In the 700 odd pages of this book are disclosed the author's methods of work, his habits of thought, his concepts of catalytic reactions. These should be of interest to all workers in this field. The book is in every sense what the author intended it to be, namely, his "chemical autobiography." Accordingly, the presentation is more or less chronological, beginning with his early work on dehydration and dehydrogenation of alcohols and closing with his more recent work on destructive hydrogenation, polymerization and alkylation. In between, appear sections devoted to isomerization, condensation and pressure hydrogenation. A chapter is devoted to the author's theories of catalysis, particularly as applied to liquid phase hydrogenation. The book reports a very large number of experiments, the results of which are in many cases given in considerable detail. For the specialist, these should be of considerable interest. The arrangement is such, however, that the general reader will be able to maintain reasonable continuity.

One cannot read this book without a feeling of regret that the author's early researches were not more generally known by the other pioneer workers in the field of catalysis. The author was one of the first to appreciate that the material out of which the apparatus is constructed might have catalytic properties which must not be disregarded. His early experiences illustrate how equipment problems may determine the whole course of subsequent research. In studying the decomposition of alcohols he observed that considerable carbon was deposited when the reaction occurred in an iron tube. In order to determine whether the catalytic effect was due to the iron tube or to the carbon deposited, he lined the tube with graphite. The graphite contained kaolin as a binder, to which (so he states) he attached no catalytic significance. Why, is difficult to understand in view of his earlier observations that the material of the apparatus might have pronounced catalytic effects. Be that as it may, experiments with the new apparatus disclosed that iron and not carbon was the catalyst with which he had been dealing in his previous experiments. The carbon tube, however, gave an entirely different result than the iron, in that it produced almost exclusively ethylene and water. The author ascribed this reaction to the kaolin binder rather than the carbon. In his search for the active constituent of the kaolin, he discovered the catalytic properties of alumina. Then followed an extended study of alumina during which he disclosed that its catalytic properties were related in an important manner to its state of hydration which in turn could be controlled by its method of preparation. Likewise in his hydrogenation studies the author found that the method of preparation of metal and oxide catalysts was very important. For example, in the case of nickel, the state of oxidation, its previous heat treatment, rate of reduction—each of these had an influence on its catalytic properties. The author was one of the earliest, maybe the first, to recognize the so-called promoter action of certain substances which, by themselves, have no obvious catalytic effect and yet in contact with a catalyst do modify its properties favorably. There is frequent reference throughout the book to substances which have an adverse effect upon the catalyst, such as accidental impurities originally present in the catalyst or in the reactants involved. Since he recognized that certain substances could slow up a reaction, even stop it completely, it seems strange that he did not consistently avoid such materials in his own investigations. For example, on page 171, in referring to certain work of Sabatier and Senderens (whose investigations, by the way, receive considerable critical attention in this book), the author states: "Sabatier and Senderens were careful about the purity of the reduced nickel; I paid no attention to its purity." Again on page 182, referring to the work of Schröter, he states: "In my first experiments on the hydrogenation of naphthalene, I used the naphthalene as obtained from Kahlbaum, whereas Schröter paid serious attention to the purity of his naphthalene and was therefore able to hydrogenate it at a lower pressure."

In considering the mechanism of catalytic reactions the author feels that many investigators have been too much concerned with physical concepts. Catalysts, says he, must have very special chemical as well as physical properties. To understand a catalytic process one must consider the "mutual chemical action of the components participating in the reaction." In advancing theories explaining some of his own reactions he has adhered to the proposition that it is as impossible to formulate a single theory covering all catalytic reactions as it is to formulate a general explanation for all known types of chemical reactions. In the case of hydrogenation the author assumes a role for water which some investigators in this field may question.

Some readers may feel that the author has been a little too controversial at times. Some, that he has insisted too frequently upon the priority of his own investigations. On the whole, however, the book affords interesting and instructive reading. This reviewer believes it to be an important and timely contribution. Its reading and careful study are strongly recommended.

ALFRED T. LARSON

Die Fermente und ihre Wirkungen. (Enzymes and their Action), Supplement. Lieferung 2 (Bd. 1. Specieller Teil: Hauptteil VIII). By Prof. CARL OPPENHEIMER, Dr. Phil. et Med. W. Junk Verlag, Scheveningsche Weg 74, The Hague, Holland, 1935. 160 pp. 13 figs. 20.5 × 28 cm. Price, $6.80. Lieferung 3 Supplement (Bd. 1. Specieller Teil: Hauptteil VIII, IX). 1936. 160 pp. 25 figs. Price, $6.80. Lieferung 4 Supplement (Bd. 1. Specieller Teil: Hauptteil IX–XII). 1936. 160 pp. 10 figs. Price, $6.80.

Since the publication of Lieferung, or Part 1 dealing with the recent chemistry of the esterases [reviewed in THIS JOURNAL, **58**, 538 (1936)], three additional parts: 2, 3 and 4 have appeared. The same plan has been followed as in the first part. Parts 2, 3 and the first part of 4 are devoted to the chemistry of the carbohydrases and their substrates. The subject matter covered in Part 2 is chiefly the recent literature on the oligases, *i. e.*, enzymes specific to the hydrolysis of glycosidic linkages in the simpler sugars and glycosides. Part 3 takes up the chemistry of the amylases as well as some of the recent views concerning the constitutions of different starches as revealed by their enzymatic behaviors. The first part of Lieferung 4 also deals with the chemistry of poylases, although more particularly the glucanases, like cellulase, the fructanases, the polyuronidases and pectinases. The remainder of Part 4 takes up first nucleosidases, nucleic acids, aminases, acylic amidases, etc., followed by a discussion of some of the more recent views concerning the constitutions of proteins. The latter is intended to serve presumably as a background for a review of the more recent work in the field of proteolytic enzymes to be taken up in the next Lieferung.

As mentioned in the previous review of Part I, the author has succeeded in mentioning practically all of the large mass of literature which has appeared, in this part of enzyme chemistry, during the ten years elapsing since the publication of the original Hauptwerk. Although he has, by means of discussion in the text, tried to correlate and integrate as much as possible the more significant data contained in the literature, the supplement will be welcomed by chemists as an excellent and complete source of references, rather than as a critical review.

J. M. NELSON

Semi-Micro Qualitative Analysis. By CARL J. ENGELDER, Ph.D., Professor of Analytical Chemistry, University of Pittsburgh, TOBIAS H. DUNKELBERGER, B.S., University of Pittsburgh, and WILLIAM J. SCHILLER, Ph.D., Mount Mercy College, Pittsburgh, Pennsylvania. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1936. x + 265 pp. 15.5 × 24 cm. Price, $2.75 net.

In the words of the authors, it has been their aim in this textbook "to apply the methods and technique of microanalysis to the ordinary (macro) schemes of qualitative analysis with the objects: first, of confining the operations to drops or, at most, to one or two cubic centimeters of solution; second, of developing a micro scheme which could be placed in the hands of undergraduate students taking their first course in qualitative analysis; and, third, by dispensing with the use of microscopes, of bringing the micro technique within practical pedagogic and economic reach of large laboratory classes of sophomore or even freshman students."

The book is divided into four parts: fundamental principles of qualitative analysis, reactions of the cations, reactions of the anions and systematic microanalysis. Approximately ninety pages are devoted to the fundamental theory of qualitative analysis, embracing the customary topics; there is a brief discussion of the Werner theory of valence, and of chelate compounds. The group separations of the cations follow the conventional macro scheme. The separations employed within the groups are again the usual ones in most instances. For the identification tests extensive use is made of the new spot reactions developed by F. Feigl and others, which are carried out on drop-reaction paper or a spot plate. In most cases two or three such tests are described for each cation, and in addition many other drop reactions are mentioned together with literature references. Inclusion of the sensitivities of the tests described would have added greatly to the practical value of the book.

Doubtless there will be a difference of opinion among teachers concerning the advisability of introducing the student to practical qualitative analysis via the semi-micro technique. The reviewer believes many will feel that the operations of qualitative analysis as ordinarily carried out are effected on an unnecessarily large scale, and that semi-micro and micro procedures have great advantages over the older technique in point of certainty and economy of time. To those favoring the new departure in analysis the present work is recommended.

E. B. SANDELL

Inorganic Chemistry for Colleges. A Textbook for Students who have had a Preparatory Course in Chemistry. Second edition. By WILLIAM FOSTER, Ph.D., Russell Wellman Moore, Professor of Chemistry in Princeton University. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1936. xi + 925 pp. Illustrated. 14 × 22.5 cm. Price, $3.90.

In this revised edition, the general plan of the former edition has been followed (confer the review on p. 1617 of THIS JOURNAL, 1931). Many of the sections of the book have been rewritten so as to incorporate any theories that have been enunciated.

An entire chapter is devoted to atomic structure, and the subject matter has been considerably extended along with many other things. This chapter contains a modified Bohr–Thomsen and Periodic Tables; the Electron Theory of Valence; the Main Facts Concerning Heavy Hydrogen and Heavy Water; A Discussion of the Transmutation of the Elements as well as a brief statement of the Quantum Theory. The chapters on Ionization have been thoroughly modified, and the new definitions of acid and base are given.

New problems and questions have been introduced; the reading references have been thoroughly revised, and extended; and the appendix enlarged. The Textbook has been modernized by an attempt not to include too large an amount of physical chemistry and physics, while at the same time, retaining an adequate amount of descriptive and industrial chemistry.

HERMAN SCHLUNDT

An Introduction to Organic Chemistry. By ALEXANDER LOWY, Ph.D., University of Pittsburgh, and BENJAMIN HARROW, Ph.D., College of the City of New York. Fourth edition. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1936. xiv + 429 pp. 15.5 × 24 cm. Price, $3.00.

The fourth edition of this well known text follows closely early editions which have been reviewed in THIS JOURNAL, **47,** 900 (1925); **54,** 4468 (1932). Considerable additional material has been added including formulas proposed for certain of the vitamins and hormones.

R. R. RENSHAW

Allgemeine Untersuchungsmethoden. Erster Teil. Physikalische Methoden. (**General Research Procedures.** Part I. Physical Methods.) Edited by A. BÖMER. Vol. II, Bömer-Juckenack-Tillmans, "Handbuch der Lebensmittelchemie." Verlag von Julius Springer, Linkstrasse 23–24, Berlin W 9, Germany, 1933. x + 536 pp. 401 figs. 17.5 × 26 cm. Price, RM. 66; bound, RM. 69.

This volume, comprising approximately half of the second one of a series of eight which when completed will constitute an encyclopedic treatise on food chemistry, is devoted exclusively to comprehensive discussions of the underlying principles and descriptions of those methods and tools of the physical chemist which find application in this field as the Germans define it. Some eleven authors have contributed to the compilation of this volume of 21 chapters, each of which is practically a small monograph on the subject in hand.

The chapter headings and the author responsible for the contents are: specific gravity (16 p.), viscosity (12 p.), ultra-filtration (12 p.), dialysis and electrodialysis (16 p.) and surface tension, adsorption phenomena and capillary analysis (20 p.), by K. Täufel; solubility (11 p.), melting point and boiling point (23 p.), and heat of combustion (14 p.) by A. Bömer and R. Grau; cryoscopy (11 p.) by R. Strohecker; bathometry or measurement of *p*H (36 p.), indicators (22 p.) and electrolytic conductivity (28 p.) by A. Thiel; acidimetry and alkalimetry (20 p.) and oxidation–reduction potentials (17 p.) by P. Hirsch; refractometry (31 p.) by F. Löwe; spectroscopy and spectrophotometry (58 p.) by H. Ley; polarimetry (47 p.) and color measurement (20 p.) by F. Volbert; colorimetry and nephelometry (16 p.) by H. Freund; luminescence analysis (24 p.) by P. W. Danckwortt; and microscopy (74 p.) by C. Griebel.

The general treatment of the several subject matters is uniformly excellent. Illustrations have been generously used throughout this work. A few chapters follow somewhat the literature review pattern, yet this does not seem to detract from their interest or value. Some authors, as for example Täufel, Griebel, Freund and Volbert, have added to their literature citations brief references to the book literature for amplification, if the reader is so disposed. Danckwortt accomplishes this end by referring him to his larger work on luminescence analysis (1929). The field of micro-analysis has not been overlooked for included herein are its applications to cryoscopy, spectroscopy and the determinations of melting points and heats of combustion.

It is the opinion of the reviewer that this volume, perhaps under another less specialized caption and certainly enlarged as to make it more serviceable, by the addition of an index, would arrest the attention of others and serve them equally as well as the food chemist to whom it is obviously addressed.

H. A. SCHUETTE

Ebulliometry. By WOJCIECH ŚWIETOSLAWSKI, Professor of Physical Chemistry at the Polytechnic Institute of Warsaw. The Jagellonian University Press, Krakow, Poland, 1936. x + 196 pp., 52 figs. 18 × 25.5 cm.

In recent years ebulliometric technique has been improved in convenience and precision, as well as extended in its applications, by Professor Świetosławski and his coworkers. Modern methods and applications of ebulliometry are described comprehensively in this book, which is a revised and enlarged English edition of the monograph "Ebuljometrja" published in Polish in 1935. It is written in a straightforward and logical style. The description of experimental technique and the illustrations of apparatus are of such clarity and detail that the book serves as a laboratory manual as well as a text of principles and an interesting source of information, data, and references.

Perhaps the most important uses of Świetosławski's ebulliometers are the determination of exact boiling points (±0.002°), of dp/dt ratios, and the degree of purity of liquid substances. The last determination usually depends on the measurement of the difference between the boiling point and condensation temperature. For an absolutely pure liquid, these temperatures are, of course, identical, but in the presence of impurities their difference, and in many cases particularly the condensation temperature, changes markedly and uniformly with the quantity of the impurity. For example, by this method 0.002 per cent. of benzene is readily detected in toluene, and by similar measurements the moisture content of solids as well as of liquids can often be determined with high accuracy, even when of the order of only 0.001 per cent. In addition to measurements customarily classified as ebulliometric, many others, of which the following are noteworthy, can be made by these methods: the degree of thermal decomposition of substances, the solubilities of solids, the amounts of substances adsorbed on the surface of solids or occluded in crystals, the calibration of thermometers, esterification constants, deviations from Raoult's law, osmotic coefficients, the detection and analysis of azeotropic mixtures and the displacement of azeotropic points with change in pressure.

An excellent discussion is given of the phenomenon of azeotropy and its application to the purification of liquids, particularly with respect to the dehydration of liquids like toluene and ethanol by azeotropic distillation. Important data on accurate boiling points and dp/dt ratios of pure liquids are tabulated. A bibliography of the 64 references cited in the text is given at the end.

The increasing recognition in physical chemistry of the convenience and precision of comparative methods of measurement with the use of water as a primary standard may well lead to the universal adoption of Świetosławski's ebulliometric technique for the determination of many physical constants of liquid substances and mixtures as well as for the examination of their purity.

JOURNAL OF THE
AMERICAN CHEMICAL SOCIETY

VOLUME 58 DECEMBER 17, 1936 NUMBER 12

[CONTRIBUTION FROM THE SIR WILLIAM RAMSAY LABORATORIES OF INORGANIC AND PHYSICAL CHEMISTRY, UNIVERSITY COLLEGE]

The Critical Concentration for Micelles in Solutions of Cetane Sulfonic Acid

BY G. S. HARTLEY

The existence of a fairly critical transition with change of concentration in solutions of some micelle-forming substances was first demonstrated by Bury and collaborators,[1] who explained the phenomenon by application of the mass-action law to the equilibrium between micelles and single ions or molecules. The critical phenomenon is strikingly apparent in the conductivity of unhydrolyzed higher paraffin chain salts, the equivalent conductivity showing a sudden fall when the concentration is increased beyond a certain value, as was first observed by Lottermoser and Püschel[2] in various salts of higher alkyl sulfuric acids and later by the author and collaborators in other salts.[3] Ekwall[4] found a sudden inflection in the equivalent conductivity–concentration curves for soaps in dilute solution, a phenomenon which has probably the same explanation, but is modified by the enhanced conductivity due to hydrolysis.[5] Murray and Hartley extended in some respects the theoretical treatment of Bury and applied it to the abnormal solubility–temperature curves of paraffin chain salts, and Murray[6] has also applied it to the surface tension data of Lottermoser and collaborators.

McBain's well-known theories of the constitution of soap solutions were based on data obtained at higher concentrations than those with which most of the work quoted above has been concerned. This work has necessitated a considerable modification of McBain's former conception of the nature of the dilute solutions, chiefly in that we now know colloidal aggregates to be formed in considerably lower concentrations than was previously thought to be the case. McBain and Betz,[7] in discussing their conductivity, f. p. and e. m. f. data on several paraffin sulfonic acids, have in part accepted the newer point of view, but they make no mention of the critical phenomenon, although such of their data as are given in detail are not inconsistent with its existence. McBain[8] now considers the "bulk of the transition from simple electrolyte to colloid" to take place between 0.05 and 0.15 N in the case of the C_{11} and C_{12} acids and at a still lower concentration in the C_{14} acid. From the results of earlier work on the C_{16} acid he previously concluded[9] that at so high a concentration as 0.1 N there was still less than 15% of the acid in colloidal form. The C_{16} acid is, however, almost certain to be more aggregated than the C_{14}.[10]

(10) Unless the difference is to be attributed to the effect of temperature, the diagram for the C_{16} acid being worked out from data at 90° and the recent work on the other acids referring to 0 and 25°. The influence of temperature is dealt with later in this paper.

The object of this paper is to present the results of a closer study than has previously been made of the conductivity in the immediate neighborhood of the critical concentration and of the influence on this concentration of changes of temperature and addition of other solutes. Since McBain (in a private communication) has suggested that the observations recorded on the critical phenomenon may have been due to incomplete solution at the higher concentrations, and Ekwall[4] made a similar suggestion with regard to his own work, particular attention has been paid to the question of reversibility.

Experimental

Cetane sulfonic acid was prepared by a modification of the method described by Murray.[11] Fifty grams of pure cetyl bromide[3c] was stirred for three hours at 60° with 1 liter of 0.5 *N* solution of caustic potash in 95% alcohol, previously saturated with hydrogen sulfide and kept saturated during the reaction. Sufficient strong hydrochloric acid was then added to drive off the hydrogen sulfide and solid iodine added till its color persisted in order to oxidize the mercaptan to the stable disulfide which is less soluble in alcohol. The mixture was cooled and filtered, the residue washed with hot water to remove salts and recrystallized from ethyl acetate, a yield of about 40 g. of disulfide melting at 54° being obtained. The disulfide was oxidized on the steam-bath with redistilled nitric acid and the product dried in a vacuum desiccator over solid caustic soda. The resulting solidified foam was recrystallized from redistilled (40–50°) petroleum. The warm solution (which goes brown if kept warm) deposits lustrous plates on cooling, but these are impossible to remove by filtration. Accordingly the warm solution was placed in warmed centrifuge cups and allowed to cool during centrifuging. A hard crust of crystals was obtained from which the mother liquor could be poured off fairly completely. The process was several times repeated, drying the product if necessary in between as it takes up water readily from the air and its solubility in petroleum ether may in consequence rise inconveniently high. The product, after drying *in vacuo* over anhydrous calcium chloride, was white in color and free from ash and from nitrate. It gave, however, a milky solution in hot water which became clear only if kept hot and concentrated for a long time. A clear solution, at temperatures above about 36°, was given more quickly by acid which had been fused and kept molten for some minutes, but the molten acid becomes rapidly brown.

A weighed sample of the product, which melted about 53–54°, was heated slowly in a high vacuum. It did not then melt till 74° and was found to have lost in weight by 5.8%. This is in good agreement with Noller and Gordon's[12] finding that the acids ordinarily obtained are monohydrates (theoretical loss on conversion to anhydrous form 5.5%). The fused anhydrous acid also went brown on continued heating, but without further loss of weight. Titration of a 0.01 *N* solution of the anhydrous acid with standard alkali, using brom cresol purple as indicator, gave the equivalent weight as 305 (theoretical 306). The anhydrous acid went into perfectly clear solution when kept at about 80° for three hours, initial opalescence gradually disappearing during this time, probably a similar phenomenon to that attributed by McBain and Betz to the slow solution of an anisotropic phase. Once the clear solution has been obtained, it may be allowed to form an opaque curd by cooling, but the curd, if stored in Pyrex or quartz vessels, will, no matter how old, always quickly become completely clear on warming. If stored in soft glass vessels, small crystals, presumably of alkali salt, are slowly produced and these require a higher temperature for solution. The color of the resulting solution at a concentration of *ca.* 0.3 *N* was about the same as that of *N*/300,000 methyl orange (alkaline).

As there seemed room for doubt, from the behavior described, about the purity of the resulting solution, stock solutions (*ca.* 0.01 *N*) were made up from the hydrated acid by four different methods. These stock solutions, all becoming clear above 35°, were standardized by titration with alkali and their conductivities were determined at different dilutions at 60°, the intrapolated values at two concentrations being given in Table I. Within experimental error the two different solutions gave the same results and we can conclude that no appreciable amounts of unstable impurities of a nature which might affect the conductivity are present. The concentrations as determined by titration with standard barium chloride solution (using the simultaneous disappearance of foaming power and coagulation of precipitate as end-point) agreed with those determined by alkali titration within the experimental error (±0.5%) of the former. The extrapolated value of the equivalent conductivity at infinite dilution was 543 ± 3, to which the hydrogen ion alone would, according to intrapolation of Johnston's[13] data, contribute 507. Johnston's figures however were calculated from conductivity data on the assumption that the potassium and chloride ions are equally mobile at higher temperatures. If the value of MacInnes and Longsworth[14] of 0.490 for the cation transport number in potassium chloride at 25° held good at 60°, we should have to reduce the hydrogen value to 504. The maximum probable value for the infinite dilution equivalent conductivity of the cetane sulfonate ion at 60° is thus seen to be 42. The value for the cetylpyridinium ion, which will have about the same mobility, was found[3a] to be 21 at 25°. Multiplying by the viscosity ratio, we should expect a value of 40 at 60°. There is therefore little room for the presence of other anions of higher mobility. The absence of

TABLE I

	Method of treatment of recrystallized acid	Equiv. cond. at 60° 0.0005 *N*	Equiv. cond. at 60° 0.003 *N*
I	80° in air for 5 minutes	535.3	225.0

sulfate, the most probable anion arising from oxidation of cetane sulfonic acid, was confirmed by addition of 0.1 N magnesium nitrate solution to an equal volume of 0.001 N cetane sulfonic acid, evaporation to 0.1 of the initial volume, cooling, filtering and testing the filtrate with barium chloride solution. No immediate precipitate resulted. A slight precipitate appeared slowly but similar behavior resulted when the magnesium cetane sulfonate on the filter was washed with N magnesium nitrate and was therefore considered due to the slight solubility of the magnesium cetane sulfonate itself. Addition of sulfate in amount equivalent to 0.3 equivalent % of the original sulfonate gave an immediate precipitate. It can be concluded that sulfate certainly is not present in greater amount than this.

Cetyl pyridinium chloride was prepared from the bromide[3c] by recrystallizing several times from hydrochloric acid and then drying the product *in vacuo* over solid caustic soda until a *ca.* 0.1 N solution was no longer appreciably acid to α-naphthylamine-azo-p-benzyltrimethylammonium nitrate[15] (*i. e.*, pH > 5). A 0.01 N solution was standardized by electrometric titration with standard silver nitrate solution (equivalent weight, found 359, calcd. for monohydrate 358).

Conductivity water, free from ammonia and collected in carbon dioxide-free air ($\kappa_{25°}$ 0.11–0.16 × 10^{-6} ohm^{-1} cm.$^{-1}$), was used throughout but no attempt was made to exclude atmospheric carbon dioxide from the conductivity cell as it is almost completely undissociated in the acid solutions examined.

Dilution was carried out by weight in a 250-cc. stoppered conical Pyrex flask. The densities of the solutions used are not appreciably different from that of water and no correction for this very small difference was made. Dilution was always made so as to have the flask nearly full and thus reduce the volume of froth formed on shaking, since otherwise considerable depletion of solute from the bulk of the solution was found to occur when dealing with very dilute solutions. All concentrations are expressed in gram equivalents per liter at the temperature studied, allowance being made for the expansion of water.

The conductivity cell used was of Jena 16 III glass, fitted with smooth platinum electrodes of about 1 cm. diameter, having a cell constant of 1.431 cm.$^{-1}$ and a capacity of about 25 cc. It was filled from the top by means of a pipet and closed by a ground stopper sunk within a protecting collar so that the cell could be placed in the thermostat with the ground neck below the level of the liquid without danger of contaminating the solution. At least three fillings at each concentration were measured and the solution heated above the temperature of the thermostat before filling to prevent formation of air bubbles on the electrodes. Water was used in all cases for the **thermostat** liquid, but for work at 60 and 80° was covered with a layer of paraffin oil.

Resistance measurements were made on a direct-reading Wheatstone bridge with 6-dial non-inductive decade resistance box and equal ratio, fed by a valve-oscillator giving three frequencies of about 1000, 1000 × $\sqrt{2}$ and 2000 cycles per second, detection being by tuned amplifier and telephones. The common point of the variable resistance and cell was directly earthed and error from capacitative coupling between oscillator and output coils was eliminated by commutating the leads from output coil to bridge, and taking the mean of the readings. Error due to non-ideal capacity between the leads to the cell was determined by calibration with a standard resistance box in the cell position. Error in measurement of high resistances due to resistance–capacity shunts in the cell was eliminated by extrapolation against square of frequency to zero frequency. Error due to polarization in measurement of low resistances was eliminated by extrapolation against inverse square of frequency to infinite frequency. Except for the polarization error, which amounted to only 0.3% in the lowest resistances measured, the error, for a given leads system, frequency and oscillator-bridge connection, is a single-valued function of the measured resistance and so, by previous calibration, the procedure was considerably simplified.

Results and Discussion

In order to decide whether cetane sulfonic acid is behaving as a strong electrolyte in dilute solution, it is necessary to know what fall of equivalent conductivity with concentration is to be expected. Owing to the absence of reliable data for the dielectric constant of water at higher temperatures, it is not possible to apply Onsager's equations directly. The behavior must therefore be compared with that of an acid known to be strong—*e. g.*, hydrochloric acid. Data for 100°

[15] An indicator whose color change is associated with a change from a univalent to a divalent cation and is not therefore displaced by cationic paraffin chain salts; see Hartley, *Trans. Faraday Soc.*, **30**. 444 (1934).

already available[13] show that the relative fall of equivalent conductivity with concentration is not much greater than at room temperature, but no accurate measurements were available on very dilute solutions at intermediate temperatures. Accordingly measurements were made at 60°. The results of these, and of the measurements on cetane sulfonic acid (solution IV) at this temperature, are given in Table II. C is the concentration in gram equivalents per liter and λ the equivalent conductivity. In the third column are given the values calculated from the equation $\lambda = \lambda_0 - A\sqrt{C}$, λ_0 being the infinite dilution value of λ and A a constant. In the fourth column the experimental values have been subtracted from the values given by this equation.

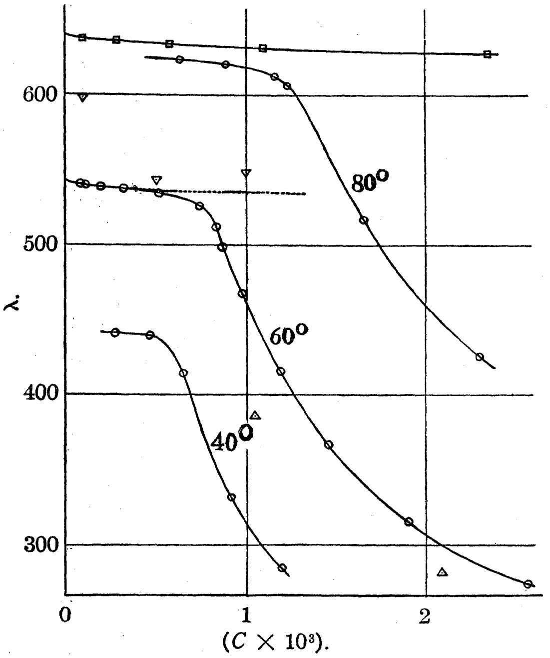

Fig. 1.—Equivalent conductivity of hydrochloric acid (□) at 60° and of cetane sulfonic acid (○) at 40, 60 and 80°. Dotted line represents approximate conductivity if cetane sulfonic acid behaved as a normal strong acid. (△), data of Reychler at 60°; (▽), data of McBain and Williams at 90°.

The data for hydrochloric acid are fitted, within the experimental error, by $\lambda_0 = 640.0$ and $A = 250$, except at the two highest concentrations. The value of λ_0 obtained by intrapolation of Johnston's[13] figures is 640.5. At 25°, where $\lambda_0 = 426$, Onsager's formulas give $A = 157$. A/λ_0 is thus, as expected, slightly greater at 60 than at 25°. It was assumed that the ratio of A for cetane sulfonic acid to A for hydrochloric acid would be the same at 60 as at 25°. Taking λ_0 for cetane sulfonic acid at 25° to be 371, we obtain $A = 144$, and therefore, at 60°, $A = 230$. Below 0.0003 N, the agreement is within the experimental error. At 0.0005 N the observed conductivity is appreciably smaller. At 0.00074 N the deviation amounts to 2% of the whole conductivity, increases to about 12% for a further increase of 30% in concentration, and is no less than 30% at twice this concentration. This behavior, almost equivalent to a sudden change of direction of the λ–c curve at about 0.0008 N, is to be expected if the deviation is due to the formation only of fairly large aggregates. That association is playing a considerable part in these low concentrations is now recognized by McBain, but his conclusion that, in sufficiently dilute solution, the behavior is that of a "simple partially dissociated electrolyte" could only be maintained if there were a range of concentration in which the deviation is proportional to concentration. The effect of aggregation extends to too low a concentration for it to be possible to separate a deviation proportional to the first power of concentration from that proportional (when small) to a much higher power. It is improbable that, in the lower sulfonic acids examined by McBain and Betz, it would be any more simple to separate these effects, because, although the region of great deviation is displaced to higher concentrations, it will also spread over a greater range of concentration, both absolutely, and, owing to the micelles being smaller, relatively. The experimental points of McBain and Betz are, in any case, insufficiently close together in the dilute solutions for this separation to be attempted.

That there is an appreciable formation of covalent acid, except in the aggregates, is extremely improbable from theoretical considerations[5] (p. 17). An experimental test was made by examining the behavior in a solvent appreciably less polar than water, namely, a mixture of glycerol and water. Simple dissociation will certainly be less complete than in water. Aggregation will probably also be less, since the solvent will have less tendency to expel the paraffin chains from solution. The conditions will therefore be more favorable for a separation of the two effects. It was found that the λ–C curve is of the same form as in water, but the critical concentration is increased some three times. Below

0.002 *N*, however, cetane sulfonic acid in the glycerol–water mixture is as strong as hydrochloric acid, *and apparently stronger than in water.* Since the solvent (water diluted to twice its volume at room temperature with ordinary "pure" glycerol, containing *ca.* 56.3% by weight of glycerol) had a considerable residual conductivity (17.1 ohm^{-1} cm.$^{-1}$ at 60°), the procedure adopted was to subtract the value of κ/C (*i. e.*, the equivalent conductivity without correction for solvent conductivity) for cetane sulfonic acid from that for hydrochloric acid at the same concentration. If the two acids have, at the same concentration, the same effect on the solvent conductivity,[16] this difference will be equal to that of the corrected λ values. The data are given in Table III and the difference plotted against concentration in Fig. 2.

		0.665	166.7	194	27
		.332	182.9	210	27

Quite different is the effect of another nonelectrolyte, *n*-amyl alcohol, which, unlike glycerol, has a highly unsymmetrical distribution of affinity and will therefore tend to be sorbed by the aggregates and so, in sufficient concentration, will facilitate their formation. The concentration may be kept too low for there to be any possible effect on the unaggregated acid. In this case the additional solute was used at a constant concentration with respect to the cetane sulfonic acid, dilution being by addition of water only. The data are given in Table IV and plotted in Fig. 2. It will be seen that the effect is, as expected, to lower the critical concentration.[17]

The critical concentration is also lowered by the presence of another strong acid. In Table IV are given the results of measurements on a solution containing hydrochloric acid in about the same concentration as cetane sulfonic acid and on dilutions of this solution with water. From the observed conductivity was subtracted the product of the concentration of hydrochloric acid by its equivalent conductivity in a pure solution of concentration equal to the total acid concentration of the mixture. The quantity λ is the quotient of this difference by the cetane sulfonic acid concentration and is plotted in Fig. 2. The critical concentration of sulfonate[18] in this mixture is lower than in pure

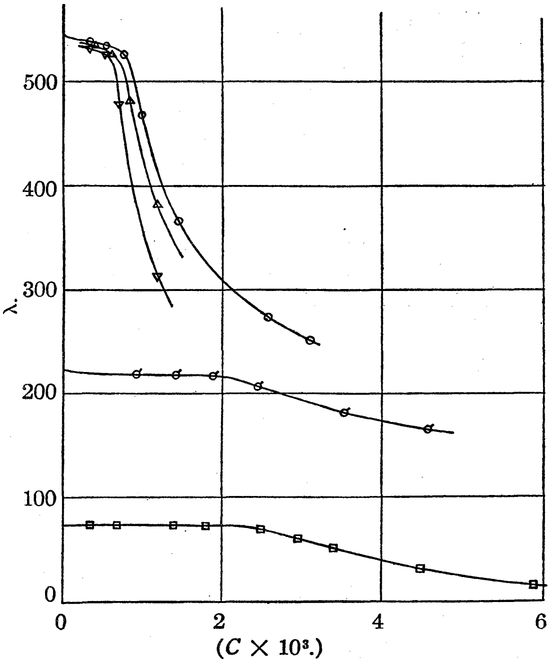

Fig. 2.—Equivalent conductivity of cetane sulfonic acid at 60°: (○), in water; (△), in dilute aqueous amyl alcohol; (▽), in dilute aqueous hydrochloric acid; (□), $\lambda_{C_{16}H_{33}SO_3H} - \lambda_{HCl} + 100$ in glycerol–water mixture. Also, (○-), equivalent conductivity of cetyl pyridinium chloride at 80° in water.

---

(16) This is due *mainly* to a weak acid, as the λ values obtained by subtracting the whole conductivity of the solvent are too low in low concentrations, but not *entirely*, as κ/C curves sharply upward. The two acids will certainly have nearly the same effect below the critical concentration and above it the correction is in any case small.

(17) It is possibly this effect which may be responsible for the data obtained by Reychler [*Bull. soc. chim. Belg.*, **27**, 113 (1913)] being consistently lower than mine, as is seen in Fig. 1. Reychler's final stage of preparation was the evaporation of an alcoholic solution and his product (which was in any case only 90% pure) may have contained some ethyl ester, which, being far more absorbable than amyl alcohol, might have a profound influence on the conductivity when present in even small amount. The data for dilute solutions of McBain and Williams [THIS JOURNAL, **55**, 2250 (1933)] at 90° are also obviously not in agreement with mine, but their internal consistency is obviously not good. The neutralization by glass mentioned below may have played a part. The work here described was repeated on the other three solutions with results agreeing everywhere to within 0.5%. A measurement by Mr. C. S. Samis on solution III at a concentration of 0.02 *N* was in good agreement with McBain and Williams' data, if the latter's value at 0.047 *N* is set aside as being a misprint or otherwise in error.

(18) This result is not in conflict with that of McBain and Searles [*J. Phys. Chem.*, **40**, 493 (1936)], who found that the conductivity

cetane sulfonic acid solution, but that of total acid is greater, as is to be expected if the aggregates, primarily of cetane sulfonate ions, are partly neutralized by hydrogen ions, attached either electrostatically or by covalent linkage or even only forming a close "atmosphere."

TABLE IV

EQUIVALENT CONDUCTIVITY OF CETANE SULFONIC ACID AT 60° IN WATER IN PRESENCE OF HYDROCHLORIC ACID AND AMYL ALCOHOL

Concn. $C_5H_{11}OH$ = 8.4 × concn. $C_{16}H_{33}SO_3H$		Concn. HCl = 0.958 × concn. $C_{16}H_{33}SO_3H$			
$C \times 10^3$	λ	$C \times 10^3$	$\kappa \times 10^6$	λ_{HCl}	λ

1.180	382.6	1.172	1073.4	628.1	313

Measurements were also made on cetane sulfonic acid at 40 and 80° (Table V, Fig. 1) and on cetyl pyridinium chloride at 80° (Table V, Fig. 2). The curves for cetane sulfonic acid at the three temperatures are very similar. The critical concentration at 80° is about 1.5 times that at 60°, and that at 60° is 1.3 times that at 40°. The temperature coefficient of the critical concentration therefore increases with increasing temperature in this range and is about 2% per degree at 60°. This is more than twice as great as the coefficient for the higher alkyl sulfates obtained, though with less certainty, from the data of Lottermoser and Püschel.[2] That cetane sulfonic acid is at least not unique in having this high temperature coefficient is evident from the increase in the critical concentration of cetyl pyridinium chloride from 0.0009 at 25°[3a] to 0.0022 at 80°.

TABLE V

EQUIVALENT CONDUCTIVITIES AT OTHER TEMPERATURES

$C_{16}H_{33}SO_3H$ 40°		$C_{16}H_{33}SO_3H$ 80°		$C_{16}H_{33}NC_5H_5Cl$ 80°	
$C \times 10^3$	λ	$C \times 10^3$	λ	$C \times 10^3$	λ
0.263	440.9	0.628	623.4	0.906	218.8
.454	439.3	.884	620.2	1.411	217.9
.641	414.2	1.155	612.1	1.889	216.9
.902	331.5	1.224	606.6	2.455	206.1
1.178	283.6	1.647	517.7	3.536	182.1
		2.307	426.3	4.580	164.9

That the critical phenomenon is due either to supersaturation or to incomplete solution is extremely improbable since it is equally evident at 40, 60 and 80°, while the curd form of cetane sulfonic acid gives place to a perfectly clear solution some 4° below the lowest of these temperatures. Although the clear solution has not been examined in the ultramicroscope, that of cetyl pyridinium chloride, the macroscopic crystals of which dissolve at about 18°, showed no ultramicrons, yet it has a well-defined critical concentration, even at 80° (see Fig. 2).

In cetane sulfonic acid solutions, a slow increase of resistance of the solution in the glass cell was always found, greatest at the highest temperature and amounting in the most dilute solutions examined to some 3% in twenty-four hours. This drift was not peculiar to the colloidal electrolyte, being found to almost as great an extent in hydrochloric acid. It was undoubtedly due to slow neutralization of the acid by alkali from the glass, and, in the case of cetane sulfonic acid, minute crystals of the alkali salt became visible after about forty-eight hours at 60°. The solution attained a resistance, constant except for this steady drift, within ten minutes after introduction into the cell. All the results recorded were obtained from measurements made after this time, except in the work with glycerol, when twenty minutes was allowed. A sample of one solution, kept in a quartz vessel in the thermostat for twenty-four hours, had a resistance only 0.03% less than that of a sample freshly heated from room temperature.

In the case of the neutral salt, cetyl pyridinium chloride, the glass solubility introduces no disturbing effect, and a more satisfactory test of reversibility can therefore be made. A solution of concentration about 0.0014 *N* was cooled down slowly in the cell from 80°. At about 60° a fairly abrupt increase in the rate of change of conductivity with temperature indicated that below this temperature aggregates are formed. The bath was therefore kept constant at a somewhat lower temperature, 53.7°, where aggregated and unaggregated salt must exist in comparable amount, so that the resistance would be very sensitive to changes of aggregation. The cell was then maintained at 80° for half an hour, put back into the thermostat and the resistance measured at one-minute intervals. After eight minutes the resistance had reached a value which was constant to 1 part in 6000 for the next half hour. The cell was then cooled[19] to 20°, main-

---

of soaps and a simple salt with common ion were approximately simply additive, because we are here dealing with the increased degree of aggregation of the partly aggregated acid, whereas McBain and Searles are dealing, in higher concentration, with an effect on the fully aggregated soap.

(19) The cell had been almost completely filled for this experiment, and the stopper was sealed with mercury before cooling, so that solution of air was prevented, a precaution rendered necessary because air bubbles, if formed, adhere very tenaciously to the electrodes in this solution.

tained at that temperature for half an hour, put back in the thermostat and resistance readings taken as before. In eleven minutes the resistance had fallen to identically the same steady value previously reached, and decreased by only 2 parts in 6000 during the next twenty-four hours.

The high temperature coefficient of the critical concentration in cetane sulfonic acid gives rise to the existence also of a fairly definite critical temperature at one concentration. In Fig. 3 is plotted the specific conductivity of a 0.00073 *N* solution as a function of temperature, obtained by allowing the bath in which the cell was contained to cool slowly (about 10° per hour). The temperature coefficient in the range AB is the normal one (*ca.* 0.7% per degree) for a fully dissociated acid, while in the range BC it is very much greater (*ca.* 1.7% per degree). At B, aggregation commences and increases as the solution is cooled further. Once in the AB range and once in the BC range the fall of temperature was arrested and in each case the conductivity remained constant, after a slight fall as the temperature of the cell, which was of course slightly higher than that of the bath during cooling, fell to bath temperature. Quite different is the behavior when the second break, at C, occurs. Here curd fibers form slowly in the supersaturated solution. By quick cooling, values irregularly spaced below the dotted extension of the BC curve were obtained, but these fell in about half an hour to approximately constant values lying on the full line CD. It is a discontinuity of this latter type, more pronounced in the higher concentrations examined, which has been described by Reychler[20] and by Laing and McBain.[21] It is quite distinct from the break at B, which is caused by the rapid reversible formation of amicroscopic aggregates.

The formation of large aggregates in equilibrium with the simple ions is the only satisfactory explanation[22] which has been advanced of the existence of a fairly well-defined critical concentration. I have in the foregoing avoided the use of the word "micelle" as it was presumably my previous use of this word which led McBain and Betz to consider that I regarded aggregates as containing paraffin chain ions only.[23] I do not identify the aggregates formed in these dilute solutions with either the "ionic micelle" or the "neutral colloid" of McBain, as I do not believe that the separate existence of these entities is established. Evidence of a more direct nature has been put forward elsewhere,[3,5] that, just above the critical concentration, what I have there called micelles do in fact exist, and their nature has also been discussed[5] as fully as our present knowledge permits.

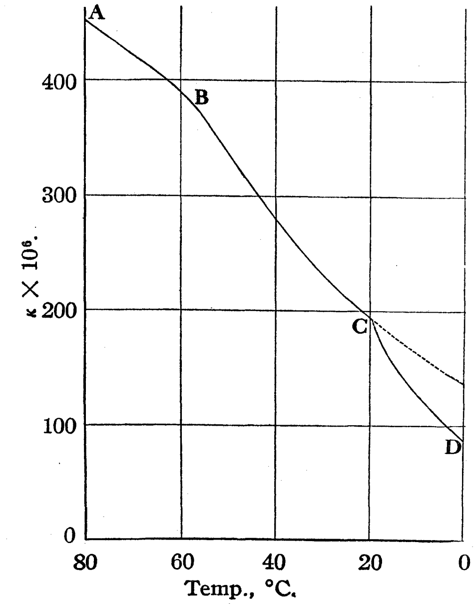

Fig. 3.—Specific conductivity of 0.00073 *N* cetane sulfonic acid on cooling.

It is reasonably certain that nearly all the paraffin chain ions in excess of the critical con-

---

(20) Reychler, *Bull. soc. chim. Belg.*, **26**, 193 (1912); **27**, 113 (1913).

(21) Laing and McBain, *J. Chem. Soc.*, **117**, 1506 (1920).

(22) In a recent publication [*Proc. Roy. Soc.* (London), **155A**, 386 (1936)] Howell and Robinson have advanced an entirely different theory of the critical phenomenon. They believe that the paraffin chain ions, owing to their great "*rotational* volume," form a loose *network* which obstructs the passage of the small ions of opposite charge. They do not state how this theory can explain an *abrupt* change of properties, and the theory does not explain the observed increase of mobility of the paraffin chain ions when the critical concentration is exceeded,[3c] nor the increase of equivalent conductivity in high fields.[3c] Howell and Robinson's experimental data confirm the small temperature coefficient of the critical concentration in the case of the alkyl sulfates.

(23) McBain and Betz[7] (p. 1907) quote values for *A* in the equation $\lambda = \lambda_0 - A\sqrt{C}$ calculated by Mukherjee for uni-deci, and unicenti-valent electrolytes from Onsager's limiting formulas. They then combine these with the λ_0 value for the univalent acid and obtain λ values far lower than the experimental ones. They conclude that the ionic micelle does not behave as an "ordinary" polyvalent ion. Mukherjee's figures, however, were derived from formulas containing no term for the radius of the ion, and other simplifying approximations which made these formulas possible are certainly not applicable in solutions of very high-valent electrolytes in concentrations accessible to measurement. In an attempt, admittedly tentative, to estimate the real magnitude of effects of the Debye–Hückel type in colloidal electrolytes [*Trans. Faraday Soc.*, **31**, 55 (1935)], I concluded that the fall of conductivity in dilute solutions of paraffin chain salts could *not* be explained adequately in this way, and that the adherence of a considerable number of oppositely charged ions to the micelles must be assumed.

centration exist in micelles, and the concentration of single paraffin chain ions probably decreases absolutely.[24] By extrapolation of the figures given here, the critical concentration for cetane sulfonic acid at 90° will be about 0.0015 *N*. The aggregation will therefore be almost complete in a 0.01 *N* solution. According to McBain's diagram[9] it is only just appreciable at this concentration.

Summary

The critical fall of conductivity in dilute solutions of paraffin chain salts has been examined in considerable detail in the case of cetane sulfonic acid. A stable equilibrium has been shown to exist in the solution in the neighborhood of the critical concentration. The critical concentration, about 0.008 *N* in water at 60°, has been shown to increase with temperature by about 2% per degree. Addition of glycerol raises the critical concentration, while addition of amyl alcohol or hydrochloric acid lowers it.

The conductivity data lend no support to the belief that the acid is not a strong one in concentrations where it is not aggregated.

It is concluded that aggregation must be practically complete in a 0.01 *N* solution.

Heat Capacities and Entropies of Organic Compounds. II. Thermal and Vapor Pressure Data for Tetramethylmethane from 13.22°K. to the Boiling Point. The Entropy from its Raman Spectrum

BY JOHN G. ASTON AND GEORGE H. MESSERLY[1]

The high symmetry of tetramethylmethane along with the absence of polarity makes this compound an inviting one for a comparison of the entropy calculated from its Raman spectrum and moments of inertia[2] and from calorimetric data using the third law of thermodynamics. In the present paper the necessary measurements are described and such a comparison is made.[3]

Tetramethylmethane.—The partially purified compound was kindly furnished by Dr. F. C. Whitmore and his students.[4] About 700 cc. was fractionally sublimed. The resulting material (freezing point about −23°) was twice distilled, at 370–400 mm., through an efficient glass fractionating column (packed with glass spirals) in which fractionation could be carried out in the absence of air in an all glass system.[5] The middle fraction was collected in a glass bulb. A 30-cc. middle portion was distilled from this fraction into a weighed 30-cc. sample bulb connected to the line by a ground glass joint. This sample was cooled to liquid air temperature and pumped out to less than 10^{-6} mm., melted, cooled again and repumped to remove the last traces of air.

The bulb was sealed off at a constriction below the ground glass joint and reweighed along with the joint. A correction to vacuum weights was made to ascertain the weight of tetramethylmethane. The sample bulb was equipped with a side arm closed by an inner-sealed capillary. For introduction into the calorimeter, the side arm was attached to the filling line which was evacuated to less than 10^{-5} mm. After cooling the tetramethylmethane to liquid air temperature the inner-sealed capillary was broken by a piece of iron sealed in glass and activated by a solenoid. The weight of sample was checked on removal from the apparatus. The impurity was 0.73 mole per cent. as estimated from the melting point range.

The Apparatus.—This was similar to that described by Giauque and Wiebe[6] except for details mentioned below. The calorimeter was made from 2.5-cm. copper tubing (0.025 cm. wall) and was 8 cm. long. Heat conduction was furnished by thirty-nine perforated disks (0.008 cm. thick) which made a spring fit with the walls and with a central tube, re-entrant from the bottom, which served as the well for the standard thermocouple.[7] The latter was fastened in with Wood's metal. A 3-mm. soft glass filling tube was sealed onto a short platinum tube brazed to the top. The whole was gold plated inside and out.

The calorimeter was wrapped with a gold resistance thermometer-heater (No. 40 B. and S. gage, double silk insulated annealed gold wire, containing 0.175% silver and drawn using only jewel dies). It was similar to that used by Giauque and Wiebe, except that a gap was left in the center in which a constantan resistance thermometer-heater for use below 25°K. was wound. It had a resistance at room temperature of 140 ohms, and 20 ohms at 25°K. The lower half, with a resistance of 81 ohms at room temperature, was used for heat of vaporization

measurements. The constantan resistance thermometer-heater, which was of No. 40 B. and S. gage double silk insulated thermocouple wire had a room temperature resistance of 114 ohms and below 25°K. an approximately constant temperature coefficient of 0.00145 deg.$^{-1}$. Both were wound as described by Ahlberg and Latimer,[8] and cooled several times to liquid air temperatures before use. However, both were continuously calibrated during the calorimetric measurements against the standard copper–constantan thermocouple S-2 whose calibration has already been described.[9a] The temperature scale was extended above 273°K. using carbon bisulfide vapor pressures.[9b]

The temperature head between the gold heater wire and the inside of the calorimeter was about 0.05°K. for a one cal. per minute energy input. In the case of the constantan heater below 25°K. it was several times this value.

The radiation shield together with the massive cylinder, which formed its top and with which the lead wires and the filling tube made good thermal contact, contained 1890 g. of copper and 4800 g. of lead.

The built-in hydrogen liquefier and cryostat were exactly as described by Latimer and Greensfelder.[10]

In cooling the calorimeter after filling it was found necessary to keep the entire filling tube hotter than the calorimeter at all times. Otherwise solid tetramethylmethane condensed in the tube as a solid plug which was very difficult to drive back into the calorimeter. A stream of warm air passing over the tube leading to the cryostat and onto the top of the cryostat allowed the temperature of these to be kept considerably above the temperature of the calorimeter, while allowing the cooling to proceed from the bottom. Liquid air was added at the bottom of the Dewar. In addition the tube and the heavy top of the radiation shield were electrically heated while cooling.

The Heat Capacity Measurements.—The electrical connections and method of measurement were as described by Giauque and Wiebe.[6,11]

The White potentiometer and standard resistances were calibrated by (or against standards calibrated by) the Bureau of Standards. The one-tenth second stop watch was calibrated frequently against an astronomical clock set with the Arlington time signals.

Three standard cells were constantly intercompared and frequently checked by the Bureau of Standards during the measurements. A thermometer current was chosen to give in most cases a sensitivity of 0.001° in reading the temperature rise.

The various corrections described by Giauque and Wiebe have been applied. In addition a correction was applied to the resistance for the temperature of the pair of 5-cm. leads from the terminals on the radiation shield to each of the resistance thermometers. This was taken as the mean of the shield and calorimeter temperatures. This correction was necessary because these leads formed part of the measured resistance, and during calibration the shield was at the same temperature as the calorimeter; it reduced the heat capacity by 0.14% at all temperatures above 60°K. For the calorimeter of G. and W. this correction was negligible (0.025%). The shield was kept above the calorimeter at all temperatures above 110°K. to prevent condensation. The vapor pressure measurements described later were used in correcting for material vaporized into the filling line, whose volume was determined accurately. In the calculation the density taken for the liquid was that given by Whitmore and Fleming[4]; that for the solid (0.73 g./cc.) was ascertained by the contraction on freezing.

The molal heat capacities are given in Table I and Fig. 1.

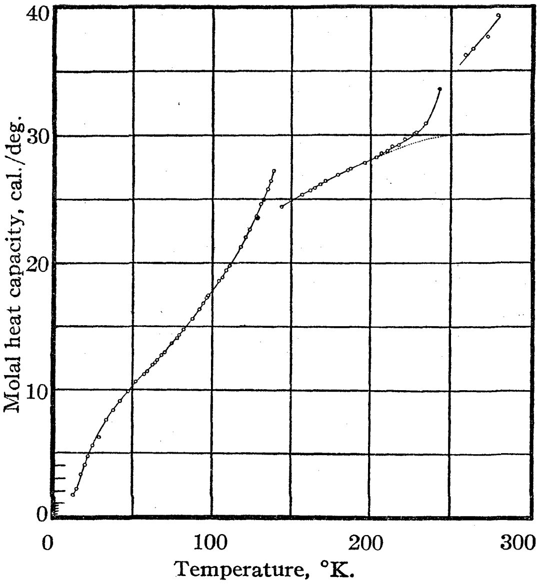

Fig. 1.—Heat capacity of tetramethylmethane.

In this and all other tables the molecular weight of tetramethylmethane was taken as 72.09, and the ice point as 273.16°K. One calorie (15°) was taken equal to 4.1852 absolute joules and one international joule to 1.00041 absolute joules.[12a] The present United States Standards were taken as yielding energy in international joules.[12b]

The error in these measurements from the various sources depends on the temperature. Below 25°K. the results may be in error by more than 1% due largely to the short range of calibration of the constantan resistance thermometer (10.9–26.2°K.) and the comparative insensitivity of the thermocouple in this range. Between 25 and 40°K. the lower points may be in error by about 1% due to the rapid change of derivative of the gold resistance thermometer. From 40 to 240°K. the error does not exceed a few tenths of a per cent. In the case of the points for the liquid the error may be somewhat above 0.5%. The error

due to the increased heat leak correction at the higher temperatures has been reduced by an accurate treatment of the drifts where these were non-linear.[13]

The High Energy Absorption near 140°K.—The abnormal rise in the heat capacity curve for the solid precedes what is perhaps an isothermal transition at 140.02°K.[14] However, the "transition" may be purely of the ammonium chloride type,[15] with very high heat capacities over a short range. In this connection it is noteworthy that up to almost 140°K. equilibrium was rapidly attained, whereas when energy was supplied in the neighborhood of 140.02°K. equilibrium was attained much more slowly (almost an hour). Table II records equilibrium temperatures at various fractions "transformed" as estimated from the fraction of the "transition" heat supplied, assuming this to be isothermal. The temperature at 80% transformed may be high due to difficulty in attaining equilibrium and less probably due to impurity.

135.534–146.911	1023.7	407.9		615.9
			Mean	615.9 ± 0.6
Fusion at 256.53°K.				
240.407–259.847	1609.9	854.1	23.5	779.3
240.913–261.442	1662.7	910.7	25.0	777.0
			Mean	778.2 ± 3.5

Table III contains a summary of data on the heat of "transition." For the calculation of $\int C_p dT$ the heat capacity curves on either side were extrapolated linearly to 140.02°K.

The two heat capacity measurements IIIx and IIIy recorded in Table I are lower than the best curve through the other series by 1.3%. This may indicate hysteresis in the neighborhood of the "transition" point. For this reason a history of the cooling for, and of the course of, the various series of heat capacity determinations is of interest. Before series I the solid material was heated until melting started and then cooled over two days to 10°K. Up to 70°K. the points were taken continuously. The apparatus was then cooled to 60°K. and the rest of the points of series I taken. Series II and III were taken on another filling from the same sample. In series II the cooling procedure was essentially the same except the calorimeter was cooled only to slightly below 60°K. Points were taken continuously to below the "transition" point; the material was carried through the transition with one application of energy. In series III the cooling to 60°K. occupied nine days. Points were taken continuously to just above the "transition" point. The calorimeter was then slowly cooled to obtain the point III_x, which was taken at the temperature where cooling stopped. The first heat of "transition" measurement was then taken. Point IIIy was taken after a similar cooling, and followed by the second heat of "transition" measurement. The rest of the points of series III were taken continuously to the melting point. Apparently hysteresis occurs only in the neighborhood of the "transition" point.

The Melting Point.—The equilibrium temperature of the system was observed with 50 and 97% of the sample melted as ascertained by measuring the heat required to melt the remaining solid as in a regular heat of fusion measurement. From the results and the heat of fusion the impurity present was found to be 0.727 mole per cent., assuming no solid solution. The melting point of pure tetramethylmethane calculated on this basis is 256.53 ± 0.10°K. (The freezing point of our sample was 255.31°K.) Previous melting points recorded in the literature[4] are: 253°K. (Lwow, 1871); 253.7°K. (Whitmore and Fleming, 1933).

Heat Capacities in the Premelting Range.—In the range between 200°K. and the melting point the tabulated heat capacities require correction for heat absorbed in fusion. The lower curve in Fig. 1 has been obtained from the upper one through the experimental points by subtracting this correction, obtained from the thermodynamic freezing point equation and the heat of fusion at the melting point without allowance for its change with temperature. (The heat capacity of the increasing quantity of liquid could be assumed equal to that of the solid without serious error.) This lower curve was extrapolated to the melting point as indicated by the extension to obtain heat capacities used in calculating the heat of fusion.

The Heat of Fusion.—The method described by Gibson and Giauque[11] was used. The results are recorded in Table III.

The correction for premelting (col. 4) is the area between the upper and lower curves (Fig. 1). The estimated error does not include the error due to our estimation of this correction. This may produce about 1% error in the heat of fusion, but does not seriously affect the entropy. Indeed if the whole fusion had been treated as a heat capacity in calculating the entropy, the effect on the final entropy would have been only to add the almost negligible entropy of mixing of the impurity—($-0.0073\ R \ln 0.0073 - 0.9927\ R \ln 0.9927 = 0.088$ e. u.).

The Vapor Pressure Measurements.—The measurements were made as already described.[9] The results for the liquid are given in Table IV. Column 1 gives the absolute temperature as read by the thermocouple; col. 2 gives the observed pressure, and col. 3 the pressure calculated from equation (1).

$$\log_{10} P_{\text{mm.}} = -1525.0/T - 2.16979 \log_{10} T + 13.59527 \qquad (1)$$

Column 4 gives the temperature deviation corresponding to the pressure difference. Since the boiling range of the sample used was about 0.1°, as ascertained by vapor pressure measurements on fractions distilled from it, these measurements should hold for pure tetramethylmethane to about 0.1° in the temperature. Vapor pressure data were also obtained on the solid, but are without significance as the partial pressure of impurity above the liquid is steadily increased as the solid crystallizes. For completeness we give equation (2), which represented our data on the solid between 230°K. and the melting point.

$$\log_{10} P_{\text{mm.}} = 11642.30/T + 258.6890 \log_{10} T - 0.241380\, T - 604.2570 \qquad (2)$$

The only other data on tetramethylmethane are the measurements of Whitmore and Fleming.[4] A comparison of their results on the solid with equation (2) shows that their material contained more impurity than ours, as does also the freezing point which they record for it. In col. 5 of Table IV are given the deviations (W. and F.–A. and M.) between the pressures observed by Whitmore and Fleming at their nearest temperature and those calculated from equation (1). From equation (1) the boiling point has been found to be 282.61°K. Previous boiling points recorded in the literature[4] are: 282.7°K. (Lwow, 1871); 282.6°K. (Whitmore and Fleming, 1933).

TABLE IV

VAPOR PRESSURES OF LIQUID TETRAMETHYLMETHANE

(g for State College, 980.124 ("I. C. T.")) (0°C. = 273.16°K.). Boiling point 282.61°K.

280.396	700.30	700.82	+.017	
282.897	767.72	767.93	+.006	0.3

The Heat of Vaporization.—Our procedure differed from that described by Giauque and Wiebe (method II)[6] only in the method of collecting the vaporized material. A thin-walled glass bulb, connected to the line by a vaseline sealed glass joint, was used for this purpose. It was immersed in a well-stirred bath of benzene and benzene ice, along with excess water, contained in a silvered dewar. During vaporization the pressure remained constant to within a few millimeters except during the initial period required to build up the head necessary for heat transfer across the bulb, when it rose by about 20 mm. Before a measurement the calorimeter was brought to within a degree of the temperature of the bath of benzene–benzene ice. The surroundings were at such a temperature as to be above that of the calorimeter at all times during the vaporization. The drift of the calorimeter was observed with the resistance thermometer until a sudden decrease in its value indicated that material had started to condense in the bulb. The heater was then turned on. The energy for the vaporization before the heater was turned on was calculated from the heat leak. At the end of the measurement the heater was shut off at a predetermined time and a stopcock connecting the calorimeter to the rest of the line (manometer, condensing bulb, etc.) simultaneously closed. The drifts were followed until the calorimeter reached equilibrium. The correction for the varying pressure and hence temperature of the surface from which vaporization occurred was simply made as follows.

Consider n moles of liquid whose initial temperature is T' and whose vaporization temperature varies from T' to T. Let Q be the heat absorbed in heating the n moles from T' and vaporizing them. Let C_p be the heat capacity of the gas (assumed constant), and $\Delta H'$ the heat of vaporization at the temperature T'. Then

$$Q = \int_0^n [\Delta H' + C_p(T - T')]\, dn \qquad (3)$$

Over the small range of temperatures involved $(T - T') = k(P - P')$, where P and P' are the vapor pressures at T and T'. Substituting in (3) and integrating

$$Q = \Delta H'n - \alpha P'n + \int_0^n \alpha P\, dn \ (\alpha = kC_p) \qquad (4)$$

As the number of moles vaporized is proportional to the time of energy input

$$Q = \Delta H'n - \alpha P'n + \beta \int_0^t P\, dt \qquad (5)$$

where β is a new constant. If P had a constant value P_e

$$Q = \Delta H'n - \alpha P'n - \beta P_e t \qquad (6)$$

Comparing (5) and (6) it is seen that the vaporization may be considered as occurring at an effective pressure

$$P_e = 1/t \int_0^t P \, dt \qquad (7)$$

The integral (7) accordingly was evaluated graphically to obtain the effective pressure (and temperature) of the vaporization.

The number of moles of liquid vaporized was calculated from the increase of pressures in the line, and the weight of material condensed in the bulb. The pressure in the calorimeter line up to the closed stopcock was obtained from its equilibrium temperature at the end of the vaporization period; that in the manometer and bulb from the manometer reading when the bulb was sealed off.[16] The results are given in Table V.

TABLE V

HEAT OF VAPORIZATION OF TETRAMETHYLMETHANE

(662.2 int. mm. (278.59°K.)) (mol. wt. 72.09)

Moles vaporized	Time of energy input, min.	Total input, cal./mole	$\int C_p dT$, cal./mole	ΔH, cal./mole
0.05545	25.50	6281	797	5484
.06378	28.00	5980	447	5528[a]
			Mean	5506 ± 30
Corrected to one atm. (282.61°K.)				5438 ± 30
Calculated at one atm. from equation (1) and thermodynamics; Berthelot correction = 244 cal.				5490

[a] A correction of −5 cal. applied for difference in effective pressure.

The correction for raising the temperature of the liquid remaining in the calorimeter to the final temperature and the number of moles of liquid vaporized to the effective temperature of vaporization are given in col. 4. The mean value has been corrected to the boiling point using the measured heat capacities for the liquid and for the gas the heat capacities calculated by adding to 12/2 R (the translational and rotational heat capacity + $C_p - C_v$) the vibrational heat capacity calculated from the Raman spectrum using the equation

$$C_{\text{vib.}} = R \sum x_i^2 e^{x_i}/(e^{x_i} - 1)^2 \; (x_i = hc\tilde{\nu}/kT) \qquad (8)$$

with frequencies and constants discussed later. (The correction to the real gas state is here negligible.) It is of interest to compare the measured heat of vaporization with the one calculated from the vapor pressures (equation (1)) and thermodynamics using the modified Berthelot equation

$$PV = RT\,[1 - 9PT_c(1 - 6T_c^2/T^2)/128P_cT] \qquad (9)$$
$$T_c = 432°\text{K.}; \quad P_c = 33 \text{ atm.}^{17}$$

to calculate the volume of the gas. The heat of vaporization, thus calculated from the vapor pressures, at the boiling point, is included in Table V. The agreement justifies the equation of state chosen for the later correction of the entropy.

The Entropy.—Table VI summarizes the calculation of the entropy of the gas at the boiling point from the experimental data. The correction to the perfect gas state has been made using equation (9) and thermodynamics.[6]

TABLE VI

THE ENTROPY OF TETRAMETHYLMETHANE

(Mol. wt. 72.09)

	E. u./mole
0–13.14°K. Debye function $h\vartheta_m/k$ = 106.7 (six degrees of freedom)	0.56
13.14–140.02°K. graphical[a]	24.13
"Transition" 615.9/140.02	4.39
140.02–256.53°K. graphical[a]	16.55
Fusion 778.2/256.53	3.03
256.53–282.61°K. graphical[a]	3.63
Vaporization 5438/282.61	19.24
Entropy of actual gas at boiling point	71.53 ± 0.3
correction for gas imperfection	0.18
Entropy of ideal gas at boiling point	71.71 ± 0.3

[a] $\Delta S = \int C_p d \ln T$.

The classical rotational and translational entropy of the gas at 298.16°K. and one atm. has been calculated by Kassel to be 73.957 e. u.[2c] using 1.53 and 1.11 Å. for the C–C and C–H distances respectively. We have used 1.54 Å. for the former throughout, but have retained the latter.

The equation for the translational and classical rotational entropy, assuming zero potential associated with the rotation of the methyl groups, neglecting nuclear spin, and using 972 for the symmetry number, is then

$$S_{\text{T,R}} = 27.45011 \log_{10} T - 4.57504 \log_{10} P_{\text{atm.}} + 6.05751 \qquad (10)$$

The vibrational entropy has been calculated by the equation

---

(16) To seal off the bulb a stopcock leading to it was closed before cooling in liquid air and sealing off at a constriction.

(17) T_c and P_c were ascertained as follows. An inspection of the data in the "I. C. T." reveals that for isomers of a given class P_c and T_c/T_b are respectively about the same (where T_b is the normal boiling point); *e. g.*, for *n*-pentane P_c = 33.0; T_c/T_b = 1.521, while for isopentane P_c = 32.8, and T_c/T_b = 1.529. For *n*-butane and isobutane P_c = 35.5, 37; T_c/T_b = 1.558, 1.546. With some confidence therefore we take P_c and T_c/T_b for neopentane the same as for isopentane.

$$S_{\text{vib.}} = R \sum x_i/(e^{x_i} - 1) - \ln (1 - e^{-x_i}) \; (x_i = hc\tilde{\nu}_i/kT) \quad (11)$$

using the Raman frequencies determined by Rank and Bordner.[18] These are, respectively, 335 (2), 414 (3), 733 (1), 925 (3), 1252 (4), and 1455 (8) cm.$^{-1}$, where the figures in parentheses give the multiplicities. For the first four frequencies which are due to the carbon skeleton this assignment is that of Rank and Bordner and is based on analogy with the Raman spectrum of carbon tetrachloride. The two higher frequencies, as Rank and Bordner point out, undoubtedly are due to deformation of the methyl groups, but they hesitate to estimate the multiplicity. Two similar frequencies appear in methyl chloride, namely, 1355 (1) and 1460 (2).[19] It seems justifiable to take four times these multiplicities in the case of tetramethylmethane where there are four methyl groups. The effect of the higher frequencies is negligible. In the calculation the constants R = 1.9869 cal.$_{15}$/deg./mole, hc/k = 1.4325 cm. deg., were used. A comparison of the calorimetric and spectroscopic values of the entropy is given in Table VII.

TABLE VII

COMPARISON OF CALORIMETRIC AND "SPECTROSCOPIC" ENTROPIES OF TETRAMETHYLMETHANE AT ONE ATMOSPHERE

	Temperature, °K.	282.61 E. u./mole	298.16 E. u./mole
I	Translational and rotational	73.34	73.98
II	Vibrational (carbon skeleton)	5.38	5.89
III	Vibrational (other modes)	0.17	0.25
IV	Absolute	95.42	96.65
V	Total (less nuclear spin)	78.89	80.12
VI	Calorimetric corrected to ideal gas state	71.71	
VII	Discrepancy	7.18	
		($5\,R \ln 2 = 6.89$)	

Discussion.—The spectroscopic entropy exceeds that calculated from the calorimetric data by $5\,R \ln 2$ within experimental error. The chief experimental errors lie in the heat of vaporization and in the extrapolation. That due to the former could hardly exceed 0.2 e. u. Any serious error in the extrapolation (on the basis of the actual crystal) is unlikely as the results fit a Debye function, calculated for six degrees of freedom, within experimental error.

The specific entropy of the impurity (probably isobutylene, $S_{298.1,\ 1\ \text{atm.}}$ = 67.3 e. u. per mole)[20] would be sufficiently similar so that the error on this account should be less than 0.1 e. u.; the entropy of mixing has already been eliminated without appreciable error as evident from its magnitude.

In the absence of any other calorimetric data on tetramethylmethane which might serve as an over-all check, we have made several isolated heat capacity measurements on methyl alcohol between 90°K. and room temperature, and the results have always been in agreement with those of Kelley[21] within the estimated accuracy of the respective observers.

An examination of the assignment of the four Raman frequencies due to the carbon skeleton also furnishes no obvious method of eliminating or materially reducing the discrepancy. Of the single frequency there is little doubt. Indeed this is true of the two highest pentatomic frequencies, of which the lower is a singlet and the higher a triplet, in the case of both methane and carbon tetrachloride. Inversion of the multiplicities of the two lower frequencies would raise the entropy calculated by 0.33 e. u.

If the above agreement of the discrepancy with $5\,R \ln 2$ is not fortuitous, it might be taken to indicate 2^5 possible arrangements in the crystal such as have been proposed by Giauque to explain discrepancies of a similar nature in the case of carbon monoxide,[22,23] and nitrous oxide;[24,25] and by Pauling for water,[26,27] although the possibility of rotation of the methyl groups in certain of the symmetry varieties must not be overlooked. A situation similar to the latter for the case of hydrogen has been discussed by Giauque and Johnston.[28,29]

In this connection it is to be noted that for methane the calorimetric and spectroscopic entropies are in agreement,[30] but there is a peak in the heat capacity curve at 20.4°K.[31]

The entropy corresponding to the area between the peak and the normal heat capacity curve is 1.78 e. u. This is close to the sum (1.63 e. u.) of the entropy of mixing of the degenerate lowest

rotational states of the triplet ($9/16\ R \ln 3 = 1.23$ e. u.) and the corresponding quantity for the quintet variety ($2/16\ R \ln 5 = 0.40$ e. u.) assuming the high temperature equilibrium mixture. It therefore seems probable that rotational states are present in methane down to this temperature and there rotation practically ceases. The energy differences between the orientations of minimum potential energy are then evidently sufficiently large compared with kT to cause a unique arrangement of all but a small fraction of the molecules.

It is likely that the abnormal heat capacity rise prior to the "transition" of tetramethylmethane is caused by rotation starting for at least one degree of freedom and perhaps not unreasonable that this is one of the angular coördinates for the carbon skeleton.

It would be of interest to investigate the heat capacity of methyl deuteride from 10 to 30°K. as the symmetry situation is changed and hence if the above interpretation for methane is correct it should present a peak of quite a different kind.

Data on the heat capacity of ethane[32] below 67°K. would make possible a third law comparison which might throw light on the tetramethylmethane discrepancy.

The apparatus for the investigation of both of these compounds down to 10°K. is now practically complete. It is also planned in the near future to investigate tetramethylmethane, and, if necessary, ethane, down to 1°K.

Acknowledgment.—We wish to express our appreciation of the assistance of Messrs. C. W. Siller and Maxwell Eidinoff with the experimental work. Mr. J. E. Key (late of the Department of Industrial Engineering), Messrs. G. F. Nelson and W. J. Cummings of the University of California are responsible for the excellent construction of certain parts of the apparatus essential to the work. The many suggestions of Professor W. F. Giauque have been invaluable. We wish to thank the National Research Council for Grants-in-Aid, without which this work would have been impossible.

Summary

1. The heat capacities of tetramethylmethane have been determined from 13°K. to the boiling point.

2. The vapor pressure of liquid tetramethylmethane has been determined from the melting point to the boiling point, and an equation derived to represent the data. An equation for the vapor pressure below the freezing point is given but not considered significant.

3. The melting point of tetramethylmethane is 256.53°K. (−16.63°C.) and the boiling point 282.61°K. (9.45°C.). There is an energy absorption which is perhaps isothermal at 140.02°K. (−133.14°C.) but which is preceded by an abnormal rise in the heat capacity.

4. The molal entropy of the ideal gas at the boiling point, calculated from the experimental data, is 71.71 ± 0.3 e. u. This value is, within experimental error, $5\ R \ln 2$ lower than the corresponding value of 78.89 e. u. calculated from the Raman spectrum and moments of inertia.

5. The "spectroscopic" entropy, calculated from the Raman spectrum and moments of inertia, is 80.12 e. u. per mole at 298.16°K. and one atmosphere neglecting nuclear spin.

A Vertical Microelectrophoresis Cell with Non-Polarizable Electrodes

BY HAROLD A. ABRAMSON, LAURENCE S. MOYER AND ANDR. VOET[1]

The measurement of the electric mobility of microscopic particles in horizontal electrophoresis cells may be complicated by the settling out of the particles under observation. It would be of advantage to have the cell constructed so that the same particle could be studied for periods even as long as one hour. Furthermore, it is of importance that non-polarizable electrodes be employed. An apparatus of this type in which the electrophoresis cell itself is *vertical* is described in this communication. It should not be construed from this paper that the vertical cell is more suitable for all systems, but it may be of advantage in the investigation of particles similar to those described here.

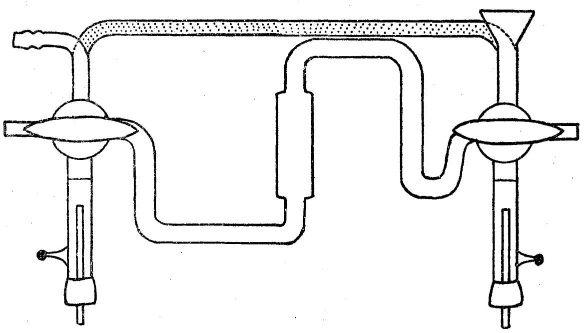

Fig. 1.

Description.—The instrument is constructed and calibrated similarly to that previously described by Abramson[2,3] (a modification of a type developed by Northrop and Kunitz) and discussed recently in some detail by Moyer.[4] As shown in Fig. 1, the apparatus is provided with the arrangement of electrodes developed for the horizontal cell. This arrangement combines the features of non-polarizability and use of plaster of Paris plugs designed to eliminate disturbances at the electrodes due to precipitation of sols. In addition, the instrument is constructed of one piece of glass with no rubber or other connections. This provides a device which may be fixed rigidly onto the stage of the microscope and hence eliminates completely the disturbing vibrations which are so commonly encountered in three-piece instruments. Cleaning is therefore facilitated and the cell may readily be removed for filling or for cleaning. For a detailed description of construction, electrical connections and calibration, see references 2, 3 and 4. The cell is used with the microscope tilted horizontally. The bar running across the top (Fig. 1) is fused onto the (L-shaped bore) stopcock sleeve. This bar (stippled) can then be suspended by hooks, made to fit from strap brass, in front of the objective and clamped to the stage by a spring brass clip. The clip can be adapted to the size and shape of the microscope stage and to glass microscope slides (not shown in the figure) which may be cemented to the horizontal bar and side arms to provide a flat resting surface for the cell against the stage of the microscope. The connections of the cell itself with the two electrodes may be altered to fit the needs of the investigator. Thus, the funnel may be made larger or replaced by other devices for filling; the side arms may be run directly to the cell from the stopcocks, etc. Both the horizontal and vertical instruments may be obtained from Mr. J. D. Graham of Haddonfield, New Jersey. Dimensions of the central chambers of the vertical and horizontal instruments used in these experiments are given in Table I.

