XVIII) with simple alkyl halides (methyl and ethyl) although considerable amounts are formed when more active unsaturated halides are used. In the case of diphenylbutanetrione enol, however, carbon-alkylation is the dominant reaction and alkylation at the enol oxygen-4 (formula IIB) was not observed although it may have occurred to a very small extent. Diazomethane reacts with hydroxynaphthoquinone to give exclusively the 2-oxygen ether, but in the case of our enol there is formed a mixture of the ethers I(B) and II(B). Catalytic etherification of I(A) leads to the formation of the cyclic ether III(B); however, with hydroxynaphthoquinone, where cyclization and chelation are excluded on steric grounds, only the 2-ether is formed. Both hydroxynaphthoquinone ethers XVI and XVII are hydrolyzed easily by alkali as are the enol ethers I(B) and II(B) (the 4-ethers in both series appear consistently to be more easily hydrolyzed than the 2-ethers). The cyclic ether III(B), in contrast with true enol ethers, is not hydrolyzed by alkali with the same degree of ease.

Experimental Part

The experiments on the two isomeric enols were largely repetitions of earlier experiments by methods described elsewhere, and since in most cases they are referred to specifically in the foregoing discussion, details are unnecessary.

The sodium salt of the enol is best prepared by treating an alcoholic solution with the calculated amount of sodium alcoholate, the salt being obtained as a yellow precipitate which is difficultly soluble in cold water but dissolves hot and does not crystallize out on cooling. Acidification generates the yellow form of the enol.

The sodium salt yielded unchanged enol after being subjected to the action of an excess of dimethyl sulfate under a variety of conditions including refluxing in inert solvents, benzene or isopropyl ether. Similarly, practically no alkylation resulted when experiments were conducted in aqueous media under various conditions of time, temperature and alkalinity.

When the sodium salt or the free enol is treated in alcohol with an excess of dimethyl sulfate, a nearly quantitative yield of the cyclic ether III (B) corresponding to the alcohol used as solvent is obtained regardless of whether dimethyl or diethyl sulfate is used. It is obvious that the dialkyl sulfate undergoes hydrolysis and the acid generated liberates the enol and catalyzes etherification.

The silver salt of the enol was obtained as a brilliant yellow precipitate by adding 2% silver nitrate solution to a cooled aqueous solution of the sodium salt. It is somewhat unstable and often turns dark on standing and drying. *Anal.* Calcd. for $C_{16}H_{11}O_3Ag$: Ag, 30.1. Found: Ag, 30.0. Alkylation with dimethyl sulfate in methanol or ethanol gave the cyclic alkyl ether corresponding to the solvent used. Apparently the alkylation is far too slow to avoid hydrolysis, liberation of the enol and catalytic etherification.

The quinoxaline reactions were carried out by dissolving the compound and an equal weight of *o*-phenylenediamine in alcohol and heating to boiling, the product crystallizing directly or on subsequent cooling of the solution. The products were recrystallized from ethanol. The following compounds were recovered unchanged under these conditions: I(B), III(B), VII, VIII, X and XIV(A). The compounds III(B), VIII, X and XIV(A) were recovered unchanged also after four hours of refluxing with the reagent. The enol, the enol benzoate XII, the cyclic chloro compound IX and the acetoxychlorofuran XIV(B) reacted immediately on boiling, the orange crystals of the quinoxaline IV appearing directly or upon seeding. Dibenzoylmethoxyethylene after four hours of refluxing with the reagent gave IV in good yield. Under these conditions dibenzoylaminoethylene VII gave largely unchanged material, and on six hours of refluxing with the reagents gave a 40% yield of IV.

2-Phenyl-3-phenacylquinoxaline, IV, is bright orange in color, even after careful purification including distillation in the vacuum oven. It is difficultly soluble in ethanol from which it was recrystallized; melting point 169–170° (corr.). *Anal.* Calcd. for $C_{22}H_{16}ON_2$: C, 81.5; H, 4.94. Found: C, 81.3; H, 5.15.

Oxidation was carried out by treating 2 g. of IV in 10 cc. of hot concd. acetic acid with 3 g. of chromic acid in 6 cc. of 50% acetic acid, the mixture being boiled for two minutes. The products were separated by successive extractions from an ether solution by sodium carbonate and by sodium hydroxide, giving a practically quantitative yield of benzoic acid (separated from V by extraction with hot water), 1.0 g. (79%) of VI, and a small amount of V.

2-Chloro-2,5-diphenyl-3-furanone (IX) was prepared by the action of benzoyl chloride containing a trace of concd. sulfuric acid on the enol. When shaken with cold sodium methylate solution for five minutes it is converted into III(B) in good yield. On standing for one hour in dilute methanolic sodium hydroxide solution, it is converted in good yield into the enol.

2-Benzoyloxy-2,5-diphenyl-3-furanone, X.—(a) Half a gram of IX with 2 g. of silver benzoate (freshly precipitated from alcoholic silver nitrate by means of sodium benzoate and washed with isopropyl ether) was suspended in 30 cc. of isopropyl ether and the mixture refluxed for ten hours. On filtering and working up the product 0.4 g. of nearly pure X was obtained.

(b) A mixture of 3 g. of enol, 9 g. of benzoic anhydride, and one drop of concd. sulfuric acid, was allowed to stand for one hour. The benzoic anhydride was decomposed with aqueous sodium bicarbonate solution. The residue on crystallization from isopropyl ether gave 2 g. of nearly pure X, m. p. 162–163° (corr.). *Anal.* Calcd. for $C_{23}H_{16}O_4$: C, 77.50; H, 4.53. Found: C, 77.49; H, 4.67.

The reactions outlined in the diagram were carried out in the usual way. The hydrolysis to the enol took place within a few minutes at room temperature.

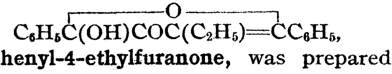
2-Benzoyloxy-1,2-dibenzoylethylene (dibenzoylethenol benzoate), XII (or XIII), was prepared in yields of 50% or less by adding benzoyl chloride to a well-stirred suspension of the enol in an excess of aqueous sodium hydroxide solution. The product, obtained as an oil, was recrystallized from isopropyl ether or ethanol. The alkaline solutions always contained considerable enol which was recovered on acidification; m. p. 139° (corr.). *Anal.* Calcd. for $C_{23}H_{16}O_4$: C, 77.50; H, 4.53. Found: C, 77.30; H, 4.57.

The conversion to III(B) was accomplished by allowing the benzoate to stand for several hours in methanol saturated with hydrogen chloride. Both sodium hydroxide in 80% methanol and sodium methylate solution quickly hydrolyzed it to the enol. On standing for one-half to one hour in acetic anhydride or acetyl chloride containing a trace of concd. sulfuric acid, followed by hydrolysis and recrystallization, good yields of XIV (A) and (B), respectively, were obtained.

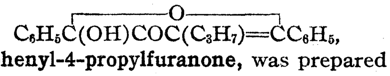
2-Hydroxy-2,5-diphenyl-4-methylfuranone, XV.—A mixture of 5 g. of the silver salt, 4 g. of methyl iodide and 35 cc. of isopropyl ether was refluxed for one hour. The solution was then filtered to remove silver halide, and extracted with 10% sodium hydroxide to remove the product, which is readily soluble in alkali. The alkaline solution was acidified and the crude product isolated by extraction with ether. The original isopropyl ether solution after the alkali extraction was evaporated and gave an oil from which 0.3 g. (about 10%) of dibenzoylmethoxyethylene was obtained. The carbon-alkyl product was purified by repeated crystallizations from isopropyl ether and melted at 143–144° (corr.), yield 70%. *Anal.* Calcd. for $C_{17}H_{14}O_3$: C, 76.7; H, 5.30. Found: C, 76.6; H, 5.47.

The carbon-alkyl compound does not react with diazomethane under ordinary conditions and gives no color test with alcoholic ferric chloride, but reacts readily with bromine and dissolves easily and directly in dilute sodium hydroxide.

Hydrolytic fission was effected by steam distillation of a barium hydroxide solution. Propiophenone was isolated from the distillate and identified as the semicarbazone by mixed melting point with an authentic sample. The barium hydroxide solution on acidification and extraction with ether gave phenylglyoxylic acid (also identified as the semicarbazone).



$C_6H_5C(OH)COC(C_2H_5){=}CC_6H_5$, **2-Hydroxy-2,5-diphenyl-4-ethylfuranone,** was prepared and isolated in 50% yield by following the above procedure using ethyl iodide. The yield of dibenzoylethoxyethylene obtained as a by-product was 20%. The carbon-alkyl compound was purified by repeated crystallizations from isopropyl ether; m. p. 113° (corr.). It is soluble in dilute sodium hydroxide. *Anal.* Calcd. for $C_{18}H_{16}O_3$: C, 77.1; H, 5.76. Found: C, 76.9; H, 5.93. Hydrolytic fission with barium hydroxide, carried out as described above, gave phenylglyoxylic acid and phenyl propyl ketone which were identified as the semicarbazones.



$C_6H_5C(OH)COC(C_3H_7){=}CC_6H_5$, **2-Hydroxy-2,5-diphenyl-4-propylfuranone,** was prepared as above using *n*-propyl iodide (yield 45%). From the non-acidic oily residues no crystalline *o*-alkyl product was obtained. The product was purified by repeated crystallization from isopropyl ether; m. p. 137.5° (corr.). It is soluble in sodium hydroxide. *Anal.* Calcd. for $C_{19}H_{18}O_3$: C, 77.5; H, 6.17. Found: C, 77.3; H, 6.20.

Hydrolytic fission carried out as above gave phenylglyoxylic acid and phenyl *n*-butyl ketone, identified as semicarbazones.

Summary

New studies including the application of the quinoxaline reaction have been made on 1,4-diphenyl-1,2,4-butanetrione enol and derivatives. These studies, together with reconsideration of known facts, show that the methyl ether obtained from the enol by catalytic etherification, and the chloro compound obtained by the action of thionyl chloride, have cyclic formulas.

The benzoylation of the enol under different conditions gives a cyclic oxygen-benzoyl compound, an open chain enol benzoate, and a carbon-benzoyl derivative.

Evidence is given for the simultaneous formation in considerable amounts of the true structurally isomeric enol ether, diphenyl-4-methoxy-1,2-butenedione in the methylation of the enol with diazomethane.

The bearing of the new facts on the structure of the two forms of the enol is discussed.

Alkylation of the silver salt leads to a mixture of oxygen and carbon-alkyl compounds, the latter type predominating.

The analogy between the enol and hydroxynaphthoquinone is discussed.

The Mechanism of Carbohydrate Oxidation. XXI.[1] The Synthesis of Glucosidoglyceraldehyde Derivatives

BY HAROLD W. ARNOLD AND WILLIAM LLOYD EVANS

In interpreting the results of the alkaline degradation of gentiobiose (6-glucosidoglucose), Evans and Hockett[2] postulated the intermediate formation of 3-glucosidoglyceraldehyde as the result of the fragmentation of the gentiobiose in an alkaline solution. It was with the ultimate purpose of testing this hypothesis that the synthesis of 3-glucosidoglyceraldehyde derivatives was undertaken.

The synthesis involved the condensation of acetobromo-*d*-glucose with glyceraldehyde benzyl-cyclo-acetal[3] (a compound of the type known to have an unblocked hydroxyl group on the third carbon atom) according to the procedure of Königs and Knorr[4] as improved by Kreider and Evans[1,5] with the formation of crystalline 3-β-*d*-glucosido-glyceraldehyde benzyl-cyclo-acetal tetraacetate (I). In order to test the applicability of Hudson's rules of isorotation to disaccharide derivatives containing the glyceraldehyde benzyl-cyclo-acetal residue, 3-β-*l*-arabinosidoglyceraldehyde benzyl-cyclo-acetal triacetate (II) was like-

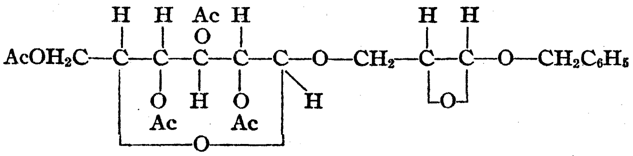
wise prepared by the condensation of acetobromo-*l*-arabinose with glyceraldehyde benzyl-cyclo-acetal.

Upon hydrogenation in the presence of palladium black, (I) yielded amorphous 3-β-*d*-glucosidoglyceraldehyde tetraacetate (III). The complete cleavage of glyceraldehyde benzyl-cyclo-acetal acetate and related compounds had already been demonstrated by Fischer and Baer.[3] More thorough studies by Richtmyer[6] had shown that only benzyl glycosides are completely split by catalytic hydrogenation.

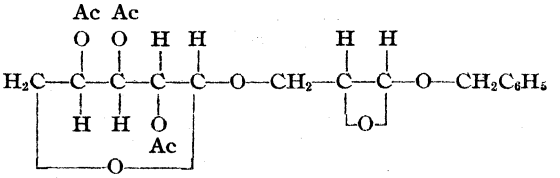
Refluxing of (III) with anhydrous pyridine, followed by acetylation, yielded a sirup which reacted with *p*-nitrophenylhydrazine to form the crystalline *p*-nitrophenylhydrazone of β-*d*-glucosidodihydroxyacetone pentaacetate.[5] The yield of this hydrazone indicated an 8–9% conversion of the glucosidoglyceraldehyde derivative to the corresponding glucosidodihydroxyacetone derivative. Fischer, Taube and Baer,[7] in similar studies of the action of pyridine on glyceraldehyde, found a maximum conversion to dihydroxyacetone of 49%.

In the course of experiments carried out in the attempt to improve the yield of glyceraldehyde benzyl-cyclo-acetal from glyceraldehyde, it was found that glyceraldehyde diacetate on treatment with titanium tetrachloride according to the method of Pacsu,[8] smoothly yielded acetochloroglyceraldehyde. This underwent the Königs–Knorr[4] reaction with benzyl alcohol to form what was apparently a mixture of isomeric benzyl glycoside acetates. From the mixture it was possible to separate the benzyl-cyclo-acetal acetate described by Fischer and Baer.[3]

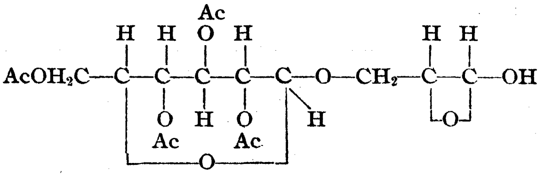
In formulating the compounds shown, the ethylene oxide formula has been ascribed to the glyceraldehyde residues. This has been done to conserve space and is not meant to imply that the glyceraldehyde derivatives described have this structure. Although many of the properties of dimeric glyceraldehyde and its simple derivatives can be accounted for on the basis of an associated ethylene oxide formula, more recent work[9] points to a dioxane ring structure for dimeric glyceraldehyde and its derivatives. The β-*d*-glucosidoglyceraldehyde benzyl-cyclo-acetal tetraacetate described in this paper appears to be almost entirely dimeric in benzene at the freezing point and almost wholly monomeric at the temperature of melted camphor.