TABLE I

DIMENSIONS OF CENTRAL CHAMBERS OF CELLS DISCUSSED

Dimension	Vertical cell, mm.	Horizontal cell, mm.
Length	42	37
Av. depth	0.615	0.795
Width	12.0	12.0
k	20	15

Use of the Cell.—Since the central chamber is of nearly rectangular cross section, the position of the stationary levels may be calculated. Calculation of the stationary levels from Komagata's equation[5] (which has been checked by Komagata as well as more recently by van Gils[6])

$$y_{(v_w = 0)} = \pm b[(1/3) + (128/\pi^5 k)]^{1/2} \qquad (1)$$

where y is the level measured from the central axis, k is the ratio of half the width to half the thickness, b (see Table I for values of k), yields levels which do not differ significantly from 0.2 and 0.8 of the total depth.

Any difficulties encountered in finding the true focus of the ceiling and floor may be obviated by filling the cell with powdered glass or quartz suspended in water and laying it flat for a sufficient time to permit a few particles to stick on both walls.

Since the electrical and gravitational forces operating on the particle are superimposed, the

particle, although falling, tends to remain in the same level of the cell with respect to its thickness. If it is at the stationary level it will remain there and may be kept under observation for long periods of time. However a correction must be made for gravitational forces. This is done by timing the particle while moving it in one direction and then reversing the electrical field and timing for the same distance in the opposite direction. The effects of small convection currents, if not large enough to produce turbulence, are apparently also canceled out by this method, although such forces may be largely eliminated at the start by carefully equilibrating both the instrument and solutions to room temperature before filling the cell. Particles which move too rapidly under gravity may set up local turbulence which disturbs the normal mobility of smaller particles in their neighborhood. When such effects occur, letting the apparatus stand for a time without applying the field frequently eliminates the difficulty by allowing the large particles to settle out. Water-cooled lighting devices should be used, of course, for illuminating the sol.

In a given medium large particles are affected more by gravity than small particles of the same substance, even when both have the same electric mobility, so that the electric mobility *appears* to be dependent on size. However, when large and small particles are timed over the same distance, it is found that the differing effect of gravity cancels out and the resultant electric mobilities are not dependent upon size and shape. This is similar to the effects noted by Mooney.[7] Hence it is not sufficient to time a series of particles moving in one direction and then a series in the other and average, but each particle should be timed over the whole distance. For long observation where the eye is kept constantly at the microscope, a metronome may be used instead of a stop watch.

Interesting observations of these effects were made in a system consisting of gelatin-coated collodion particles (about 0.5 μ) and gelatin-coated, long asbestos needles (up to 50 μ). In the horizontal cell, both collodion particle and needle under these conditions migrate with the same mobility in either direction. On the other hand, in the vertical cell the long needles are operated on by a greater gravitational component which increases the observed mobility to such an extent, when particles are falling, that they migrate faster than the collodion particles. On reversing the current, however, so that the particles now migrate against gravity, the asbestos needles experience greater retardation and both particles are thus made to travel over the total distance in the same time.

Table II gives comparative measurements made on a mixed suspension of gelatin-coated collodion and asbestos particles in 0.01 *M* acetic acid. It will be noted that both types of particles move with the same mobility, irrespective of size, shape or orientation.

Table II

Times Required for Gelatin-coated Particles of Different Sizes to Travel a Fixed Distance in a Constant Electric Field

	Collodion particles, sec.		Asbestos needles, sec.	
	12.5	11.6	11.8	12.6
	12.3	12.2	12.1	11.8
	11.8	11.2	12.0	12.6
	13.4	12.5	12.2	12.1
	12.3	12.5	12.9	12.5
Average	12.23		12.26	

Comparison with Other Cells.—As far as the writers are aware, the instruments under discussion here are the only ones which have been shown to yield values comparable with those obtained in U-tubes (although Bull[8] checked his cell against streaming potential) and therefore may well be used as standards in measurements of this kind.

The recent measurements of Howitt[9] of the electric mobility of mammalian red blood cells by a moving boundary method in a U-tube afford an additional direct comparison of the validity of the entire method. It had been shown[3] previously that the mobility of various mammalian red blood cells is constant for each species investigated. For instance, the human erythrocyte exhibits the same mobility in isotonic phosphate buffer at *p*H 7.4 independent of sex, blood group, age or race of the individual. Table III presents data obtained on the red cells of different mammals, suspended in 0.067 *M* phosphate buffer at *p*H 7.4. Note the agreement, well within the usual limits of error of the methods concerned.

To demonstrate the symmetry and flatness of the vertical cell, collodion particles were coated with 1% Coignet gelatin, which was also used to coat the walls of the cell. The gelatin was then

Vertical	1.25	..	..	..	..

diluted to 0.1% by adding acetic acid so that its final concentration was 0.01 M. While keeping the field strength constant, mobilities were determined at various levels in the cell. It is clearly seen in Fig. 2 that no significant differences were observed between measurements made in the two instruments (vertical, open circles, and horizontal, closed circles). The smooth curve has been drawn from the equation

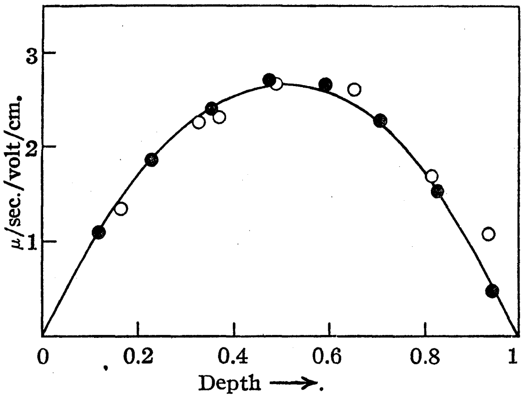

Fig. 2.

$$V(x) = 10.65\ (x - x^2) \qquad (2)$$

where V is the mobility at any depth, x, after a plot of the data in the form of a straight line, as discussed in a previous paper,[10] showed that the intercept was not significantly different from 0 (*i. e.*, the ratio of the electroösmotic to the electrophoretic mobility was 1.0). It may be observed that the electrophoretic mobility (at the 0.2 and 0.8 levels, = 1.70 μ/sec.) agrees with that found for the asbestos needles in the previous experiment.

Discussion

It is of some importance that the needle-shaped particles such as the asbestos ones investigated here assume a position with both ends of the needle at the same electroösmotic level. This is not found in the horizontal cell where needles are frequently observed with one end in one level and the other end at another level. The fact that the needles in the vertical cell thus assume a position with practically no velocity gradient acting upon them makes the vertical cell more suitable for investigations of this type of particle. It should be emphasized, however, that within the limits of time ordinarily adopted for a single experiment and within the. limits of the field strengths employed, little or no orientation of these rod-shaped particles occurs. It is very remarkable indeed to see asbestos needles up to 50 microns in length migrate independently of their orientation under these new and more favorable conditions, thus confirming previous experiments.[3] In accord with our previous results[10] on the ratio of electroosmosis to electrophoresis, recently confirmed independently by van Gils,[6] a ratio of 1.0 was found for gelatin-coated surfaces in dilute solutions (here at an ionic strength of about 3 × $10^{-4}\,M$). Under the seconditions, no motion was ever observed near the wall in either cell.

Summary

The horizontal microelectrophoresis cell has not been adapted to the measurement of particles which settle out of suspension. A vertical cell has been devised which embodies all of the useful characteristics of the one-piece glass cell described previously by Abramson and discussed more recently by Moyer. This vertical cell has been checked by comparing measurements on protein-coated collodion particles, asbestos needles, and blood cells with measurements obtained in a calibrated horizontal cell and a U-tube. Agreement within the usual limits of experimental error was obtained. The advantages and disadvantages of the vertical cell are discussed.

Studies in the Physical Chemistry of Amino Acids, Peptides and Related Substances. VIII. The Relation between the Activity Coefficients of Peptides and their Dipole Moments

BY EDWIN J. COHN, THOMAS L. MCMEEKIN, JESSE P. GREENSTEIN AND JOHN H. WEARE

Whereas the activity coefficients of ions depend upon their valence, those of dipolar ions depend largely upon their dipole moments. This had been suggested on the basis of theoretical considerations,[1,2] but further development of the field had to await more detailed experimental studies.

For ions, the effect of electrostatic forces can be distinguished from that of non-electrical forces since the former varies as the square root of the concentration, whereas the latter varies as the concentration. This distinction cannot be so readily made for dipolar ions because the effect of electrostatic forces is linear with the concentration and does not vary as its square root. It follows that even in very dilute aqueous solutions of amino acids and proteins the forces are not necessarily purely electrostatic in nature.

Electrostatic forces due to dipolar ions increase not with the quantity κ of Debye's theory,[3] but with κ^2. κ^2 increases not only with increase in concentration but with decrease in temperature and in dielectric constant. Electrostatic forces thus become more important the lower the temperature and the lower the dielectric constant.

The study of the influence of neutral salts upon glycine in ethanol–water mixtures demonstrated that at sufficiently low dielectric constants the logarithm of the solubility ratio multiplied by the dielectric constant ratio $(D/D_0) \log N/N_0$ was a function of κ^2. So plotted measurements in 60, 80, 90 and 95% ethanol containing neutral salts essentially coincide suggesting that under these conditions the activity coefficients of the amino acids studied were largely ascribable to electrostatic forces.[2,4]

These preliminary experiments on amino acids led to the choice of conditions for the studies of peptides here reported. The solvent employed was 80% ethanol containing varying concentrations of sodium chloride. At this alcohol concentration sodium chloride solutions up to 0.25 molar can be prepared, and the solubility of glycine in this most concentrated salt solution was 3.73 g. per liter, or approximately one-fourth the concentration of salt. In the absence of salt glycine is soluble only to the extent of 2.00 g. per liter in 80% ethanol. It is this solvent action associated with change in ionic strength with which we are here concerned, and not with the effect of change in medium which reduces the solubility of glycine in 80% ethanol one hundred-fold from its solubility in water of 216.6 g. per liter at 25°.

The peptides of glycine have been chosen for comparison rather than aliphatic amino acids of long dipole moment because of their far lower solubility in both water and alcohol–water mixtures. This is related to the far greater density of glycine peptide crystals.[5] As a result, although β-alanine and ϵ-aminocaproic acid are far more soluble than the corresponding α-amino acids (though they have closely the same densities in the solid state), the tightly packed glycine peptides are progressively less soluble in water the longer their molecules, despite their larger dipole moments. This is not true, as Fischer[6] pointed out, of certain peptides with paraffin side chains.

Lysylglutamic acid is extremely soluble in water. Its solubility in 80% ethanol is none the less very low, the very rapid falling off of solubility with dielectric constant depending upon its multipolar nature. In this its behavior resembles to a considerable extent proteins such as egg albumin, with which it is compared in a subsequent communication. The solubility of all of the peptides studied is so small in 80% ethanol that the composition of the solutions approaches closely those of the pure solvents.

I. Methods and Materials

Solubility has been determined by methods that have been described previously.[7,8] Fresh

aliquots of solvent were repeatedly saturated with the solute. It was demonstrated that solubility was independent of the amount of saturating body and the time of equilibration. The temperature for these experiments was 25.00 ± 0.05°.

Glycine and its peptides were prepared and purified by the methods that have been described previously.[5,7] Lysylglutamic acid was prepared by the method of Bergmann, Zervas and Greenstein.[9]

The hydantoic acids of glycine and of diglycine were the same preparations as were studied in the previous paper.[8] The heptyl esters of the hydantoic acids were prepared by the method described by Fischer for the preparation of the ethyl esters of hydantoic acids.[10]

Hydantoic Acid Heptyl Ester.—The heptyl ester hydrochloride of glycine was dissolved in water and an equivalent of potassium cyanate was added. On standing, the heptyl ester of hydantoic acid crystallized out. After recrystallizing from benzene, it melted at 98–99°.

II. Composition of Solvents

The three-component solvents employed in this investigation are most conveniently characterized by first considering the ethanol–water mixture and then the changes in the properties of the ethanol–water mixture brought about by the neutral salt.

The densities of ethanol–water mixtures are reported in the "International Critical Tables." Over the range in the neighborhood of 80% ethanol, they are given by the relation

$$\rho_0' = 0.85510 - 0.1672\ (N_2 - 0.5197)$$

where 0.5197 is the mole fraction of ethanol, 0.85510 the density of 80% ethanol and ρ_0' that of some other mixture of not very different mole fraction, N_2.

The addition of sodium chloride to an 80% ethanol–water mixture increases its density. The weight of ethanol in such mixtures is 628.05 g. per liter. In a subsequent paper in this series, we shall compare the results when the ratio of the weight of water to alcohol is retained constant with those here reported in which the weight of water is diminished as the concentration of salt increases. Solubility in solvents defined in either way may be computed from both sets of measurements, and yield the same result. In many of the experiments recorded in this paper, especially those with the peptides, it proved convenient to prepare the large volumes of solvent required by weighing the salt and ethanol into volumetric flasks, and then adding water to volume. All weights were corrected for air buoyancy.

TABLE I

Concn. of NaCl, C	Water g. per liter, g.	Density of solvent, ρ	$\frac{\rho - \rho_0'^{a}}{C}$	Apparent molal volume of NaCl,[a] Φ
0.00	227.04	0.85510		
.05	225.92	.85690	0.0408	20.7
.10	224.75	.85864	.0402	21.3
.15	223.52	.86033	.0398	21.8
.25	220.97	.86364	.0393	22.5

[a] The values of ρ_0' calculated from "International Critical Tables" for the weight per cent. of alcohol and water in the mixture were, respectively, 0.85486, 0.85462, 0.85436, 0.85382.

Since dielectric constant measurements cannot be made in the presence of electrolytes, it remains an open question whether solutions would be more nearly isodielectric where the volume occupied by the salt is considered to have the same properties as the water replaced, or whether the effect of the salt on the dielectric constant should be considered negligible.

III. Apparent Molal Volumes

When the apparent molal volumes of the sodium chloride in these solvents were at first calculated, we questioned the results since they were so much higher than those in water, defined by Gucker[11] by the equation

$$\Phi_{NaCl} = 16.28 + 2.22\sqrt{C}$$

For this reason a 25-cc. pycnometer was constructed which was employed in most of the above measurements. The remaining density determinations were carried out with 10-cc. pycnometers. The more accurate results confirm the order of those calculated from our routine density determinations, and indicate a higher apparent molal volume in 80% ethanol than in water, although the reverse might have been ex-

---

(9) Bergmann, Zervas and Greenstein, *Ber.*, **65**, 1692 (1932).

(10) Fischer, *ibid.*, **35**, 1095 (1902).

(11) Gucker, *Chem. Rev.*, **13**, 111 (1933).

pected as a result of increased electrostriction of the solvent. These measurements as well as those to be reported subsequently may tentatively be defined by the equation

$$\Phi_{\mathrm{NaCl}} = 19.5 + 6\sqrt{C}$$

Solubilities in these solvents of all of the peptides are smaller than those of glycine, and the densities of the solutions deviate appreciably therefore from those of the solvent only in the case of glycine and the hydantoic acids. The densities of these saturated solutions are given in Table II and apparent molal volumes in 80% ethanol calculated.

IV. Solubility Measurements

The solubilities in the various solvents are reported in Table III, as well as the ratio of solubility, expressed as mole fraction, in systems containing salt to that in the salt-free ethanol–water mixtures. The results would be essentially the same if the solubility ratios were calculated as volume concentrations, S/S', since the very large medium effects considered in the previous communications[7,5,8] are retained as nearly constant as possible in this study in which we are concerned only with the influence of salts upon amino acids, peptides and their derivatives.

The logarithm of the solubility ratio is plotted as ordinate in Fig. 1 and the concentration of sodium chloride as abscissa. The curves appear to belong to the same family and reveal effects of two kinds. In the first place the longer the peptide the greater the solvent action of the neutral salt. In the second place the larger the peptide the more this solvent action diminishes with increasing salt concentration. The solvent action of sodium chloride upon the hydantoic acids studied is far smaller than that upon these dipolar ions. It is greatest for the hydantoic acid of diglycine, which has two peptide linkages, and smallest for the hydantoic acid of α-aminocaproic acid which contains a larger number of nonpolar CH_2 groups.

[a] Calculated.

Hydantoic acid contains one less CH_2 group than diglycine and the hydantoic acid of diglycine one less CH_2 group than triglycine. Additional CH_2 groups might be expected to decrease slightly the solvent action of neutral salts. The far greater influence of sodium chloride upon the peptides may be ascribed, therefore, to their dipolar ion structure.

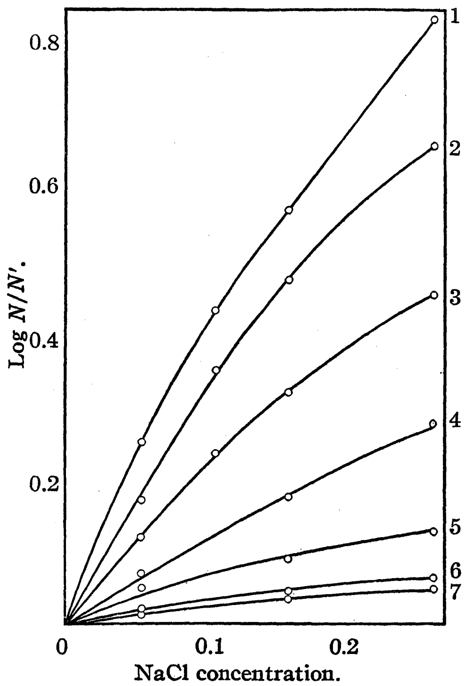

Fig. 1.—Solubility in 80% ethanol containing NaCl of 1, lysylglutamic acid; 2, triglycine; 3, diglycine; 4, glycine; 5, diglycyl hydantoic acid; 6, hydantoic acid; 7, α-aminocaproic hydantoic acid.

The logarithm of the activity coefficient varies as the reciprocal of the second power of the dielectric constant in Debye's theory. The dielectric constant of 80% ethanol is 35.72 and of water 78.54 at 25°.[12] The logarithm of the solubility ratio is therefore multiplied by D/D_0 in the last column of Table III. The concentration of salt, multiplied by D_0/D, given in the second column yields a quantity proportional to κ^2 in Debye's theory. The dielectric constants of the solvents are corrected in this calculation for the influence of glycine and the peptides. The values of δ tentatively adopted are those for water. The only amino acid sufficiently soluble to be studied thus far in 80% ethanol, α-aminobutyric acid, has a value of 24.0 in this solvent as compared with 23.5 in water.[13] Although the dielectric constant increments, δ, also given in Table III[14] are greater the longer the peptide, the solubility of all the peptides studied is so small in these solvents that the correction is appreciable only in the case of glycine. Correction for difference in volume between solvent and solution is negligible in 80% ethanol, though not in the lower ethanol–water mixtures subsequently to be reported. In order to facilitate comparison the hydantoic acids are also multiplied by the dielectric constant ratio of the solvent. Their own contributions to the dielectric constant of solutions is still in doubt.

Although it is certain that the longer peptides have the greater dipole moments, no satisfactory method is available for estimating the moments of dipolar ions. In a recent discussion of the problem two approximations were compared.[15] In the one, the molecules are considered extended in solution, as in the solid state, and the increment in the distance separating successive peptides taken as 3.5 Å. Structural considerations suggest that the dipole distance of glycine lies between 3 and 3.3 Å. The intermediate value of 3.17 Å. estimated by Kirkwood[2] from our solubility studies may be tentatively adopted. The ratio $[(D/D_0) \log N/N']/R'$, where R' represents the dipole distance estimated in this way, is calculated in Table IV. This ratio is plotted against $(D_0/D)C$ in Fig. 2. The agreement at low concentrations of salt indicates that *the logarithms of the activity coefficients of amino acids and peptides are, as a first approximation, proportional to their dipole moments.* At higher concentrations the influence of the larger molecules in diminishing their activity coefficients is reflected by the greater curvatures in Fig. 2.

[14] Wyman and McMeekin, *ibid.*, **55**, 908 (1933).

[15] Cohn, "Annual Review of Biochemistry," Vol. IV, Stanford University, California, 1935, p. 93.

The dipole distances of lysylglutamic acid have been estimated from structural considerations by Greenstein, Wyman and Cohn.[16] The longest dipole is 14.23 Å. The shorter dipole, which has the same configuration as glycylglycine, has a length in the direction of the chain of 3.5 Å. The logarithm of the solubility ratio divided by the vector sum, 17.73 Å., also is plotted in Fig. 2.

These estimates of R' may be considered maximal. Presumably there is at least some bending around the free bonds in these molecules, resulting in smaller dipole moments than those estimated from structural considerations. As a lower limit we may tentatively adopt the square root rule proposed by Werner Kuhn[17] for very long hydrocarbon chains. Assuming again the dipole distance of glycine to be 3.17 Å. and that of the peptides to increase as the square root of their dielectric constant increments, values of R have been calculated for these peptides.[15] The ratio $[(D/D_0) \log N/N']/R$ is also given in Table IV.

The results in Fig. 2 and Table IV suggest that in dilute solution, as a first approximation, the logarithms of the activity coefficients of dipolar ions increase as the concentration of the salt, and the dipole distance, R or R', of the peptides. The limiting slopes $[(D/D_0) \log N/N']/(D_0/D)C$ are 0.30 to 0.32 for glycine, 0.57 to 0.59 for diglycine, 0.75 to 0.80 for triglycine and 1.12 to 1.2 for lysylglutamic acid. These slopes will be proportional to the first term of any equation for the change in free energy of dipolar ions with change in ionic strength. They are approximately one-tenth the dipole distances estimated as proportional to the square root of dielectric constant increments and taken as 3.17 for glycine and 12.25 for lysylglutamic acid.

Kirkwood has developed an equation for this effect for spherical molecules and applied it to glycine.[2] The first term for this equation is $0.125\ R^2/a$, where a is the sum of the radii of ion and dipolar ion. The peptides that have now been studied cannot be considered spherical. Rather they are cylindrical or ellipsoidal, depending on whether they are stretched or somewhat constricted in solution as a result of rotation around free bonds. Kirkwood has now calculated the effect for an elliptical model[18] and finds that under these circumstances the first term in the free energy equation is proportional to R, as indicated by these experiments.

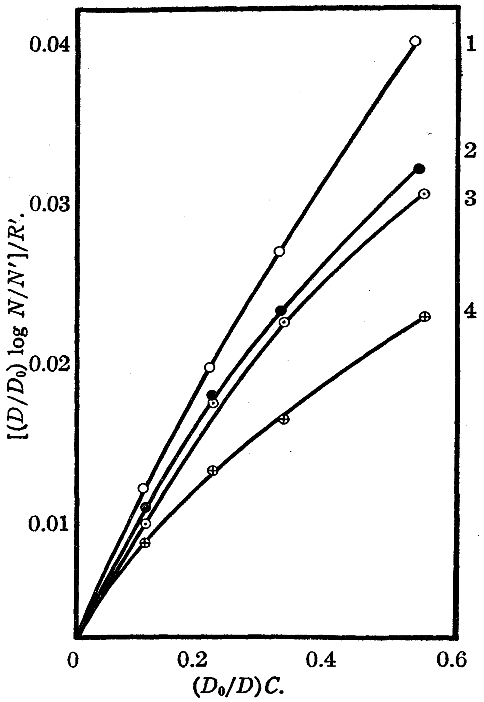

Fig. 2.—Solubility ratios of amino acids and peptides in 80% ethanol, containing sodium chloride, divided by their dipole distances as estimated by structural considerations: 1, glycine; 2, diglycine; 3, triglycine; 4, lysylglutamic acid.

The dipole moments of dipolar ions may be estimated by multiplying these distances by the charge on the electron. On this basis the moment of glycine is 15×10^{-18} e. s. u., and that of diglycine between 26 and 32×10^{-18} e. s. u. These moments are far greater than those due to the polar groups of these molecules. The moment of the ethyl ester of glycine, and those of other α-amino acids have been studied in benzene by Wyman and McMeekin[19] and estimated to be 2.1×10^{-18} e. s. u. That of the ethyl ester of diglycine they estimated to be 3.2×10^{-18} e. s. u.

Hydantoic acids terminate in NH_2 and COOH groups. That is to say, their structure is that classically ascribed to amino acids before the studies of Adams and of Bjerrum. With the exception of the movement of a proton, hydantoic acid differs from diglycine by possessing one less CH_2 group. The ester of hydantoic acid and of hydantoic α-aminocaproic acid might therefore

[19] Wyman and McMeekin, THIS JOURNAL, **55**, 915 (1933).

be expected to have moments close to that of diglycine. Their heptyl esters have therefore been prepared and measured in benzene and found to have moments of 3.6 and 3.5 × 10^{-18} e. s. u., respectively.[20] The moments of these larger molecules in benzene fall off rapidly with concentration. They suggest a value of 1.4 or 1.5 × 10^{-18} e. s. u. for the peptide linkage, whereas the dipole moment of the amide group has been estimated to be 3.2[21] in the gaseous state and 3.6 to 3.8 in non-polar solvents.[22,23] The solvent action of neutral salts upon the hydantoic acids studied also suggests higher moments than are indicated by the measurements in benzene.

The moments of the esters of amino acids, peptides and of their hydantoic acids are, however, small in comparison with the superimposed effects due to dipolar ionization, and it is for the most part the latter which are responsible for the very large activity coefficients of peptides in salt solutions in regions of low dielectric constant. In regions of high dielectric constants, where the solubilities of amino acids and peptides are relatively high, the same contributions of Coulomb forces to activity coefficients presumably obtain, but are there supplemented by forces other than those due to the purely electrostatic interaction of ions and dipolar ions.

Summary

1. The interaction between ions and dipolar ions has been studied in regions of low dielectric constant in order to estimate the electrostatic forces involved.

2. Solutions of sodium chloride in 80% ethanol at 25° were employed as solvents, and glycine, diglycine, triglycine and the tetrapole lysylglutamic acid as solutes.

3. Hydantoic acids prepared from glycine and diglycine were studied in the same solvents in order to estimate what proportion of the effect was due to the dipolar ion structure of amino acids and peptides and what to the polar groups of these molecules.

4. The solvent action of neutral salts upon amino acids and peptides in dilute solution appears, as a first approximation, to be a function of their dipole moments.

Studies in the Physical Chemistry of the Proteins. XIII. The Solvent Action of Sodium Chloride on Egg Albumin in 25% Ethanol at −5°

BY RONALD M. FERRY, EDWIN J. COHN AND ETHEL S. NEWMAN

Introduction.—The relation of the properties of amino acids and peptides to their chemical structure, and to the number and distribution of the electrostatic charges which they bear, has been considered in recent investigations.[1–3] Even when they have no net charge, these molecules, by virtue of their dissociated ammonium and carboxyl groups, have large electric moments and contribute markedly to the dielectric constants of their aqueous solutions, thereby diminishing electrostatic forces. The solubility of these dipolar ions diminishes, however, with diminution of the dielectric constant of the solvent, and under these conditions the properties of the solutions approach those of the pure solvents, and the effects of electrostatic forces are more readily observed.

It is of interest to extend these investigations to more complex dipolar and multipolar ions.[4] We have, accordingly, studied the solubility of isoelectric egg albumin in 25% ethanol–water mixtures at −5°. Egg albumin is a well-defined, easily purified, protein. Its molecules are roughly spherical with a radius of about 22 Å.[5] Early estimates revealed twenty-seven dissociable acids and the same number of dissociable basic groups,[6] whereas a recent study suggests a slightly higher number of dissociable groups.[7] Albumins are de-

fined as proteins "soluble in pure water and coagulable by heat." Aqueous solutions containing 40% of egg albumin are readily prepared, but in the experiments reported in 25% ethanol the solubility of egg albumin was only 0.13 g. per liter, and neutral salts increased its solubility many fold, as they do with globulins in aqueous solution.

Although knowledge of their chemical structure is incomplete, it appears possible from this study and those subsequently to be reported that proteins may be completely characterized in terms of their size, shape, the length of their paraffin side chains, and the number and distribution of their polar, and especially of their charged, groups.

Methods and Materials.—The egg albumin used in these experiments was crystallized five times from ammonium sulfate solutions according to the procedure described by Sørensen.[8] Subsequently it was dialyzed in cellophane membranes against distilled water until the dialysate gave a negative sulfate test. In our early experiments it was then concentrated in negative pressure dialyzers[8] and dialysis continued until heat coagulated albumin yielded no sulfate or chloride to large volumes of hot water, even after its concentration from a volume of about 300 to 1-2 cc.

Our early experiments suggested that the saturating body contained traces of protein salt as well as uncombined isoelectric protein. Electrodialysis was therefore also used. The material obtained after dialysis in cellophane membranes was placed in a Pauli electrodialysis apparatus with a potential of 110 volts between electrodes. The contents of the cell were stirred at intervals, and dialysis continued against conductivity water, until the current passing through the cell became constant. A very small amount of insoluble material often appeared during this process and was filtered off. The soluble material was readily crystallizable.

After electrodialysis the egg albumin was concentrated in negative pressure dialyzers as before, where it reached a concentration of about 40% by weight. It was next dried according to the method of Adair[9] at about 2° in a vacuum over phosphorus pentoxide. The dry material was ground to a fine powder in a porcelain mortar and stored in vacuum desiccators over phosphorus pentoxide. It was readily soluble and crystallizable from ammonium sulfate solutions. Of the crystal forms figured by Sørensen and Hoyrup[10] the rhombic plates, rather than the needles, were most often observed.

The solvents employed were made up to contain 25% ethanol by volume at 20° and varying amounts of C. P. sodium chloride. The systems containing most salt therefore contained slightly less water. It may ultimately be desirable to calculate solubilities in systems having the same ethanol–water composition.[3]

The thermostat employed was maintained at $-5 \pm 0.05°$, and contained kerosene. Weighed amounts of dry powdered egg albumin were placed in double stoppered Pyrex centrifuge bottles. One of these is shown in Fig. 1. These were placed in a holder in the bath and completely filled with solvent which already had been cooled to $-5°$. The outer caps (B) were well greased, but not the inner ground glass stoppers (A). The bottles were slowly rotated in a horizontal position until equilibrium was attained.

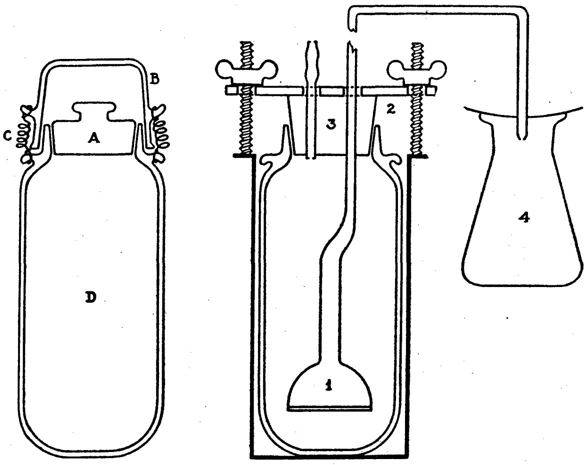

Fig. 1.—A, ground glass stopper; B, outer ground cap; C, springs; D, Pyrex bottle; 1, sintered filter; 2, yoke to hold stopper; 3, rubber stopper; 4, weighing bottle.

Although ninety hours of rotation apparently sufficed for saturation, rotation was continued for five to seven days. At the end of this time, rotation was stopped, the bottles were placed in a vertical position, and undissolved egg albumin allowed to settle. Sintered Jena glass filters (porosity G 4)—previously cooled to $-5°$—were then introduced into the equilibrium bottles without removing the latter from the bath (see Fig. 1). The supernatant fluid was filtered under 15 lb. (1 atm.) pressure of nitrogen gas into glass-stoppered weighing bottles, and the content of protein in the weighed sample determined.

After removing the supernatant fluid as completely as possible from the equilibrium bottles, they were again filled with solvent at $-5°$ and again equilibrated. Equilibrium was always approached by the saturation of solvents, the operation often being repeated as many as twelve times with a single sample of egg albumin. Even at the end of months of rotation in the thermostat by far the greater part of the undissolved material remained soluble and crystallizable. The small amount of denatured protein had no marked influence on these experiments. The solubility of egg albumin, denatured in 25% ethanol at room temperature, did not exceed 0.004 g. for 1000 g. solution under the conditions of our experiments, a quantity small in comparison with the solubilities here reported. Moreover, under these conditions, no solvent action of salt on the denatured egg albumin was detected.

Two different analytic procedures were employed. In case the solvent contained no salt, egg albumin was estimated gravimetrically. Weighed aliquots were dried to constant weight in an oven at 95°.

In the case of solutions containing salt the alcohol was first evaporated. A few cubic centimeters of acetate buffer of *p*H 4.85 and about 0.5 g. of potassium sulfate were

[10] Sørensen and Hoyrup, *Compt. rend. trav. lab. Carlsberg*, **12**, 164 (1917).

then added in order to ensure complete coagulation of the protein over the steam-bath. The coagulated protein was transferred quantitatively to weighed sintered glass crucibles, of porosity G4, and washed until the filtrate gave a negative sulfate test. The crucibles and contents were dried to constant weight at 95°. The results obtained accorded satisfactorily with those based on Kjeldahl nitrogen analysis. Aliquots containing from 0.02 to 0.6 g. of dry protein were analyzed. Duplicate analyses accord within 0.3 to 0.4 mg. The errors due to change in weight of crucibles and losses in transfer did not exceed 0.5 mg., or at most 3%. Other factors not so well defined, such as variation in *p*H, presence of traces of protein salt, etc., gave rise to larger discrepancies and will be discussed subsequently. Change in the apparent dissociation constants of buffer acids in alcohol rendered their use undesirable as solvents in these investigations. The *p*H of each solution was, however, colorimetrically estimated at room temperature against standard buffers—0.05 *N* in acetate—in 25% ethanol.[11] The apparent isoelectric point of egg albumin in 25% ethanol is presumably increased by something less than one *p*H unit, the estimated values being more acid the larger the concentration of salt and protein in the systems.

Solubility Measurements.—The solubility of the first preparation studied diminished with each successive equilibration with solvent. An experiment of this kind is reported in Table I. Often more than a month would elapse until solubility became constant in successive solvents. Since the saturating body always contained egg albumin, which was both soluble and crystallizable, the slow diminution in solubility was believed to be due to the washing out of a more soluble impurity, and not to denaturation of the protein. Accordingly electrodialysis was resorted to in order to reduce the conductivity of the preparations as far as possible, even at the risk of denaturating some of the egg albumin. The electrodialyzed material generally exhibited constant solubility, as is indicated by the experiment reported in Table I. Thus prepared egg albumin had from the beginning the same solubility as was ultimately reached by the earlier preparation.

[a] Electrodialyzed.

---

[11] Michaelis and Mizutani, *Z. physik. Chem.*, **116**, 135 (1925).

made, was electrodialyzed. In the case of the earlier series in which non-electrodialyzed material was used we have tabulated only those values which indicated that a reasonably constant solubility had been attained. In later experiments with electrodialyzed material at low salt concentrations a few points, which were clearly discordant, are given in parentheses and not included in the averages. These were probably due to temporary failure in the thermoregulator, a source of trouble only recently overcome by removing the relay from the cold room. At the highest salt concentrations only the first value for solubility is given, since at such high solubilities it was difficult to provide sufficient saturating body for repeated equilibration.

The deviations are far greater than in most studies from the laboratory, because of the difficulty of achieving equilibrium and of controlling small deviations in *p*H and in alcohol concentration. None the less, because of the very large solvent action at low sodium chloride concentrations, these determinations yield a very satisfactory estimate of the influence of salt on the solubility of egg albumin. Average values of solubility, expressed as grams per 1000 g. of solution, are given in the last column of Table II. Taking the density of the solvents as given by the approximate relation

$$\rho = 0.9761 + 0.043\ C$$

and the apparent specific volume of egg albumin as 0.75[12] and its molecular weight as 34,000, its solubility has been computed as moles per liter at −5° and mole fraction in Table III.

Results.—The influence of neutral salts on each other increases with the square root of the ionic strength of the solvent, and with the valence type of the salt.[13,14] A tenth molal solution of potassium nitrate increases the solubility of thallous chloride approximately 20%,[15] of barium iodate 80%.[16] The solubility of luteo-hexacyanocobaltiate, a tri-trivalent electrolyte studied by Brönsted and Peterson,[17] is increased over ninefold by 0.1 mole of potassium chloride. Only an electrolyte of such high valence type approximates the behavior of proteins[18] at finite concentration.

The influence of neutral salts upon dipolar ions is not identical with that upon ions. Dipolar ions in the isoelectric condition have no net charge. In an extension of Debye's theory to the interaction between ions and dipolar ions, Scatchard and Kirkwood[19] have shown that the first term in the equation for the logarithm of the solubility ratio is proportional to the ionic strength, and not to its square root. The results upon egg albumin reported here are consistent with this prediction.

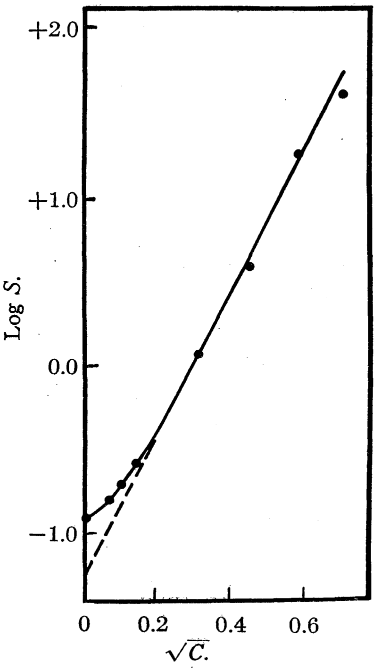

Fig. 2.—The influence of NaCl on the solubility of egg albumin in 25% ethanol at −5°.

In Fig. 2 the logarithm of the solubility is plotted against the square root of the concentration of

sodium chloride. The logarithm of solubility does not appear to be proportional to $\sqrt{C}$ when the latter is less than 0.1. In high concentrations of salt, where Debye's law for ions would not be expected to hold, however, the points so plotted apparently fall on a straight line as noted in an earlier study.[18]

Cystine, a tetrapole, is the least soluble of the naturally occurring amino acids. Its solubility also demonstrates that the logarithm of the activity coefficient is not linear in the square root, but is a function of the concentration (see Fig. 2, ref. 20).[20] Although the solubility of cystine is only increased 10% by 0.1 mole of sodium chloride, the same concentration of salt increases the solubility of egg albumin almost ten-fold.

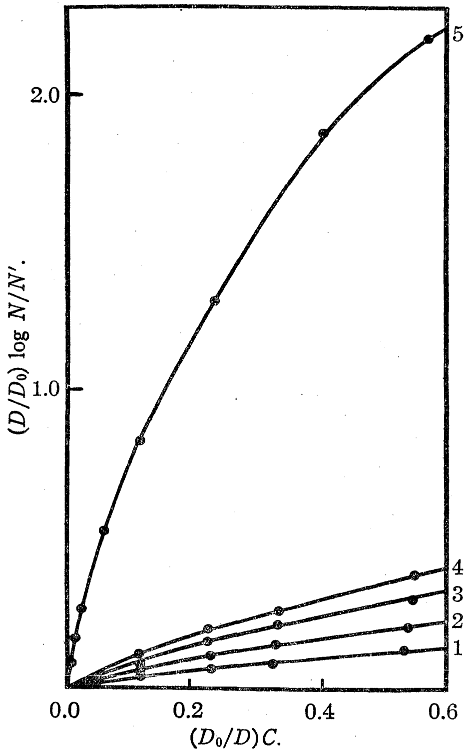

Fig. 3.—Solvent action of NaCl on: (1) glycine; (2) diglycine; (3) triglycine; (4) lysylglutamic acid and (5) egg albumin.

Many amino acids and peptides are so soluble in water, and increase the dielectric constant of the solutions to such an extent that electrostatic forces due to the interaction between ions and dipolar ions cannot be studied in this medium. They have accordingly been studied in alcohol–water mixtures in which their solubility was reduced and electrostatic forces due to this interaction increased. Under these circumstances it has been demonstrated for glycine that as a first approximation the logarithms of the solubility ratio increase as the second power of the reciprocal of the dielectric constant, as demanded if the effect is due primarily to Coulomb forces. Measurements made in from 60 to 95% ethanol, and plotted with (D/D_0) log N/N_0 as ordinate, and $(D_0/D)\Gamma_2$—a quantity proportional to κ^2 in Debye's equation—as abscissa, fall on the same curve.[1,2]

The measurements on egg albumin in 25% ethanol are plotted in this manner in Fig. 3. This method of plotting has the advantage that it presumably yields that part of the activity coefficient due to Coulomb forces that also obtain in aqueous solution. The dielectric constant of 25% ethanol at −5°, obtained by interpolation from Wyman's data,[21] is taken as 78.6. That of water at −5° was estimated by Wyman by extrapolation to be 90.0.[21] Accordingly the value 0.874 for D/D_0 has been employed tentatively in our calculations without any correction for the influence of salt or of egg albumin on the dielectric constant. It is conceivable that measurements upon egg albumin at still lower dielectric constant would reveal even greater changes in solubility with change in ionic strength, and that the maximum slope has not been attained even in 25% ethanol at −5°. The solubility of egg albumin falls off so rapidly with further decrease in dielectric constant, however, that the accuracy of the measurements would be still further reduced, and it seemed preferable therefore to study another protein, hemoglobin, in a series of alcohol–water mixtures. This study will be reported subsequently.

The curve for egg albumin is compared in Fig. 3 with that of the peptides of glycine and with the tetrapole lysylglutamic acid that has been studied in 80% ethanol at 25°.[3] The solvent action of neutral salts on these molecules is in the order of their influence on the dielectric constant of solutions, and presumably of their electric moments. The shapes of the curves suggest that the general phenomenon is the same for amino acids, peptides and proteins, and the far greater influence of salts upon the latter suggests that they have far greater dipolar and multipolar moments. Their size is also far greater and this presumably accounts for the very rapid falling off of protein

solubility curves from their limiting slopes with increase in salt concentration.

This phenomenon is more readily analyzed if we plot some function of change in solubility with change in concentration against some function of concentration. This has been done in Fig. 4. The forces which lead to the salting out of proteins are clearly manifest even in dilute solutions of protein and salt at low temperature. Whereas the measurements upon glycine fall on an essentially straight line, when plotted as in Fig. 4, and those upon lysylglutamic acid show some curvature; the curvature in the case of egg albumin is far greater.

There is no uncertainty in determining the limiting slope of glycine to be 0.30 to 0.32 by this method, or of lysylglutamic acid to be 1.1 to 1.2. The estimate for egg albumin, however, is not independent of the method of extrapolation. The average values of (D/D_0) log N/N' in Table III appear to be linear in $(D_0/D)C$ for values of the latter less than 0.02, and to yield 14 for the limiting slope.

The study of peptides[3] led to the conclusion "that, as a first approximation, the logarithms of the activity coefficients of dipolar ions increase as the concentration of the salt, and the dipole distance." Assuming the same rule to hold for egg albumin, and the dipole distance, R, of glycine[2] to be 3.17, would yield 140 Å. The peptides studied were, however, roughly rod shaped, whereas glycine and egg albumin are roughly spherical. Kirkwood has developed a theoretical equation for the activity coefficients of dipolar ions considered as spheres,[2] the first term of which gives the limiting slope for a single dipole as proportional to R^2/a. For egg albumin a, the sum of the radii of the protein and salt, may be taken as 23 Å. On this basis R would be 52 Å. or only slightly greater than the diameter of the molecule. Although the large number of charges involved precludes a unique solution of the distribution of the charges on the surface of the vast protein molecule, a preliminary study[22] suggests that egg albumin should not be treated as a single dipole, but that the quadropole and octopole moments dominate the interaction with salts.

The influence of dipolar ions on the dielectric constant of solutions may also be considered, as a first approximation, a function of the electric moment, presumably of its second power.[23] In the case of peptides, plotting the limiting slope against the square root of the dielectric constant increment, δ, yields a roughly linear relationship.[3] Errera[24] reports dielectric constants from which values of δ can be calculated of 10,000 and Shutt[25] of 4000. Assuming δ proportional to 2.3 $R^{2,20}$ yields values of R of 42 Å. and 66 Å. on the basis, respectively, of Shutt's and Errera's dielectric constant measurements. This result is in as good agreement as can be expected with the value 52 Å. on the basis of our solubility studies and the first term of Kirkwood's equation. There is thus little doubt that it is the distribution of charges and the effective electrical moments of the molecule that determine both its influence on the dielectric constant of solutions and on the interaction with ions and other dipolar ions.

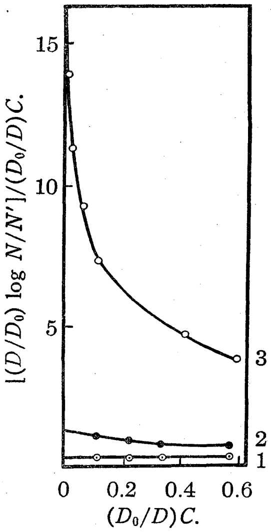

Fig. 4.—Diminution of solvent action of NaCl with increase in concentration upon: (1) glycine; (2) lysylglutamic acid; (3) egg albumin.

Summary

1. The solubility of egg albumin has been studied in 25% ethanol at −5°. Under these conditions denaturation was slight and the solubility of the albumin so low, 3.7×10^{-6} mole per liter, that its contribution to the dielectric constant of the solution was neglected.

2. Neutral salts increased the solubility of egg albumin under these conditions much as they do the solubility of globulins in water.

3. The solvent action of the neutral salt has been considered a measure of the electrostatic forces between the ions and the protein and compared with the comparable forces between ions, amino acids and peptides.

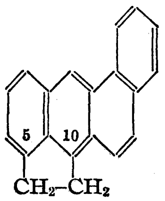
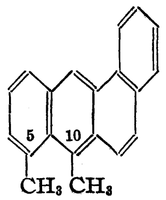
The Synthesis of 1,2-Benzanthracene Derivatives Related to Cholanthrene

BY LOUIS F. FIESER AND MELVIN S. NEWMAN[1]

Of the various hydrocarbons known to possess cancer-producing properties, the most potent are methylcholanthrene and cholanthrene (I).[2] In the regularity and rapidity with which they produce tumors in experimental mice these substances so far outshadow all of the many other derivatives of 1,2-benzanthracene thus far investigated (largely by Cook and co-workers[2]) that it is a matter of considerable interest to attempt to define the features of structure responsible for their striking activity. Clearly the methyl group present in methylcholanthrene in the 6-position of the 1,2-benzanthracene nucleus is relatively unimportant, for cholanthrene is as active, or very nearly as active, as methylcholanthrene.[2] Of other carcinogenic derivatives of the itself inactive 1,2-benzanthracene the 5-methyl compound is weakly active, the 5,6-dimethyl and 5,6-trimethylene derivatives are slightly more so, and the 8,9-dimethylene compound shows some activity,[3] but none of these hydrocarbons is comparable with cholanthrene (I) in potency. It should be possible to determine whether the special activity of cholanthrene is associated with the presence of the five-membered ring including carbon atoms 5 and 10, or merely with the presence of alkyl substituents at these positions, by investigating the biological actions of 5,10-dimethyl-1,2-benzanthracene, II. With this end in view we undertook the synthesis of the latter hydrocarbon and of the likewise interesting 10-methyl-1,2-benzanthracene.

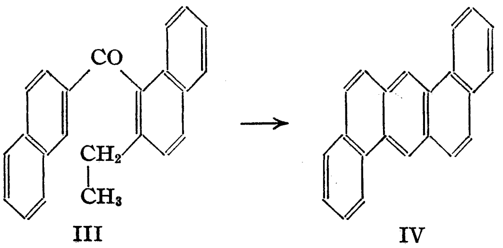


I



II

Considering the success of the modified Elbs reaction developed by one of us with Seligman[2b] for the preparation of cholanthrenes, it seemed possible that 10-methyl anthracenes or benzanthracenes might be obtainable by the pyrolysis of suitable *o*-ethyl diaryl ketones, for example 2-ethyl-3-methylphenyl-α-naphthyl ketone. As a preliminary trial of the reaction in a simple case, the ketone (III) from α-naphthoyl chloride and β-ethylnaphthalene was submitted to pyrolysis, but the resulting hydrocarbon, obtained in a yield quite good for such reactions, proved to be identical with 1,2,5,6-dibenzanthracene (IV), indicating the loss of a methyl group from the 10-position. Similarly the ketone from 2,5-dimethylbenzoyl chloride and β-ethylnaphthalene gave in small amounts an unidentified hydrocarbon having the composition of a monomethyl rather than a trimethyl 1,2-benzanthracene. This type of reaction was therefore abandoned, although from more recent work in this Laboratory (A. M. Seligman) it appears that in some cases the condensation proceeds without degradation of an *n*-alkyl group.



III IV

As another possible approach we investigated a method used by Cook and Haslewood[4] for the synthesis of cholanthrene. α-(*o*-Tolyl)-α-(2-naphthyl)-ethane, V, was prepared by the addition of *o*-tolylmagnesium bromide to methyl β-naphthyl ketone, dehydration of the resulting carbinol, and hydrogenation of the olefin. Attempts were made to introduce a carboxyl group in the 1-position of the naphthalene nucleus by the bromination of the hydrocarbon and carbona-

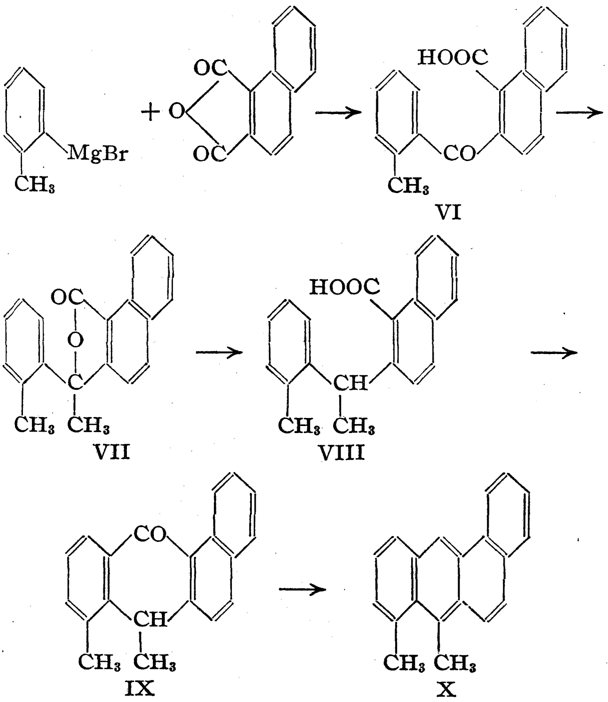
tion of the Grignard reagent, and by the hypochlorite oxidation of the (crude) acetyl derivative obtained by the Friedel and Crafts reaction, but a crystalline acid was not isolated. On submitting the acid mixture obtained by the first procedure to cyclization and reduction, there was isolated in very small amount through the picrate a hydrocarbon having the expected composition of a dimethylbenzanthracene, but the substance did not have the properties of a pure individual.

Following these unpromising results a successful synthesis was developed starting with 1,2-naphthalic anhydride (naphthalene-1,2-dicarboxylic anhydride), a compound easily prepared synthetically in any desired quantity.[5] On reaction with one mole of *o*-tolylmagnesium bromide this gave a mixture from which the desired keto acid VI was easily isolated in 40% yield. Reaction at the more hindered carbonyl group took place to a less extent, only about 3% of the isomeric 2-*o*-toluyl-1-naphthoic acid being isolated. The structures of the acids were established by decarboxylation to the known *o*-tolyl α- and β-naphthyl ketones.[6] 1,2-Naphthalic anhydride thus behaves in the Grignard reaction[7] much as it does in the Friedel and Crafts condensation with hydrocarbons.[8] On condensing the anhydride with cumene, Cook[9] isolated the keto acids resulting from condensation at the β- and α-carbonyl groups, respectively, in 23 and 10% yields.

The addition of the methyl Grignard reagent to the ketonic group of 2-*o*-toluyl-1-naphthoic acid (VI) was at first accomplished by using the ester, but about 20% of the keto acid usually was recovered unchanged and no more than 50% of the material utilized was converted into the desired reaction product, 2-(α-hydroxy-*o*,α-dimethylbenzyl)-1-naphthoic acid lactone (VII). The yield was considerably improved by treating the keto acid (VI) itself with two moles of methylmagnesium iodide, and when methylmagnesium bromide was employed no appreciable amount of acid was recovered and the yield of good product rose to 86%. The lactone VII exists in two apparently polymorphic modifications. Attempts to prepare 2-(*o*,α-dimethylbenzyl)-1-naphthoic acid (VIII) by the reduction of the lactone with zinc dust and alkali were unpromising, but as Martin[10] has shown recently that γ-phenylbutyrolactone can be reduced to γ-phenylbutyric acid with amalgamated zinc and hydrochloric acid, this method was tried. The desired acid was obtained in this way in excellent yield (76%) and purity and the reaction proceeded particularly smoothly in acetic acid solution. The acid VIII was cyclized with concentrated sulfuric acid at room temperature to an anthrone (IX) which was not isolated in a pure condition but reduced with zinc dust and alkali to the desired 5,10-dimethyl-1,2-benzanthracene (X). The hydrocarbon was obtained in good yield and was easily purified.



10-Methyl-1,2-benzanthracene was prepared by using phenylmagnesium bromide in the first step of the synthesis and proceeding as above. The free 2-benzoyl-1-naphthoic acid gave a good yield in the Grignard reaction and the normal ester, prepared with the use of diazomethane, gave a moderately satisfactory result. It was observed that the substance obtained by esterifying the acid with alcohol–hydrogen chloride and described in the literature[8] as methyl 2-benzoyl-1-naphthoate does not react with methylmagnesium iodide, except possibly to undergo hydrolysis.

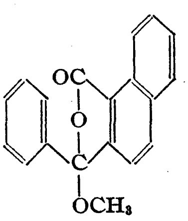
[10] Martin, THIS JOURNAL, **58**, 1438 (1936).

The substance is thus regarded as the lactol ether XI. The formation of such a compound in the Fischer esterification reaction is in striking contrast to the behavior of *o*-benzoylbenzoic acid.[11]



XI

In the hope of introducing a long aliphatic chain in the 10-position, the keto acid VI or its methyl ester was treated with octadecylmagnesium bromide, but the only product isolated proved to be the lactone of the hydroxy acid resulting from the reduction of the carbonyl group of VI to a carbinol group by the reagent. This was reduced further with zinc and acid to 2-*o*-tolylmethyl-1-naphthoic acid, and the identical substance was obtained by the action of the same reagents on the keto acid VI. This acid was put through the remaining steps of the synthesis and afforded the known 5-methyl-1,2-benzanthracene.[12] A reducing action also was noticed in a preliminary study of the reaction of ethylmagnesium bromide with 2-*o*-toluyl-1-naphthoic acid (VI), but in this case some addition also occurred.

While the reducing action of at least certain alkyl Grignard reagents imposes some limits on the synthetic method, it may be possible to avoid this difficulty by reversing the order of the two Grignard reactions. We hope to investigate this possibility and to explore other applications of the synthesis.

The new hydrocarbons are being tested for carcinogenic activity by Dr. M. J. Shear, and although the experiments have been in progress only for a comparatively short time the preliminary results are of considerable interest. 5,10-Dimethyl-1,2-benzanthracene was injected subcutaneously into mice, using approximately 10 mg. of the crystalline material per animal. Severe ulceration at the cite of injection was noted in all of the mice after the first month. After three and one-half months tumors had been produced in seven of fifteen mice, the first two tumors making their appearance at the end of two and one-half months. From these results it appears that the new hydrocarbon is at least roughly comparable in carcinogenic activity with the most potent of the compounds previously investigated, namely, methylcholanthrene, cholanthrene and 3,-4-benzpyrene,[13] and that it is considerably more powerful in its action than any of the known monomethyl or dimethyl derivatives of 1,2-benzanthracene.[2] 5-Methyl-1,2-benzanthracene, injected subcutaneously into twenty mice in 5-mg. dosages, produced no noticeable effect in thirty-seven days, while 10-methyl-1,2-benzanthracene in the same dosage produced either ulceration, thickening of the tissue, or both, in thirteen of twenty mice during the same period.

From the present indications, it appears that the five-membered ring characteristic of the cholanthrene system is of importance in contributing to the carcinogenic potency of hydrocarbons of this type only in that it includes carbon substituents at the 5- and 10-positions. The presence of the intact ring is by no means essential, for simple alkyl groups at these positions produce nearly the same effect. Substitution at the meso position 10 seems to be particularly important, and it is interesting to note that 3,4-benzpyrene may be regarded as a 1,2-benzanthracene derivative with a carbon substituent at one of the meso positions (9). Heretofore the hypothesis that cancer-producing hydrocarbons may be formed in the organism by the abnormal metabolism of cholesterol or of bile acids has found support in the demonstration that two different bile acids can be transformed by chemical means into methylcholanthrene,[2] and in the striking circumstance that this outstandingly potent hydrocarbon carries as a mark of its possible origin the cyclopenteno ring characteristic of the sterols. While the possibility of the biological formation of methylcholanthrene remains undisputed, if, to be sure, quite unestablished, the observation that comparable activity is exhibited by a simpler hydrocarbon lacking both the C_{20}-methyl group and the cyclopenteno ring characteristic of the sterols, and of a type not likely to arise in the process of metabolism, weakens somewhat the circumstantial evidence favoring acceptance of the hypothesis.

(12) Cook, *J. Chem. Soc.*, 1592 (1933).

(13) In previous publications from this Laboratory the carcinogenic hydrocarbon isolated from coal tar by J. W. Cook, C. L. Hewett and I. Hieger has been referred to as "1,2-benzpyrene," in accordance with the system of numbering originally employed by the discoverers of the substance. Following a plea for unanimity from the editor of "Beilstein," and in agreement with Dr. J. W. Cook, we will employ hereafter the numbering system for pyrene favored in Germany and used in *Chemical Abstracts*, according to which the carcinogenic hydrocarbon becomes 3,4-benzpyrene.

Experimental Part[14]

Pyrolysis of 1-(2-Naphthoyl)-2-ethylnaphthalene (III).–β-Ethylnaphthalene, b. p. 122–125° (14 mm.), picrate, yellow needles, m. p. 76.5–77° from alcohol, was prepared in 52% yield by the Clemmensen–Martin procedure[10] and condensed with β-naphthoyl chloride with aluminum chloride in carbon bisulfide solution. The crude ketone, b. p. 235–240° (2–2.5 mm.), resulted in 91% yield but did not crystallize, and on pyrolysis at 425–430° for one and one-half hours 6 g. of the material gave 1.3 g. (23%) of a hydrocarbon melting at 261–262° and identified by analysis and mixed melting point determinations as 1,2,5,6-dibenzanthracene.

Pyrolysis of 1-(2,5-Dimethylbenzoyl)-2-ethylnaphthalene.—2,5-Dimethylacetophenone was prepared more satisfactorily than previously reported[15] by adding 45 g. of aluminum chloride during one and one-half hours to a stirred solution at 0° of 31 g. of *p*-xylene and 25 g. of acetyl chloride in 450 cc. of carbon bisulfide. After three hours at 0° with stirring, twelve hours at 0–5°, and one to two hours at 25°, the light yellow complex was collected with suction, washed with carbon bisulfide, and decomposed with dilute hydrochloric acid. A small additional amount of the ketone was recovered from the filtrate and the combined product distilled at 106.2° (14 mm.), yield 40.8 g. (95%). The ketone was converted to 2,5-dimethylbenzoic acid, m. p. 132–133°, with potassium hypochlorite from the commercial calcium salt in 93% yield by the general procedure reported.[16] The acid chloride (b. p. 101.5° at 11–12 mm.), prepared with thionyl chloride, was condensed with β-ethylnaphthalene as above and the ketone, b. p. 188–192° (2 mm.), yield 84%, was pyrolyzed at 450–455° for fifteen minutes. From 5.9 g. of the ketone 1.3 g. of hydrocarbon, m. p. 124–126°, was obtained after two crystallizations from alcohol. This yielded a picrate which after two crystallizations from benzene–ligroin formed red needles, m. p. 155–156°, and had the composition of a methylbenzanthracene picrate.

Anal. Calcd. for $C_{19}H_{14}\cdot C_6H_3O_7N_3$: C, 63.68; H, 3.64. Found: C, 63.93, 63.86; H, 3.80, 3.60.

Attempted Synthesis from α-(*o*-Tolyl)-α-(2-naphthyl)-ethane, V.—The Grignard reagent from 94 g. of *o*-bromotoluene, 13.4 g. of magnesium, and 500 cc. of ether was added to 85 g. of methyl β-naphthyl ketone in 225 cc. of benzene during one and one-half hours and after distilling the ether the benzene solution was refluxed for one hour. After hydrolysis with dilute hydrochloric acid the carbinol was heated at 200–250° to effect dehydration and the resulting **α-(*o*-tolyl)-α-(2-naphthyl)-ethene** was distilled at 2 mm., giving 83 g. (68%) of a colorless oil which immediately crystallized. Recrystallization from alcohol gave colorless prisms, m. p. 66–66.5°.

Anal. Calcd. for $C_{19}H_{16}$: C, 93.40; H, 6.60. Found: C, 93.51; H, 6.57.

Hydrogenation of the olefin proceeded smoothly in glacial acetic acid solution with Adams catalyst and the resulting liquid hydrocarbon boiled at 177–179° (1.5–2 mm.), yield 86%. In attempted Friedel and Crafts condensations of the hydrocarbon with acetyl chloride under various conditions, naphthalene was always obtained as a fore-run, there was much resinous material, and the portion boiling in the range 160–200° (1.5–2 mm.) yielded no appreciable amount of acid on hypochlorite oxidation in aqueous medium or in pyridine,[17] or by other methods.[18] Chloroacetylation was also unsuccessful.

In other experiments the hydrocarbon V was brominated according to Cook and Haslewood[4] and the product was treated with pyridine, converted into the Grignard reagent, and this was carbonated and submitted to hydrogenation, as described by these authors. The acidic material obtained did not crystallize, even when seeded later with the pure acid VI. After several preliminary tests, cyclization was effected by warming the crude acid mixture for one-half hour with 90% sulfuric acid at 40°. The solid material which precipitated on treatment with ice was boiled with zinc dust and alkali for ten hours with added toluene. The resulting product yielded a picrate which after repeated crystallization formed apparently homogeneous, red needles, m. p. 152–153°, but the hydrocarbon recovered from it, although it formed excellent pale yellow needles from alcohol, melted over the range 149–168°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.70; H, 6.30. Found: C, 93.56; H, 6.53. Picrate, calcd.: C, 64.32; H, 3.95; N, 8.66. Found: C, 64.56; H, 4.08; N, 8.53.

The product does not correspond at all with the pure 5,10-dimethyl-1,2-benzanthracene described below and as the yield was very poor the substance was not investigated further.

Synthesis of 5,10-Dimethyl-1,2-benzanthracene

Reaction of 1,2-Naphthalic Anhydride with *o*-Tolylmagnesium Bromide.—The 3,4-dihydronaphthalene-1,2-dicarboxylic anhydride was prepared with the use of sodium ethylate as described by Fieser and Hershberg[5] and with the same yield (81%) when employing as much as 254 g. of ethyl γ-phenylbutyrate. With large quantities it was found convenient to powder the sodium under xylene by simply agitating the mixture with a Hershberg wire stirrer.[19] The dehydrogenation was conducted as described,[5] using 213.5 g. of material. The product twice distilled and once crystallized from benzene was sulfur-free and suitable for the Grignard reaction; yield 163.5 g. (77.5%). The mother liquor afforded 11.5 g. of anhydride of the same melting point but giving a slight test for sulfur.

After a number of trials and variations the following procedure for the addition reaction was adopted as the most satisfactory. The Grignard reagent prepared from 19 g. of *o*-bromotoluene, 3.5 g. of magnesium, and 100 cc. of ether was filtered through a plug of glass wool under nitrogen pressure and forced *all at once* under pressure of the gas into a well-stirred (Hershberg stirrer) solution of 20 g. of sulfur-free 1,2-naphthalic anhydride in 400 cc. of warm thiophene-free benzene. A yellow complex

separated immediately. The mixture was heated with stirring, the ether was allowed to distil, and the benzene was then kept refluxing for two hours. After cooling and treating with dilute hydrochloric acid, the benzene layer was diluted with 200 cc. of ether and extracted thoroughly with potassium carbonate solution. The residual ether–benzene solution contained no easily recovered products (some anhydride was obtained in early runs with less efficient stirring). The combined carbonate extracts were acidified and the keto acid mixture was taken into ether and the solution was washed with saturated sodium chloride solution and evaporated. A solution of the residue in 150 cc. of hot benzene was treated with 20–30 cc. of warm hexane to produce a saturated solution, and the crystalline material (m. p. 130–145°) which separated on standing overnight was taken up in 50 cc. of glacial acetic acid. After standing for twelve to sixteen hours (no longer) the dense, diamond-shaped prisms of **2-*o*-toluyl-1-naphthoic acid** (**VI**) which separated were collected; yield 11–12.5 g. (38–43%), m. p. 147–149°. This material was used for the next step. A sample for analysis was crystallized to constant melting point from glacial acetic acid, m. p. 149.5–150.5°.

1-*o*-Toluyl-2-naphthoic acid, m. p. 210–211°, was obtained from the first acetic acid mother liquor and purified by repeated recrystallization from the solvent. It forms heavy diamond-shaped prisms resembling those of VI; yield about 1 g. (3%).

Anal. Calcd. for $C_{19}H_{14}O_3$: C, 78.60; H, 4.86. Found (VI): C, 78.69; H, 5.05. (Isomer): C, 78.17, 78.31; H, 4.83, 5.29.

Methyl 2-*o*-Toluyl-1-naphthoate was obtained in 97% yield as a very viscous, pale yellow oil, b. p. 215–216° (2.5 mm.), by refluxing the acid with methyl alcohol–hydrogen chloride for five hours. An ester similar in appearance and in its behavior in the Grignard reaction was obtained using diazomethane.

Decarboxylation of the Acids.—The reaction proceeded well on a small scale (0.5 g.) using as catalyst a small amount of the blue copper salt of the appropriate acid and heating a mixture of the salt and free acid in a bath at 230–245°. After about ten minutes the product of decarboxylation was distilled at 9 mm. pressure and taken into hexane. The ketones crystallized slowly but well. The acid VI afforded a product identical with Martin's[10] *o*-tolyl-β-naphthyl ketone, m. p. and mixed m. p. 67–68°, while 1-*o*-toluyl-2-naphthoic acid gave *o*-tolyl α-naphthyl ketone, m. p. and mixed m. p. 51.5–52.5°.

Lactone of 2-(α-Hydroxy-*o*,α-dimethylbenzyl)-1-naphthoic Acid, VII.—The condensation of methyl 2-*o*-toluyl-1-naphthoate with slightly more than one equivalent of methylmagnesium iodide, filtered through a plug of glass wool under nitrogen and added inversely, was tried in ether, ether–benzene and ether–xylene at temperatures from 25 to 100° for two to three hours with nearly the same results. After decomposing the reaction mixture with dilute hydrochloric acid the organic layer was washed with water and extracted with potassium carbonate solution. The carbonate extract yielded 15–18% of the original keto acid resulting from the hydrolysis of the ester, and the ether or ether–benzene solution on drying and removing the solvent gave the lactone, which was crystallized from benzene–alcohol or benzene–hexane. The lactone apparently is formed directly in the course of the reaction or during the hydrolysis of the magnesium derivative; hydrolysis of the keto ester also occurs prior to the working up of the reaction mixture. The yields were from 40 to 51%, based on the acid consumed. Methyl zinc chloride gave none of the desired reaction product.

When the free keto acid was used and treated in benzene–ether solution with two equivalents of methylmagnesium iodide, distilling the ether and refluxing four or five hours, 10–40% of the acid was recovered unchanged and the yield of lactone, allowing for the recovery, rose to 70–80%. The most satisfactory results were obtained using methylmagnesium bromide and employing a considerable excess of the reagent (using the ester, an excess of Grignard reagent caused a decrease in the yield). For the preparation of the reagent 0.032 mole of magnesium was covered with ether and methyl bromide was introduced slowly by distillation until the magnesium was very nearly all dissolved. The solution was filtered under nitrogen pressure and added gradually to a benzene–ether solution of 0.01 mole of 2-*o*-toluyl-1-naphthoic acid. A white precipitate of the MgBr-salt separated and changed to a greenish-yellow and then a bright yellow complex. After stirring for three and one-half hours at room temperature, the mixture was refluxed for one-half hour and treated with dilute acid. The potassium carbonate extract contained no appreciable quantity of keto acid, and the lactone was obtained in a good condition in 86% yield.

The lactone dissolves readily in benzene and crystallizes well after the addition of either alcohol or hexane. At first the substance was obtained in a low-melting form which separated as large, flat, elongated, transparent prisms, or as small needles, m. p. 103–104°. In later experiments a second modification appeared more frequently, either alone or together with the low-melting form. This separated as long, square, transparent prismatic rods, m. p. 119–120°. When a solution of the pure low-melting form was seeded with the other material either the high-melting form crystallized directly or a mixture melting between 110 and 117° resulted and gave the pure high-melting form only on further crystallization. On one occasion the low-melting form was obtained as clusters of needles on seeding a solution of the high-melting modification, but usually it was difficult to obtain any but the high-melting form once it had been isolated.

Anal. Calcd. for $C_{20}H_{16}O_2$: C, 83.30; H, 5.60. Found (m. p. 103–104°): C, 83.25; H, 5.62; (m. p. 119–120°): C, 83.43; H, 5.90.

2-(*o*,α-Dimethylbenzyl)-1-naphthoic Acid, VIII.—Using Martin's modification[10] of the Clemmensen method, 0.9 g. of the lactone VII was refluxed with a mixture of 40 g. of amalgamated zinc, 20 cc. of water, 40 cc. of toluene, 10 cc. of glacial acetic acid, and 40 cc. of concentrated hydrochloric acid for twenty-one hours, adding two 30-cc. portions of concentrated acid. The organic material was collected in toluene–ether and the reduction product obtained by extraction with potassium carbonate solution. Unchanged lactone was recovered in a good condition from the toluene–ether. The results were variable, for in one case the pure reduction product was obtained in 80% yield and no lactone was recovered, while more usually 20–26% of starting material was recovered and the yield, allowing for this, was 40–76%. It seems better to use a homogeneous solution. Using 1.5 g. of lactone, 50 g. of amalgamated zinc, 50 cc. of glacial acetic acid and 25 cc. of concentrated hydrochloric acid, and refluxing for eleven hours with the dropwise addition of 150 cc. more acid during this period, the nearly pure reduction product, isolated as above and crystallized from benzene–hexane, amounted to 1.15 g. (76%).

A sample of the acid recrystallized for analysis from benzene–hexane formed clusters of transparent prisms, m. p. 183.5–184°.

Anal. Calcd. for $C_{20}H_{18}O_2$: C, 82.72; H, 6.25. Found: C, 82.71; H, 6.30.

5,10-Dimethyl-1,2-benzanthracene.—To 10 cc. of concentrated sulfuric acid at 20° 0.8 g. of powdered 2-(*o*,α-dimethylbenzyl)-1-naphthoic acid was added with swirling, and after five minutes the material had all dissolved to an orange solution. After two hours this was poured onto 100 g. of crushed ice, and after standing for two hours at 0° the precipitated, light yellow anthrone was collected and washed with water. As the substance is very sensitive and alterable, the moist anthrone was at once transferred to a flask and a mixture of the substance with 2 g. of zinc dust, 10 g. of sodium hydroxide, and 100 cc. of water was refluxed vigorously for six hours. The yellow, at first oily, material gradually disappeared and gave way to light-colored crystals of the hydrocarbon. The mixture was treated with excess hydrochloric acid to dissolve most of the zinc, and the crude product was collected, dried and crystallized from benzene–alcohol. The yield of colorless material melting at 146–147°, uncorr., was 0.45 g. (64%).

The hydrocarbon forms a picrate which separates from benzene as deep reddish-black flat needles, m. p. 173.7–174.2°. The hydrocarbon regenerated from the purified picrate crystallized from benzene–alcohol or benzene–hexane as colorless plates, m. p. 147–147.5°, having an intense blue fluorescence in ultraviolet light.

Synthesis of 10-Methyl-1,2-benzanthracene

Reaction of 1,2-Naphthalic Anhydride with Phenylmagnesium Bromide.—The Grignard reaction was carried out as above and the chief reaction product, **2-benzoyl-1-naphthoic acid,** was isolated in 30% yield. The pure substance melted at 141.8–142.8° (Waldmann[8] and v. Braun[20] report the value 139–140°, uncorr.), and gave β-benzoylnaphthalene, m. p. 82–83°, on decarboxylation. The isomeric **1-benzoyl-2-naphthoic acid,** m. p. 223.5–224.5° (Waldmann,[8] 219–220°, uncorr.), seemed to be present to a greater extent than in the case noted above.

Waldmann[8] obtained these two acids by the Friedel and Crafts condensation of 1,2-naphthalic anhydride with benzene, and he reports that the esterification of 2-benzoyl-1-naphthoic acid with methyl alcohol and hydrogen chloride gave an ester, m. p. 153–154°, uncorr. We prepared the substance by this method (m. p. 156–156.5°) and found that after being refluxed for four hours in benzene–ether with one equivalent of methylmagnesium iodide, no addition occurred and after saponification nearly all of the material was recovered as 2-benzoyl-1-naphthoic acid. The compound therefore is regarded as the lactol ether XI. The true **methyl 2-benzoyl-1-naphthoate,** prepared using diazomethane, was found to react normally with the Grignard reagent. The substance forms slender colorless needles from methyl alcohol, or better from hexane, m. p. 72.5–73.5°.

Anal. Calcd. for $C_{19}H_{14}O_3$: C, 78.60; H, 4.86. Found: C, 78.38; H, 5.16.

Lactone of 2-(α-Hydroxy-α-methylbenzyl)-1-naphthoic Acid.—The reaction of the normal ester with one equivalent of methylmagnesium iodide was conducted as above. No acid was recovered and the yield of purified lactone was 56%. On treating the free acid in benzene–ether with three equivalents of methyl bromide and refluxing for three and one-half hours, no appreciable amount of acid was recovered and the lactone was obtained in a very satisfactory condition in 89% yield. Once recrystallized from benzene–alcohol, the substance formed colorless prisms, m. p. 173.8–174.2°.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.18; H, 5.15. Found: C, 83.49; H, 5.34.

2-(α-Methylbenzyl)-1-naphthoic Acid.—On reducing the lactone with amalgamated zinc and acid in the presence of toluene 33% of the lactone was recovered and 90% of the material consumed was obtained as the acid. Using dilute acetic acid the process was simpler and the yield of acid based on the lactone taken was 74%. The acid gives well-formed prisms from benzene–hexane but these contain solvent which is lost only with difficulty. After drying in vacuum at 60° for three hours the product sintered at 118° and melted at 122–124°, and after two crystallizations from glacial acetic acid it finally formed dense prisms melting at 128–129°. This melting point is reached at once when the solvated material is melted and then crystallized from acetic acid.