(I) 3-β-*d*-Glucosidoglyceraldehyde benzyl-cyclo-acetal tetraacetate



(II) 3-β-*l*-Arabinosidoglyceraldehyde benzyl cyclo-acetal triacetate



(III) 3-β-Glucosidoglyceraldehyde-tetraacetate

The results obtained in the study of the alkaline degradation of glucosidoglyceraldehyde tetraacetate will be incorporated into a later paper.

Experimental Part

Preparation of Reagents and Starting Materials.—The crystallineglyceraldehyde used in this work was obtained from the laboratory of Dr. Fraenkel and Dr. Landau, Berlin-Oberschöneweide. It melted at 141°.

The acetobromo-*d*-glucose was prepared according to the procedure of Freudenberg.[10] It was recrystallized twice from anhydrous ether and extensively dried *in vacuo*.

The acetobromo-*l*-arabinose was prepared as described by Hudson and Dale.[11] It was purified as described above.

The glyceraldehyde benzyl-cyclo-acetal was prepared, with a few minor modifications, according to the method of Fischer and Baer.[3] The pyridine used was purified by refluxing and fractionating over barium oxide.

Other materials were prepared and purified as described by Kreider and Evans.[12]

3 - β - *d* - Glucosidoglyceraldehyde Benzyl - cyclo - acetal Tetraacetate.—The preparation of this compound was carried out in a three-necked flask fitted with a powerful mercury-sealed stirrer. One neck of the flask carried a

dropping funnel, the other a calcium chloride tube. The following mixture was introduced into the flask and rapidly stirred for thirty minutes: 11.0 g. of glyceraldehyde benzyl-cyclo-acetal (1 mol), 22.0 g. of silver carbonate, 50.0 g. of finely powdered "Drierite," and 120 cc. of benzene. A solution of 25.1 g. (1 mol) of acetobromo-*d*-glucose in 110 cc. of benzene was then slowly added through the dropping funnel, the initial rate of addition being somewhat faster than at the end. The addition required approximately thirty minutes. As the addition progressed there was a rapid evolution of carbon dioxide, a marked rise in temperature (10°), and a noticeable change in color. The mixture was stirred for at least five hours after the addition of the acetobromoglucose was complete. It was then filtered by suction and the residue repeatedly washed with small quantities of benzene. The benzene solution was then evaporated to dryness *in vacuo* at room temperature. The half crystalline residue was dissolved in the least possible volume of boiling ethyl alcohol. When allowed to cool the product precipitated in clumps of needles. After three recrystallizations from ethyl alcohol and two from methyl alcohol the melting point was constant at 172–173° (corr.). The weight of crystals (needles) was 15.5 g., corresponding to a yield of 50%, calculated on the basis of the acetobromoglucose used; $[\alpha]^{23}_D$ −19.9° (*c*, 1.7; $CHCl_3$).

Anal. Calcd. for $C_{16}H_{18}O_8(COCH_3)_4$: acetyl, 7.83 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 7.79 cc., 7.80 cc. *Mol. wt.* Calcd. for $(C_{24}H_{30}O_{12})_2$: 1020. Found: (cryoscopic in benzene) 995. Calcd. for $C_{24}H_{30}O_{12}$: 510. Found: (Rast) 562.

The compound is readily soluble in ether, chloroform, benzene, ethyl acetate and acetone. It is insoluble in water and petroleum ether, and only slightly soluble in cold methyl or ethyl alcohol. The substance reduces hot Fehling's solution only after hydrolysis by dilute mineral acid.

3-β-*l*-Arabinosidoglyceraldehyde Benzyl-cyclo-acetal Triacetate.—The procedure which was followed in preparing this compound was exactly the same as that described under the preparation of the corresponding β-*d*-glucosido derivative. The following quantities of reactants were used: glyceraldehyde benzyl-cyclo-acetal, 3.06 g. (1 mol); silver carbonate, 9.88 g.; "Drierite," 20.0 g.; acetobromo-*l*-arabinose, 5.8 g. (1 mol); benzene, 150 cc. The product was crystallized to constant melting point and rotation from methyl alcohol. The weight of the pure product (needles) was 0.51 g., corresponding to a yield of 7%, calculated on the basis of the acetobromoarabinose used; m. p. 142–143° (corr.) $[\alpha]^{22}_D$ +4.2° (*c*, 1.2; $CHCl_3$).

Anal. Calcd. for $C_{15}H_{17}O_7(COCH_3)_4$: acetyl, 6.84 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 6.78 cc.

3-β-*d*-Glucosidoglyceraldehyde Tetraacetate.—Because of the danger of hydrolysis of the glycosidic link in acid media, the cleavage of β-*d*-glucosidoglyceraldehyde benzyl-cyclo-acetal tetraacetate was carried out in purified methyl alcohol. The palladium catalyst was prepared according to the method of Tausz and von Putnoky.[13] The apparatus used was a modification of that described by Gattermann–Wieland.[14] The following procedure was followed in carrying out the hydrogenations. The catalyst and the solvent were introduced into the hydrogenation flask and rapidly shaken in a hydrogen atmosphere until absorption of hydrogen ceased. The sample was then introduced and the system flooded with hydrogen. The flask was again shaken until absorption of hydrogen ceased. At the beginning practically none of the substance was in solution, whereas, when hydrogen absorption was complete, the solution was homogeneous. At the end of a run the odor of toluene was very marked. The solution was filtered rapidly through a porous-bottomed crucible, care being taken to prevent contact of the catalyst with the air because of the danger of igniting the solvent vapors.

The results of two typical hydrogenations are tabulated below.

Wt. of compound, g.	3.21	4.00
Wt. of catalyst, g.	1.00	1.00
Vol. of CH_3OH, cc.	100	100
Vol. of H_2 absorbed (std. concns.), cc.	158	291
Theoretical vol. of H_2 (1 mol), cc.	144	176
Theoretical wt. of debenzylated compound, g.	2.70	3.30
Actual wt. of reaction product, g.	2.68	3.27

After removal of the catalyst by filtration, the filtrate and washings were evaporated *in vacuo* to about one-fourth their volume. The remaining solution was decolorized with Norite, chilled in ice for several hours, and filtered. The filter and all other vessels used were washed out repeatedly with methyl alcohol to ensure complete transference of the product. The solution was evaporated in a crystallizing dish to a thick, colorless sirup in a vacuum desiccator. This was redissolved in a small volume of chloroform and the solution again evaporated to dryness. The same treatment was repeated successively with pure chloroform, 50% chloroform and petroleum ether (30–60°), 20% chloroform in petroleum ether, and three times with petroleum ether. The dish was covered with a watch glass during these operations to prevent loss by spattering. After the foregoing treatment, the product could be powdered. Microscopic examination showed it to be amorphous. All attempts to bring about crystallization from a large number of solvents and combinations of solvents have failed up to the present.

Anal. Calcd. for $C_9H_{12}O_8(COCH_3)_4$: acetyl, 9.52 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 9.65 cc., 9.57 cc. *Mol. wt.* Calcd. for $(C_{17}H_{24}O_{12})_2$: 850. Found: (cryoscopic in benzene) 840.

The amorphous solid melts to a thick sirup at 63°. Since this amorphous substance was analytically pure, a determination of the specific rotation was thought to be of value. The following result was obtained: $[\alpha]^{24}_D$ −15.5° (*c*, 1.8; $CHCl_3$). Attempts to prepare crystalline derivatives by acetylation and benzoylation failed. Likewise did the attempts to prepare substituted phenylhydrazones. The substance rapidly reduces Fehling's solution in the cold.

Conversion of β-*d*-Glucosidoglyceraldehyde Tetraacetate to β-*d*-Glucosidodihydroxyacetone Pentaacetate.—The record of two experiments is given below. The

glucosidoglyceraldehyde tetraacetate was refluxed with anhydrous pyridine (drying tube) at a bath temperature of 135–140°. The solution was then cooled somewhat and 10 cc. of acetic anhydride was added. The mixture was then allowed to stand overnight. It was poured into 500 cc. of ice water which was then extracted with 200 cc. of chloroform in small portions. The chloroform solution was washed successively with dilute sulfuric acid, sodium bicarbonate solution and water. It was dried over calcium chloride. Removal of the chloroform left a thick sirup which could not be crystallized. It was taken up in ethyl alcohol and heated on the water-bath with a saturated ethyl alcohol solution of *p*-nitrophenylhydrazine. The solution was then allowed to concentrate spontaneously over a period of a week. At the end of this time, reddish-yellow crystals had separated out. These were recrystallized three times from 95% ethyl alcohol, giving pale yellow needles which melted at 187° (corr.). Mixed melting point with an authentic sample of the *p*-nitrophenylhydrazone of *β*-*d*-glucosidodihydroxyacetone pentaacetate was likewise 187°; $[\alpha]^{23}\text{D}$ −126.5°. In calculating the per cent. conversion, the reaction between the dihydroxyacetone derivative and *p*-nitrophenylhydrazine is assumed to be complete. Experimental losses are also neglected.

Wt. of glucosidoglyceraldehyde tetraacetate, g.	1.5	1.5
Vol. of pyridine, cc.	15	15
Time of refluxing, hrs.	2	3.5
Wt. of pure *p*-nitrophenylhydrazone, g.	0.18	0.20
Per cent. conversion	8.4	9.4

Acetochloroglyceraldehyde.—The results of a series of experiments on the action of titanium tetrachloride on dimeric glyceraldehyde diacetate are given below in tabular form.

The glyceraldehyde diacetate was dissolved in purified chloroform. A 10% solution of purified titanium tetrachloride in anhydrous, alcohol-free chloroform was rapidly added and the mixture protected from moisture by a drying tube. Immediately after mixing a lemon-colored addition compound precipitated out. The mixture was then refluxed on the water-bath or allowed to stand at room temperature. The precipitated solid gradually became darker in color, being almost black at the end of the reaction. The mixture was poured into a large volume of ice water. The chloroform layer was separated and the water layer repeatedly extracted with small portions of chloroform until the volume of chloroform solution amounted to 200 cc. per gram of diacetate used. The chloroform layer was washed several times with water and then with sodium carbonate solution. It was dried over calcium chloride. Evaporation of the chloroform under reduced pressure left a light brown-colored residue which was recrystallized by dissolving in the least possible quantity of boiling chloroform. When the solution had reached room temperature, an equal volume of petroleum ether (30–60°) was added and the mixture cooled in ice for several hours.

The pure compound crystallized in fine needles. It was insoluble in water and petroleum ether, sparingly soluble in chloroform, ether, and benzene at ordinary temperatures, and easily soluble in acetone.

SUMMARY OF RESULTS

Diacetate, g.	$TiCl_4$, g.	Time of refluxing, hours	Yield, %
1.0	1.0	4	49.7
4.0	4.0	4	35.0
4.5	4.8	6	15.4
1.0	1.0	14—rm. temp.	87.0
1.0	1.0	18—rm. temp.	83.3
1.0	1.0	23—rm. temp.	81.0

M. p. 174–175° (corr.). *Anal.* Calcd. for $C_3H_7O_3Cl$: Cl, 23.56. Found: Cl, 23.52.

Reaction of Acetochloroglyceraldehyde with Benzyl Alcohol.—A mixture of 2.1 g. of acetochloroglyceraldehyde, 6 g. of silver carbonate and 30 cc. of benzyl alcohol was shaken for eighteen hours at room temperature. At the end of this time it was heated on the water-bath for one hour. Following this it was cooled in ice for several hours before filtering. The residue was dried as far as possible by suction filtration, being washed with a little ice-cold ethyl alcohol to remove excess benzyl alcohol. It was then repeatedly extracted with boiling ethyl alcohol and finally with boiling chloroform, the alcohol and chloroform extracts being combined. The solvents were removed by a warm air stream, and the residual crystals recrystallized from the least possible volume of boiling 50% alcohol. The weight of crystals after the first recrystallization was 2.3 g. The melting range was very wide. Melting began at 110° and was complete at 135°. After five recrystallizations from the same solvent, the weight of the substance was 0.75 g. and the melting point was constant at 141–142° (corr.). A mixed melting point with glyceraldehyde benzyl-cyclo-acetal acetate, prepared according to the procedure of Fischer and Baer,[3] showed no depression.

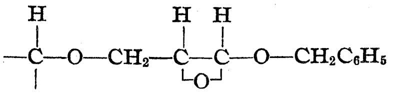
Anal. Calcd. for $C_{10}H_{11}O_3COCH_3$: acetyl, 4.50 cc. of 0.1 *N* NaOH per 100 mg. Found: acetyl (for substance melting at 110–135°), 4.44 cc.; (for substance melting at 141–142°) 4.45 cc.

By appropriate procedures it was possible to isolate from the mother liquors a small quantity of crystals melting at 109–110° (corr.). The quantity was not large enough for further work.

The results seem to point to the presence of two isomeric benzyl-cyclo-acetal acetates.

Discussion

In a manner similar to that suggested by Kreider and Evans[12] the rotations of *β*-*d*-glucosidoglyceraldehyde benzyl-cyclo-acetal tetraacetate and *β*-*l*-arabinosidoglyceraldehyde benzyl-cyclo-acetal triacetate may be considered in accordance with Hudson's views to be the sum of two components, A and B, A being used to designate that part of the rotation due to the group



$$-\overset{H}{\underset{|}{\overset{|}{C}}}-O-CH_2-\overset{H}{\overset{|}{C}}-\overset{H}{\overset{|}{C}}-O-CH_2C_6H_5$$

and B that due to the remainder of the molecule. Since *l*-arabinose has been shown by Isbell[15] to be

---

(15) H. S. Isbell, *J. Chem. Ed.*, **12**, 96 (1935).

genetically related to *d*-glucose, the A values for the *d*-glucosido derivative and the *l*-arabinosido derivative should have the same sign. If the principle of optical superposition is valid, the A values should also have approximately the same magnitude. The B values for the two derivatives may be calculated from the rotations of the α- and β-forms of the fully acetylated parent sugars. The A values may then be calculated from the experimentally determined rotations of the two glycosido derivatives. The values for the molecular rotation of A as calculated by this method are: β-*d*-glucosidoglyceraldehyde benzyl-cyclo-acetal tetraacetate, A $-30{,}500$; β-*l*-arabinosidoglyceraldehyde benzyl-cyclo-acetal triacetate, A $-31{,}990$. The difference between the numerical values of Hudson's A for the two derivatives is very nearly equal to that reported by Kreider and Evans[12] for the corresponding dihydroxyacetone derivatives.