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84. Found: C, 82.76; H, 6.32.

10-Methyl-1,2-benzanthracene was prepared from the above acid exactly as described for the higher homolog, the total yield of pure product, collected partly as such and partly as the picrate, being 66%. The hydrocarbon crystallizes from benzene–hexane as long, flat, very nearly colorless needles, m. p. 140.2–140.8°, bright blue fluorescence in ultraviolet light. Slender needles are formed from benzene–alcohol. The picrate separates from benzene as dark red needles, m. p. 173.5–174°.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.17; H, 5.83. Found: C, 94.08; H, 6.03. Picrate, calcd. for $C_{19}H_{14}\cdot C_6H_3O_7N_3$: C, 63.68; H, 3.64. Found: C, 63.47; H, 3.87.

Other Experiments; 5-Methyl-1,2-benzanthracene

2-(*o*-Toluyl)-1-naphthoic Acid with Ethyl- and with Octadecyl-magnesium Bromide.—The reaction of the ester of the above acid with octadecylmagnesium bromide proceeded very poorly and better results were obtained by treating the free acid in benzene–ether with three equivalents of the reagent. In contrast with the experiences above the complex in this case dissolved completely. The

[20] v. Braun, Manz and Reinsch, *Ann.*, **468**, 277 (1929).

material from the neutral fraction of the reaction mixture was refluxed for one hour with alcoholic potassium hydroxide, and from the alkaline extract there was obtained on acidification and crystallization (28% yield) a substance identified as the **lactone of 2-(α-hydroxy-*o*-methylbenzyl)-1-naphthoic acid.** The substance forms colorless, pearly plates from benzene–hexane, m. p. 157–157.8°.

Anal. Calcd. for $C_{19}H_{14}O_2$: C, 83.18; H, 5.15. Found: C, 83.23, 83.16; H, 5.27, 5.32.

From the residue unsaponified in the above treatment there was isolated in small amount a substance having the properties of *n*-hexatriacontane, pearly white plates, m. p. 77–78°.

A reducing action also was observed in the reaction of 2-(*o*-toluyl)-1-naphthoic acid (free acid) with ethylmagnesium bromide (3 equivalents), but in this case some of the normal reaction product also was isolated. The neutral fraction from the reaction mixture was first crystallized from a rather dilute solution in benzene–hexane, when crystals of 2-(α-hydroxy-*o*-methylbenzyl)-1-naphthoic acid lactone were deposited in nearly pure condition and in 34% yield. The material in the mother liquor was recovered and crystallized from alcohol, affording fairly pure **2-(α-hydroxy-*o*-methyl-α-ethylbenzyl)-1-naphthoic acid lactone** in 23% yield. On further crystallization from alcohol the substance formed thin hexagonal plates, m. p. 124–125°.

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.41; H, 6.00. Found: C, 83.24; H, 6.13.

2-(*o*-Methylbenzyl)-1-naphthoic Acid.—This was obtained in 38% yield by the Clemmensen–Martin reduction of 2-(α-hydroxy-*o*-methylbenzyl)-1-naphthoic acid lactone and also, in very poor yield, by the zinc amalgam acid reduction of 2-*o*-toluyl-1-naphthoic acid in acetic acid solution. Attempted reduction with zinc dust and alkali was unsuccessful. The acid forms clusters of small, thick needles from benzene–hexane, m. p. 144–145°.

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84. Found: C, 82.56; H, 6.05.

5-Methyl-1,2-benzanthracene was obtained by cyclization and reduction exactly as described above, the yield of purified product being 78%. Crystallized from benzene–hexane, the hydrocarbon formed fluorescent, colorless plates, m. p. 158.5–159.1°; picrate, m. p. 165.8–166.3°. Cook[12] reports the melting point 157.5–158.5°, uncorr., for the hydrocarbon and 163–163.5°, uncorr., for the picrate.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.17; H, 5.83. Found: C, 93.80; H, 6.20.

Summary

A rather general method is described for the synthesis of substituted 1,2-benzanthracenes, with or without a methyl group at the 10-position, starting with 1,2-naphthalic anhydride (naphthalene-1,2-dicarboxylic anhydride) and an arylmagnesium halide. The methyl group is introduced if desired by the reaction of the free 2-aroyl-1-naphthoic acid with an excess of methylmagnesium bromide. The 5-methyl, 10-methyl and 5,10-dimethyl derivatives of 1,2-benzanthracene have been prepared in this way for comparison with the carcinogenically active 5,10-dimethylene derivative (cholanthrene). Preliminary results of biological tests indicate that 5,10-dimethyl-1,2-benzanthracene has cancer-producing properties and is comparable in potency with methylcholanthrene, cholanthrene and 3,4-benzpyrene.

The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. VII. 5,9-Dimethoxy-1′,3′-diketo-1,2-cyclopentenophenanthrene

BY L. F. FIESER AND E. B. HERSHBERG

In continuation of other work[1,2] it seemed desirable to prepare for bio-assay a methoxylated derivative of the previously described 1′,3′-diketo-1,2-cyclopentenophenanthrene.[2] It was thought that the keto acid I would afford a convenient starting point for the synthesis of such a compound, but, although this acid was obtained in nearly quantitative yield by the condensation of 1,5-dimethoxynaphthalene with succinic anhydride, an unexpected difficulty was encountered in the reduction of the substance with amalgamated zinc and hydrochloric acid, using toluene with or without the addition of acetic acid.[3] Considerable resinification occurred and the desired product of normal reduction (II) was isolated in only 20–25% yield from the distillable material present, although it crystallized well and could be separated readily from more soluble substances. The acid was converted successfully by the sequence of reactions previously described[2] into 5,9-dimethoxy-1′,3′-diketo-1,2-cyclopentenophenanthrene (III), although an unexpected

ether-interchange necessitated the repetition of some of the steps of the process. On boiling 1,5-dimethoxyphenanthrene - 1,2 - dicarboxylic anhydride with ethyl alcoholic hydrogen chloride for conversion to the corresponding diethyl ester, a methyl ⟶ ethyl interchange occurred at one of the two methoxyl groups, probably that located at the more reactive 9-position. This was established by the analyses and by the observation that the diketone obtained differed from the true dimethoxy compound (III) subsequently prepared through the corresponding dimethyl ester.

The Clemmensen reduction of methoxylated keto acids has been observed to proceed rather poorly in certain other cases,[3] but the present reduction appeared exceptional not only because of the very low yield but because the normal reaction product evidently was accompanied by a considerable amount of monomeric material. In the hope of discovering the nature of the side reaction this material was examined carefully and, after some trials, the principal constituent was isolated in a pure, crystalline condition. The substance is acidic, and from the analyses and properties, and from the conversion of the compound by alkaline oxidation into 3-methoxyphthalic acid (V), it can be assigned the structure of γ-(8-methoxytetralyl-1)-butyric acid (IV). While Haberland[4] has reported that the 6-substituted isomer, which he prepared synthetically, is smoothly dehydrogenated by sulfur to the corresponding γ-naphthylbutyric acid, the acid IV on similar treatment gave no crystalline products and the formation of butyric acid was indicated by the odor. Selenium, acting on a crude acid fraction containing IV, gave α-methoxynaphthalene as the only identified product.

The abnormal product of the Clemmensen reduction probably is formed as a result of the primary addition of hydrogen to the conjugated system formed by the carbonyl group and the nuclear double linkages, the elimination of methyl alcohol and the complete saturation of the hydro-aromatic ring occurring at some stage of the process. The mechanism is still obscure. Boiling hydrochloric acid alone slowly attacks the keto acid I with cleavage to 1,5-dimethoxynaphthalene, and consequently it is not likely that the abnormal reduction proceeds through a partially demethylated intermediate. There are no indications that a similar side reaction takes place to an appreciable extent even with similarly constituted compounds. β-*p*-Methoxybenzoylpropionic acid and β-(4-methoxy-1-naphthoyl)-propionic acid give the normal reduction products in 85% and 53% yields,[3] and the by-products are resinous. The reduction of β-(2,6-dimethoxy-1-naphthoyl)-propionic acid was investigated but no by-product comparable with IV was discovered. In view of these observations it is hardly possible to define any general features of structure responsible for the abnormal hydrogenating action noted in this one example of the Clemmensen reduction.

Experimental Part[5]

β-(1,5-Dimethoxy-4-naphthoyl)-propionic Acid.—1,5-Dimethoxynaphthalene was prepared conveniently by methylating the technical dihydroxy compound, distilling the product at 25 mm., and crystallizing the ether from glacial acetic acid. Colorless material melting at 178–180° was obtained in 65–70% yield by weight. A solution of 0.4 mole of the ether and 0.41 mole of succinic anhydride in 400 cc. of tetrachloroethane and 80 cc. of nitrobenzene was cooled and kept at 0 to 5° while adding 0.85 mole of aluminum chloride. After standing at 0° for forty hours, the red-brown solution was poured onto ice and 100 cc. of concentrated hydrochloric acid, the solvent was removed with steam, and the product was precipitated from a sodium carbonate solution after clarification. A pale brown

[5] All melting points are corrected. Analyses by Mrs. G. M. Wellwood.

product, m. p. 168–170°, was obtained in 93% yield. Using three equivalents of aluminum chloride instead of two, the yield of material, m. p. 172–175°, was 98%. Crystallized twice from benzene, the acid formed clusters of small, colorless leaflets, m. p. 175–176°.

Anal. Calcd. for $C_{16}H_{16}O_5$: C, 66.64; H, 5.59. Found: C, 66.33; H, 5.30.

The ethyl ester, obtained in 87% yield by the Fischer method, distilled at 200–210° at about 7 microns without decomposition and separated from ether–petroleum ether as lustrous leaflets, m. p. 53–53.5°.

Anal. Calcd. for $C_{18}H_{20}O_5$: C, 68.31; H, 6.39. Found: C, 68.06; H, 5.82.

Clemmensen Reduction.—In a typical experiment 20 g. of β-(1,5-dimethoxy-4-naphthoyl)-propionic acid was suspended in a mixture of 125 g. of amalgamated zinc, 100 cc. of concentrated hydrochloric acid, 50 cc. of water, 75 cc. of toluene and 5 cc. of glacial acetic acid. The keto acid dissolved after refluxing the mixture for about two hours; the boiling was continued for a total of twenty-five hours, during which time 100 cc. more acid was added in portions. The toluene layer was separated after some cooling and the aqueous layer was diluted and extracted with benzene. After washing the hydrocarbon solution with water, 25 cc. of 6 *N* sodium hydroxide and 50 cc. of water were added, together with 0.5 g. of sodium hydrosulfite, and the solvent was removed with steam. For remethylation the alkaline solution was treated with 13 cc. of dimethyl sulfate, and the solution was then acidified. The crude acid which precipitated was dried in vacuum in a distilling flask and distilled at 3 mm. There was obtained at 200–240° 13.5–14.5 g. of a colorless distillate which partially solidified in the receiver, and a considerable amount of resinous material was left as a residue. The distillate was triturated with about 50 cc. of ligroin, which dissolved some of the oil and left a somewhat oily solid. On dissolving this material in 35 cc. of benzene and adding an equal volume of ligroin there was deposited on cooling 3.9–4.8 g. (20–25%) of γ-(1,5-dimethoxy-4-naphthyl)-butyric acid in a nearly pure condition, m. p. 152–154°. Very little of this acid appeared to be left in the ligroin or benzene–ligroin mother liquors while the by-product was isolated from both sources, as described below.

In other experiments the conditions were varied by doubling the time of refluxing, by using as much as 20 cc. of acetic acid, by substituting 50 cc. of methyl alcohol for this solvent, or by omitting a water-miscible solvent, but there was no material change in the total amount of distillable product or in the yield of the easily isolated normal reduction product. The results also were essentially the same when the ethyl ester of the keto acid was employed.

γ-(1,5-Dimethoxy-4-naphthyl)-butyric Acid (II).—Purified by crystallization from benzene, the acid formed small, glistening, colorless blades, m. p. 154–154.5°.

Anal. Calcd. for $C_{16}H_{18}O_4$: C, 70.07; H, 6.57. Found: C, 69.93; H, 6.95.

The methyl ester, obtained in 94% yield, formed large thin plates from methyl alcohol, m. p. 65–65.5°.

Anal. Calcd. for $C_{17}H_{20}O_4$: C, 70.78; H, 7.01. Found: C, 70.72; H, 7.06.

The ethyl ester (90% yield), b. p. 201–203° (1 mm.), crystallized as thin plates, m. p. 47–47.5°.

γ-(8-Methoxytetralyl-1)-butyric Acid (IV).—This by-product of the Clemmensen reduction was first isolated from the benzene mother liquors remaining after the crystallization of the normal product II resulting from 50 g. of the keto acid. The solution was concentrated to a small volume and diluted with ligroin, and on standing 12 g. of crystalline material separated. After two crystallizations from ligroin, in which it is moderately soluble even when pure, the acid was obtained as thick, colorless plates, m. p. 74.5–75.5°.

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.52; H, 8.14. Found: C, 72.56; H, 8.24.

In earlier experiments the mother liquor remaining after triturating the crude distillate with ligroin was evaporated and the residual oil was fractionally distilled. A fraction taken at 183–184° (1 mm.) apparently contained a considerable amount of the above acid along with other substances (found: C, 73.63; H, 8.47), for on standing for several weeks it partially crystallized, and the solid material after purification was identical with the substance described above.

Attempts to dehydrogenate the tetralin derivative with sulfur at temperatures up to 230° were unsuccessful. No crystalline products were isolated and the formation of butyric acid was evident from the odor. Dehydrogenation with selenium was tried only with a liquid fraction of the crude acid, b. p. 203–204° (3 mm.). Considerable butyric acid was formed, and there was isolated after demethylation a small amount of a substance identified as α-naphthol. At a time when the identity was still in doubt, **1-methyl-4-methoxynaphthalene,** b. p. 164.5–165° (21 mm.) (found: C, 83.55; H, 6.88) was prepared for comparison; its picrate forms red needles from alcohol, m. p. 148–149° (found: N, 10.61).

Evidence of the structure of the acid IV was obtained by exhaustive oxidation of the substance in dilute alkaline solution with potassium permanganate (steam-bath). The manganese dioxide was removed by centrifugation and on acidifying the filtrate a clear solution resulted. (When the oxidation is incomplete a gummy precipitate appears.) The solution was extracted with ether in a continuous extractor, and the residue remaining on evaporation of the ether was sublimed in vacuum and then extracted with water in order to remove oxalic acid. On twice crystallizing the residue from ether, elongated prismatic needles softening at 155° and melting at 160–161° were obtained. The substance did not depress the melting point of 3-methoxyphthalic anhydride prepared from 3-nitrophthalic acid.

5,9 - Dimethoxy - 3,4 - dihydrophenanthrene - 1,2 - dicarboxylic Anhydride.—Ethyl γ-(1,5-dimethoxy-4-naphthyl)-butyrate (14.2 g.) was condensed with ethyl oxalate in the presence of potassium ethylate, following the standard procedure,[1] and the crude oxalyl derivative obtained by acidification and extraction was warmed on the steam-bath with 30 cc. of 70% sulfuric acid and then with 300 cc. of 78% acid. After one to two hours the at first oily product of cyclization became completely solid. After cooling it was collected and washed with acid, water and alcohol. The crude product (6.5 g.) gave satisfactory material on one crystallization from 100 cc. of glacial acetic acid; yield 5.3 g. (36%), m. p. 227–230°. Recrystallized from the same solvent, the anhydride formed carmine-colored needles, m. p. 231–232°.

Anal. Calcd. for $C_{18}H_{14}O_5$: C, 69.66; H, 4.55. Found: C, 69.69; H, 4.62.

Incidentally it was noted that the ester condensation proceeded less satisfactorily using the methyl ester of the starting material (II) and ethyl oxalate. Using methyl oxalate the solubility of the potassium methylate addition compound was so slight that no appreciable reaction occurred on adding the ester of II.

5,9 - Dimethoxyphenanthrene - 1,2 - dicarboxylic Anhydride.—A mixture of 500 mg. of the unsaturated red anhydride and 55 mg. of sulfur was heated at 250–300° for three minutes and the product was distilled at 1 mm. and crystallized from glacial acetic acid. It formed cottony clusters of fine yellow needles, m. p. 288–289°, yield 430 mg. (85%). Recrystallized from dioxane the compound melted at 289–290°.

Anal. Calcd. for $C_{18}H_{12}O_5$: C, 70.11; H, 3.93. Found: C, 69.98; H, 4.24.

Dimethyl 5,9 - Dimethoxy - 3,4 - dihydrophenanthrene - 1,-2-dicarboxylate.—The ester was obtained in 72% yield by refluxing the corresponding anhydride with methyl alcohol saturated with hydrogen chloride for two days. It separated from benzene–ligroin as long, greenish-yellow prisms melting at 151–153° and turning red during the process.

Anal. Calcd. for $C_{20}H_{20}O_6$: C, 67.38; H, 5.68. Found: C, 67.41; H, 5.98.

Dimethyl 5,9 - Dimethoxyphenanthrene - 1,2 - dicarboxylate.—The unsaturated ester described immediately above (500 mg.) was dehydrogenated with sulfur (45 mg.) as described for the anhydride; yield 82%. Recrystallized from methyl alcohol, it formed light greenish-yellow prisms, m. p. 133–134°.

Anal. Calcd. for $C_{20}H_{18}O_6$: C, 67.78; H, 5.12. Found: C, 67.52; H, 5.23.

5,9 - Dimethoxy - 1',3' - diketo - 1,2 - cyclopentenophenanthrene (III).—The above ester (1.15 g.) was refluxed with 8 cc. of ethyl acetate and 0.5 g. of sodium for two hours, and then 5 cc. of ethyl acetate and 0.3 g. of sodium were added and the refluxing was continued for four hours longer. A yellow sodium derivative separated during the process, and after adding 50 cc. of dry ether to the cooled mixture this was collected; additional material was recovered from the ethereal filtrate. Decarboxylation to the diketone was effected by boiling the sodium derivative with dilute hydrochloric acid for a few minutes and the product was crystallized from dioxane; yield 0.56 g. (58%). The fully purified material formed deep yellow needles which softened at about 265° and melted at 281–283° with decomposition.

Anal. Calcd. for $C_{19}H_{14}O_4$: C, 74.49; H, 4.61. Found: C, 74.47; H, 4.91.

A Case of Ether-Interchange.—In an early experiment 5,9-dimethoxyphenanthrene-1,2-dicarboxylic anhydride (3.75 g.) was refluxed for twenty-four hours with 150 cc. of ethyl alcohol saturated with hydrogen chloride, in the expectation of obtaining the corresponding diethyl ester. The crude product (4.29 g.) contained a persistent yellow impurity which was removed after six crystallizations from methyl alcohol, and the product was obtained as thick, colorless needles, m. p. 109.5–110°. Analysis indicated that one of the two phenolic ether groups had been transformed from methoxyl to ethoxyl in the course of the esterification and that the substance obtained is **5(9)-methoxy-9(5)-ethoxy-1,2-dicarbethoxyphenanthrene.**

Anal. Calcd. for $C_{23}H_{24}O_6$: C, 69.67; H, 6.11. Found: C, 69.59, 69.71; H, 6.28, 6.02.

This conclusion was confirmed by conversion of the ester into a phenanthrindanedione as above, for the product (yield 81%) differed from the dimethoxy compound (III) already described and had the composition of **5(9)-methoxy - 9(5) - ethoxy - 1',3' - diketo - 1,2 - cyclopentenophenanthrene.** The substance crystallized from dioxane–alcohol as fine, fluffy, yellow needles, m. p. 207–208°.

Anal. Calcd. for $C_{20}H_{16}O_4$: C, 74.98; H, 5.03. Found: C, 74.61; H, 4.83.

β-(2,6-Dimethoxy-1-naphthoyl)-propionic Acid.—Prepared as above by the Friedel and Crafts reaction in 82% yield, this acid crystallized from benzene as colorless needles which became opaque on drying, m. p. 156–156.5°.

Anal. Calcd. for $C_{16}H_{16}O_5$: C, 66.64; H, 5.59. Found: C, 66.40; H, 5.83.

γ - (2,6 - Dimethoxy - 1 - naphthyl) - propionic Acid.—Clemmensen reduction of 34 g. of the above keto acid by Martin's procedure[3] gave, after remethylation and vacuum distillation, 17.5 g. of crude, solid reduction product, the residue being resinous. Crystallization from benzene gave, in the first crop, 11 g. of the normal reduction product in a nearly pure condition, and evaporation of the mother liquor yielded further crops of the same substance. No trace of a by-product comparable with that obtained in the other series was observed. The acid formed needles from benzene, m. p. 122–124°.

Anal. Calcd. for $C_{16}H_{18}O_4$: C, 70.04; H, 6.61. Found: C, 70.25; H, 6.92.

Summary

The diketone mentioned in the title was synthesized by standard methods and in the course of the work an interesting side reaction was observed to occur in the reduction of β-(1,5-dimethoxy-4-naphthoyl)-propionic acid by the Clemmensen method. In the formation of the abnormal product the ketonic group is reduced as usual, but the aromatic ring to which it is attached is hydrogenated in the course of the reaction and a methoxyl group in the para position is eliminated as well.

The Solubility of Nicotine Silicotungstate in Solutions of Dilute Hydrochloric Acid

BY JOSEPH R. SPIES

In determining small quantities of nicotine by the silicotungstic acid method,[1] it was necessary to know the solubility of nicotine silicotungstate in dilute hydrochloric acid. No exact quantitative data on the solubility of this substance appear in the literature. Bertrand and Javillier[2] first determined the sensitivity of silicotungstic acid as a reagent for nicotine by noting the maximum dilutions at which turbidity could be obtained when solutions of the two substances containing different concentrations of hydrochloric acid were mixed. The maximum sensitivity was obtained in 1–1000 hydrochloric acid, and it decreased with increasing acid concentration. Chapin[3] later used silicotungstic acid for the precipitation of nicotine as the basis of the widely used gravimetric method for its determination. He found that the loss due to the solubility of nicotine silicotungstate was negligible in the macro method.

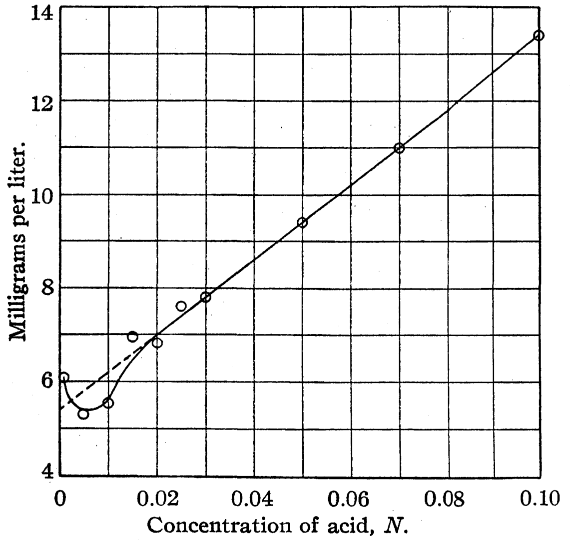

Fig. 1.—Effect of dilute hydrochloric acid on the solubility of nicotine silicotungstate.

The solubility of pure nicotine silicotungstate has been determined at 25 ± 0.02°[4] in distilled water (*p*H 6.5 as determined colorimetrically with brom thymol blue) and in 0.001 to 0.1 *N* hydrochloric acid solutions. The results are summarized in Table I and shown graphically in Fig. 1.

TABLE I

SOLUBILITY OF NICOTINE SILICOTUNGSTATE IN DILUTE SOLUTIONS OF HYDROCHLORIC ACID

Evaporations[a]	Concn. of acid, *N*	Soln. evaporated, ml.	Av. weight of residue, mg.	Av. soly.,[b] mg./liter	Av. deviation from mean ($\Sigma d/N$) mg./liter	Av. deviation from mean ($\Sigma d/N$) %
6	0.10	40	0.543	13.4	0.3	2.2

[a] Two evaporations were made from each saturated solution, and the average weights given in the fourth column are based on the total number of evaporations. [b] Calculated as $SiO_2 \cdot 12WO_3 \cdot 2H_2O \cdot 2C_{10}H_{14}N_2$. Factor = 1.127. The residue (column 4) was corrected for blank (dissolved glass) at the rate of 0.80 mg. per liter for water and 1.70 mg. per liter for 0.1 *N* acid. Intermediate acid concentrations were corrected proportionately. [c] Distilled water, *p*H of 6.5.

The maximum solubility, 38.5 mg. per liter, was found with water, and the minimum between 0.015 and 0.001 *N* acid. The lowest value obtained was 5.30 mg. per liter in 0.005 *N* acid. The results obtained for from 0.015 to 0.1 *N* acid fall on a straight line, the solubility increasing from 6.96 to 13.4 mg. per liter. It is probable that the break in the curve between 0.015 and 0.001 *N* acid is real and not due to experimental error, since the value obtained at 0.01 *N* is 14.5% lower than it would be if it fell on the straight line passing through the other points. The maxi-

(1) While the results of the determinations reported in this paper express the "maximum solubility," or the solubility of pure nicotine silicotungstate in solutions of dilute hydrochloric acid, they also accurately represent the actual amount of nicotine lost in analytical determinations involving only nicotine. From analytical data presented by the author (paper accepted for publication in the *Analytical Edition* of *Industrial and Engineering Chemistry*) the excess (up to ten times) silicotungstic acid used apparently does not produce a detectable decrease in solubility of nicotine silicotungstate. The analytical results also indicate that the usual practice of permitting freshly precipitated nicotine silicotungstate to stand overnight (eighteen hours) to crystallize allows sufficient time for even unstirred solutions to attain equilibrium. The solubility values as determined in this paper, therefore, can be used in applying corrections for lost nicotine in analytical procedures where nicotine alone is present.

(4) The thermometer used, graduated in 0.1°, was checked against a National Bureau of Standards calibrated thermometer.

mum deviation from the mean found in all the other determinations is 5.3% while the average of the deviations is only 1.8%. No explanation is offered for the occurrence of this minimum solubility. It was more difficult to duplicate saturated solutions in water than when acid was present. This is shown in Table I by the greater deviation from the mean in this case.

At acid concentrations below 0.025 *N* the solid phase settled more slowly when stirring was interrupted. In a preliminary study some colloidal particles passed through the fritted-glass filter used to filter off the saturated solutions. These solutions showed a Tyndall cone when examined with a powerful light beam. At higher acid concentrations this difficulty did not occur, as settling was rapid and clear solutions readily were obtained. In the work reported in this paper a porcelain filterstick with a dense filtering surface was used, and the saturated solutions obtained even at concentrations below 0.025 *N* showed no distinct Tyndall cone.

Solutions saturated at 25° were prepared both by cooling solutions saturated at higher temperature and by stirring nicotine silicotungstate with the solvent at 25°. Where more than one saturated solution was prepared at a given acid concentration, both methods generally were used. The close agreement of the results indicates that true equilibrium was attained.

Experimental

Preparation of Nicotine Silicotungstate.—1.26 g. of nicotine[5] (n^{22}_D 1.5241) was dissolved in 700 ml. of 0.086 *N* hydrochloric acid, and 14.2 g. (slight excess) of silicotungstic acid ($4H_2O \cdot SiO_2 \cdot 12WO_3 \cdot 22H_2O$) in 200 ml. of distilled water was added slowly with stirring. After standing twenty hours with occasional stirring, the precipitate was filtered off and washed with dilute hydrochloric acid on the filter. It was stirred up once with dilute hydrochloric acid, filtered, washed and dried by exposure to air at room temperature. The crystalline character of the precipitate was shown by the familiar scintillating effect produced when the solid was stirred with the dilute acid solution, and was verified by microscopic examination.

Anal. Calcd. for $SiO_2 \cdot 12WO_3 \cdot 2H_2O \cdot 2C_{10}H_{14}N_2 \cdot 5H_2O$: C, 7.29; H, 1.28; N, 1.70; $SiO_2 \cdot 12WO_3$, 86.32. Found: C, 7.29, 7.24; H, 1.28, 1.29; N, 1.75, 1.76;[6] $SiO_2 \cdot 12WO_3$, 86.48, 86.28.

Apparatus.—Pyrex glassware was used throughout. To minimize solution of glass each vessel was leached on the steam-bath with dilute hydrochloric acid for several hours before being used. All apparatus used for measurement of solutions was calibrated.

Preparation of Saturated Solutions.—One-tenth gram of nicotine silicotungstate was agitated with 250 ml. of distilled water on the steam-bath in a 1-liter three-necked Pyrex flask equipped with a glass mechanical stirrer. After about five minutes of warming the flask was placed in the constant-temperature bath at 25 ± 0.02° and the solution stirred until cooled to bath temperature. Sufficient constant-boiling hydrochloric acid was then added to give the desired acid concentration. The alternative procedure was to place the nicotine silicotungstate directly in the hydrochloric acid solution without warming. In either case the solutions were stirred for at least twenty hours, which experiment had shown to be ample for the attainment of equilibrium. A 9-cm. porcelain filterstick was used for withdrawal of the saturated solution so that filtration by suction could be made without removing the flask from the constant-temperature bath. The saturated solutions were stored in glass-stoppered Erlenmeyer flasks in the constant-temperature bath.

Evaporation of Saturated Solutions.—Accurately measured volumes, in 10-ml. portions, were pipetted from the flasks into 15-ml. platinum crucibles that had previously been ignited to constant weight at 650°. To protect the crucibles from dust the evaporations were carried out in an electrically heated (95–105°) glass cylinder of 50 mm. diameter to which two glass wells were sealed to hold the crucibles upright. Air was aspirated through the cylinder to remove the water vapor. To avoid contamination by dust the air was filtered through cotton and a fritted-glass plate, respectively, before it entered the evaporation chamber. With this apparatus 10 ml. of water could be evaporated from a crucible in five hours with no danger of spattering or contamination by dust.

Ignition and Weighing of Residue.—When evaporation of the solution was complete, the crucibles were ignited for fifteen minutes in an electric furnace at 646–652°. This procedure was chosen for the following reasons. It is well known that tungstic oxide is appreciably volatile at the temperature attainable with a Meker burner. Platinum also shows sufficient loss of weight to be detectable on the microchemical balance when ignited for ten minutes at this temperature. In view of these facts, and because of the small amounts of oxides of tungsten and silicon weighed, it was necessary to find a temperature at which small quantities of nicotine silicotungstate could be completely ignited without loss in weight of the residual oxides. Experiments in which weighed quantities of nicotine silicotungstate were ignited in platinum crucibles and weighed under conditions simulating those used in the solubility determinations showed 650° to be a suitable temperature.[7] The nicotine silicotungstate was weighed into the platinum crucibles, which contained residues from previous ignitions. After ignition the crucibles were cooled in air for thirty to forty minutes and then weighed. Table II gives the results of some of these experiments.

The residues were weighed on a Kuhlmann microchemi-

TABLE II

IGNITION OF NICOTINE SILICOTUNGSTATE AT 650°

Time of ignition, min.	Nicotine silicotungstate mg.	Residue, mg.	
		Found	Calcd.
15	2.737	2.366	2.363
15	3.172	2.741	2.738
45	2.107	1.818	1.819
45	2.146	1.869	1.852

cal balance the rider of which was checked against a 10-mg. weight calibrated by the National Bureau of Standards. The tares were adjusted so as to avoid the use of fractional weights. Since weighings were by difference and were sometimes made several days apart, it was necessary to use similar platinum crucibles for tares to eliminate errors due to change in pressure, temperature and humidity. The use of the usual glass lead-shot tares was found to introduce an appreciable error due to these causes. Throughout the experiments the crucibles were handled with platinum-tipped forceps.

The Distilled Water.—Stock distilled water was carefully redistilled into a leached 12-liter flask, with the use of a block-tin condenser. When about half the determinations had been made, blanks were run on the water alone and with 0.1 normal solutions of the hydrochloric acid used. The procedure and apparatus were the same as were used in the preparation of the saturated solutions. On the basis of three runs each, the values of the blanks were 0.80 ± 0.14 mg. per liter for the water and 1.70 ± 0.14 mg. per liter for the acid. The amount of the correction for dissolved glass was applied in proportion to the acid concentration of the solvent.

The author wishes to acknowledge the interest of Nathan L. Drake in this work.

Summary

The solubility of nicotine silicotungstate in water and in 0.001 to 0.1 *N* hydrochloric acid solutions has been determined. The maximum solubility, 38.5 mg. per liter, is found in water and a minimum of 5.30 mg. per liter in 0.005 *N* hydrochloric acid. The solubility increases from 6.96 mg. per liter in 0.015 *N* acid to 13.4 mg. per liter in 0.1 *N* hydrochloric acid.

The Mechanism of Carbohydrate Oxidation. XXIII.[1] A Contribution to the Alkaline Hydrolysis of Oligosaccharides[1a]

BY HARRY GEHMAN, LEONARD C. KREIDER AND WM. LLOYD EVANS

After studying the action of aqueous potassium hydroxide on maltose (4-α-glucosidoglucose) to form lactic acid, Benoy[2] and one of us came to the conclusion that the hexose (reducing) portion of the molecule was first degraded by the alkali to form the following fragments: formaldehyde, glycolaldehyde and 2-glucosidoerythrose. Hydrolysis of the latter was then assumed to occur to produce glucose and erythrose. As it was quite certain from previous work[3] that formaldehyde, glycolaldehyde and erythrose would produce no lactic acid in alkaline solution, it was probable that when maltose was degraded by alkali the entire reducing half of the molecule was lost to lactic acid production. The hexosido-(non-reducing) portion, being released by hydrolysis as glucose, should then produce lactic acid as glucose was known to do. The fact that a solution of maltose (0.25 *M*) yielded approximately half as much lactic acid as was obtained under identical conditions from an equivalent amount of glucose (0.50 *M*) lent considerable weight to this argument.

Later in a similar study of the alkaline degradation of cellobiose (4-β-glucosidoglucose) and lactose (4-galactosidoglucose) Hockett[4] and one of us showed that these disaccharides also yielded only such amounts of lactic acid as would have been expected from their hexosido (non-reducing) portions alone.

The 6-hexosidohexoses, like gentiobiose (6-glucosido-glucose) and melibiose (6-galactosidoglucose), present a different type of behavior, for here the amount of lactic acid produced is considerably greater than that expected from the hexosido portion of the molecule alone. This was explained by pointing out that the reducing portion of these molecules contributed a part of the lactic acid. Simultaneous with the degradation

of the reducing half of the molecule, or following it, hydrolysis would liberate the non-reducing half and make it subject to alkaline degradation so it too could make its normal contribution of lactic acid to the total.

This paper offers a mechanism for the alkaline hydrolysis postulated above and presents additional evidence to support and extend the previous theories[2,4] of the action of alkali on oligosaccharides. The use of the recently synthesized glucosidodihydroxyacetone pentaacetate,[5] cellobiosidodihydroxyacetone octaacetate,[5] and gentiobiosidodihydroxyacetone octaacetate[5] was invaluable in the latter phase of this work.

Experimental Part

Carbohydrate Materials.—Glucosidodihydroxyacetone pentaacetate, gentiobiosidodihydroxyacetone octaacetate, and cellobiosidodihydroxyacetone octaacetate were prepared according to directions already published.[5] Dihydroxyacetone monoacetate,[6] cellobiose octaacetate, lactose octaacetate,[7] and glucose pentaacetate, were specimens prepared in the conventional ways and recrystallized until pure. The gentiobiose octaacetate was obtained from The Laboratory Products Co., Cleveland, Ohio.

Analytical Procedure.—The general procedure outlined by Nadeau, Newlin and Evans[8] was followed for the isolation of the lactic acid. The use of acetylated sugars necessitated a normality correction due to the neutralizing action of the acetyl groups and also to the greater expansion of the reaction mixture in these cases. The normalities of alkali reported are corrected values. A nitrogen atmosphere was also used in the reaction flasks instead of an air atmosphere as had formerly been customary. All the work was carried out at a temperature of 50°. The amount of carbohydrate material and volume of alkali used to degrade it are as follows: glucosidodihydroxyacetone pentaacetate, 1.4443 g. (0.25 *M*) in 12.5 cc. KOH; glucose tetraacetate, 1.0878 g. (0.25 *M*) plus dihydroxyacetone monoacetate, 0.4125 g. (0.25 *M*) in 12.5 cc. KOH; glucose pentaacetate, 2.4375 g. (0.50 *M*) in 12.5 cc. KOH; gentiobiose, 1.0687 g. (0.25 *M*) in 25.0 cc. KOH;[4] β-gentiobiose octaacetate, 1.6957 g. (0.20 *M*) in 12.5 cc. KOH; β-gentiobiosidodihydroxyacetone octaacetate 1.5002 g. (0.20 *M*) in 10.0 cc. KOH; β-cellobiose octaacetate, 1.6957 g. (0.20 *M*) in 12.5 cc. KOH; β-cellobiosidodihydroxyacetone octaacetate, 1.8760 g. (0.20 *M*) in 12.5 cc. KOH; gentiobiose octaacetate 1.6957 g. (0.20 *M*) plus dihydroxyacetone monoacetate, 0.3302 g. (0.20 *M*) in 12.5 cc. KOH; β-cellobiose octaacetate, 1.6957 g. (0.20 *M*) plus dihydroxyacetone monoacetate, 0.3302 g. (0.20 *M*) in 12.5 cc. KOH; glucose pentaacetate, 1.56 g. (0.40 *M*) plus dihydroxyacetone monoacetate, 0.3302 g. (0.20 *M*) in 12.5 cc. KOH; glucosidodihydroxyacetone pentaacetate, 0.924 g. (0.20 *M*) plus glucose pentaacetate, 0.78 g. (0.20 *M*) in 10.0 cc. KOH; β-lactose octaacetate 2.197 g. (0.25 *M*) in 12.5 cc. KOH.

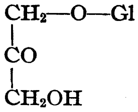
The isolation of non-volatile saccharinic acids other than lactic acid was carried out according to the procedure outlined by Plunkett.[9]

Experimental Results.—The quantitative data obtained in this work are shown in graphical form in Figs. 1 to 6. The lactic acid yields in moles per mole of sugar used are plotted as functions of the corrected alkali normalities.

Theoretical Part

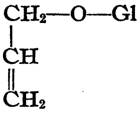
The hydrolysis of glucosides and oligosaccharides usually is achieved with dilute acid and by the aid of enzymes in a neutral solution. Hydrolysis in an alkaline medium has been reported in relatively fewer instances, and hence it is not so well known. The evidence obtained from the action of aqueous alkali on certain disaccharides was of such a nature as to compel Benoy,[2] Hockett[4] and one of us to postulate alkaline hydrolysis during the alkaline degradation of the carbohydrates studied, and results reported here are in complete harmony with this view.

The following comparison of certain of our experimental data is of much interest in connection with the main purposes of this paper. Since glucosidodihydroxyacetone (I) yields lactic acid in alkaline solution, while allyl glucoside (II) does not produce this acid under the same conditions, an explanation for this difference in chemical behavior of these two compounds was sought in some possible change in molecular structure which one of them might undergo in alkaline solutions. If (I) is written in the customary *keto*-form it is evident that the structure of both compounds is the same at the glucosidic link



$$\begin{array}{l} \text{CH}_2\text{—O—Gl} \\ | \\ \text{CO} \\ | \\ \text{CH}_2\text{OH} \end{array}$$

(I)



$$\begin{array}{l} \text{CH}_2\text{—O—Gl} \\ | \\ \text{CH} \\ \| \\ \text{CH}_2 \end{array}$$

(II)

and hence alkaline hydrolysis would be expected in both cases if it were known to occur in either one. From our experimental results it was concluded that glucosidodihydroxyacetone in alkaline solution must possess a different structure at the glucosidic link than does allyl glucoside. If glucosidodihydroxyacetone should undergo enolization in alkaline solution[10] a possible enolic iso-

mer would be 1-triosenediol glucoside, a change which may be shown as follows

(A) 
$$\begin{array}{l} CH_2{-}O{-}Gl \\ | \\ CO \\ | \\ CH_2OH \end{array} \rightleftarrows \begin{array}{l} H{-}C{-}OGl \\ \| \\ C{-}OH \\ | \\ CH_2OH \end{array}$$

It may then be assumed that 1-triosenediol glucoside undergoes hydrolysis as shown by the equation

$$\text{(B)}\quad CH_2OHC(OH){=}CHOGl + HOH \longrightarrow CH_2OHC(OH){=}CHOH + C_6H_{12}O_6$$

Both the triosenediol and glucose thus formed are sources of lactic acid. Since allyl glucoside does not yield lactic acid under our experimental conditions, it is to be concluded that hydrolysis did not take place, *i. e.*, there was no structural opportunity for isomerization to yield an enolic form.

For these reasons the authors examined the literature to ascertain whether certain given types of compounds existed which would undergo alkaline hydrolysis, and on the other hand whether certain other definite types would resist such hydrolysis. The reduction of heated Fehling's solution was accepted as a criterion of hydrolysis in the absence of direct statements, or other experimental evidence that was decisive, such as the production of lactic acid. This statement would of necessity assume that the aglycone was inactive toward the oxidizing solution. Our examination makes it fairly certain that the literature of alkaline hydrolysis is not yet sufficiently understood to justify a conclusive statement concerning the existence of sharply defined classes of compounds that on the one hand undergo alkaline hydrolysis, while another group resists this action. The following facts verify this point of view. (a) Methyl,[11] ethyl,[11] glycol,[11] propyl[12] and benzyl[13] glucosides and trehalose[14] are representatives chosen from a large number of similar compounds that undergo no hydrolysis in aqueous alkali. In our experiments we found that methyl, glycol and allyl glucosides, and trehalose, when treated with aqueous solutions of potassium hydroxide (4.0 *N* and above) for forty-eight hours at 50°, yielded no lactic acid. These results confirm the absence of hydrolysis in these cases. It should be noted that all of these compounds cannot isomerize to an enolic form as given above for glucosidodihydroxyacetone. (b) There are other glycosides that contain a still different type of an aglycone, some of which undergo alkaline hydrolysis while others do not. Helferich and Kühlewein[15] found that the glycosides of theophylline (galactose, glucose and arabinose), chlorotheophylline *d*-glucoside, tetraacetyl-trichloropurine *d*-glucoside, dichloroadenine *d*-glucoside did not reduce Fehling's solution, while the glycosides of theobromine (galactose and glucose), and tetraacetylhydroxycaffeine *d*-glucoside did reduce the same reagent. In those cases where reduction took place, the compound could be isomerized to contain the group $N{=}\underset{|}{C}{-}O{-}Gl$, while in the cases where no reduction occurred the glycosidic portion reacted with the purine compound to form the link N–C, thus excluding the possibility of isomerization after the manner indicated above. Fischer and Helferich[16] found that theobromine glucoside is decomposed by water into its components at ordinary temperature in the course of a few hours. Levene and Sobotka[17] report that tetraacetylhydroxycaffeine was found so unstable that it could not be deacetylated at all without opening the purine linkage. (c) The phenolic glycosides present much interest in this connection. Helferich and Schmitz-Hillebrecht[18] found that the acetylated glucosides of phenol, α- and β-naphthol, methyl arbutin, guaiacol and α- and β-galactosides of phenol and certain other similar glycosides reduce Fehling's solution. On the other hand Helferich and Winkler[19] report that tetraacetyl-phenol-β-*d*-mannoside would not reduce Fehling's solution without previous acid hydrolysis. In the phenolic glycosides we find the group ${=}\underset{|}{C}{-}O{-}Gl$, which was postulated to form in alkaline solutions of compounds possessing the structure which would yield the enolic isomer, and hence were expected to undergo hydrolysis.

More recently Gardner and his collaborators[20] have made a study of hydrolysis of α-hydroxyanthraquinone β,*d*-glucoside and β,*d*-arabinoside,

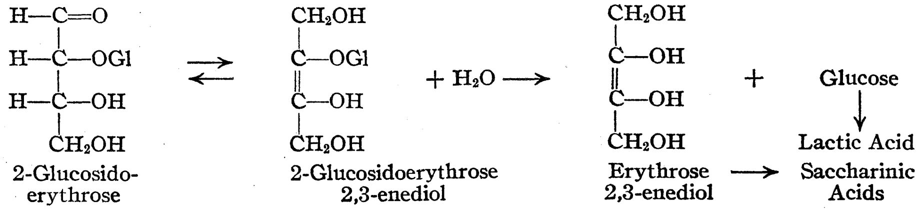
1,5- and 1,8-dihydroxyanthraquinone glucoside, and β-hydroxyanthraquinone β,*d*-glucoside in aqueous solutions of potassium hydroxide, borax and hydrochloric acid. These compounds were found to undergo hydrolysis in the three reagents chosen. (d) In striking contrast to the resistance toward alkaline hydrolysis of certain compounds noted in (b) that contain the group N–C at the purine–glycosidic union is the behavior observed by Maurer[21] and Scheidt[21] of certain glycosides of amino acid esters which were found to undergo hydrolysis in alkaline solutions.

It is evident from this brief survey that it is possible for alkaline hydrolysis of *oligosaccharides* to occur in molecules where the biosidic link exists either in the form $\mathrm{Gl{-}O{-}\underset{|}{C}{=}}$, or where the structure can be transformed by the alkaline medium to assume that arrangement.

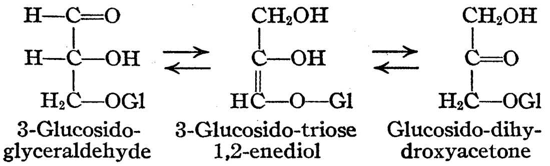
Such a structure could be induced in the fragment 2-glucosidoerythrose, which was postulated as an intermediate in the alkaline degradation of maltose[2] and of cellobiose.[4] The reactions that probably take place are shown in the following

(C)

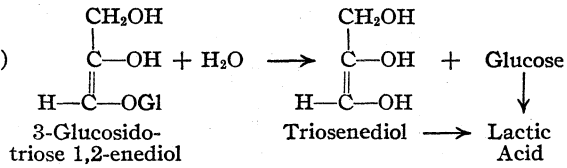


In like manner the various fragments postulated in the degradation of disaccharides of the gentiobiose type[4] could undergo enediolization to form the grouping $\mathrm{Gl{-}O{-}\overset{|}{C}{=}}$ which will then permit hydrolysis in the alkaline medium to liberate the non-reducing portion to the attack of the alkali. For example, if gentiobiose should fragment as postulated[4] to yield glyceraldehyde and 3-glucosidoglyceraldehyde, the latter could undergo the following reactions culminating in an alkaline hydrolysis to form glyceraldehyde and glucose as shown in following reactions

(D)



(E)



The actual isolation of the monosaccharides set free in such an hydrolysis is not possible when working with the stronger alkaline solutions. However, Lobry du Bruyn and Alberda van Ekenstein,[22] using much weaker alkalies, isolated galactose from lactose (4-galactosidoglucose) solutions, but obtained no glucose. This result was a reasonable one because the latter undoubtedly was partially degraded before the alkaline hydrolysis occurred.

Discussion of Experimental Data

Glucosidodihydroxyacetone and Gentiobiose.—From previous studies of the action of alkali on gentiobiose,[4] it was assumed that the reducing half of the molecule was the first to suffer degradation. This action produced fragments of two types: (1) those that form monosaccharides, and (2) those that result in the formation of disaccharides. By the action of alkalies on the monosaccharides so formed, glycol aldehyde yields no lactic acid, the triose gives much lactic acid, and the tetrose no lactic acid. Of the possible disaccharides, 5-glucosidopentose, 3-glucosidotriose and glucosidoglycol aldehyde, the 3-glucosidotriose yields much lactic acid. The newly formed disaccharides could then suffer a similar degradation in the reducing portion of their molecules, or they could undergo alkaline hydrolysis according to the mechanism outlined above. Reactions D and E may be considered the steps in a typical example of such an hydrolysis. The glucose thus liberated could then undergo fragmentation in the presence of alkali with the resulting production of lactic acid.

An experimental study of the amounts of lactic acid produced by the alkaline degradation of the

[22] Lobry du Bruyn and Alberda van Ekenstein, *Rec. trav. chim.*, **18**, 147 (1899).

individual disaccharide fragments should yield important data regarding the mechanism of the alkaline degradation of gentiobiose itself. One of these compounds, a glucosidotriose, is now available for study in the recently prepared glucosidodihydroxyacetone pentaacetate.[4] In discussing Fig. 1 three cases will be noted.

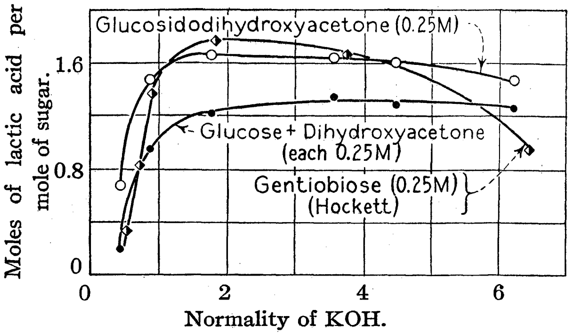

Fig. 1.—A comparison of the lactic acid yields obtained from 0.25 *M* solutions of glucosidodihydroxyacetone with those of a mixture of glucose and dihydroxyacetone, and with those of gentiobiose in the presence of potassium hydroxide at 50°.

(a) This keto sugar should react in alkaline solution in accordance with Reaction D to produce the corresponding aldo sugar, 3-glucosidoglyceric aldehyde,[23] one of the postulated intermediates formed in the alkaline degradation of gentiobiose. If the remaining fragments obtained from the gentiobiose molecule consisted chiefly of formaldehyde and glycol aldehyde, the yields of lactic acid from glucosidodihydroxyacetone at different alkalinities should be approximately the same as those obtained from gentiobiose itself provided the concentration of this glucosidotriosenediol in this very complex mixture were the same in both cases. From Fig. 1 it may be fairly concluded that at alkalinities below 1 *N* gentiobiose molecules have not undergone a sufficient degree of fragmentation to yield a concentration of the glucosidotriosenediol molecules at a given alkalinity equal to that produced by the glucosidodihydroxyacetone used. (b) At favorable alkalinities, it is conceivable for the gentiobiose molecules to undergo fragmentation in the direction of yielding one molecule each of 3-glucosidoglyceric aldehyde and glyceric aldehyde. Since glyceric aldehyde itself is also a source of lactic acid, the total yield of this acid under these conditions may be greater than in the previous case, provided the degree of fragmentation of the gentiobiose molecules is sufficiently great to furnish the required concentration of the enediolic isomers of glyceric aldehyde and of the glucosidoglyceric aldehyde necessary for this purpose. This explanation would account for the greater yields of lactic acid from gentiobiose between 1.2 and 4 *N* (Fig. 1) than those from glucosidodihydroxyacetone in the same alkaline range. (c) If at the highest alkalinities the fragmentation of gentiobiose molecule yields a tetrose and glucosidoglycol aldehyde the yields of lactic acid should tend toward that obtained from the glucose molecule (a hydrolytic product) under the same conditions. It will be shown later that in addition to the effect of such a postulated fission on the yields of lactic acid produced in these cases, the formation of saccharinic acids exercises a marked influence in this connection.

The assumption that glucosidoglyceric aldehyde is a possible intermediate in the alkaline degradation of gentiobiose seems justified by the discussion set forth above concerning the experimental facts presented in Fig. 1. Unfortunately, the other disaccharide fragments have not yet been synthesized in a pure form, so that they too could be tested for lactic acid production. However, by making use of the accumulated experience of previous workers,[2,4,24] we can predict with a fair degree of assurance that the glucosidobioses will yield about the same amount of lactic acid as their constituent glucose portions alone would produce and that glucosidotetroses and glucosidopentoses would probably yield somewhat more lactic acid than their constituent glucose portions.

Glucosidodihydroxyacetone and Cellobiosidodihydroxyacetone.—Benoy,[2] Hockett,[4] and Evans postulated that in the alkaline degradation of 4-glucosidoglucoses, such as maltose and cellobiose, the reducing section of the molecule would decompose into fragments which were not sources of lactic acid, while the hexosido portion of the disaccharide molecule was the only available source of this acid. The recent syntheses[5] of glucosidodihydroxyacetone pentaacetate and cellobiosidodihydroxyacetone octaacetate has made it possible to test this assumption in a very simple manner.

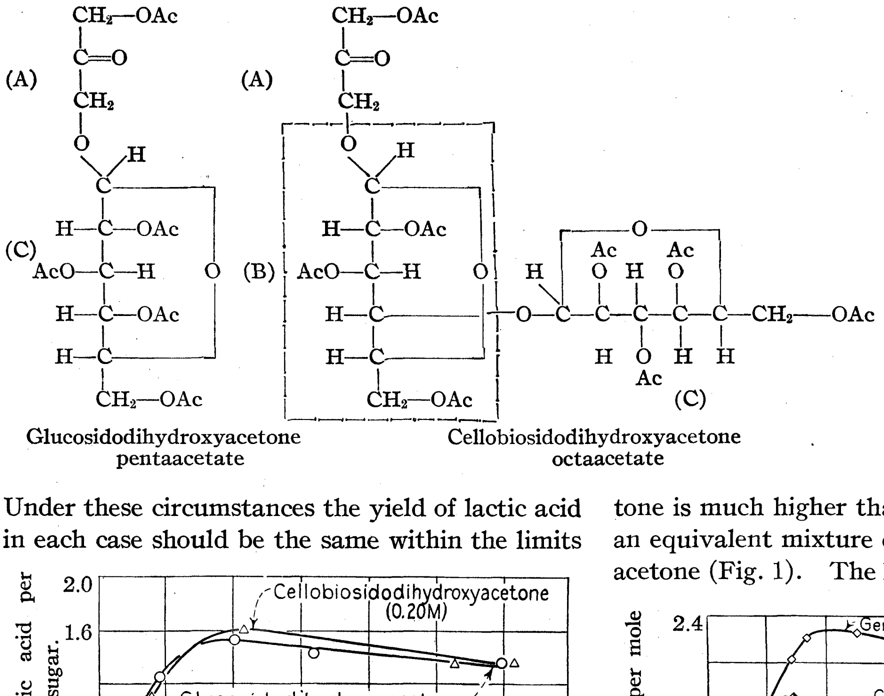
If glucosidodihydroxyacetone pentaacetate undergoes alkaline hydrolysis in the manner indicated in Reactions D and E, two lactic acid producing compounds, namely, dihydroxyacetone

---

[23] L. C. Kreider and W. L. Evans, THIS JOURNAL, **57**, 229 (1935).

[24] W. L. Evans, *Chem. Rev.*, **6**, 281 (1929).

and glucose, would be formed in the reaction mixture. If cellobiosidodihydroxyacetone octaacetate were subjected to the same treatment under the same experimental conditions, dihydroxyacetone and glucose derived from the hexosido section of the molecule would be present in the reaction mixture in addition to the non-lactic acid producing fragments into which the hexose section of the molecule was decomposed. Thus it is seen that both systems would contain the same common lactic acid sources. A comparison of the structural formulas of these two carbohydrates will make this point more clear. The monosaccharide sections designated A and C produce lactic acid when degraded by alkali, while section B produces no lactic acid under the same conditions.[4]



Glucosidodihydroxyacetone pentaacetate

Cellobiosidodihydroxyacetone octaacetate

Under these circumstances the yield of lactic acid in each case should be the same within the limits of experimental error. This is shown to be the case in Fig. 2.

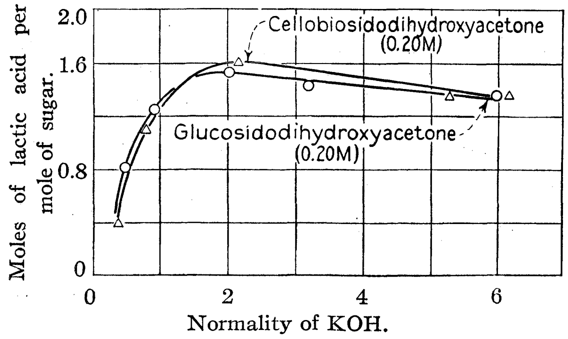


Fig. 2.—A comparison of the lactic acid yields obtained from 0.20 M solutions of glucosidodihydroxyacetone with those of cellobiosidodihydroxyacetone in the presence of potassium hydroxide at 50°.

Cellobiosidodihydroxyacetone and Gentiobiosidodihydroxyacetone.—In Fig. 3 we note that gentiobiose (0.20 M) produces between 0.5 and 0.6 mole more lactic acid at the maximum than does cellobiose (0.20 M). Since a comparable difference exists between the gentiobiosidodihydroxyacetone and the cellobiosidodihydroxyacetone it is evident that whatever may be the mechanism of the fragmentation of these molecules its effects on the parent disaccharides are analogous. The degradation proceeds so that the cellobiosidic portion reacts as cellobiose and the gentiobiosidic portion reacts as gentiobiose. This is evidence that the mechanism of break at the oxygen link connecting the dihydroxyacetone is such that the non-reducing portions of the residual disaccharides are not disturbed until after their hydrolysis has taken place, and that all alkaline degradations originate at the reducing regions only.

Relative Yields of Lactic Acid from Oligosaccharides and their Hydrolytic Fractions.—The lactic acid yields from these oligosaccharides can be shown to differ markedly from those of their possible hydrolytic fractions. The yield of lactic acid from glucosidodihydroxyacetone is much higher than the yield obtained from an equivalent mixture of glucose plus dihydroxyacetone (Fig. 1). The lactic acid produced by the

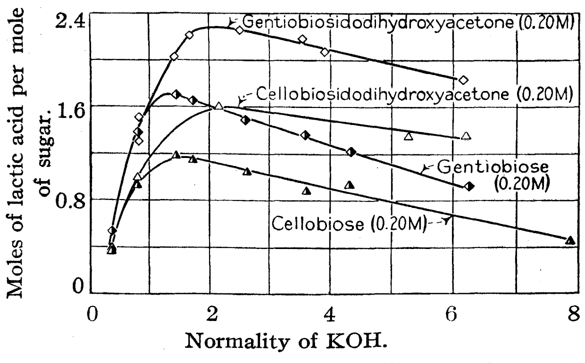

Fig. 3.—A comparison of the lactic acid yields obtained from 0.20 M solutions of gentiobiosidodihydroxyacetone with those of gentiobiose, and cellobiosidodihydroxyacetone with those of cellobiose in the presence of potassium hydroxide at 50°.

alkaline degradation of cellobiosidodihydroxyacetone differs greatly from the possible hydrolytic products that might be formed (Fig. 4). In the same way there is an absence of any correlation between the lactic acid yields obtained from gentiobiosidodihydroxyacetone and from any of its possible hydrolytic products is shown in Fig. 5. These facts can best be interpreted as evidence that, in general, oligosaccharides do not hydrolyze immediately and entirely when they are placed in alkali, but rather that hydrolysis is a relatively slow process and is probably preceded by a partial alkaline degradation of the reducing end of the molecule. It should also be pointed out that the possible hydrolytic fractions and their degradation products tend to undergo rearrangements in alkaline solutions to form their respective saccharinic acids, thus proportionally reducing the yields of lactic acid, which itself may be considered the saccharinic acid of the trioses.

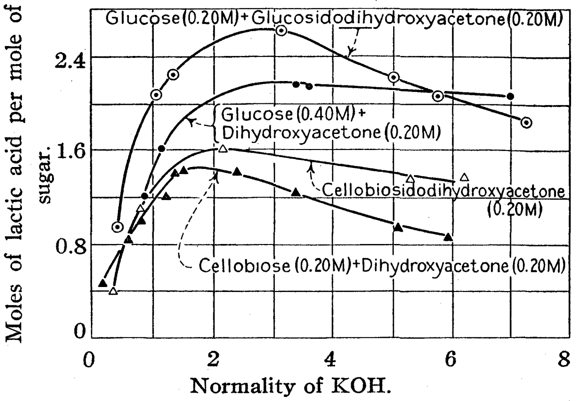

Fig. 4.—A comparison of the lactic acid yields obtained from 0.20 *M* solutions of cellobiosidodihydroxyacetone in the presence of potassium hydroxide at 50° with mixtures of its theoretically possible saccharidic components.

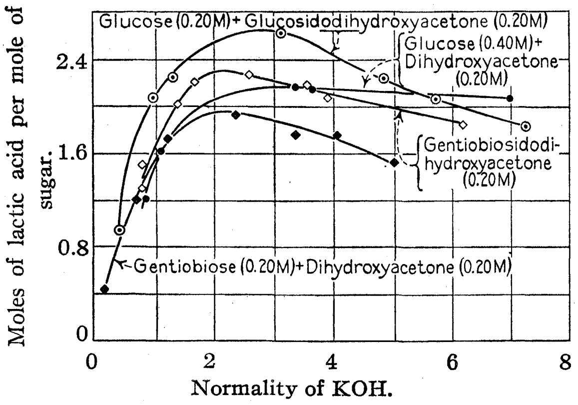

Fig. 5.—A comparison of the lactic acid yields obtained from 0.20 *M* solutions of gentiobiosidodihydroxyacetone in the presence of potassium hydroxide at 50° with mixtures of its theoretically possible saccharidic components.

The yields of lactic acid obtained from glucosido-dihydroxyacetone, cellobiosidodihydroxyacetone, and gentiobiosidodihydroxyacetone are in general greater than those obtained from mixtures simulating the products obtained in the first step in the alkaline hydrolysis of these oligosaccharides, *i. e.*, glucose and dihydroxyacetone, cellobiose and dihydroxyacetone, and gentiobiose and dihydroxyacetone, respectively (Figs. 1, 4 and 5). In the case of mixtures representing other possible hydrolytic reactions, the yields of lactic acid tend to be higher than those obtained from the oligosaccharide itself.

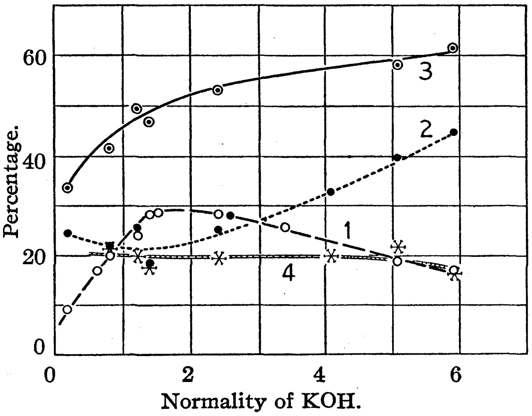

Fig. 6.—A comparison of the lactic acid and saccharinic yields obtained from a mixture of cellobiose octaacetate (0.20 *M*) and dihydroxyacetone monoacetate (0.20 *M*) in the presence of potassium hydroxide at 50°: 1, percentage of the sugars returned as lactic acid; 2, percentage of the sugars returned as saccharinic acids other than lactic acid; 3, total saccharinic acids recovered; 4, zinc oxide content of the salts obtained in 2.

The much slower release of the carbohydrate material of the parent oligosaccharide into the alkali sensitive hydrolytic portions makes possible a more efficient formation of lactic acid. This result is in agreement with an earlier observation of Shaffer and Friedemann[25] concerning the effect of the concentration of sugar molecules on the yields of lactic acid.

Lactose (4-Galactosidoglucose).—The use of an improved technique enabled us to obtain well crystallized zinc lactate in small amounts from

---

(25) P. A. Shaffer and T. E. Friedemann, *J. Biol. Chem.*, **86**, 345 (1930).

the alkaline degradation of this sugar. Lactose being a disaccharide linked in the same fashion as cellobiose, it was expected that its lactic acid yields plotted on a molar basis should closely approximate those of galactose just as those of cellobiose[4] and maltose[2] approximate those of glucose. This was found to be true.

Non-volatile Saccharinic Acids Other than Lactic Acid.—The materials extracted at this stage were found to be distinctly salt forming in nature with the zinc oxide content of these salts varying widely according to the carbohydrate source. As stated above it is reasonable to assume that the formation of these other saccharinic acids occurs at the expense of lactic acid formation so that a reciprocal relationship with the latter would be established. This condition was not always realized experimentally, but Fig. 6 shows the results from the cellobiose octaacetate and dihydroxyacetone monoacetate mixture. The acids involved here are undoubtedly of varying carbon content.

The zinc oxide content of the acids obtained in the case mentioned above remains constant at about 20% (approximately that required for a 6-carbon saccharinic acid). However, in some cases the cellobiosidodihydroxyacetone, for example, these salts showed a regular rise from about 10% zinc oxide content at the lower alkalinities to that required for the C_6 acids. Undoubtedly the lower zinc oxide indicates the formation of glycosidic saccharinic acids, the lactic acid yields always being low in these cases. The method used here for their isolation was not such as to permit their identification, a feature of the work that should be investigated further. It was not possible to account for 100% of the sugar because of its removal by decolorizing agents of tars which probably consist of polymeric acetol, formaldehyde, and condensed forms of other carbonyl compounds. The formation of acetic and formic acids in the alkali reactions is well known.

Summary

1. Following the interpretation of Benoy,[2] Hockett and Evans[4] for the alkaline degradation of reducing disaccharides, a mechanism has been proposed for the alkaline hydrolysis of the theoretically possible intermediates that may form. These intermediates are assumed to form glucosidic enediols that in turn are hydrolyzed to glucose and an enediol which in the case of triosenediol is converted to lactic acid, and in that of tetrosenediol is converted to the corresponding saccharinic acids. The glucose released in the hydrolysis is also a source of lactic acid.

2. A comparative study of the lactic acid yields obtained from gentiobiose and glucosidodihydroxyacetone justifies the assumption that the corresponding glucosidoaldotriose, 3-glucosidoglyceric aldehyde, is a fragmentation product of gentiobiose in alkaline solution.

3. A comparative study of the lactic acid yields obtained from alkaline solutions of glucosidodihydroxyacetone and cellobiosidodihydroxyacetone confirms[2,4] the view that the hexosido section of the 4-hexosidohexoses is the source of the lactic acid and not the hexose section.

4. A comparative study of the yields of lactic acid obtained from gentiobiosidodihydroxyacetone and gentiobiose, and also those from cellobiosidodihydroxyacetone and cellobiose confirms the general view expressed in 3.

5. The yields of lactic acid obtained from mixtures of the possible hydrolytic products of the oligosaccharides investigated are greater than those from the parent carbohydrate in each case except in those instances involving the release of dihydroxyacetone as the first step in these alkaline hydrolyses. This may be ascribed either to a slow degradation of the oligosaccharides, or to the concurrent rearrangements taking place with the resulting formation of saccharinic acids, or both.

6. A study of alkaline solutions of varying normalities which contained a mixture of cellobiose octaacetate and dihydroxyacetone monoacetate shows that there is a definite relation between the yields of lactic acid obtained and those of the saccharinic acids.

Stereochemical Relationships of the Isomeric 2,3-Butanediols and Related Compounds; Evidence of Walden Inversion

BY CHESTER E. WILSON AND HOWARD J. LUCAS

This investigation has been undertaken for the purpose of synthesizing *cis*- and *trans*-2-butene in a pure state and of studying the Walden inversion. Incidentally, the work has constituted an independent confirmation of the observation that the butene produced in the dehydration of 1-butanol in the presence of sulfuric acid is approximately 68% *trans*-2-butene and 32% *cis*-2-butene.[1] The reliability of this result has been questioned,[2] on the basis that the dibromide method of analysis[3] is faulty.[4] This confirmation rests upon the observation that *cis*-2-butene is converted through the chlorohydrin to *cis*-2,3-epoxybutane and that the crude epoxybutane mixture obtained from the crude butene mixture is approximately 65% *trans*-2,3-epoxybutane and 35% *cis*-2,3-epoxybutane, with little or no 1,2-epoxybutane.

The Method of Synthesis.—This is outlined below: 1-butanol $\xrightarrow{-H_2O}$ 2-butenes $\xrightarrow{HOCl}$ 3-chloro-2-butanols $\xrightarrow{-HCl}$ 2,3-epoxybutanes $\xrightarrow{distn.}$ *cis* (or *trans*)-2,3-epoxybutane $\xrightarrow{H_3O^+}$ *dl* (or *meso*)-2,3-butanediol $\xrightarrow{Ac_2O}$ *dl* (or *meso*)-2,3-butanediol diacetate $\xrightarrow{HBr}$ *meso* (or *dl*)-2,3-dibromobutane $\xrightarrow{Zn}$ *trans* (or *cis*)-2-butene. The butene mixture from the decomposition of 1-butanol was converted into a mixture of chlorohydrins and this into a mixture of epoxybutanes by hot potassium hydroxide solution. Fractionally distilling the oxides is more satisfactory than distilling the butenes because the former are liquids, whereas the latter are gases, and because the difference in boiling points of the isomeric 2,3-epoxybutanes is 6°, whereas it is 2.7° for the isomeric 2-butenes. Each oxide, contaminated with a small amount of its stereoisomer, was hydrated to a 2,3-butanediol, which could be purified from the small amount of its diastereomer by crystallization. Conversion of the glycol to its diacetate afforded another opportunity for purification, especially in the case of the lower melting (liquid) glycol, for its diacetate is a solid. Each pure diacetate was converted into a pure 2,3-dibromobutane by saturated, aqueous hydrobromic acid. The dibromides are known to yield the isomeric 2-butenes.[5]

A necessary condition of obtaining pure compounds at the different steps is the avoidance of racemization, that is, there must be, at each asymmetric carbon atom, either zero or 100% Walden inversion. Fortunately, under the conditions employed, this condition held. No attempt was made to modify conditions so as to bring about racemization.

Possibility of Walden Inversions.—An odd number of Walden inversions are involved, starting with a pure 2-butene and passing, through the changes outlined above, to a pure 2-butene, since *cis*-2-butene is obtained from *trans*-2-butene. Because of the symmetrical structure of the compounds involved, it should be possible to determine whether only one Walden inversion takes place during the following changes:

Epoxybutane → butanediol
Butanediol → butanediol diacetate
Butanediol diacetate → dibromobutane
Dibromobutane → 2-butene

In order to establish the possibility of Walden inversions, the compounds involved (except the 2-butene) must be prepared with optical activity. An epoxybutane and a diol have been obtained with optical activity, although not in the pure form. The hydration of the epoxybutanes to the butanediols takes place through a Walden inversion, which is 100% in each case.[6] Although

---

[1] Young and Lucas, THIS JOURNAL, **52**, 1964 (1930). A similar conclusion has been drawn independently by H. B. Hass, who has separated the isomeric 2,3-epoxybutanes and has converted each to a glycol (private communication).

[2] Komarewsky, Johnstone and Yoder, *ibid.*, **56**, 2705 (1934); Pines, *ibid.*, **55**, 3892 (1933).

[3] Dillon, Young and Lucas, *ibid.*, **52**, 1953 (1930).

[4] See also Young and Winstein, *ibid.*, **58**, 102 (1936).

[5] The purity of the dibromides was regarded as proof that pure butenes would result, for it has been shown already, Ref. 1, that a butene and its dibromide are interconvertible. Since this work was started, Kistiakowsky, *et al.*, *ibid.*, **57**, 879 (1935), have obtained these hydrocarbons in a high state of purity.

[6] Walden inversions have been observed in the hydration of epoxy compounds to glycols: Kuhn and Ebel, *Ber.*, **58B**, 919 (1925); Van Loon, Thesis, Delft, 1918; Böeseken, *Rec. trav. chim.*, **47**, 683 (1928).

the hydration of the oxide is the only step for which there is a definite proof of Walden inversion in this work, it is probable that a total of five single inversions are involved in passing from *cis*-2-butene to *trans*-2-butene, as outlined in Fig. 1, in which the stereochemical relationships of the different compounds are shown. Similar stereochemical relationships are outlined in Fig. 2 for the conversion of *trans*-2-butene to *cis*-2-butene. In this case the second compound, the chlorohydrin, has not yet been obtained pure. A Walden inversion is indicated by the letters W. I. In the case of the *dl*-compounds, the configuration of but one of the two possible antipodes is shown.

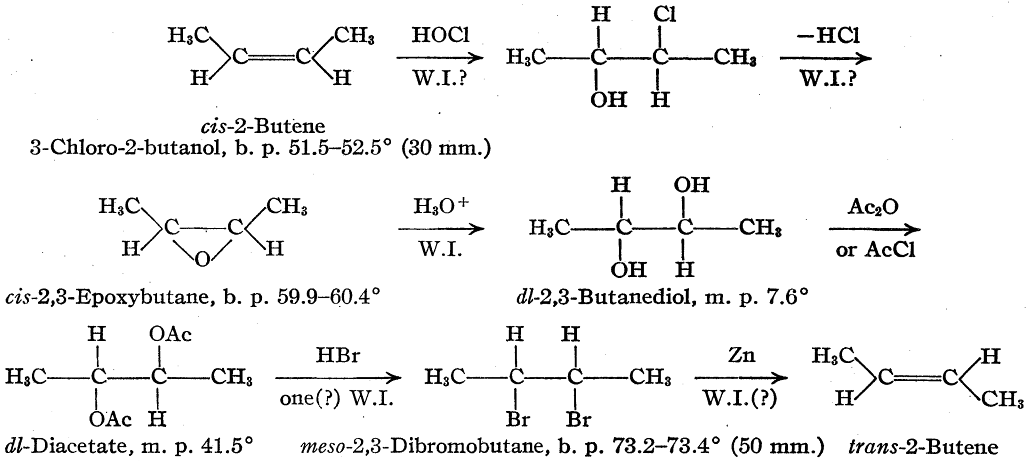

Fig. 1.—*trans*-2-Butene from *cis*-2-Butene.

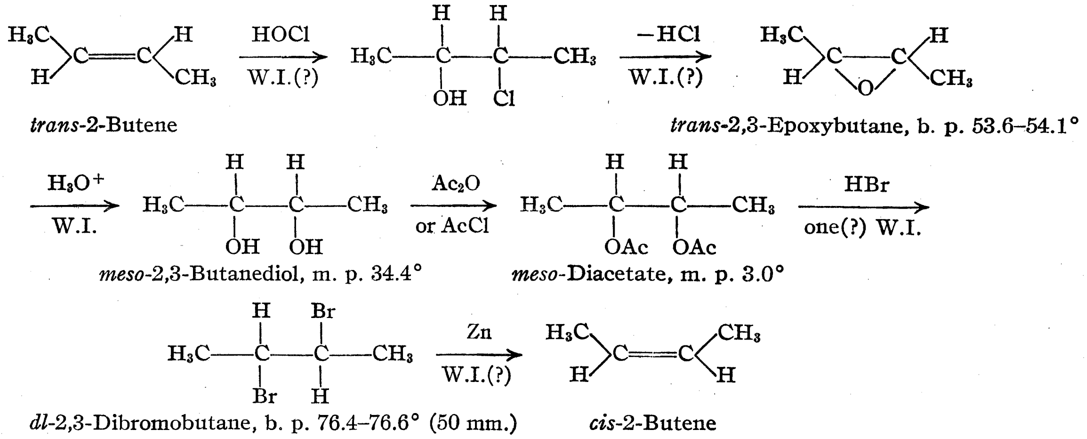

Fig. 2.—*cis*-2-Butene from *trans*-2-Butene.

Although no evidence is available as yet to show that a Walden inversion is involved in the conversion of the butenes to the chlorohydrins, and of these to the oxides, it is reasonable to postulate an inversion at the first step, in conformity with the general rule of *trans* addition to the double bond.[7] If this is true, then an inversion is involved at the second step, that is, during the closing of the oxide ring. At the third step, *i. e.*, the opening of the oxide ring through hydration, a Walden inversion is definitely proved, by establishing the configuration of the oxides and glycols.