Summary

1. β-*d*-Glucosidoglyceraldehyde benzylcyclo-acetal tetraacetate and β-*l*-arabinosidoglyceraldehyde benzyl-cyclo-acetal triacetate have been prepared in crystalline condition.

2. Cleavage of β-*d*-glucosidoglyceraldehyde benzyl-cyclo-acetal tetraacetate by catalytic hydrogenation yields β-*d*-glucosidoglyceraldehyde tetraacetate as an amorphous solid with an acetyl number and a molecular weight in good accord with the theory.

3. Refluxing β-*d*-glucosidoglyceraldehyde tetraacetate in anhydrous pyridine, followed by acetylation, gives β-*d*-glucosidodihydroxyacetone pentaacetate in yields of 8–9%, based on the quantities of the *p*-nitrophenylhydrazone of the latter compound isolated.

4. Acetochloroglyceraldehyde has been prepared in the crystalline condition. This reacts with benzyl alcohol to yield what is apparently a mixture of isomeric glyceraldehyde benzyl-cyclo-acetal acetates.

Hydroxy Polyketones. III.[1] Benzoylformoin

BY A. H. BLATT

In an earlier article[2] we described the alkylation of benzoylformoin and presented the evidence for a revision of the structures formerly assigned to its alkylation products. In this article we complete our description of the chemical behavior of the formoin and its derivatives.

The chemistry of benzoylformoin is that of a tautomeric mixture of the ene-diol (I) and the dihydroxyfuranone (II). While certain of its reactions may be ascribed to the alternative ene-diol (III) and to the hydroxy ketone (IV), there are no reactions of the material which require the existence of these latter two forms and the entire behavior of the formoin can be accounted for on the basis of an equilibrium between (I) and (II). The reactions which form the basis for these conclusions will now be described.

Salt formation, oxidation and quinoxaline formation characterize benzoylformoin as an ene-diol. Werner described, without analytical data, a series of lakes obtained from the formoin and salts of several heavy metals.[3] Sidgwick[4] considers that these salts are derived from the completely chelated ene-diol (III) and that they contain two five-membered chelate rings. In the absence of all details as to the composition of the salts this conclusion seems to us to be somewhat hazardous. We have succeeded in securing a copper derivative of the formoin which is obviously derived from an ene-diol for its composition corresponds to the replacement of two atoms of hydrogen by one of copper. However,

[1] Second paper, THIS JOURNAL, **58**, 81 (1936). Shortly after the present article was submitted to the Journal a paper by Karrer and Litwan appeared [*Helv. Chim. Acta*, **19**, 829 (1936)] in which conclusions similar to ours about the structure of the formoins are advanced on the basis of iodine titrations.

[2] Blatt, THIS JOURNAL, **57**, 1103 (1935).

[3] Werner, *Ber.*, **41**, 1070 (1908).

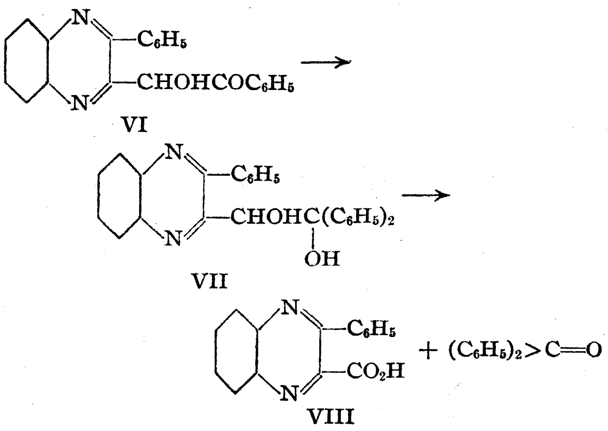
[4] Sidgwick, "Electronic Theory of Valence," Oxford University Press, Oxford, England, 1932, p. 245.

no indication as to which of the two possible ene-diols is involved in the salt formation is available from the metallic derivatives of the formoin.

The ease of oxidation of benzoylformoin is in agreement with its formulation as an ene-diol. The earliest work with the formoin showed that it was oxidized to diphenyl tetraketone (V) by nitric acid and by bromine.[5] It is also oxidized to the tetraketone by thionyl chloride. Quite recently, Karrer[6] has shown that the formoin is oxidized by iodine in acid solution and from the results of iodine titrations has concluded that it exists in solution to the extent of 57% as an ene-diol. We have not succeeded in isolating the tautomeric modifications whose existence is indicated by these titrations but we have found that the stable yellow crystalline formoin when vacuum distilled furnishes a deep red unstable liquid distillate which gradually reverts to the stable yellow modification. Since the color of the distillate is so similar to that of the alkaline solutions of benzoylformoin and to that of the unstable material which is first obtained on acidification of these alkaline solutions, we are of the opinion that the liquid is the ene-diol while the stable crystalline form is the dihydroxyfuranone. It is because of the greater volatility of the unstable modification that we have suggested the hydrogen bond (chelate linkage) shown in formula I.

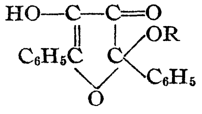
Benzoylformoin is also oxidized by copper acetate in aqueous acetic acid.[6] Since we had found that the closely related dibenzoylcarbinol on oxidation with copper acetate furnishes benzil instead of diphenyl triketone,[1] we sought the oxidation product of the formoin with this reagent. The product is benzil. Diphenyl tetraketone likewise furnishes benzil on oxidation with copper acetate, as does benzoin. From these results it is evident that not only are α-hydroxy ketones oxidized by copper acetate in an acid medium but also that the oxidative elimination of carbonyl groups from linear tri- and tetraketones is a general reaction. We have confirmed this by oxidizing 2,4,6-trimethylbenzoylformoin and find that the process is completely analogous and furnishes dimesityl diketone.

With o-phenylenediamine, benzoylformoin furnishes the quinoxaline (VI) whose structure was established by the following sequence of reactions.

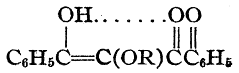


Quinoxaline formation may be ascribed to the hydroxy ketone tautomer (IV). We believe it is more reasonably considered as a reaction of the ene-diol (I) followed by ketonization and in a later paragraph we shall show that enolization of the hydroxy ketone system even in the quinoxaline (VI) can be brought about with surprising ease.

Alkylation and acylation of the formoin are predominantly the reactions of the furanone (II) but the course of these reactions can be directed by controlling the acidity or alkalinity of the reaction medium. Thus, alkylation with an alcohol and acid leads, as was shown earlier,[2] to cyclic derivatives such as (IX). Alkylation with methyl sulfate in sodium hydroxide solution, however, furnishes the open-chain ether (X, R = CH_3).



IX



$C_6H_5\overset{\overset{\displaystyle OH\cdots\cdots}{|}}{C}=C(OR)\overset{\overset{\displaystyle O}{\|}}{C}\overset{\overset{\displaystyle O}{\|}}{C}C_6H_5$

X

Acetylation leads to three acetyl derivatives: a diacetate and two isomeric monoacetates. Acetic anhydride alone or containing sulfuric acid, acetyl chloride alone or in pyridine, all furnish the cyclic diacetate (XI, R = CH_3). The two acetyl groups in this substance are easily hydrolyzed either by acids or bases.[5] Treatment with o-phenylenediamine effects partial hydrolysis removing the enolic ester group to furnish the monoacetate (XII). That it is the enolic ester group which is eliminated is shown by the fact that the acetate (XIII) on treatment with o-phenylenediamine undergoes a parallel reaction to furnish the methoxyl compound (IX, R = CH_3). With acetic anhydride and sodium hydroxide the formoin yields an isomeric monoacetate (XIV).

This monoacetate, like its isomer, may be hydrolyzed by acids or bases and with acetic anhydride and sulfuric acid forms the cyclic diacetate (XI). With *o*-phenylenediamine the monoacetate (XIV) furnishes the hydroxyquinoxaline (XV).

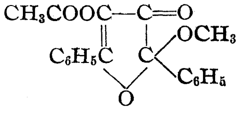
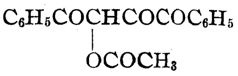
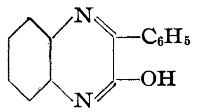
XII



XIII

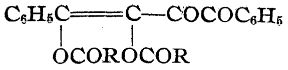


$$\underset{\displaystyle OCOCH_3}{C_6H_5CO\overset{|}{C}HCOCOC_6H_5}$$
XIV

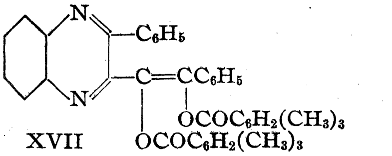


XV

The acetyl derivatives of the formoin are so readily hydrolyzed that it is difficult to secure reliable information about them. In order to get around this difficulty, we treated benzoylformoin with 2,4,6-trimethylbenzoyl chloride, expecting that the resulting highly substituted acyl derivative would be relatively insensitive. This proved to be the case and we obtained a diacyl derivative of the ene-diol having the structure (XVI, R = 2,4,6-$(CH_3)_3C_6H_2$—) for it reacted with *o*-phenylenediamine to form the quinoxaline (XVII) which could be oxidized to the known hydroxyquinoxaline (XV). It is not improbable that acetylation with acetyl chloride in pyridine, which eventually leads to the diacetate (XI, R = CH_3), furnishes first a diacetate (XVI, R = CH_3) which is rearranged by acids to the product actually obtained, for the diacyl derivative (XVI, R = 2,4,6-$(CH_3)_3C_6H_2$—) is converted by prolonged treatment with acid to an isomer which does not react with *o*-phenylenediamine. The di-(trimethyl)-benzoate (XVI) in which no mobile hydrogen atom is present is the only derivative of the ene-diol to which a structure free from ambiguity can be ascribed.

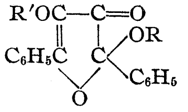


$$C_6H_5\underset{OCOR}{C}=\underset{OCOR}{C}-COCOC_6H_5$$
XVI

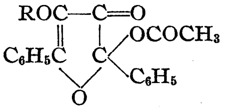


XVII

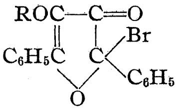
Considering next the dialkyl derivatives of benzoylformoin which have the structure (XVIII), we find that the glycosidic alkyl group is distinguished from the enolic alkyl group by its behavior toward acetic anhydride and sulfuric acid and toward hydrogen bromide in acetic acid. With the former reagent alkoxyl is replaced by acetoxyl to furnish the alkoxy acetate (XIX), isomeric with the previously mentioned acetate (XIII) and differing from it in that it is unaffected by *o*-phenylenediamine. With hydrogen bromide both the dialkyl derivatives (XVIII) and the alkoxy acetates (XIX) yield the bromofuranone (XX). The bromofuranone was not isolated in a pure state because it was always accompanied by the dimolecular product (XXI). The ease of formation of dimolecular products is even more pronounced in the case of our bromofuranones than with the analogous triphenylbromofuranone recently described by Kohler.[7] Our bromofuranones (XX) are converted to the dimolecular compounds by prolonged treatment with hydrogen bromide in acetic acid—a fact of particular interest in connection with recent observations on the reduction of α-bromo ketones by hydrogen bromide.[8]



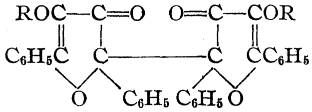
XVIII



XIX



XX



XXI

The open chain monomethyl derivative of benzoylformoin, like benzoylformoin, shows the behavior of a tautomeric mixture of the two forms: (X, R = CH_3) and (XXII, R = CH_3). With *o*-phenylenediamine it furnishes the quinoxaline (XXIII), on acid methylation the dialkyl derivative (XVIII, R, R′ = CH_3), on acetylation the acetate (XIX, R = CH_3) and with hydrogen bromide the dimolecular product (XXI, R = CH_3). The ordinary crystalline pale yellow monomethyl derivative is probably the furanone (XXII, R = CH_3). On distillation it furnishes a red modification, presumably (X, R = CH_3), whose color is analogous to that of the alkaline

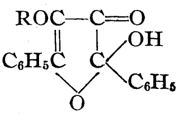
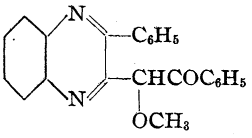
solutions of the ether and to the color of the first unstable product obtained by acidifying these alkaline solutions.

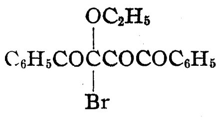


XXII

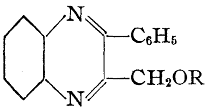


XXIII

The facts presented up to this point furnish a consistent picture of benzoylformoin and its open chain monoalkyl derivatives as ene-diol—hydroxyfuranone tautomers, and of its cyclic mono- and di-alkyl derivatives as alkoxyfuranones. There are two facts, however, which, while they are no better interpreted on any alternative formulation, are less concordant. The first is the stability of the formoin and its open chain monoalkyl derivatives toward alkali. While they are cleaved, as one would expect of α-diketones, by alkaline peroxide, they do not undergo a benzilic acid rearrangement with alkali alone. The second is the behavior of the open chain monoethyl derivative (X, R = C_2H_5, and XXII, R = C_2H_5). On acid alkylation, with hydrogen bromide, and with acetic anhydride and sulfuric acid it behaves like its methyl analog. With *o*-phenylenediamine, however, it does not give a quinoxaline analogous to (XXIII) but, instead, like the acetate (XIV) furnishes the hydroxyquinoxaline (XV). With bromine it yields a monobromo derivative for which no other structure than (XXIV) is reasonable but which is remarkably stable for a substance having such a structure.



$C_6H_5COC(OC_2H_5)(Br)COCOC_6H_5$
XXIV



XXV

Finally attention should be called to the behavior of the quinoxalines (VI) and (XXIII) toward sodium methylate. On treatment with this reagent they form intensely colored solutions reminiscent of those of the metallic derivatives of stilbene diol. These solutions gradually lose their color and furnish methyl benzoate, benzoic acid, the hydroxyquinoxaline (XV) and from the quinoxaline (VI) the carbinol (XXV, R = H), from the quinoxaline (XXIII) the ether (XXV, R = CH_3). The formation of methyl benzoate, the carbinol (XXV, R = H) and its methyl ether (XXV, R = CH_3) are obviously due to the addition of alcohol or alcoholate and subsequent cleavage—a process similar to the alcoholysis of dibenzoylcarbinol.[1] The formation of the hydroxyquinoxaline (XV) must be a result of an oxidation process.

Experimental

Benzoylformoin distils at about 240° at a pressure of 0.5 mm. The deep red distillate on standing or on solution in alcohol reverts to the ordinary yellow stable crystalline form. Our previous statement[2] that the formoin decomposed on melting is incorrect. The formoin undergoes gradual autoxidation on standing.