Configurations of the Isomeric 2,3-Epoxybutanes.—These were established by obtaining one (the lower boiling isomer) with optical activity, although not as a pure isomer. For this purpose the oxide was converted by the usual steps to a corresponding *dl*-3-dimethylamino-2-butanol, *dl*-α,β-dimethylcholine iodide and *dl*-α,β-dimethylcholine. The latter was partially resolved with tartaric acid. Distillation of the active base with aqueous sodium hydroxide gave trimethylamine and an *optically active* butene

---

[7] Michael, *J. prakt. Chem.*, **52**, 344 (1893); Chavanne, *Rev. gen. sci.*, **35**, 229 (1924).

oxide.[8] It was shown further that each *dl*-α,β-dimethylcholine gave the pure oxide from which it had been prepared. Therefore the original lower boiling oxide, b. p. 54°, as well as the recovered active oxide, must have the *trans* configuration, and the higher boiling, b. p. 60°, must have the *cis* configuration.

Configurations of the Isomeric 2,3-Butanediols.—These have been established by three independent observations, as follows: (a) when the optically active oxide is hydrated, the inactivity of the resulting glycol, which is the higher melting isomer, shows that it is the internally compensated form; (b) when the lower melting glycol is partially esterified by *d*-camphor sulfonic acid, the optical activity developed in the unesterified glycol shows that this is the *dl*-glycol; (c) when the higher boiling, *cis*-oxide undergoes hydration in the presence of either *d*-camphor sulfonic acid or *d*-tartaric acid, the optical activity possessed by the resulting, lower melting glycol shows that it is the *dl*-glycol. These results confirm those of Böeseken and Cohen,[9] who resolved the acid sulfate of the liquid glycol by means of brucine. An independent confirmation of their results seemed desirable because of the possibility that a Walden inversion may have taken place in their work, and also because it is sometimes assumed that the solid glycol is the *dl*-isomer since it is produced by bacterial fermentation, and possesses some optical activity.[9,10]

A Walden Inversion.—The hydration of the optically active, *viz.*, the *trans* oxide, to the inactive, *viz.*, the *meso* glycol, proves that a complete Walden inversion, *i. e.*, a *trans* opening of the oxide ring, takes place. If there were no inversion, *i. e.*, if there were *cis* opening of the ring, the resulting glycol should possess optical activity, since an optically active glycol would be present. The optical activity could disappear only by conversion to the *meso* form through racemization at one carbon atom or to its antipode through racemization at both asymmetric carbon atoms. Racemization, even at one carbon atom, was never observed during the hydration of the inactive oxides, for a pure *dl*- or *meso*-glycol was obtained.

Other Possible Inversions.—Inspection of Figs. 1 and 2 shows that either zero or an even number of inversions are involved between the glycols and the final butenes. It is hardly likely that an inversion accompanies the formation of the diacetate, since the C–O bonds are not altered. It is probable that an inversion accompanies the conversion of each butene to its dibromide, and *vice versa*,[1] in line with similar changes[7]. If this is the case, then only one Walden inversion is involved in the formation of the dibromides from the diacetates. This would constitute an unusual and unexpected type of Walden inversion.[11] It is planned to investigate this possibility by attempting to prepare an optically active diacetate and dibromide.

It seems probable, therefore, that five Walden inversions in all are associated with the changes shown in each of Figs. 1 and 2. Of these, the first two are not susceptible of direct proof by the stereochemical method, whereas the last three are. A Walden inversion has been shown to accompany the third step; the fourth and fifth steps require further study.

This research has been aided by a grant from Dr. George Piness, of Los Angeles, whose financial aid is gratefully acknowledged. For the advice and assistance of his colleague, Dr. Gordon A. Alles, the authors desire to express their appreciation and thanks.

Experimental

Preparation of 2-Butene.—The 2-butene,[1] obtained by heating a mixture of 444 g. (6.0 moles) of 1-butanol,[12] 400 ml. of water, and 600 ml. of concd. sulfuric acid, and purified by passing through a sodium hydroxide solution, sulfuric acid, 50–55% by wt., and a drying tower, is condensed, at −15 to −20°, in previously weighed ampoules; yield 130–180 g. (38–48%).

Preparation of 3-Chloro-2-butene.—In a 2-liter three-necked flask provided with a mercury-sealed stirrer, a delivery tube and a reflux condenser cooled by carbon dioxide and alcohol,[13] is placed 400–500 g. of a mixture of water and ice, and 295 g. of H. T. H.[14] (1.34 moles of calcium hypochlorite). The flask is cooled by a freezing bath at −10 to −15° and 150 g. (2.68 moles) of liquid butene is poured into the flask through the delivery tube from the weighed

[9] Böeseken and Cohen, *Rec. trav. chim.*, **47**, 839 (1928).

[10] Harden and Walpole, *Proc. Roy. Soc.* (London), **77B**, 399 (1906). The optical activity is due to contamination by an active form.

[11] A similar change in configuration has been observed in the case of the 4,5-octanediols and corresponding dibromooctanes by Young, Jasaitis and Levanas, who will publish their results soon.

[12] 2-Butanol was not used because it might possibly be contaminated by 2-methyl-2-butanol.

[13] The condenser is made of two large concentric glass tubes in the shape of a Dewar flask, except that there are two small tubes leading into the annular space, *viz.*, a vertical tube at the bottom, up which the warm gas rises and a horizontal tube near the top, out of which the uncondensed gas passes. A mixture of solid carbon dioxide and alcohol is placed in the inner tube.

[14] H. T. H., 65% available chlorine, manufactured by the Mathieson Alkali Works, is a mixture of calcium hypochlorite and sodium chloride.

ampoule. The tube is then replaced by a dropping funnel and 175 ml. (2.9 moles) of glacial acetic acid is slowly run in during vigorous agitation and good cooling. The time is two to three hours, unless one does not object to excessive refluxing.

Nitric acid is added to break the emulsion, the chlorohydrin is separated and the aqueous phase is extracted with three 100-ml. portions of isopropyl ether. After adding a small amount of water to the combined chlorohydrin–ether extracts, the contained acid is neutralized by the addition of potassium carbonate, in small portions. A part of the dissolved water is removed by the addition of calcium chloride and the mixture is then fractionally distilled under reduced pressure. After dichlorobutane, b. p. 50–60° at 80 mm., 30–40° at 30 mm., has been removed, the mixture of the two *dl*-chlorohydrins distils at 50–60° under a pressure of 30 mm.;[15] yield, 160 g. (55%).

Some attempt was made to separate the mixture of chlorohydrins by fractional distillation, but when it was found that the oxides could be separated more easily, the purification of the chlorohydrins was abandoned. Later, when a good supply of *cis*-2-butene was available, its chlorohydrin was prepared and the properties determined as follows: b. p. 51.5–52.5° (30 mm.); d^{20}_4 1.0626; $n^{20}\text{D}$ 1.4403.

Preparation of 2,3-Epoxybutane.—In a 2-liter three-necked flask provided with a mercury-sealed stirrer, a bent tube leading to a condenser, a dropping funnel, and a thermometer extending nearly to the bottom of the flask, 1000 g. (16–17 moles) of technical potassium hydroxide flakes (or pellets) is dissolved in 500 ml. of water, with stirring. With the solution at a temperature of 90°, 400 g. (3.72 moles) of 3-chloro-2-butanol is slowly added during vigorous agitation, over a period of about two hours. A slow current of air drawn through the apparatus at the end will carry over some additional oxide. The liquid is dried by anhydrous potassium carbonate (calcium chloride must not be used, as it forms an addition product with the higher boiling oxide), filtered and distilled. The 50–60° fraction is collected;[16] yield 235 g. (87–90%).

The Isomeric 2,3-Epoxybutanes.—A quantity of 1700 g. of the mixed epoxybutanes was subjected to three fractional distillations through a 2-meter column filled with glass rings and under total reflux, using a high reflux ratio, and making cuts at 0.5° intervals. Bromobenzene was added to the last fraction, as a still base. The distillation curves are shown in Fig. 3. The over-all recovery at the end of the third distillation was 90%. No 1,2-epoxybutane could be isolated. The physical properties of the isomeric oxides are given in Table I.

TABLE I

PROPERTIES OF THE ISOMERIC 2,3-EPOXYBUTANES

	trans	*cis*

Sp. gr., 20/20	0.8053	0.8272
Refractive index, $n^{20}\text{D}$	1.3736	1.3826
Molar refraction, *M*D	20.45	20.34
M. p., ° C.	−85 (?)	−80 (?)
Weight recovered, g.	661	280
Estimated purity, %	96	90

The specific gravities were determined with a 10-ml. pycnometer; the refractive indices with an Abbé refractometer; and the melting points, which are approximate only, with a pentane thermometer immersed in a small test-tube of the material cooled with liquid air in a Dewar flask. The tube was raised or lowered until crystals surrounded the lower half of the thermometer bulb, and the reading was taken after it had remained constant over a period of time while there was no appreciable melting or freezing. The purity of each oxide was estimated from the melting point of the crude glycol obtained when the oxide was hydrated.

Later, after the pure chlorohydrin had been prepared from pure *cis*-2-butene, pure *cis*-2,3-epoxybutane was prepared in 75% yield. Because of the relatively small amount, *viz.*, 10.7 g., the yield was low and the constants were not as satisfactory as those in Table I; b. p. 58.4–61.3°; $n^{20}\text{D}$ 1.3822.

Optically Active 2,3-Epoxybutane

Preparation of *dl*-3-Dimethylamino-2-butanols.—In a pressure bottle are placed 30 g. (0.417 mole) of crude 2,3-epoxybutane (*cis* and *trans* mixture) and 75 ml. of approximately 30% (6.1 normal) aqueous dimethylamine solution (0.457 mole). The bottle is placed in a water-bath which is slowly brought to boiling and kept at this temperature for about one hour. After cooling, several batches are united, nearly saturated with potassium carbonate and extracted three times with ether. The ether extracts, after drying with powdered potassium hydroxide, are fractionated under a pressure of 30 mm. through a 2-meter column with total reflux, yielding 33% of product distilling at 53.7–54.7°, 47% at 72.0–72.3°, total recovery, including intermediate fractions, 86%. At 743 mm. the two main fractions distilled at 141.0–142.0° and 152.5–153.5°, respectively.[17] These dimethylamino alcohols were also prepared from the pure oxides, but since these amino alcohols are more easily purified than the oxides, it is preferable to proceed as described above.

Since the *cis* oxide yielded the lower boiling and the *trans*

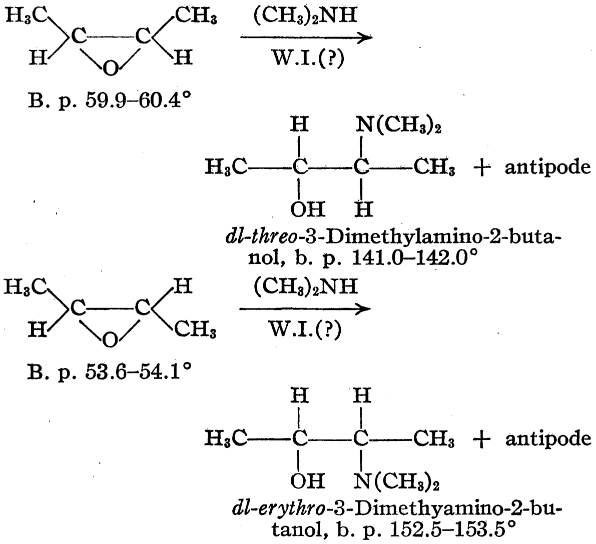
---

[15] Fourneau and Puyal, *Bull. soc. chim.*, **31**, 424 (1922), reported 138–140° as the boiling point of the chlorohydrin.

[16] Fourneau and Puyal[15] report 56° as the boiling point.

[17] Forneau and Puyal[15] report the boiling point of 3-dimethylamino-2-butanol as 53° under 18 mm., and 145° under ordinary pressure.

oxide the higher boiling dimethylamino alcohol, it is possible to assign a provisional configuration to each of these *dl*-amino alcohols, assuming that a Walden inversion takes place here, as it does when the oxides are hydrated. In conformity with the nomenclature adopted for the α,β-dihydroxybutyric acids[18] the amino alcohol corresponding to the *dl* glycol is called the *threo* and the one corresponding to the *meso* glycol is called the *erythro* amino alcohol (Fig. 4).



dl-threo-3-Dimethylamino-2-butanol, b. p. 141.0–142.0°

dl-erythro-3-Dimethyamino-2-butanol, b. p. 152.5–153.5°

Fig. 4.—Configurations of the *dl*-3-dimethylamino-2-butanols.

Preparation of *dl*-α,β-Dimethylcholine Iodides.—A solution of 29.5 g. (0.252 mole) of a pure *dl*-3-dimethylamino-2-butanol in 150 ml. of absolute ether is added to a similar solution of 36 g. (0.254 mole) of methyl iodide. A cloudiness develops at once. The higher boiling alcohol reacts much more rapidly than the lower boiling isomer and it is necessary to cool the solution of the former. After standing for several days at room temperature the solid is filtered off and dried. Yields are 93 and 84%, respectively. Iodine,[19] found, 48.8%; calculated for $C_7H_{18}ONI$, 49.0%.

Regeneration of 2,3-Epoxybutanes from *dl*-α,β-Dimethylcholine Iodides.—An aqueous solution of the choline, obtained by adding 9 g. (an excess) of silver oxide to 20 g. of a pure iodide in 20 ml. of water and filtering out the silver iodide, is distilled through a well-cooled condenser. On saturating the aqueous distillate with potassium carbonate, a lighter phase of trimethylamine and epoxybutane separates. This is dried with solid potassium carbonate and fractionally distilled. The yield of oxide is 2.4 g. (43%). The iodide prepared from the lower boiling dimethylamino alcohol yielded an oxide, b. p. 56.0–58.3°, the glycol from which melted at about 4°, while the one from the higher boiling alcohol yielded an oxide, b. p. 51.3–53.8°, whose glycol melted at 28°. This shows that the original oxide was regenerated in each case.

Resolution of *dl-erythro*-α,β-Dimethylcholine.—To 128 g. (0.497 mole) of dimethylcholine iodide prepared from *dl-erythro*-3-dimethylamino-2-butanol dissolved in 350 ml. of absolute alcohol is added an excess of silver oxide which has been washed with alcohol. The mixture is agitated until the solution fails to give a precipitate with silver nitrate in dilute nitric acid and the solid is filtered out. To the solution is added 76.5 g. (0.510 mole) of *d*, tartaric acid. The resulting bitartrate, at first an oil, is recrystallized many times from absolute alcohol. The specific rotation of the first fraction was $[\alpha]_{Hg}$ +17.9°, and of the final fraction, +19.1°, after nine crystallizations. Although this final product was probably contaminated with some of its stereoisomer, it was used for preparing an oxide having optical activity.

Anal. Calcd. for $C_{10}H_{21}O_7N$: N, 5.24. Found:[19] N, 5.11.

Optically Active 2,3-Epoxybutane.—The pyrolysis of cholines, by the method of Rabe and Halbensleben and of Read and Campbell,[8] was applied to the α,β-dimethylcholine obtained from the tartrate of higher rotation, without, however, isolating the choline. To a solution of 14 g. (0.05 mole) of α,β-dimethylcholine bitartrate, $[\alpha]_{Hg}$ +18.8°, from the lower boiling oxide, in water, made neutral to phenolphthalein with dilute sodium hydroxide, was added an aqueous solution of 19 g. (0.112 mole) of silver nitrate. After filtering off the silver tartrate, the specific rotation, $[\alpha]_{Hg}$, of dimethylcholine nitrate, was +3.0°. The volume was reduced to 15 ml. by evaporation under reduced pressure, 5 g. of sodium hydroxide was added and the solution was distilled at atmospheric pressure. The aqueous distillate, 12–14 ml., was diluted to 18 ml. Its observed rotation, α, was −1.40° in a 2-dm. tube. Assuming a 50% yield of oxide, as in other experiments, the specific rotation $[\alpha]_{Hg}$ of the oxide is approximately −7°. The distillate obtained by the same procedure from unresolved *dl-erythro*-α,β-dimethylcholine *d*-tartrate had zero rotation. The active oxide was not isolated, but was hydrated to a glycol.

The 2,3-Butanediols and the 2,3-Dibromobutanes

Preparation of the Inactive 2,3-Butanediols.—The 2,3-epoxybutanes hydrate readily to the corresponding glycols, in the presence of a strong acid. The best acid to use is perchloric acid[20] and the weight ratio of water to oxide should not be much below 3, otherwise undesirable by-products, probably ethers, result. To a mixture of 300 ml. of water and 90 g. (1.25 mole) of 2,3-epoxybutane is added 6 drops of 60% perchloric acid and the mixture is cooled under the tap from time to time so that the stopper will not be forced from the flask. After five or ten minutes the undissolved oxide goes into solution. The solution is neutralized at the end of an hour and then fractionally distilled at reduced pressure, the pressure being decreased gradually so that the temperature of the liquid does not rise above 100°. The water fractions are used for hydrating subsequent batches of the same oxide; yield 101–107 g. (90–95%).

The glycols are purified by crystallization from dry isopropyl ether.[21] The *meso* glycol, m. p. 34.4°, is but mode-

[21] Drying is easily accomplished by distillation through an efficient fractionating column and discarding the fraction distilling below 67°.

rately soluble and a good recovery is obtained when the solution is cooled from about 27 to 0°. Four crystallizations give a very pure product. The *dl*-glycol, m. p. 7.6°, is very soluble and the solution must be cooled to temperatures approaching that of solid carbon dioxide. Five or six crystallizations are necessary.

Properties of the 2,3-Butanediols.—Some physical properties of the inactive glycols and derivatives are shown in Table II. The melting point of each crude glycol shows that the purity of the *meso* isomer was about 96%, and of the *dl* isomer about 90% (from Fig. 5), assuming that no water was present. Since water was present, the purity was actually higher than indicated by the above figures.

TABLE II

PROPERTIES OF THE INACTIVE 2,3-BUTANEDIOLS

Glycol, configuration	*meso*	*dl*
Oxide from which obtained	*trans*	*cis*
Glycol, b. p., ° C., 742 mm.	181.7	176.7
Glycol, b. p., ° C., 16 mm.	89	86
Glycol, m. p., ° C.	34.4	7.6
Glycol, m. p., ° C., crude	31.8	3.0
Diacetate, m. p., ° C.	2.5–3.0	41.0–41.5
Diacetate, b. p., ° C., 5.5 mm.	66	70
Dibenzoate, m. p., ° C.	75.5–76.2	53.0–54.0
Di-*p*-bromobenzoate,[a] m. p., ° C.	139.0–139.8	205–209

[a] Analysis[19] of the di-*p*-bromobenzoates for bromine by the Carius method gave: *meso* ester, 36.5%; *dl*-ester, 34.2%; calculated for $C_{18}H_{16}O_4Br_2$, 35.1%.

The esters were prepared by the use of a large excess of the corresponding acid chloride in the presence of either pyridine or dimethylaniline. The yields were above 100% on the basis of monoesters. The liquid diacetate was crystallized from isopropyl ether by cooling with solid carbon dioxide. The lower melting dibenzoate cannot be obtained crystalline unless the glycol is quite pure. It is surprising that the higher melting glycol yields a lower melting diacetate and di-*p*-bromobenzoate, but a higher melting dibenzoate.

For larger scale preparation of the diacetates, the following procedure gave good results: to a mixture of 117 g. (1.15 moles) of acetic anhydride and 45 g. (0.50 mole) of the glycol is added a drop of concd. sulfuric acid. It is necessary to cool the flask after a short time. After standing a day the mixture is fractionally distilled under reduced pressure. When this is 5.5 mm., the *meso* diacetate distils at about 66° and the *dl* at about 70°; yield 78–83 g. (90–95%). A given glycol yields the same diacetate, whether prepared with acetyl chloride in the presence of a tertiary amine or with acetic anhydride, as above. The *dl*-diacetate is easily purified by crystallization from petroleum ether. It is more convenient to purify this diacetate than to attempt to purify the corresponding glycol. Harden and Walpole[10] give 181–183° as the boiling point, and 28° as the melting point of their glycol, obtained by bacterial fermentation. Böeseken and Cohen[9] report a boiling point of 177–180° and a melting point of 25° for a similar product. Ciamician and Silber[22] report that one dibenzoate melts at 77° and that the other is a liquid.

Melting Point Curve.—The effect of mixing each inactive glycol with a small amount of the other is shown in Fig. 5. The readings were obtained by slowly warming, in a stoppered test-tube provided with a calibrated thermometer, a partially solidified mixture of the two glycols. The glycols are very hygroscopic and must be protected from the moisture of the air. When water is added, the curve obtained with the *meso* glycol, on a molal basis, is almost identical with the one shown.

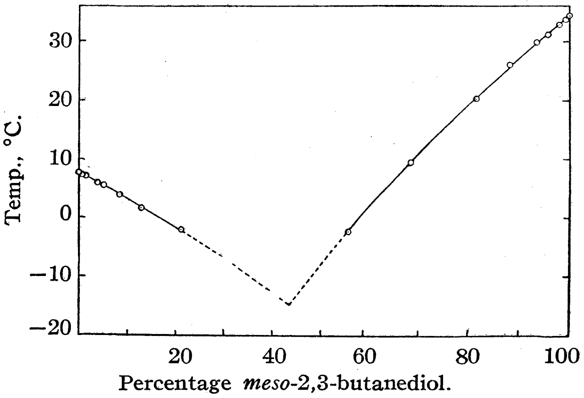

Fig. 5.—Melting point curve of the inactive 2,3-butanediols.

Configurations of the 2,3-Butanediols; Hydration of the Active Oxide.—The aqueous distillate obtained from the decomposition of the partially resolved dimethylcholine (page 2400) contained trimethylamine and an optically active 2,3-epoxybutane. It was carefully acidified with 60% perchloric acid and the solution was allowed to stand for a day. The solution was cooled, freed from trimethylammonium perchlorate by filtration, and was then found to have zero rotation. The resulting solid glycol was therefore the internally compensated form. If it were not, then it should possess optical activity. **Partial Resolution of the Liquid Glycol.** A mixture of 11.1 g. (0.123 mole) of the liquid glycol and 13.8 g. (0.059 mole) of *d*-camphorsulfonic acid was placed in a small flask in an oven at 65°, and left there for three weeks. The unreacted glycol was then distilled out of the mixture under a pressure of 3 mm. The 2.9 g. of recovered glycol was dissolved in 18 ml. of water; the solution had an observed rotation of +0.13 ± 0.02°. When the solid glycol was similarly treated, the product had zero rotation. **Asymmetric Hydration of *cis*-2,3-Epoxybutane (Higher Boiling).** When 10 g. (0.139 mole) of the *cis* oxide was added to a solution of 5 g. of *d*-camphorsulfonic acid in 25 ml. of water, heat developed at once. The observed rotation of the resulting glycol, 9.5 g. (0.105 mole) in a 1-dm. tube, was +0.06°, and of 11 g. of glycol, from another experiment, was +0.13° in a 2-dm. tube. The glycol was a liquid. The *trans* oxide, under the same treatment, yielded a solid glycol of zero rotation. Likewise, when the *cis* oxide was hydrated in the presence of *d*-tartaric acid, and the tartrate ion was removed as insoluble silver tartrate before distillation, the observed rotation of the resulting liquid glycol was −0.05°; the solid glycol from the *trans* oxide had zero rotation.

---

(22) Ciamician and Silber, *Ber.*, **44**, 1280 (1911).

Preparation of the Isomeric 2,3-Dibromobutanes.—When attempts were made to prepare these from the glycols by the usual methods, *i. e.*, concentrated hydrobromic acid, concentrated hydrobromic acid and zinc bromide, phosphorus tribromide or phosphorus pentabromide, the mixtures became dark colored and only very small yields of the dibromides were obtained. Moreover, the products were mixtures. A pinacol rearrangement was responsible for the low yields. This was established by isolating methyl ethyl ketone from the reaction mixture. The dibromides can be prepared in good yield by the action of hydrobromic acid upon the diacetates.

Saturated aqueous hydrobromic acid is prepared by saturating the constant boiling acid with dry hydrogen bromide (from tetralin and bromine). In 200 ml. of this solution is dissolved 52 g. (0.3 mole) of a diacetate and the mixture is allowed to stand at room temperature for three or four days. In a short time the solution becomes cloudy and after some time a layer of dibromobutane rises to the top. This is separated, washed with water, aqueous sodium carbonate and water and then dried with calcium chloride; yield of crude dibromide, 61 g., 94%. When fractionated through a 40-cm. Weston column[23] with total reflux, about 50 g. distils within a range of 0.2°.

Properties of the Dibromides.—The properties of the dibromides, shown in Table III, are practically identical with the properties of the dibromobutanes obtained by a wholly different synthetic method.[24] The configurations of the butenes, assumed in a previous paper, are now known to be the correct ones, for they have been settled by Brockway and Cross[25] through electron diffraction studies.

TABLE III

PROPERTIES OF THE INACTIVE 2,3-DIBROMOBUTANES

Dibromide configuration	*dl*	*meso*
Diacetate from which obtained	*meso*	*dl*
Dibromide, b. p., ° C., 50 mm.	73.2–73.4	76.4–76.6
Dibromide, sp. gr., d^{20}_4	1.7783	1.7922
Dibromide, n^{25}D	1.5098	1.5120
Dibromide, k^a	0.0541	0.0285

[a] Specific reaction rate constant with KI; see ref. 3; the authors are indebted to Mr. Saul Winstein for these values.

The dibromobutanes shown in Table III are reassigned the configurations previously given them. These configurations still appear to be the correct ones, in the absence of new evidence, on the usual assumption that one Walden inversion takes place when bromine adds to a pure 2-butene.[1,17]

Summary

trans-2-Butene has been obtained from *cis*-2-butene through a series of changes, as follows: *cis*-2-butene ⟶ 3-chloro-2-butanol ⟶ *cis*-2,3-epoxybutane ⟶ *dl*-2,3-butanediol ⟶ *dl*-butanediol diacetate ⟶ *meso*-2,3-dibromobutane ⟶ *trans*-2-butene. Through a similar series of changes, *cis*-2-butene has been obtained from *trans*-2-butene.

The lower boiling 2,3-epoxybutane has been shown to have the *trans*, and the higher boiling to have the *cis* configuration. The liquid 2,3-butanediol has the *dl* and the solid the *meso* configuration.

It has been shown that a Walden inversion is involved in the formation of the *dl*-glycol from the *cis* oxide and of the *meso* glycol from the *trans* oxide. It is believed that five inversions are involved when either of the 2-butenes is converted into its stereoisomer, as outlined above.

The inactive 2,3-butanediols undergo a pinacol rearrangement in contact with concentrated hydrobromic acid.

The butene mixture resulting from the decomposition of 1-butanol by hot sulfuric acid (60 by volume) is approximately 35% *cis*-2-butene and 65% *trans*-2-butene.

The Structure of the Pentaborane B_5H_9

BY S. H. BAUER AND LINUS PAULING

The hydrides of boron are especially interesting to the chemist because of the failure of the usual valence theory to account for their observed formulas and properties. Despite the large amount of experimental[1] and theoretical[2] work which has been done in this field in recent years, little progress has been made in assigning structural formulas to these substances, and it seems probable that in order for this to be done with confidence it will be necessary to obtain information about the structure of the molecules by the application of physical methods. Electron diffraction and x-ray methods have been applied in a few cases: the boron–boron distance in B_2H_6 has been evaluated as 1.8–1.9 Å. from x-ray powder photographs,[3] the structure of $B_3N_3H_6$ has been shown to be similar to that of benzene by an electron-diffraction study,[4] and the unit of structure and space-group symmetry of $B_{10}H_{14}$ have been determined.[5] We have now investigated the pentaborane B_5H_9 by the electron diffraction method, and have found a model which accounts satisfactorily for our photographs and which can be accepted with considerable confidence as representing correctly the atomic arrangement in molecules of this substance.

Preparation of the Photographs.—We were provided with 18 cc. (S. T. P.) of B_5H_9 gas through the generosity of Dr. Anton B. Burg of the University of Chicago. The substance (with melting point $-46.9°$ and vapor pressure 65 mm. at $0°$) had been prepared from diborane by the method of Schlesinger and Burg[6] and purified by repeated fractional condensation. The amount of boron trichloride and foreign boron hydrides present is believed to have been very small.

Eleven useful photographs, of varying density, were prepared with the electron diffraction apparatus designed and recently described[7] by Brockway, using the standard technique of handling the borane.[8] The gas was kept at liquid-air temperature in a bulb connected with the nozzle of the apparatus through a stopcock and was warmed to room temperature only long enough for each exposure to be made, in order to minimize the chance of decomposition and reaction with stopcock grease. The film distance was 10.43 cm. and the electronic wave lengths used about 0.06 Å.

Description and Interpretation of the Photographs.—The photographs show five rings, with the qualitative character sketched in Fig. 1. The first ring appears as a small maximum followed by a barely perceptible minimum, the second ring looking like a shelf. The third ring is sharp and strong, with well-pronounced minima on each side. The fourth ring appears broad, and the fifth sharp. Values of s ($= (4\pi \sin \theta/2)/\lambda$) for the apparent maxima and minima are given in Table I; these are averages of closely-agreeing measurements made on eleven photographs by two experienced observers (Brockway and Pauling). Estimated apparent intensities (I) of the rings are also given in the table.

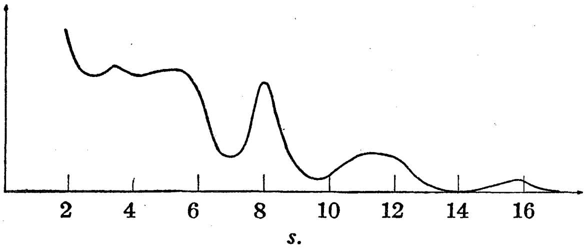

Fig. 1.—Curve representing the visual appearance of electron diffraction photographs of B_5H_9.

culated for these *s* and *I* values is shown in Fig. 2. The peaks at 1.17 and 1.73 Å. can be accepted as representing bonded B–H and B–B interactions, respectively, and that at 2.52 Å. as representing in the main the interaction of boron atoms separated by another boron atom in a chain or ring, the ratio 2.52/1.73 corresponding to a B–B–B bond angle of 93°. The outer peaks are not reliable, and the curve provides no further evidence for choice among various ring and chain models.

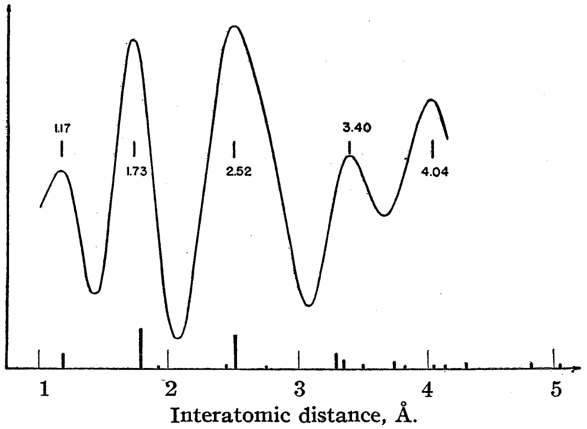

Fig. 2.—Radial distribution curve for B_5H_9. The small rectangles below represent interatomic distances for the final model R.

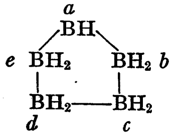
Intensity curves were calculated for eighteen models, described below. In all of these models except B the B–H distances were taken as 1.18 Å., the sum of the single-bonded radii,[10] this value being supported by the radial distribution value 1.17 Å. Bonded B–B distances were assumed in the neighborhood of 1.78 Å. (the sum of single-bond radii), 1.73 Å. (as given by the radial distribution curve), or 1.60 Å. (sum of double-bond radii). The hydrogen atoms were located at tetrahedron corners for boron atoms forming four bonds and at coplanar triangular corners for boron atoms forming three bonds. The B–B–B bond angles were taken as 109°28′ for boron atoms forming four bonds and 120° for those forming three bonds except where otherwise noted.

A–D, Models of type



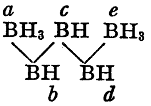
A. All angles 108°; all B–B bond distances 1.78 Å.

B. Same as A, except all B–H distances 1.25 Å.

C. Angles *c* and *d* 107°, *b* and *e* 105°, *a* 116°; B–B distances *ab* and *ae* 1.66 Å., others 1.78 Å.

D. Angles *c* and *d* 106°, *b* and *e* 104°, *a* 120°; B–B distances *ab* and *ae* 1.60 Å., others 1.78 Å.

E–G, Models of type

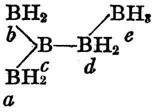


E. All B–B–B angles tetrahedral; B–B distances 1.78 Å.

F. Angles at *c* 120°, others tetrahedral; B–B distances *bc* and *cd* 1.66 Å., others 1.78 Å.

G. Same as F, but with *bc* and *cd* 1.60 Å.

H–J, Models of type

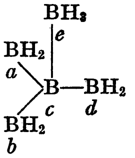


H. B–B–B angles at *c* 120°, others tetrahedral; B–B distances *ca*, *cb*, and *cd* 1.60 Å., *de* 1.78 Å.

I. All B–B–B angles tetrahedral; all B–B distances 1.78 Å.; boron atom *e* oriented to minimize distances *ae* and *be*.

J. Same as I, but with maximum values of *ae* and *be*.

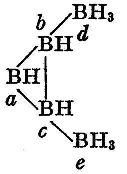
K.



Boron atoms *abcd* coplanar, with 120° angles at *c*, and bond *ce* perpendicular to plane; B–B distances *ac*, *be* and *cd* 1.60 Å., *ce* 1.78 Å.

L. Same as K but with all angles at *c* tetrahedral and all B–B distances 1.78 Å.

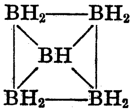
M.



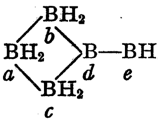
Angles tetrahedral except for distortion to 60° in triangle; B–B distances 1.78 Å.; atoms *d* and *e* both above plane of triangle.

N. Same as M except *d* above and *e* below plane of triangle.

O. Square pyramid, with BH above plane of BH_2's. All B–B distances 1.78 Å.



P–R. Models



Angles in coplanar square 90°; HBH angles tetrahedral; all B–B distances 1.78 Å.

P. Boron atom *e* above plane of square, with angle *ade* 90°.

Q. Same as P but with *ade* 135°.

R. All boron atoms coplanar.

In calculating the intensity curves, shown in Figs. 3, 4 and 5, all terms in the expression[11] $I = \Sigma_{ij}Z_iZ_j(\sin l_{ij}s)/l_{ij}s$ were used except those corresponding to two hydrogen atoms separated by three or more boron atoms. Only one orientation of each BH_3 group was considered, the effect of rotation being negligible.

(10) L. Pauling and M. L. Huggins, *Z. Krist.*, **87**, 205 (1934).

(11) L. Pauling and L. O. Brockway, *J. Chem. Phys.*, **2**, 867 (1934).

All models A to N are eliminated by comparison of their curves (Figs. 3 and 4) with the photographs (Fig. 1), there being not even rough qualitative agreement in any case. The discrepancies are so striking as to show that not only these models but also others obtained from them by small changes in distances and angles or by rearrangement of hydrogen atoms are unsatisfactory.[12]

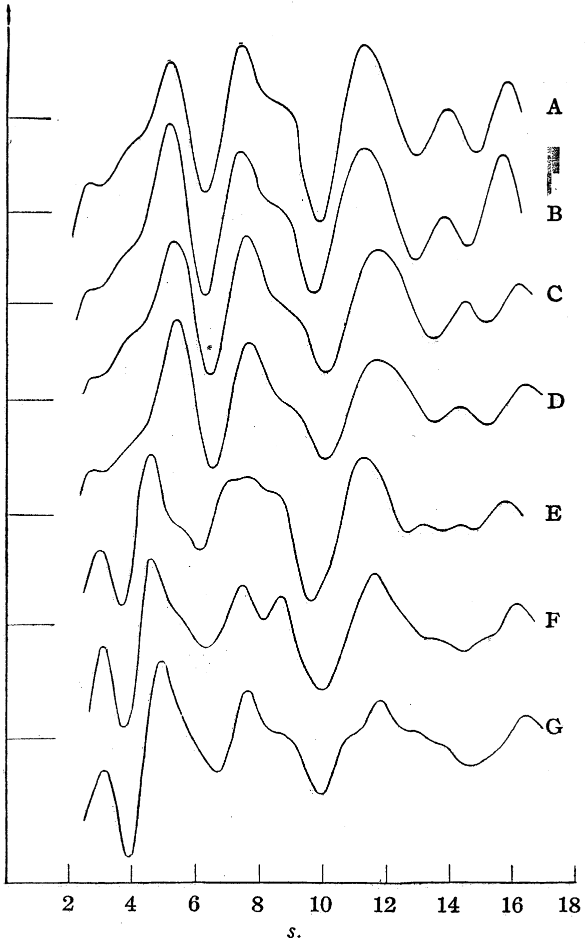

Fig. 3.—Calculated intensity curves for models A to G, with vertical scale twice that in Figs. 4 and 5.

On the other hand, each of the models involving a four-membered square boron ring (Fig. 5) shows rough agreement with the photographs, especially in regard to the strong and sharp third ring. Whereas models O, P and Q are not completely satisfactory, however, the agreement shown by model R is extremely good, the visual appearance of the photographs being well reproduced for all five rings. (The absence on the photographs of a small peak shown at about s = 14 on the curve for R may be attributed to the weakness of the photographs in this region, the much larger peak at s = 16 appearing only faintly.) We accordingly accept model R as representing the structure of the B_5H_9 molecule. The quantitative comparison of $s_{\text{obsd.}}$ and $s_{\text{calcd.}}$ values shown in Table I leads to the value 1.76 Å. for the B–B distances, with an estimated probable error of ±0.02 Å.

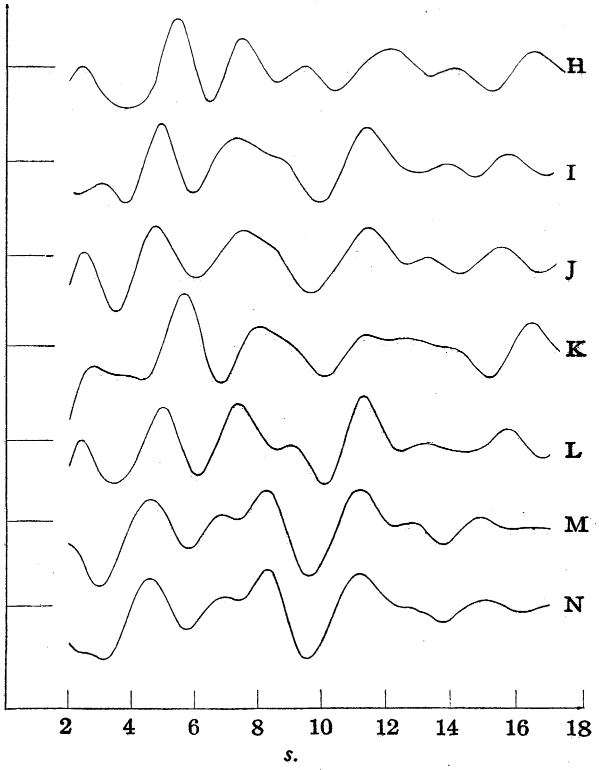

Fig. 4.—Calculated intensity curves for models H to N.

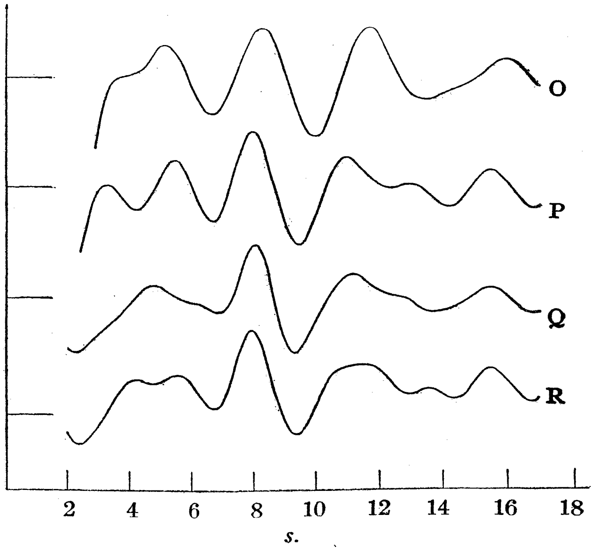

Fig. 5.—Calculated intensity curves for models O to R

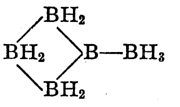
---

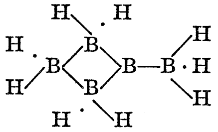
(12) Models A to G were also eliminated by application of the analytic method [S. H. Bauer, *ibid.*, **4**, 406 (1936)].

Discussion of the Structure.—We have shown that the various ring and chain models which suggested themselves to us for test are unsatisfactory except for those involving a four-membered ring of boron atoms, and that of these the model in which the fifth boron atom is coplanar with the ring is definitely superior to the others. In this structure



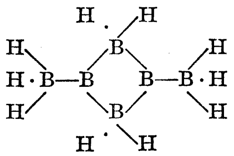
we have not tested the assumed distribution of the hydrogen atoms among the boron atoms; that shown seems to us to be the only reasonable one. The value 1.76 ± 0.02 Å. found for the boron–boron bond distances may be an average of several which differ slightly from one another. For the B–H bond distance the comparison of Table I leads to 1.17 Å., which is, however, determined to a large extent by the assumed model. The radial distribution curve also leads to the value 1.17 Å. We have not endeavored to test the possibility of distortion of the four-membered ring from a square. From experience with other substances we would estimate from the agreement shown by model R that the angles are equal to within about 10° and the B–B distances are equal to within about 5%.

At present discussion of the electronic structure of the boron hydrides is still speculative. We might point out that the structure

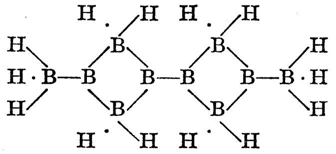


for B_5H_9, involving electron-pair bonds between boron atoms and electron-pair or one-electron bonds between boron and hydrogen atoms,[13] with no more than one one-electron bond per boron atom, is closely similar to the structure  suggested for B_2H_6 by Sidgwick[14] and Pauling,[15] and that these structures are supported by the observed interatomic distances, which correspond to single bonds.

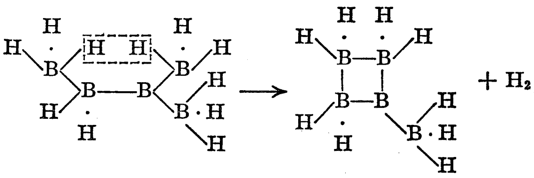
Starting with the basic assumption that a four-membered ring of boron atoms such as is found in B_5H_9 brings about a stability of the hydride as contrasted with a straight or forked chain arrangement which introduces in the other boranes a characteristic lack of stability, we tentatively suggest the related structures



(or the corresponding 1,2-structure) and



for B_6H_{10} and $B_{10}H_{14}$, respectively. Of the entire class of hydrides these show the closest analogies to B_5H_9 in most chemical properties. These structures are compatible in the main with the chemical behavior of the substances. Besides the factor of stability we may mention that the number of molecules of ammonia these boranes add is reported to be equal to the number of one-electron bonds present in the above structures. Further, the reported synthesis of B_5H_9 from B_5H_{11} is reasonably accounted for in the following way



and a similar reaction can be written for the formation of B_6H_{10} from B_6H_{12}. The facts that B_5H_{11} is produced under very similar but milder conditions than is B_5H_9[16] and that under the less stringent circumstances the higher hydride is always present along with the lower one lend strong support to the above equation.

We wish to thank Dr. Anton B. Burg for giving us the pentaborane and for a number of interesting communications, and Dr. L. O. Brockway for the use of the electron diffraction apparatus and for his aid during the investigation.

Summary

From the study of electron diffraction photographs of B_5H_9 it is concluded that the substance

---

[13] There is, of course, resonance between the B:H and B·H bonds, making the hydrogen atoms equivalent. In these formulas we have used a line to represent an electron-pair bond and a dot to represent a one-electron bond.

has the structure  the fifth boron atom being coplanar with the square four-membered ring. The values found for interatomic distances are B–B = 1.76 ± 0.02 Å. and B–H = 1.17 ± 0.04 Å.

The Molecular Structures of the 2-Butenes and the 2,3-Epoxybutanes

BY L. O. BROCKWAY AND PAUL C. CROSS

During an investigation of the reactions of the 2-butenes and some of their derivatives conducted in this Laboratory by Professor Howard J. Lucas[1,2] and his collaborators it was necessary to distinguish between the *cis* and *trans* forms of the 2-butenes and also of the 2,3-epoxybutanes. At the request of Professor Lucas these substances have been investigated by the electron diffraction method of determining the molecular structure of gas molecules. The experimental procedure has been described in detail.[3]

2-Butenes.—The two isomers of 2-butene have boiling points of 3.0 and 0.3°, respectively, at 745 mm. The compounds were photographed at a camera distance of 10.43 cm. with electrons having a wave length of about 0.06 Å. The photographs from each of the compounds show four maxima and in general are very similar in appearance. Two distinguishing features were observed, however. Photographs from the lower boiling butene show a pronounced inner maximum (preceding the first measured maximum at $s = 5.67$ in Fig. 1) which does not appear on the other photographs. The fourth minimum in the photographs of this compound is broad and flat in comparison with the sharp, distinct fourth minimum in the photographs of the higher boiling compound.

Calculations of the theoretical diffraction curves were made with the aid of the formula, $I = \Sigma_i\Sigma_j Z_iZ_j \frac{\sin sr_{ij}}{sr_{ij}}$, in which r_{ij} is the distance between the *i*th and *j*th atoms; the summations extend over all of the atoms in the molecule. The curves for 2-butene in Fig. 1 are based on models in which the four carbon atoms are coplanar with a distance of 1.38 Å. between the two center atoms and 1.54 Å. for the bond distances connecting the outer atoms. The C–H distances are 1.06 Å. The angle between adjacent carbon–carbon bonds is 125° and the H_3C–C–H bond 110°. In the *cis* model the two methyl groups lie on the same side of the line joining the center atoms and on opposite sides in the *trans* model. All of the interatomic interactions were included in the calculation with the exception of those with small coefficients corresponding to the H–H separations.

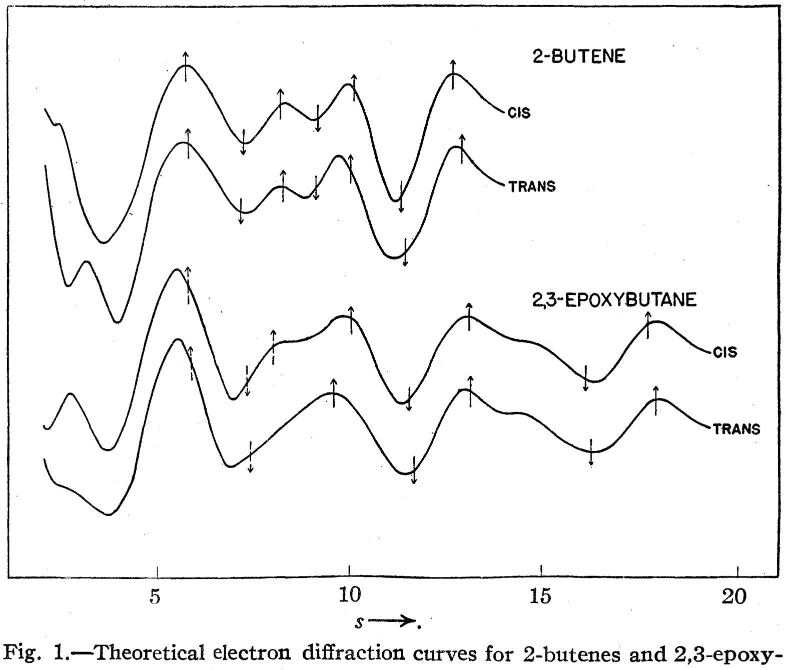

Fig. 1.—Theoretical electron diffraction curves for 2-butenes and 2,3-epoxybutanes. The arrows mark the positions of the observed maxima and minima.

[1] W. G. Young, R. T. Dillon and H. J. Lucas, THIS JOURNAL, **51**, 2528 (1929).

[2] C. E. Wilson and H. J. Lucas, *ibid.*, **58**, 2396 (1936).

[3] L. O. Brockway, *Rev. Modern Phys.*, **8**, 239 (1936).

The curves are very much alike because most of the interatomic distances are the same in the *cis* and the *trans* models. Comparison of the coefficients of the terms in the scattering formulas shows that 80% of the total scattering is represented by terms which are identical for the two models. For this reason there are only small differences by which the *cis* and *trans* compounds can be distinguished. One such difference is the maximum at $x = 3.13$ which occurs only in the *trans* curve. Accordingly we conclude that the lower boiling compound has the *trans* configuration. The comparison of the fourth minima for the two compounds supports this assignment. As mentioned above the photographs of the lower boiling compound have a fourth minimum which is less sharp and distinct than the corresponding minimum from the higher boiling compound. The difference between the theoretical curves at this point is not marked but the *trans* curve definitely has the broader fourth minimum. The compound boiling at 0.3° (745 mm.) is, therefore, the *trans* isomer and the compound boiling at 3.0° (745 mm.) is the *cis* isomer.

G. B. Kistiakowsky and co-workers[4] have made the same assignment of the molecular configurations of the 2-butenes on the basis of their heats of hydrogenation. The compound whose heat of hydrogenation is nearly the same as that of cyclohexene was chosen as the *cis* isomer. These authors report *cis*-2-butene, b. p. 3.73° (759.8 mm.), f. p. −139.3°; and *trans*-2-butene, b. p. 0.96° (760 mm.), f. p. −105.8°.

The determination of the size of the molecule is given in Table I. The observed s values are defined by $4\pi(\sin\theta/2)/\lambda$, in which θ is the observed angle of scattering for the successive maxima and minima and λ is the effective wave length of the bombarding electrons. The calculated s values depend on the interatomic distances assumed in the molecular model described above. The general agreement between the observed points and the maxima and minima on the theoretical curves indicates that the model is probably the correct one. The final column in Table I shows the measured values of the carbon–carbon single bond distance for all of the observed points. The average value in the *cis* modification is 1.54 ± 0.03 Å., and the double bond distance is accordingly 1.38 ± 0.03 Å. The final values for the *trans* modification are 1.56 and 1.40 Å., respectively, but an extra uncertainty in the accelerating potential during the exposures allows a somewhat larger error than in the results from the *cis* compound; the deviations from the accepted value, 1.54 Å., for the single carbon–carbon bond is not significant.

TABLE I

2-BUTENES

4		12.89	12.75	1.556
			Average	1.563
			Av. dev.	0.019

[a] See text for description of model.

Final result: C—C = 1.56 ± 0.04 Å.; C═C = 1.40 ± 0.04 Å.

2,3-Epoxybutanes.—The photographs of the 2,3-epoxybutanes show an extra maximum beyond those observed for the butenes. The second and third maxima of the butene photographs are only partly resolved in one of the epoxybutanes and not at all resolved in the other. Photographs of the two modifications are very similar but they are distinguishable by the partial resolution of the second maximum and the appearance of a marked inner maximum (preceding the first measured maximum at $s = 5.80$) in the photographs of the lower boiling modification.

The molecular models for which theoretical curves were drawn consist of a chain of four carbon atoms separated by distances of 1.54 Å. and with angles of 109°28′. An oxygen atom is connected to the two center atoms by bonds 1.43 Å. in length. The two center carbon atoms also

---

(4) G. B. Kistiakowsky, J. R. Ruhoff, H. A. Smith and W. E. Vaughan, THIS JOURNAL, **57**, 879 (1935).

have a hydrogen atom attached to each at 1.06 Å. and angles of 109°28′ and the end carbon atoms each hold three hydrogen atoms. The CCO plane bisects the H–C–CH_3 angles on each of the center carbons and the two models differ in having the methyl groups on the same or opposite sides of the CCO planes. Terms for all interactions were included in the calculation with the exception of the H–H terms.

TABLE II

2,3-EPOXYBUTANES

Cis b. p. = 54° (747 mm.)

Max.	Min.	*s*, obsd,	*s*, calcd.[a]	C–C, Å.

4		17.68	17.91	1.560
			Average	1.537
			Av. dev.	0.020

[a] See text for description of model.

Final result: C—C = 1.54 ± 0.03 Å.; C—O = 1.43 ± 0.03 Å.

Trans b. p. = 60° (747 mm.)

Max.	Min.	*s*, obsd.	*s*, calcd.[a]	C–C, Å.
1		5.89	5.55	(1.451)
	2	7.46	6.98	(1.442)
2		9.59	9.58	1.538
	3	11.69	11.47	1.513
3		13.16	13.05	1.526
	4	16.25	16.32	1.547
4		17.89	18.07	1.556
			Average	1.536
			Av. dev.	0.013

[a] See text for description of model.

Final result: C—C = 1.54 ± 0.03 Å.; C—O = 1.43 ± 0.03 Å.

The curve in Fig. 1 corresponding to the *cis* modification shows the inner maximum (at *s* equals about 3.0) and the slightly resolved second maximum. Accordingly, the correct assignment of the isomers of 2,3-epoxybutane is the following: *cis*—b. p. 54° (747 mm.); *trans*—b. p. 60° (747 mm.). In the work reported in reference 2 the same identification of these isomers was made by a study of the optical activity of the glycols obtained on hydrolysis of the epoxybutanes.

The results of the quantitative comparison of the photographs and the curves are contained in Table II. The observed distances from the first two points are much smaller than the average from the remaining points because of the contrast effect of the dense central image on the measurement of heavy photographs taken at short distances. The averages for each compound lead to the values: C—C = 1.54 ± 0.03 Å. and C—O = 1.43 ± 0.03 Å.

Summary

The direct determination of the molecular structures by electron diffraction of the vapors has led to the following identification of the isomeric forms and molecular sizes of *cis* and *trans* 2-butene and *cis* and *trans*-2,3-epoxybutane:

	B. p., °C.	Mm.	C–C, Å.	C=C, Å.
		2-Butene		
Cis	3.0	746	1.54 ± 0.03	1.38 ± 0.03
Trans	0.3	744	1.56 ± .04	1.40 ± .04
		2,3-Epoxybutane		
				C–O, Å,
Cis	54	747	1.54 ± .03	1.43 ± .03
Trans	60	747	1.54 ± .03	1.43 ± .03

A New Method for the Preparation of Aldehydo Sugar Acetates

BY ELMER W. COOK AND RANDOLPH T. MAJOR

Aldehydo sugar acetates have been prepared by acetylation of the aldehydo mercaptals[1] followed by removal of the thio-acetal groups and also by acetylation of the aldehydo semicarbazones or oximes[2] with the subsequent removal of the semicarbazone or oxime groups.

A new method based upon Rosenmund's[3] method for the reduction of acyl chlorides to aldehydes by means of hydrogen in the presence of palladiumized barium sulfate has been found. The acetyl derivatives of the sugar acid chloride may be reduced almost quantitatively to aldehydo sugar acetates.

Experimental

Aldehydo-*d*-glucose Pentaacetate.—Pentaacetyl-*d*-gluconyl chloride[4] (5 g.) in 25 cc. of anhydrous xylene (dried over sodium) was heated under reflux in the presence of 2 g. of 5% palladiumized barium sulfate. Hydrogen was passed in at such a rate that the catalyst was kept in a lively suspension. The reduction was complete within one and one-half hours as shown by the absence of ammonium chloride fumes when a rod moistened with ammonium hydroxide was held in the escaping gases. Complete reduction may also be determined by passing the exit gases through water and testing for chloride ion. After reduction the hot xylene solution was filtered. Upon cooling aldehydo-glucose pentaacetate[5] crystallized. It was recrystallized from xylene; yield was nearly quantitative; m. p. 117–118°; $[\alpha]^{20}_{\mathrm{D}}$ $-3°$ (dry chloroform, *c*, 2); $[\alpha]^{20}_{\mathrm{D}}$ $+10°$ (in methanol, 5 min., *c*, 2) changing slowly in the dextro direction.

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.21; H, 5.68. Found: C, 49.52, 49.34; H, 5.85, 5.60.

Summary

Aldehydo-*d*-glucose pentaacetate has been prepared by the reduction of pentaacetyl-*d*-gluconyl chloride.

Temperature–Concentration Equilibria in the Systems Chloroform–Chlorine and Chloroform–Bromine. The Chloroform Chlorinates[1]

BY J. ALLEN WHEAT, II, AND A. W. BROWNE

In view of the well-known fact that chlorine occupies a higher position than bromine in the activity series of electronegative elements and radicals[2] arranged in the descending order of electronegativity, it has seemed reasonable to suppose that dissolved chlorine should be removed from chloroform more readily than dissolved bromine on treatment with metallic sodium. Quite the opposite is true.

As the result of an extended series of experiments in which chloroform solutions containing free bromine and chlorine in molar ratios (Br_2:Cl_2) ranging from about 0.25 to 2.50 were subjected at room temperature to the action of metallic sodium in excess, it was found that a considerable amount of free chlorine remained in solution in every case after complete removal of the bromine had been effected.

This entirely unanticipated result might conceivably be attributable either (1) to chemical action of the chlorine upon the chloroform and lack of similar action on the part of the bromine, or (2) to formation of one or more coördination compounds between molecular chlorine and chloroform and either (a) non-formation of similar bromine compounds, or (b) formation of relatively less stable bromine compounds. The first explanation is clearly invalidated by the presence of "free" (though possibly coördinated) chlorine in the residual solutions, as already noted, and by

the absence of hydrogen chloride and carbon tetrachloride from these solutions, as well as from controls to which no sodium was added.

In order to test the validity of the second explanation an investigation of the temperature–concentration equilibria in the binary systems chloroform–chlorine and chloroform–bromine has been undertaken. The results of this investigation are presented herewith.

Experimental Procedure.—Freezing points in the systems under investigation were determined in the conventional manner with the aid of a calibrated pentane thermometer, and with liquid air or solid carbon dioxide as refrigerant. The mixtures of chloroform and chlorine were quantitatively synthesized either (1) by introducing successive measured volumes of chlorine gas into a known amount of chloroform, or (2) by adding successive measured volumes of chloroform to a known amount of liquid chlorine. The composition of the system was accurately determined at the end of each series of temperature measurements, by treatment with potassium iodide in excess, and titration of the liberated iodine against standard sodium thiosulfate. The absence of hydrogen chloride and carbon tetrachloride from the solutions justifies the conclusion that no *chloridation*[3] of the chloroform has taken place under the conditions prevailing in the experiments.

[3] Since the term chlorination seems appropriate as a means of designating the process by which solvates ("chlorinates") are formed in liquid chlorine solutions, it is suggested that *chloridation* be used for the process of chloride formation.

The mixtures of chloroform and bromine were prepared in each case by bringing together accurately measured volumes of the two liquid components.

Results Obtained.—Temperature–concentration data of the system chloroform–chlorine are presented in Table I and are plotted in Fig. 1.

Temperature–concentration data of the system chloroform–bromine are presented in Table II and are plotted in Fig. 2.

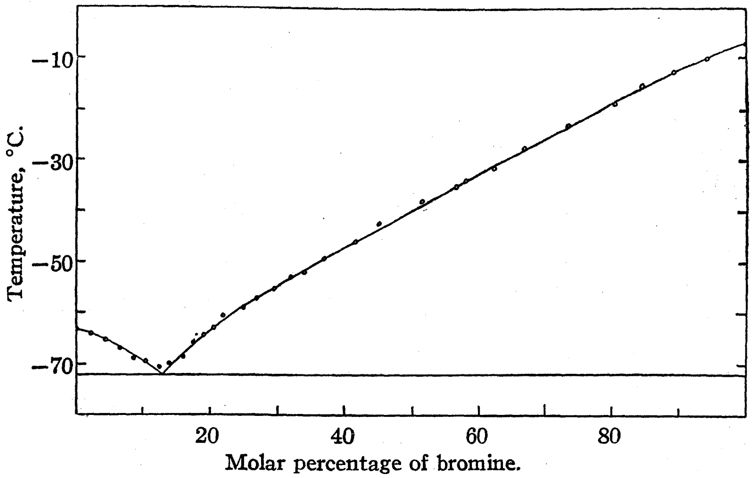

Fig. 2.—Temperature–concentration curves of system chloroform–bromine.

Table II

Temperature–Concentration or Solubility Data of the System $CHCl_3$–Br_2

Temp., °C.	Concn., mol. % Br_2	Temp., °C.	Concn., mol. % Br_2
−63.5	0.0	−53.0	32.0
−64.0	2.1	−52.0	34.0
−65.5	4.5	−49.5	37.1
−67.0	6.5	−46.0	41.5

−64.5	18.9	−23.0	73.4
−63.0	20.5	−18.5	80.6
−61.0	22.0	−15.0	84.6
−59.5	24.8	−12.5	89.4
−57.5	27.3	−10.0	94.4
−55.5	29.7	− 7.0	100.0

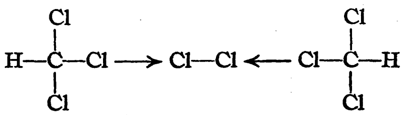
Discussion of Results.—It is obvious from the foregoing that bromine forms no solvates with chloroform, while chlorine forms four solvates, with congruent melting points, as follows:

(1) chloroform hemichlorinate, $(CHCl_3)_2 \cdot Cl_2$, −80.0°
(2) chloroform monochlorinate, $CHCl_3 \cdot Cl_2$, −96.5°
(3) chloroform dichlorinate, $CHCl_3 \cdot 2Cl_2$, −112.5°
(4) chloroform trichlorinate, $CHCl_3 \cdot 3Cl_2$, −115.0°

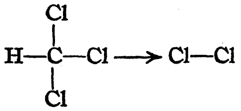
While no evidence whatsoever concerning the structure of these compounds is furnished by the current investigation, the authors venture to make the following tentative statement. It seems rather improbable that the chlorine molecules should be attached to the chloroform by other than coördinate links.

That the chlorine does not coördinate through the hydrogen of the chloroform is attested (1) by the paucity of evidence, up to the present time, that coördination through hydrogen attached to carbon is likely to occur;[4] (2) by the failure of the authors to obtain a chloroform tetrachlorinate; and (3) by the existence of a carbon tetrachloride tetrachlorinate.[5]

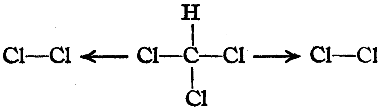
On the assumption that coördination takes place through the chlorine of the chloroform it is conceivable that this chlorine might serve either (1) as the acceptor, or (2) as the donor. For reasons that may be reserved for later discussion it seems that the latter alternative is preferable. The following tentative formulas are therefore suggested as the best present means of indicating the structure of the four chlorinates of chloroform



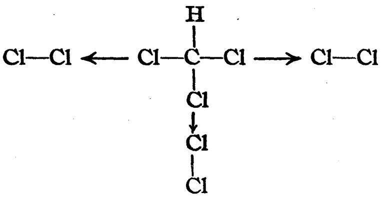
$$\mathrm{H{-}\underset{Cl}{\overset{Cl}{C}}{-}Cl \longrightarrow Cl{-}Cl \longleftarrow Cl{-}\underset{Cl}{\overset{Cl}{C}}{-}H}$$



$$\mathrm{H{-}\underset{Cl}{\overset{Cl}{C}}{-}Cl \longrightarrow Cl{-}Cl}$$



$$\mathrm{Cl{-}Cl \longleftarrow Cl{-}\underset{Cl}{\overset{H}{C}}{-}Cl \longrightarrow Cl{-}Cl}$$



$$\mathrm{Cl{-}Cl \longleftarrow Cl{-}\underset{\begin{array}{c}Cl\\ \downarrow\\ Cl\\ |\\ Cl\end{array}}{\overset{H}{C}}{-}Cl \longrightarrow Cl{-}Cl}$$

---

[4] See N. V. Sidgwick, "The Electronic Theory of Valency," Oxford University Press, Oxford, England, 1927, p. 117.

[5] It has been established by a series of preliminary experiments performed in this Laboratory that carbon tetrachloride forms a tetrachlorinate, $CCl_4 \cdot 4Cl_2$, which shows a congruent melting point at −113°. Investigation of this system, and of various binary systems containing inorganic and organic halides is now in progress in this Laboratory, and results will be communicated in later articles.

Summary

The formation of four chlorinates of chloroform has been demonstrated during an investigation of the temperature–concentration relations of the system chloroform–chlorine:

(1) *chloroform hemichlorinate,* $(CHCl_3)_2\cdot Cl_2$ (m. p. −80.0°)
(2) *chloroform monochlorinate,* $CHCl_3\cdot Cl_2$ (m. p. −96.5°)
(3) *chloroform dichlorinate,* $CHCl_3\cdot 2Cl_2$ (m. p. −112.5°)
(4) *chloroform trichlorinate,* $CHCl_3\cdot 3Cl_2$ (m. p. −115°)

The five eutectic points are located, respectively, at −90, −102, −118, −121 and −123°.

On the assumption that one or more atoms of chlorine in the chloroform may act as donor to the free chlorine, tentative structural formulas for the chlorinates have been suggested.

Bromine forms no coördination compounds with chloroform. The eutectic point of the system chloroform–bromine is located at −72°.

Temperature Dependence of the Energy of Activation in the Rearrangement of N-Chloroacetanilide

BY JOHN O. PERCIVAL AND VICTOR K. LA MER

Introduction

Until recently it has been an almost universal assumption to consider the energy of activation, defined as $E_{\text{act}} = RT^2(\text{d} \ln k/\text{d}T)$, as independent of the temperature. In 1933 La Mer[1,2] showed that Tolman's statistical development[3] demanded in general that E_{act} must be a function of temperature. He pointed out the importance of considering not only the energy but also the entropy and consequently the free energy of activation as concepts important for the interpretation of reaction velocity. A similar treatment involving a more explicit use of statistical formulas,[4,5] or the concept of an energy surface[6] for the calculation of the properties of the state and the reactivity of the intermediate complex for gaseous reactions[7] has proved useful in the hands of the authors cited.[8]

The reluctance in many quarters toward accepting E_{act} as a function of temperature arises from the fact that the precision obtainable in the study of the kinetics of gaseous reactions is rarely sufficient to establish small variations. On the other hand, the situation is quite different for reactions in solution.

A reinvestigation of the depolymerization of diacetone alcohol in the presence of dilute sodium hydroxide has established that $\text{d}E_{\text{act}}/\text{d}T$ not only may be surprisingly large, but that E_{act} reaches a maximum at about 35°.[9]

Since further information regarding the behavior of the E_{act} for different types of reaction is of importance for the elucidation of chemical kinetics, we have studied the rearrangement of N-chloroacetanilide to C-chloroacetanilide in 0.2 molal hydrochloric acid, a reaction which requires simultaneous catalysis by H^+ and Cl^- ions. Harned and Seltz[10] found that E_{act} increases with temperature, but their E_{act} values do not agree with those which we calculate from Rivett's[11] earlier work, as shown in Fig. 1. The length of the arrows indicates the probable experimental error.

A preliminary study disclosed disturbing factors which had not been considered previously: *e. g.* (a) the possibility of interfering side reactions which might invalidate conclusions regarding E_{act}; (b) the unreliability of certified thermometers as temperature standards. We will present evidence that side reactions are insignificant, and will submit more precise values for E_{act} over a carefully selected set of temperatures, using an improved analytical technique.

Mechanism

The mechanism of the conversion has received

attention in Orton's laboratory.[12–16] In acetic acid solution, the reaction proceeds in two stages, the first of which is the rate determining step

(A) $C_6H_5NClAc + HCl \rightleftharpoons C_6H_5NHAc + Cl_2$

(B) 
$$C_6H_5NHAc + Cl_2 \rightarrow \begin{cases} o\text{-}ClC_6H_4NHAc \\ p\text{-}ClC_6H_4NHAc \end{cases}$$

N-Chlorinated anilides oxidize iodide ion to iodine while C-chlorinated anilides do not. The reaction is followed by titrating the iodine liberated with sodium thiosulfate when a sample is run into potassium iodide solution. Although direct proof is lacking, considerable circumstantial evidence exists to indicate that the above mechanism applies to aqueous solutions also.[14,16,17]

Blanksma[18] using 20% acetic acid as solvent and Rivett[11] using aqueous solutions found the rate of disappearance of the N-chloroacetanilide to be first order and proportional to the square of the hydrochloric acid concentration. Harned and Seltz[10] show for aqueous solutions that the observed rate is proportional to the activity of the hydrochloric acid

$$k = k_{\text{obsd.}}/a_{\text{HCl}} \qquad (1)$$

where $a_{\text{HCl}} = a_{\text{H}^+} \cdot a_{\text{Cl}^-} = a^2_{\pm}(\text{HCl}) = m^2f^2_{\pm}$ (a is thermodynamic activity, f is activity coefficient, m is molality).

Soper and Pryde[19] state that the observed rate is proportional not only to the activity of hydrochloric acid but also to the activity coefficient of the N-chloroacetanilide

$$k = k_{\text{obsd.}}/a_{\text{HCl}}f_{:\text{NCl}} \qquad (2)$$

and that the following interfering side reactions occur for which corrections should be made

(C) $C_6H_5NClAc + OH^- \rightleftharpoons C_6H_5NHAc + OCl^-$

(D) $ClC_6H_4NHAc + Cl_2 \longrightarrow ClC_6H_4NClAc + HCl$[20]

Pryde and Soper[19] conclude that (C) causes a 6% rate decrease in one tenth molar acid by a study of the rate of disappearance of N-chloroacetanilide in the presence of sulfuric, nitric, and chloric acids using phenol to remove hypochlorite. Soper[16] and Pryde and Soper[26] find the rate of hydrolysis in neutral solutions to be very small. We measured the hydrolysis at each temperature. It is only 0.1% of the rate of (A) in 0.2 molal hydrochloric acid.

It does not seem reasonable to suppose that the 6% decomposition of N-chloroacetanilide in acid solution was due to reaction (C), which is the reverse of the preparative reaction. Reaction (C) is analogous to (E)

(E) $Cl_2 + OH^- \rightleftharpoons Cl^- + ClO^- + H^+$

One would expect hydrogen ion to reverse both (C) and (E). Jakowkin[27] found this to be true for (E). Accordingly the effect they observe can be explained by (F) proposed by Rivett[11] where X is any acid anion

(F) $C_6H_5NClAc + HX \longrightarrow C_6H_4NXAc + HCl$

followed by reaction (A) *et cetera*. Belton reports[28] instability of N-chloroacetanilide in sulfuric acid solutions even with no phenol present. Chattaway and Orton[29] have detected the formation of hydrochloric acid in solutions of N-chloroacetanilide in other acids. Soper[16] states that (D) causes a decrease in k of about 9% for 0.2 molal hydrochloric acid. If reaction (D) occurs, since its rate is a function of the concentration of the ortho and para chloroacetanilides, which increase with time by (B), the contribution of the N-chlorochloroacetanilide to the titer will become progressively greater causing k to drift downward.

However, since no time drift in k has been reported to date, nor detected in the present investigation after a careful search, we conclude that Soper's postulated side reaction (D) cannot occur to any perceptible extent.

Equation (2) of Soper and Pryde received experimental support from data making these two extensive corrections. Belton,[30] using NaCl–HCl mixtures and making no corrections, obtains data more satisfactorily explained by equation (1) than (2). For the present investigation, the reaction rates were obtained at constant activity of hydrochloric acid by equation (1).

(30) J. W. Belton, *J. Chem. Soc.*, **116** (1930).

The above considerations show that the rate of disappearance of N-chloroacetanilide catalyzed by hydrochloric acid may be followed through its reaction with iodide ion without interfering side reactions and is suitable for a temperature coefficient study.

Precision Analysis

The important variables are: temperature (T), time (t), analyses for the concentration of the reacting compound (A, $A - x$), thermodynamic activity of the hydrochloric acid. The relation of these variables to E is shown in equations (1), (3) and (4)

$$E = \frac{RT_1T_2 \ln (k_2)/(k_1)}{T_2 - T_1} \tag{3}$$

$$k_{\text{obsd.}} = \frac{1}{t} \ln \frac{(A)}{(A - x)} \tag{4}$$

The influence of errors in determination of the variables on E was investigated by partial differentiation of these equations. The experimental procedure was then adjusted so that the combined effect of all calculable errors would be less than the effect of the uncertainty in the activity of hydrochloric acid given in the literature. Table I shows the effect of significant errors on k and E.

TABLE I

Experimental

The saturated solution of the compound was prepared by agitation *at the temperature of the run*[31]; a calculated amount was taken such that when mixed with the constant boiling hydrochloric acid, weighed out in a sealed thin glass capsule, would give a solution 0.2 m in hydrochloric acid. The reaction was terminated by pipetting samples into potassium iodide in the larger compartment of a special 125-cc. glass-stoppered Erlenmeyer flask[34] and by immediate mixing with a sodium hydroxide–sodium acetate solution contained in a side arm compartment. The final concentration of iodide was 4%[35]; the sodium hydroxide–sodium acetate was calculated to leave the solution at a pH of 5.75 ± 0.20.[36] This was verified by e. m. f. measurements using a glass electrode.

The liberated iodine was titrated with sodium thiosulfate from a weight buret using a starch indicator *within fifteen minutes* after taking the sample. The weight *in vacuo* of thiosulfate per gram of sample was substituted directly in equation (4). The precipitate formed during the reaction—of which no mention occurs in the literature—is excluded from the sample by drawing it through a sintered glass filter funnel. The extent of hydrolysis was determined by a second analysis of the saturated solution at the end of the experiment.

Preparation of the *N*-Chloroacetanilide.—The A solution was prepared according to directions of Barnes and Porter[37]; the remainder of the procedure was modified as follows. B solution, 9.6 g. of sodium hydroxide and 3.2 g. of sodium carbonate are dissolved in 150 cc. of solution. C solution, 1.9 g. potassium iodide in 37 cc. water; add 0.1 cc. of concentrated sulfuric acid immediately before addition of sample; add 2 cc. of 0.5% starch solution at the end-point. Chlorine is passed into B solution at 5° until 1 cc. added to C solution requires between 1.6/M and 1.8/M cc. of M molar thiosulfate. Add (220/Mn) cc. (n is the number of cc. of thiosulfate used) of solution B to solution A at 5°. Preserve the compound in a darkened vacuum desiccator over phosphorus pentoxide. If solution B is made from sodium carbonate only, the chlorine causes vigorous evolution of carbon dioxide which interferes with sampling.

Any method of recrystallizing involving heat treatment gave colored products with excessive melting point changes of from −10 to +70° due to decomposition. Addition of excess water at room temperature to an absolute alcohol solution was found to be the only satisfactory method of purification. The crystals were always white needles of reproducible m. p., 89.5°.

Temperature.—The temperature variation of the thermostats was ±0.005° or less. Baudin thermometer No. 18537 was used as a standard of temperature. The method of calibration leaves no doubt regarding the self-consistency of the scale.