Salt Formation and Oxidation.—In ethereal solution shaken with copper acetate benzoylformoin furnishes a brown copper derivative of the ene-diol. For analysis the copper derivative was washed with ether and vacuum dried.

Anal. Calcd. for $C_{16}H_{10}O_4Cu$: Cu, 19.23. Found: Cu, 18.84.

When benzoylformoin was boiled with thionyl chloride a carmine red solution resulted. Evaporation of this solution over alkali in a desiccator left diphenyl tetraketone (V). The tetraketone crystallized from benzene in splendid scarlet crystals melting at 110–112° and was identified by a mixed melting point with a synthetic sample prepared by the nitric acid oxidation of benzoylformoin.[9] The product of the nitric acid oxidation is the tetraketone hydrate which is easily converted to the anhydrous material by high vacuum distillation.

When benzoylformoin was dissolved in 60% acetic acid and warmed at 80° for one hour with an excess of saturated aqueous copper acetate, then filtered hot from the precipitated cuprous oxide and diluted with water, an excellent yield of benzil was obtained. On similar treatment diphenyl tetraketone and benzoin also gave benzil.

When 2,4,6-trimethylbenzoylformoin[10] was oxidized in the same way with copper acetate the product melted at 117–118°. Since the melting point did not suffice to distinguish between the two possible products, dimesityl triketone[11] and dimesityl diketone,[12] the product was analyzed and found to be the diketone. (*Anal.* Calcd. for $C_{20}H_{22}O_2$: C, 81.6; H, 7.5. Found: C, 81.6; H, 7.67.) The yield is excellent and the process makes readily available this highly hindered diketone.

Quinoxaline Formation.—When 5.4 g. of benzoylformoin dissolved in 30 cc. of hot methanol was boiled for one hour with an excess (3.0 g.) of *o*-phenylenediamine, the solution on cooling deposited 4.7 g. of the quinoxaline (VI). For analysis the material was crystallized from acetic acid. It was sparingly soluble in the ordinary solvents and melted to a red liquid at 187–188°.

Anal. Calcd. for $C_{22}H_{16}O_2N_2$: C, 77.6; H, 4.7. Found: C, 77.36; H, 4.7.

To establish the structure of the quinoxaline (VI) it was converted to the glycol (VII) which was then oxidized.

---

(9) Abenius and Söderbaum, *Ber.*, **24**, 3034 (1891).

(10) Gray and Fuson, THIS JOURNAL, **56**, 1367 (1934). We are indebted to Dr. R. C. Fuson for a sample of the formoin.

(11) Fuson, Matuszeski and Gray, *ibid.*, **56**, 2100 (1934).

(12) Kohler and Baltzly, *ibid.*, **54**, 4024 (1932).

For this purpose 1.7 g. of the powdered quinoxaline was added to an excess of magnesium-free phenylmagnesium bromide and the reaction mixture on decomposition with sulfuric acid furnished 1.9 g. of the glycol. The material, which was sparingly soluble in the ordinary solvents, crystallized well from benzene and petroleum ether in fine needles melting at 163–164°.

Anal. Calcd. for $C_{28}H_{22}O_2N_2$: C, 80.4; H, 5.3. Found: C, 80.7; H, 5.4.

When the quinoxaline glycol (VII) suspended in warm glacial acetic acid was oxidized with the calculated amount of chromic oxide, the reaction mixture taken up in ether, washed with water and extracted with sodium carbonate, the extract furnished on acidification 3-phenylquinoxaline 2-carboxylic acid (VIII)—identified by comparison with a sample prepared according to the directions of Wahl.[13] From the ether, by evaporation and steam distillation, benzophenone was obtained.

In order to be certain that no benzoic acid (which would show the presence of a quinoxaline isomeric with VI but having the positions of the hydroxyl and carbonyl groups interchanged) had been formed in the oxidation and had been lost by admixture with the quinoxaline acid (VIII), we did a second oxidation of the glycol (VII) using a large excess of chromic acid. In this oxidation the products were benzophenone and the hydroxyquinoxaline (XV).[14] The hydroxyquinoxaline being soluble in alkali hydroxides and insoluble in alkali carbonates permitted a chemical separation from any benzoic acid which might have been formed. No benzoic acid was found. We had previously assured ourselves by a separate experiment that the quinoxaline acid (VIII) was converted to the hydroxyquinoxaline (XV) by chromic oxide.

Acylation.—The cyclic diacetate (XI, R = CH_3) was described by Abenius, who obtained it from the formoin and acetic anhydride.[5] We find that it is prepared in quantitative yield by treatment of the formoin with acetic anhydride and a little sulfuric acid. Other methods of preparation have been described in the introduction. The cyclic diacetate is stable and since it can be hydrolyzed to the formoin with alkali and converted to the furanone ethers (IX) with alcoholic acid, it is useful for storing the formoin. We were unable using alkali hydroxides to effect partial hydrolysis of the diacetate. This was possible, however, with *o*-phenylenediamine. Thus, when 1.7 g. of the diacetate in 25 cc. of boiling benzene was heated for two hours with 0.6 g. of the diamine and the solvent then removed *in vacuo*, a yellow solid was obtained. After crystallization from alcohol or acetic acid the pale yellow product melted at 198°.

Anal. Calcd. for $C_{18}H_{14}O_5$: C, 69.7; H, 4.5. Found: C, 69.7; H, 4.8.

The cyclic monoacetate (XII) is converted by acetic anhydride and sulfuric acid to the diacetate (XI, R = CH_3). With methyl alcohol and hydrochloric acid it furnishes the cyclic ether (IX, R = CH_3) and with alcoholic alkali it furnishes benzoylformoin.

When 2.7 g. of the formoin in 40 cc. of water containing 0.8 g. of sodium hydroxide was shaken for two hours with 2 cc. of acetic anhydride, the deep red color of the solution disappeared and 3.0 g. of a colorless solid precipitated. After crystallization from dilute alcohol the product melted at 109–110°.

Anal. Calcd. for $C_{18}H_{14}O_5$: C, 69.7; H, 4.5. Found: C, 69.7; H, 4.4.

The open chain monoacetate (XIV or its enol) is converted to the cyclic diacetate (XI, R = CH_3) by acetic anhydride and sulfuric acid and on treatment with *o*-phenylenediamine furnishes the hydroxyquinoxaline (XV).

When 7.3 g. of 2,4,6-trimethylbenzoyl chloride was added to a cold solution of 5.4 g. of the formoin in 40 cc. of pyridine and the reaction mixture was left for forty hours then decomposed with iced dilute hydrochloric acid a mixture of a solid and a sticky oil was obtained. Ether was added and the solid, 4.4 g., was separated by filtration. The ether extract, after washing with dilute acid, was evaporated and furnished an additional 3.1 g. of the solid. The product after crystallization from acetic acid melted at 145°.

Anal. Calcd. for $C_{36}H_{32}O_6$: C, 77.1; H, 5.7. Found: C, 76.9; H, 5.8.

The di-(2,4,6-trimethyl)-benzoate of benzoyl formoin (XVI, R = 2,4,6(CH_3)$_3$$C_6H_2$—) is sparingly soluble in the ordinary solvents. When 0.5 g. of the material was suspended in 20 cc. of boiling methyl alcohol containing 0.2 g. of *o*-phenylenediamine and boiled for four and one-half hours, the solution after the usual ether extraction gave 0.2 g. of the quinoxaline (XVII). The very sparingly soluble quinoxaline was crystallized from acetic acid and melted at 182–183°. (*Anal.* Calcd. for $C_{42}H_{36}O_4N_2$: C, 79.7; H, 5.7. Found: C, 79.2; H, 6.0.) The quinoxaline was oxidized with chromic oxide in hot glacial acetic acid and furnished the hydroxyquinoxaline (XV), m. p. and mixed m. p.

In one preparation of the diacyl derivative (XVI, R = 2,4,6-(CH_3)$_3$$C_6H_2$—) we obtained two products: the 145° compound already described and an isomer which melted at 189°. (*Anal.* Calcd. for $C_{36}H_{32}O_6$: C, 77.1; H, 5.7. Found: C, 76.8; H, 5.6.) The formation of the 189° isomer could not be repeated but we found that when 0.5 g. of the 145° isomer suspended in 25 cc. of methyl alcohol and 2 cc. of concd. hydrochloric acid was boiled for two hours, it was converted into the 189° isomer. The 189° isomer did not react with *o*-phenylenediamine after six hours of boiling in an alcoholic suspension.

The alkylation products of benzoylformoin can also be acetylated with acetic anhydride and sulfuric acid. The glycosidic monomethyl derivative (IX, R = CH_3) furnishes the acetate (XIII) already described by Abenius.[5] When 1.6 g. of the acetate (XIII) in benzene solution was boiled for an hour with 0.54 g. of *o*-phenylenediamine, it regenerated the methoxyl compound (IX, R = CH_3). The cyclic dialkyl derivatives (XVIII) undergo replacement of the glycosidic alkoxyl group by acetoxyl on treatment with acetic anhydride and sulfuric acid. Thus, when 3.0 g. of the dimethyl derivative (XVIII, R, R′ = CH_3) was dissolved in 10 cc. of acetic anhydride containing a drop of sulfuric acid, the reaction mixture soon solidified. Decomposition with water furnished a quantitative yield of the methoxy acetate (XIX, R = CH_3) which melted, after crystallization from acetone, at 164–165° and which was

---

[13] Wahl, *Bull. soc. chim.*, [4] **1**, 461 (1907).

[14] Buraczewski and Marchlewski, *Ber.*, **34**, 4009 (1901).

unaffected by *o*-phenylenediamine in benzene solution. (*Anal.* Calcd. for $C_{19}H_{16}O_5$: C, 70.4; H, 4.9. Found: C, 70.3; H, 5.0.) In similar fashion, the diethyl derivative (XVIII, R, $R' = C_2H_5$) furnishes with acetic anhydride and sulfuric acid, the ethoxy acetate (XIX, $R = C_2H_5$) which, after crystallization from alcohol, melts at 133°. (*Anal.* Calcd. for $C_{20}H_{18}O_5$: C, 71.0; H, 5.3. Found: C, 70.7; H, 5.1.)

That it is the glycosidic alkyl group which is replaced on treatment of the dialkyl derivatives with acetic anhydride and sulfuric acid is shown by the fact that when the open chain monoalkyl derivatives of benzoylformoin (X) or (XXII) are treated with acetic anhydride and sulfuric acid they furnish the same cyclic alkoxy acetates (XIX) as are obtained from the dialkyl derivatives. Thus the methyl derivative (XXII, $R = CH_3$) furnishes (XIX, $R = CH_3$) while the ethyl derivative (XXII, $R = C_2H_5$) furnishes (XIX, $R = C_2H_5$).

Reactions with Hydrogen Bromide in Acetic Acid.—On treatment with this reagent the formoin and all of its derivatives which do not contain an alkyl group in the position occupied by R′ in formula XVIII or R in formula XXII are destroyed and no definite products can be isolated. Derivatives of the formoin containing an alkyl group in the position indicated, for example the dialkyl derivatives (XVIII), the alkoxy acetates (XIX) and the monoalkyl derivatives (XXII) undergo replacement of alkoxyl, acetoxyl or hydroxyl by bromine with subsequent reduction of the resulting bromofuranones (XX) to the dimolecular products (XXI). Thus, the dimethyl derivative (XVIII, $R,R' = CH_3$), the methoxy acetate (XIX, $R = CH_3$) and the monomethyl derivative (XXII, $R = CH_3$), on solution in acetic acid and addition of a saturated solution of hydrobromic acid in acetic acid, gradually deposited a mixture of bromofuranone (XX, $R = CH_3$) and dimolecular product (XXI, $R = CH_3$). The dimolecular product interfered with the purification of the bromofuranone, so we contented ourselves with showing that the impure bromo compound could be converted to the dimolecular product by heating or by treatment in acetone solution with acidified potassium iodide. The dimolecular product was purified by crystallization from benzene and ligroin (70–90°) and from benzene alone. It melted at 226–227°.

Anal. Calcd. for $C_{34}H_{26}O_6$: C, 77.0; H, 4.9. Found: C, 76.9; H, 4.9.

The diethyl derivative (XVIII, $R,R' = C_2H_5$) and the monoethyl derivative (XXII, $R = C_2H_5$) with hydrogen bromide in glacial acetic acid furnish the ethoxy dimolecular product (XXI, $R = C_2H_5$). Purified by crystallization from benzene and ligroin, this dimolecular compound melted at 218–219°. (*Anal.* Calcd. for $C_{36}H_{30}O_6$: C, 77.4; H, 5.4. Found: C, 77.0; H, 5.5.) That it is the glycosidic alkyl group which is replaced in the reaction with hydrogen bromide is shown by the fact that ethyl methyl benzoylformoin (XVIII, $R = C_2H_5$, $R' = CH_3$) on treatment with this reagent furnishes the methoxy dimolecular product (XXI, $R = CH_3$).

The bromoethoxy compound (XXIV) has been described by Abenius.[5] It can be vacuum distilled without decomposition and is reduced by acidified potassium iodide to regenerate the monomethyl derivative (X or XXII, $R = CH_3$). With *o*-phenylenediamine the bromo compound gives the hydroxyquinoxaline (XV). Attempts to synthesize the bromo compound by adding ethyl bromide to diphenyl tetraketone were not successful.

The Action of Sodium Methylate on the Quinoxalines (VI) and (XXIII).—When 1.36 g. of the quinoxaline (VI) was dissolved in 30 cc. of methyl alcohol containing 1.6 g. of sodium an intensely purple colored solution resulted. The color of this solution faded very slowly in a stoppered container, rapidly when exposed to the air. In either case the odor of methyl benzoate was pronounced. After the color of the solution had bleached, water and ether were added. The aqueous layer was acidified, then made alkaline with sodium carbonate. The precipitate at this point consisted of 0.35 g. of the hydroxyquinoxaline (XV). The sodium carbonate filtrate was acidified and furnished 0.2 g. of benzoic acid. From the ethereal extract on evaporation there was obtained 0.5 g. of the quinoxalyl carbinol (XXV, $R = H$) which was purified by crystallization from ether and petroleum ether and from dilute methanol. It melted at 140–141° and could be distilled in a high vacuum.

Anal. Calcd. for $C_{15}H_{12}ON_2$: C, 76.3; H, 5.1. Found: C, 76.2; H, 5.2.

When the quinoxaline (XXIII)[2] was treated in similar fashion with sodium methylate, the alkaline solution was a vivid red. On working up the products of the reaction, methyl benzoate was identified by its odor, benzoic acid and the hydroxyquinoxaline (XV) by mixed melting points. The fourth product of the reaction, quinoxalyl carbinol methyl ether (XXV, $R = CH_3$), was obtained in much larger amounts than was the corresponding carbinol from the quinoxaline (VI). The ether was purified by high vacuum distillation and by crystallization from dilute methanol. It melted at 78–79°.

Anal. Calcd. for $C_{16}H_{14}ON_2$: C, 76.8; H, 5.6; OCH_3, 12.4. Found: C, 77.1; H, 5.7; OCH_3, 12.8.

The structures of the quinoxalyl carbinol and its methyl ether were established by etherification of the former to yield the latter and by oxidation of the carbinol to the known quinoxaline acid (VIII). Thus, 0.24 g. of the carbinol was dissolved in methyl iodide and boiled with a half gram of powdered sodium hydroxide for three hours. After removal of the methyl iodide, the reaction product was vacuum distilled and gave a quantitative yield of the methyl ether (XXV, $R = CH_3$). When 0.15 g. of the carbinol was oxidized in acetic acid with the calculated amount of chromic acid, the reaction mixture taken up in ether and washed with water, then extracted with sodium carbonate, the extract furnished on acidification 0.10 g. of the quinoxaline acid (VIII).

Summary

A description of the chemical behavior of benzoylformoin and its derivatives is presented. On the basis of this description it is concluded that the formoin and its open-chain monoalkyl derivatives are ene-diol hydroxyfuranone tautomers, while its cyclic mono- and dialkyl derivatives are alkoxyfuranones.

The Action of Alkali on Acylated Ketoximes. II.[1] Steric Hindrance to Alkaline Hydrolysis

BY A. H. BLATT AND R. P. BARNES

Although chemists have not agreed upon the relative importance to be assigned to steric factors in chemical reactions, they have recognized the existence of hindrance in the alkaline hydrolysis of esters since the early experiments of Victor Meyer.[2] The acylated ketoximes are esters of organic acids and oximes and as such one would expect that their alkaline hydrolysis would be subject to hindrance when the acyl group involved was properly substituted. Since we were unable to find any data bearing directly on this point, and since we had need of specific information on it, we have examined the behavior toward alkali of the benzoates and 2,4,6-trimethylbenzoates of benzophenone oxime and the α-oxime of *p*-chlorobenzophenone. In addition, in order to make certain that configuration played no part, we included the benzoates and trimethylbenzoates of both oximes of *p*-methoxybenzophenone.

As our interest was in the existence of hindrance rather than in the exact amount of hindrance, we have not made quantitative studies of reaction rates but have, instead, contented ourselves with comparative tests. Our procedure consisted in determining first the conditions under which an oxime benzoate was completely hydrolyzed. We then made parallel runs with the benzoate and the corresponding trimethylbenzoate under these previously determined conditions. As was to be expected, hydrolysis was suppressed by hindrance for, without exception, the 2,4,6-trimethylbenzoates were unaffected by the treatment which served to hydrolyze the benzoates completely.

The structures of the oxime benzoates employed were established both by their method of preparation and by their hydrolysis. The structures of the oxime trimethylbenzoates followed with near certainty from their method of preparation, for it is known that oximes of the benzophenone type on treatment with pyridine and an acid chloride furnish acylated oximes and not rearrangement products unless the acid chloride is derived from a strong acid—*e. g.*, benzenesulfonic acid. 2,4,6-Trimethylbenzoic acid is of the same order of strength but somewhat weaker than benzoic acid so that a rearrangement in the preparation of the trimethylbenzoates seemed most improbable.[3] Since, however, our experiments with the trimethylbenzoates were meaningless unless these substances had the structures assigned them, we have hydrolyzed all the trimethylbenzoates by prolonged heating with alcoholic hydrochloric acid. This treatment furnished in each case trimethylbenzoic acid and the ketone from which the oxime was derived, showing that our starting materials were acylated ketoximes. This precaution was particularly necessary in the case of the β-oxime of *p*-methoxybenzophenone for it gave two isomeric products on treatment with 2,4,6-trimethylbenzoyl chloride. Both isomers on acid hydrolysis furnished *p*-methoxybenzophenone and 2,4,6-trimethylbenzoic acid and neither isomer was hydrolyzed by alkali. Presumably this is a case of dimorphism but it is not absolutely certain.

The fact that the hydrolysis of these acylated ketoximes is subject to hindrance is strong presumptive evidence that it proceeds through an addition reaction. An observation which we made during the hydrolysis of the benzoates has confirmed this and has enabled us to show the nature of the addend. When the benzoates were hydrolyzed by treatment in alcoholic solution with aqueous sodium hydroxide and the reactions were stopped by pouring into large volumes of water, the products were not oxime and sodium benzoate but oxime and ethyl benzoate. The isolation of the small amount of ethyl benzoate formed was not feasible under the conditions of our experiments. Consequently, in order to establish the formation of an ester in the alkaline reaction medium, we hydrolyzed the *p*-phenylbenzoate of acetoxime (I) using methyl alcohol and aqueous sodium hydroxide. This gave methyl *p*-phenylbenzoate (II). In our opinion the only reasonable interpretation of these facts is that the alkaline hydrolysis of acylated ketoximes under the condi-

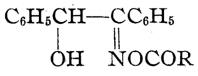
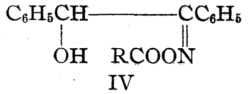
The application of this mechanism to the alkaline hydrolysis and alcoholysis of carboxylic esters is sufficiently obvious to make specific comment unnecessary.

With the existence of hindrance in the alkaline hydrolysis of acylated ketoximes thus established, we have made use of it in order to secure additional information about the two processes which take place when acylated benzoin oximes are treated with alkali. It has previously been shown[1] that acylated α-benzoin oximes (III) on treatment with alkali are cleaved to benzaldehyde, benzonitrile and the acid corresponding to the acyl group present, while the isomeric acylated β-benzoin oximes (IV) on similar treatment do not undergo cleavage but instead are hydrolyzed to oxime and acid.



$$\underset{OH}{C_6H_5CH}{-}\underset{NOCOR}{\overset{}{CC_6H_5}}$$

III



$$\underset{OH}{C_6H_5CH}{-\!-\!-\!-}\underset{RCOON}{CC_6H_5}$$

IV

To determine the effect of hindrance on these two processes we have examined the behavior toward alkali of the trimethylbenzoates of both benzoin oximes. The trimethylbenzoate of α-benzoin oxime (III, R = 2,4,6-$(CH_3)_3C_6H_2$—) on treatment with aqueous sodium hydroxide or alcoholic sodium carbonate cleaves, at least as readily as do the unhindered esters of this oxime, to benzonitrile, benzaldehyde and trimethylbenzoic acid. The trimethylbenzoate of β-benzoin oxime (IV, R = $(CH_3)_3C_6H_2$—) under the same conditions is unaffected. The application of these results to the acylated benzoin oximes is straightforward. Hydrolysis, here as in other acylated ketoximes, is the usual type of ester hydrolysis which proceeds through an addition reaction and which is stopped by hindrance. Cleavage, which is not affected by hindrance, obviously does not involve an addition reaction and must follow a quite different course.

The most probable course for the cleavage is one which is an application to the acylated α-benzoin oximes of the mechanism which Mills[4] has proposed for the action of alkali on aldoxime acetates. Stereoisomeric aldoxime acetates on treatment with alkali undergo cleavage to nitrile and acid or hydrolysis to aldoxime and acid. Mills has suggested that the first step in both cases is the loss of the aldehydic hydrogen atom as a proton. The resulting gap molecules will then, depending upon their configuration, either lose an acetate ion—cleavage—or undergo hydrolysis and regain a proton. This mechanism, applied to the acylated benzoin oximes with which we are dealing, involves the loss of the hydroxyl hydrogen atom as a proton from both isomers. It is in complete agreement with all the available facts insofar as the α-derivatives, those which cleave, are concerned. In the case of the β-derivatives we have already shown that the reaction involved is the usual type of ester hydrolysis proceeding through an addition reaction and we see no necessity for the assumption of the loss of a proton and the formation of gap molecules.

The essential difference between our point of view and that of Mills is that while Mills regards configuration as determining the behavior of the gap molecules once they are formed, we regard configuration as determining the ease of formation of the gap molecules. These alternatives can be tested by making use once more of the trimethylbenzoate of β-benzoin oxime (IV, R = 2,4,6-$(CH_3)_3C_6H_2$—). If configuration determines the behavior of the gap molecule, then this trimethylbenzoate should be unaffected by any alkaline treatment. If, however, configuration simply determines the ease of formation of the gap molecule then, since hydrolysis is stopped by hindrance, this trimethylbenzoate should cleave if the alkaline treatment is made sufficiently drastic. This latter is the case. The trimethylbenzoate of β-benzoin oxime, which is unaffected by the treatment which serves to cleave its α-isomer, is itself cleaved by alcoholic sodium hydroxide.

Experimental

The acylated oximes were prepared by mixing cold pyridine solutions containing equivalent amounts of oxime and acid chloride, allowing them to stand for twenty-four hours at room temperature and then pouring them onto ice and dilute hydrochloric acid. The benzoates solidified promptly; the trimethylbenzoates were generally obtained as oils which crystallized only after they had been dissolved

in ether and shaken thoroughly with dilute acid. The solvents used for purification, with the melting points and analyses of the products, are given in Table I. The benzoate of benzophenone oxime has already been described.[5] A more detailed description of the trimethylbenzoates of the benzoin oximes is given later.

Attempts to determine whether the 75 and 120° trimethylbenzoates of the *β*-oxime of *p*-methoxybenzophenone were dimorphous were inconclusive because the melts of these isomers did not crystallize satisfactorily on cooling.

Each of the above 2,4,6-trimethylbenzoates was hydrolyzed by boiling its alcoholic solution to which a small amount of concd. hydrochloric acid had been added, for from two to six hours. Water was then added, the solutions were made alkaline with carbonate and steam distilled. The distillates contained in each case the ketone from which the oxime was derived, while the residual alkaline liquid furnished on acidification 2,4,6-trimethylbenzoic acid.

Since the procedure in most of the alkaline hydrolysis experiments was similar, a generalized description will suffice for all but the exceptional cases. After preliminary experiments had shown the time required for complete hydrolysis of a benzoate, a solution of 1.0 g. of that benzoate in a definite volume of alcohol was prepared. At the same time a solution of 1.0 g. of the corresponding trimethylbenzoate was made up in the same volume of alcohol. To these solutions equal volumes of 5% sodium hydroxide solution were added. Then, after both solutions had been left for a time sufficient to hydrolyze the benzoate, half of the solution containing the trimethylbenzoate was poured into a large volume of water while all of the solution containing the benzoate was similarly treated. The precipitates thus obtained, after filtering and drying, were identified by melting points and mixed melting points. Finally, after a much longer reaction time, the remaining half of the solution of the trimethylbenzoate was poured into water and worked up. In every case the product from the benzoates (reaction time from thirty to ninety minutes) consisted of oxime produced by hydrolysis. The alcoholic solutions smelled strongly of ethyl benzoate. In every case the product from the trimethylbenzoates (reaction time from thirty minutes to twenty-two hours) consisted of unchanged starting material.

When a solution of 1.2 g. of the *p*-phenylbenzoate of acetoxime (I) in 90 cc. of methyl alcohol and 10 cc. of sodium hydroxide was poured into water after standing for one hour, there was obtained a quantitative yield of methyl *p*-phenylbenzoate (II) which was identified by comparison with an authentic specimen of that ester.[6]

The 2,4,6-trimethylbenzoate of *α*-benzoin oxime crystallizes splendidly from ether and petroleum ether or alcohol and water in clusters of small needles which melt irregularly at about 92°. The material undergoes cleavage on heating so that the melting point is not sharp. Even on standing the material cleaves to such an extent that it is not possible to secure acceptable analytical results. Carbon and hydrogen determinations are both inconsistent and low, presumably as a result of autoxidation of the benzaldehyde formed by cleavage. In the absence of analytical data the structure of the material is based on its alkaline cleavage to furnish benzaldehyde, benzonitrile and trimethylbenzoic acid and its hydrolysis, on standing in alcoholic solution with hydrochloric acid at room temperature, to furnish benzoin.

The 2,4,6-trimethylbenzoate of *β*-benzoin oxime crystallizes from ether and petroleum ether and melts at 151°. This material is quite stable and does not decompose on standing. (*Anal.* Calcd. for $C_{24}H_{23}O_3N$: C, 77.2; H, 6.2. Found: C, 77.25; H, 6.2.)

The trimethylbenzoate of *α*-benzoin oxime is completely cleaved to trimethylbenzoic acid, benzaldehyde and benzonitrile by shaking for fifteen minutes with an excess of 5% aqueous sodium hydroxide. Shaken for fifteen minutes in alcoholic solution with one mole of aqueous sodium carbonate the same cleavage occurs. Identification of the cleavage products was made by the method used in earlier work.[1] The trimethylbenzoate of *β*-benzoin oxime is recovered unchanged after the treatments just described. However, when it is treated in alcoholic solution with an excess of 5% aqueous sodium hydroxide for fifteen minutes, it is cleaved to benzaldehyde, benzonitrile and trimethylbenzoic acid.

Summary

The hydrolysis of acylated ketoximes by alkali in aqueous alcoholic solution proceeds through an addition of alcohol and can be stopped by the introduction of hindrance in the acyl group. The cleavage of acylated ketoximes of the benzoin type by alkali is not affected by hindrance. The mechanism of the cleavage process is discussed.