The pipets were constructed from eight and twenty-four mm. Pyrex with no constriction of the tip to reduce errors of timing and heat losses in the fast runs. The main body was removed 4 to 5 cm. from the line of stems and was suspended in the thermostat before use long enough to reach temperature equilibrium. The pipets delivered 26 ± 2 cc. in less than two seconds, the exact value being determined by weight.

---

[31] The solution is customarily prepared by boiling several hours in water.[10,11] Porter and Wilbur,[32] and Bradfield[33] show that complete decomposition occurs within one-half to two hours at 100°.

[37] C. D. Barnes and C. W. Porter, THIS JOURNAL, **52**, 1721 (1930).

Buffer.—A buffer is required for the following reasons. (a) Oxidation of iodide ion to iodine by dissolved oxygen will occur in the solution before the end-point is reached, unless the hydrochloric acid catalyst is neutralized. (b) Thiosulfate titrations[36] of dilute iodine require a definite acidity for quantitative results. (c) Hydrogen ion is needed for the reaction between the N-chloroacetanilide and iodide

$$C_6H_5NClAc + 2I^- + H^+ \longrightarrow C_6H_5NHAc + Cl^- + I_2$$

If N-chloroacetanilide is run into neutral potassium iodide, the *p*H rises to 10.75 and the reaction stops with only 60% of the compound reduced. Subsequent addition of acid will not yield the theoretical amount of iodine. (d) The fast running pipets used do not deliver reproducible quantities of solution (within ±2 cc.). The sodium acetate–sodium hydroxide mixture meets these requirements.

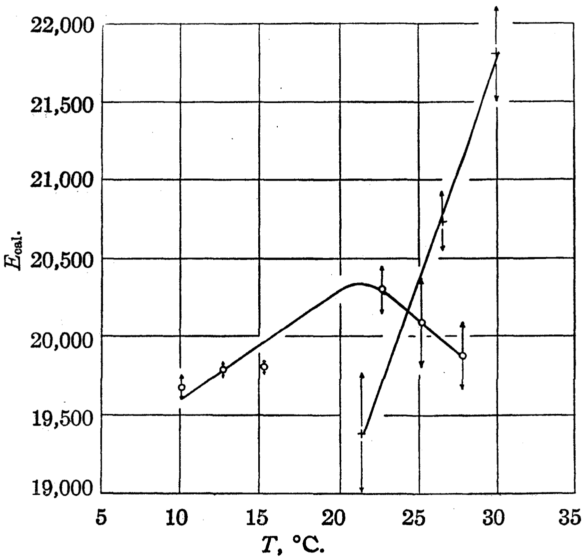

Fig. 1.—Energy of activation–temperature: +, Harned and Seltz; ○, Rivett.

Analysis.—The starch–iodine end-points are observed by holding the flask on a line with the eye and a lamp behind translucent glass in an otherwise light-tight box; the room is darkened. As the reaction progresses, the solution becomes slightly yellow so that successive end-points cannot be compared to obtain reproducibility. The solution is over-titrated with one drop of thiosulfate; a few cc. are placed in the side-arm and iodine added in 0.003-g. portions to the main body until the first perceptible difference in shade is observed between the two portions. This end-point is highly reproducible; when reaction products are present, it is red-yellow. A normality change of 1 × 10^{-6} is readily detected. The a. d. of four iodine–thiosulfate titrations was one-half this quantity. *Light.*—No difference was found on comparing runs in clear and blackened flasks. *Reagents.*—Eimer and Amend Technical Purity grade sodium thiosulfate was twice recrystallized between 60 and 5°. Approximately 0.02 *M* solutions were made in carbon dioxide-free water[38] which were kept free of carbon dioxide with soda-lime tubes. No decomposition of these solutions could be detected during the period of any run. Iodine was distilled from potassium iodide and copper sulfate[35] and sublimed three times. Potato starch ground for five hundred hours in a ball mill readily forms a suspension in water at room temperature. The blank for 2 cc. of a 0.5% solution is 2.1 × 10^{-7} equivalent of iodine. The constant boiling hydrochloric acid was prepared by the standard methods.[39,40]

TABLE II

k, *E*, *B* AT CONSTANT ACTIVITY HCl

T, °C.	k_{av}	Δk ± (%)	E_{act}	ΔE ± (%)	*B*	ΔB ± (%)
0.305	0.008550	0.79				
6.333			19170	1.36	13.23	1.5
12.362	.03792	.39

18.925			20090	.49	13.96	.50
24.954			20590	.51	14.33	.56
24.984	.1742	.42				
31.264			20750	1.09	14.45	1.10
37.545	.7178	.52				

Calculation of Results

Values of *k*, E_{act} and *B* at constant activity of hydrochloric acid are shown in Table II with their experimental error. The errors represent the deviation between duplicate runs. *k* and *E* were calculated from (4), (1) and (3); *B* from (5).

$$B = \log k + (E_{act}/2.3\ RT) \qquad (5)$$

The activity coefficients were calculated to within ±0.0005 by the equation of Harned and Ehlers.[41] E_{act} and *B* are plotted against temperature in Figs. 2 and 3, respectively. The data of Rivett were recalculated to a molal basis. The E_{act} from Rivett, and Harned and Seltz were calculated using the activity coefficients of Harned and Ehlers[41] and are plotted in Fig. 1. The error in Rivett's data was calculated from the a. d. of a single run at each temperature. Harned and Seltz do not indicate whether they made duplicate runs, merely stating that "the maximum variation in a series was ±1%." This figure was used to calculate their ΔE. Our *k* values and those of Harned and Seltz agree at 25° to 3% when the latter are multiplied by 2.303. Time is in minutes.

Discussion

The increase of *E* from 19,170 to 20,750 cal. for the temperature range 6.333 to 31.264° corresponds to a mean molar heat capacity of activa-

tion of 63 cal./deg. Figure 1 compared with Fig. 2 shows our data to give the most precise values of E. The change with temperature is unquestionably greater than experimental error, and cannot be due to side reactions nor to inconsistencies in the temperature scale used.

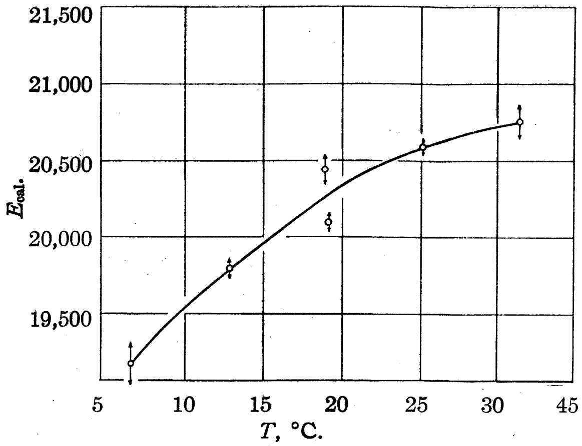

Fig. 2.—Energy of activation-temperature.

By integrating $\partial \ln k/\partial T = E_{act}/RT^2$ under the general assumption that $E_{act} = f(T)$, La Mer obtained

$$\ln k = \text{frequency constant} + (S_{act}/R) - (E_{act}/RT) \quad (6)$$

where S_{act} is the entropy of activation. When E_{act} is considered independent of temperature, S_{act}/R vanishes, since it is equal to

$$\frac{1}{R}\int_0^T \left(\frac{\partial E_{act}}{\partial T}\right) dT/T$$

He evaluated the constant of integration by assuming a collisional mechanism for the reaction, in which case the frequency term = ln $Z°$. Comparison of eq. (5) with eq. (6) shows that for this mechanism

$$B = \log Z° + S_{act}/2.3R \quad (7)$$

The experimental value of B, equal to 13.23 at 6.33°, compares favorably with the value of log $Z°$ equal to 13.10, assuming σ equal to 5A°. However at 31.26° B has increased 1.22 units. whereas log $Z°$, which varies as $T^{1/2}$ has increased but 0.02 unit. This constitutes further experimental proof of the existence of an appreciable entropy of activation. The simple collision theory of reaction kinetics obviously is quite inadequate.

Eyring has proposed a statistical theory which avoids the collisional mechanism for evaluating the frequency constant in eq (6). His theory yields

$$B = \log \kappa kT/h + S_{act}/2.3R \quad (8)$$

Here kT/h is a universal frequency which varies as T; κ is a transmission coefficient representing the probability that the activated complex will not be reflected back after passing the energy barrier. Calculations of κ are not available except for extremely simple reactions.

The entropy of activation in (7) differs from that in (8) in that the collisional mechanism for the process $A + B \rightleftarrows X$ apportions the entropy contribution associated with the ordinary translational degrees of freedom of A, B and X to $Z°$, whereas in eq. (8) these contributions are included under S_{act}.

It is of interest to note the striking similarity between the form of the curve, E_{act} *versus* T (Fig. 2), and that for the depolymerization of diacetone alcohol.[9] Our reaction involves a neutral molecule and two oppositely charged ions, while the latter reaction concerns a neutral molecule and one negative ion.

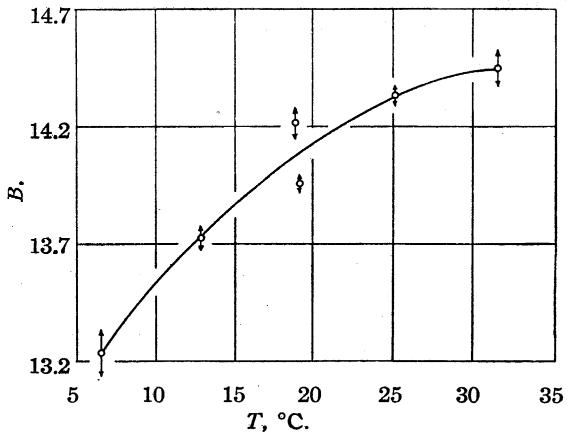

Fig. 3.—B-Temperature.

Summary and Conclusions

1. The rate of conversion of N-chloroacetanilide in the presence of aqueous 0.2 molal hydrochloric acid has been measured at 0, 12.5, 25, 37.5°. The temperature dependence of the energy of activation has been calculated for a constant activity of hydrochloric acid.

2. The analytical procedure has been refined so that the velocity constants can be reproduced to 0.5%.

3. The complete absence of time drifts of the velocity constant shows that the secondary N-chlorinations postulated recently by Soper do not exist.

4. The E_{act} rises steadily from 19,170 cal.

for the interval 0–12.5° to 20,750 cal. for 25–37.5°, corresponding to a mean heat capacity of activation of 63 cal./deg.

5. The form of the curve E *versus* T for this reaction is similar to that for the depolymerization of diacetone alcohol by hydroxyl ion.

6. The action constant B—which is equal to the entropy of activation plus a frequency term—varies from 13.2 at 6.33° to 14.45 at 31.3°. The magnitude and temperature dependence of B furnish additional evidence of the inadequacy of the collision theory, and of the existence of an appreciable entropy of activation.

Orthobaric Densities of Substances as a Function of Reduced Temperatures

BY HAROLD A. FALES AND CLARA S. SHAPIRO

In the present investigation it is our purpose to make a comparative study of the equilibrium between the liquid and vapor phases of different elements and chemical compounds over the entire range of coexistence of the two phases from the melting point to the critical temperature with particular reference to the relationship between the orthobaric densities and the "reduced" temperatures.

Cailletet and Mathias studied the densities of the liquid and gaseous phases and discovered in 1886[1] that the arithmetical mean of their sum is a function of centigrade temperature. Likewise, they found that the "reduced" mean density can be expressed as a function of "reduced" temperature; this relationship is discussed in detail by Van Laar.[2] Recently two interesting papers have appeared along the lines of our subject. One is by C. H. Meyers[3] in which orthobaric volumes are connected with "reduced" pressures and absolute temperatures. This author shows for twenty-three substances that provided the vapor pressure–temperature relation for the saturated fluid, the critical pressure, and approximate values for liquid densities are known, the specific volume of the saturated vapor can be calculated, except near the critical temperature, with the determination of one empirical constant in the equation

$$\log_{10}\left(1-\frac{pv}{RT}\right)\left(1-\frac{pv'}{RT}\right) = A\log_{10}\frac{p}{2.718p_c} \qquad (1)$$

where p = saturation pressure, p_c = critical pressure, v and v' = specific volumes of liquid and vapor respectively, R = gas constant, T = absolute temperature and A = empirical constant which varies slightly from 0.72 for noble gases to 0.61 for methanol, with an average value of 0.69 for twenty-three substances. The above relationship is very accurate up to one-fourth to one-half the critical pressure, which corresponds to 0.8 to 0.9 the absolute critical temperature.

The second paper is by J. Horiuchi[4] and deals with the expression $\ln v_g/v_l$. Assuming that Maxwell's distribution law and van der Waals' equation apply to the equilibrium liquid $\rightleftharpoons$ saturated vapor, and introducing a certain correction Horiuchi develops an equation which expresses $\ln v_g/v_l$ in terms of two variables: the volumes themselves and the absolute temperatures, namely

$$\ln v_g/v_l = \frac{A}{RT}\left(\frac{1}{v_l - E} - \frac{1}{v_g - E}\right) \qquad (2)$$

where A and E are constants characteristic for each substance. This equation holds well for a large number (60) of organic and inorganic liquids up to 0.8–0.9 of the critical temperature. It deviates considerably in the case of methyl alcohol and does not hold at all for water; according to Horiuchi this discrepancy is due to the strong association of these liquids. As to constants A and E they differ in numerical value for different substances. For normal organic liquids $A = 32.3\ T_{cr}^2/P_{cr}$ and $E = 0.17\ V_{cr}$, so that a "reduced" equation is obtained for these liquids[4]

$$\ln\frac{\phi_g}{\phi_l} = \frac{1.47}{R\tau}\left(\frac{1}{\phi_l - 0.17} - \frac{1}{\phi_g - 0.17}\right) \qquad (3)$$

where τ, ϕ_g, ϕ_l are the reduced temperatures and reduced volumes, respectively.

The expression $\ln v_g/v_l$ has previously received considerable attention in the literature, mostly in

the effort to connect it with the latent heat of evaporation. Of the numerous though only partially successful attempts in this direction the most interesting is perhaps the equation of Crompton[5]

$$\ln\frac{v_g}{v_l} = \frac{Ml_{ev}}{2RT} \tag{4}$$

where M is the molecular weight, l_{ev} the latent heat of evaporation, R the gas constant, and T the absolute temperature.

This equation is approximately true for many organic liquids, giving particularly good agreement in the neighborhood of the critical point, but it shows considerable deviation for alcohols, acetic acid, ammonia, water and other liquids commonly called "associated" although the deviations become small as the critical point is approached.

Considering the relationships which Horiuchi and Crompton have sought to develop one might infer that liquids fall into two types, commonly known as associated and non-associated, since equations (2) and (4) give agreement with observed values in a certain number of cases but not in others. On the other hand, no such division into classes follows from the equation of Meyers because it applies equally well to twenty-three diverse substances including alcohols, ammonia and water.

The question may now be asked: is there some inherent peculiarity in the function $\ln v_g/v_l$ which necessitates that liquids be divided into two classes? We will attempt to show in this paper that it is possible to use the function $\ln v_g/v_l$ in conjunction with "reduced" temperature and obtain a relationship which is equally applicable to substances of the utmost chemical diversity and that on the basis of this there is no support to the contention that liquids are divisible into two classes.

We have selected thirty substances which represent every type of element, inorganic substance and organic compound for which measurements of orthobaric densities are available.

These substances arranged in the ascending order of the volume ratio are:

1 Helium
2 Hydrogen
3 Neon
4 Argon
5 Oxygen
6 Carbon monoxide
7 Nitrogen
8 Ethylene
9 Ethane
10 Hydrogen chloride
11 Nitrous oxide
12 Acetylene
13 Methyl ether
14 Carbon tetrachloride
15 Benzene
16 *i*-Pentane
17 *n*-Pentane
18 Monofluorobenzene
19 Sulfur dioxide
20 Ammonia
21 Methyl formate
22 Ethyl ether
23 *n*-Hexane
24 Acetic acid
25 Ethyl propionate
26 Sulfur trioxide
27 Water
28 Methyl alcohol
29 Ethyl alcohol
30 Nitrogen tetroxide

In studying the ratio of the volumes we have employed the natural log of the ratio v_g/v_l instead of the ratio itself, since the variation of the latter with temperature is far too fast. We have also employed the reduced temperature instead of the absolute temperature in order to have a common scale of comparison. It is obvious that at the critical point the ratio becomes unity and its natural log becomes zero for all substances; therefore in plotting the $\ln v_g/v_l$ against the reduced temperature $\tau = T/T_{cr}$ for different substances we obtain a series of curves all having a common origin at the point $\tau = 1.000$. Comparing these curves we find that they all belong to one and the same family as illustrated by the eight representative curves a,. . .h, in Fig. 1.

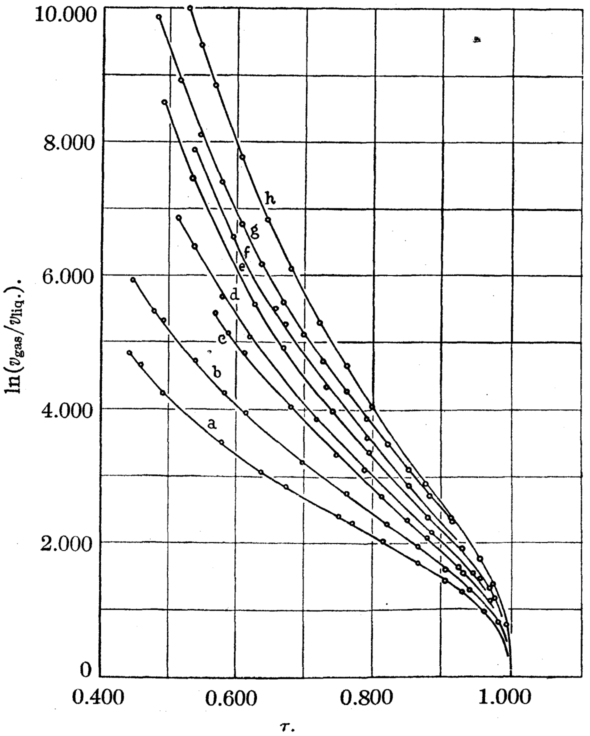

Fig. 1.—$\ln(v_{gas}/v_{liq.}) = k[(1-\tau^2)^m/\tau^n]$: a, helium; b, hydrogen; c, neon; d, nitrogen; e, carbon tetrachloride; f, *n*-hexane; g, water; h, ethyl alcohol.

---

[5] Crompton, *Proc. Chem. Soc. London*, **17**, 61 (1901).

The domain bounded by the curves a and h includes all the curves for the thirty typical substances, while the more restricted domain bounded by c and g includes a majority of the curves. The eight representative curves a, . . .h portray the behavior of the following substances:

a—Helium
b—Hydrogen
c—Neon
d—Nitrogen
e—Carbon tetrachloride
f—*n*-Hexane
g—Water
h—Ethyl alcohol

Analytical Expression of the Curves.—We find that all these curves can be represented by the equation

$$\ln \frac{v_g}{v_l} = k \frac{(1 - \tau^2)^m}{\tau^n} \qquad (5)$$

where v_g and v_l are the orthobaric volumes; $\tau = T/T_{cr}$ is the reduced temperature and k, m and n are constants characteristic for a given liquid.

If we use "reduced" volumes instead of orthobaric volumes we get the same functional relationship, namely

$$\ln \frac{\phi_g}{\phi_l} = \ln \frac{\dfrac{v_{gas}}{v_{cr}}}{\dfrac{v_{liq.}}{v_{cr}}} = k \frac{(1 - \tau^2)^m}{\tau^n} \qquad (6)$$

where ϕ_g and ϕ_l are the "reduced" volumes.

Equation (5), as well as (6), is applicable to all substances tried and in most cases represents the data within the experimental accuracy as will be seen from the ensuing Tables I to III. It embraces substances of utmost diversity in physical and chemical properties. Thus the critical temperature ranges from 5.19°K. for helium to 674.2°K. for water; the number of atoms from 1 for helium to 20 for hexane; and the molecular weight from 2 for hydrogen to 153 for carbon tetrachloride.

This equation holds equally well for associated and non-associated liquids. It will be seen from the tables that the typical associated substances—acetic acid, water, ethyl alcohol, ammonia—show just as good an agreement between calculated and experimental curves, as do the representatives of normal liquids—benzene, carbon tetrachloride or hexane.

In Table I we give an example of our calculations in detail for water represented in Fig. 1 by curve g. In this table the three reference points used for calculating k, m and n are marked with an asterisk; at these points the deviation is, of course, always zero. Also in this table are given the de-

[a] Values are the differences, $\ln_{obsd.} - \ln_{calcd.}$. [b] Values are the percentage differences, $\dfrac{\Delta \ln v_g/v_l}{\ln v_g/v_l} \times 100$.

* Asterisks signify the reference points used for calculating k, m and n.

viations between calculated and observed values of $\ln v_g/v_l$. They are expressed as actual differences in the natural log, and also as percentage differences. By percentage difference we mean the proportional error in the logarithm of the ratio of the volumes × 100, namely, $\Delta \ln v_g/v_l / \ln v_g/v_l \times 100$.

If it is desired to find the percentage difference in the ratio of the volumes themselves, multiply the differences $\ln_{\text{obsd.}} - \ln_{\text{calcd.}}$ in column 7 of Table I by 100. This follows from the property of natural logarithms that for two nearly equal numbers the difference between their natural logarithms is sensibly equal to the proportional difference of the numbers themselves, thus

$$\ln (x + \Delta x) - \ln x = \ln x + \ln \left(1 + \frac{\Delta x}{x}\right) - \ln x =$$
$$\ln \left(1 + \frac{\Delta x}{x}\right) = \frac{\Delta x}{x} - \frac{1}{2}\left(\frac{\Delta x}{x}\right)^2 + \ldots \doteq \frac{\Delta x}{x}$$

In Table II we give the differences between observed and calculated values of $\ln v_g/v_l$ for the remaining seven substances of Fig. 1 represented by curves (a) helium, (b) hydrogen, (c) neon, (d) nitrogen, (e) carbon tetrachloride, (f) *n*-hexane, (h) ethyl alcohol, and one additional substance, acetic acid, the curve for which is closely adjacent to that for water (g). The differences $\ln_{\text{obsd.}} - \ln_{\text{calcd.}}$ were obtained from an enlarged graph giving the differences as ordinates against τ as abscissa and then selecting for each substance the values of the differences corresponding to τ = 0.400, τ = 0.450, *et cetera*. The average difference in each case was obtained by integrating the area under a curve and dividing this area by the appropriate length of the abscissa.

[a] The curve for acetic acid is closely adjacent to that for water.

If it is desired to find the percentage difference in the ratio of the volumes themselves, multiply the differences $\ln_{\text{obsd.}} - \ln_{\text{calcd.}}$ by 100.

Table III gives a summary of the results obtained for all 30 substances. For each substance its calculated curve was constructed from only three known density data, and the differences between observed and calculated values were obtained for the whole experimental range exactly as illustrated in Table I, but for lack of space the results are given only in very condensed form.

The liquids are arranged in the ascending order of the curves in the coördinate system. In each case are given: the critical temperature, the molecular weight, the number of atoms, the value of $\ln v_g/v_l$ at τ = 0.600, the values of the constants *k*, *m*, *n*, the average difference $\ln_{\text{obsd.}} - \ln_{\text{calcd.}}$, and the average percentage difference. These two sets of values were obtained by the use of graphs in a manner entirely analogous to that described in the preceding paragraph for Table II. For the sake of comparison estimated deviations are also given in the last column. These estimates are based upon the assumption that the effects of errors in v_g and T_{cr} upon $\ln v_g/v_l$ are additive as explained subsequently in the text.

Evaluation of the Constants *k*, *m* and *n*.—In evaluating the constants *k*, *m* and *n* it has been our purpose to find a method applicable to any known substance for which only three density measurements have been made (at three different temperatures). With this view in mind, we have used only three known data for densities and corresponding temperatures in calculating the constants *k*, *m* and *n* of each substance given in Table III.

In selecting the three reference points we have been guided by the following considerations: (1) to use a uniform procedure for all substances, so as to obtain comparable results; (2) to use only those density values as reference data which have been actually observed, or calculated from a trustworthy equation of state; (3) to have the first reference point always between the melting and the boiling point, *i. e.*, at $\tau = 0.5$ to 0.65; to have the third point always in the abrupt region of the curve, namely, the third point should always lie between $\tau = 0.96$ and 0.97 but not any closer to unity. This is an important precaution to observe, since in the region between $\tau = 0.97$ to 1.000 the expression $1 - \tau^2$ becomes so small as to be very much influenced by the errors in measurements of the critical temperature. Hence, in this small region the equation is not expected to hold with the same accuracy as in the other parts of the curve. The second point is always to be chosen as close as possible to midway between the two extreme points. This was found by experience to be the best procedure. (4) To choose the intervals between the points 1 and 2 and the points 2 and 3 as large as possible, which is in accordance with the mathematical theory of equations. In a few cases one or more of these conditions could not be observed, for lack of corresponding density data. In such cases the calculated constants were considered slightly inaccurate and in Table III they are enclosed in parentheses.

Accuracy of the Proposed Equation.—In the two columns preceding the last of Table III we have given the averages of the actual and the percentage differences of the function $\ln v_g/v_l$. We see upon examining the differences that they vary from substance to substance. This variation is to be expected since the equation

$$\ln v_g/v_l = k \frac{(1 - \tau^2)^m}{\tau^n} \tag{5}$$

TABLE III

SUMMARY OF RESULTS

A = number of atoms. The substances in this table are arranged in the ascending order of the curves.

	Substance	[a]	T_{cr}, °K.	Mol. wt.	A	$\ln v_g/v_l$ obsd. for $\tau = 0.600$
1	Helium	(1)	5.19	4.00	1	3.35
2	Hydrogen	(2)	33.18	2.0156	1	4.100
3	Neon	(3)	44.38	20.18	1	5.03
4	Argon	(2)	150.65	39.94	1	5.10
5	Oxygen	(2)	154.19	32.00	2	5.25
6	Carbon monoxide	(4)	132.89	28.00	2	5.40
7	Nitrogen	(2)	125.99	28.02	2	5.43
8	Ethylene	(5)	282.6	28.03	6	5.56
9	Ethane	(6, 12)	405.3	30.05	8	5.67
10	Hydrogen chloride	(6)	324.6	36.46	2	5.85
11	Nitrous oxide	(6)	309.6	44.02	3	5.87
12	Acetylene	(6)	309.1	26.02	4	Below triple point
13	Methyl ether	(6)	400.0	46.05	9	6.00 (extrap.)
14	Carbon tetrachloride	(7)	556.2	153.83	5	6.05
15	Benzene	(7)	561.6	78.05	12	6.17
16	*i*-Pentane	(7)	460.6	72.09	17	6.20
17	*n*-Pentane	(7)	470.3	72.09	17	6.30
18	Monofluorobenzene	(7)	559.6	96.04	12	6.37
19	Sulfur dioxide	(8)	430.3	64.06	3	6.38
20	Ammonia	(9)	406.1	17.03	4	6.43
21	Methyl formate	(7)	487.1	60.03	8	6.45
22	Ethyl ether	(7)	466.9	74.08	15	6.49
23	*n*-Hexane	(7)	507.9	86.11	20	6.53
24	Acetic acid	(7)	594.7	60.03	8	6.78
25	Ethyl propionate	(7)	546.0	102.08	17	7.03
26	Sulfur trioxide	(6)	491.4	80.06	4	7.50 (extrap.)
27	Water	(10)	647.2	18.02	3	6.83
28	Methyl alcohol	(7)	513.2	32.03	6	7.75
29	Ethyl alcohol	(7)	516.2	46.05	9	7.95
30	Nitrogen tetroxide	(11)	431.3	92.02	6	8.00 (extrap.)

[a] The numbers in column 3 indicate the corresponding references on orthobaric densities and critical data, given in Table V.

TABLE III (*Concluded*)

$$\ln \frac{v_g}{v_l} = k\,\frac{(1-\tau^2)^m}{\tau^n}$$

		Constants[b]			Average differences actual[c]	Average percentage differences actual[d]	Average percentage deviations estimated[e]
		k	m	n			
1	Helium	2.659	0.4003	0.8215	0.023	0.56	4.0

25	Ethyl propionate	3.967	.3842	1.443	.004	.05	.5
26	Sulfur trioxide	(4.297)	(.4012)	(1.102)	.017	.73	.5[f]
27	Water	4.122	.3770	1.338	.017	.26	.25
28	Methyl alcohol	4.329	.3780	1.460	.004	.08	.5
29	Ethyl alcohol	4.266	.3883	1.558	.010	.20	.5
30	Nitrogen tetroxide	(4.910)	(.4197)	(1.240)	.010	.20	.5[f]

[b] Values of the constants **k, m, n** in parentheses are not quite reliable, since the corresponding substances have only a very short range of observed densities. Consequently the intervals between the three reference points are too small. Also, in the case of ethylene, ammonia and nitrogen tetroxide, the third reference point lies below $\tau = 0.96$, *i. e.*, above the characteristic abrupt portion of the curve, because the corresponding vapor densities are not accurately known near T_{cr}. [c] Values are the average of the differences $\ln_{\text{obsd.}} - \ln_{\text{calcd.}}$. [d] Values are the average of the percentage differences $(\Delta \ln v_g/v_l)/(\ln v_g/v_l) \times 100$. [e] Values are estimated deviations based on the assumptions that the effects of errors in v_g and T_{cr} upon $\ln v_g/v_l$ are additive as explained subsequently in the text. [f] The figures given for sulfur trioxide and nitrogen tetroxide in the last 3 columns are for the range of temperatures: 100–218.3° and 0–60°, respectively.

is influenced largely by errors in the measurements of critical temperature and to some extent by errors in the measurements of vapor density; and these errors are not the same in all cases.

The effect of an error in τ can be obtained by differentiation of equation (5) whence

$$\frac{\Delta \ln v_g/v_l}{\ln v_g/v_l} = -\frac{\Delta\tau}{\tau}\left(\frac{2m\tau^2}{1-\tau^2} + n\right) \qquad (7)$$

One finds that for a given absolute error in τ, the corresponding proportional error in $\ln v_g/v_l$ is large either for $\tau = 0$ or 1 and is a minimum between these values, while for a given proportional error in τ, the corresponding proportional error in $\ln v_g/v_l$ is n times as large when $\tau = 0$ and infinite when $\tau = 1$.

In this connection we should like to point out the following: although in general the temperature can be measured very accurately, yet at the critical point the procedure is a very difficult one. It follows from the survey of critical data by Pickering[6] that even the most careful observers do not always check each other, since for some substances the critical temperature values differ by one or more degrees. Therefore, we believe it is fair to assume that the critical temperature is known accurately to within ±0.1–0.5° only. The effect of an error in T_{cr} upon τ is obviously

$$\Delta\tau/\tau = \Delta T_{cr}/T_{cr} \qquad (8)$$

---

(6) Pickering, *Bur. Standards Sci. Papers*, No. 541, p. 598 (1926).

or the proportional error in τ is equal to the proportional error in T_{cr}.

On the basis of equations (7) and (8) we can figure out the effect of an error in the measurement of the critical temperature upon the calculation of $\ln v_g/v_l$. Taking ten representative substances we get the results tabulated in Table IV.

TABLE IV

Substance	Crit. temp., T_{cr}, °K.	Error in crit. temp., ΔT_{cr}, °K.	Effect upon $\ln v_g/v_l$ $\frac{\Delta \ln v_g/v_l}{\ln v_g/v_l} \times 100$, % $\tau = 0.5$	0.75	0.9	1.0
Helium	5.19	0.1	2.0	3.6	9.6	∞
Hydrogen	33.18	.1	1.2	2.0	4.5	∞
Neon	44.38	.2	0.5	0.6	1.5	∞
Nitrogen	125.99	.5	.5	.6	1.5	∞
Ethylene	282.6	.5	.25	.35	0.70	∞
Ammonia	406.1	.2	.08	.12	.23	∞
Sulfur dioxide	430.3	.5	.16	.23	.46	∞
n-Hexane	507.8	.5	.13	.18	.37	∞
Acetic acid	594.7	.5	.12	.17	.35	∞
Water	647.2	.3	.08	.12	.23	∞

The effect of separate errors in the measurements of v_g and v_l upon the $\ln v_g/v_l$ can be shown to be

$$\frac{\Delta \ln v_g/v_l}{\ln v_g/v_l} = \frac{\Delta v_g/v_g + \Delta v_l/v_l}{\ln v_g/v_l} \qquad (9)$$

The liquid density can be measured very easily to 1 part in 2000 or better, so that the term $\Delta v_l/v_l$ is usually negligible and (9) reduces to

$$\frac{\Delta \ln v_g/v_l}{\ln v_g/v_l} = \frac{\Delta v_g/v_g}{\ln v_g/v_l} \qquad (10)$$

which involves only the error in the vapor volume.

For large values of $\ln v_g/v_l$ and a given proportional error in v_g the corresponding proportional error in $\ln v_g/v_l$ is small, while at the critical temperature where $\ln v_g/v_l = 0$, the corresponding proportional error in $\ln v_g/v_l$ is infinite.

In applying equation (10) we must have knowledge of the proportional error $\Delta v_g/v_g$ for each individual case. The most accurate work is probably that of the Bureau of Standards for ammonia and water where the errors in v_g do not exceed a few tenths of one per cent.[7] In Young's work on organic liquids the vapor density is known to 0.0001 which amounts to about 2% in the neighborhood of the normal boiling point and to only about a few tenths of one per cent. as we approach the critical point.[8]

The Leiden laboratory gives only two significant figures for the vapor densities of hydrogen, nitrogen and oxygen in the region below the boiling point.[9] We assume, therefore, that the accuracy of their data is of the same order as Young's density measurements for the range normal boiling point to critical point.

We see that for most substances the proportional error in v_g for $\tau = 0.6$ is of the order 2 to 3% and decreases with increasing τ until at $\tau = 0.95$ it is about 0.3–0.5%. From Fig. 1 it is evident that the least value of $\ln v_g/v_l$ for $\tau = 0.6$ is 3.25 for helium, and the greatest value is 7.95 for ethyl alcohol, while for $\tau = 0.95$ the values range from 1.0 for helium to 1.7 for ethyl alcohol; therefore from equation (10) the proportional error in $\ln v_g/v_l$ will be between 0.25–0.50% for $\tau = 0.6$ and between 0.2–0.5% for $\tau = 0.95$. For water and ammonia because of the high accuracy of the v_g data the proportional error in $\ln v_g/v_l$ will not exceed 0.1% for the same range of τ. The above shows that the proportional error in $\ln v_g/v_l$ is practically constant for $\tau = 0.6$–0.95, and can be taken as equal to 0.1% for water and ammonia, and equal to 0.3% for the remaining substances.

We can now estimate the total effect of errors in the measurement of critical temperature and of vapor volumes upon the calculated values of $\ln v_g/v_l$. It is obvious that the total proportional error in $\ln v_g/v_l$ will not exceed the sum of the two effects: effect *a* due to error in the critical temperature as shown in Table IV and effect *b* due to errors in the vapor volumes as discussed above.

For each substance we estimated effect *a* as a percentage difference for intervals of τ equal to 0.05 and obtained the average. Effect *b* was considered constant and equal to 0.1% for water and ammonia and 0.3% for the remaining substances; these values were added to the average of effect *a* in the respective cases. The sums thus obtained, we believe, represent fair estimates of the upper limits of the proportional errors in $\ln v_g/v_l$ arising from errors of experimentation. They give a view of the reliability of the proposed equation (5) for the range melting point to 0.95 critical point and therefore are included in Table III (last column)

---

(7) The Bureau of Standards data for v_g are calculated from the measured latent heat of evaporation. For details, see Bur. Standards Circ. No. 142, 1923; and Osborn, Stimson and Ginnings, *Mech. Eng.*, **57**, 162 (1935).

(8) Correspondingly, we find only two significant figures at the normal boiling point in Young's vapor densities as given by "Int. Crit. Tables," Vol. III, 1928, p. 244. Other observers usually give less accurate measurements. For the estimate of error in density measurements of Young and others, see J. Timmermans, *ibid.*, p. 244.

(9) The density tables and the discussion of experimental errors are given in the papers by Mathias and co-workers: *Ann. phys.*, **17**, 416–474 (1922).

for comparison with the percentage differences actually found.

Both the actual and estimated deviations refer to temperature ranges for which the vapor densities are accurately known, namely, measured or calculated from a reliable equation of state. Some of the substances investigated by Young, such as benzene, carbon tetrachloride, etc., have vapor densities roughly extrapolated (by Young) in the region below the boiling point. The corresponding values of ln v_g/v_l are unreliable and were not taken into account in making the computations.

We see upon examination of the table that twenty-seven substances show smaller actual deviations than the estimated, while three, argon, sulfur dioxide and sulfur trioxide, show greater.

A few words should be said regarding sulfur trioxide and nitrogen tetroxide. Each of these substances gives a curve which in part follows the typical shaped curves shown in Fig. 1 and in part deviates more or less as shown by the dotted lines in Fig. 2.

In the case of sulfur trioxide the explanation of this behavior seems to be that part of the data (100–218.3°) was observed[10] while the rest of the data (44–100°) was apparently calculated by means of an equation involving mean density.[11] In plotting the ln values against τ we find that the observed values (100–218.3°) give the typical shape while the calculated values (44–100°) depart from it. The constants k, m and n in Table III were evaluated from the observed data; accordingly we find upon applying the proposed equation (5) that it holds fairly well only for the range (100–218.3°) and not at all for the range (44–100°).

As to nitrogen tetroxide, its densities have been observed all along the saturation line by Mittasch and co-workers (0 to 55°),[12] and by Bennewitz and Windish (30 to $t°$ crit.).[12] In constructing the corresponding curve we find that the portion (0 to 60°) falls right along that of ethyl alcohol, but the portion (60 to 158.2°) is very unusually shaped (Fig. 2 dotted line). We expected our equation to fit in the range (0–60°) and this was found to be the case with very good agreement, but above 60° the deviation from observed values of ln is very large. It is possible that this discrepancy is caused by partial dissociation of $N_2O_4 \longrightarrow 2NO_2$ under saturation pressure[13] which is probably small below 60° and hence does not affect the corresponding value of ln $v_{\text{gas}}/v_{\text{liq}}$.

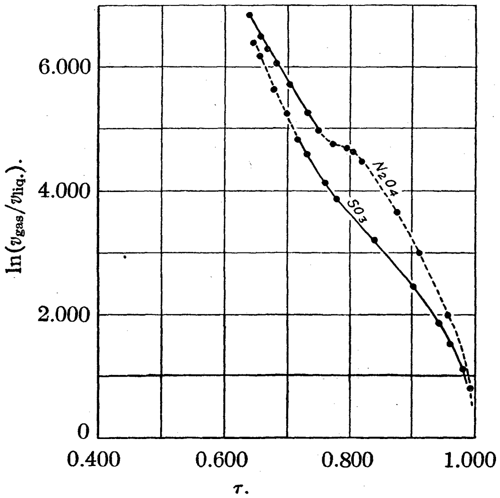

Fig. 2.—――――― Part of experimental curve which follows equation; - - - - - - part of experimental curve which deviates from equation.

Comparison of the Constants k, m **and** n.—When we compare the values of the three constants for different substances given in Table III, we see that each of them varies but little in comparison with the wide variation in physical and chemical properties.

Thus k increases from about 3.2 to 4.3 with the two exceptions helium, $k = 2.66$; nitrogen tetroxide, $k = 4.9$.

m ranges from 0.347 to 0.420 and for many organic substances it is equal to about one-tenth of k.

n ranges from 0.821 to 1.558.

The curves are described accurately by the proposed equation and consequently the order of arrangement should bear close relationship to the corresponding values of the constants k, m and n. We find that m and n do not show any striking regularity, but k is quite characteristic. It increases regularly in about the same order in which the curves succeed each other with a few exceptions. Further, we observe that in general closely adjacent curves such as those for nitrogen and carbon monoxide, or normal and i-pentane, have almost identical values of k.

(13) Nitrogen tetroxide dissociates partially under saturation pressure as is indicated in the corresponding pressure–temperature table (bottom line). See "Int. Crit. Tables," Vol. III, 1928, p. 229.

The close parallelism between the values of k and the location of the curve $\ln v_g/v_l$ suggests at once that the constant k itself is a function of the physical and chemical properties of substances.

This supposition proves to be correct. We find that both the position of the curve and the value of the constant k depend very closely on the properties of substances in the critical state, namely, on their critical constants.

Relation between the Constant k and the Critical Coefficient.—Upon examining the values for k we find that they are almost identical with the critical coefficient for gases K_{cr} defined by the equation

$$K_{cr} = RT_{cr}d_{cr}/Mp_{cr} \qquad (11)$$

In Table V we give the results of this comparison. The thirty substances studied are the same as before. They are arranged in the ascending order of the curves. In columns 3–5 we give the number of atoms in the molecule and the values of k and K_{cr}. The ratio K_{cr}/k is calculated for each substance and is given in column 6.

TABLE V

A = number of atoms. $k = [\ln d_l/d_g]/[(1 - \tau^2)^m/\tau^n]$. $K_{cr} = RT_{cr}d_{cr}/Mp_{cr}$.

The substances in this table are arranged in the order of ascending position of curves

(12) Critical data for ethane by Cardozo, see Pickering's table, "Int. Crit. Tables," Vol. III, 1928, p. 248.

The agreement between k and K_{cr} is as follows:

% Difference	0.5–6	6–10	10–15	23–26
Number of substances	21	4	3	2

The deviations from unity can in part be accounted for by errors in the critical coefficients, these errors being mostly due to errors in the determination of the critical density. Beattie and co-workers[14] discuss this question and assign an estimate of error of about 1–2% for the best values of critical volumes; however, it must be said that in some of the earlier work the critical volumes are probably in error by as much as 5–10%. It appears, therefore, that for the large majority of cases the ratio of K_{cr} to k is very nearly equal to unity.[15] This fact leads to an important conclusion.

The theory of corresponding states requires that the critical coefficient be a constant for all substances and all known equations of state lead to a constant value of K_{cr}, independent of the nature of the substance.[16] (Thus van der Waals' equation gives $K_{cr} = 2.67$; Dieterici's and Wohl's equations lead to the values $K_{cr} = 3.69$ and 3.75, respectively.)

Actually, however, the critical coefficient is far from being a constant. Table V shows that it changes from about 3.0 for monoatomic to about 4.0 for polyatomic substances and in some cases it is greater than 4.0. In general organic substances have an almost constant value of K_{cr} averaging 3.7. These substances are considered normal.[16]

As to the values of K_{cr} departing from the constant value 3.7, the corresponding substances are classed as abnormal. It is customary to explain these departures as being due to the association of the given liquid.[16] As far as we know, a rational treatment of this question has not yet been attempted.

The investigation of the ratio of orthobaric densities here presented leads to another view of this matter.

Comparing the values of k and K_{cr} we see that they change quite parallel to each other as we go from substance to substance. Since the ratio K_{cr}/k is close to unity and both factors in the ratio are established by independent methods, it follows that K_{cr} cannot be a constant. Its gradual rise follows the order of the curves ($\ln v_g/v_l$) in the coördinate system. Therefore, it appears to be a normal phenomenon not at all indicative of the molecular association of the given liquid. It further appears that a correct equation of state should take account of the variation of K_{cr} from substance to substance.

We should like to express our appreciation to Mr. David L. Fiske, Editor of the Refrigerating Data Book, New York, for many valuable suggestions and for his interest in this work. We should also like to thank Dr. Henry Fleishmann and the Educational Alliance, New York, for the financial assistance given to one of us (C. S.) during this work.

Conclusions

1. The ratio of orthobaric densities is a function of reduced temperature and consequently

---

[14] Beattie, Poffenberger and Hadlock, *J. Chem. Phys.*, **3**, 96 (1936).

[15] With respect to the five discrepant cases, where k and K_{cr} differ by more than 10%, namely helium, sulfur dioxide, acetic acid, sulfur trioxide and nitrogen tetroxide, we can offer no explanation at present.

[16] A collection of the best known equations of state and a discussion of the critical coefficient are given in the "Handbuch der Experimental-Physik," Vol. VIII (2), 1929, pp. 224–234.

the vapor volume can be expressed as a function of reduced temperature and liquid volume along the saturation line, namely

$$\ln v_g/v_l = k\,\frac{(1-\tau^2)^m}{\tau^n} \qquad (5)$$

$$v_g = v_l \exp.\, k\,\frac{(1-\tau^2)^m}{\tau^n} \qquad (12)$$

2. The constant k of the suggested equation is almost identical with the critical coefficient K_{cr}, their ratio being nearly equal to unity for most substances investigated.

The critical coefficient is not a constant but varies from substance to substance, increasing with the order of curves ($\ln v_g/v_l$) in the coördinate system.

3. There seems to be a definite similarity in the mechanism of evaporation of substances as shown by the fact that the respective expansion curves can be expressed by one and the same equation and that the constants of this equation have values very close to each other for substances of the most diverse chemical and physical properties.

The Kinetics of Thermal *Cis-Trans* Isomerization. VI

BY G. B. KISTIAKOWSKY AND WALTER R. SMITH

In one of the earlier papers[1] of the present series, evidence was presented indicating that the first order rate of isomerization of methyl cinnamate began to fall off at a pressure of 6 mm. Unfortunately, due to the analytical method employed, it was not feasible to study the reaction at still lower pressures. This compound and dimethyl maleate[2] have been the only two in a series of geometric isomers in which this phenomenon, characteristic of unimolecular reactions, has been observed.

In β-cyanostyrene the number of contributing degrees of freedom could be expected to be appreciably less than in methyl cinnamate, because of substitution of a CN group for the $COOCH_3$ group. Hence, with β-cyanostyrene the rate might begin to fall off at a higher pressure and an extensive study of the rate–pressure dependence could be made.

The present paper describes a number of experiments on the rate of isomerization of β-cyanostyrene performed at various temperatures and over an extensive range of pressures.

Experimental Details

Preparation of β-Cyanostyrene.—The nitrile was prepared according to the method of Ghosez[3] by the condensation of benzaldehyde and cyanoacetic acid in the presence of pyridine. Sixty per cent. of the theoretical yield was obtained.[4]

The resulting mixture of the geometric isomers was distilled in an all glass still 3 m. tall and 18 mm. in diameter, packed with Pyrex glass spirals.[5] A 20–1 reflux ratio was used. Two fractions were obtained, one boiling at 139.1° at 30 mm. and the other at 152° at 30 mm. The high boiling fraction was further purified by freezing and allowing it to melt at 20°. The solid portion remaining was distilled at 122° at 2 mm. in a Claisen flask. The weight ratio of high to low boiling isomers was 62:38. Ghosez[3] obtained 63% high boiling compound.

The high boiling isomer melted at 22° and had $n^{20.2}D$ 1.6031. For the low boiling isomer the melting point was −4.4° and $n^{20.2}D$ 1.5843. According to Ghosez and in conformity with other evidence[6] the low boiling isomer must be assigned the *cis* configuration. This is also in agreement with equilibrium data presented below.

Analytical Method.—The appreciable difference in the refractive indices of the two isomers provided a rapid and convenient method of analyzing the reaction mixtures. An Abbé refractometer, thermostated to 20.2° and employing a sodium vapor lamp, was calibrated with a series of known mixtures of the isomers. A strictly linear relationship between composition and refractive index was found. It was possible to detect 0.5% of either isomer.

The melting points of these mixtures were also determined by means of a single junction copper–constantan thermocouple. The couple was used sometimes to check the values obtained from the refractometer, as described below.

The apparatus was of the usual static type. Both it and the experimental procedure have already been described elsewhere.[2]

Some of the earlier runs were analyzed both by the refractive index method and the freezing point. In all cases the two methods gave analyses agreeing to 1%, which is to be regarded as indicating the absence of side reactions.

The reaction was further established by connecting the nitrile to cinnamic acid. The product from a run on the

[6] Wright, *ibid.*, **57**, 1993 (1935).

high boiling isomer gave a refractive index indicating the presence of 21% low boiling isomer; 1.69 g. of this product was refluxed for twenty-four hours with 25 cc. of an aqueous 7% sodium hydroxide solution. The solution was then neutralized with dilute hydrochloric acid and the precipitated cinnamic acid was washed free of chloride ion and dried. An 82% yield was obtained. The product melted at 133°. A sample of pure high boiling isomer gave a yield of 81% cinnamic acid, melting at 133°. This evidence, together with the agreement of the refractive index and the melting point methods, indicates clearly that the reaction studied is primarily isomerization.

Experimental Results

No real pressure change could be noted in any of the runs. The product of all runs, except those at the lowest pressure, was clear and colorless. In the latter case a slight grayish turbidity appeared. This settled out on standing and did not interfere with the refractometer readings.

The position of thermal equilibrium at 352° was determined by heating known mixtures of the isomers, in the gas phase, for varying lengths of time. The results of these experiments are reproduced in Fig. 1. At 352° equilibrium exists at 63% high boiling isomer.

A few runs on the low boiling isomer at 352° and at a pressure of 390 mm. gave average velocity constants of 4.03×10^{-5} sec.$^{-1}$. The average constant for the high boiling isomer at these conditions is 2.89×10^{-5} sec.$^{-1}$. The equilibrium concentration of 60% high boiling isomer obtained from these values is in satisfactory agreement with the more accurate value obtained above.

Since these values are nearly identical with the value obtained in preparing the compound at temperatures lower than 100°, it is obvious that the value of ΔH is too small to be determined by studying the equilibrium over any convenient temperature range.

The results of all runs on the high boiling (*trans*) isomer are presented in Table I. The velocity constants have all been calculated allowing for equilibrium at 63% high boiling isomer.

Runs were made over a pressure range of 450 to 20 mm. At the lower pressures there is a marked increase in the velocity constants. At the lowest temperature this increase is nearly threefold. At the highest temperature the constants are nearly identical at all pressures. Runs in a packed flask with about six times the surface gave a marked increase in the constants at the lowest pressure, while such an increase was not noted at the higher pressures.

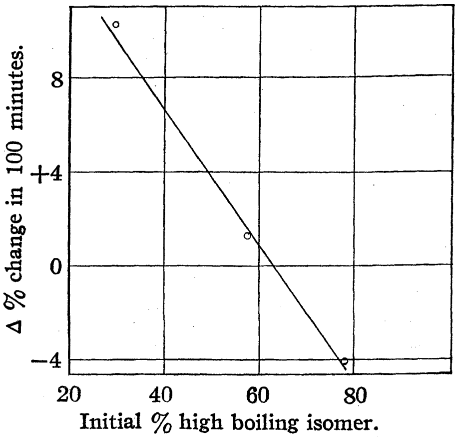

Fig. 1.—Equilibrium composition at 352°.

It is evident that at the lower pressure a wall reaction occurs to some extent. It does not interfere with the rate measurements of the homogeneous reaction at higher pressures, but makes very uncertain the detection of a possible falling off of the rate constant with pressure. Hence the originally intended study of the falling off was abandoned and only the high pressure rate studied.

[a] Six times surface.

Figure 2 shows the temperature dependence of the rate of isomerization. Only the runs at the highest pressures have been used. The activation energy is found to be 46,000 ± 1000 cal., which is somewhat higher than those obtained earlier for other *cis–trans* isomerizations involving phenylethylene groups.[1] With this value for the activation energy, the reaction rate constant at high pressures receives the form

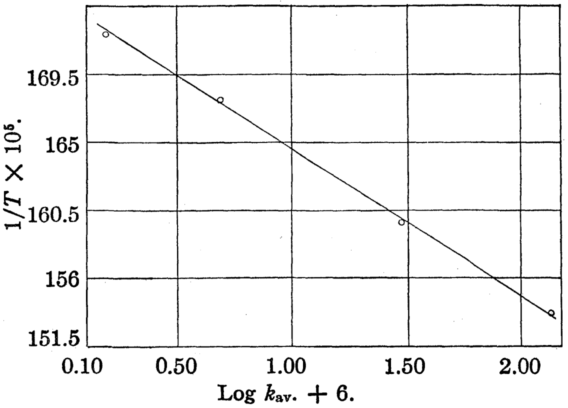

Fig. 2.—Log k–$1/T$ plot of the first order isomerization rate constant.

$$k = 10^{11.6 \pm 0.4}\, e^{-(46{,}000 \pm 1000)/RT}$$

Little new can be added to the comments which were made in earlier papers on the *cis–trans* isomerization, but we wish to point out once more that apparently in all reactions involving rotations of heavy groups, the "A" factor is considerably lower than the "normal" value, 10^{13}, to be expected from statistical considerations.

The Eyring[7] theory, which in a simplified version, possibly applicable to the present case, gives the rate constant as

$$k = \nu e^{-E/RT}$$

ν being here presumably the frequency of the torsional vibration around the double bond, leads to values of this frequency which are of the order of 1–10 cm.$^{-1}$, hence rather too small.

Summary

1. The rate of isomerization of β-cyanostyrene has been studied and found to be of the first order. The velocity constant at higher pressures is given by

$$k = 10^{11.6 \pm 0.4}\, e^{-(46{,}000 \pm 1000)/RT} \text{ sec.}^{-1}$$

2. The equilibrium mixture at 352° contains 63% high boiling (*trans*) isomer. The equilibrium composition appears to be practically independent of temperature.

Some Characteristics of the Residue from the Cracking of Castor Oil[1]

BY ARTHUR A. VERNON AND HALKEY K. ROSS

Much work has been done to determine the chemical nature of castor oil and the results of Krafft,[2] Walden[3] and Kasansky[4] have shown that it consists mainly of the glyceride of ricinoleic acid. More recently Eibner and Münzing[5] have shown that the fatty acid content of castor oil is 95%; 80% is ricinoleic acid and the remaining 15% is a mixture of oleic, linoleic, stearic and dihydroxystearic acids. The structural formula indicates that the probable place of breaking under the influence of heat would be between the twelfth and thirteenth carbon to yield an aldehyde as is the case with hydroxy acids. The glyceryl portion of the molecule[6] should rupture readily to give acrolein and such is experimentally found to be true on this basis. The third product of decomposition should be undecylenic acid but in actual practice the residue from atmospheric cracking, after removal of heptaldehyde and acrolein, is a complex mixture. Perkins and Cruz[7] found that the distillation at 400° under a pressure of 50 mm. produced a distillate composed of about 40% heptaldehyde and 20% of undecylenic acid. Roy[8] studied the changes in castor oil when heated to 140° in the presence of oxygen and nitrogen. The viscosity, iodine number, acid number and index of refraction were found to

increase in the presence of oxygen. It was felt that an investigation of the properties of the products of the pyrolysis of castor oil might give information concerning the mechanism of the breakup under the influence of heat and therefore an investigation was made of the acid value, saponification value, acetyl value and iodine number of the residue. Barbot[9] has suggested a molecular rearrangement as the way in which the molecule may break up under the influence of heat and the results of this work may be of value for his interpretations.

Apparatus.—The castor oil was allowed to flow at a constant rate into a heated silica tube 65 cm. long and 2 cm. inside diameter and the product condensed in a water-cooled condenser. The temperature inside the tube was measured with a chromel–alumel thermocouple enclosed in glass.

Material.—The castor oil was Baker chemical grade with these constants: acid value, 12.5; saponification number, 178.3; acetyl value, 152.1; iodine value, 87.13.

Procedure.—The tube was heated to the desired temperature and the oil allowed to flow into the tube at a rate of 505 g. per hour. The first 10–15 cc. of the cracked product was discarded and then about 150 cc. of the material was collected.

This substance was steam distilled until the removal of heptaldehyde was complete. The remaining material was washed, then dried with anhydrous sodium sulfate in an oven at about 100°. According to Woodman[10] this is the customary method of drying oils and fatty acids. Samples were then analyzed to determine the chemical constants.

The acid and saponification values were determined according to the A. O. A. C. Book of Methods.[11]

The acetyl values were made according to the method of Andre-Cook.[12] The iodine numbers were found according to the Wijs Method.[11]

TABLE I

DATA CONCERNING THE RESIDUE

Temp., 0°	Acid number	Saponification number	Acetyl value	Iodine value
299	3.46	178	151.0	85
340	12.40	176	140.0	92
405	55.30		130.5	107
410		164		
450	148.80	82	93.8	
475	155.50	79	41.3	113
510	170.00	70	33.2	
540	171.20			117
620	187.50	48	23.5	119
675	217.00	42		124
750				123

The results of the determinations are summarized in Table I.

The results of the acid number, saponification number and acetyl value determinations are plotted in Fig. 1 to show how these three characteristics vary with the temperature of pyrolysis.

It was noted that dark brown fumes were emitted and that there was no smell of acrolein in the distillate above 800°. A decomposition took place above 800° which resulted in the production of some aromatic compounds.

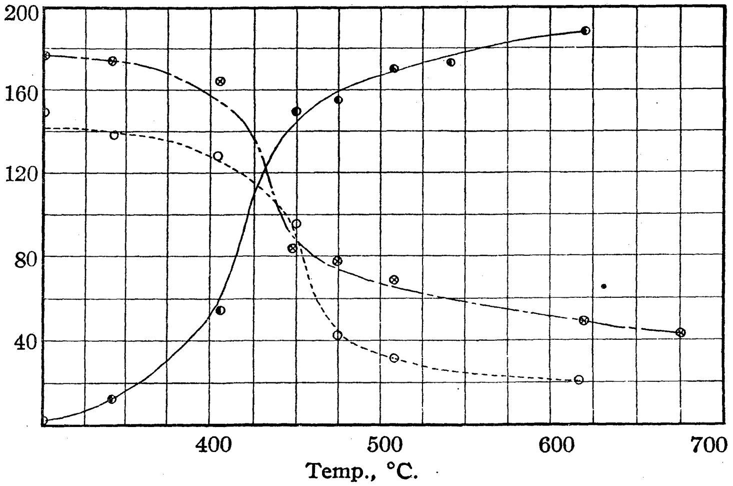

Fig. 1.—Variation of characteristics of castor oil residue with temperature of pyrolysis: ◐, free acid value; ⊗, saponification number; ○, acetyl value.

In order to determine the place of undecylenic acid in the pyrolysis, a test was made in which it was subjected to the same temperatures as castor oil at the same rate of 505 g. per hour, and the iodine value of the residue was determined. The results of this experiment are shown in Table II.

TABLE II

IODINE VALUE OF UNDECYLENIC ACID

Temp., °C.	Iodine value
135	126.6
214	127.2
280	126.9
355	129.0
505	127.8
565	135.0
640	142.0
735	113.6

A plot of the values of Table II appears in Fig. 2 together with the determinations of the iodine number of cracked castor oil.

Discussion of Results

Figure 1 shows a sharp drop in saponification value at about 425° and this would indicate that the glyceryl portion of the molecule is broken off at this temperature. Figure 1 also shows an increase in the acid value at the same temperature, which is added evidence for the formation of free acid. It would seem from this that the first pyrolytic action to occur is the decomposition of the glyceryl portion and the production of acrolein. Figure 1 further shows that the acetyl value drops at 465°, which means that the hydroxyl grouping of the castor oil disappears at this point. This would indicate the formation of heptaldehyde and undecylenic acid. A valuable check on this hypothesis can be made if the characteristics of the residue after the removal of heptaldehyde and acrolein can be shown to be similar to the characteristics of the product of the pyrolysis of undecylenic acid alone. If the acetyl value of the castor oil residue is taken at some temperature and the amount of undecomposed castor oil is calculated, then the amount of iodine number contributed by that undecomposed castor oil can be calculated. If the remainder of the iodine value is attributed to undecylenic acid and its decomposition products, this value can be obtained from Fig. 2 at the corresponding temperature. The sum of these two values should agree with the corresponding iodine value of the castor oil residue.

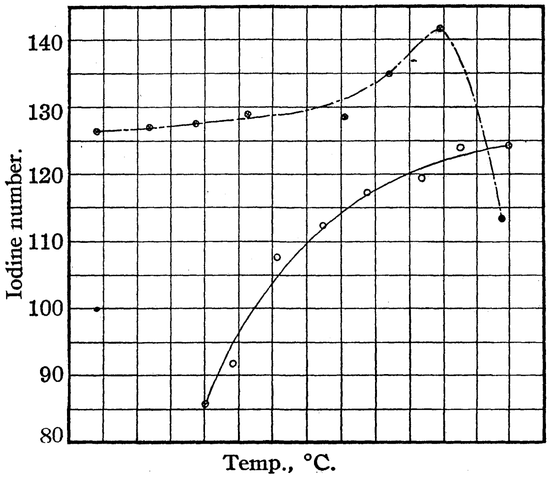

Fig. 2.—Variation of iodine number with temperature of pyrolysis: ⊗, undecylenic acid; ○, castor oil.

The agreement shown in the table is within the precision of the iodine number determinations.

TABLE III

CALCULATED AND OBSERVED IODINE VALUE OF THE CASTOR OIL RESIDUE

Temp., °C.	Calcd. iodine value of residue	Observed value of residue
300	85	85
450	104.7	110
475	115.7	113
500	117	115
550	123.4	118
600	126.6	120.5
650	130	122
700	125	123
725	114.5	121

Ho, Wan and Wen[13] have shown that the iodine value is influenced by the amount of excess iodine solution used for a given sample. The weight of the sample taken for these determinations was always approximately the same, and the iodine solution added was always the same. Since the unsaturation of the samples varied, therefore the iodine excess must have been greater in some samples than in others. This undoubtedly influenced the values obtained. Part of the discrepancy might be attributed to the 20% of the other substances present in castor oil.

The most favorable yield of heptaldehyde obtained was 28.9% by weight of castor oil while the theoretical yield would be 34%.

Work is at present in progress to determine quantitatively the amounts of acrolein and heptaldehyde which are produced at various temperatures. It is hoped that in this way a careful check can be made on the possible mechanism which seems to be indicated by the results obtained. These would be valuable since Shepard[14] has stated that ricinoleic acid has not been cracked successfully to give heptaldehyde. However, the conditions of the pyrolysis in the cracking of castor oil may not be the same as the chemical condition when ricinoleic acid is pyrolyzed.

Summary

1. Castor oil was submitted to pyrolysis at various temperatures in a heated silica tube. The acrolein and heptaldehyde were removed and the iodine number, acetyl value, saponification value and acid value of the residue was determined.
2. Undecylenic acid was submitted to pyrolysis under the same conditions.
3. The results may be explained by assuming

[14] M. G. Shepard, private communication.

that acrolein splits off first and then the molecule breaks down to give heptaldehyde. The latter reaction requires a higher temperature.

KINGSTON, R. I. RECEIVED JULY 21, 1936

The Lead–Uranium Ratio of Henvey Cyrtolite[1]

BY O. B. MUENCH

In September, 1931, Dr. H. V. Ellsworth of the Department of Mines, Canada, sent a lump of cyrtolite obtained from the Besner Mine, Henvey Township, Ontario, to the University of Missouri. At that time work on the Hybla Cyrtolite[2] was planned and partly under way, so it was found impossible to do more than a little preliminary work on the Henvey Cyrtolite. Work on this cyrtolite was carried to definite results during the summer of 1935. A lead–uranium ratio on this cyrtolite is interesting for comparison with the one on a Besner Uraninite[3] which has been available for some time.

The occurrence of this cyrtolite and its mineral associates are described by Spence[4] and also Ellsworth[3] (p. 173).

The Sample.—The sample was mostly in one large piece with feldspar at one end. It was very homogeneous, of black pitchy luster and seemed to be altered very little, if any. Only the black homogeneous part was taken, and pulverized in an iron mortar until all of it passed through an 80-mesh sieve. This sieve had no solder from which contamination might be derived. The pulverized sample of cyrtolite weighed 242 g.

Methods of Analysis

In general, the procedure followed in the determination of the uranium, after the sample was in solution was as follows. The zirconium and hafnium were removed as phosphates in acid solution, and then after the removal of the iron, etc., as sulfides in ammonium carbonate solution, the uranium was precipitated as the phosphate in a solution slightly acid with acetic acid. The phosphate method was used because phosphate had been introduced in the removal of the zirconium and hafnium and it was therefore the most direct method to follow. The thorium, after the sample was in solution, and the zirconium and hafnium had been removed by precipitation as phosphates in sulfuric acid solution, was precipitated as the oxalate in oxalic acid solution. Two different methods were followed from this point on. In the peroxide method, the oxalate was converted to the nitrate and the thorium precipitated with hydrogen peroxide from a neutral solution of ammonium nitrate. The precipitate on ignition changes to the oxide. In the iodate method, the oxalate was first converted to the nitrate, and then precipitated with potassium iodate in strong nitric acid solution. The iodate precipitate was dissolved in hydrochloric acid and the thorium precipitated with ammonium hydroxide. Finally this precipitate was dissolved in hydrochloric acid and then the thorium precipitated with oxalic acid. The oxalate was ignited to the oxide and weighed. The lead was determined by the usual procedure of separation as a sulfide, conversion to a sulfate, extraction with ammonium acetate and final precipitation as a chromate.

Uranium.—One-gram samples were fused with sodium peroxide (which oxidized all the carbon) in a nickel crucible. The fused samples were then dissolved in hydrochloric acid, baked in a porcelain dish, taken up with dilute hydrochloric acid and filtered. The residue, after volatilization with hydrofluoric and sulfuric acids, was added to the filtrate. The solution was made alkaline with pure ammonium hydroxide. After three precipitations with pure ammonium hydroxide, the precipitate was dissolved in 30 ml. of concd. sulfuric acid. From this point on, the procedure as given in the paper, "The Age of a Canadian Cyrtolite,"[2] near the bottom of p. 489 was followed.

Thorium.—Five-gram samples were taken for analysis. The method as given in the above

paper[2] was followed, except that after the treatment with hydrofluoric acid the samples were treated with nitric and sulfuric acids and heated to fuming in order to remove carbon. After the samples were taken to the point described at the bottom of p. 491, two samples were analyzed by the iodate method.[5] The third sample was analyzed by Fenner's[6] modification of the peroxide method. His method was followed for this sample from p. 376, when the residue is taken up with 100 ml. of 20% ammonium nitrate solution.

Lead-uranium ratio,

$$\frac{\text{Ra G}}{\text{U} + 0.36\text{Th}}, \frac{0.036}{1.83 + 0.36 \times 0.01} = 0.019$$

Lead.—The method used for the lead determination was essentially that described in the paper "The Age of a Canadian Cyrtolite."[2]

Recoveries of lead were made on the filtrates and are included in the weights of the lead chromate precipitates. Carefully tested, lead-free reagents were used.

Approximate Age of the Mineral.—We have no atomic weight determination of the lead from this cyrtolite. Assuming the absence of ordinary lead, the approximate age calculated from the above lead-uranium ratio is

$$\frac{0.019 \times 1.15 \text{ million years}}{1.57 \times 10^{-4}} = 139 \text{ million years.}$$

Acknowledgment.—The writer wishes to express his gratitude to Dr. H. Schlundt for his interest in this work and also the use of the Laboratories and other facilities of the University of Missouri. The author is indebted to Dr. A. C. Lane for his many suggestions and to Dr. H. V. Ellsworth for furnishing the mineral sample. Thanks are here expressed to the National Research Council for financial aid.

Conclusion

As pointed out by Lane,[7] the lead ratio is abnormally low and only about a sixth of that of the uraninite from the same mine. He gives a possible explanation of this.

Practically the entire sample was used for the determinations described in this paper, leaving an insufficient amount for an atomic weight determination of the lead. The approximate age of this mineral in the absence of an atomic weight determination of the lead, is calculated from the analysis as one hundred and thirty-nine million years.

The amount of thorium is so small that no critical test of the two methods is indicated by the results.

The percentage of sulfur is higher in this cyrtolite than in the other cyrtolites which were analyzed at the same time for sulfur.

On the Application of the Raman–Krishnan Theory to Dipole Moment Measurements by the Dilute Solution Method

BY H. O. JENKINS AND S. H. BAUER

It has been suggested by Le Fèvre and Le Fèvre[1] that the Raman–Krishnan theory of anisotropic dielectrics[2] provides an explanation of the effect of the medium on the determination of the moment by the dilute solution method. We wish to point out that strong theoretical objections to the Raman–Krishnan treatment itself can be raised and to demonstrate empirically that the particular application is not useful since accurate predictions cannot be made by means of it.

To begin with, it is difficult to justify the expression given by the latter investigators for the local field (equation 11, note 2) when the parameters are given the meaning they intend them to have. An extended argument for the model they had in mind is presented by Krishnan and Rao,[3] who attempt to show that the field at the center of an ellipsoidal cavity of the dimensions of a single molecule immersed in a medium of uniform polarizability is the proper value to be taken for the local field. We should like to draw attention to the restrictions to which the equations used in obtaining the field in a cavity are subjected, *viz.:* the cavity must be so large that it contains many of the volume elements over which the necessary integrations are to be performed and hence must contain many molecules, while at the same time it must be sufficiently small so that the polarization does not vary appreciably across it. As the cavity is made smaller quadrupole and higher order terms should be taken into consideration, and when its dimensions approach those of a single molecule the integration of the polarization over the surface of the cavity should further be replaced by a summation. If these latter troublesome evaluations are to be avoided, the cavity must be made of dimensions of the order of thousands of molecules and then, obviously, the local field will be independent of the shape chosen.

Hence, as far as we can see, for solutions one cannot escape calculating the contribution to the local field of the material inside the cavity (called F_3), which requires that special assumptions be made regarding the distribution of charges around the dipole in question. To emphasize the complexity of the situation we shall list the factors which must be taken into consideration in expressing the mean volume polarization of a sufficiently dilute solution (one in which dipole–dipole interactions may be neglected) in terms of molecular constants: (a) the effect of the impressed field upon the solvent molecules; (b) the effect of the dipoles on the solvent molecules in their immediate vicinity; (c) the effects of solvent molecules on each other (usually quite small); (d) the effect of the impressed field upon the solute molecules; (e) the effect of the polarization of the solvent on the solute molecules (due to factors a, b and c); (f) the statistical fluctuations in the above effects (those of a and c are usually considered; the others are neglected). Since a rigorous treatment of all the above factors would be indeed a formidable task,[4] an empirical or semi-empirical method of approach seems the most promising at present. It is encouraging to note that F. E. Hoecker[5] has obtained highly accurate measurements on extremely dilute solutions of ethyl alcohol in various non-polar solvents and found that in the usual treatment an apparently anomalous behavior often takes place at great dilutions. By slightly modifying the analysis he was able to perform the extrapolation to zero concentration to obtain for the electric moment a value which agreed very well with the accepted one for the gas.

Since the ultimate value of a theory may best be ascertained by investigating its usefulness in predicting the results of experiments, we assumed the final form of the R–K formula (equation 23) and made the following empirical test. It was, however, first necessary to derive from the latter an expression which is applicable to a dilute solution. [We here wish to indicate that the Le Fèvre equation is not the one which is obtained

(4) Lars Onsager, THIS JOURNAL, **58**, 1486 (1936), considered some of these factors but restricted his discussion to spherical isotropic molecules immersed in an isotropic medium.

(5) F. E. Hoecker, *J. Chem. Phys.*, **4**, 431 (1936).

through the strict application of the theory since it gives only the most significant term but omits others which may be appreciable (see tables below); also that one should keep in mind that two assumptions must be made in attempting the suggested application: (a) the volume polarizations of the components are additive (*i. e.*, no interactions between solute and solvent molecule takes place which will alter their moments); (b) the new constants entering into the formulation are to be characteristic of the molecules themselves and not of the state of aggregation.] Under this circumstance

$$\frac{\epsilon_{12}-1}{\epsilon_{12}+2}\,\frac{M_1f_1+M_2f_2}{\rho_{12}} = \frac{4\pi N}{3}\left\{\left(\frac{a_{ii}+a_{jj}+a_{kk}}{3}\right)_1 f_1 + \left(\frac{a_{ii}+a_{jj}+a_{kk}}{3}\right)_2 f_2\right\} + N\,\frac{\epsilon_{12}-1}{\epsilon_{12}+2}\,(\psi_1f_1+\psi_2f_2) + \frac{N}{3kT}\left\{\frac{4\pi}{3}\,\mu^2 + \frac{\epsilon_{12}-1}{\epsilon_{12}+2}\,\theta_2\right\} f_2 \quad (1)$$

(suffix $_1$ refers to solvent; $_2$ to solute; $_{12}$ to solution), and M, f, N, ρ, k, T have their usual significance.

$\theta_2 = (\mu_i^2\sigma_i + \mu_j^2\sigma_j + \mu_k^2\sigma_k + \text{negligible cross terms})_2$

with $\sigma_i = p_i - \dfrac{4\pi}{3}$

$\mu_{i,j,k}$ are the components of the permanent electric moment of the solute molecule resolved along the principal axes of electric polarizability

$p_{i,j,k}$ are the factors determining the polarization field acting along any particular axis when the external field is along that axis

$\psi_2 = \dfrac{1}{3}\,(a_{ii}\sigma_i + a_{jj}\sigma_j + a_{kk}\sigma_k)_2$

and similarly for ψ_1

where $a_{ii,jj,kk}$ are the diagonal elements of the induced moment tensor.

The ψ's and θ_2 are therefore measures of the anisotropy of the molecules composing the mixture.[6] Equation (1) may be rewritten

$$(P_{12}) \equiv (P_1^{\text{g}})f_1 + (P_2^{\text{g}})f_2 = \frac{4\pi N}{3}\left\{\left(\frac{a_{ii}+a_{jj}+a_{kk}}{3}\right)_1 f_1 + \left(\frac{a_{ii}+a_{jj}+a_{kk}}{3}\right)_2 f_2 + \frac{\mu^2}{3kT}f_2\right\} = \frac{\epsilon_{12}-1}{\epsilon_{12}+2}\left\{\frac{M_1f_1+M_2f_2}{\rho_{12}} - N(\psi_1f_1+\psi_2f_2) - \frac{N}{3kT}\,\theta_2f_2\right\} \quad (2)$$

from which it may appear that one may solve for P_2^{g} from the value of ϵ_{12} at any concentration provided the molecular anisotropy constants are known. The molecular polarization symbols are therefore placed in parentheses to indicate that this is not legitimate as dipole–dipole and other interactions have not been taken into consideration in equation (2). The usual procedure of extrapolating to infinite dilution must be resorted to. Since in the range of concentrations used it has been experimentally verified that[7]

$$\begin{aligned}\epsilon_{12} &= \epsilon_1(1+K_1f_2+K_2f_2^2)\\ \rho_{12} &= \rho_1(1+R_1f_2+R_2f_2^2)\end{aligned} \quad (2a)$$

one finds

$$(P_2^{\text{g}})_\infty = \frac{\epsilon_1-1}{\epsilon_1+2}\,\frac{M_1}{\rho_1}\left\{\frac{M_2}{M_1} - R_1 + \frac{3\epsilon_1K_1}{(\epsilon_1-1)(\epsilon_1+2)}\right\} - \frac{3\epsilon_1K_1N}{(\epsilon_1+2)^2}\,\psi_1 - \frac{\epsilon_1-1}{\epsilon_1+2}\,N\left(\psi_2+\frac{1}{3kT}\,\theta_2\right) \quad (3)$$

which is an expression for the "gas" value of the polarization obtained by extrapolating data on dilute solutions using the R–K equation. But the first term of the right member of (3) is equal to P_2^{sol};[8] whence

$${}_\infty P_2^{\text{sol}} = (P_2^{\text{g}})_\infty + \frac{\epsilon_1-1}{\epsilon_1+2}\,N\left\{\psi_2+\frac{\theta_2}{3kT}\right\} + \frac{3\epsilon_1NK_1}{(\epsilon_1+2)^2}\,\psi_1 \quad (4)$$

---

(6) One may indicate at this point why the R–K equation as applied for the purpose at hand breaks down. Although in the first paper on the subject written by these authors it is stressed that the ψ's and θ's are to depend on the state of aggregation as well as on the characteristics of the particular molecules, in the subsequent work, however, these quantities were treated consistently as molecular constants and, in fact, must be so considered if their values are to be calculated theoretically.