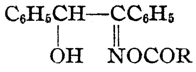
The Action of Alkali on Acylated Ketoximes. III. Hydrogen Bond Formation in Derivatives of the *o*-Hydroxybenzophenone Oximes

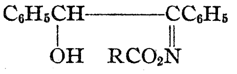
BY A. H. BLATT AND LILLIAN A. RUSSELL

In the earlier articles of this series[1] it was shown that, when hindrance does not intervene, the behavior of acylated benzoin oximes toward alkali is determined by their configuration. Acylated α-benzoin oximes (I) are cleaved by alkali while acylated β-benzoin oximes (II) are hydrolyzed. The mechanism of these two processes has been discussed but no explanation was advanced for the one-to-one correlation between configuration and mode of reaction. It is our purpose in this article to consider this latter point.



$$\begin{array}{ll} C_6H_5CH & \!\!-CC_6H_5 \\ | & \;\| \\ OH & NOCOR \end{array}$$

I



$$\begin{array}{ll} C_6H_5CH & \!\!-\!\!-\!\!-\!\!-CC_6H_5 \\ | & \qquad\;\| \\ OH & RCO_2N \end{array}$$

II

Since configuration is the determining factor, one seeks an explanation in terms of steric differences between the isomers. The most striking difference is the proximity in the α-series (I) of the unshared electron pair on the nitrogen atom to the hydroxyl group, and their separation in the β-series (II). We suggest, therefore, that the cleavage of acylated α-benzoin oximes is a consequence of incipient hydrogen bond formation (chelation) between the hydroxyl hydrogen atom and the spatially adjacent unshared electron pair on the nitrogen atom. The interaction between hydroxyl hydrogen and the unshared electron pair on nitrogen would be favored by their proximity in the α-series and it would be prevented in the β-series both by their separation and by the screening effect of the intervening acyl group. That such an interaction does take place is indicated by the infra-red absorption of the acetates of the benzoin oximes. The molal absorption area of β-benzoin oxime acetate (II, R = CH_3) approximates but is somewhat less than that of compounds containing a normal hydroxyl group, while the shape of the absorption curve shows some deviation from normal. α-Benzoin oxime acetate (I, R = CH_3), however, shows a marked suppression of hydroxyl group absorption and, more significant, a broad absorption curve.[2]

The acylated benzoin oximes, though useful as suggesting the explanation which we have just presented, are not of assistance in testing it. The requirements for complete hydrogen bond formation are well established: a system, capable of resonance, made up of a hydroxyl group and a conjugated system of double bonds terminating in oxygen or nitrogen. Such a system is not present in the acylated benzoin oximes though they contain one which approaches it and which constitutes a borderline case. Derivatives of the *o*-hydroxybenzophenone oximes, however, do meet exactly the requirements for hydrogen bond formation and, if our explanation is valid, stereoisomeric pairs of acylated *o*-hydroxybenzophenone oximes should show a difference in their chemical behavior comparable to that shown by stereoisomeric acylated benzoin oximes, while one isomer should show complete hydrogen bonding detectable by appropriate physical methods.

We have verified these consequences by an examination of the acetates of both oximes of *o*-hydroxybenzophenone and of both oximes of 2-hydroxy-5-methylbenzophenone. The isomeric oximes of *o*-hydroxybenzophenone were available as a result of the work of Kohler and Bruce;[3] we were able to obtain the previously unknown isomer of 2-hydroxy-5-methylbenzophenone oxime by applying the method of conversion of Kohler and Bruce to the known oxime. Since the two pairs of isomeric oximes thus available show perfectly parallel behavior, it will only be necessary to describe one pair and we shall confine our discussion with few exceptions to the acetates of the oximes of *o*-hydroxybenzophenone.

On treatment with excess sodium hydroxide the acetates of both *o*-hydroxybenzophenone oximes are hydrolyzed to the parent oximes. This perhaps means that under these conditions hydrolysis takes place more rapidly than cleavage. More likely, however, it indicates that salt formation occurs at the phenolic hydroxyl group and destroys the hydrogen bond. In either case,

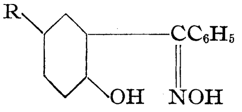
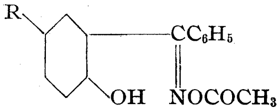
(2) The measurements of the infra-red absorption of these acetates have been published: Hilbert, Wulf, Liddel and Hendricks, *ibid.*, **58**, 548 (1936). We are indebted to Dr. Oliver Wulf and his associates of the Bureau of Chemistry and Soils of the U. S. Department of Agriculture for the measurements and for discussing with us their interpretation. We are, of course, responsible for the particular interpretation presented here.

(3) Kohler and Bruce, *ibid.*, **53**, 1569 (1931).

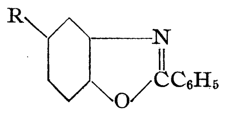
hydrolysis is most convenient for it permits one to relate the configurations of the acetates to those of the parent oximes by a chemical transformation. With sodium carbonate, that is, under conditions comparable in this series to the use of sodium hydroxide with the benzoin oxime acetates, differences in behavior are observed. The acetate (IV, R = H) undergoes a Beckmann rearrangement to furnish the benzoxazole (V, R = H)—a process which is the counterpart here of the cleavage of α-benzoin oxime acetate, for in both reactions the bond between the α-carbon atom and the carbon atom of the C=N group is broken. The acetate (VIII, R = H) on treatment with sodium carbonate undergoes hydrolysis to the parent oxime (VII, R = H) just as does β-benzoin oxime acetate. On pyrolysis, the acetate (IV, R = H) furnishes cleanly the benzisoxazole (VI, R = H). Pyrolysis of the stereoisomeric acetate (VIII, R = H) is not a smooth process; it furnishes in small yields a mixture of products from which it is possible to isolate the isoxazole (VI, R = H).



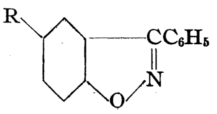
III



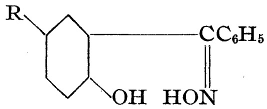
IV



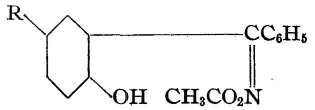
V



VI



VII



VIII

The behavior of the acetates (IV, R = H) and (VIII, R = H) on pyrolysis is particularly interesting in view of earlier attempts at ring closure made with the parent oximes. Meisenheimer and Meis,[4] who were unable to dehydrate the oxime (VII, R = H) to the isoxazole (V, R = H), concluded that such a dehydration would take place only in the, then unknown, isomer (III, R = H) where it would result from the operation of residual valence forces. Kohler and Bruce,[3] who first prepared the oxime (III, R = H), found that it could not be dehydrated to the isoxazole and this, together with the observation of v. Auwers and Jordan[5] that the oxime of 2,2'-dihydroxybenzophenone could not be converted to an isoxazole, seemed to discredit pretty thoroughly Meisenheimer's suggestion. However, Lindemann[6] found that the acetates of a number of *o*-hydroxybenzaldoximes and *o*-hydroxyacetophenone oximes furnished isoxazoles on pyrolysis. Lindemann in no case had isomeric oxime acetates. Our results with the acetates of the *o*-hydroxybenzophenone oximes and the 2-hydroxy-5-methylbenzophenone oximes show clearly that pyrolysis to an isoxazole is a smooth reaction only when the acylated oximino group is *anti* to the hydroxyl group. And, although no *trans* dehydration of an oxime to a heterocyclic compound has yet been observed, the assumption that a *trans* ring closure of an oxime *derivative* may take place, for example, in the Beckmann rearrangement of α-benzil dioxime[7] becomes much more plausible.

It is clear from the foregoing description that the difference in chemical behavior—hydrolysis *vs.* cleavage—which was observed with the isomeric benzoin oxime acetates is also found in the isomeric *o*-hydroxybenzophenone oxime acetates. It remains to be shown that cleavage is associated with the presence of a hydrogen bond in the molecule. Our evidence on this point is from two sources: infra-red absorption and solubility. Dr. Oliver Wulf and his associates at the Bureau of Chemistry and Soils of the U. S. Department of Agriculture, have determined the infra-red absorption of the four acetates (IV, R = H and CH_3) and (VIII, R = H and CH_3). They find that the acetates (IV, R = H and CH_3), in which the hydroxyl group and acetylated oximino group are spatially distant with respect to each other, show no absorption in the hydroxyl region. The acetates (VIII, R = H and CH_3), in which the hydroxyl group and acetylated oximino group are spatially adjacent with respect to each other, show normal hydroxyl group absorption. Their data for the acetate (VIII, R = CH_3) are shown graphically in Fig. 1.[8] Since the work of these investigators[9] has shown that the disappearance of hydroxyl group absorption is a criterion of hydrogen bond formation between hydroxyl hydrogen

[8] The data for the acetates (IV, R = H and CH_3) and (VIII, R = H) are presented in an article by Hendricks, Wulf, Hilbert and Liddel, THIS JOURNAL, **58**, 1991 (1936).

[9] Hilbert, Wulf, Liddel and Hendricks, *Nature*, **135**, 147 (1935). See also references 2 and 8.

and either carbonyl oxygen or trivalent nitrogen, their results establish definitely the existence of hydrogen bonds in the acetates (IV, R = H and CH_3) and their absence in the acetates (VIII, R = H and CH_3).

In connection with this discussion of the infra-red absorption data we wish to point out that it furnishes a new and absolute method for determining the configuration of oximes of the type under consideration. The results obtained by this method as applied to the oxime acetates can be related to the parent oximes by the fact that each oxime furnishes a single acetate from which the parent oxime can be cleanly regenerated. When the configurations of the oxime acetates, as determined by their infra-red absorption, are related back to the parent oximes, it is found that the configurations thus obtained are in complete agreement with those obtained from the Beckmann rearrangement of the oximes on the assumption of a *trans* shift of groups during rearrangement.

The conclusions from infra-red absorption are supported by the solubilities of the four acetates under discussion. The acetates (IV, R = H and CH_3) are soluble in carbon tetrachloride to the extent of forming one-tenth molar solutions at room temperature. The stereoisomeric acetates (VIII, R = H and CH_3) are so sparingly soluble that it is not possible to prepare one one-hundredth molar solutions in this solvent under the same conditions. While we realize that the use of solubility in assigning structure must be made with proper caution, in a case such as this where the solubilities of stereoisomers are being compared it seems legitimate to conclude that the tenfold greater solubility of the acetates (IV, R = H and CH_3) in a non-polar solvent like carbon tetrachloride indicates the disappearance of the polar hydroxyl group in these acetates. Corroborating the solubilities in carbon tetrachloride are those in alcohol where the acetates (VIII, R = H and CH_3) possessing a polar hydroxyl group are more soluble than their stereoisomers (IV, R = H and CH_3).

The material presented in this article furnishes a firm foundation for the suggestion that the alkaline cleavage of acylated oximes of the α-benzoin and *o*-hydroxybenzophenone types is a consequence of hydrogen bond formation in these substances. In addition, it makes possible a study of the chemical effects which accompany hydrogen bond formation. It is obvious from our results that hydrogen bond formation between oxygen and nitrogen is completely conditioned by steric factors. Because of this and because of the existence in isomeric forms of compounds containing an unsaturated trivalent nitrogen atom, it is possible for the first time to secure and study isomers which differ from each other only in that one contains a hydrogen bond while the other does not.[10] It has already been shown that occurrence of hydrogen bonding is accompanied by ease of cleavage of the molecule. It is also true that hydrogen bond formation in the *o*-hydroxybenzophenone oxime acetates is accompanied by a decrease in the acidity of the phenolic hydrogen atom. It is our intention to continue the study of systems where hydrogen bonding between oxygen and nitrogen can take place so as to secure additional information about the chemical effects which accompany it. It is our hope that a more complete knowledge of these chemical effects will be of use in the development of a physical interpretation of the hydrogen bond.

Experimental

A. Derivatives of *o*-Hydroxybenzophenone

Preparation of *syn*-Phenyl 2-Hydroxyphenyl Ketoxime Acetate (IV, R = H).—To 5.0 g. of the oxime (III, R = H)[11] was added 10 cc. of acetic anhydride. On gentle warming the oxime dissolved and on cooling the acetate

---

[10] The existence of isomers of this type has been postulated by Pauling, THIS JOURNAL, **58**, 94 (1936), in connection with the infra-red absorption of certain ortho substituted phenols. However, the isomerism predicted by Pauling would result from two different configurations of the hydroxyl group while the isomers with which we are dealing result from different configurations of the atom to which the hydroxyl hydrogen atom is bonded.

[11] The preparation of this oxime is much more satisfactory if twice the quantity of hydroxylamine hydrochloride recommended by Kohler and Bruce,[3] is employed. Compare the directions given below for *syn*-phenyl 2-hydroxy-5-methylphenyl ketoxime.

crystallized. Decomposition of the excess anhydride with water and crystallization of the product from alcohol furnished 3.5 g. of pure acetate, melting at 96–97°.

Anal. Calcd. for $C_{15}H_{13}O_3N$: C, 70.6; H, 5.1. Found: C, 70.6; H, 4.9.

Action of Sodium Hydroxide on the Acetate (IV, R = H).—When 0.5 g. of the acetate was shaken with 10 cc. of 5% sodium hydroxide a slight yellow color developed but much of the solid did not dissolve. On addition of 20 cc. of alcohol a clear yellow solution was obtained. After five minutes it was diluted with water, iced and acidified with dilute hydrochloric acid. The resulting colorless precipitate, which weighed 0.35 g., melted at 110–125°. Mixed with the *syn* oxime (III, R = H), m. p. 142–143°, it melted at 133–138°, and mixed with the *anti* oxime (VII, R = H), m. p. 140–141°, it melted below 105°. A single crystallization of the product from benzene and ligroin furnished the pure *syn* oxime (III, R = H).

Action of Sodium Carbonate on the Acetate (IV, R = H).—When a solution of 0.5 g. of sodium carbonate in 5.0 cc. of water was added to 0.5 g. of the acetate in 25 cc. of alcohol there was a transient yellow color while a small amount of material precipitated. After five minutes, the addition of 70 cc. of water precipitated 0.35 g. of a colorless solid which melted at 80–85°; mixed with 2-phenylbenzoxazole (V, R = H)[12] it melted at 95–100°, and mixed with 3-phenylbenzisoxazole (VI, R = H)[13] it melted below 65°. Crystallization from alcohol furnished the pure benzoxazole, m. p. and mixed m. p. 102–103°.

Pyrolysis of the Acetate (IV, R = H).—When 0.2 g. of acetate was slowly heated in a Späth bulb connected to an oil pump it began to decompose at about 65° while between 140–150° a pale yellow oil distilled. There was almost no charring in the bulb. The distillate dissolved in 2 cc. of hot alcohol, gave on cooling 0.1 g. of 3-phenylbenzisoxazole (VI, R = H) melting at 83–84°. The melting point of the product was not lowered by admixture with a synthetic sample of the benzisoxazole but a mixture of the product and 2-phenylbenzoxazole (V, R = H) melted below 70°.

Preparation of *anti*-Phenyl 2-Hydroxyphenyl Ketoxime Acetate (VIII, R = H).—To 2.4 g. of the oxime (VII, R = H)[14] 8 cc. of acetic anhydride was added. The reaction was worked up as with the *syn* acetate (IV, R = H) and crystallization of the product from 15 cc. of alcohol and 10 cc. of water furnished 2.1 g. of pure acetate which melted at 156°.

Anal. Calcd. for $C_{15}H_{13}O_3N$: C, 70.6; H, 5.1. Found: C, 70.57; H, 4.9.

Action of Sodium Hydroxide on the Acetate (VIII, R = H).—When 0.5 g. of the acetate was shaken with 10 cc. of 5% sodium hydroxide all save a trace of the material dissolved. After fifteen minutes the solution was filtered, diluted, iced and acidified. It furnished 0.4 g. of the *anti* oxime (VII, R = H), melting at 140–141°, and whose melting point was not lowered by admixture with the *anti* oxime.