(7) The use of a quadratic form is somewhat unusual. It is, however, a simple matter to show that this is essential in a number of cases. The authors wish to stress particularly that the graphical methods of extrapolation which are almost universally employed in this work are not sufficiently sensitive to detect deviations from linearity which may introduce as much as five per cent. error in the values of K_1 and R_1. Thus, for nitrobenzene in *n*-hexane, the K_1 derived from measurements on a solution for which $f_2 = 0.046$, was 7.566 when a linear relation was used but reduced to 7.232 when a quadratic one was assumed.

(8) With the aid of (2a), an expansion results in the following analytic expression for the quantity usually referred to as

$$P_2^{\text{sol}} = \phi_0 + \phi_1f_2 + \phi_2f_2^2 + \phi_3f_2^3 + \ldots \text{ where}$$

$$\phi_0 = \frac{\epsilon_1-1}{\epsilon_1+2}\,\frac{M_1}{\rho_1} \equiv P_1^{\text{g}}$$

$$\phi_1 = \frac{\epsilon_1-1}{\epsilon_1+2}\,\frac{M_1}{\rho_1}\left\{\frac{M_2}{M_1} - 1 - R_1 + \frac{3\epsilon_1K_1}{(\epsilon_1+2)(\epsilon_1-1)}\right\}$$

$$\phi_2 = \frac{\epsilon_1-1}{\epsilon_1+2}\,\frac{M_1}{\rho_1}\left\{R_1^2 - R_1\left(\frac{M_2}{M_1}-1\right) - R_2 + \frac{3\epsilon_1K_1}{(\epsilon_1+2)(\epsilon_1-1)}\left(\frac{K_2}{K_1}+\frac{M_2}{M_1}-1-R_1-\frac{\epsilon_1K_1}{\epsilon_1+2}\right)\right\} \text{ etc.}$$

It is clear then that although in the final value of ${}_\infty P_2^{\text{sol}}$ the second order coefficients of f_2 do not appear, they do make a contribution to P_2^{sol} and their non-vanishing may introduce significant changes in the values of K_1 and R_1 which will affect the limiting value. Again, for nitrobenzene in *n*-hexane, ϕ_2 varies by approximately 12% in going from $f_2 = 0.046$ to 0.015 (H. O. Jenkins, *J. Chem. Soc.*, 480 (1934)). It is thus of interest to raise the question whether the extrapolations made heretofore on the assumption of a linear variation of P_2^{sol} with f_2 are valid in the range of concentrations investigated. Apparently, even though the slope of the line may vary by large amounts as indicated above, the limiting value actually changes slightly due to the fact that the ratio $\phi_2f_2/(\phi_0+\phi_1)$ is a small quantity.

As a rule, the $\frac{\epsilon_1 - 1}{\epsilon_1 + 2} N\psi_2$ term is of the order of a cc. and may be neglected.[9]

In making the test of the applicability of the theory we calculated values of θ_2 for a number of polar solutes and compared them with the values which one must assume in order to explain the solvent effect. To obtain ψ_1 and θ_2, one must first compute the appropriate σ and a terms. There are several possible sources for these: (1) x-ray diffraction data for the liquid, giving closest distances of approach, as recommended by Krishnan and Rao. We desire to stress that such values are only significant when derived through the use of the Ehrenfest–Keesom equation, within the limitations indicated by Warren;[10] (2) light scattering data on the liquids; (3) the variation of the polarization of the liquids with pressure;[11] (4) molecular geometry as derived through the use of tables of covalent radii[12] and electron diffraction data (published by Pauling, Brockway and others). The eccentricity of the ellipsoidal cavity produced by the removal of the molecule of interest from the body of the medium which is considered as continuous may be assumed to be determined by the molecular dimensions only; the formulas given by Lord Rayleigh[13] are to be used. Method (4) enabled the authors to calculate the σ's while the a's were determined from light scattering data according to the procedure outlined by Krishnan and Rao. The following values were obtained.

TABLE I

Compound	ψ_1	a_{ii}	a_{jj} ($\times 10^{24}$)	a_{kk}	σ_1	σ_2	σ_3
n-Hexane	-2.1×10^{-24}	13.9	10.8	10.8	−1.68	0.82	0.82
Cyclohexane	−1.3	12.0	12.0	10.0	−0.58	−0.58	1.12
Carbon tetrachloride	−0.0						
Benzene	−5.2	12.9	12.9	6.38	−1.18	−1.18	2.32
Carbon disulfide	−7.0	5.74	5.74	13.0	1.47	1.47	−2.92

	θ_2	σ*
Nitrobenzene	-43.4×10^{-36}	−2.46
Chlorobenzene	− 7.6	−2.36
4-Chlorodiphenyl	− 8.9	−3.48
4-Nitrodiphenyl	−68.2	−3.52
α-Nitronaphthalene	−31.6	−1.88
β-Nitronaphthalene	−49.5	−2.46

* In making these calculations, the coördinate system was so chosen as to orient one of the major axes parallel to the direction of the resultant dipole. Then only one σ term appears in the expression for θ_2. The appropriate ones are listed.

By analogy with the corresponding chloro compounds the gas electric moments of α- and β-nitronaphthalene have been assumed to be 4.1 *D* and 4.5 *D*, respectively. The shape of the β-compound was considered to be approximately ellipsoidal while that of the α an oblate spheroid.

The following two tables give the values of θ_2 which are required to explain the experimental facts for nitrobenzene and chlorobenzene. The total polarization of these at 25° in the gas phase are 400 cc. and 91 cc., respectively.[14]

TABLE II

NITROBENZENE IN VARIOUS SOLVENTS

Solvent	$_\infty P^{\text{sol}}$	$\frac{3N\psi_1 K_1\epsilon_1}{(\epsilon_1 + 2)^2}$	$\theta_2 \times 10^{36}$	$\theta'_2 \times 10^{36}$
n-Hexane	372.5	− 3.4	−21.4	−24.4
Cyclohexane	360.0	− 2.4	−30.1	−32.0
Carbon tetrachloride	353.1	− 0.0	−32.7	−32.7
Benzene	353.8	−11.6	−23.5	−31.4
Carbon disulfide	310.0	−19.3	−40.6	−51.6

CHLOROBENZENE IN VARIOUS SOLVENTS

Solvent	$_\infty P^{\text{sol}}$	$\frac{3N\psi_1 K_1\epsilon_1}{(\epsilon_1 + 2)^2}$	$\theta_2 \times 10^{36}$	$\theta'_2 \times 10^{36}$
n-Hexane	86	− 0.7	− 3.8	− 4.4
Cyclohexane	84	− 0.7	− 5.0	− 5.6
Carbon tetrachloride	81	− 0.0	− 7.0	− 7.0
Benzene	81	− 1.7	− 5.6	− 6.8
Carbon disulfide	75	− 2.3	− 7.6	− 9.0

From Table II it can be seen that whether the effect of the solvent has been taken into consideration in the ψ_1 term (column 3) or whether it has been neglected (column 4), within the range of 50% θ_2 is not a molecular constant.[6]

Experiments also indicate that the polarizations of many substances are closely alike in benzene and carbon tetrachloride solutions but since ψ_1 is 5.2×10^{-24} for the former and zero for the

---

[9] Le Fèvre and Le Fèvre neglected the term involving ψ_1 as well.

latter, the theory predicts that a difference should always exist. For nitrobenzene this difference is predicted to be 11 cc. but only 1 cc. has been found experimentally. The theory also indicates the presence of considerable divergences in the behavior of substituted diphenyl and naphthalene derivatives from that of the corresponding benzene compounds. That this is unlikely is demonstrated by the fact that the polarization of 4-chlorodiphenyl in benzene is close to that of chlorobenzene; further experimental work will be undertaken shortly to test this point.

Acknowledgments.—The authors wish to express their thanks to Professors Pauling and Houston and to Dr. Wheland for the many discussions relating to the material here presented. One of us (H. O. J.) is indebted to the Commonwealth Fund for a fellowship.

Summary

Theoretical objections to the Raman–Krishnan theory of anisotropic dielectrics are raised.[15] Empirical tests further indicate that the application of the above theory to dielectric constant measurements of dilute solutions of polar solutes in non-polar media would enable one to predict the difference between the moments as determined by the dilute solution method and those derived from gas measurements only as to order of magnitude.

[15] Subsequent to the submittal of this manuscript to the Editor a paper by Hans Mueller appeared [*Phys. Rev.*, **50**, 547 (1936)] in which essentially similar conclusions were reached through the use of arguments quite unlike those presented here.

[CONTRIBUTION FROM THE PHYSICO-CHEMICAL LABORATORY OF THE NEW YORK STATE EXPERIMENT STATION]

The Influence of Neutral Salts on the Optical Rotation of Gelatin. V. Rotatory Dispersion of Gelatin in Sodium Bromide Solutions[1]

BY D. C. CARPENTER AND F. E. LOVELACE

Previous work from this Laboratory[2] has shown that a single term Drude equation $[a]_\lambda = k/(\lambda^2 - \lambda_0^2)$ expressed the rotatory dispersion of gelatin dissolved in sodium iodide solutions and that the dispersion was governed by an absorption band at 2200 Å. At 40° the rotatory dispersion constant k was linearly related to sodium iodide concentration and at 0.5° was found to be expressed by the sum of two equations, $C_{\mathrm{NaI}} = k \log [a/(1 - a)] - \log (1/K)$ and the linear equation $K_{0.5°} = K - k_0 C_{\mathrm{NaI}}$. It was concluded that the tremendous effect of sodium iodide on the rotation of gelatin at 0.5° was due to an association or dissociation of the gelatin molecule.

The purpose of the present investigation was to continue the rotatory dispersion studies using sodium bromide solutions as solvent and ascertain if the above equations were applicable to other alkali metal halide systems.

Experimental

The procedure for preparing the solutions and for the measurement of rotations, density, *p*H, etc., was the same as has been described before.[3]

The specific rotations of gelatin solutions at 0.5 and 40° were measured at five different wave lengths in the visible spectrum, *viz.*: red lithium line, $\lambda = 6707.86$ Å.; sodium D line, $\lambda = 5892.617$ Å. (optical mean); yellow mercury line, $\lambda = 5780.13$ Å. (optical mean); green mercury line, $\lambda = 5460.73$ Å.; and the deep blue mercury line, $\lambda = 4358.34$ Å. The various light filters employed have been described. The gelatin concentration of the solutions was 0.7824 g. per 100 g. of solution.

Discussion and Conclusions

In Tables I and II are given our data for 0.5 and 40°, respectively, for the wave lengths employed. In Figs. 1 and 2 these data are graphed, plotting the reciprocal of specific rotation against the squares of the wave lengths at which the rotations were obtained. The relationship is linear, which means that a single-term Drude equation adequately expresses the results.

As with sodium iodide solutions of gelatin, the straight lines cut the x-axis at the same point, corresponding to $\lambda_0 = 2200$ Å., the location of the absorption band of gelatin. The same value for λ_0 was obtained by solving our data mathematically by the method used before. The values of k, numerator in the Drude equation, were calculated for each concentration of sodium bromide and appear in Table III and are graphed in Fig. 3. At 40° the k values bear a linear relation to

concentration of sodium bromide as given by the equation

$$k_{40^\circ} = 44.517 - 4.415C_{\mathrm{NaBr}} \qquad (1)$$

At 0.5° the curve for the k values is made up of two simultaneously occurring effects, the one a linear relationship to concentration of sodium bromide

$$k_{0.5^\circ} = 46.330 - 4.8476C_{\mathrm{NaBr}} \qquad (2)$$

similar to the one above except for the fact that the constants are slightly different in magnitude from those at 40°, and a second relationship

$$C_{\mathrm{NaBr}} = \frac{1}{1.33}\log\left(\frac{a}{1-a}\right) - \log\,(1/K) \qquad (3)$$

where a represents the fraction dissociated as shown by the change in magnitude of the dispersion constants $k_{0.5^\circ}$. In Table III are given the a values for the dissociated fraction and the calculated values obtained for log $(1/K)$. The latter agree very well with one another and indicate a mean value of 2.002. The factor 1/1.33 preceding the dissociation term regulates how rapidly the dissociation or association takes place.

TABLE III

ROTATORY DISPERSION CONSTANTS AT 0.5 AND 40°

Soln.	Concn. NaBr, molal	$k_{0.5^\circ}$	a	Log $(1/K)$	k_{40°
1	0	99.541	..	...	44.517
2	0.50	97.117	..	...	42.407
3	1.01	92.261	0.045	2.010	40.110
4	1.34	86.723	.116	1.995	38.553
5	1.65	78.023	.254	2.002	37.122
6	1.95	65.723	.458	2.005	35.756
7	2.20	54.064	.654	1.992	34.548
8	2.45	45.375	.795	2.008	33.167

10	3.05	33.558	.962	1.993	30.842
11	3.40	30.568	.987	2.002	29.275
12	4.20	25.971	1.000	...	25.974

$k_{0.5} = 99.541 - XC_{\mathrm{NaBr}}$ where $X = 4.8476$
$k_{40} = 44.517 - XC_{\mathrm{NaBr}}$ where $X = 4.4149$
Mean log $(1/K) = 2.002$.

Attention is called to the identity of the ratio, for the salts sodium iodide and sodium bromide, between the respective constants for the linear equation (eq. 1 and 2); $k_{40}/k_{0.5^\circ} = 0.92$ for sodium iodide and 0.91 for sodium bromide. Attention

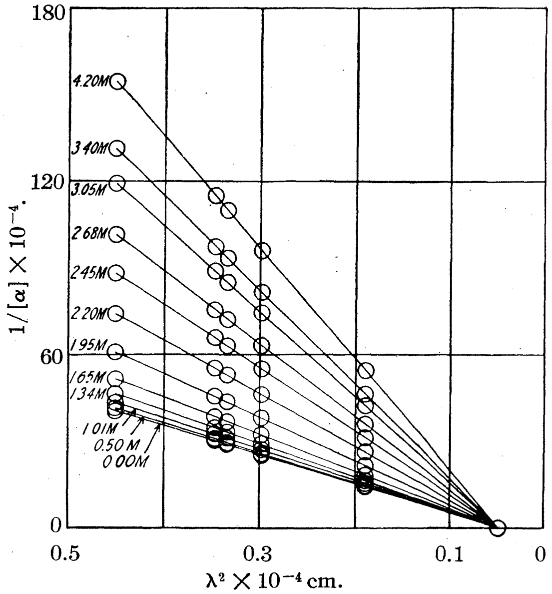

Fig. 1.—Graph of reciprocal of specific rotation *versus* wave length squared at 0.5°.

is also directed to the change in the value of the constant preceding the logarithmic term, log $[a/(1 - a)]$ (eq. 3), in going from sodium iodide to the bromide. With sodium bromide this constant (1/1.33) is exactly double that found for sodium iodide (1/2.66). Our preliminary experiments with sodium chloride indicate a value of 1/0.67, a further doubling of the value of this constant. The log $(1/K)$ term meanwhile changes from 0.9983 for sodium iodide to 2.002 for sodium bromide, an almost exact doubling; a preliminary value of 4.0 is indicated for sodium chloride, again a doubling. It is clear that for all the sodium halides the various log $(1/K)$ terms can be rewritten now as a common constant k' log $(1/K)$ of value 2.66, k' being the reciprocal of the former k.

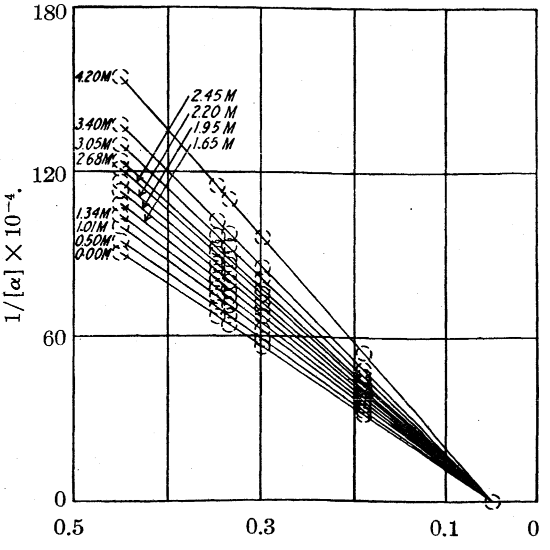

Fig. 2.—Graph of reciprocal of specific rotation *versus* wave length squared at 40°.

It is clear that in our experiments the influence of salts on the optical rotation cannot be explained as the polarization of the optically active molecules in an ionic atmosphere. According to Debye and Hückel, such an effect would require a greater effect for ions with small radii and large charges. If this were the case chlorides would be expected to have a greater effect on the rotation than iodides, which is contrary to fact.

It is not at present clear as to why the k constants preceding the dissociation term (1/0.67, 1/1.33 and 1/2.66) bear this mathematical regularity, respectively, for chlorides, bromides and iodides. It is pointed out that the sixth power of the ionic radii of the halogens as recorded by Wasastjerna[4] (Cl = 1.72; Br = 1.92; I = 2.19 Å.) gives a ratio 26:49:109, almost exactly the 1:2:4 ratio given by the respective denominators of the above k constants. While the principal effect of neutral salts on gelatin at 0.5° is no doubt due to the anion of the salt, nevertheless, the cation has a slight influence which is not accounted for in the sixth power relationship mentioned above.

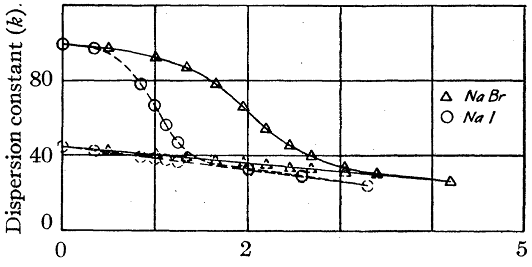

Fig. 3.—Rotatory dispersion constant of gelatin in sodium bromide solutions at 0.5 and 40°.

Smith[5] concluded that the effect of heating gelatin was to cause a bimolecular reaction to take place in which two molecules of the original protein were united together into one molecule at elevated temperatures. We have noted before[6] that heating to 40° caused a doubling of the molecular weight of the simplest species of casein. Weber and Stover[7] record osmotic pressure data

giving the molecular weight of muscle protein as 81,000 in water solution and as 300,000 in ammonium thiocyanate solution. We have shown[3] that potassium thiocyanate has the same sort of effect on the optical rotation of gelatin at 0.5° and of about the same magnitude as potassium iodide and that the effect of the sodium halides follows the dissociation (association) formulation stated before. The effect of the halide salts on the rotation at 0.5° also appears to be the same effect as that of raising the temperature, recorded by Smith. It seems fairly well established that the influence of the halide salts on gelatin at low temperatures is to cause an association of the protein molecule.

On applying the Lucas formulation[8] for two optically active components

$$k = \left[\frac{[\alpha]_1 - [\alpha]_2}{[\alpha]_1 - [\alpha]_n}\right]_{\lambda_a} = \left[\frac{[\alpha]_1 - [\alpha]_2}{[\alpha]_1 - [\alpha]_n}\right]_{\lambda_b} = \left[\frac{[\alpha]_1 - [\alpha]_2}{[\alpha]_1 - [\alpha]_n}\right]_{\lambda_c} \text{etc.} \quad (4)$$

to our data, the constants given in Table IV were obtained for the various combinations employed. It is obvious that a constant is actually obtained for any combination for a series of different wave lengths, as is required for a mixture of two optically active substances. We conclude therefore that the behavior of gelatin at 0.5° in the presence of sodium bromide is entirely analogous to its behavior with sodium iodide, that two and only two optically active species are present and that one optically active form is converted to the other by the action of the neutral salt and that one active form is the associated form of the other.

TABLE IV

CALCULATION OF THE LUCAS CONSTANT FOR GELATIN-SODIUM BROMIDE SYSTEM CONTAINING TWO OPTICALLY ACTIVE COMPONENTS (0.5°)

Summary

The rotatory dispersion of gelatin has been examined in various concentrations of sodium bromide at 0.5 and 40°, at five different wave lengths in the visible spectrum.

As was previously shown with sodium iodide solutions, a single term Drude equation expressed the experimental results. An absorption band at 2200 Å. governed the dispersion.

The rotatory dispersion constants of gelatin at 40° follow the linear equation $k_{40°} = 44.517 - 4.415\, C_{\text{NaBr}}$.

The rotatory dispersion constants at 0.5° were found to be expressed by the sum of two equations

$$C_{\text{NaBr}} = \frac{1}{1.33} \log \left(\frac{a}{1-a}\right) - \log (1/K)$$

and the linear equation

$$K_{0.5°} = 46.330 - 4.8476 C_{\text{NaBr}}$$

It was concluded that the great change in rotation caused by halides at 0.5° is due to an association of the gelatin molecule.

Based on the Lucas formulation, two and only two optically active species exist in gelatin solutions and gels.

Sodium Naphthalene. I. A New Method for the Preparation of Addition Compounds of Alkali Metals and Polycyclic Aromatic Hydrocarbons

By N. D. Scott, J. F. Walker and V. L. Hansley

The direct reaction of alkali metals with certain aromatic hydrocarbons has been reported previously in the literature, the reaction of sodium with anthracene in ethyl ether solution[1] being an example. Efforts to extend this reaction to simpler hydrocarbons such as naphthalene and diphenyl have met with very limited success. Schlenk and Bergmann were able to cause lithium to react with these hydrocarbons to a sufficient extent to make some examination of the products[2] but reported no detectable reaction with sodium under similar conditions.

A solution of sodium in liquid ammonia also has been used to bring about the addition of sodium to naphthalene but in this case the reaction is complicated by the rapid ammonolysis of the products.[3] Liquid ammonia as a solvent has the added disadvantage of reacting with carbon dioxide, interfering with the use of this reagent in characterizing the sodium compounds.

We have found that when methyl ether is used as the solvent medium the previously known sodium reactions take place many times faster than in ethyl ether. Furthermore, with this solvent it is possible to increase the scope of the reaction to include naphthalene and diphenyl as well as many other aromatic hydrocarbons. This striking difference of methyl ether compared with ethyl ether is more than a difference in the rate of the reaction, for if ethyl ether is added to a solution of sodium naphthalene in dimethyl ether the rate of formation of the sodium compound is gradually decreased. If sufficient ethyl ether is added the formation of the sodium compound is inhibited completely and the compound already formed decomposes with the liberation of the original hydrocarbon and elementary sodium. With concentrated solutions of hydrocarbons in pure methyl ether it is possible to dissolve one or two gram atoms of sodium per liter in two hours or less. It is already known that the first member of most homologous series of organic compounds shows the more characteristic properties of the series to a unique degree but the surprising difference between methyl ether and ethyl ether has not been fully appreciated by previous investigators. Methyl ethyl ether is the only other monoether in which these reactions occur readily. The formation of sodium naphthalene is slow but detectable in the methyl propyl ethers.[4]

In seeking for suitable solvents that are liquid at ordinary temperatures, we discovered that the dimethyl ether of ethylene glycol (b. p. 85°) is substantially equivalent to dimethyl ether as a solvent for sodium reactions. Contrary to the conclusions that might have been drawn from the behavior of monoethers it was found that all fully alkylated glycols and polyhydric alcohols are effective solvents for sodium addition reactions.[5] It was also found that trimethylamine and a few other amino compounds are effective although they offer little advantage over the ethers.

For most purposes dimethyl ether and the dimethyl ether of ethylene glycol are the most suitable solvents for the reaction, and the latter is the more convenient by reason of its boiling point. It is, however, slowly attacked by sodium naphthalene at room temperature with the formation of methyl vinyl ether, presumably in accordance with the equation

$$C_{10}H_8Na_2 + 2CH_3OCH_2CH_2OCH_3 \longrightarrow C_{10}H_{10} + 2CH_3ONa + 2CH_3OCH{=}CH_2$$

The methyl vinyl ether was identified by its boiling point and unsaturation toward bromine.

The presence of the special solvent is required not merely for the initiation of the reactions but for the existence of sodium naphthalene. This can be shown by preparing a solution of sodium naphthalene in dimethyl ether and then completely evaporating the ether at room temperature. The dark green solution deposits a very dark green solid which changes to gray in color with loss of the last traces of ether. The solid will then on treatment with water evolve nearly the theoretical amount of hydrogen as such. When sodium naphthalene solution is treated with water no hy-

drogen is evolved. If the solid be extracted with heptane a residue is obtained consisting almost entirely of sodium. For most purposes the isolation of sodium naphthalene in the solid state is not attempted since its reactions are conveniently carried out in solution.

The special solvents which are effective for the reaction of sodium with naphthalene can be used in similar fashion with the other alkali metals. In place of naphthalene one may use methyl naphthalenes, acenaphthene, diphenyl or phenanthrene, none of which react with sodium in ethyl ether solution. The special solvents also have a striking effect in facilitating the addition reactions of sodium with anthracene and with benzophenone, causing much more rapid reaction than occurs in ethyl ether. The special solvents do not appear to facilitate the reaction of sodium with hydrocarbons such as triphenylmethane, fluorene, or acetylene where the characteristic reaction is one of substitution.

Solutions of sodium naphthalene display many unusual properties. The solutions are dark green in color and have good electrical conductivity. No quantitative measurements have been made of the heat of the reaction by which they are formed, but it is not large. This is consistent with the ease of dissociation of the compound either by removing the ether solvents by evaporation or by dilution with a large volume of hydrocarbon solvent, or by removing the sodium, for example by shaking with mercury. The amount of sodium which will dissolve readily in a solution of naphthalene or diphenyl is only one atom per molecule of hydrocarbon. Inasmuch as many of the reactions of the solution correspond with a disodium naphthalene addition compound, this raises the question of the formula of the compound. The formula $C_{10}H_8Na_2{\cdot}C_{10}H_8$ correctly represents the proportions of sodium and naphthalene while avoiding the question of structure. Discussion as to structure will largely be deferred to later papers dealing more fully with the reactions.

The reactions of sodium naphthalene can be divided into two classes. In the first the naphthalene is recovered unchanged, the solution behaving much like dissolved sodium. In this class one may mention the reactions with mercury, with oxygen, and with benzyl chloride. In the second class of reactions the naphthalene is reduced to dihydronaphthalene or its derivatives depending on the reagent used. With water, alcohols or the wide range of organic compounds capable of forming sodium derivatives where sodium replaces hydrogen, the products are dihydronaphthalene and the sodium compound of the material used as source of hydrogen. For example with acetylene the reaction can be represented by the equation

$$C_{10}H_8Na_2{\cdot}C_{10}H_8 + 2C_2H_2 \longrightarrow C_{10}H_{10} + C_{10}H_8 + 2C_2HNa$$

This is a convenient method for the preparation of a variety of sodium derivatives.

In general, the only requirements for the formation of sodium naphthalene and related compounds in dimethyl ether and other active ether solvents are that the solvent be pure and dry and that the hydrocarbon be reasonably pure. It is also imperative that a clean surface of alkali metal be exposed to initiate the reaction. Once started, the reaction thoroughly cleans any metal surface that was not originally clean. When pieces of sodium that are reacting come in contact in the reaction mixture, they fuse together, even at −30° and lower. Impurities such as water, methanol and carbon dioxide prevent the reaction from starting by forming products which coat the surface of the alkali metal as soon as it is exposed. If they are only present in traces, however, persistent scratching of the metal surface will eventually lead to their destruction and the reaction will proceed.

Experiments

Preparation of Sodium Naphthalene Solutions

A. In Dimethylglycol Ether.—One liter of a molal solution of naphthalene in pure dry dimethyl glycol ether is placed in a two-liter three-necked flask equipped with a mercury-sealed stirrer in which an atmosphere of pure dry nitrogen is maintained. About 25 g. of sodium is then added, the metal being cut in the form of sticks 2–3 cm. long and 3–5 mm. square on the end. After the sodium has been added the mixture is agitated mechanically. The stirring should be rapid at the start but should be decreased considerably after the reaction has commenced. With a good grade of dimethylglycol ether the reaction should start in one to three minutes. Some cooling is required, and this can be accomplished safely by the use of a methanol cooling bath to which solid carbon dioxide is added as required. The reaction mixture should be kept between −10 and +30°. At temperatures below −10° the reaction rate falls off considerably in dimethylglycol ether. At 20–25° the reaction is complete in about two hours. Unreacted sodium which is usually stuck together in a single piece can then be removed easily from the mixture with forceps.

The progress of the reaction can be measured from time to time by removal of small samples of the reaction mixture and determination of their sodium content, after dilution with alcohol, by titration with standard acid using methyl red. This does not discriminate between sodium naphthalene and other suspended or dissolved alkaline sodium compounds in the solution but when pure solvent is used it gives a close approximation of the sodium naphthalene that has been formed.

B. In Dimethyl Ether.—The preparation of sodium naphthalene in dimethyl ether is carried out in much the same way as in dimethylglycol ether except for the changes occasioned by the low boiling point (−25°). The flask in which the reaction is to be carried out is cooled to about −50° in a bath of solid carbon dioxide and methanol, and the solvent is led in as a gas from a cylinder and condensed. The reaction is best carried out at a temperature of −30°. The nature of the solvent makes it difficult to make analyses in this case, but an approximate measure of the reacted sodium can be obtained easily by weighing the unreacted sodium recovered after the completion of the reaction.

Dimethylglycol Ether.—This reagent was prepared by the methylation of the monomethyl ether of ethylene glycol. It must be purified and thoroughly dried for use in alkali metal reactions. It is a colorless fluid with a characteristic ether-like odor boiling at 85°.

Dimethyl Ether.—This ether was sufficiently pure as obtained from the Ammonia Department of E. I. du Pont de Nemours & Company, Inc.

Summary

The reaction of aromatic hydrocarbons with sodium is so greatly facilitated by employing dimethyl ether or dimethylglycol ether as the solvent, in place of diethyl ether, that with the use of these special solvents even such hydrocarbons as naphthalene and diphenyl can be converted easily into sodium compounds.

The Separation of Primary Aryl Amines from Secondary Alkylaryl Amines

BY CLAYTON W. FERRY AND JOHANNES S. BUCK

In the course of the preparation of a series of unsymmetrical alkylaryl ureas and thioureas[1,2] a number of secondary alkylaryl amines, substantially free from primary aryl amines, was required (small amounts of tertiary amines are unimportant, since they form no ureas). When alkoxy and certain N-alkyl groups are present in the secondary amine, the usual methods of preparation (*e. g.*, *via* the acyl derivatives, nitroso compounds, etc.) are not satisfactory[2] and it is necessary to alkylate the primary aryl amine directly and to remove unchanged primary amine from the product. A method for carrying out this removal, suggested by the work of Eibner and by several patents[3] and outlined by DeBeer, Buck, Ide and Hjort[2] is here described, whereby the primary amine is removed readily by shaking the crude secondary amine with benzaldehyde–sodium bisulfite compound and water. The primary amine combines with the reagent and is recoverable, while the secondary amine remains unattacked.

Experimental

Twenty grams each of primary aryl amine and secondary alkylaryl amine (the secondary amines mentioned in this report were all purified *via* the nitroso compound) were mixed and shaken mechanically with water and benzaldehyde–sodium bisulfite compound at room temperature. The mixture was then filtered from the solid with suction, the solid well washed with ether and the filtrate extracted with ether. The total ether was washed with brine, the ether evaporated and the residual amine tested for primary amine.

In the first series of experiments, designed to investigate the conditions of reaction, the above process was repeated until tests showed the absence of any appreciable amount of primary amine (< 0.5%). In the first treatment 50 cc. of water and one mol of bisulfite compound (calculated on the primary amine present) were used. In the second treatment 30 cc. of water and 0.5 mol of bisulfite compound and in the third and subsequent treatments, 30 cc. of water and 0.25 mol of bisulfite compound were used. In all cases the shaking was for two hours per treatment.

When this method was applied to mixtures of methyl aniline, *n*-butylaniline, ethyl-*m*-toluidine, ethyl-*p*-toluidine and ethyl-*o*-phenetidine, with the corresponding primary amine, over 80% of the secondary amine, containing less than 0.5% of the primary amine was obtained after the third treatment. Similar mixtures from ethyl-*p*-phenetidine and isopropyl-*p*-anisidine required, respectively, four and five treatments, about 54% of the secondary amine being recovered. A mixture from ethyl-*o*-toluidine was not purified to less than 10% of primary amine, even after five treatments.

The second series of experiments was carried out in order to simplify the process practically, and to reduce the losses in manipulation. It was found that, using the same mixture (20 g. primary amine, 20 g. secondary amine), efficient separation could be obtained by six hours of shaking

[2] DeBeer, Buck, Ide and Hjort, *ibid.*, **57**, 19 (1936).

[3] German Patent 181,723, 132,621, 157,909; Eibner, *Ann.*, **316**, 89 (1901).

with two mols (calculated on the primary amine present) of bisulfite compound and 140 cc. of water. The yield also was much improved. Thus, with mixtures of methylaniline, *n*-butylaniline, ethyl-*m*-toluidine, ethyl-*p*-toluidine and ethyl-*p*-phenetidine with the corresponding primary amine, the content of primary amine was reduced to 0.5% or less. The recovery was, respectively, 80, 94, 92, 90 and 78% of the secondary amine taken. In practice, 50% of primary amine in a mixture is rarely encountered and the amount is usually much less, so that the separation would be correspondingly facilitated.

The major part of the primary amine may be recovered from the aqueous liquors from the extractions and from the solid filtered off, by adding to these 200 cc. of water containing 25 cc. of concd. sulfuric acid and steam-distilling the mixture. Benzaldehyde comes over and may be largely recovered. The acid liquid in the flask is then made alkaline with 30% sodium hydroxide solution and the steam distillation continued, the receiver being changed. The primary amine may be recovered by saturating the distillate with salt and extracting four times with ether. After drying, the ether is evaporated and the residual amine distilled. From the mixtures cited above there was recovered aniline, 92%; aniline 87%; *m*-toluidine, 88%; *p*-toluidine, 90%; and *p*-phenetidine, 75%, respectively.

The boiling points of the recovered secondary amines were the same as those of authentic specimens[4] (the yields throughout refer to distilled amines of the correct boiling point). As an additional check the recovered secondary amines from the first series of experiments were converted into the α-naphthyl ureas and these were compared with specimens prepared from authentic amines. The melting points of the ureas from the recovered amines were in general only two or three degrees lower than those of the corresponding purified ureas, except in the cases of ethyl-*o*-phenetidine and ethyl-*p*-phenetidine, where the melting points were, respectively, eight and five degrees lower. The yields, in all cases, were substantially the same from either recovered or authentic amine.

α-Naphthyl Ureas.—Three cc. of α-naphthyl isocyanate (20–25% excess) was added to 2 cc. of amine (weighed) in 15 cc. of hexane. The oil which separated soon crystallized, and was filtered off and well washed with petroleum ether and its melting point determined. The ureas (from authentic amines), recrystallized from alcohol, form small, glistening, granular crystals, readily soluble in hot alcohol and in hot benzene, that from ethyl-*o*-toluidine being considerably more soluble than the others. The α-naphthyl ureas, not previously described, are tabulated below.

α-ALKYL-α-ARYL-β-(α-NAPHTHYL) UREAS

α-Groups	Formula	M. p., °C.	Analyses, %N Calcd.	Found
Methyl, phenyl	$C_{18}H_{16}ON_2$	99	10.14	10.29
n-Butyl, phenyl	$C_{21}H_{22}ON_2$	99	8.80	9.03
Ethyl, *o*-tolyl	$C_{20}H_{20}ON_2$	85.5	9.21	9.27
Ethyl, *m*-tolyl	$C_{20}H_{20}ON_2$	95.5	9.21	9.39
Ethyl, *p*-tolyl	$C_{20}H_{20}ON_2$	103	9.21	9.51
Isopropyl, *p*-anisyl	$C_{21}H_{22}O_2N_2$	147	8.38	8.48
Ethyl, *o*-phenetyl	$C_{21}H_{22}O_2N_2$	136.5	8.38	8.43
Ethyl, *p*-phenetyl	$C_{21}H_{22}O_2N_2$	111	8.38	8.43

Benzaldehyde–sodium bisulfite compound was prepared in the usual manner and well washed with water. The product is satisfactory for ordinary purposes, but for the present work it was recrystallized from water, then washed with ether when dry.

Primary amines were tested for by a spot method, an adaptation of the method of Cumming, Hopper and Wheeler,[5] using both "R" salt and (better) "H" salt and comparing the colors produced with those given by known mixtures. The carbylamine reaction, also used, was carried out in the usual manner, with alcoholic potassium hydroxide and chloroform. Both tests readily showed the presence of 0.5% primary amine.

In attempting to purify ethyl-*o*-toluidine several bisulfite compounds were tried (from anisaldehyde, *m*-nitrobenzaldehyde, and salicylaldehyde) but without much improvement. The reaction of ethyl-*o*-toluidine with isocyanates is relatively sluggish, and this fact allows a fair separation from primary amine to be made. A specimen of ethyl-*o*-toluidine, containing 10% *o*-toluidine, in 4 volumes of petroleum ether was well cooled and phenyl isocyanate (1.5 times calcd. for the primary amine present) added in one lot. After two and one-half minutes strong ammonium hydroxide was added (twice the volume of the amine), the whole chilled and the crystalline material filtered off and washed with petroleum ether. The total petroleum ether, after washing with water and drying (potassium hydroxide) was evaporated and the residual amine distilled. There was obtained in 80% yield, ethyl-*o*-toluidine, b. p. 103–104.5° (16 mm.), containing about 1% *o*-toluidine.

The recovered secondary amines usually contain small amounts of benzaldehyde, which can be readily removed if necessary by dissolving the amine in acid. Estimated as acid-insoluble material, the benzaldehyde varied, with different amines, between 0.3 and 1.7%, but was usually close to the lower figure.

Attempts to extend the method to the separation of aliphatic amines were finally abandoned. In general the solubility of the amines in water, the instability of the azomethine compounds usually formed and the solubility of these compounds in organic solvents render a practical separation not feasible. The use of formaldehyde–sodium bisulfite compound helps matters somewhat, but the method still is not practical.

Summary

An expeditious method for separating mixtures of primary aryl amines with secondary alkylaryl amines is here described. The method depends on the preferential combination of benzaldehyde–sodium bisulfite compound with primary aryl amines, and is very generally applicable. An alternative method, involving the use of phenyl isocyanate, is suggested for mixtures of *o*-toluidine and ethyl-*o*-toluidine. Some α-naphthyl ureas derived from the secondary amines are described.

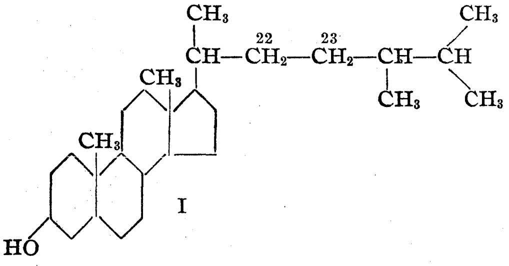
α-Sitosterol

BY EVERETT S. WALLIS AND E. FERNHOLZ[1]

It can now be stated with a fair degree of certainty that the structural formulas of cholesterol, ergosterol and stigmasterol are well established. Our knowledge, however, of the most common plant sterol, sitosterol, is still unsatisfactory. This is due to the fact that sitosterol is in reality a mixture of several sterols, and that their separation is effected with great difficulty. This observation was first made by Anderson, Shriner and Burr.[2] These investigators showed that sitosterol obtained from various sources is not a homogeneous substance but that it contains dihydrositosterol and at least three other sterols. They named these latter compounds α, β- and γ-sitosterol. γ-Sitosterol, which is the least soluble, was isolated by them in nearly a pure state. The purification of β-sitosterol was not so complete. The α-sitosterol was obtained only in a very impure condition; no satisfactory method for its purification was discovered.

Recently certain information has become available regarding the constitution of β- and γ-sitosterol. Bengtsson[3] has compared derivatives of β-sitostanol with stigmastanol. From his experiments he has come to believe that these compounds are identical, and that, therefore, β-sitosterol is in reality 22-dihydrostigmasterol (I).



I

This conclusion has indeed a high degree of probability.

A valuable contribution to our knowledge of γ-sitosterol has been made recently by Oppenauer.[4] This investigator prepared dehydroandrosterone (II) from sitosterol If we assume that a sufficiently pure γ-sitosterol was used in these experiments, this fact proves that the ring system of both β- and γ-sitosterol is the same, and that they differ only in the structure or stereochemical arrangement of the side chain.

In this connection mention should be made also of certain other observations. Bonstedt[5] has reported that γ-sitostane and stigmastane, when mixed together, give a strong depression of the melting point. This fact supports the idea that β- and γ-sitosterol are different compounds, and not more or less impure specimens of the same substance. Anderson[2] expresses the opinion that the different sitosterols are isomers.

In this paper we wish to report certain experiments which show that such a conclusion cannot be reached for the most soluble fraction of the sitosterol complex, called by Anderson and co-workers,[2] α-sitosterol.[6] From recrystallization of 500 g. of a sitosterol obtained from wheat germ oil we separated 36 g. of a material rich in α-sitosterol. A method of purification of this material had to be developed since Anderson and his co-workers[2] were unsuccessful in effecting a separation by crystallization of the acetates, and by bromination. Preliminary experiments showed that this could be accomplished by means of a fractional crystallization of the corresponding benzoates. Accordingly this mixture of sterols (36 g.) was converted into the corresponding benzoates. By a single crystallization 23 g. of a benzoate, m. p. 144°, which was mainly β-sitosteryl benzoate, was removed. The α-sitosteryl benzoate remained in the mother liquor. This more soluble benzoate was then hydrolyzed and converted into the corresponding m-dinitrobenzoate. By fractional crystallization two new dinitrobenzoates were isolated in a pure state. The least soluble α_1-sitosteryl m-dinitrobenzoate was obtained in a yield of 1 g. The more soluble α_2-sitosteryl m-dinitrobenzoate, which seems to be the more plentiful constituent, was obtained only in a yield of 0.4 g. It is possible that other

(5) Bonstedt, *Z. physiol. Chem.*, **205**, 137 (1932).

(6) Burian [*Monatsh.*, **18**, 551 (1897)], who also observed the difference in the solubility of this fraction from the bulk of the sitosterol, named it para-sitosterol.

sterol *m*-dinitrobenzoates were present in the mother liquors.

The properties of α_1- and α_2-sitosterol and their derivatives are given in the table.

Derivative	α_1-Sitosterol		α_2-Sitosterol	
	M. p., °C.	$[\alpha]^{25}_D$	M. p. °C.	$[\alpha]^{25}_D$
Sterol	166	-1.7	156	$+3.5$
Acetate	137	$+29$	126	$+17$
Benzoate	172	$+42$	166	$+27$
m-Dinitrobenzoate	222	$+37$	206	$+26$

We also wish to report certain other important observations. These two new sterols are *not* isomers of β- and γ-sitosterol. α_1-Sitosterol is an isomer of stigmasterol, $C_{29}H_{48}O$, and α_2-sitosterol is in all probability a homolog, $C_{30}H_{50}O$. Titration with perbenzoic acid shows that two double bonds are present in both sterols. Both sterols give the same color reaction (Liebermann). The final color is a dark blue with a reddish tint. The Salkowski reaction for both α_1- and α_2-sitosterol is similar to that of ergosterol; the sulfuric acid layer becomes colored, while the chloroform stays colorless. The opposite is true for cholesterol, γ-sitosterol, and stigmasterol; α_1- and α_2-sitosterol are precipitated by digitonin.

Experimental Part

Five hundred grams of sitosterol,[7] isolated from wheat germ oil (m. p. 134–137°, $[\alpha]^{20}_D$ $-30°$ in chloroform), was subjected to a systematic crystallization from a mixture of alcohol and benzene, and from alcohol. The most soluble fractions were collected. They had a total weight of 36 g., and melted unsharply at 141°, $[\alpha]^{20}_D$ $-24°$.

The shape of these crystals is different from those of the main portion. They are small needles. β- and γ-sitosterol crystallize in large leaflets.

This material (36 g.) was dissolved in 150 cc. of pyridine and to the solution was added 30 cc. of benzoyl chloride. The mixture was kept on a boiling water-bath for an hour. The benzoate, so formed, was taken up in ether, and recrystallized from a mixture of benzene and alcohol. Twenty-three grams of a benzoate was obtained in well-defined leaflets which melted at 144°. This is mainly β-sitosteryl benzoate. Ten grams of a crude benzoate, m. p. 115–140°, was also isolated from the mother liquors. This latter fraction was hydrolyzed with 5% alcoholic potassium hydroxide solution. It yielded 7.5 g. of a sterol which melted unsharply at 150°. This sterol was dissolved in 50 cc. of pyridine and treated with 7 g. of *m*-dinitrobenzoyl chloride. The mixture was kept on a boiling water-bath for one hour. The dinitrobenzoate was taken up in ether, and the solution decolorized with animal charcoal. On evaporation of the solvent, 10.8 g. of material, m. p. 170–180°, was obtained.

Isolation of α_1-Sitosteryl *m*-Dinitrobenzoate.—The crude dinitrobenzoate described above was dissolved in 100 cc. of hot ethyl acetate. The solution was allowed to cool; 3.4 g. of yellowish brittle plates crystallized, m. p. 197–207°. This material was recrystallized from the same solvent until the melting point and rotation were constant. The pure crystals melted at 222°. 25.8 mg. dissolved in 2 cc. of chloroform solution gave α^{24}_D $+0.48$; $[\alpha]^{24}_D$ $+37.2°$.

Anal. Calcd. for $C_{36}H_{50}N_2O_6$: C, 71.24; H, 8.31; N, 4.62. Found: C, 71.16; H, 8.31; N, 4.78.

α_1-Sitosteryl *m*-Dinitrobenzoate Dioxide.—Twenty-five and eight-tenths milligrams of the above dinitrobenzoate was kept for three days at 0° with an excess of a chloroform solution of perbenzoic acid. The substance consumed 1.33 mg. of oxygen (theoretical amount for 2 atoms of oxygen is 1.36 mg.). The chloroform solution was washed with sodium carbonate solution. The dioxide was recrystallized from a mixture of benzene and petroleum ether. Small needles were obtained which melted at 209–212°.

Anal. Calcd. for $C_{36}H_{50}N_2O_8$: C, 67.67; H, 7.89; N, 4.39. Found: C, 67.70; H, 8.00; N, 4.44.

α_1-Sitosteryl Benzoate.—The above *m*-dinitrobenzoate was hydrolyzed and the free sterol so obtained was dissolved in pyridine and treated with benzoyl chloride. The mixture was kept on a boiling water-bath for one hour. After working up the product in the usual manner a benzoate was obtained which crystallized from alcohol and benzene in the form of flat needles; m. p. 168–172°; $[\alpha]^{27}_D$ $+41.8°$ (28.2 mg. in 2 cc. chloroform solution gave α^{27}_D $+0.59°$).

Anal. Calcd. for $C_{36}H_{52}O_2$: C, 83.68; H, 10.15. Found: C, 83.93; H, 10.16.

α_1-Sitosterol.—The pure benzoate (m. p. 172°) was hydrolyzed by refluxing it for one hour with a 5% alcoholic solution of potassium hydroxide. The sterol was then precipitated by the addition of water. Purification was accomplished by crystallization from alcohol. Needles were obtained which melted at 164–166°; $[\alpha]^{28}_D$ $-1.7°$ (23.6 mg. in 2 cc. of chloroform solution gave α^{28}_D $-0.02°$). α_1-Sitosterol is precipitated by digitonin.

Anal. Calcd. for $C_{29}H_{48}O$: C, 84.38; H, 11.73. Found: C, 83.8;[8] H, 11.5.

α_1-Sitosteryl Acetate.—This acetate was prepared by heating a sample of α_1-sitosterol for one hour on the water-bath with acetic anhydride. The acetate crystallized on cooling. Recrystallization from alcohol gave leaflets which melted at 137°; $[\alpha]^{28}_D$ $+28.6°$ (27.3 mg. in 2 cc. of chloroform solution gave α^{28}_D $+0.39°$).

Anal. Calcd. for $C_{31}H_{50}O_2$: C, 81.87; H, 11.09. Found: C, 81.95, 81.68; H, 10.98, 11.05.

α_2-Sitosteryl *m*-Dinitrobenzoate.—The mother liquor obtained from the first crystallization of α_1-sitosteryl *m*-dinitrobenzoate was concentrated, and alcohol was added until needles started to crystallize from the boiling solution. The material so obtained (m. p. 180–190°) was recrystallized several times from ethyl acetate and alcohol, and from acetone until the melting point, and rotation re-

---

[7] The sitosterol used in these experiments was purchased from the University of Iowa.

[8] As is so often the case with sterols, α_1-sitosterol seems to retain a small amount of solvent of crystallization. This is very difficult to remove completely and lowers the value for the percentage of carbon.

mained unchanged. The yield of pure α_2-sitosteryl *m*-dinitrobenzoate was only 0.4 g. An attempt to increase the yield by recrystallization of the material in the mother liquors was unsuccessful.

α_2-Sitosteryl *m*-dinitrobenzoate melted at 206°. It is much more soluble than α_1-sitosteryl *m*-dinitrobenzoate, and forms needles which are white with a yellowish tint. It gives a depression of the melting point when mixed with the α_1-*m*-dinitrobenzoate; $[\alpha]^{30}\text{D}$ +26.4° (24.2 mg. in 2 cc. of chloroform solution gave $\alpha^{30}\text{D}$ +0.32°).

Anal. Calcd. for $C_{37}H_{52}N_2O_6$: C, 71.57; H, 8.45; N, 4.51. Found: C, 71.70, 71.71; H, 8.24, 8.20; N, 4.81.

Titration with Perbenzoic Acid.—Twenty-four and two-tenths milligrams took up 1.38 mg. of oxygen on standing for four days at 0° with an excess of perbenzoic acid. This is equivalent to 2.26 atoms of oxygen. In another experiment 34.4 mg. took up 1.65 mg. of oxygen on standing for two days at 0°. This is equivalent to 1.82 atoms of oxygen. These values are not as good as in α_1-sitosteryl *m*-dinitrobenzoate. They do show, however, the presence of two double bonds.

α_2-Sitosterol.—The *m*-dinitrobenzoate described above was hydrolyzed on the water-bath with a 5% alcoholic solution of potassium hydroxide. The free sterol was recrystallized from alcohol and petroleum ether.

α_2-Sitosterol melts at 156°. It is soluble in the common solvents; $[\alpha]^{25}\text{D}$ +3.5° (22.6 mg. in 2 cc. of chloroform solution gave $\alpha^{25}\text{D}$ +0.04°).

Anal. Calcd. for $C_{30}H_{50}O$: C, 84.43; H, 11.82. Found: C, 84.40; H, 11.91.

α_2-Sitosteryl Benzoate.—α_2-Sitosterol was dissolved in pyridine and treated with benzoyl chloride. The solution was kept on the water-bath for one hour. The product was worked up in the usual manner. The benzoate was purified by recrystallization from a mixture of benzene and alcohol.

α_2-Sitosteryl benzoate is very soluble in benzene, and sparingly soluble in alcohol. It forms needles which melt at 164–166°. The melting point is not depressed by α_1-sitosteryl benzoate. $[\alpha]^{26}\text{D}$ +27.4° (25.6 mg. in 2 cc. chloroform solution gave $\alpha^{26}\text{D}$ +0.35°).

Anal. Calcd. for $C_{37}H_{54}O_2$: C, 83.71; H, 10.26. Found: C, 83.59, 83.39; H, 10.19, 10.32.

α_2-Sitosteryl Acetate.—α_2-Sitosterol was converted into its acetate by heating with acetic anhydride for one hour in a boiling water-bath. The acetate was recrystallized from alcohol. It forms small leaflets which melt at 124–126°. It is soluble in most solvents, but only sparingly soluble in methyl alcohol $[\alpha]^{27}\text{D}$ +16.5° (24.2 mg. in 2 cc. of chloroform solution gave $\alpha^{27}\text{D}$ + 0.20°).

Anal. Calcd. for $C_{32}H_{52}O_2$: C, 81.98; H, 11.19. Found: C, 81.75, 81.83; H, 11.07, 11.28.

We wish to express our thanks to Merck and Company, Inc., Rahway, N. J., for all the analyses in this article and for a grant-in-aid for this work.

Summary

Two new double unsaturated sterols have been isolated in a pure state from the most soluble fraction of the sitosterol complex obtained from wheat germ oil and formerly named by Anderson α-sitosterol.

The acetates, benzoates and *m*-dinitrobenzoates of these two sterols have been prepared and characterized.

α_1-Sitosterol is an isomer of stigmasterol.

α_2-Sitosterol is probably a homolog.

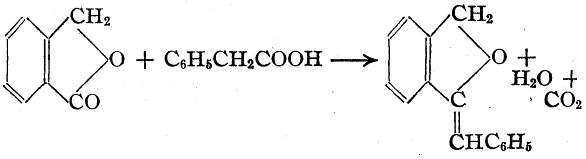
The Synthesis of Benzalphthalane

BY SAMUEL NATELSON AND AARON PEARL

In a recent paper[1] the relationship between benzalphthalide and certain naturally occurring materials was pointed out and a procedure for its conversion to compounds related to this series was demonstrated.

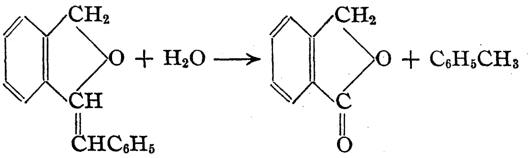
Since the hitherto unknown benzalphthalane offered promise of becoming a valuable intermediate in this field of research, its synthesis appeared desirable. An unsuccessful attempt was made to obtain this product by condensation of phthalide with phenylacetic acid as follows



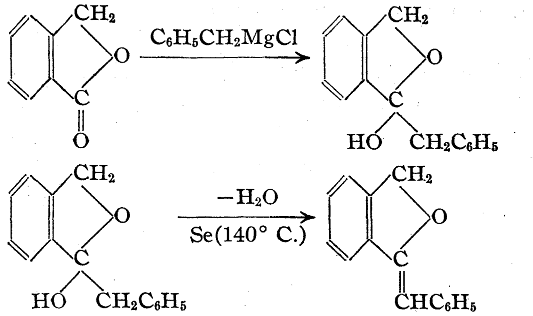
In this reaction carbon dioxide and water, along with large yields of phthalide and toluene, were formed. Since phenylacetic acid under similar conditions does not evolve carbon dioxide, benzalphthalane was probably the initial reaction product but immediately hydrolyzed in accordance with the equation

---

(1) Natelson and Gottfried, THIS JOURNAL, **58**, 1432 (1936).



However, a very satisfactory synthesis was effected by conversion of phthalide through a Grignard synthesis, employing benzylmagnesium chloride, to 1-benzyl-1-hydroxyphthalane, followed by dehydration of this product with the use of selenium.



Benzalphthalane is observed to be split readily, to yield phthalide, by numerous acidic or basic reagents, or even on exposure to air for several months. Because of this instability and the excellent results now obtained with derivatives of benzalphthalide, the application of the former in synthesis has been abandoned in favor of the latter.

Reaction between Phthalide and Phenylacetic Acid.—In four experiments 27 g. of phthalide, 27.5 g. of phenylacetic acid, 2 g. of freshly fused sodium acetate, and a pinch of pumice were heated in a sand-bath until the melt reached 140, 160, 180 and 230°, respectively. At 140° some water and carbon dioxide were evolved and at 180° all of the carbon dioxide was evolved. Even when a temperature of 230° was maintained for three hours, the reaction mixture, recrystallized from carbon bisulfide, yielded 25 g. of phthalide (m. p. 74.5°). (*Anal.* Calcd. for $C_8H_6O_2$: C, 71.64; H, 4.55. Found: C, 71.73; H, 4.61.) Distillation of the filtrate gave a fraction of b. p. 110° which was identified as toluene. In no case was benzalphthalane obtained.

In confirmation of the assumption that benzalphthalane is an intermediary product in the above reactions, it was found that phenylacetic acid either alone or admixed with fused sodium acetate does not evolve carbon dioxide when heated to 180°.

1-Benzyl-1-hydroxyphthalane.—An ether solution of benzylmagnesium chloride, prepared by dissolving 10 g. of magnesium in a solution of 60 g. of benzyl chloride in 300 cc. of anhydrous ether was added drop by drop with vigorous stirring to a cooled suspension of 52 g. of phthalide, prepared by the method of Russert,[2] in 200 cc. of anhydrous ether. As the Grignard reagent hits the phthalide suspension a vigorous reaction ensues and an orange color appears which disappears on stirring. After the addition was complete the reaction mixture was stirred for thirty minutes longer and then allowed to stand well corked overnight. Crushed ice and 380 cc. of 10% sulfuric acid were then added, the mixture was well shaken and the ether layer separated. The lower layer was again washed with ether and the combined ether washings were dried over anhydrous sodium sulfate and evaporated on a steam-bath. The oily residue crystallizes on stirring and cooling with alcohol and petroleum ether mixture and may be recrystallized from alcohol or from carbon bisulfide in long white needles; m. p. 137° yield 50 g.; insol. petroleum ether, sol. alcohol and carbon bisulfide.

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.64; H, 6.19. Found: C, 79.33; H, 6.44.

Benzalphthalane. Method 1.—Fifty grams of 1-benzyl-1-hydroxyphthalane is ground with 5 g. of selenium and heated on a sand-bath to 140°. The water given off is collected through a bent tube into a graduated cylinder. When the water ceases to come off, the material is allowed to cool and is recrystallized from alcohol, in which it is rather insoluble when cold. Benzalphthalane crystallizes as wedge-shaped golden crystals, m. p. 94°; yield 42 g.

Anal. Calcd. for $C_{15}H_{12}O$: C, 86.53; H, 5.77. Found: C, 86.33; H, 5.93.

Method 2.—To 50 g. of 1-benzyl-1-hydroxyphthalane was added 20 g. of cold concd. sulfuric acid. The mixture was shaken and then gently warmed to 40° for a few minutes. The mixture was allowed to come to room temperature and washed free of sulfuric acid with water and recrystallized from alcohol; m. p. 94°; yield 10–18 g.

Summary

1. Benzalphthalane is prepared by dehydration of 1-benzyl-1-hydroxyphthalane formed by the action of benzylmagnesium chloride on phthalide.

2. The reaction between phthalide and phenylacetic acid in the presence of sodium acetate is studied and a rationale proposed for the inability to obtain benzalphthalane from this reaction mixture.

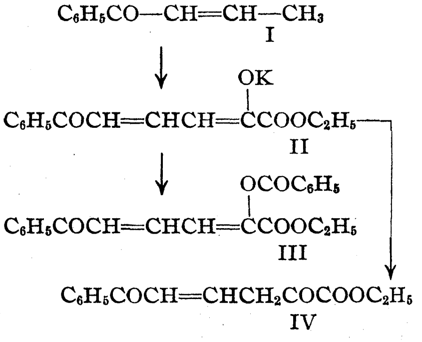
The Condensation of Propenyl Ketones with Ethyl Oxalate

BY REYNOLD C. FUSON, R. E. CHRIST[1] AND G. M. WHITMAN

Propenyl ketones and their higher vinylogs[2] might be expected to exhibit the properties characteristic of methyl ketones. Thus condensation with ethyl oxalate would lead to the synthesis of substances of the type $\mathrm{RCO(CHCH{=})_{\mathit{n}}{-}CH_2COCOOC_2H_5}$ analogous to the unsaturated keto esters of the type $\mathrm{RO_2C(CH{=}CH)_{\mathit{n}}CH_2{-}COCOOR}$ derived from crotonic ester and its vinylogs.[3] The realization of this expectation would open the way to the preparation of keto acids of the type $\mathrm{RCO(CH{=}CH)_{\mathit{n}}COOH}$.

As a first step in this process we have studied the action of ethyl oxalate on two propenyl ketones—phenyl propenyl ketone (I) and mesityl propenyl ketone (V). Phenyl propenyl ketone was treated with ethyl oxalate in ether solution, potassium ethoxide being employed as a catalyst. The reaction led to the formation of the potassium salt (II); this demonstrates that the methyl group of I possesses the activity which was to be predicted.



$$\mathrm{C_6H_5CO{-}CH{=}CH{-}CH_3}\quad \text{I}$$

$$\downarrow$$

$$\mathrm{C_6H_5COCH{=}CHCH{=}\overset{OK}{C}COOC_2H_5}\quad \text{II}$$

$$\downarrow$$

$$\mathrm{C_6H_5COCH{=}CHCH{=}\overset{OCOC_6H_5}{C}COOC_2H_5}\quad \text{III}$$

$$\mathrm{C_6H_5COCH{=}CHCH_2COCOOC_2H_5}\quad \text{IV}$$

When treated with benzoyl chloride, the salt was converted into the benzoate (III). The free keto ester (IV) was produced by dissolving the potassium salt in water and acidifying with acetic acid. This is a somewhat unstable substance. As first obtained, it is a light yellow crystalline compound. Upon exposure to air, it assumes a brilliant orange color and finally changes to a reddish oil. Its alcoholic solution is colored a light brown by ferric chloride, showing that it exists to some extent, at least, in its enolic form. It is readily soluble in alkali.

Phenyl propenyl ketone was found to give a positive iodoform test; however, the production of iodoform is slow. Undoubtedly, the alkali employed in this reaction is capable of splitting the ketone into acetophenone and acetaldehyde, both of which would give the iodoform reaction. At any rate, the hydrolytic cleavage of the double bond conjugated with the carbonyl group was accomplished by refluxing the ketone with potassium carbonate solution. The acetophenone was actually isolated and characterized, but the aldehyde underwent condensation in the presence of the carbonate solution. This is in accord with the results of Meyer[4] on the hydrolytic cleavage of similar unsaturated ketones.

Mesityl propenyl ketone (V), a new compound, was prepared from crotonyl chloride and mesitylene, employing the Friedel–Crafts synthesis.

$$\mathrm{(CH_3)_3C_6H_2{-}CO{-}CH{=}CH{-}CH_3}$$

V

$$\mathrm{(CH_3)_3C_6H_2{-}CO{-}CH{=}CH{-}CH_2{-}CO{-}COOC_2H_5}$$

VI

$$\mathrm{(CH_3)_3C_6H_2COOH}$$

VII

This ketone was condensed with ethyl oxalate in an alcoholic solution, using potassium ethoxide as a catalyst. The product isolated was the expected keto ester (VI). It is a light yellow crystalline substance, which, unlike the corresponding phenyl compound, is quite stable in air. It is readily soluble in alkali, showing that it exists in its enolic form. Oxidation with hydrogen peroxide leads to the formation of β-isodurylic acid (VII).

Experimental

Crotonyl Chloride.—This substance was prepared by a slight modification of the method of Kohler.[5] Crotonic acid and thionyl chloride were used instead of sodium crotonate and phosphorus oxychloride.

One mole (86 g.) of crotonic acid was heated under reflux with 300 cc. of thionyl chloride in a 1-liter, three-necked flask, equipped with a stirrer and reflux condenser, until the evolution of hydrogen chloride ceased. The mixture was then fractionally distilled from a modified Claisen flask. The excess thionyl chloride distilled at 75–80°. The temperature then rose rapidly to 124°, where the crotonyl chloride began to distill. The yield was 90 g., b. p. 124–126°, or 86% of the theoretical amount.

Phenyl Propenyl Ketone.—The directions of Kohler[5] were used to prepare this ketone with the modification that benzene was substituted for carbon disulfide as solvent.

Two hundred grams of aluminum chloride was placed in a 1-liter, three-necked flask with 600 cc. of benzene. The mixture was cooled to 0° and exposed to the rays of a mercury vapor lamp. With vigorous stirring, 146 g. of crotonyl chloride was run in over a period of thirty minutes. There was brisk evolution of hydrogen chloride and the deposition of a colorless aluminum chloride complex. After fifteen minutes, the contents was poured into an ice–hydrochloric acid mixture, extracted with ether, washed with 10% sodium hydroxide solution, dried and distilled under reduced pressure. The fraction having a boiling point of 90–95° (2 mm.) was collected as the desired ketone. The total weight was 124 g., representing a 61% yield; $n^{26}\text{D}$ 1.5475.

The residue in the flask solidified upon cooling. Recrystallization from alcohol gave 65 g. of a product having a melting point of 74°. This was the product ($C_6H_5CH(CH_3)CH_2COC_6H_5$) obtained by Kohler by the condensation of two molecules of benzene with one of crotonyl chloride.

Hydrolytic Cleavage of Phenyl Propenyl Ketone.—In an all-glass refluxing apparatus were placed 4.0 g. of phenyl propenyl ketone, 10 g. of potassium carbonate and 50 cc. of water. To the top of the reflux condenser was attached a tube leading into a solution of 4 g. of semicarbazide hydrochloride and 4 g. of sodium acetate dissolved in 50 cc. of water. The object of this was to collect any acetaldehyde which might be formed from the hydrolysis. The solution was refluxed for a period of twenty-one hours. Twice during this time, the water was removed from the condenser to allow a small amount of vapor to pass over into the semicarbazide solution. It was hoped that in this way any acetaldehyde would be detected. However, the semicarbazone isolated proved to be that of acetophenone; m. p. 201°.

The solution remaining in the flask was extracted twice with ether, washed and then dried over calcium chloride. Upon distillation, 2.11 g. of product was obtained, having a boiling point of 196–203°. About 0.5 g. of higher boiling material remained in the flask. The semicarbazone of the 196–203° fraction was prepared, and was found to have a melting point of 200°. A mixed melting point with an authentic sample of acetophenone semicarbazone (m. p. 202°) was found to be 201°. This proved that acetophenone was formed by the hydrolytic cleavage of the phenyl propenyl ketone. The other product, which would have to be acetaldehyde, was not isolated. It probably underwent condensation in the presence of alkali, accounting for the residue remaining in the distilling flask.

Iodoform Reaction with Phenyl Propenyl Ketone.—In this test the reagent of Fuson and Tullock[6] was used. A small amount of iodoform was obtained.

Condensation of Ethyl Oxalate with Phenyl Propenyl Ketone.—Twenty-six grams of finely cut potassium was placed in a flask with 170 cc. of dry ether and cooled to 0°; 116 cc. of absolute alcohol was added, with shaking.

To the ether solution of potassium ethoxide was then added 48.8 g. of ethyl oxalate dissolved in 20 cc. of ether. Fifteen minutes later, 48.8 g. of phenyl propenyl ketone dissolved in 20 cc. of ether was added, with continued shaking. The color of the solution began to darken after a period of time. The mixture was allowed to stand in an ice box for twenty-four hours; a heavy layer of brilliant orange crystals of the potassium salt (II) settled out.

The mixture was filtered rapidly, and the potassium salt was then washed several times with dry ether. Afterward it was dried in a desiccator for twelve hours under reduced pressure. The weight of the final product was 77 g.; yield 81.3%.

Reaction of the Potassium Salt (II) with Benzoyl Chloride.—Ten grams of the salt was mixed with 5.3 g. of benzoyl chloride dissolved in 75 cc. of ether and allowed to stand for a period of twelve hours at room temperature.

The solution was practically colorless by this time, and a precipitate of potassium chloride crystals was on the bottom of the flask. After addition of water, the insoluble ether layer was separated and washed several times. The solvent was then evaporated, leaving a yellow crystalline mass of the benzoyl derivative. This was collected on a filter, washed with 10% sodium hydroxide to remove any benzoyl chloride or benzoic acid present and then recrystallized three times from alcohol.

The final product was a light yellow crystalline substance having a melting point of 123°. The total weight was 5.28 g., representing a 43% yield.

Anal. (semi-micro) Calcd. for $C_{21}H_{18}O_5$: C, 71.99; H, 5.18. Found: C, 71.75; H, 5.30.

Preparation of the Keto Ester (IV) from the Potassium Salt.—Ten grams of the salt was dissolved in 100 cc. of water. The addition of an excess of 2 *N* acetic acid caused a yellow semicrystalline mass to be thrown out of solution. The weight of crude material, obtained by filtering and drying by suction, amounted to 7.8 g.

The keto ester is somewhat unstable. Even during the crystallization a change appears to take place. The best solvent was found to be alcohol to which a few drops of acetic acid had been added. The crystals, as first obtained, have a faintly yellow color and melt at 106°, with decomposition. Upon exposure to air, they assume a brilliant orange color, and finally melt to form a reddish oil. When the compound is stored in a desiccator at reduced pressure, no change occurs. The compound dissolves in alkali, giving a light yellow coloration.

Anal. (semi-micro) Calcd. for $C_{14}H_{14}O_4$: C, 68.26; H, 5.73. Found: C, 68.14; H, 5.79.

Preparation of Mesityl Propenyl Ketone.—This is a new compound. It was prepared from crotonyl chloride and mesitylene by use of the Friedel–Crafts synthesis.

Two hundred eighty grams of aluminum chloride was placed in a 2-liter, three-necked flask with 800 cc. of carbon disulfide. The mixture was cooled to 0° and exposed to the rays of a mercury vapor lamp. With vigorous stirring, 209 g. of crotonyl chloride and 240.2 g. of mesitylene dissolved in 200 cc. of carbon disulfide were run in slowly over a period of two hours. There was a vigorous evolution of hydrogen chloride. The solution was stirred for an additional two hours at room temperature. The contents were then poured into iced hydrochloric acid solution, extracted with ether, washed with alkali, dried over calcium chloride and distilled under reduced pressure. A total of

---

[6] Fuson and Tullock, THIS JOURNAL, **56**, 1638 (1934).

284 g. of the desired ketone was obtained; b. p. 128° (5 mm.); n^{20}_{D} 1.5330; d^{20}_{4} 0.9819. This represents a yield of 75%.

Anal. (semi-micro) Calcd. for $C_{13}H_{16}O$: C, 82.92; H, 8.57. Found: C, 82.61; H, 8.46.

Condensation of Mesityl Propenyl Ketone with Ethyl Oxalate.—A total of 6.5 g. of finely cut potassium was placed in a flask with 45 cc. of dry ether. Absolute alcohol (29 cc.) was added, with shaking, to convert the potassium to potassium ethoxide.

To the ether solution was then added 12.2 g. of ethyl oxalate dissolved in 15 cc. of ether. Fifteen minutes later, 15.7 g. of mesityl propenyl ketone dissolved in 15 cc. of ether was added, with continued shaking. The color of the solution soon changed to a dark red. The mixture was allowed to stand for a period of twenty hours in an ice box.

The solution was then treated with water and neutralized with acetic acid. The ether layer was separated and dried. Evaporation of the solvent left a crystalline mass. Crystallization from alcohol gave 22 g. of beautiful light yellow crystals which melted, with decomposition, at 156°; yield 90%.

Anal. (micro) Calcd. for $C_{17}H_{20}O_4$: C, 70.78; H, 6.99. Found: C, 70.74; H, 6.96.

Oxidation with Hydrogen Peroxide.—One gram of the ester was placed in a flask with 20 cc. of 10% sodium hydroxide solution and 100 cc. of 3% hydrogen peroxide solution. The mixture was allowed to stand for a period of twelve hours at room temperature.

The solution was then acidified with acetic acid. The precipitate which formed was collected on a filter and redissolved in alkali. It was then thrown out of solution again by the addition of more acetic acid. Recrystallization from a mixture of benzene and low-boiling petroleum ether gave 0.34 g. of beautiful colorless crystals of β-isodurylic acid; m. p. 152°.

Summary

Phenyl propenyl ketone (I) has been prepared from crotonyl chloride and benzene by use of Friedel–Crafts synthesis. The ketone was condensed with ethyl oxalate in ether solution, potassium ethoxide being employed as a catalyst.

The potassium salt (II) was converted into the benzoate (III) by treatment with benzoyl chloride. When the salt was acidified with acetic acid, the free keto ester (IV) was produced.

Mesityl propenyl ketone (V) has been prepared in an analogous manner. It was, likewise, condensed with ethyl oxalate, producing a keto ester (VI).

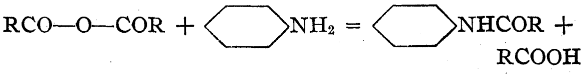
Quantitative Determination of Anhydrides of Carboxylic Acids

BY DONALD MILTON SMITH AND W. M. D. BRYANT

Organic acid anhydrides ordinarily are estimated analytically either by hydrolysis followed by titration of both acidic groups, or by the use of a reaction which converts one acidic residue into a neutral substance leaving only one carboxyl as a measure of the anhydride present. While both analytical schemes are bases of accepted methods, it is apparent that neither alone is sufficient to differentiate sharply between anhydrides and free acids. However, by using the two principles in combination, it becomes possible to determine the –CO–O–CO– content of a mixture, even though the exact nature and composition of the mixture is unknown. Radcliffe and Medofski[1] have made a careful investigation of the above-mentioned procedures as applied to acetic anhydride. The majority of these procedures make use of the fact that an anhydride reacts with aniline to form a mole each of anilide and acid, respectively[2]



The action of alcoholates of the alkali metals upon anhydrides is analogous to that of aniline, a mole of ester and a mole of alkali salt resulting from the reaction carried out as a titration.[3]

Except for the closely related work of Holde[4] on the titration of higher fatty acid anhydrides with alcoholic sodium hydroxide, little use has been made of the above reaction in an analytical way.

In the present investigation a standard solution of sodium methylate was used in place of aniline,

[2] Menschutkin and Vasiliev, *J. Russ. Phys.-Chem. Soc.*, **21**, 190 (1889).

[3] Caudri, *Rec. trav. chim.*, **48**, 778 (1929).

[4] Holde and Smelkus, *Ber.*, **53**, 1889 (1920); Holde and Tacke, *ibid.*, **53**, 1898 (1920).

since it offered the advantage of combining into a single step the cleavage and neutralization processes of the older method while sharing its high reactivity. Total acidity was determined on a separate sample by titration with aqueous sodium hydroxide. In this connection it was found that the addition of a large amount of pyridine just before titration greatly accelerated the hydrolysis of anhydrides rendering it in most cases instantaneous. The two basic reactions involved are

$$\mathrm{RCO{-}O{-}COR} + \mathrm{CH_3ONa} = \mathrm{RCOOCH_3} + \mathrm{RCOONa} \tag{1}$$

and

$$\mathrm{RCO{-}O{-}COR} + 2\mathrm{NaOH} = 2\mathrm{RCOONa} + \mathrm{H_2O} \tag{2}$$

It is readily apparent that in mixture with other acidic materials the distinctive measure of anhydride present is the amount of acyl radical rendered unavailable as ester, or the equivalent difference between the titers of the above reactions. The initial presence of free acids is without effect upon this determination.

A group of ten anhydrides selected for wide differences in structure were analyzed by this method with an average precision of ±0.2%. The method is stoichiometric within this limit as shown by results obtained with glutaric, phthalic and camphoric anhydrides, the substances obtained in the highest purity. All of the compounds except camphoric anhydride were titrated directly in the cold. Due to steric hindrance arising from the presence of an adjacent tertiary carbon atom, the latter material required thirty minutes of heating at 60° with an excess of reagent, followed by back-titration with standard acid. The analytical data are given in Table I.