Action of Sodium Carbonate on the Acetate (VIII, R = H).—A solution of 0.5 g. of sodium carbonate in 5 cc. of water was added to 0.5 g. of the acetate in 25 cc. of alcohol. A pale yellow color developed and a slight precipitate, apparently inorganic, was formed. After fifteen minutes, the addition of 70 cc. of water gave a clear solution. Careful acidification with dilute hydrochloric acid furnished 0.35 g. of the *anti* oxime melting at 140–141°. The melting point of the product was not lowered by admixture with the *anti* oxime (VII, R = H) but it was lowered to 115–120° by admixture with the *syn* oxime (III, R = H).

Pyrolysis of the Acetate (VIII, R = H).—When 0.2 g. of the acetate was distilled in vacuum there was much charring. The yellow oily distillate dissolved in 1 cc. of alcohol and diluted with water furnished 0.07 g. of a colorless solid which melted at 72–78° and whose melting point was raised by admixture with 3-phenylbenzisoxazole and with 2-phenylbenzoxazole. The solid behaved like a mixture of the oxazole and isoxazole. Crystallization from alcohol and water furnished 0.03 g. of 3-phenylbenzisoxazole (VI, R = H) melting at 79–81° with preliminary softening. Mixed with pure benzisoxazole (83–84°) the recrystallized material melted at 82–84°, mixed with the pure benzoxazole (102–103°) it melted at 67–70°.

B. Derivatives of 2-Hydroxy-5-methylbenzophenone

Preparation of *syn*-Phenyl 2-Hydroxy-5-methylphenyl Ketoxime (III, R = CH_3).—Since the preparation and purification of this oxime are reported to be quite troublesome,[15] we present the following procedure based on that of Kohler and Bruce for the unmethylated analog. Ten grams of 2-hydroxy-5-methylbenzophenone is shaken with 80 cc. of 40% potassium hydroxide. The solid dissolves and an orange-yellow potassium derivative separates. The reaction mixture is then cooled and shaken while 15.0 g. of hydroxylamine hydrochloride is added over a period of forty-five minutes. When no more heat is evolved the flask is stoppered and shaken mechanically for four hours or left to stand overnight. The resulting clear yellow solution is then diluted, iced and acidified with dilute hydrochloric acid. The crude oxime, thus precipitated, weighs 10.1 g. and melts at 127–135°. Crystallization from 25 cc. of benzene and an equal volume of ligroin (70–90°) furnishes 8.2 g. of pure oxime melting at 135–136°. The oxime develops a bright yellow color on exposure to direct sunlight.

Preparation of *syn*-Phenyl 2-Hydroxy-5-methylphenyl Ketoxime Acetate (IV, R = CH_3).—To 2.0 g. of the oxime (III, R = CH_3) there was added 4 cc. of acetic anhydride. Solution was effected by warming and the acetate crystallized on cooling. Purified by crystallization from 25 cc. of alcohol the acetate melted at 125–126°; yield, 1.8 g.

Anal. Calcd. for $C_{16}H_{15}O_3N$: C, 71.4; H, 5.6. Found: C, 71.6; H, 5.6.

---

(12) Prepared according to Ladenburg, *Ber.*, **9**, 1526 (1876), and melting at 102–103°.

(13) Prepared according to Kohler and Bruce, This Journal, **53**, 646 (1931), and melting at 83–84°.

(14) The gummy by-products formed in the conversion of the *syn* to the *anti* oxime (*cf.* ref. 3) can be removed conveniently by incompletely neutralizing the strongly alkaline reaction mixture, after dilution with water, with carbon dioxide. This precipitates the by-products so that on acidification of the filtered solution with dilute hydrochloric acid the *anti* oxime is obtained as a colorless, crystalline solid.

(15) (a) Von Auwers and Jordan, *Ber.*, **58**, 34 (1925); (b) Von Auwers and Czerny, *ibid.*, **31**, 2694 (1898).

Action of Sodium Hydroxide on the Acetate (IV, R = CH_3).—When 0.5 g. of the acetate was shaken with 10 cc. of 5% sodium hydroxide, the material dissolved in part to furnish a yellow solution. Addition of 20 cc. of alcohol effected solution, and on dilution with water and acidification with hydrochloric acid 0.4 g. of crude *syn* oxime was obtained. The crude product melted at 110–120°; mixed with the *syn* oxime it melted at 120–133° and, on crystallization from benzene and ligroin, furnished pure *syn* oxime melting at 135–136°.

Action of Sodium Carbonate on the Acetate (IV, R = CH_3).—A solution of 0.5 g. of sodium carbonate in 5 cc. of water was added to 0.5 g. of the acetate in 25 cc. of alcohol. A slight yellow color developed and a small amount of material precipitated. After fifteen minutes the addition of 70 cc. of water precipitated 0.35 g. of a colorless solid which melted at 80–88°. A mixture of this material and 2-phenyl-5-methylbenzoxazole (V, R = CH_3)[16] melted at 90–95°, while a mixture with 3-phenyl-5-methylbenzisoxazole (see below) melted below 65°. Crystallization from alcohol furnished the pure benzoxazole, m. p. and mixed m. p. 102–103°.

Pyrolysis of the Acetate (IV, R = CH_3).—When 1.0 g. of the acetate was pyrolyzed the product distilled at about 160° in an oil pump vacuum. Taken up in 4 cc. of alcohol the solution deposited on cooling 0.5 g. of impure 3-phenyl-5-methylbenzisoxazole (VI, R = CH_3). On crystallization from alcohol the pure benzisoxazole, melting at 92–93°, was obtained. Identification was made by a mixed melting point with a synthetic sample.

Synthesis of 3-Phenyl-5-methylbenzisoxazole (VI, R = CH_3).—A mixture of 2-chloro-5-methylbenzophenone and 2-methyl-5-chlorobenzophenone was prepared from *p*-chlorotoluene according to the directions of Heller.[17] Since the 2-chloro-5-methylbenzophenone did not crystallize, the mixture of isomers was treated with hydroxylamine and then with alkali according to the procedure of Kohler and Bruce for the preparation of 3-phenylbenzisoxazole.[13] The reaction mixture was then extracted with ether, the ether removed and the residue vacuum distilled. The fraction boiling at about 160° when dissolved in alcohol slowly deposited the characteristic large crystals of the isoxazole which melted at 92–93° and which were identical with the previously described pyrolysis product.

Anal. Calcd. for $C_{14}H_{11}ON$: C, 80.4; H, 5.26. Found: C, 80.2; H, 5.3.

Preparation of *anti*-Phenyl 2-Hydroxy-5-methylphenyl Ketoxime (VII, R = CH_3).—Strongly alkaline solutions at the boiling point convert the *syn* oxime (III, R = CH_3) into a mixture of the *syn* and *anti* forms. Fortunately the *syn* modification is precipitated from its alkaline solutions by carbon dioxide before the *anti*, so that the isolation of the *anti* form from the mixture presents no special difficulties. Our preferred procedure consists in boiling for two hours 1.0 g. of the pure *syn* oxime with 40 cc. of 40% sodium hydroxide. At the end of the first hour a clear yellow solution is obtained; at the end of the second hour a precipitate is suspended in the alkaline liquid. The hot alkaline reaction mixture is diluted with cold water to 300 cc., 50 g. of crushed ice added and a rapid stream of carbon dioxide passed in for from an hour to an hour and a quarter. At this point the yellow solution is filtered from a small flocculent precipitate of the *syn* oxime which is rejected. To the filtrate, 150 g. of crushed ice is added and then dilute hydrochloric acid is added with stirring until a vigorous evolution of carbon dioxide occurs. At this point the precipitation of the *anti* oxime is complete and it is unnecessary to add additional acid. The reaction mixture at no time is acid to litmus. If no seed is available the *anti* oxime precipitates as a gray curdy mass; once seed is available, the precipitate is lighter in color and granular in form. From three such runs 2.0 g. of crude *anti* oxime is obtained. The material is purified by crystallization from benzene (using 2.5 cc. per gram of solid) by diluting with an equal volume of ligroin (70–90°). The pure *anti* oxime melts at 136–137°, almost the same point as the *syn* modification, but mixtures of the two melt below 115°. The *anti* oxime precipitated from alkaline solutions picks up an electric charge very readily and is difficult to handle.

Anal. Calcd. for $C_{14}H_{13}O_2N$: C, 74.0; H, 5.7. Found: C, 74.5; H, 5.65.

Beckmann Rearrangement of the *anti* Oxime (VII, R = CH_3).—A solution of 1.0 g. of the *anti* oxime in 25 cc. of absolute ether was cooled while 1.0 g. of phosphorus pentachloride was added. After one hour, after which time there was no increase in the amount of precipitate, the reaction mixture was poured on ice and the ether layer was separated. Evaporation of the ether, after appropriate washing and drying, left a sticky brownish residue which dissolved completely in 5% sodium hydroxide. Acidification of the alkaline solution and crystallization of the precipitate from dilute alcohol furnished *p*-cresotinic anilide melting at 160–162° and whose melting point was not lowered by mixture with a synthetic sample of the anilide (m. p. 162–163°).[18]

Preparation of *anti*-Phenyl 2-Hydroxy-5-methylphenyl Ketoxime Acetate (VIII, R = CH_3).—Two grams of crude *anti* oxime was warmed with 4 cc. of acetic anhydride for half a minute. The oxime dissolved and the reaction mixture while still warm solidified. After cooling, water was added and the crude acetate was crystallized from dilute alcohol; yield 2.1 g. The pure *anti* acetate melted at 157–158°.

Anal. Calcd. for $C_{16}H_{15}O_3N$: C, 71.4; H, 5.6. Found: C, 71.24; H, 5.9.

Action of Sodium Hydroxide on the Acetate (VIII, R = CH_3).—When 0.5 g. of the acetate was shaken with 10 cc. of 5% sodium hydroxide, all save a few specks dissolved. After thirty minutes the pale yellow solution was diluted, iced and acidified with dilute hydrochloric acid. The precipitate thus obtained weighed 0.4 g. and melted at 135–136° and its identity as the *anti* oxime was established by mixed melting points with the *syn* and *anti* oximes.

Action of Sodium Carbonate on the Acetate (VIII, R = CH_3).—When 0.5 g. of sodium carbonate was added to 0.5 g. of the acetate in 25 cc. of alcohol, there was a transient deep yellow color and a slight inorganic precipitate. After fifteen minutes, the addition of 70 cc. of

---

[16] Prepared by a Beckmann rearrangement of the *syn* oxime, compare ref. 15, and melting at 102–103°.

[17] Heller, *Ber.*, **46**, 1500 (1913).

[18] *p*-Cresotinic acid, Zeltner, *J. Chem. Soc.*, **104**, 726 (1913); *p*-cresotinic anilide, reference 15(a), p. 34.

water formed a clear pale yellow solution. Acidification with dilute hydrochloric acid gave 0.4 g. of the *anti* oxime melting at 120–125°; mixed with the *anti* oxime it melted at 128–133° and mixed with the *syn* oxime it melted below 110°. Crystallization from benzene and ligroin gave the pure *anti* oxime.

Pyrolysis of the Acetate (VIII, R = CH_3).—When 0.2 g. of the acetate was vacuum distilled, it charred badly and the yield of distillate, a yellow oil, was poor. Dissolved in alcohol and diluted with water it gave 0.1 g. of a solid melting by 70° and whose melting point was raised by admixture with either the isoxazole (VI, R = CH_3) or the oxazole (V, R = CH_3). Careful crystallization from alcohol gave a small amount of 3-phenyl-5-methylbenzisoxazole (VI, R = CH_3) melting at 91–92° and whose melting point was not lowered by mixing with the pure benzisoxazole, m. p. 92–93°, but which was lowered to 70° by mixing with the oxazole, m. p. 102–103°.

Summary

It has been suggested that the cleavage of acylated α-benzoin oximes by alkali is a consequence of incipient hydrogen bond formation in these compounds. By an examination of acylated *o*-hydroxybenzophenone oximes it has been shown that hydrogen bond formation, sterically conditioned, does take place and that its occurrence is accompanied by behavior comparable to that observed in the acylated α-benzoin oximes. It is pointed out that the existence of stereoisomers, only one of which contains a hydrogen bond, makes possible a study of the chemical effects associated with hydrogen bonding.

The Thermodynamics of Hydrochloric Acid in Dioxane–Water Mixtures from Electromotive Force Measurements. I. Standard Potentials

BY HERBERT S. HARNED AND JOHN OWEN MORRISON[1]

The further development of the physical chemistry of ionized solutes and ionic equilibria requires a knowledge of the variation of the fundamental thermodynamic property, the relative partial molal free energy, as a function of all the intensive variables. Such a comprehensive study of many electrolytes by different methods of measurement is a tremendous task, only to be carried out by many investigators over a long period of time. As a part of this general scheme, we have undertaken in this Laboratory a comprehensive study of the relative partial molal free energy of a single electrolyte as a function of its concentration, the temperature and dielectric constant of the solvent medium over as wide a range of values of these variables as will be found possible.

To achieve this purpose, the cell

$$H_2\ (1\ \text{atm.})\ |\ HCl\ (m),\ X\%\ \text{Dioxane},\ Y\%\ H_2O\ |\ AgCl\text{–}Ag \qquad (1)$$

is peculiarly adapted. The cell reaction is well known and the electrodes are very reproducible. Dioxane–water mixtures because of their complete miscibility and because of the low dielectric constant of pure dioxane (∼2) afford a wide range of variation of the dielectric constant. These properties have been shown to be of great value by Kraus and Fuoss[2] and Fuoss and Kraus,[3] who measured conductances of some electrolytes in these mixtures.

As part of this program, Åkerlöf and Short[4] have determined the dielectric constant of dioxane–water mixtures from 0 to 80°. The present communication contains electromotive force measurements of the above cells containing 20, 45 and 70% dioxane, respectively. Measurements have been made from 0 to 50° at 5° intervals, and from them the standard potentials of the cell from 0 to 50° inclusive have been calculated.

Experimental Procedure

In order to obtain electromotive forces in these mixtures with an accuracy equal to that obtained by Harned and Ehlers in water[5] and Harned and Thomas[6] in methanol–water mixtures, it was necessary to develop a new type of cell and a specialized technique. It was found that complete air elimination in all-glass apparatus was essential. Any contact of vapor or liquid in the cells with rubber rendered the measurements erratic and uncertain. Upon elimination of these difficulties, very accurate results may be obtained with a potentiometer circuit and a high sen-

sitivity galvanometer in solutions of dielectric constant ranging from 80 to 10. With a quadrant electrometer or an amplified galvanometer circuit, we have reason to believe that accurate results may be obtained in media of dielectric constant of the order 5, or even less.

Dioxane was purified by distillation over sodium and subsequent recrystallization. The freezing point of the material used was always within 11.76–11.78°, a value which agrees with the value 11.78° reported by Kraus and Vingee.[7]

The composition of the water–dioxane mixtures prepared from this material was known to within ±0.01%. The hydrochloric acid content of any mixture employed was known to within less than ±0.05%.

The hydrogen electrodes, consisting of platinum foils 0.4 cm. by 2.5 cm., were plated with platinum black. The silver–silver chloride electrodes were those designated by Harned[8] as type 2.

All electromotive forces were measured by an Eppley Feussner type calibrated potentiometer and Leeds and Northrup HS galvanometer. Saturated Weston cells certified by the Eppley Laboratory were used as final standards of electromotive force. The correction of pressure to 1 atm. hydrogen was made by the usual method. The solvent vapor pressures were determined by Mr. Dale Dreisbach of the Morley Chemical Laboratory of Western Reserve University, who employed the method of Hovorka and Dreisbach.[9] These were placed at our disposal by Mr. Dreisbach, for which kindness we are most grateful. The temperature control was ±0.02°.

Cells were run in triplicate. If the values of E deviated from the mean by more than ±0.05 mv., they were discarded. Each set of cells was measured over a temperature range of 25°. One series was begun at 25° and measured at 5° intervals up to 50°, then brought back to 25°. Although six to twelve hours had elapsed between the two readings at 25°, during which the cells were rather severely treated, the difference between the two readings at 25° never exceeded 0.1 mv. and was in most cases less than 0.05 mv. A second series of cells were begun at 25°, reduced to 0°, and finally brought back to 25°. The agreement of the two readings at 25° was excellent. Indeed, in some cases after sufficient experimental skill was acquired, cells were measured at 25°, reduced to 0° by 5° changes in temperature, brought back to 25°, raised to 50° by 5° changes in temperature, and then finally lowered to 25°. The agreement of the three measurements at 25° was very good (~0.05 mv.) even though the measurements had been extended over periods of twenty-four to thirty-six hours.

Electromotive Forces

Since the cells containing the solution of a given composition were measured at eleven temperatures, a table of all the original data is too voluminous for presentation. In its place, we have resorted to the expedient of expressing the results by the quadratic equation

$$E = E_{25} + a(t - 25) + b(t - 25)^2 \qquad (2)$$

E is the cell electromotive force at the centigrade temperature, t; E_{25} the electromotive force at 25°; and a and b are constants. m is the molality of the acid (moles per 1000 g. solvent). The solvent consisted of X% by weight dioxane and Y% by weight of water. Table I contains the constants of the equation at the molalities actually employed in 20, 45 and 70% dioxane–water mixtures. These values were determined by the method of least squares. In the fifth column of the table, the maximum deviation, Δ_M, between the observed and calculated results is given.

TABLE I

[7] Kraus and Vingee, THIS JOURNAL, **56**, 511 (1934).

[8] Harned, *ibid.*, **51**, 416 (1929).

[9] Hovorka and Dreisbach, *ibid.*, **56**, 1664 (1934).

It is clear that a quadratic equation affords a very close representation of the results. The data in the two solvents richer in dioxane are somewhat more consistent than in the 20% mixtures. Since the 20% mixtures were the first to be studied, we attribute this greater consistency to the skill acquired with longer experience with the technique.

The Evaluation of the Standard Potentials

As expressed by Harned and Thomas,[6] the electromotive force of cell (1) in a mixture of any composition may be expressed by

$$E = E_0 + \frac{RT}{F}\ln y - \frac{2\,RT}{F}\ln \gamma\, m = E' - 2\,k\log \gamma\, m \tag{3}$$

E_0 is the standard potential in water, E_0' the standard potential in the solvent in question and k equals 2.3026 RT/F. γ and m are the activity coefficient and molality of the acid, respectively. In water, $y = 1$, $E_0 = E_0'$. The term containing y is a measure of the medium effect.

Since the law of Debye and Hückel is to be employed in the evaluation of E_0', it is necessary to use the rational activity coefficient, f, which is related to γ according to the equation

$$a = \gamma\, m = f\, N\, s' \tag{4}$$

where a is the relative activity, and N is the mole fraction of the acid, s' a constant factor required to take care of the convention that f becomes unity in a given solvent when N or m equal zero. From this we find that

$$\log \gamma = \log f + \log s' - \log (1 + 0.002\, m\, G_0) + \log 0.001\, G_0 \tag{5}$$

where G_0 "the mean molecular weight" of solvent is given by

$$G_0 = 100\Big/\left(\frac{X}{M_1} + \frac{Y}{M_0}\right) \tag{6}$$

M_1 and M_0 are the molecular weights of dioxane and water, respectively. According to equation (5), f equals unity when m equals zero only when $\log s' = -\log 0.001\, G_0$, or $s' = 1/0.001\, G_0$. Imposing this condition, equation (5) becomes

$$\log \gamma = \log f - \log (1 + 0.002\, m\, G_0) \tag{7}$$

It also follows that

$$E = E' - 2\,k\log \gamma\, m = E' - 2\,k\log s' - 2\,k\log N f = E_0'' - 2\,k\log N f \tag{8}$$

where E_0'' is the standard potential on the mole fraction scale. We note that the standard potential, E_0'', on the f scale differs from that on the γ scale by the term $2\,k \log 0.001\, G_0$. We shall employ the Debye and Hückel limiting equation with a linear term, namely

$$\log f = -\frac{1.843 \times 10^6}{(DT)^{3/2}}\sqrt{c} + B\,c = -u\sqrt{c} + B\,c - \ldots \tag{9}$$

Combining equations (3), (7) and (9) and rearranging, we obtain

$$E + 2\,k\log m - 2\,k\,u\sqrt{c} - 2\,k\log (1 + 0.002\, G_0\, m) = E' = E_0' - Bc \tag{10}$$

a convenient form for purposes of extrapolation. If the left of equation (10) which we represent by E' be plotted against c, its value at zero c is the desired standard potential, E_0'.

For c we have substituted md_0 where d_0 is the density of the pure solvent. This will cause no error in extrapolation since at the limit ($m = 0$), it is strictly true. The values of the densities of the dioxane–water mixtures, at the desired compositions and temperatures, were obtained from suitable graphs of the density data of Mr. Dale Dreisbach of Western Reserve University. We thank Mr. Dreisbach for placing these results at our disposal before publication.

The values of the dielectric constants of the mixtures required for the computation of the limiting slopes, u, were taken from the data recently obtained in this Laboratory by Åkerlöf and Short.[4]

Table II contains the values of the densities, the dielectric constants and the limiting slopes, which combined with the electromotive force data in Table I made possible the computation of the left side of equation (10). Values of all fundamental constants employed in these computations were those adopted by the "International Critical Tables."

The actual plots of E' *versus* c uniformly exhibited a slight curvature which nearly vanished in the neighborhood of the intercept. The uncertainty in reading the values at the intercept was estimated to be of the order of ±0.05 mv. All experimental results were plotted without any sort of experimental smoothing. In the case of the 20% series, the plotted points differed from the plot used for extrapolation only at the lowest acid concentration ($m \sim 0.005$). In the cases of the 45 and 70% series, the extrapolations were made directly through the large majority of points. Of the points not lying directly on the plots, less than 10% were farther distant than 0.2 mv., and for not a single point was the deviation greater than 0.3 mv.

TABLE II

50	1.0014	53.43	.7999	1.0139	33.43	1.616	1.0149	15.37	5.185

The values obtained for the electrode potential of the cell E'_0 are given in Table III. These results were then expressed by the quadratic equation

$$E_0 = E'_{0(25)} + a_0\,(t - 25) + b_0\,(t - 25)^2 \qquad (11)$$

The constants were evaluated by the method of least squares. The deviations between the observed values and those computed by equation (11) are indicated by the numbers in parentheses immediately following the result. These deviations are given in hundredths millivolt and are positive when the calculated is greater than the observed value. The constants of equation (11) are given at the bottom of the table.

Our experience indicates that there is little doubt as to the reproducibility and reliability of the experimental results. An uncertainty arises in the extrapolation in the more concentrated dioxane solutions which is due to the fact that we have employed the Debye and Hückel function when perhaps a more extended function containing a factor to account for ionic association would be better. We shall reserve such considerations for future discussion when more results in media of low dielectric constant are available. The discussion of different extrapolations in pure methyl alcohol solutions ($D = 31.5$) given by Harned and Thomas[6] is a partial answer to this difficulty. Their computations indicate that our standard potentials are very near the true values.

Summary

1. Measurements of the cells

H_2 (1 atm.) | HCl (m), $X\%$ dioxane, $Y\%$ H_2O | AgCl–Ag

have been made at 5° intervals from 0 to 50° in solutions containing 20, 45 and 70% dioxane and hydrochloric acid at various concentrations between 0.003 and 0.2 M.

2. From these the standard electrode potentials have been evaluated.

The Ionization Constant of Acetic Acid in Dioxane–Water Mixtures

BY HERBERT S. HARNED AND GEORGE L. KAZANJIAN[1]

Accurate determinations of the ionization constants of weak electrolytes in media other than water are scarce. Harned and Embree[2] have obtained the ionization constant of acetic acid in 10 and 20% by weight methanol–water mixtures from suitable electromotive force measurements. The 20% methanol mixtures possess a dielectric constant of approximately 70 which is not far from that of water. In order to determine this ionization constant over a much wider range of variation of the dielectric constant, we have measured the cells

$$H_2\ (1\ \text{atm.})\ |\ \text{HAc}(m_1),\ \text{NaAc}(m_2),\ \text{NaCl}(m_3),\ X\%\ \text{dioxane}–Y\%\ H_2O\ |\ \text{AgCl–Ag} \quad (1)$$

containing 20, 45 and 70% by weight of dioxane at 5° intervals from 0 to 50°. The dielectric constants of these solvents at 25° are 60.79, 38.48 and 17.69, respectively. From these results, the ionization constant of the acid has been evaluated by the method of Harned and Ehlers.[3]

Experimental Results

The measurements of these cells were made in the manner described by Harned and Morrison.[4] The only detail different from their procedure consisted in the preparation of the buffered acetic acid solution, and the subsequent preparation of the cell solutions.

An approximately 1 *M* hydrochloric acid was standardized by gravimetric analysis. Its strength was estimated to have been known to ±0.02%. A 1.5 *M* sodium hydroxide solution free from carbon dioxide was standardized by weight titration by means of the hydrochloric acid solution. All weighings were reduced to vacuum. These titrations checked to within ±0.02%.

Glacial acetic acid was distilled three times in an all-glass still, the first two times from a 2% solution of chromic anhydride. The middle fraction of the third distillate was diluted with conductivity water to form an approximately 3 *M* solution. The strength of this solution was determined by weight titration against the standard sodium hydroxide solution. Deviations from the mean of several titrations were not more than ±0.03%.

Carefully purified sodium chloride dried in a muffle furnace at 500° was employed.

From these standard solutions a stock buffer solution was prepared. Six kilograms of the standard acetic acid solution was weighed in a bottle on a balance sensitive to less than one gram. To this was added an approximately equal weight of the standard sodium hydroxide solution to produce a buffer containing acetic acid and sodium acetate at nearly equal molalities. Then sufficient sodium chloride was weighed and introduced so as to make its molality equal to that of the sodium acetate. To prevent any change in concentration, the bottle containing the solution was equipped with a bulb containing the solution. It was estimated that the acetic and sodium acetate concentrations were known to within ±0.05%. The error in salt concentration was considerably less than this.

The cell solutions were prepared from this stock buffer solution, conductivity water and dioxane purified as described by Harned and Morrison. About 1800 cc. of solution was prepared in 2-liter solution flasks. Allowing for the water to be added in the buffer solution, about 20 g. less than the desired amount of water was weighed into the solution flask on a balance sensitive to about 0.02 g. Next was added the buffer solution from a weight buret. Finally, the dioxane was introduced and weighed. Vacuum corrections were applied to all weights and the amount of water required to adjust the solvent composition to the desired water–dioxane ratio was added. Errors in the weighings were less than 1 part in 500. The solvent composition was known to within 0.02%. The electrolyte concentration was known to within ±0.05%. All concentrations of electrolytes are expressed in moles per 1000 g. of solvent.

These solutions were rendered air free by the passage of hydrogen.[4] The cell technique and electrode preparation was also carried out according to their directions.

Measurements of electromotive forces were made with an Eppley–Feussner type calibrated potentiometer and with Weston cells frequently calibrated against standard Eppley saturated Weston cells. A Leeds and Northrup Type H. S. galvanometer was employed.

The first readings of the electromotive forces were taken from 6 to 8 hours after the cell had been started. Readings were then taken at one-half hour intervals until constancy was obtained, then the temperature was changed. Two series of measurements were made for each concentration, one from 0 to 25° at 5° intervals, and the other from 25 to 50°. The cells were measured in triplicate. In the 20% dioxane solutions the reproducibility was of the order of ±0.05 mv. In the 45% dioxane solution, the agreement was within ±0.1 mv. Sometimes difficulties were encountered at temperatures from 40 to 50°. In general, the results at the lower temperatures were somewhat more reliable. In the 70% series, the electromotive forces were reproducible to ±0.05 mv. in most cases. In the more dilute solutions, the electromotive forces were more difficult to measure because of the higher internal resistance of the cells. It was possible in all cases,

however, to estimate the electromotive forces with a certainty of 0.05 mv.

We have expressed the results by the equation

$$E = E_{25} + a(t - 25) + b(t - 25)^2 \qquad (2)$$

In many cases, the first order differences of E showed no tendency to vary with the temperature so that the constant b was zero. In the other cases b was of a small magnitude. In Table I, E_{25} and the constants a and b are given. In the fifth column of the table, the maximum deviation, Δ_M, between the observed results and those computed by equation (2) are given. In the last column, the average magnitude of the deviations, Δ_A, is given. It is apparent that Δ_A is for all cases 0.06 mv. or less. The range of applicability of equation (2) is from 0 to 50°.

The Ionization Constant

The equation for the electromotive force of the cell may be transposed to

$$\frac{F}{2.303\ RT}(E - E_0') + \log\frac{(m_1 - m_H)m_3}{(m_2 + m_H)} = \log\frac{\gamma_H\gamma_{Cl}\gamma_{HAc}}{\gamma_H\gamma_{Ac}} - \log K = -\log K'^{(2)(3)} \qquad (3)$$

where E_0' is the molal electrode potential of the cell, K the ionization constant of acetic acid, and γ and m are the activity coefficients and molalities of the species indicated by subscripts.[2,3] In order to evaluate K, the left side of this equation, $-\log K'$, was computed from the observed molalities, the observed electromotive forces, and the values of E_0' determined by Harned and Morrison.[4] Since K is of the order of 10^{-6} or less, $(m_1 - m_H)$ and $(m_2 + m_H)$ may be replaced by m_1 and m_2, respectively, without causing an error greater than the experimental. $(-\log K')$ was then plotted against the ionic strength, μ, and $(-\log K)$ was read off the intercept at zero μ.