TABLE I

ANALYTICAL DATA FOR ANHYDRIDES

Anhydride	Millimoles per gram sample NaOH (a)	NaOCH$_3$ (b)	–CO–O–CO– (a–b)		% of theoretical –CO–O–CO–	
Acetic	19.61	9.88	9.73	(4)[a]	99.3	± 0.2
Propionic	15.40	7.79	7.61	(3)	99.0	.2
n-Heptylic	8.21	4.21	4.00	(1)	96.9	
Succinic	19.83	10.35	9.48	(4)	94.8	.2

Glutaric	17.42	8.67	8.75	(2)	99.8	.1
Camphoric	10.99	5.49	5.50	(2)	100.2	.4
Benzoic	8.84	4.45	4.39	(2)	99.3	.1
Phthalic	13.50	6.75	6.75	(2)	99.9	.3
Furoic	9.61	4.97	4.64	(4)	95.6	.2

[a] Figures in parentheses indicate number of individual determinations.

The matter of interfering substances was also investigated and as the probable titration behavior of lactones was in doubt several examples of this class were examined and the results recorded in Table II. Ordinary esters and stable lactones like phthalide and coumarin are inert toward the reagents as ordinarily employed, hence do not interfere. Readily hydrolyzed compounds of these classes such as alkyl formates and glucono-δ-lactone although unaffected by sodium methylate undergo hydrolysis in aqueous solution and so lead to ambiguous results in mixtures. β-Methylumbelliferone, a substituted coumarin, reacts as an acid with both reagents, hence does not affect the determination of anhydrides.

TABLE II

ANALYTICAL DATA FOR LACTONES

Lactone	Millimoles per gram sample NaOH (a)	NaOCH$_3$ (b)	Δ (a − b)
Glucono-δ-lactone	5.65	0.05	5.60
Phthalide[a]	0.11	.02	0.09
Coumarin	.05	.02	.03
β-Methylumbelliferone	5.63	5.62	.01

[a] Obtained from British Drug House, Ltd.; remaining lactones Eastman products.

Experimental

Compounds Investigated.—With two exceptions all of the anhydrides studied in the present research were Eastman products, and were used without further purification. **Phthalic anhydride** ("Aero" Brand) was obtained from American Cyanamide and Chemical Corp., and **glutaric anhydride** was prepared from the acid by the method of Mol.[5] In this connection, evidence was obtained that solid anhydrides adsorb large quantities of water vapor on short exposure to moist air. Decomposition is not instantaneous but takes place to a serious extent during subsequent storage. To minimize this difficulty, samples for analysis were dispensed by means of a simple "dry manipulator."

Analytical Procedure

One to three grams of sample is weighed into a dry 250-cc. g. s. volumetric flask (calibration unnecessary) or similarly designed vessel. If the sample is a solid, 20 to 30 cc. of dry methanol or acetone is added, warming if necessary to complete solution. The solution is then titrated directly with 0.5 *N* sodium methylate in methanol to a phenolphthalein or thymol blue end-point. The indicator should be made up in dry dioxane or acetone (an alcohol solution would be unsuitable for use in the next step). This titer is a measure of the anhydride plus any free acid present.

A second weighed sample is mixed with 25 cc. of C. P. pyridine and titrated with 0.5 *N* aqueous sodium hydroxide to the indicator previously employed. Alcohol should be omitted in order to avoid ester formation. This titer is a measure of the total acidity of the sample. The true anhydride content is measured by the difference between the two titers expressed in moles per gram of sample.

---

[5] Mol, *Rec. trav. chim.*, **26**, 373 (1907).

The sodium methylate solution is prepared by dissolving the required amount of metallic sodium in dry c. p. methanol. Although precautions should be taken to keep the solution dry, the presence of up to 1% of water introduces only a small error. The two alkalies should be compared frequently with standard 0.5 *N* acid. Anhydrides that are unreactive because of steric hindrance, may be heated with an excess of either alkali and back titrated cold with standard acid. In such cases, however, esters must be absent to avoid interference. Camphoric anhydride was the sole example of this class encountered.

Summary

1. A rapid and precise method for the determination of anhydrides of carboxylic acids based on sodium methylate titration has been developed. The method has been applied successfully to the following anhydrides: acetic, propionic, *n*-heptylic, succinic, glutaric, maleic, camphoric, benzoic, phthalic and furoic.

2. In connection with the above method, the hydrolytic cleavage of anhydrides was found to be accelerated by the use of pyridine.

3. The interference of lactones has been investigated. Phthalide and coumarin do not react. β-Methylumbelliferone reacts but does not interfere. Glucono-δ-lactone interferes with anhydride determinations.

Wilmington, Del. Received October 7, 1936

[Contribution from the Kedzie Chemical Laboratory, Michigan State College]

The Surface Tensions, Densities, Free Surface Energies and Parachors of Some Derivatives of Benzylated Phenols[1]

By D. T. Ewing and Frances W. Lamb

In this paper data are presented for the measurement of the surface tension and density at different temperatures of a series of new organic compounds, which are derivatives of benzylated phenols. From these values the molal free surface energy and parachors have been calculated. Although these physical factors have been evaluated for a number of organic compounds, reliable surface tension values of only four diphenyl and two triphenyl compounds have been reported previously.

The compounds used in these investigations were those prepared by R. C. Huston and associates in a series of investigations in this Laboratory. These substances were found to be of sufficient purity to warrant direct measurement without further purification. In each case the compounds had been carefully distilled many times.

Density measurements were made at different temperatures with a pycnometer which was essentially a bulb of glass blown on a capillary. A special pycnometer was made partly because in several cases the sample of liquid was limited to a few ml. and partly because the best density bulb is one which is spherical in form with only a fine capillary opening. In each case the pycnometer was carefully calibrated with water at the several temperatures. Density measurements were made at 25, 35 and 50°. For this purpose the substances were equilibrated in constant-temperature water-baths which did not vary in temperature more than 0.005°.

Surface tension measurements were made with a metal drop weight apparatus[2] supported on a heavy concrete pillar free from the floor of the laboratory to avoid any vibration. The radius of the tip was carefully determined with a Gaertner comparator and found to have a value of 0.26740 cm. The drop weight assembly with the liquid was lowered below the surface of the water in the thermostat and allowed to remain until the temperature of the liquid was a constant when the drop weight determinations were made. For each liquid, when the volume available permitted, 25 to 30 drops were formed very slowly into a weighing bottle and from this weight that of the drop was determined.

From the weight of the drop and the density of the liquid the surface tension γ was calculated by the equation

$$\gamma = \frac{mg}{2\pi r f(r/v^{1/3})}$$

where m = mass of drop in grams
g = 981 dynes
r = 0.26740 cm. the radius of the tip
v = volume of the drop

[a] Reliable data not obtained because of high viscosity of compounds at 25°.

The f functions of $r/v^{1/3}$ were those determined by Harkins and Brown.[2]

The thirteen compounds investigated are as follows: 2-chlorophenylbenzyl ether and 2-chloro-4-benzylphenol, both prepared by G. W. Warren,[3] 2-chlorobenzylphenyl ether, 2-*o*-chlorobenzylphenol and the benzoyl ester of 2-*o*-chlorobenzylphenol, all prepared by P. S. Chen,[4] 2-*m*-methyl-4,6-dibenzylphenol prepared by Huston, Swartout and Wardwell,[5] 3-methyl-2,6-dibenzylphenol as prepared by Huston and Houk,[6] 4-methyl-2,6-dibenzylphenol prepared by Huston and Lewis,[7] 6-benzyl-2-phenylphenol, 4-benzyl-2-phenylphenol, 6-benzyl-4-bromo-2-phenylphenol and 6-bromo-4-benzyl-2-phenylphenol, all prepared by G. W. Warren,[8] and *o*-hydroxy-1,1-diphenylbutane by Strickler.[9]

The values obtained for the surface tension and density at the three temperatures are tabulated for each of the compounds. The molal free sur-

(9) Strickler, Master's thesis, 1927.

face energies $\gamma(m/d)^{2/3}$ and the parachors are evaluated from these experimental values and also tabulated. The parachor observed is calculated from Sugden's formula $P(\text{obsd.}) = m/d\gamma^{1/4}$ in which m is molecular weight, d the density and γ the surface tension.

In Table I it should be noted that compounds 1, 2, 3 and 4 are isomeric and have a molecular weight of 218.5. Compounds 6, 7 and 8 are isomeric, and have a molecular weight of 288.2. Compound 9 is isomeric with compound 10 (mol. wt. 260.1), and compound 11 is isomeric with compound 12 (mol. wt. 339.0).

A summary of the molal free surface energies and parachors (observed) at 35° together with the respective names of the liquids is given in the above table. The parachors (calculated) are given, column no. 8. These are obtained by adding the proper atomic and structural parachors for each compound.[10] In the last column the difference ΔP between the parachor (observed) at 35° and parachor (calculated) is tabulated.

In the table it is noted that in general as the molecular weights increase, the differences in the calculated and observed parachors increase. The values for ΔP are negative except in the first case and range from $+5$ to -35. Since the parachor values are proportional to molecular volume these negative values for ΔP would seem to indicate that these molecules are more closely packed together than is accounted for by the present structural parachors. In a calculation of parachor observed and parachor calculated for diphenylmethane[11] and diphenylethane,[1] Harkins and Ewing show negative values for ΔP of the same order as those found here. These results seem to indicate a need for the application of an additional structural parachor for compounds having two or more phenyl groups.

The parachor (calculated) is the same for compounds isomeric with one another; however, it is interesting to note the variation of the values for parachor (observed) for the different isomers. The observed parachor for compound 1, in which the chlorine and CH_2 groups are not on adjacent carbon atoms in the benzene ring, is 481.41 while in compound 2, in which they are on adjacent carbon atoms in the benzene ring, the value is 470.8, a difference of 10.59. Upon comparing compounds 3 and 4 in the same manner, it is noted that compound 4, where the chlorine and CH_2 group are on adjacent carbon atoms of the benzene ring, the value is 463.42, and for compound 3, in which these groups are not on adjacent carbon atoms, the value is 473.79. Here the difference is 10.37 and agrees with the above value of 10.59. Thus it would seem that with sufficient data some important relations could be evaluated for isomeric compounds in regard to their parachors.

The molal free surface energies range from 132.6 to 138.8 ergs for those compounds containing two phenyl groups, while the molal free surface energies for all compounds containing three phenyl groups range from 160 to 175 ergs.

Conclusion

1. Surface tensions and densities of 13 new derivatives of benzylated phenols have been determined, and their molal free surface energies and parachors have been evaluated.

The Potentiometric Iodide–Silver Titration at Extreme Dilutions

BY I. M. KOLTHOFF AND J. J. LINGANE

In a study of the solubility of slightly soluble (10^{-3} to 10^{-5} N) silver salts in solutions of various electrolytes and in water it was necessary to develop an accurate method for the determination of very small amounts of dissolved silver. We have found that the potentiometric titration of silver with iodide is very suitable for this purpose, and as little as one part of silver in twenty million parts of solution (5×10^{-7} N) may be titrated with an accuracy of a few per cent. when 500 ml. of the solution is taken for analysis. At this high dilution the potentiometric method is more accurate than any other method of analysis, especially in the presence of large amounts of indifferent electrolytes.

Experimental

Apparatus and Materials.—The potentiometric apparatus and the general technique of the iodide–silver titration have been described already.[1] Silver iodide electrodes were used, since our experience has shown that these are somewhat more satisfactory than plain silver electrodes. A saturated calomel electrode, with a saturated potassium nitrate bridge, was used as reference electrode. Titrations were performed in the absence of light in the one liter titration beaker previously described.[1] The potassium iodide titrating solution was delivered from a 10-ml. microburet, with which volumes could be read easily to ±0.005 ml.

The nitric acid, water and salts were purified carefully by the usual methods. Mallinckrodt reagent quality potassium iodide (ground and dried at 200°) was used in most of the experiments since in titrating the very dilute silver solutions it gave the same results as the carefully synthesized salt.[1]

Approximately 0.01 N stock solutions of silver nitrate and potassium iodide were prepared by weighing out the dried salts. The more dilute solutions were prepared by diluting the stock solutions in carefully calibrated volumetric apparatus. The potassium iodide titrating solutions varied in concentration from 10^{-3} to 5×10^{-5} N, depending on the concentration and volume of silver solution to be titrated. These solutions were stable for several weeks when made up in pure water that was entirely free from traces of copper and stored in the dark. The concentrations of the various solutions were known to ±0.1%.

Data of the Titrations.—For the purpose of illustrating a typical titration we may consider the case of the most dilute silver solution that was titrated, which was only 5.15×10^{-7} N in silver. The data obtained in this titration are given in Table I and Fig. 1. These data show that the

[a] R. T. = room temperature.

end-point of the titration (maximum value of $\Delta E/\Delta V$) is still well defined at this extreme dilution, and the error of +3.2% is remarkably small when it is realized that the total amount of silver titrated was only 0.028 mg. in a volume of 500 ml.

A summary of the results obtained in twenty-six titrations in which the concentration of silver titrated was varied between 5×10^{-7} and 10^{-5} N, is given in Table II. Some of these titrations were carried out in the absence of air, by bubbling a rapid stream of carbon dioxide through the solution, in order to see whether atmospheric oxygen had any influence on the accuracy of the titration. Titrations were also made in solutions that contained large amounts of very pure barium nitrate and potassium sulfate. A few titrations were also made at 60°.

The column headed "av. $E_{E.P.}$" in Table II, contains the average values of the e. m. f. at the end-point of the titrations (equivalence potential); the significance of these values will be explained later.

Discussion

Steady e. m. f. readings are obtained relatively rapidly in these "dilute" titrations, except in the immediate vicinity of the end-point where ten to fifteen minutes are required between each addition of the potassium iodide solution. The e. m. f. becomes steady more quickly in these "dilute" titrations than in titrations of ordinary amounts of silver because the amount of solid silver iodide present is so extremely small that adsorption effects are negligible. The time required for the e. m. f. to become steady simply corresponds to the time required to re-establish solubility equilibrium after each addition of potassium iodide. This is substantiated by the fact that the direction of the drift is toward decreasing values of the e. m. f., *i. e.*, toward decreasing silver ion activity.

When the titration is carried out at 60° the e. m. f. becomes steady more quickly, because solubility equilibrium is attained more rapidly at the higher temperature. A titration at room temperature requires about one to one and one-half hours, but at 60° this time is reduced to about one-half. In titrating a 10^{-5} N silver solution at 60° the maximum value of $\Delta E/\Delta V$ is only about one-third as great as at room temperature, but is still sufficiently sharp to allow an accurate determination of the end-point.

An inspection of the data of Table II shows that a 10^{-5} N silver solution can be titrated at room temperature with an accuracy of at least ±0.2%, a 10^{-6} N solution can be titrated with an accuracy of about 1–2% and a 5×10^{-7} N solution with an accuracy of about 3%. Since the percentage error is a linear function of the amount of silver titrated, it is evident that the absolute error is constant and independent of the amount of silver titrated in this range of concentrations.

The data also show that air has no marked effect on the accuracy of the titration, although a comparison of series nos. 3 and 4 and nos. 11 and 12 indicate that somewhat better results are obtained in the presence of carbon dioxide when titrating very small amounts of silver or when titrating at 55–60°.

Large amounts of barium nitrate have no influence on the results. Potassium sulfate (sulfate ion) in large amounts on the other hand causes a large positive error (no. 7). The deleterious influence of the sulfate ion on the behavior of silver electrodes appears to be rather general; it has been observed previously in work with the silver electrode.[2]

The interference of large amounts of sulfate

---

(2) I. M. Kolthoff, *Z. anorg. allgem. Chem.*, **119**, 202 (1921); **132**, 117 (1923).

ion at these high dilutions is to be attributed to the reaction

$$Ag^+ + SO_4^= \rightleftharpoons AgSO_4^-$$

which results in a decrease of the silver ion activity, an increase in the solubility of silver iodide, and an asymmetric location of the equivalence point; *i. e.*, the equivalence point no longer corresponds exactly to the maximum value of $\Delta E/\Delta V$.

We have also found that the titration can be carried out with the same degree of accuracy in dilute potassium bicarbonate medium (*p*H about 8.3) as in dilute nitric acid.

The titration may be simplified and made more convenient by simply titrating to the equivalence potential instead of recording the data of the entire titration curve.[3] The average value of the equivalence potential found was +0.097 ± 0.005 v. against the saturated calomel electrode, as shown by the data of Table II. This value is in excellent agreement with that found in the titration of ordinary amounts of silver.[1] We have found that the value of the equivalence potential is practically the same (within ±5 mv.) in dilute potassium bicarbonate medium as in dilute nitric acid, and it is evident from Table II that it is also practically independent of temperature, and the presence of large amounts of barium nitrate. Titrations to the equivalence potential gave identically the same results as by the ordinary method, and are more convenient because the constant attention of the operator is not required.

It is evident from these results that this titration should be a valuable analytical method of investigating the solubility and activity relations of slightly soluble silver salts. We are using the method in a study of the activity of silver chloride and silver iodate in various salt solutions. Obviously the method could also be applied to the determination of very small amounts of iodide by adding an excess of silver nitrate solution to the unknown iodide solution and back-titrating the excess silver.

Acknowledgment.—We wish to express our appreciation to the Graduate School of the University of Minnesota for financial assistance in this work.

Summary

1. The accuracy of the potentiometric iodide–silver titration at extreme dilutions has been investigated. Using a 500-ml. sample, a 10^{-5} *N* silver solution can be titrated with an accuracy of ±0.2%, a 10^{-6} *N* solution with an accuracy of 1–2% and a 5×10^{-7} *N* solution with an accuracy of about 3% at room temperature. Large amounts of barium nitrate have no influence on the results, but a large positive error was found in the presence of high concentrations of sulfate ions.

2. The titration is recommended as an analytical tool in investigations of the solubility and activity relations of slightly soluble silver salts.

The Structure of Crystalline Bromine

BY B. VONNEGUT AND B. E. WARREN

Introduction

There is very little crystallographic information available concerning crystalline bromine. The material melts at −7.3° and single crystals are readily obtained from the vapor. It would be expected that the crystalline structure of bromine should be very similar to that of orthorhombic iodine.[1] This has turned out to be the case, and the structure analysis has been considerably simplified by making comparison with the known structure of iodine.

Experimental

Bromine crystals were formed from the vapor on the surface of a round-bottomed flask filled with dry ice and placed over the mouth of a beaker containing liquid bromine. The crystals showed a pronounced elongation along the direction of the *c*-axis, and were thus readily oriented for rotation and oscillation patterns about *c*. They were mounted by being placed upon a smooth surface of dry ice, and cemented to a fine glass rod with a soft vaseline which froze upon cooling. The crystal was maintained at about −150°

---

[1] Harris, Mack and Blake, THIS JOURNAL, **50**, 1583 (1928).

during the exposure by being placed in the exhaust stream from a liquid air container. Since the crystal is bathed completely in a stream of dry cold air, there is no trouble from water vapor freezing out upon the crystal. The vapor pressure of the bromine crystal was sufficiently reduced by the cooling, so that a single crystal would last through a twelve-hour oscillation exposure. The experimental arrangement is shown schematically in Fig. 1.

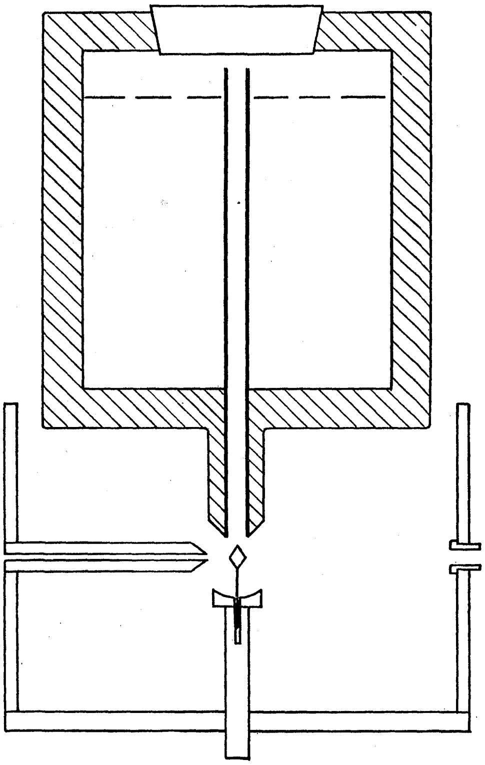

Fig. 1.—Method for producing low temperature x-ray diffraction patterns of bromine by placing crystal in liquid air exhaust.

Three 38° oscillation photographs were made in a cylindrical camera of radius 8.61 cm. The radiation used was Mo Kα with 0.30 mm. aluminum sheet in front of the film to reduce the blackening by fluorescent bromine radiation.

Unit Cell and Space Group.—From the layer line separations on the three oscillation patterns, the length of the c-axis was determined directly as 8.72 Å. By assuming that the axes of bromine would all stand in about the same ratio to the corresponding axes in iodine, tentative values of a and b were obtained which allowed a satisfactory indexing of all the spots on the oscillation patterns. Final values of the axes were then calculated from $h00$ and $0k0$ reflections; a = 4.48 Å., b = 6.67 Å.

All reflections hkl were missing except for $h + k$ = even. In addition, the reflections $0kl$ and $hk0$ were missing except for even indices. These vanishings are consistent with the space group *Ccma* (V_h^{18}) which is the space group found previously for orthorhombic iodine.[1]

Since the isomorphism of the bromine and iodine structures is completely established by the intensity comparisons which are given below, one can assume 8 atoms per unit cell as in iodine and calculate the density of bromine at about −150°.

$$\rho = \frac{8 \times 79.9}{0.606 \times 8.72 \times 6.67 \times 4.48} = 4.05$$

This is in satisfactory agreement with most of the values given in the literature; 4.107 (−194°),[2] 4.13 (−253°).[3] The value 3.4 for the density of crystalline bromine given in the "International Critical Tables" is much too low.

Atomic Arrangement.—The eight atoms in the bromine unit cell are in the 8-fold position f of V_h^{18}. The coördinates are

$x,0,z$	$\bar{x},0,\bar{z}$	$x,\frac{1}{2},\frac{1}{2} - z$	$\bar{x},\frac{1}{2},\frac{1}{2} + z$
$\frac{1}{2} + x,\frac{1}{2},z$	$\frac{1}{2} - x,\frac{1}{2},\bar{z}$	$\frac{1}{2} + x,0,\frac{1}{2} - z$	$\frac{1}{2} - x,0,\frac{1}{2} + z$

Structure factors were calculated for several values of the parameters x and z. The best general agreement between calculated and observed intensities was given for the values x = 0.135, z = 0.110.

The intensities of the spots on the oscillation patterns are given roughly by the relation[4]

$$I \alpha F^2/\xi$$

No attempt was made to apply any correction for temperature motion or absorption in the crystal. By looking for close agreement only among spots in the same row line, the neglect of these factors is not serious. Table I gives a comparison of values of $F/\xi^{1/2}$ calculated for x = 0.135, z = 0.110 and the visually estimated intensities of the spots. The agreement is sufficiently good to substantiate the proposed structure. No serious attempt was made to deduce precise values of the parameters x and z as the absorption in the sample was large, and only low order reflections were present on the oscillation patterns.

Discussion of Structure.—The resulting structure for bromine is shown in Fig. 2, projected on

the 010 plane. Each atom has one nearest neighbor at a distance 2.27 Å., the other member of the Br_2 molecule. The x-ray crystal value of the Br–Br distance 2.27 Å. is to be compared with the band spectrum value[5] 2.28 Å. and the electron diffraction value[6] 2.28 Å. The close agreement is fortuitous as the x-ray value is probably uncertain by ±0.10 Å.

Each atom has three other close neighbors in the same reflection plane (plane of paper) at distances: 3.30, 3.30, 3.75. Eight more neighbors in the planes above and below are at slightly larger distances: 4.00, 4.00, 3.98, 4.10.

Crystalline bromine is definitely a molecular structure, the Br_2 molecule being easily recognized in the crystalline structure from consideration of the observed interatomic distances. The structure of orthorhombic bromine is isomorphous with that of iodine,[1] but apparently different from the structure of crystalline chlorine.[7] The structure of bromine forms one more example of the application of the 8-N law to the structures of the B sub-group elements in columns IV–VII.

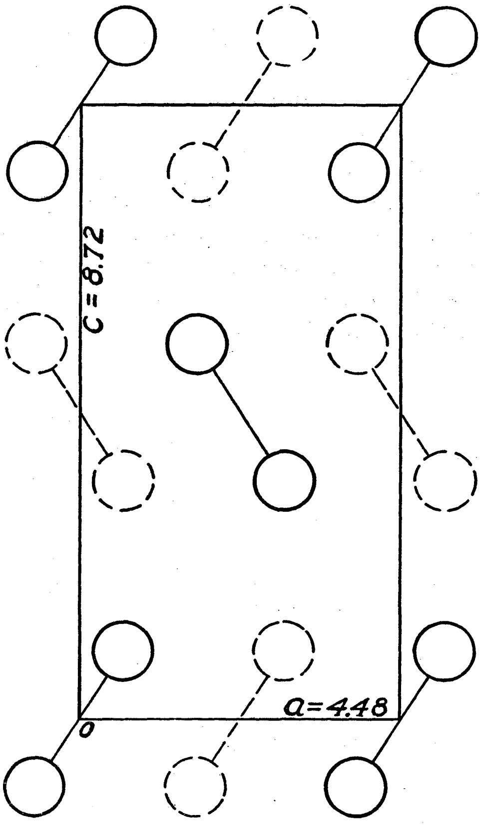

Fig. 2.—Structure of crystalline bromine projected upon the 010 plane. Full circles represent atoms in the plane of the paper, broken circles represent atoms above and below the plane of the paper by *b*/2. The Br_2 molecules are indicated by the connecting lines.

Summary

Oscillation patterns about the *c*-axis were made of a bromine crystal held at about −150°. The lattice is orthorhombic with axes: $a = 4.48$ Å., $b = 6.67$ Å., $c = 8.72$ Å. The 8 atoms are in the position 8*f* of the space group *Ccma* (V_h^{18}), with $x = 0.135$ and $z = 0.110$. The structure is isomorphous with that of iodine, and shows a definite Br_2 molecule with Br–Br distance of 2.27 ± 0.10 Å. The x-ray density at about −150° is 4.05.

The Photodecomposition of Ammonia

BY HENRY J. WELGE AND ARNOLD O. BECKMAN

Introduction

Although the photodecomposition of ammonia was one of the first photochemical reactions to be studied carefully and the initial investigation of Warburg[1] has been followed by many others, the nature of the reaction has remained in doubt. The results of the various investigations are summarized in Table I.

TABLE I

SUMMARY OF PREVIOUS INVESTIGATIONS

Photochemical unless otherwise noted

Date	Investigator	NH_3 pressure, mm.	Minimum products for H_2 detn., mm. × 10^3	H_2 yield, %	N_2H_2 yield	Quantum yield
1911	Warburg	45–900				0.25
1926	Kuhn[2]	5–900				.2 –0.5
1926	Dickinson and Mitchell[3]	0– 1	5	70 (sens.) 87 (dir.)		
1927	Bates and Taylor[4]		40	96 (dir.) 89 (sens.)	Amt. small	
1931	Koenig and Brings[5]	250			Small amt.	
1932	Gedye and Rideal[6]	44			0–57% of NH_3 decomp.	
1932	Wiig and Kistiakowsky[7]	0–760	15	75		.24
1934	Ogg, Leighton and Bergstrom[8]	1– 9	Large	75		.14
1935	Wiig[9]	0–900	20	75		.10– .33

Several investigators obtained as products only hydrogen and nitrogen in 3:1 molal ratio and a quantum yield of about 0.25 molecule of ammonia decomposed per quantum absorbed. Others obtained higher hydrogen to nitrogen ratios and still others obtained hydrazine in varying amounts.

The present investigation includes a study of the reaction products and determination of the quantum yields for both the direct photochemical decomposition and the mercury sensitized decomposition. Evidence is presented which makes possible a reconciliation of some of the apparently conflicting data of earlier investigations and which sheds new light on the nature of the decomposition. The results are of particular interest when the amount of decomposition is small; in some cases the partial pressure of the non-condensable products was as low as 10^{-4} mm. of mercury.

Materials and Apparatus

Commercial anhydrous ammonia, free from hydrazine and hydroxylamine, was drawn under vacuum into a storage bulb containing C. P. potassium hydroxide and was purified by repeatedly freezing in a liquid air trap and pumping off the non-condensable gases. Several samples of ammonia from different sources were used during the course of the investigation with completely concordant results.

Most of the apparatus employed has been described previously.[10,11] The vacuum system included mercury diffusion pump, McLeod gage, quartz fiber gage, a reaction cell of quartz (attached to the rest of the system through a quartz–Pyrex graded seal), a storage bulb for the ammonia, and several stopcocks and mercury cut-offs. The cut-offs were so placed that no stopcocks were included in that part of the system in which measurements were made.

The direct decomposition of ammonia was studied with the aid of radiation from a high-voltage condensed spark between water-cooled aluminum electrodes. Energy for the spark was supplied by a 13,000-volt, 10-kva. transformer with a 0.1-mf. condenser placed in parallel with the spark. The sensitized decomposition was produced by the 2537 Å. resonance radiation from a water-cooled quartz mercury arc. Radiation of wave length shorter than 2400 Å. was removed by an acetic acid filter.

In the quantum yield experiments monochromatic radiation, vacuum thermopiles and high-sensitivity galvanometers were used. The thermopiles had fused quartz windows attached with wax and were continuously evacuated by an oil diffusion pump. Monochromatic radiation was

obtained by means of a quartz monochromator and was focused on the vane of one of the thermopiles, T_t (transmission). The fused quartz reaction cell, provided with plane windows, was inserted in this light path. The front window of the cell, attached at an angle of 45°, reflected a fraction of the incident radiation onto the vane of the second (reflection) thermopile, T_r. A recording device provided continuous records for both thermopiles.

Experimental Method

Since the decomposition products were very small in amount, it was essential to keep the system thoroughly outgassed. This was achieved by almost continuous evacuation during the investigation. The reaction system would retain for hours a vacuum better than 10^{-6} mm.

In experiments to determine the composition of the non-condensable products, a sample of purified ammonia was irradiated and the pressure and composition of the products not condensable in liquid air were determined by combined use of the McLeod and quartz fiber gages. These products were assumed to contain only hydrogen and nitrogen; it has been shown[12] that this method of analysis gives accurate results with such mixtures. The quartz fiber gage was calibrated frequently, using both nitrogen and hydrogen.

Quantum yields were measured by an absolute method. In each experiment the ratio of the transmission and reflection thermopile readings with the empty cell was first determined. The purified ammonia was then admitted and irradiated, a continuous photographic record being taken of both thermopile readings. Liquid air was applied and the pressure and composition of the non-condensable products determined. Calibrations of the quartz fiber gage were alternated with quantum yield runs. Blank experiments were also run, in some of which the shutter of the monochromator remained closed throughout the experiment; in others the shutter was opened as usual but the ammonia was kept frozen. The sensitivity of the transmission thermopile was measured frequently with the aid of standardized carbon lamps supplied by the Bureau of Standards. The transmission factors of the rear window of the cell and of the window of the transmission thermopile for the radiations used were determined experimentally.

Experimental Results

Products of the Photochemical Decomposition.—When the amount of ammonia decomposed was relatively large (*i. e.*, partial pressure of products greater than 0.05 mm.) the non-condensable products contained approximately 75% hydrogen and 25% nitrogen, in agreement with the results reported by several of the previous investigators (Table I). However, when the amount of decomposition was successively decreased, the percentage of hydrogen increased, approaching 100% in the limiting case. The data for the photochemical decomposition are represented by the circles in Fig. 1, in which the ordinates are the percentages of hydrogen in the non-condensable decomposition products and the abscissas are the total pressures of the non-condensable products as measured with the McLeod gage. The lowest pressure on which accurate analyses could be made was about 3×10^{-4} mm.

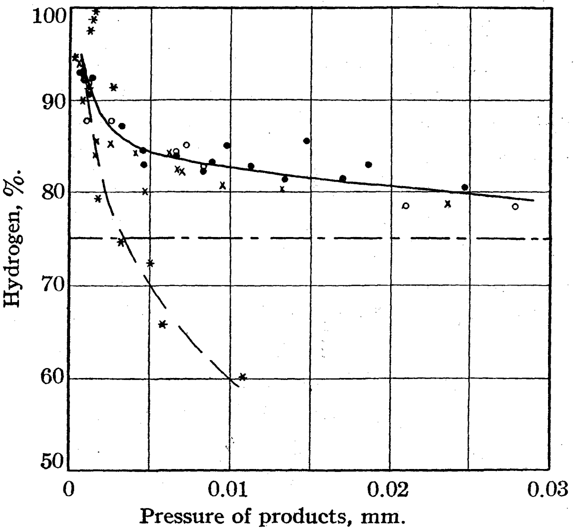

Fig. 1.—Composition of the non-condensable gases: ●, direct photochemical decomposition, 4 mm. NH_3; ○, direct photochemical decomposition, 20 mm. NH_3; $*$, mercury sensitized decomposition, 4 mm. NH_3, fresh cell; ×, mercury sensitized decomposition, 20 mm. NH_3.

To prove that the results could not be attributed to easily decomposed impurities in the ammonia, experiments were made not only with fresh samples of ammonia but also with the residual ammonia remaining from previous experiments, in which large amounts of decomposition had taken place and in which 75% hydrogen had been obtained. In all cases, the percentage of hydrogen was considerably greater than 75% for very small amounts of decomposition and decreased progressively toward 75% as the amount of decomposition was increased.

Percentages of hydrogen in excess of 75% indicate the formation of hydrazine during decomposition. Varying amounts of hydrazine in the decomposition products of ammonia have been reported by certain investigators who used a flow method. Thus Bates and Taylor[4] and Koenig and Brings[5] obtained small amounts of hydrazine, while Gedye and Rideal[6] reported hydrazine yields ranging from 0 to 57% of the amount stoichiometrically possible from the amount of ammonia decomposed. Other investigators obtained no evidence of hydrazine formation.

---

(12) Beckman and Dickinson, THIS JOURNAL, **50**, 1870 (1928).

Hydrazine, if present, might be expected to condense with the undecomposed ammonia when liquid air is applied to the freezing-out trap. In several experiments the trap containing the condensed material was removed from the vacuum system and the contents dissolved in dilute acid. Tests with iodate, ammoniacal silver, and gold chloride failed to give a positive indication for hydrazine. Since the amount of hydrazine theoretically present (calculated from the pressure and composition of the non-condensable gases, assuming that the hydrazine is the only other product formed in the decomposition) is not greatly in excess of the minimum amount capable of detection (about 10^{-8} mol) by these methods, and since hydrazine is known to be strongly adsorbed on glass and quartz, it appeared probable that failure to detect hydrazine was due to the fact that most of the hydrazine remained in the reaction cell. Consequently, tests were made in which acidified, de-aerated water was added directly to the reaction cell and the aqueous liquid withdrawn and tested for hydrazine with ammoniacal silver nitrate. Positive indications for hydrazine were obtained in all cases. Control experiments made under identical conditions except that the ammonia was not irradiated gave no tests for hydrazine.

Quantum Yield for the Photochemical Decomposition.—The results of the quantum yield determinations for the direct decomposition of ammonia, using monochromatic radiation of 1990 Å., are given in Table II. In these experiments the amount of decomposition was always very small and the percentage of hydrogen in the non-condensable gases was large, averaging about 95%. Assuming that hydrazine, hydrogen and nitrogen are the only products, this means that 16 molecules of ammonia decompose to give hydrogen and hydrazine for every molecule that decomposes to hydrogen and nitrogen. The number of molecules of ammonia decomposed may be found by means of the stoichiometric relation

$$N_{\mathrm{NH_3}} = 6(f - 0.667)N\frac{pV}{RT} \tag{1}$$

where N is Avogadro's number, p is the total pressure of non-condensable gas and f is the mole fraction of hydrogen.

The number of quanta of 1990 Å. radiation absorbed may be calculated from the relation

$$N_{\mathrm{Q}} = \frac{(\beta D_{\mathrm{r}}S_{\mathrm{r}} - D_{\mathrm{t}}S_{\mathrm{t}})t}{\alpha_1\alpha_2hc/\lambda} \tag{2}$$

where β is the ratio of galvanometer deflections with the empty cell, D_{r} and D_{t} are the galvanometer deflections for the reflection and transmission thermopiles, S_{r} and S_{t} are the sensitivities of the transmission thermopile at deflections of D_{r} and D_{t}, *i. e.*, the number of ergs per second required to give unit deflection, t is the time of irradiation, α_1 and α_2 are the transmission factors for λ 1990 Å. of the rear window of the reaction cell and the window of the transmission thermopile, h is Planck's constant, c the velocity of light and λ is the wave length 1990 Å. The quantum yield is obtained by dividing $N_{\mathrm{NH_3}}$ by N_{Q}.

In the first four experiments listed in Table II the reaction cell was thoroughly outgassed by

[a] For these experiments the hydrogen in the non-condensable products was assumed to be 95%. For the remaining experiments the percentage of hydrogen was determined by analysis.

baking and evacuating prior to the experiment. Since it is known that hydrogen readily "cleans up" on fresh quartz surfaces,[13] it was felt that the observed quantum yields (av. = 0.70) might be low for that reason. Therefore, for the remainder of the experiments, prior to the admission of ammonia to the cell, hydrogen at a pressure of a few millimeters in the presence of mercury vapor was irradiated for several hours with intense mercury resonance radiation, followed by thorough evacuation. With such treatment of the cell, the observed quantum yields rose to an average value of 0.87. Blank experiments showed that irradiation of the empty treated cell produced negligible amounts of gas, proving that the increased quantum yield was not due to outgassing of adsorbed hydrogen. In Fig. 2 the quantum yields for the direct decomposition of ammonia are represented by the circles. The yields seem to approach unity as a limit and are not affected by changes in ammonia pressure nor the amount of products, when the latter is less than 10^{-3} mm.

Mercury Sensitized Decomposition.—The products of the sensitized decomposition were the same as in the direct decomposition. The percentage of hydrogen in the non-condensable products again varied from nearly 100% down to about 75% as the amount of decomposition increased, as shown in Fig. 1, where the crosses represent sensitized decompositions. It will be noticed that the same curve fits either type of decomposition, except when the ammonia pressure is low and a fresh cell is used. In this event, hydrogen is cleaned up on the walls to such an extent that its fraction in the gases drops considerably below 0.75 on continued irradiation with λ 2537 Å. When hydrogen alone is similarly irradiated in the cell, its pressure slowly falls off.

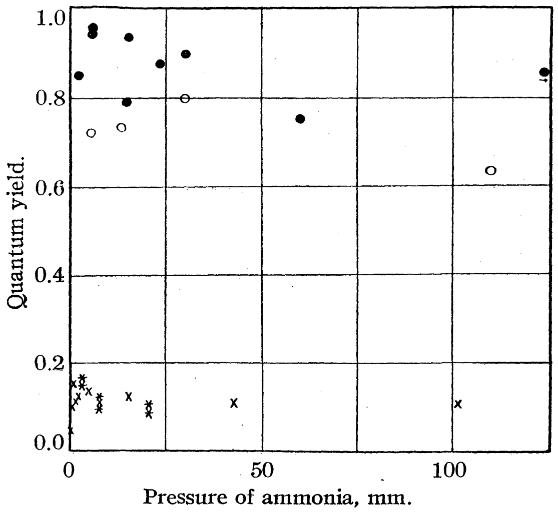

Fig. 2.—Quantum yield of the photodecomposition of ammonia: ○, direct decomposition, fresh cell; ●, direct decomposition, cell saturated with H atoms; *, sensitized decomposition; ×, sensitized decomposition, 95% H_2 assumed.

---

(13) Cario and Franck, *Z. Physik*, **11**, 161 (1922).

The quantum yield of the sensitized decomposition was, however, much smaller than that of the direct decomposition, having an average value of 0.12, as shown in Table III, and in Fig. 2, where the crosses again represent sensitized decompositions. This value of the yield was independent of the amount of decomposition, if small, and of the ammonia pressure, except below 1 mm., where it fell rapidly to zero.

Discussion

The primary process in the photochemical decomposition of ammonia may be assumed to be a dissociation, since the absorption spectrum of ammonia is of the predissociation type,[14,15] involving the rupture of one of the hydrogen–nitrogen bonds.

$$NH_3 + h\nu \longrightarrow NH_2 + H$$

The most direct experimental evidence for this primary process is the work of Geib and Harteck,[16] who showed that the photochemical decomposition products of ammonia could effect the conversion of para to ortho hydrogen and therefore presumably contained hydrogen atoms.

In the lower limit of small amounts of decomposition, the products are substantially only hydrogen and hydrazine. The following mechanism accounts for their formation

$$\begin{aligned} NH_3 + h\nu &\longrightarrow NH_2 + H \\ H + H + M &\longrightarrow H_2 + M \\ NH_2 + NH_2 + M &\longrightarrow N_2H_4 + M \end{aligned}$$

This mechanism accounts satisfactorily for the additional experimental fact that the quantum yield is unity, independent of ammonia pressure. Other reaction steps assumed by previous investigators[4,7,8] are not needed. In particular, the reaction

$$H + NH_2 + M \longrightarrow NH_3 + M$$

leading to the re-formation of ammonia, does not play an important role, since the quantum yield is nearly unity.

The decomposition, with the exception of the primary process, probably proceeds heterogeneously on the walls of the reaction vessel at the low pressures of these experiments. Hydrogen atoms are known to be strongly adsorbed on glass[17] and are probably also adsorbed on quartz. The fact that no reducing substance was obtained in freezing-out traps may be taken as evidence that either NH_2 or N_2H_4 or both are adsorbed on the cell walls.

A little of the hydrazine will probably be decomposed by the hydrogen atoms, as shown by Dixon,[18] even when its amount is small. The decomposition of hydrazine in this way will give ammonia and some nitrogen, thus slightly reducing the hydrogen fraction below 100% and reducing the quantum yield below the value of unity. With larger amounts of products the effect is exaggerated, and the lower quantum yields obtained by previous investigators may be due in part to this effect. There is general agreement in recent investigations[7,9] that the non-condensable gaseous products contain 75% hydrogen and 25% nitrogen when relatively large amounts of products are obtained. These percentages also appear as the limiting values in the present experiments as the amount of decomposition successively increases. For small amounts of decomposition, however, the percentage of hydrogen is much greater, a fact which has a marked influence upon the calculation of the quantum yields. From equation 1 above, it is to be seen that for a given volume of non-condensable gas, the calculated number of ammonia molecules decomposed will be four times as large when the gas is 100% hydrogen as when it is 75% hydrogen. If the quantum yields given above in Table II had been computed on the assumption that the non-condensable gas consisted of 75% hydrogen and 25% nitrogen, the calculated quantum yields would have been reduced to approximately 0.25, in agreement with the results of others. Since the analyses showed that the non-condensable gas was substantially all hydrogen, the actual quantum yields are much larger, nearly unity.

The marked change in the composition of the products in the region of small amounts of decomposition illustrates a point which is often overlooked in photochemical investigations. Because of the difficulties which usually attend the analysis of the small amounts of products obtainable from quantum yield experiments, it is a common practice to get relatively large amounts of products for analysis, often radically changing the intensity of radiation, degree of monochromatization, concentration of the reactants, etc., from the conditions of the quantum yield experiments. Yet it is usually assumed that the reaction follows the

(16) Geib and Harteck, *Z. physik. Chem.*, Bodenstein Festband, 849 (1931).

(17) Bonhoeffer, *ibid.*, **113**, 199 (1924).

(18) Dixon, THIS JOURNAL, **54**, 4262 (1932).

same course in both cases. The present experiments show that this assumption must be viewed with suspicion. The safe plan is to perform the experiments leading to a deduction of reaction mechanism under the same conditions as the quantum yield experiments, or better still to combine them in the same experiments.

The mercury-sensitized decomposition differs from the photochemical decomposition in the nature of the primary processes and by the fact that marked fluorescence was observed.[3]

$$\begin{aligned} Hg + h\nu_1 &\longrightarrow Hg' \\ Hg' + NH_3 &\longrightarrow NH_3' + Hg \\ NH_3' &\longrightarrow NH_3 + h\nu_2 \\ NH_3' &\longrightarrow NH_2 + H \end{aligned}$$

The low quantum yield for the photosensitized decomposition may be attributed to fluorescence and suggests that the quantum of λ 2537 Å. (approximately 112,000 cal. per mole) is barely sufficient to produce decomposition.

Summary

The photochemical and mercury photosensitized decompositions of ammonia have been investigated in the region of very small amounts of decomposition. In contrast to the results obtained with large amounts of decomposition, namely, a quantum yield of 0.25 and gaseous products consisting of 75% hydrogen and 25% nitrogen, with small amounts of decomposition the quantum yield approaches unity and the gaseous products approach pure hydrogen, in the case of the photochemical decomposition. For the photosensitized decomposition a quantum yield of 0.12 was obtained.

The Rearrangement of Acetylchloroaminobenzene in the Presence of Radioactive Hydrochloric Acid

BY A. R. OLSON, C. W. PORTER, F. A. LONG AND R. S. HALFORD

The mechanism of the Hofmann rearrangement of N-substituted aromatic amines has been under investigation, intermittently, over a period of sixty years. As early as 1881 Michael[1] advanced the theory that in the rearrangement of methylaniline hydrochloride into the hydrochloride of *p*-toluidine, the first step is a dissociation into methyl chloride and aniline. The methyl chloride is then supposed to act upon the aniline, substituting the methyl group for the para hydrogen atom. In 1920 Michael[2] reaffirmed this conclusion and referred to the dissociation mechanism as a "self-evident explanation."

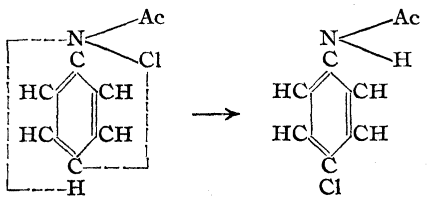
Orton and his colleagues[3] outlined a mechanism for the rearrangement of acetylchloroaminobenzene which has become almost universally accepted. They envisage the reaction as proceeding in three steps: (1) the hydrolysis of the chloroamine; (2) the production of chlorine from hydrochloric and hypochlorous acids; (3) the chlorination of acetanilide.

$$C_6H_5NClAc + H_2O \rightleftarrows C_6H_5NHAc + HClO \quad (1)$$

$$HClO + H^+ + Cl^- \rightleftarrows H_2O + Cl_2 \quad (2)$$

$$C_6H_5NHAc + Cl_2 \longrightarrow ClC_6H_4NHAc + H^+ + Cl^- \quad (3)$$

At the Richmond meeting of the American Chemical Society (1927) one of us presented the view that the arrangement is intramolecular.[4] It was postulated that a bond is formed between the chlorine atom and the para carbon atom while the chlorine is still attached to the nitrogen. Similarly it was assumed a bond is formed between the nitrogen atom and the para hydrogen atom in advance of any dissociation process. These weak bonds are represented by dotted lines in formula I. When molecules in state I become



I II

sufficiently activated the bonds represented by dotted lines become full valence bonds and the rearrangement is accomplished. In the Richmond

[4] C. W. Porter, paper read at the April meeting, 1927.

meeting this mechanism was referred to, derisively, as the "flip-flop theory."

The discovery of methods for producing artificial radioactivity has furnished a new tool for investigating problems of this type. Thus in this rearrangement, if we use ordinary acetylchloroaminobenzene and radioactive hydrochloric acid as a catalyst, we can determine the distribution of radioactivity among the products as the reaction progresses. This distribution will depend on the following factors: (1) the reaction mechanism or mechanisms; (2) the amount of exchange between radioactive chloride ion and chlorine (a) on the nitrogen of the chloroaminobenzene, (b) on the carbon of the chloroacetanilide and (c) of the molecular chlorine or hypochlorous acid in solution.

Of these factors 2b and 2c need no further investigation. Olson and Long[5] have shown that the exchange between chloride ion and chlorine on an aliphatic carbon is very slow. The exchange on an aromatic carbon is probably even slower and so it can be neglected in the present investigation. Also Long and Olson[6] have just shown that the equilibrium between chlorine and chloride ion is completely established before the chlorine can react with acetanilide. The remaining factors are considered in the present work.

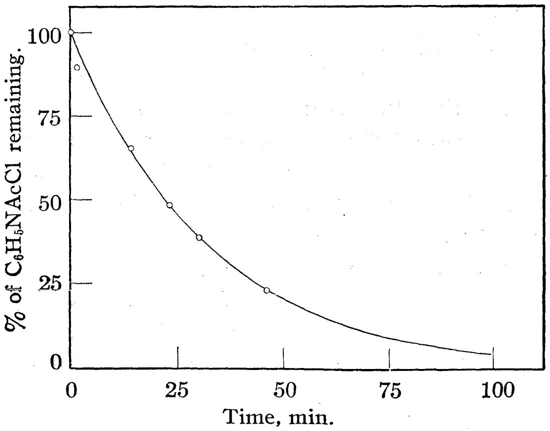

Fig. 1.—The circles are the experimental results for the chemical rate as taken from Table I. The solid line has been calculated from a unimolecular rate constant, k_1 = 0.0316 min.$^{-1}$.

Experimental

The acetylchloroaminobenzene was prepared by the method of Barnes and Porter.[7]

The radioactive chlorine was prepared in Professor E. O. Lawrence's radiation laboratory, by bombarding solid sodium chloride with deuterons.

The concentrations of the reagents and the temperature were chosen so that the half-life of the reaction was somewhat shorter than the half-life of the radioactive chlorine. The solvent was aqueous alcohol (20% alcohol by volume).

In making a run, the acetylchloroaminobenzene was dissolved in the aqueous alcohol solution to which enough sulfuric acid had been added to make it 1 *N* with respect to hydrogen ion. The radioactive sodium chloride was dissolved separately in a predetermined volume of the same solvent, so that after a portion of the solution had been used for the initial radioactive analysis, the remaining portion, when mixed with the chloroamine, would produce a solution 0.04 molar with respect to both acetylchloroaminobenzene and radioactive sodium chloride. The solutions were brought to the temperature of the thermostat before mixing and the time of mixing was taken as the zero time for the reaction.

At times shown in Table I, 5-cc. samples were withdrawn and analyzed in the usual manner by adding excess potassium iodide solution and titrating the liberated iodine with standard thiosulfate. The results are given in Table I and plotted in Fig. 1. The solid line in this figure has been calculated using a unimolecular rate constant, k_1 = 0.0316.

TABLE I

DATA FOR CHEMICAL RATE

Time, min.	Thio used, cc.	% C_6H_5NAcCl unreacted
0	3.90	100
1.5	3.50	89.8
14	2.55	65.4
23	1.90	48.7
30	1.50	38.5
46	0.90	23.0

In addition to following the rate of rearrangement in the usual chemical way, we determined the rate of change with time of the radioactivity of the chloride ion in solution. This change was due not only to the natural radioactive decay but also to the fact that some radioactive chloride ions were used in the reaction and were replaced by non-radioactive chloride ions. At regular intervals 100-cc. samples were withdrawn from the reaction vessel, silver nitrate solution was added and the silver chloride was filtered off, washed and dried. A weighed amount of this silver chloride was then dissolved in a known volume of ammonium hydroxide and the radioactivity of the chloride ion was determined by the method outlined by Olson, Libby, Long and Halford.[8]

In addition to these measurements, two determinations of a different type were made. In the first of these the radioactivity of the rearranged product, *p*-chloroacetanilide, was obtained. This was done by taking a somewhat larger sample than usual, destroying the chloroamine with iodide ion, reducing the liberated iodine with thiosulfate, then extracting the rearranged product with benzene. After evaporating the benzene, the chloroacetanilide was fused with potassium hydroxide, dissolved in water and

[7] C. D. Barnes and C. W. Porter, *ibid.*, **52**, 1721 (1930).

[8] A. R. Olson, W. F. Libby, F. A. Long and R. S. Halford, *ibid.*, **58**, 1313 (1936).

acidified with nitric acid. Excess silver nitrate was then added, the silver chloride filtered off, dried and examined for radioctivity in the usual manner. Two sources of inaccuracy entered into this determination. First, the silver chloride was quite dark, indicating the presence of some silver sulfide. Second, the amount of silver chloride obtained from this experiment was only one-fifth as much as we otherwise used for a radioactive determination.

The second experiment was devised to determine the rate with which radioactive chlorine replaces the non-radioactive chlorine on the nitrogen of the acetylchloroaminobenzene. After the reaction was about one-fourth over, a sample of the reaction mixture was removed and sufficient sodium carbonate was added to make the solution somewhat alkaline. This was done to convert any slight amount of chlorine into hypochlorite and chloride ions. The chloroamine and chloroanilide were then extracted with benzene. This benzene extract was shaken thoroughly with an aqueous solution of sodium sulfite which reduced the chloroamine to chloride ion and acetanilide. The aqueous solution was acidified, the chloride precipitated as silver chloride and its radioactivity determined.

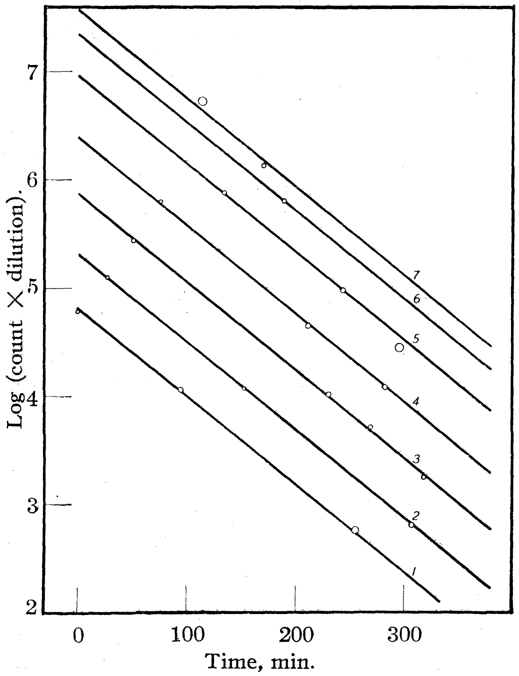

Fig. 2.—The numbers of the curves refer to the correspondingly numbered samples in Table II. The curves have been displaced upward by 0.6 unit from the preceding curve with the exception of Curve 6 which has been displaced twice this amount.

In Fig. 2 we have plotted the time of counting against the logarithm of the product of the net count times the dilution for all these silver chloride samples. In every case the slope of the line corresponds to the known half-life of radioactive chlorine. If we call the radioactivity of the control sample 100%, then, from the intercepts of these lines on the $t = 0$ axis, we can calculate immediately the percentages of radioactivity in each of these samples as compared with the control. The results of these calculations are given in Table II, and the data for the chloride ion in solution have been plotted in Fig. 3.

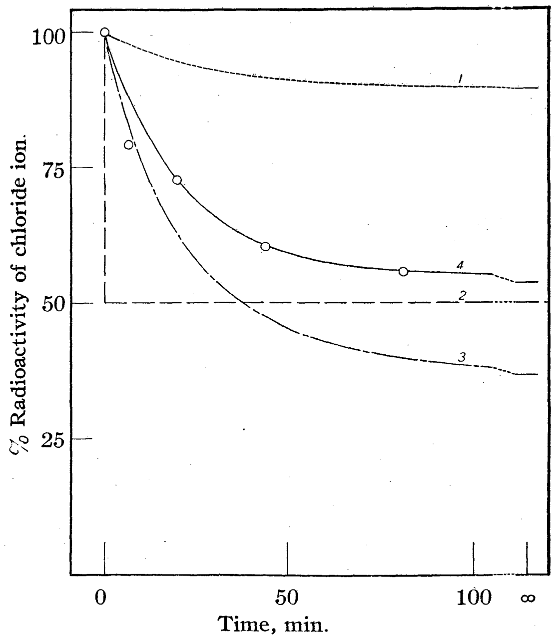

Fig. 3.—Graphic representation of the results for various mechanisms. Curve 1 is for intramolecular rearrangement with exchange on the nitrogen. Curves 2 and 3 give the upper and lower limits for the chlorine intermediate path. Curve 4 is for the two mechanisms proceeding simultaneously. The circles are the experimental results as shown in Table II.

With the datum given in Table II it is possible to calculate the specific rate of the exchange reaction

$$C_6H_5NAcCl + {}^*Cl^- \xrightarrow{k_2} C_6H_5NAcCl^* + Cl^-$$

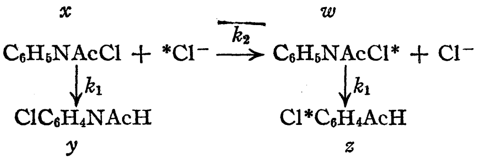
with an accuracy sufficient for our purpose, by assuming that the concentration of radioactive chloride ion is, over this short time interval, constant and equal to its initial value. Table II shows that approximately 4% of the chlorine of the acetylchloroaminobenzene is radioactive after 11.16 minutes. This corresponds to a specific rate constant for this reaction of $k_2 = 0.094$ mole^{-1} min.$^{-1}$.

In addition to the data given above several preliminary runs were made. The data for these runs are not included here, for, while the results are in accord with this run, they are not sufficiently accurate to merit inclusion.

Detailed Consideration of Possible Mechanisms

(1) Intramolecular rearrangement without exchange on the nitrogen of the chloroamine: This mechanism alone cannot possibly account for the experimental facts since, then, there would be no decrease of the radioactivity of the chloride ion in solution as the reaction progressed.

(2) Intramolecular rearrangement, allowing for exchange on the nitrogen: Schematically this mechanism can be represented by



$$\begin{array}{ccc} x & & w \\ C_6H_5NAcCl + {}^*Cl^- & \xrightarrow{k_2} & C_6H_5NAcCl^* + Cl^- \\ \downarrow k_1 & & \downarrow k_1 \\ ClC_6H_4NAcH & & Cl^*C_6H_4AcH \\ y & & z \end{array}$$

The specific rate of interchange of chlorine on the nitrogen of the chloroamine is given by k_2 and the specific rate of the rearrangement is given by k_1.

To obtain the rate expression for this mechanism, let x, y, w and z be the concentrations of C_6H_5NAcCl, ClC_6H_4NAcH, $C_6H_5NAcCl^*$ and $Cl^*C_6H_4AcH$, respectively, at time, t. In addition, let a be the initial concentration of C_6H_5NAcCl and b be the initial concentration of radioactive chloride ion.

We can therefore write

$$\begin{aligned} dx/dt &= -k_1x - k_2(b - w - z)x \\ dw/dt &= k_2(b - w - z)x - k_1w \\ dy/dt &= +k_1x \\ dz/dt &= +k_1w \end{aligned}$$

Since the hydrogen ion and the total chloride ion concentrations do not change during a run (except very slowly due to side reactions) we have included the magnitude of these factors in k_1, the chemically determined rate constant. The equations then represent the fact that under these conditions the chemical rate is unimolecular, depending only on $x + w$, the total concentration of chloroamine. The rate at which chloroamine is converted into the radioactive variety depends not only on the concentration of the inactive chloroamine, but also upon $b - w - z$, the concentration of the radioactive chloride ion, since this, as distinguished from b, the total chloride ion concentration, is a function of the time.

This set of equations can be solved conveniently by a series of approximations. In the first approximation we set the radioactive chloride ion concentration, $^*Cl^-$, equal to b. Integration with this assumption gives

$$\begin{aligned} x &= ae^{-(k_1 + k_2b)t} \\ w &= a[e^{-k_1t} - e^{-(k_1 + k_2b)t}] \\ z &= a\left[\frac{k_2b}{k_1 + k_2b} + \left(1 - \frac{k_2b}{k_1 + k_2b}\right) e^{-(k_1 + k_2b)t} - e^{-k_1t}\right] \\ y &= a - (x + w + z) \end{aligned}$$

Making use of the values $k_1 = 0.0316$ and $k_2b = 0.00376$, as given in earlier paragraphs, we can calculate the concentrations of radioactive chloride ion which should be present at any time t according to this mechanism. This we have done. The dotted line, labeled 1, in Fig. 3 shows the results of these calculations. The very large discrepancy between the calculated and observed percentages cannot be accounted for by the approximation which we have introduced in order to simplify the calculations, for k_2b would need to be almost ten times as large as the value found, in order to obtain an agreement between the observed and calculated values. It is obvious, therefore, that this mechanism by itself cannot account for the data observed under these experimental conditions.

(3) The reaction proceeds through the intermediate formation of chlorine: (a) The concentration of chlorine is large. All of the chemical evidence is against this assumption. However, it may not be amiss to point out that if all the chloroamine reacted to give chlorine before any of the final product were formed, then the radioactivity of the chloride ion in solution would drop to 50% of its original value and thereafter remain constant. The assumption of a large concentration of chlorine is equivalent mathematically, so far as the distribution of radioactivity in the products is concerned, to assuming that the equilibrium

$$C_6H_5NAcCl + H^+ Cl^- \rightleftarrows Cl_2 + C_6H_5NacH$$

is established rapidly. Therefore any mechanism which depends upon such a *rapid* reversible reaction must be wrong.

(b) The concentration of chlorine is small. In order to get the limiting value under this assumption we shall assume that the concentration of chlorine is infinitesimal and that no exchange on the nitrogen occurs. We can represent the mechanism as

$$C_6H_5NAcCl + H^+ + \begin{bmatrix} Cl^- \\ {}^*Cl^- \end{bmatrix} \longrightarrow C_6H_5NAcH + \begin{bmatrix} {}^*Cl_2 \\ Cl_2 \end{bmatrix} \qquad (1)$$

$$C_6H_5NAcH + \begin{bmatrix} {}^*Cl_2 \\ Cl_2 \end{bmatrix} \begin{array}{l} \nearrow {}^*ClC_6H_4NAcH \\ \searrow ClC_6H_4NAcH \end{array} + H^+ + \begin{bmatrix} {}^*Cl^- \\ Cl^- \end{bmatrix} \qquad (2)$$

where $\begin{bmatrix} {}^*Cl_2 \\ Cl_2 \end{bmatrix}$ includes all the varieties of chlorine molecules. We do not wish to commit ourselves to any particular mechanism by which molecular chlorine may be formed from the chloroamine, but wish to assume merely that molecular chlorine is an intermediate.

Since the concentration of chlorine remains small, the total rate of production of the chloroanilide must be equal to the rate of disappearance of chloroamine, and therefore equal to the chemical rate.

Designating, as before, the concentrations at time t, of C_6H_5NAcCl, ClC_6H_4NAcH and $^*Cl$-C_6H_4NAcH as x, y and z, respectively, we obtain

$$-\mathrm{d}x/\mathrm{d}t = +k_1bx = \mathrm{d}y/\mathrm{d}t + \mathrm{d}z/\mathrm{d}t$$

where, for convenience, we have replaced k_1 of a former section by k_1b. The ratio $(\mathrm{d}z/\mathrm{d}t)/(\mathrm{d}y/\mathrm{d}t)$ is equal to the ratio of the probability that a chlorine atom in molecular chlorine is radioactive, to the probability that it is inactive. Since we have shown that there is a very rapid interchange between chloride ion and chlorine, this ratio of probabilities is merely the ratio of the concentrations of radioactive chloride ion to inactive chloride ion, which in turn is $(b-z)/z$.

Our rate equations are then

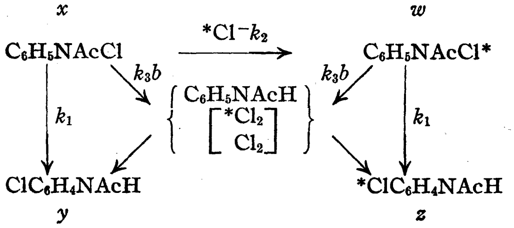
$$\begin{aligned} \mathrm{d}x/\mathrm{d}t &= -k_1bx \\ \mathrm{d}z/\mathrm{d}t &= +k_1(b - z)x \\ \mathrm{d}y/\mathrm{d}t &= +k_1zx \end{aligned}$$

The integrated expressions are

$$\begin{aligned} x &= ae^{-k_1bt} \\ b - z &= be^{-(1 - e^{-k_1bt})} = (^*Cl^-) \\ y &= a - x - z \end{aligned}$$

Curve 3 in Fig. 3 represents the values for the percentages of radioactive chloride ion in solution calculated under this assumption. Curve 2 is a plot of the percentages of radioactive chloride ion under the assumptions of paragraph (a) or the equivalent assumption that the exchange on the nitrogen is very fast. Any assumption with respect to the concentration of chlorine or with respect to the speed of the exchange on the nitrogen, but which retains the chlorine intermediate as the sole path of the reaction, must give a curve which lies intermediate between curve 3 and curve 2. Since our experimental curve lies outside of these limits, we can conclude that the reaction cannot go solely by a chlorine intermediate. It is thus evident that no single mechanism so far proposed is sufficient to explain the experimental facts which we have observed.

(4) Intramolecular rearrangement and the chlorine intermediate mechanism acting simultaneously: We can represent such a combination of these two mechanisms schematically as



As before, since chlorine does not accumulate in the solution, the chemical rate of disappearance of the chloroamine, $-(\mathrm{d}x/\mathrm{d}t + \mathrm{d}w/\mathrm{d}t)$, must be equal to the rate at which chloroacetanilide is formed by all paths, *i. e.*, $\mathrm{d}y/\mathrm{d}t + \mathrm{d}z/\mathrm{d}t$. According to this mechanism it also will be equal to $(k_1 + k_3b)(x + w)$. If we set $\mathrm{d}y/\mathrm{d}t = \mathrm{d}y'/\mathrm{d}t + \mathrm{d}y''/\mathrm{d}t$ and $\mathrm{d}z/\mathrm{d}t = \mathrm{d}z'/\mathrm{d}t + \mathrm{d}z''/\mathrm{d}t$ where $\mathrm{d}y''/\mathrm{d}t$ and $\mathrm{d}z''/\mathrm{d}t$ are the contributions of the chlorine intermediate mechanism to the rates, we see that $(\mathrm{d}z''/\mathrm{d}t)/(\mathrm{d}y''/\mathrm{d}t)$ must as before be equal to $(^*Cl^-)/(Cl^-)$ which now becomes $(b - w - z)/(w + z)$.

The differential equations, with the same symbols as used originally, are

$$\begin{aligned} \mathrm{d}x/\mathrm{d}t &= -k_1x - k_2x(b - w - z) - k_3bx \\ \mathrm{d}w/\mathrm{d}t &= +k_2x(b - w - z) - k_1w - k_3bw \\ \mathrm{d}z/\mathrm{d}t &= +k_1w + k_3(x + w)(b - w - z) \\ \mathrm{d}y/\mathrm{d}t &= +k_1x + k_3(x + w)(w + z) \end{aligned}$$

Assuming that the concentration of radioactive chloride ion is constant and equal to the initial value, the following approximate expressions for x and w, as functions of time, are obtained.

$$\begin{aligned} x &= ae^{-(k_1 + k_2b + k_3b)t} \\ w &= a[e^{-(k_1 + k_3b)t} - e^{-(k_1 + k_2b + k_3b)t}] \end{aligned}$$

Substituting these expressions in the equation for $\mathrm{d}z/\mathrm{d}t$, we get an expression to integrate which contains an exponential to an exponential. Expanding one exponential by a series and integrating, we finally obtain

$$z = ae^{+(k_3a/m)e^{-mt}}\Big[(1 - e^{-mt}) - \frac{k_3a}{m}(1 - e^{-2mt}) + \frac{k_3^2a^2}{2m^2}(1 - e^{-3mt}) - \frac{k_3^3a^3}{6m^3}(1 - e^{-4mt}) + \dots - \frac{k_1}{m + n}(1 - e^{-(m+n)t}) + \frac{k_3a}{2m + n}\left(1 + \frac{k_1}{m}\right)(1 - e^{-(2m+n)t}) - \frac{k_3^2a^2}{m(3m + n)}\left(1 + \frac{k_1}{2m}\right)(1 - e^{-(3m+n)t}) + \dots\Big]$$

where $m = k_1 + k_3b$ and $n = k_2b$. The specific chemical rate is given by $k_1 + k_3b$. k_2 has been evaluated from the experiment on the exchange of the chlorine on the nitrogen of the chloroamine.

The fraction of chloride ion in solution which is radioactive is given by $[b-(w + z)]/b$. This obviously depends upon the values chosen for k_1 and k_3. If we choose $k_1 = 0.0136$ and $k_3b = 0.0180$ we get curve 4 in Fig. 3 which agrees well with the experimental data. The values of the rate constants chosen above correspond to 43% of the acetylchloroaminobenzene rearranging *intramolecularly* and 57% disappearing through the *chlorine intermediate* path. It is quite likely that changes in the experimental conditions would change not only the actual values of these three rate constants but also the relative amounts going by the two paths.

By calculating, according to the combined mechanisms of the preceding paragraph, $z/(y + z)$ for $t = 30$ minutes we obtain the value, 48.2%. The experimental value of this quantity, taken from Table II, is 40.5%. Considering the inaccuracies of this particular determination we feel that the check is sufficiently close.

In all of this work we must not overlook the fact that we are placing a heavy burden on the single determination of k_2. However, calculations show that a 100% change in the value of this rate constant will not affect our conclusions materially.

Summary

The rearrangement of ordinary acetylchloroaminobenzene has been induced by the action of radioactive hydrochloric acid.

The time rates of change of the percentages of radioactivity in the products have been measured. The rate with which the chlorine on the nitrogen of acetylchloroaminobenzene interchanges with the chloride ion in solution also has been measured.

For these measurements it has been shown that under the conditions of this experiment the rearrangement of acetylchloroaminobenzene does not proceed exclusively either by an intramolecular rearrangement or by a chlorine intermediate.

A combination of these two mechanisms, with 43% of the reaction going by direct rearrangement, and 57% through a chlorine intermediate, will explain all our results.

Vapor Pressures of Saturated Solutions

BY ALFRED E. HIRSCHLER

Roehl[1] has pointed out the interesting fact that when all the scanty available data on vapor pressures of saturated aqueous salt solutions are plotted as log P against $1/T$, straight lines are obtained which are all parallel to the water curve. He was unable to offer an explanation for this "unexpected" result.

While this fact does seem somewhat surprising at first sight, it is the purpose of this paper to show that a closer scrutiny reveals that this is just what would be expected from the magnitudes of the heat effects involved.

The change in fugacity of water from a continuously saturated solution of a solid solute as the temperature rises is given by the equation[2a]

$$\mathrm{d}\ln f_1/\mathrm{d}T = (H_1^* - \overline{H}_1)/RT^2 + N_2(H_2' - \overline{H}_2)/N_1RT^2 \quad (1)$$

where f_1 is the fugacity of water from the solution, H_1^* the molal heat content of attenuated water vapor, H_2' the molal heat content of the solid salt, $\overline{H}_1$, N_1 and $\overline{H}_2$, N_2 the partial molal heat contents and mole fractions of water and solute, respectively. In this equation and those to follow, constant pressure is assumed. We may choose pure liquid water, and an infinitely dilute

[1] Roehl, THIS JOURNAL, **58**, 1291 (1936).

(2) (a) Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw Hill Book Co., New York, 1923, p. 220; (b) p. 222; (c) p. 201; (d) p. 92; (e) p. 477.

aqueous solution as standard states for solvent and solute, respectively, and represent the corresponding molal heat contents by H_1^0 and H_2^0. We then have

$$\begin{aligned} \mathrm{d}\ln f_1/\mathrm{d}T &= [(H_1^* - H_1^0) - (\overline{H}_1 - H_1^0)]/RT^2 + \\ &\qquad N_2[(H_2' - H_2^0) - (\overline{H}_2 - H_2^0)]/N_1RT^2 \\ &= (\Delta H_\mathrm{i} - \overline{L}_1)/RT^2 + N_2(L_2' - \overline{L}_2)/N_1RT^2 \end{aligned}$$

where ΔH_i is the molal heat of vaporization of water into a vacuum (the so-called ideal heat of vaporization), and $\overline{L}_1$, $\overline{L}_2$ and L_2' are the relative heat contents of the substances involved. Rearranging slightly

$$\begin{aligned} \mathrm{d}\ln f_1/\mathrm{d}T &= \Delta H_\mathrm{i}/RT^2 - (N_1\overline{L}_1 + N_2\overline{L}_2 - N_2L_2')/N_1RT^2 \\ &= \Delta H_\mathrm{i}/RT^2 - (L - N_2L_2')/N_1RT^2 \qquad (2) \end{aligned}$$

where L is the relative heat content of one mole of the solution.

Now, $L - N_2L_2'$ is the total or integral heat of solution involved in the formation of one mole of the saturated solution. The mole fraction is numerically equal to the number of moles of each substance taken. Using sodium chloride as an example, we may write

$$N_2\ \mathrm{NaCl(s)} + N_1\mathrm{H_2O(l)} = 1 \text{ mole saturated solution}$$

The integral heat of solution is the value of $\Delta H_\mathrm{s} = \Delta L$ for this process, where the symbol ΔH_s represents the heat absorbed in the formation of one mole of the saturated solution from its components.

$$\Delta H_\mathrm{s} = \Delta L = L - N_2L' - N_1L_1 = L - N_2L$$

since L_1 for the liquid water is zero by choice of standard state.

Hence

$$\mathrm{d}\ln f_1/\mathrm{d}T = (\Delta H_\mathrm{i} - \Delta H_\mathrm{s}/N_1)/RT^2 \qquad (3)$$

The corresponding equation for pure water is[2c]

$$\mathrm{d}\ln f_1/\mathrm{d}T = \Delta H_\mathrm{i}/RT^2 \qquad (4)$$

These equations are exact. For practical purposes they may be modified slightly. Assuming water vapor to be a perfect gas, we can replace the fugacity by the vapor pressure, and the latter by the total pressure P if the solute is not appreciably volatile. At the same time, to be consistent, we may replace the ideal heat of vaporization by that ordinarily determined.[3] Then

$$\mathrm{d}\ln P/\mathrm{d}T = (\Delta H - \Delta H_\mathrm{s}/N_1)/RT^2 \qquad (5)$$
$$\mathrm{d}\ln P/\mathrm{d}T = \Delta H/RT^2 \qquad (6)$$

If we plot log P against $1/T$ for equations (5) and (6), the plot in each case should be a straight line of slope $-(\Delta H - \Delta H_\mathrm{s}/N_1)/2.303R$ in the case of equation (5) and of slope $-\Delta H/2.303R$ for equation (6).

It is now obvious that if the term $\Delta H_\mathrm{s}/N_1$ is small compared to ΔH, the vapor pressure curves of saturated solution and pure solvent will be nearly parallel, the more nearly so the smaller the integral heat of solution. For a solution of a non-volatile solid which forms a perfect solution the two curves should be exactly parallel, as the heat of solution is then zero.[2b]

For most aqueous salt solutions, N_1 is not far from unity, so that the magnitude of ΔH_s practically determines the size of the correction factor, the solubility having small effect. Further, the heat effect in forming one mole of solution must always involve less than 18 g. of water. Since most heats of solution, expressed in terms of 1000 g. of water, are much smaller than the heat of vaporization of water, it can be seen that $\Delta H_\mathrm{s}/N_1$ usually will be quite small compared to ΔH.

This conclusion may be illustrated by a specific example. The necessary heat quantities for sodium chloride, one of the cases cited by Roehl, have been determined.[2d] The saturated solution is 6.12 m at 25° $\overline{L}_1 = 11.5$ cal., $\overline{L}_2 = -702$ cal., $L' = -1019$ cal., $N_1 = 0.9007$ and $N_2 = 0.0993$.

$$\Delta H_\mathrm{s} = N_1\overline{L}_1 + N_2\overline{L}_2 - N_2L' = 42.6 \text{ cal.}$$
$$\Delta H_\mathrm{s}/N_1 = 47.3 \text{ cal.}$$

We may take the molal heat of vaporization of water at 25° as 10,450 cal.[2e] The difference in slope of the vapor pressure curves for pure water and for saturated solution at 25° should thus only differ by 47.3/10,450, or 0.45%, which is less than the usual experimental error.

In the foregoing discussion it has been assumed that ΔH and ΔH_s are independent of temperature. This is only true as a first approximation. ΔH at 100° is 9730 cal.[2e] While exact data on ΔH_s are lacking, it is known that in general solutions become more ideal as the temperature is raised, so that we would expect ΔH_s to decrease also. The percentage deviation of the slopes of the vapor pressure curves might well remain sensibly constant up to the boiling point of the solution.

Sodium chloride may be taken as typical of a strong electrolyte in aqueous solution. The heats of solution of many electrolytes will be found to be of the same order of magnitude. However, a heat of solution eleven times that of sodium chloride will give rise to a difference in slope of only 5%. We may thus state as a working rule that vapor pressures of saturated aqueous salt solutions plotted as log P *vs.* $1/T$ will be parallel

---

(3) Since pressure has such a small effect on vapor pressures, we may apply the equation to a liquid under a variable vapor pressure.

to the curve for pure water. In the absence of data a determination of the vapor pressure of the saturated solution at any one temperature will enable the entire curve to be drawn with a good degree of approximation.

It may be remarked that equations (5) and (6) apply equally well to the case of non-aqueous solutions, with the same assumptions, when the corresponding heat quantities are used. We may again predict a fairly close parallelism between the log P–$1/T$ curves for pure solvent and saturated solution. For a given value of ΔH_s, we would expect the deviation in slope for a non-aqueous solution to be much greater than for an aqueous solution. The heat of vaporization of water is abnormally high, and the solubility of electrolytes (or other solutes) expressed in terms of mole fractions are lower in water than in most other liquids. Consequently, for non-aqueous solutions, $\Delta H_s/N_1$ would be larger, and at the same time ΔH smaller, than for water. On the other hand, it must be pointed out that deviations of solutions from ideality are as a rule much less in other liquids than in water, particularly in the case of organic liquids, where many approximately ideal solutions are known. Therefore, for a great many solutions of organic substances, ΔH_s will be very small or zero, and for them the slopes of the vapor pressure curves will be sensibly parallel.

Finally, the assumptions under which equation (1) was derived make it possible to apply it to the case where a liquid is the saturating phase, provided only that its composition does not change with temperature. Owing to the phenomenon of mutual solubility, this will not ordinarily be true. Nevertheless, if the change in composition is not great, we may expect an approximate parallelism between the log P–$1/T$ curves if the "solute" is non-volatile; and between the log p_1–$1/T$ curves for the instance of an appreciably volatile solute.

Summary

1. An explanation is offered for the parallelism of the log P–$1/T$ curves for some saturated aqueous solutions and pure water.

2. An equation is developed from which it is predicted that this phenomenon will be true in general for saturated solutions, both aqueous and non-aqueous.

3. It is suggested that in the absence of data, a knowledge of the vapor pressure of a saturated solution at one temperature will make it possible to obtain the entire curve to a good degree of approximation.

The Acetyl Derivatives of Gluconic and Xylonic Acids

BY RANDOLPH T. MAJOR AND ELMER W. COOK

The only record in the literature of an acetylated sugar acid is that described by Upson and Bartz. These investigators prepared 2,3,4,6-tetraacetyl-*d*-gluconic acid monohydrate by the acetylation of δ-*d*-gluconolactone.[1] This reaction has been repeated in this Laboratory. Tetraacetyl-*d*-gluconic acid monohydrate with practically the same melting point reported by the previous workers was obtained but the optical activity found was different. Since the previous investigators did not report the solvent used for the measurement of the optical activity it seems probable that a different solvent was used in this Laboratory than the one used by Upson and Bartz. Tetraacetyl-*d*-gluconic acid monohydrate was also prepared by the oxidation of tetraacetyl-*d*-glucose.

Pentaacetyl-*d*-gluconic acid has been prepared by two different processes. The first was by the oxidation of aldehydo-*d*-glucose pentaacetate.[2] In the course of attempts to improve the methods of obtaining aldehydo-*d*-glucose pentaacetate, it was found that *d*-glucose tetraacetate gave the ring form of tetraacetyl-*d*-glucose semicarbazone with semicarbazide. This had been prepared previously by Wolfrom, Georges and Soltzberg by acetylation of *d*-glucose semicarbazone.[2b]

The second method of preparing pentaacetyl-*d*-gluconic acid was by further acetylation of

---

[1] Upson and Bartz, THIS JOURNAL, **53**, 4226 (1931).

[2] (a) Wolfrom, *ibid.*, **51**, 2190 (1929); (b) Wolfrom, Georges and Soltzberg, *ibid.*, **56**, 1795 (1934).

tetraacetyl-*d*-gluconic acid. All attempts to acetylate *d*-gluconic acid directly by means of acetic anhydride with either zinc chloride or pyridine gave a gummy mixture.

Ethyl pentaacetyl-*d*-gluconate was prepared by esterification of the corresponding acid. This ester had been prepared previously by Volpert by acetylation of ethyl *d*-gluconate.[3] Pentaacetyl-*d*-gluconic phenylhydrazide was synthesized by acetylating gluconic phenylhydrazide.

The tetraacetylxylonic acids have been synthesized by the oxidation of the corresponding aldehydoxylose tetraacetates. Aldehydo-*d*-xylose tetraacetate was prepared first by Wolfrom, Newlin and Stahly.[4] A more satisfactory method of obtaining this compound, as well as its levo and racemic isomers, was found to be by acetylation of xylose triacetate semicarbazone followed by treatment with nitrous acid[2b] (p. 1794). In the acetylation of xylose semicarbazone the principal product obtained was a xylose semicarbazone tetraacetate with a ring structure.

Experimental

2,3,4,6-Tetraacetylgluconic Acid Monohydrate

Acetylation of δ-Gluconolactone.—Fused zinc chloride (20 g.) was dissolved in 250 cc. of acetic anhydride and the solution cooled to 0°. δ-Gluconolactone (50 g.) was added with stirring and the mixture kept at 0° for thirty minutes. Thereafter the mixture was allowed to come to room temperature. With occasional shaking all of the lactone soon dissolved. After standing for twenty-four hours the solution was poured into 1000 cc. of ice water. The mixture was stirred for one and one-half hours when tetraacetylgluconic acid monohydrate separated; yield 80%; m. p. 114–115°.[5]

Oxidation of Tetraacetylglucose.—Tetraacetylglucose[6] (5 g.) was dissolved in 125 cc. of hot water in a flask and the solution quickly cooled to room temperature. Potassium bicarbonate (4.4 g.) was added and allowed to dissolve; this was followed by the addition of 1.5 g. of bromine. The flask was stoppered and shaken, the stopper being removed occasionally to relieve the pressure from the carbon dioxide. As soon as the bromine had reacted, additional bromine (0.9 g.) was introduced to complete the reaction. The oxidation was complete in about forty minutes. The solution was cooled to 0° and 23 cc. of 1.93 normal hydrochloric acid was added. Upon standing tetraacetylgluconic acid monohydrate separated; yield 0.7 g. An additional quantity was recovered from the mother liquors by extraction with chloroform; m. p. 114–115°; $[\alpha]^{20}_D$ −5° (alcohol; *c*, 2).

Anal. Calcd. for $C_{14}H_{22}O_{12}$: C, 43.96; H, 5.80. Found; C, 44.10; H, 5.97.

Pentaacetylgluconic Acid

***d*-Glucose Semicarbazone Tetraacetate.**—Glucose tetraacetate (0.5 g.) was dissolved in 5 cc. of warm water and the solution cooled quickly to room temperature. Semicarbazide hydrochloride (0.16 g. or 1 mol) and potassium acetate (0.22 g. or 1.6 mol) were added and the mixture shaken until dissolved. Soon glucose semicarbazone tetraacetate separated as an oil which on standing for two to three days crystallized. The product was recrystallized from water. Thus crystallized the hydrated compound sintered at 118–120° and melted around 163°. When dried at 110° the melting point became 171°; $[\alpha]^{20}_D$ −53° (alcohol; *c*, 2); $[\alpha]^{20}_D$ −6.5° (alcohol-free chloroform, *c*, 2).[7]

Anal. Calcd. for $C_{15}H_{23}O_{10}N_3$: C, 44.45; H, 5.72; N, 10.37. Found: C, 44.63; H, 5.98; N, 10.30.

Oxidation of Pentaacetylaldehydoglucose.—Pentaacetylaldehydo-*d*-glucose was oxidized with bromine by the same method previously described for the oxidation of tetraacetyl-*d*-glucose. The pentaacetylgluconic acid monohydrate obtained was recrystallized from water; m. p. 72–73°; $[\alpha]^{20}_D$ +7.5° (alcohol-free chloroform; *c*, 2); yield 64%.

Anal. Calcd. for $C_{16}H_{24}O_{13}$: C, 45.26; H, 5.69. Found: C, 45.42; H, 5.80. An acetyl determination showed five acetyl groups.

Acetylation of Tetraacetylgluconic Acid.—Tetraacetyl-*d*-gluconic acid monohydrate (50 g.) was dissolved in 188 cc. of acetic anhydride (ice-bath) containing 18 g. of zinc chloride in solution. After standing in the ice-bath for thirty minutes the solution was allowed to come to room temperature and remain at this temperature for twenty-four hours. The solution was then poured into 1000 cc. of ice water and thoroughly stirred. Pentaacetylgluconic acid crystallized after about one hour and an additional amount was recovered from the mother liquor by extraction with chloroform. The crude product thus obtained from the acetylation melted at 93–95° but on standing the melting point changed, finally becoming as low as 55°. By recrystallizing from water the monohydrate of melting point 72–73° was obtained. A mixed melting point with a specimen obtained as described in the preceding paragraph showed no depression; yield 90%.

Anhydrous Pentaacetylgluconic Acid.—Pentaacetylgluconic acid monohydrate (50 g.) recrystallized from absolute alcohol was dissolved in 500 cc. of hot toluene. About 100 cc. of the toluene was distilled on an oil-bath. Upon cooling anhydrous pentaacetylgluconic acid separated. The product was filtered and washed successively with toluene and petroleum ether; m. p. 110–111°; $[\alpha]^{20}_D$ +11.5° (alcohol-free chloroform; *c*, 2). Upon standing in the air for several days the anhydrous acid did not take up water of crystallization as its melting point remained unchanged.

Anal. Calcd. for $C_{16}H_{22}O_{12}$: C, 47.27; H, 5.46. Found: C, 47.30; H, 5.53.

Ethyl Pentaacetylgluconate.—Pentaacetyl-*d*-gluconic acid (10 g.) was dissolved in 30 cc. of absolute alcohol con-

[4] Wolfrom, Newlin and Stahly, THIS JOURNAL, **53**, 4382 (1931).

[5] Upson and Bartz[1] give 114–117° as the melting point of tetraacetylgluconic acid monohydrate.

[6] Fischer, *Ber.*, **45**, 914 (1912).

[7] Wolfrom, Georges and Soltzberg[2b] give 171–172° as the melting point and $[\alpha]^{25}_D$ −9° (chloroform, *c*, 3.8) as the optical rotation of *d*-glucose semicarbazone tetraacetate.

taining 2% hydrogen chloride and the solution warmed at 60° for four minutes. Upon cooling and stirring a solid crystallized. It was filtered and washed with a little alcohol; m. p. 103–104°; $[\alpha]^{20}D$ +20.5° (alcohol-free chloroform, *c*, 2).[8] Ethyl pentaacetylgluconate was also prepared by acetylating ethyl gluconate in the usual manner with either pyridine or fused zinc chloride. For analysis a sample fused and dried at 120° was allowed to cool and solidify *in vacuo* over sulfuric acid.

Anal. Calcd. for $C_{12}H_{26}O_{12}$: C, 49.75; H, 6.04. Found: C, 49.84; H, 6.19.

Pentaacetylgluconicphenylhydrazide.—Gluconicphenylhydrazide (10 g.) was added to 50 cc. of acetic anhydride containing 4 g. of zinc chloride (fused) in solution. The mixture was kept cold during the first thirty minutes and then was allowed to stand for twenty-four hours at room temperature. A gum formed when the acetylation mixture was poured into ice water. The mixture was extracted with chloroform and the chloroform extract washed with sodium bicarbonate in ice water and finally with water. The extract was evaporated *in vacuo*, when the gummy residue slowly started to crystallize. It was recrystallized from alcohol by the addition of ether accompanied by cooling; yield of pentaacetylgluconic phenylhydrazide, 90%; m. p. 152–154°; $[\alpha]^{20}D$ +28° (alcohol, *c*, 2).

Anal. Calcd. for $C_{22}H_{28}O_{11}N_2$: C, 53.20; H, 5.69; N, 5.64. Found: C, 53.14; H, 5.65; N, 5.65.

***d*-Xylose Semicarbazone Tetraacetate.**—Finely powdered *d*-xylose semicarbazone (26 g.) was stirred into 180 cc. of pyridine and 120 cc. of acetic anhydride at 60–70° for six hours. At the end of this time practically all the xylose semicarbazone had dissolved. After the solution had stood at room temperature for one to two days 10 g. of crystalline material separated. The acetylation mixture was poured into ice water and after standing for one hour was extracted with chloroform. The extract was washed successively with cold dilute sulfuric acid, sodium bicarbonate and ice water. After it had been dried over calcium chloride the extract was evaporated *in vacuo* and the residue crystallized from absolute alcohol. The product (3 g.) was the same as that separated from the acetylation mixture. It was recrystallized from absolute alcohol; m. p. 232–233°; $[\alpha]^{20}D$ +21° (methanol, *c*, 1). Treatment in aqueous solution with nitrous acid did not produce aldehydo-*d*-xylose tetraacetate.

Anal. Calcd. for $C_{14}H_{21}O_9N_3$: C, 44.78; H, 5.64; N, 11.20. Found: C, 45.03; H, 5.70; N, 11.37.

However, the mother liquors from the tetraacetate, m. p. 232–233°, gave a sirup which on treatment with dilute nitrous acid yielded aldehydo-*d*-xylose tetraacetate.

Aldehydo-*l*-xylose Tetraacetate.—*l*-Xylose triacetate (51 g.)[9] was added to a warm alcoholic solution containing a 10% excess of semicarbazide. After warming for fifteen to twenty minutes the solution was evaporated *in vacuo* to a gum. The gum was dissolved in 86 cc. of pyridine and treated with 57 cc. of acetic anhydride accompanied by cooling. After the solution had stood for twenty-four hours at room temperature it was poured into ice water. The mixture was allowed to stand for an hour and then extracted with chloroform. The extract was washed successively with cold dilute sulfuric acid, sodium bicarbonate and water. After it had been dried over calcium chloride the extract was evaporated *in vacuo* to a gum. The gum was refluxed for twenty minutes, in a solution of 6.5 g. of oxalic acid in 250 cc. of methanol. The gum which was obtained by evaporation *in vacuo* was dissolved in 800 cc. of water; 75 g. of sodium nitrite in 200 cc. of water was added. Accompanied by slow stirring and cooling to 15–20°, 180 cc. of 6 normal hydrochloric acid was added gradually. This was followed by portionwise addition of 60 g. of sodium nitrite and gradual addition of 120 cc. of 6 normal hydrochloric acid. Again 60 g. of sodium nitrite was added and 120 cc. of 6 normal hydrochloric acid. Finally 60 g. of sodium nitrite was added and the solution stirred vigorously with norite. The mixture was filtered and the filtrate extracted with chloroform. After the extract had been dried over calcium chloride it was evaporated *in vacuo*. Aldehydo-*l*-xylose tetraacetate soon crystallized out of the resulting gum and with the addition of dry ether was filtered. It was recrystallized from dry ether; yield 33%; m. p. 90–91°; $[\alpha]^{20}D$ +22.5° (alcohol-free chloroform, *c*, 2).[10] Aldehydo-*d,l*-xylose tetraacetate made by mixing equal quantities of the *d* and *l* forms melted at 85–86°.

Anal. Calcd. for $C_{13}H_{18}O_9$: C, 49.03; H, 5.70. Found: C, 49.09; H, 5.53.

Tetraacetylxylonic Acid.—Aldehydoxylose tetraacetate (18.7 g.) was dissolved in 400 cc. of warm water at 50° in a flask and the solution quickly cooled to room temperature. Bromine (10.5 g.) was added followed by 9.5 g. of calcium carbonate. The mixture was stirred occasionally and after two hours the oxidation was nearly complete. The mixture was extracted with chloroform to remove any unreacted aldehydoxylose tetraacetate. It was then made acid with 104 cc. of 1.9 normal hydrochloric acid and extracted with chloroform. The extract was dried over calcium chloride and evaporated *in vacuo* to a gum. Petroleum ether was added and upon stirring tetraacetylxylonic acid crystallized. It was recrystallized from benzene; yield 90%.

Tetraacetyl-*d*-xylonic acid melted at 86–88°; $[\alpha]^{20}D$ +5° (alcohol, *c*, 2); $[\alpha]^{20}D$ −2° (alcohol-free chloroform, *c*, 2).

Anal. Calcd. for $C_{13}H_{18}O_{10}$: C, 46.69; H, 5.43. Found: C, 46.46; H, 5.52.

Tetraacetyl-*l*-xylonic acid melted at 86–88°; $[\alpha]^{20}D$ −4.5° (alcohol, *c*, 2).

Tetraacetyl-*d,l*-xylonic acid melted at 134–135°; $[\alpha]^{20}D$ 0° (alcohol, *c*, 2).

Anal. Calcd. for $C_{13}H_{18}O_{10}$: C, 46.69; H, 5.43. Found: C, 46.77; H, 5.39.

A mixture of equal quantities of tetraacetyl-*d*-xylonic acid and tetraacetyl-*l*-xylonic acid crystallized out of toluene also melted at 134–135°.

---

[8] Volpert[3] gave 103.5° as the melting point of ethyl pentaacetylgluconate.

[9] Prepared by the method described by Hudson and Dale, THIS JOURNAL, **40**, 999 (1918), for the preparation of *d*-xylose triacetate.

[10] Wolfrom, Newlin and Stahly[4] give 87–89° as the melting point and $[\alpha]^{26}D$ −15.9° in chloroform as the optical rotation of aldehydo-*d*-xylose tetraacetate.

Summary

1. Tetraacetyl-*d*-gluconic acid has been prepared by the oxidation of tetraacetyl-*d*-glucose with bromine.

2. Pentaacetyl-*d*-gluconic acid was obtained by the oxidation of aldehydo-*d*-glucose pentaacetate and by acetylation of tetraacetyl-*d*-gluconic acid.

3. Ethyl pentaacetyl-*d*-gluconate and pentaacetyl-*d*-gluconic phenylhydrazide were prepared.

4. The ring form of *d*-xylose semicarbazone tetraacetate was isolated.

5. Aldehydoxylose tetraacetates have been prepared by the treatment of the corresponding semicarbazones with nitrous acid.

6. Tetraacetylxylonic acids have been obtained by the oxidation of aldehydoxylose tetraacetates.

Preparation and Properties of Pentaacetyl-2-keto-*d*-glucoheptonic Acid

BY RANDOLPH T. MAJOR AND ELMER W. COOK

The 2-keto-sugar acids have acquired in recent years considerable interest due to the fact that the enol forms of these acids have been shown to be vitamin C and its homologs.[1]

A new method of preparing the acetyl derivatives of these acids has become possible since the recent synthesis of the fully acetylated sugar acids.[2]

The acetyl sugar acid was converted into its acid chloride with phosphorus pentachloride; it is noteworthy that thionyl chloride was not a satisfactory agent for the purpose. The chloride was converted into the corresponding cyanide by means of silver cyanide. This was hydrolyzed in turn to the corresponding acid. This acid could be esterified readily.

The series of reactions described above has been carried through to completion starting with pentaacetyl-*d*-gluconic acid and through, except for the last step, with tetraacetyl-*d,l*-xylonic acid.

Attempts are being made to hydrolyze the acetyl groups and enolize the keto group of pentaacetyl-2-ketoglucoheptonic acid and its ester to give a homolog of vitamin C.

Experimental

Acetylated Sugar Acid Chloride.—The dry fully acetylated sugar acid was added with cooling to a suspension of one molecular equivalent of phosphorus pentachloride in ten times its weight of dry ether. The reaction was soon complete as shown by disappearance of the phosphorus pentachloride.

Pentaacetyl-*d*-gluconyl Chloride.—After the solution had stood at room temperature for two or three hours the ether was evaporated *in vacuo*. Dry xylene was then added. This and the phosphorus oxychloride formed in the reaction were removed by evaporation at 45 to 50° *in vacuo*. The addition of xylene followed by evaporation *in vacuo* was repeated twice. The residual gum was dissolved in dry ether. Upon evaporation in a slight vacuum beautiful white crystals separated; m. p. 68–70°; yield, 88%; $[\alpha]^{20}_D$ +2° (alcohol-free chloroform, *c*, 2).

Anal. Calcd. for $C_{16}H_{21}O_{11}Cl$: C, 45.22; H, 4.99; Cl, 8.35. Found: C, 45.60; H, 4.90; Cl, 8.27.

With water the acid chloride gave pentaacetyl-*d*-gluconic acid monohydrate, m. p. 72–73°.[2]

Tetraacetyl-*d,l*-xylonyl Chloride.—White crystals appeared soon after solution of the phosphorus pentachloride. The precipitate was recrystallized from dry ether; m. p. 90–92°; yield, 71%; $[\alpha]^{20}_D$ 0° (alcohol-free chloroform, *c*, 2).

Anal. Calcd. for $C_{13}H_{17}O_9Cl$: C, 44.26; H, 4.86; Cl, 10.08. Found: C, 44.25, 44.33; H, 4.80, 5.03; Cl, 10.18, 10.32.

Ethyl Ester of Acetylated Sugar Acids.—When a solution of an acetylated sugar acid chloride in absolute alcohol was evaporated *in vacuo* a crystalline residue was left which was washed with cold water and recrystallized from absolute alcohol.

Ethyl pentaacetyl-*d*-gluconate melted at 103–104°.[3]

Ethyl tetraacetyl-*d,l*-xylonate melted at 70–72°; $[\alpha]^{20}_D$ 0° (alcohol, *c*, 0.06).

Anal. Calcd. for $C_{15}H_{22}O_{10}$: C, 49.70; H, 6.12. Found: C, 49.53; H, 6.13.

Pentaacetyl-*d*-gluconamide.—Dry ammonia was bubbled through a solution of pentaacetyl-*d*-gluconic acid chloride in dry ether. The white precipitate which formed was washed with water to remove ammonium chloride. The pentaacetyl-*d*-gluconamide which remained melted at 183–184°.[4]

Tetraacetyl-*d,l*-xylonamide.—This compound was prepared in the same way as pentaacetyl-*d*-gluconamide except that it did not precipitate from the ether with the

ammonium chloride but could be recovered from the ether filtrate by evaporation. It was recrystallized from benzene; m. p. 130–132°; $[\alpha]^{20}\text{D}$ 0° (alcohol-free chloroform, *c*, 0.05).

Anal. Calcd. for $C_{13}H_{19}O_9N$: C, 46.83; H, 5.75; N, 4.20. Found: C, 46.82; H, 5.76; N, 4.11.

Pentaacetyl - 2 - keto - *d* - glucoheptonitrile.—Pentaacetylgluconyl chloride (10 g.) was heated for one hour with 4.7 g. of silver cyanide in a closed tube at 120 to 125°. The fused contents were shaken frequently to ensure good contact of the acid chloride with the silver cyanide. After cooling the gummy material was extracted thoroughly with anhydrous ether and filtered from the silver salts. Petroleum ether was added carefully to precipitate a part of the product as a dark colored sirup, thereby removing most of the color. Then an excess of petroleum ether was added with cooling. A gum was precipitated along with some crystalline product. The supernatant liquor was poured off and on evaporation yielded crystalline pentaacetyl-2-keto-*d*-glucoheptonitrile. The gum was dissolved in a small quantity of absolute alcohol and upon standing in the ice box for twenty-four hours yielded a quantity of pentaacetyl-2-keto-glucoheptonitrile. The product was purified by recrystallizing it from absolute alcohol; yield 34%; m. p. 116°; $[\alpha]^{20}\text{D}$ +7° (alcohol-free chloroform, *c*, 2). When this compound was heated in water with either dilute acid or base, hydrogen cyanide was evolved.

Anal. Calcd. for $C_{17}H_{21}O_{11}N$: C, 49.14; H, 5.10; N, 3.37. Found: C, 49.32; H, 5.24; N, 3.16.

Tetraacetyl-2-keto-*d,l*-gulononitrile.—This nitrile was prepared from tetraacetyl-*d,l*-xylonyl chloride in the same way as pentaacetyl-2-keto-*d*-glucoheptonitrile except that the filtrate obtained after the addition of sufficient petroleum ether to the ether extract to produce slight turbidity was treated with another larger portion of petroleum ether which precipitated a gum. Trituration of this gum with absolute alcohol yielded a solid precipitate. It was recrystallized from alcohol; m. p. 125–126°.

Anal. Calcd. for $C_{14}H_{17}O_9N$: N, 4.08. Found: N, 3.83.

Pentaacetyl-2-keto-*d*-glucoheptonic Acid.—Pentaacetyl-2-keto-*d*-glucoheptonitrile (7.55 g.) was dissolved in 20 cc. of pure dioxane. To this 13.1 cc. of 1.39 normal hydrogen chloride in dioxane was added. The solution was cooled and 0.33 cc. of water added. After this had stood in the ice box for twenty-four hours an additional 0.33 cc. of water was added. The solution was allowed to stand for another twenty-four hours, by which time ammonium chloride had precipitated. Ether was added and the ammonium chloride filtered. The filtrate was evaporated *in vacuo* to a gum. The gum was dissolved in ether and evaporation *in vacuo* repeated. The gum that remained crystallized upon scratching; m. p. 136–138°. After recrystallization from water the product melted at 160–161°; $[\alpha]^{20}\text{D}$ 0° (alcohol, *c*, 2); yield 40%. A solution of the keto acid in water was acid to congo red paper. It was extremely soluble in alcohol, ether, chloroform and acetone.

Anal. Calcd. for $C_{17}H_{22}O_{13}$: C, 46.98; H, 5.11. Found: C, 46.98; H, 5.05.

Ethyl Pentaacetyl-2-keto-*d*-glucoheptonate.—A solution of 1 g. of pentaacetyl-2-keto-*d*-glucoheptonic acid in 10 cc. of absolute alcohol containing 2% hydrogen chloride was warmed at 55–60° for five minutes. The solution was cooled quickly to nearly room temperature and then allowed to crystallize; yield, 60%; m. p. 97–98°; $[\alpha]^{20}\text{D}$ 0° (alcohol, *c*, 2).

Anal. Calcd. for $C_{19}H_{26}O_{13}$: C, 49.33; H, 5.67. Found: C, 49.19, 49.38; H, 5.91, 5.67.

Methyl Tetraacetyl-2-keto-*d*-gluconate.—One gram of methyl 2-keto-*d*-gluconate[5] was added to 5 cc. of acetic anhydride containing 0.4 g. of zinc chloride at 0°. As soon as solution was complete (about thirty minutes) the mixture was allowed to come to room temperature and remain there for twenty-four hours. It was then poured into 25 cc. of ice water; a white solid separated which was recrystallized from absolute alcohol; m. p. 168–169°; yield, 61%; $[\alpha]^{20}\text{D}$ −133° (alcohol-free chloroform, *c*, 2).[6]

Anal. Calcd. for $C_{15}H_{20}O_{11}$: C, 47.90; H, 5.36. Found: C, 47.79; H, 5.30.

Summary

1. Pentaacetyl-*d*-gluconyl chloride and tetraacetyl-*d,l*-xylonyl chloride have been prepared from the corresponding acids.

2. Ethyl pentaacetyl-*d*-gluconate and ethyl tetraacetyl-*d,l*-xylonate have been prepared from the corresponding acid chlorides.

3. Pentaacetyl-*d*-gluconamide and tetraacetyl-*d,l*-xylonamide have been prepared from the corresponding acid chlorides.

4. Pentaacetyl - 2 - keto - *d* - glucoheptonitrile and tetraacetyl-2-keto-*d,l*-gulononitrile have been prepared from the corresponding chlorides.

5. Pentaacetyl-2-keto-*d*-glucoheptonic acid has been synthesized by hydrolysis of the corresponding nitrile.

6. Ethyl pentaacetyl-2-keto-*d*-glucoheptonate has been prepared by esterification of the corresponding acid.

7. Methyl tetraacetyl-2-keto-*d*-gluconate has been prepared by acetylation of methyl 2-keto-*d*-gluconate.

RAHWAY, N. J. RECEIVED SEPTEMBER 17, 1936

New Derivatives of *l*-Allonic and *l*-Altronic Acid. I[1]

BY FRED L. HUMOLLER, W. F. MCMANUS AND W. C. AUSTIN[2]

In a previous communication[3] from this Laboratory we announced the preparation of a crystalline lactone of *l*-allonic acid as well as the calcium salt of *l*-altronic acid and their conversion into crystalline *l*-allose and *l*-altrose, respectively. At that time lack of material prevented us from making a more detailed study of *l*-allonic and *l*-altronic acids and their derivatives. The present study was undertaken in order to determine in greater detail the physical constants of the two acids and their derivatives in general, and the rotational behavior of the *l*-allonolactone, previously reported, in particular.

The allonic and altronic acids used in this study were prepared from *l*-ribose by methods already published.[3,4] The *l*-allonic acid can be isolated in the form of the crystalline lactone previously reported, if the aqueous solution of the acid is evaporated and the resulting sirup heated on the steam-bath for several hours. This lactone has an initial specific rotation of +7.2°, which becomes constant in twenty-four days at +3.6°. The melting point of this compound is at 129–130°.

When, however, a freshly prepared aqueous solution of the free acid is concentrated rapidly under reduced pressure and the resulting sirup taken up in absolute ethanol without being exposed to a temperature higher than 50°, a crystalline substance is obtained having a composition corresponding to the formula $C_6H_{10}O_6$. It is therefore a lactone of *l*-allonic acid. In contradistinction to the previously reported lactone it shows an initial specific rotation of −54.8°. A further distinction from the known lactone is its behavior toward dilute solutions of bases; for, whereas the former cannot be titrated in ice-water solution using phenolphthalein as indicator, the new lactone can be titrated practically quantitatively under these conditions. When freshly dissolved in water both lactones are neutral to litmus. Rehorst[5] has found a similar differential instability toward dilute solutions of bases among the δ- and γ-lactones that he studied.

Further evidence that this new lactone belongs to the δ-series and that the lactone previously reported belongs to the γ-series is furnished by the rate of mutarotation of these two substances as shown in Fig. 1. The relatively rapid change in rotation of the new lactone as compared with the small and slow change of the previously reported lactone indicates that they belong to the δ- and γ-series of lactones, respectively.[6] Obviously further direct evidence would be highly desirable before definitely ascribing a certain ring structure to these lactones, but the instability of the strongly mutarotating lactone would make direct methylation studies of doubtful value. Therefore until evidence to the contrary is brought forth we shall call the new, strongly mutarotating lactone the δ-lactone of *l*-allonic acid and the previously reported lactone the γ-lactone of *l*-allonic acid.

The ease with which the ring can shift in the case of the δ-lactone is shown by its peculiar behavior during the determination of its melting point. If a sample of this lactone is heated slowly (increasing the temperature about 1° per minute), it melts at 129–130°, that is, at the same temperature at which the γ-lactone melts. If, however, the temperature is raised more rapidly it will melt unsharply at 140–144°. An investigation revealed that slowly heating the δ-lactone to its melting point (130°) was sufficient to change it into the γ-form. This observation explains why we were unable to observe a depression of the melting point of a mixture of the two lactones.

The mutarotation of free *l*-allonic acid is of interest in several respects. Its initial rotation of +11° is less levo-rotatory than that of either of its lactones, hence it follows Hudson's lactone rule as modified for lactones of small rotation.[7] The allonolactones were considered to be the only

---

[1] These studies, a portion of which was reported on the program of the meeting of the American Chemical Society in Pittsburgh, Sept. 7, 1936, were in part abstracted from a dissertation submitted by Mr. McManus to the Graduate School of Loyola University in partial fulfilment of the requirements for the degree of Master of Science.

[2] Dr. W. C. Austin, whose untimely death occurred in November, 1935, participated in the initial phases of this problem.

[3] Austin and Humoller, THIS JOURNAL, **56**, 1153 (1934).

[4] Austin and Humoller, *ibid.*, **56**, 1152 (1934).

[5] Rehorst, *Ber.*, **63**, 2279 (1930).

[6] Haworth, "The Constitution of Sugars," E. Arnold & Co., London, 1929, pp. 23–24.

[7] Hudson, "Relation between Rotatory Power and Structure in the Sugar Group," Scientific Papers of the Bureau of Standards, No. 533, Government Printing Office, 1926, p. 288.

doubtful exception among the aldonic acid lactones cited, although Hudson already had predicted at that time that allonic acid would show a rotation in agreement with his theory. The peculiar type of mutarotation of *l*-allonic acid as shown in Fig. 1 strongly indicates that an aqueous solution of the acid changes upon standing in part into the δ-lactone and this in turn changes into the more stable γ-lactone.

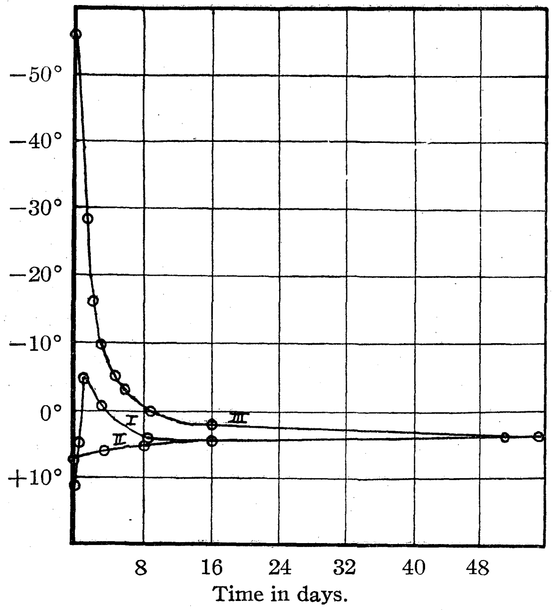

Fig. 1.—The mutarotation of *l*-allonic acid and its lactones: curve I, *l*-allonic acid; curve II, γ-*l*-allonolactone; curve III, δ-*l*-allonolactone.

Attempts to prepare a crystalline lactone of *l*-altronic acid according to the method generally employed to prepare the stable form of lactones were not successful. However, when a freshly prepared aqueous solution of the acid is concentrated rapidly under reduced pressure without exposing the acid to elevated temperature a crystalline substance is obtained. An analysis of the substance for C and H indicates that this compound is not a lactone but the free *l*-altronic acid. This conclusion is confirmed by the finding that this substance is acid to congo red and can be titrated like any organic acid.

Recently Posternak[8] pointed out in a very brief announcement that the allomucic acid prepared by E. Fischer[9] by heating mucic acid in aqueous pyridine is actually a mixture of equal parts of *d*- and *l*-talomucic acid. Posternak did not report, however, the preparation of allomucic acid. Therefore it was thought desirable to prepare allomucic acid from allonolactone and compare it with the substance obtained by the pyridine rearrangement of mucic acid. Allomucic acid prepared by the oxidation of *l*-allonolactone with nitric acid melts at 187.5° with decomposition and charring, and it crystallizes in rectangular prisms, whereas the substance prepared by Fischer's method from mucic acid melts at 166–171° with decomposition but no charring. A mixture of the two substances melts at 173°. Obviously both substances are optically inactive. The findings of Posternak together with our results seem to show that Fischer was mistaken in assuming that in the pyridine rearrangement of mucic acid both of the hydroxyl groups adjacent to the carbonyl groups are inverted. At present work is in progress to prepare derivatives of allomucic acid.

Experimental

Preparation of δ-*l*-Allonolactone.—A concentrated solution of the lactone in hot water was treated with a slight excess of sodium hydroxide. The solution was then chilled in ice water and an amount of sulfuric acid equivalent to that of the base was added. The solution was poured immediately into 10 volumes of absolute ethanol. After filtering off the precipitated sodium sulfate, the filtrate was concentrated rapidly under reduced pressure to a thin sirup. The sirup was taken up in four volumes of absolute ethanol and clarified. The filtrate was again concentrated under reduced pressure. During this second evaporation the lactone usually crystallizes out spontaneously. After crystallization was complete the crystals were filtered off and washed with alcohol and then with ether. The mother liquors yielded further crops on concentration. Recrystallization of the lactone from absolute ethanol did not change its physical constants. These together with analytical data are given in Table I.

Conversion of the δ-Lactone into the γ-Lactone.—A sample of 0.2028 g. of the δ-lactone having a specific rotation $[\alpha]^{20-25}\text{D}$ −46.9° was heated slowly in a small flask to 130°. The lactone melted at this temperature. However, it failed to crystallize on cooling. The material was dissolved in water and the solution made up to 25 cc. After clarification to remove a slight amount of color, it was found that the solution now had a specific rotation of $[\alpha]^{20-25}\text{D}$ +3.7°.

Preparation of the Phenylhydrazide of *l*-Allonic Acid.[10]—The phenylhydrazide of *l*-allonic acid was prepared from the δ-lactone by the usual method. Its specific rotation and melting point are given in Table I. They are identical with those of a sample of the phenylhydrazide prepared from the γ-lactone. A mixture of the two did not show any depression of the melting point.

[10] The melting point of this compound given by Austin and Humoller[3] was an unfortunate error, and we take this opportunity to correct it here.

TABLE I

ANALYSES AND PHYSICAL CONSTANTS OF NEW SUBSTANCES

Substance	M. p., °C.	$[\alpha]^{20-25}_D$ in water Init.	Final	Formula	Analyses, % Calcd. C	H	Found C	H
δ-*l*-Allonolactone	140–144	−54.8°	+3.66°	$C_6H_{10}O_6$	40.4	5.7	40.9	5.9
l-Altronic acid	110	−8.1°		$C_6H_{12}O_7$	36.7	6.2	37.3	6.5
Allomucic acid	187.5	Inactive		$C_6H_{10}O_8$	34.3	4.8	34.2	5.1
l-Allonic acid phenylhydrazide	142–145	−23.6°						
l-Altronic acid phenylhydrazide	151–152	+18.4°						

Preparation of *l*-Altronic Acid.—A solution of 17 g. of calcium *l*-altronate in 400 cc. of hot water was treated with sufficient oxalic acid to remove the calcium quantitatively. The filtrate from the calcium oxalate was concentrated under reduced pressure to a thin sirup. The sirup was poured into ten volumes of absolute alcohol. A small amount of insoluble material was filtered off. Upon concentration under reduced pressure the filtrate yielded 10 g. of crystalline material by spontaneous crystallization. *l*-Altronic acid was recrystallized from absolute ethanol to constant melting point. The physical constants and the analysis are given in Table I.

Preparation of the Phenylhydrazide of *l*-Altronic Acid.—*l*-Altronic acid readily formed a phenylhydrazide when treated with phenylhydrazine in the usual manner. The substance was recrystallized from hot absolute ethanol to constant melting point of 151–152°. It has a tendency to separate out from a hot alcohol solution in jelly-like masses which upon standing assume crystalline form.

Rearrangement of Mucic Acid in Aqueous Pyridine.—The reaction was carried out in general according to the procedure of Fischer.[9] If the reaction mixture was allowed to come into contact with the metal of the pressure vessel during the heating period extensive destruction took place. If the reaction mixture was kept in a glass vessel during the heating, a yield of about 12% of a substance showing all the properties described by Fischer was obtained. This racemic talomucic acid was recrystallized from hot water for the melting point determination. It is interesting to note that racemic talomucic acid resembles allomucic acid much more in solubility than it does *d*- or *l*-talomucic acid.

Preparation of Allomucic Acid.—A solution of 1 g. of γ-*l*-allonolactone in 50 cc. of nitric acid of sp. gr. 1.15 was heated on the steam-bath. When the evolution of brown fumes of oxides of nitrogen became too vigorous, the reaction was controlled by removing the reaction mixture from the steam-bath and cooling. The solution was evaporated in this manner to about half its volume. It was then diluted to about 50 cc. and concentrated to a few cc. under reduced pressure. This process of diluting and concentrating was repeated once more. During the second concentration allomucic acid began to crystallize in the distilling flask. After crystallization had gone to completion, the crystals were filtered off and washed thoroughly with water. About 0.6 g. of allomucic acid was thus obtained. The acid was recrystallized by dissolving it in hot water, concentrating the solution under reduced pressure and then cooling it for several days. The melting point and analysis of allomucic acid are given in Table I. Allomucic acid is quite insoluble in cold water but is much more soluble in hot water probably due to lactone formation, for after it has been thus dissolved it takes many days before it begins to crystallize again, even after concentrating the solution. For rotational studies 0.3461 g. of allomucic acid was dissolved in 10 cc. of a sodium hydroxide solution. No significant rotation could be observed.

All melting points cited in this paper are uncorrected for stem exposure. The authors wish to express their gratitude to Mr. D. Peterson of the Department of Biochemistry, The University of Chicago, for carrying out the micro carbon and hydrogen determinations cited in this paper.

Summary

1. A new crystalline lactone of *l*-allonic acid has been prepared and some of its physical constants determined. From its behavior toward dilute alkali and from its rate of mutarotation it has been concluded that this substance is the δ-lactone and that the previously prepared lactone is the γ-lactone of *l*-allonic acid.

2. Methods for converting one lactone into the other have been presented.

3. *l*-Altronic acid has been prepared and some of its physical constants recorded.

4. The phenylhydrazides of *l*-allonic and of *l*-altronic acids have been prepared and their melting point and specific rotation recorded. Their rotations show that these two substances follow the phenyl-hydrazide rule of rotation.[7]

5. Allomucic acid has been prepared. From a comparison of its properties with those of the substance obtained by the pyridine rearrangement of mucic acid it has been concluded that the two are not identical.

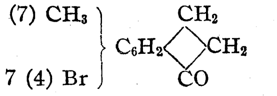
An Improved Method for the Synthetic Preparation of Methylcholanthrene

BY LOUIS F. FIESER AND ARNOLD M. SELIGMAN

Numerous requests for supplies of methylcholanthrene and inquiries concerning the two methods of preparation developed in this Laboratory have caused us for some time to give attention to the problem of producing the hydrocarbon in quantity sufficient to meet the wide-spread demand for material required for various forms of biological experimentation. The preparation from cholic acid[1] affords a fairly simple and rapid method of obtaining a few grams of the carcinogenic hydrocarbon, but the purification of the material obtained in this way is somewhat troublesome, the yield amounts to less than 4 g. from 100 g. of the bile acid, and the process becomes cumbersome when working on a large scale. The synthetic method[2] affords a better yield (11%, over-all) and a more easily purified product, but the process as originally described had the disadvantage of being rather lengthy, involving eight separate steps.

As the synthesis seemed to offer more possibility for improvement than the degradative method, a search was made for a shorter route to the required intermediates. In the initial stages of the original process, *p*-bromotoluene was converted into 4-bromo-7-methylhydrindene through a mixture of hydrindones (I) obtained through the following sequence of reactions

$$p\text{-}CH_3C_6H_4Br \longrightarrow CH_3C_6H_3(Br)CH_2Cl \longrightarrow CH_3C_6H_3(Br)CH_2CH(COOR)_2 \xrightarrow{\text{(2 steps)}} CH_3C_6H_3(Br)CH_2CH_2COOH \longrightarrow$$



$$\left.\begin{array}{r}4\ (7)\ CH_3\\ 7\ (4)\ Br\end{array}\right\} C_6H_2\langle CH_2 - CH_2 - CO\rangle \quad \text{I}$$

As an alternate route to the ketone mixture I we investigated the hydrindone synthesis of Mayer and Müller,[3] but all attempts to cyclize the chloro ketone mixture (II) obtained from *p*-bromotoluene and β-chloropropionyl chloride were unsuccessful. No trace of either of the two previously described[2] (crystalline) methylbromohydrindones (I) was observed and the only substance isolated as a solid is an isomer of these compounds and probably is a vinyl ketone (III).[4]

$$\underset{\text{II}}{CH_3C_6H_3(Br)COCH_2CH_2Cl} \longrightarrow \underset{\text{III}}{CH_3C_6H_3(Br)COCH{=}CH_2}$$

This unfavorable result was rather surprising, for Mayer and Müller report that the corresponding chloro ketone from *p*-chlorotoluene can be cyclized readily. On trying the latter reaction for comparison, the results were so generally satisfactory that it seemed worth while to investigate the use of a chlorohydrindene in place of a bromo compound in the methylcholanthrene synthesis, and eventually a very convenient process was evolved.

The Friedel and Crafts reaction with β-chloropropionyl chloride can be conducted easily with as much as one-half kilogram of *p*-chlorotoluene in one lot and the cyclization of the crude chloro ketone mixture (oil) likewise proceeds well on a large scale. A purified mixture of the hydrindones IV and V was obtained in over-all yield of 61%. Although Mayer and Müller report the isolation of only one isomer (m. p. 128°), two compounds actually are formed and a fairly sharp separation can be accomplished by fractional distillation in vacuum. Dr. W. F. Bruce has kindly informed us that he has synthesized both isomers by another method and established the fact that the higher melting compound of Mayer and Müller is 4-methyl-7-chlorohydrindone-1 (IV), while the isomer is 7-methyl-4-chlorohydrindone (V). On this basis, and from the results of our fractionation, it appears that in the original Friedel and Crafts reaction substitution ortho to the methyl group predominates in the ratio of about 2:1. The course of the reaction seems to be quite similar to that observed by Wahl[5] in a careful study of the chlorination of *p*-chlorotoluene (58% substitution ortho to the methyl group). It is interesting that in the Blanc reaction with

[1] Fieser and Newman, THIS JOURNAL, **57**, 961 (1935). Difficulty may be experienced in effecting the hydrogenation of dehydrocholic acid unless this material is reasonably free from impurities. An adequate purification of the crude oxidation product of cholic acid consists in precipitation of the acid from a solution in dilute alkali and crystallization from acetone. Four 40-g. lots of the purified acid have been hydrogenated in succession with one 3-g. charge of catalyst.

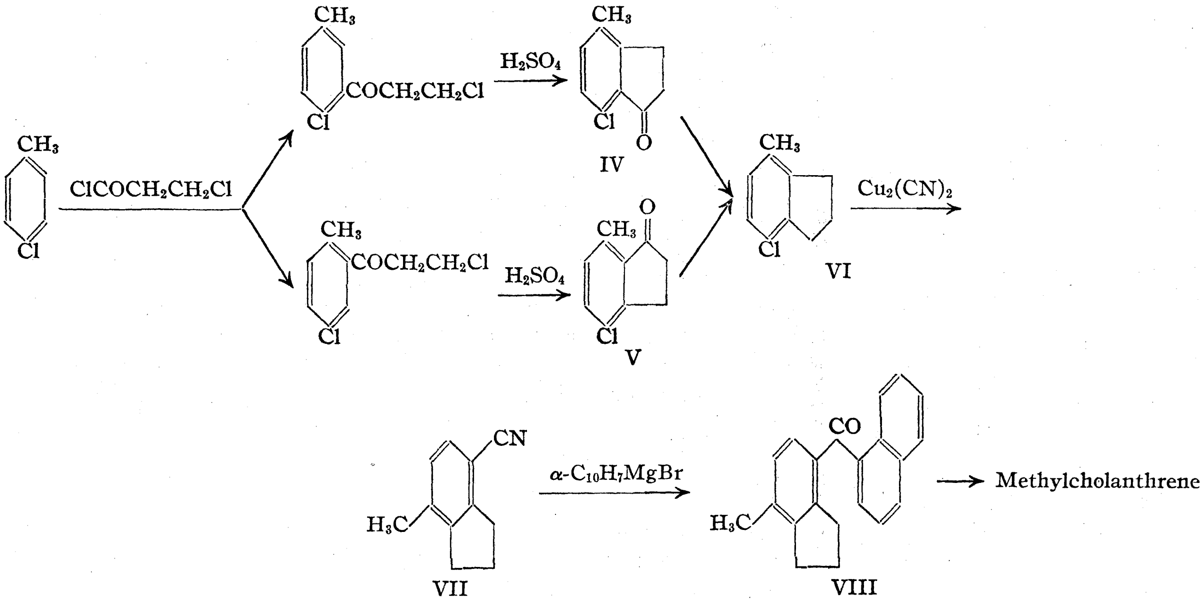
[4] This substance, m. p. 129–132° (from alcohol), was obtained in small amounts by heating crude II with concentrated sulfuric acid at 100° for one-half hour (found: C, 53.61; H, 4.35), the bulk of the product being an oil. Steam distillation of II gave a viscous oil which polymerized on standing (probably a mixture of the vinyl ketones III) and which could not be cyclized with sulfuric acid or aluminum chloride.

[5] Wahl, *Compt. rend.*, **202**, 2161 (1936).



p-bromotoluene the situation is reversed, substitution occurring chiefly adjacent to the bromine atom in the ratio 1.8:1.[2]

For the purpose of the present synthesis a separation (or distillation) is not required, and 4-chloro-7-methylhydrindene (VI) was obtained in 95% yield from the mixture of hydrindones. For the preparation of the ketone VIII the chloro compound VI was first converted into the nitrile VII by the Rosenmund–von Braun method. Fairly satisfactory results were obtained using cuprous cyanide without a solvent[6] at 265°, but a better procedure was encountered by Dr. E. B. Hershberg in the course of work on a related problem and applied by him to the present reaction. Using pyridine as solvent, as suggested in the patent literature,[7] the reaction took place at a lower temperature (220–230°) and the nitrile was obtained (pure) in 78% yield. The condensation of the nitrile with α-naphthylmagnesium bromide proceeded very smoothly and the ketimine was obtained as a crystalline yellow hydrochloride. This was hydrolyzed in the presence of toluene, and on vacuum distillation the ketone VIII was obtained in a satisfactory condition in 89% yield, based on the nitrile. The yield of the ketone is about twice as great as that obtained from 7-methyl-4-bromohydrindene and α-naphthoyl chloride,[2] and the yield in two steps from the chloro compound (69%) is better than in the single step previously employed.

No difficulty was experienced in conducting the pyrolysis of the ketone VIII on a large scale. The bulk of the methylcholanthrene was obtained in a very pure condition after one or two crystallizations of the crude distillate and the remainder was purified as the picrate, the total yield being 49%. In working with large quantities of material it was observed that the hydrocarbon invariably is accompanied by an oily substance. This was collected from the mother liquors and purified by removing traces of methylcholanthrene by its preferential reaction with sulfuric acid. The resulting pale yellow oil, b. p. 221–226° (4 mm.), had the composition of a tetrahydro derivative of methylcholanthrene, but, as it proved to be quite resistant to dehydrogenation with selenium, such a structure is unlikely. The hydrocarbon, which unfortunately yielded no picrate, more probably is 4-methyl-7-(1-naphthylmethyl)-hydrindene, formed by the reduction of the carbonyl group of the starting material (VIII). That some form of reduction process occurs during the pyrolysis is clear from the composition of the hydrocarbon, and it is interesting that products both of reduction and of oxidation[8] (anthrones) have been observed as by-products in the Elbs reaction, suggesting a process of disproportionation as a side reaction.

Each of the six steps of the new synthesis can be carried out rapidly and on a reasonably large scale, and the over-all yield (20%) is quite satis-

factory. Using ordinary equipment, 75 g. of methylcholanthrene can be prepared conveniently from 176 g. of *p*-chlorotoluene, and the first three reactions can be conducted easily with amounts three times as great. The β-chloropropionic acid required as starting material can be prepared readily from trimethylene chlorohydrin in 79% yield by a modification of the usual method[9] for which we are indebted to Professor E. H. Huntress and Dr. E. B. Hershberg. Also included in the experimental part is a procedure developed by Dr. M. S. Newman for the preparation of methylcholanthrene-choleic acid,[10] a compound of interest for biological experimentation in the form of the water-soluble sodium salt.

The modifications reported in this paper widen somewhat the scope of the general synthesis, and various further applications are at present under investigation. We are indebted to Drs. Hershberg and Newman for the contributions noted, and to Mr. Phillip A. Shaffer, Jr., for able assistance in conducting the experiments.

Experimental Part[11]

β-Chloropropionyl Chloride.—Following the procedure recommended by Huntress and Hershberg, 250 g. of trimethylene chlorohydrin was added gradually from a dropping funnel to 775 cc. of concentrated nitric acid (sp. gr. 1.42) contained in a 3-liter long-necked flask provided with a mechanical stirrer and a thermometer suspended in the liquid, and cooled in an ice-bath (hood). The temperature of the reaction mixture was carefully controlled to 25–30° throughout the addition, which required about three hours. Stirring was continued for a short time, and after standing overnight the mixture was heated for one-half hour on the steam to complete the reaction. The solution was combined with that from a second oxidation of the same amount of material and the nitric acid was removed by distillation up to about 100° at 25 mm. The β-chloropropionic acid then distilled at 115° (25 mm.), or 120° (30 mm.); yield 445–465 g. (78–81%).

The acid prepared in this way (465 g.) was refluxed with 800 g. of purified thionyl chloride (all-glass apparatus) for three hours and the excess thionyl chloride was removed by careful fractionation from a modified Claisen flask at the pressure of the water pump. The β-chloropropionyl chloride then distilled at 53° (23 mm.) or 87° (95 mm.); yield 525 g. (96%).

Friedel and Crafts Reaction.—A 5-liter three-necked flask provided with a mercury-sealed Hershberg wire-stirrer[12] and a calcium chloride tube was charged with 525 g. of β-chloropropionyl chloride, 525 g. of *p*-chlorotoluene and 2100 cc. of carbon bisulfide, and 1050 g. of aluminum chloride was added to the stirred solution in 100-g. portions over a period of three hours. Stirring was then continued at room temperature for ten hours, by which time the greater part of the aluminum chloride had been converted into a liquid complex. To complete the reaction the mixture was warmed to 40–45° and stirred for two hours without further heating. It was then cooled thoroughly by stirring in an ice-bath and the liquid was decanted into dry flasks and then poured cautiously through a funnel into a stirred mixture of ice and concentrated hydrochloric acid, using in all 12 liters of ice and 1.5 liters of acid distributed among several beakers. The residue in the reaction flask, containing aluminum chloride, was decomposed separately with ice and acid. The aqueous liquor was separated in portions and washed once with ether. The carbon bisulfide layer was extracted once with water, combined with the ethereal extract and, without drying, evaporated at the pressure of the water pump. The residual red-brown oil containing a mixture of the two β-chloropropionyl derivatives and weighing about 910 g. (theoretical, 897 g.) was used at once or else stored in the ice box.

Cyclization.—Approximately one-half of the above oil (910 g.) was added from a separatory funnel with efficient stirring (wire stirrer) to 2600 cc. of concentrated sulfuric acid contained in a 5-liter flask and preheated to 105° (hood). The addition was completed in thirty minutes, and the solution was kept at 105–110° with stirring for twenty-five minutes longer. The mixture was then carefully cooled by applying wet towels, then water, then ice, while stirring, and after reaching a temperature of 25° (twenty minutes) it was poured onto about 12 liters of cracked ice and the volume was made up to about 16 liters with water. The reaction product separated as a crystalline, tan precipitate, and this was collected on a large Büchner funnel and washed thoroughly with water. The washing removed a considerable amount of very dark tar (which is reprecipitated by the dilute acid in the filtrate) and left a light tan, granular product. This was combined with the material obtained in the same manner from the second half of the chloro ketone mixture and the product without being dried was dissolved in boiling alcohol, using a considerable excess of the solvent. For clarification the dark solution was filtered by suction through a 2-cm. pad of Norite, changing the pad frequently, as required. After a second filtration the solution was light yellow, and after suitable concentration and cooling there was deposited a first crop of nearly colorless crystals (390 g.). A second crop was obtained after clarification and concentration of the solution, and finally the remainder was precipitated with water. The total yield of light colored hydrindone mixture suitable for the next step was 460 g. (61%).

In another experiment the crude, tan hydrindone mixture from 490 g. of *p*-chlorotoluene was taken up while wet in benzene and the solution was washed with aqueous sodium chloride solution, dried and after removing the solvent the product was distilled at reduced pressure from a modified Claisen flask. There was obtained in the first fraction, b. p. 152–157° (8 mm.), 213 g. of colorless solid melting at 75–79° and consisting very largely of **7-methyl-4-chlorohydrindone-1** (V). Recrystallized several

times from alcohol, a sample of the substance formed long needles, m. p. 82–82.4°.

Anal. Calcd. for $C_{10}H_9OCl$: C, 66.47; H, 5.03. Found: C, 66.31; H, 5.10.

The second fraction distilled largely at 172–180° (8 mm.), and the colorless distillate weighed 112 g. and melted at 110–120°. Crystallization from alcohol afforded pure **4-methyl-7-chlorohydrindone-1**(IV), which formed leaf-like prisms melting at 128° as recorded by Mayer and Müller.[3] The substance is considerably less soluble than the isomer. As the total yield in this experiment was low (46%), and as a considerable residue remained from the distillation, it is probable that much material was lost during the prolonged process of fractionation, possibly through biindone formation under the influence of impurities in the crude material. For this reason the approximate ratio of the isomers V and IV (66:34) in the total distillate may be only a rough indication of the course of the original substitution. In an earlier small-scale experiment in which the distillation was carried out more rapidly without attention to the separation of isomers, the yield from 140 g. of *p*-chlorotoluene was 59%. Purification of the crude hydrindone mixture by rapid distillation thus appears to be satisfactory when handling small quantities, but in large-scale operation it is safer to crystallize the material.

4-Methyl-7-chlorohydrindene (VI).—For the Clemmensen reduction the 460-g. batch of mixed hydrindones described above was divided into three portions, each of which was dissolved in 750 cc. of alcohol. The solutions were kept hot on the steam-bath and in the course of four to five hours each solution was added in portions through a reflux condenser to a gently boiling mixture prepared by shaking 1600 g. of granulated zinc with a warm solution of 80 g. of mercuric chloride, decanting, washing once with water, and adding 500 cc. of water, 200 cc. of alcohol and 1100 cc. of concentrated hydrochloric acid. After the addition the mixtures were kept boiling for ten hours, during which time 900 cc. of concentrated hydrochloric acid was added in portions to each flask. After standing overnight to cool, the aqueous liquors were decanted, diluted with water to twice the original volume and extracted twice with ether. The greater part of the reaction product was recovered from the zinc residues by thorough extraction with ether, taking care to break up any lumps of metal. The various ethereal extracts were combined, the solvent was removed by distillation and the residual oil was steam distilled from a solution of sodium hydroxide. The colorless oil in the distillate, together with that extracted from the aqueous layer with ether, was dried and distilled, the yield of colorless, mobile liquid, b. p. 132–133° (25 mm.), being 403 g. (95%).

Anal. Calcd. for $C_{10}H_{11}Cl$: C, 72.09; H, 6.66. Found: C, 71.76; H, 6.98.

4-Methyl-7-cyanohydrindene (VII).—In the most satisfactory experiment (by E. B. H.) 27.8 g. of thoroughly dry, powdered cuprous cyanide was poured into a 30-mm. Pyrex bomb tube constricted near the top, and 49.3 g. of 4-methyl-7-chlorohydrindene was added. After shaking vigorously to wet all of the powder, 40 cc. of dry pyridine was added, taking care not to mix the layers. The tube was then sealed and given a few quick shakes to mix the contents. A pyridine–cuprous cyanide complex forms with much evolution of heat and the mixture sets to a solid mass. On being heated in a furnace to 220–230° this dissolves to a clear, dark brown solution. After twenty hours at this temperature the tube was cooled and opened and, after adding 20–30 cc. of pyridine, warmed over a flame until the solid had dissolved. The hot solution was poured into a separatory funnel containing water and the mixture was extracted with ether. The filtered ethereal extract was washed with concentrated ammonia solution to remove copper salts, then with water, and finally with dilute hydrochloric acid. The ethereal solution was filtered to remove some precipitated solid, washed with saturated salt solution, filtered and evaporated. The residue on distillation gave 36.2 g. (78%) of distillate, b. p. 162–164° (21 mm.), which solidified at once to a colorless solid. This material was suitable for use in the Grignard reaction.

When no solvent was employed (A. M. S.), the best results were obtained by heating 80 g. of 4-methyl-7-chlorohydrindene and 41 g. of dry cuprous cyanide at 265° for eighteen hours. Before the tube was sealed it was evacuated several times to mix the reagents, and after the first ten hours of heating the tube was removed and shaken well. It was found convenient to isolate the reaction product by vacuum distillation (2 mm.) directly from the bomb-tube, and for this purpose an end section of the tube was drawn down to a diameter of 6 mm. and bent upward so that it subsequently could be cleaned easily and sealed to a delivery tube leading to a bulb receiver. The reaction product, together with some starting material, distilled readily in a colorless condition and was accompanied by only a small amount of inorganic sublimate (56 g.). The material was collected and dried in ether and on fractionation there were obtained 7.5 g. of starting material and 46.5 g. of nitrile (3° range); yield 68%, based on the chloro compound actually consumed. At the above temperature the conversion invariably was incomplete, and at higher temperatures considerable material was destroyed. The collection of the product by distillation from the bomb tube seemed to give yields just as good as the very tedious process of extraction with benzene.

4-Methyl-7-cyanohydrindene crystallizes well from petroleum ether, and a dilute solution deposits large, flat, rectagonal prisms with a characteristic design resembling the section of an hourglass. The pure substance melts at 72.9–73.2°.

Anal. Calcd. for $C_{11}H_{11}N$: C, 84.01; H, 7.06. Found: C, 83.80; H, 7.21.

The corresponding **amide** was obtained by refluxing the nitrile with concentrated hydrochloric acid. It formed colorless needles from alcohol, m. p. 176–177.4°.

Hydrolysis of the amide with alkali gave **4-methylhydrindene-7-carboxylic acid;** irregular prisms from alcohol, m. p. 227–229°.

Anal. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.87. Found: C, 74.82; H, 6.87.

4-Methyl-7-(α-naphthoyl)-hydrindene (VIII).[2]—To the Grignard reagent prepared from 195 g. of α-bromonaphthalene, 37 g. of magnesium and 800 cc. of dry ether, 100 cc. of dry benzene was added and about half of the ether was removed by distillation. A solution of 120 g. of 4-methyl-7-cyanohydrindene in 650 cc. of benzene was then added rapidly with stirring, the heat of the reaction bringing the mixture nearly to the boiling point. After refluxing overnight, the mixture was poured onto 1 kg. of ice and 500 cc. of concentrated hydrochloric acid, when the ketimine hydrochloride separated as fine yellow crystals. The organic solvents were removed with steam and, after cooling, the yellow solid was collected on a Büchner funnel and transferred to a 5-liter flask. To effect hydrolysis 1 liter of water, 500 cc. of concentrated hydrochloric acid, 500 cc. of glacial acetic acid, and 600 cc. of toluene were added and the mixture was refluxed until the ketimine hydrochloride had completely disappeared (three hours). The acetic acid was found to facilitate the hydrolysis, while the toluene dissolves the ketone as it is formed and also floats the solid material and prevents bumping. The aqueous layer was extracted once with ether and the combined ether–toluene solution was washed with water and submitted to steam distillation from a mixture with dilute alkali. After removal of the solvent the distillation was continued in order to eliminate some naphthalene. The residual oil was dried in ether and distilled at 2 mm., b. p. 211–214°, the yield of light yellow, viscous oil being 194 g. (89%). On one occasion, after evaporating the bulk of the ether prior to the distillation of the crude ketone, the material crystallized to a hard solid on standing for a day or so. After this product had been distilled it remained as a glass when kept for over a week. The analytical sample from the earlier work[2] began to crystallize after about twenty months.

Methylcholanthrene.—The pyrolysis of 168.5 g. of the ketone was conducted in three lots and the products were combined for purification. In a 100-cc. flask with a sealed-on receiving bulb a portion of the ketone was warmed over a free flame and then placed in a preheated nitrate bath and heated at 405–410°, uncorr., for forty minutes. A nitrogen atmosphere is unnecessary. Since the true temperature of the bath was not determined, it may be noted that the pyrolysis temperature is sharply defined by brisk bubbling which is hardly noticeable at a temperature 5° lower. The water and hydrocarbon cleavage products collecting in the receiver amounted to 6 g. in a typical 56.5-g. run. At the end of the period of heating the flask was removed from the bath and cooled somewhat with a blast of air. A capillary was inserted, the receiver was rinsed with acetone and the hydrocarbon was distilled at 2–3 mm. pressure. It is convenient to distill the material rather rapidly and to remove traces of entrained tar in a second distillation. There was a fair amount of tarry residue in the first distillation, and the first few drops of the distillate failed to solidify.

The redistilled material from the three pyrolyses consisted of a bright yellow solid weighing 113.3 g. This was dissolved in 400 cc. of benzene, and after cooling slightly 1 liter of ether was added. The bulk of the methylcholanthrene separated in a nearly pure condition as fine yellow needles (72 g.). This was dissolved in 500 cc. of benzene and 300 cc. of ether was added; on cooling, the hydrocarbon separated as beautiful yellow needles of high purity, m. p. 178.5–179.5°; yield 63 g. The mother liquor from this crystallization was concentrated and treated with 12 g. of picric acid, affording 12.5 g. of methylcholanthrene picrate, m. p. 176–177°. The original mother liquor was evaporated and the residual oil was submitted to pyrolysis at 405–410°, uncorr., for thirty-five minutes, but no appreciable amount of water was formed. Vacuum distillation gave an oil which solidified only partially, and on warming this with 100 cc. of ether and cooling, there was obtained in all 14.6 g. of solid, consisting of quite impure methylcholanthrene. Treated with picric acid in benzene solution, this yielded, after suitable recrystallization, 14.5 g. of satisfactory methylcholanthrene picrate, m. p. 178–179°. The total yield of the hydrocarbon, collected as such or as the picrate, amounted to 77.1 g. (49%).

The ethereal mother liquor remaining after the removal of the impure methylcholanthrene left on evaporation 26 g. of a somewhat dark oil which set to a glass on cooling. Only traces of picrate could be obtained from this material, and in earlier experiments it had been found that heating the oil with selenium resulted in no noticeable increase in the quantity of methylcholanthrene still present. To remove this hydrocarbon completely a solution of the oil in about 150 cc. of tetrachloroethane was shaken mechanically with 3-cc. portions of concentrated sulfuric acid, each time decanting the solution as well as possible and washing the acid residue with fresh solvent. The acid liquor at first was colored a dull reddish-black, but after repeating the process a few times it acquired a clear, brilliant, crimson color similar to that given by pure methylcholanthrene under the same conditions. After about ten extractions the material was recovered for inspection and distilled. The product (11 g.) was then treated as before until fresh acid acquired only a light red color (about ten extractions). The decanted solution was then filtered twice through Norite on a sintered glass funnel to remove traces of acid and the nearly colorless filtrate was subjected to steam distillation. The residual oil was dried in ether over calcium chloride and twice distilled in vacuum. The pale yellow distillate (7.4 g.) formed a glass. No picrate could be obtained from the material in either alcohol or benzene. After two careful fractionations the main portion of the oil (5.2 g.) distilled at 221–226° (4 mm.). The analysis is that of 4-methyl-7-(1-naphthylmethyl)-hydrindene.

Anal. Calcd. for $C_{21}H_{20}$: C, 92.60; H, 7.41. Found: C, 92.71; H, 7.34.

A sample of the oil was treated in glacial acetic acid with sufficient dichromate for conversion to the ketone VIII, but the recovered product gave no methylcholanthrene on pyrolysis and resembled the starting material. The oily hydrocarbon is attacked only slowly on being heated with dilute nitric acid; after oxidation finally had been accomplished the clear solution was evaporated and the residue sublimed. Phthalic anhydride was identified in the first sublimate and there was then obtained a substance which crystallized from benzene as colorless prisms which became opaque on drying and melted at 189–191° (found: C, 54.27; H, 1.33).

Methylcholanthrene-choleic Acid.—Conditions have not been found under which the choleic acid crystallizes directly from a solution of the components, and the following process has been employed. Fifteen grams of commercial desoxycholic acid is dissolved in 200 cc. of absolute alcohol, the solution is filtered, 0.4 g. of methylcholanthrene is added, and the mixture is refluxed for a few minutes in order to bring the hydrocarbon into solution. On standing undisturbed overnight the solution deposits a few large clusters of long, fine, rather pale yellow needles of pure methylcholanthrene. This material is collected, and the filtrate is concentrated to a volume of about 125 cc. and allowed to stand overnight without disturbance. Methylcholanthrene-choleic acid separates at this point as small clusters of fine, colorless needles amounting to 0.7–2.1 g. The melting point usually is 196.5–197°, sometimes 197.5–198°. There is some drawing together of the particles a few degrees lower, and some darkening at the melting point. From 0.1 to 0.2 g. of methylcholanthrene, depending on the size of the first crop of the choleic acid, is dissolved in the mother liquor and on slow cooling a further crop of the choleic acid is obtained. This procedure can be repeated about four times, keeping the volume about 125 cc. If the solution darkens, it is clarified with Norite.

Summary

By a modification of the synthetic method previously described, methylcholanthrene can be prepared rapidly and on a large scale using *p*-chlorotoluene, β-chloropropionyl chloride, and α-bromonaphthalene as the starting materials. The over-all yield in the six-step process is 20%.

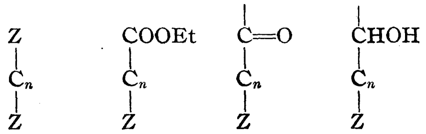
The Synthesis of Pyrrolidines, Piperidines and Hexahydroazepines[1,2]

BY JOSEPH H. PADEN AND HOMER ADKINS

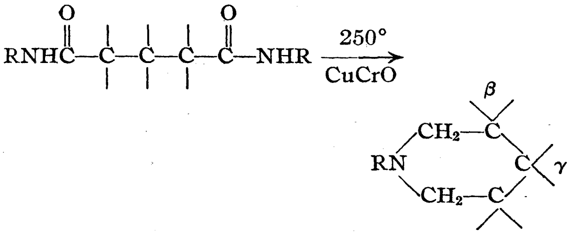
Compounds of the types



$Z{-}C_n{-}Z \qquad \mathrm{COOEt}{-}C_n{-}Z \qquad \mathrm{C{=}O}{-}C_n{-}Z \qquad \mathrm{CHOH}{-}C_n{-}Z$

where *n* is 2, 3 or 4 and Z is $-CN$, $-CONH_2$, $-CONHR$, $-\overset{|}{\underset{|}{C}}-NH_2$, $-\overset{|}{\underset{|}{C}}-NHR$, $-\overset{|}{\underset{|}{C}}-NO$, $-\overset{|}{\underset{|}{C}}-NO_2$, $-\overset{|}{C}{=}NOH$ or $-\overset{|}{C}{=}N-N{=}$ presumably may be converted into cyclic amines by catalytic hydrogenation. The present paper is concerned primarily with the synthesis of such amines from diamides of succinic, glutaric and adipic acids. Attention has been also given to the hydrogenation of imides to cyclic amides over nickel or to cyclic amines over copper–chromium oxide. In addition a new process for the preparation of cyclic amines by the alkylation of amines with glycols has been developed.

Piperidines from Glutaramides.—The eight substituted piperidines prepared by ring closure from glutaramides as indicated in Table I have substituents on the nitrogen and (or) in the gamma position.



Presumably piperidines bearing substituents in the beta position could be prepared similarly, while it is obviously impossible to prepare alpha substituted piperidines from glutaramides. Among the piperidines prepared, the group on the nitrogen was *n*-amyl, benzyl or phenethyl, while the substituents on the central carbon were methyl, dimethyl or phenyl. The yield of piperidines was not much modified by the character of the substituent, being approximately 70%, which was also the yield of piperidine obtained from glutaramide itself. The lowest yield (62%) of a piperidine was due to incomplete hydrogenation and becomes the highest (81%) if allowance is made for the recovered amide.

The other products of reaction, isolated in the yields given in Table I, can be accounted for by cleavage at the nitrogen to carbon bond in the amide or the piperidine. The effect of structure upon the extent of this type of reaction will be considered in a subsequent section.

Three dipentamethylene glutaramides of the type

---

(1) Azepine is the seven-membered ring containing one nitrogen atom and three double bonds. Hexahydroazepine was suggested by Dr. Austin M. Patterson in preference to the synonymous terms hexamethyleneimine or homopiperidine.

(2) The Wisconsin Alumni Research Foundation allotted funds for a research assistantship held by J. H. P.

TABLE I

HYDROGENATION OF AMIDES OVER COPPER–CHROMIUM OXIDE

The reactions were carried out at 250–260° under 200–400 atm. of hydrogen using 700–800 cc. of dioxane per mole of diamide.

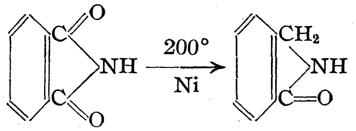
$$C_5H_{10}N-\overset{O}{\overset{\|}{C}}-CH_2-\underset{|}{\overset{|}{C}}-CH_2-\overset{O}{\overset{\|}{C}}-NC_5H_{10}$$

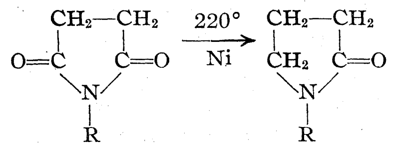
did not undergo ring closure but gave open chain diamines of the type $C_5H_{10}N(CH_2)_2(\underset{|}{\overset{|}{C}}CH_2)_2$-$NC_5H_{10}$, *i. e.*, substituted cadaverines. Di-N-pentamethyleneglutaramide also gave a 30% yield of an amino alcohol, $C_5H_{10}N(CH_2)_4CH_2OH$.

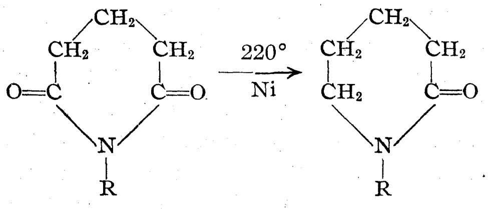
A Hexahydroazepine from an Adipamide.—The yield of 1-*n*-amylhexahydroazepine from di-*n*-amyl adipamide was half as large as that of the piperidines from the glutaramides. The formation of a hexahydroazepine was overlooked in earlier experiments[11] since it has approximately the same boiling point as di-*n*-amylamine which is also produced in the hydrogenation.

Pyrrolidones and Piperidones from Imides.—Cramer[12] observed that phthalimide was converted to phthalimidine by treatment with a nickel catalyst in methylcyclohexane solution at 200° under 200–250 atm. of hydrogen.



Attempts to obtain a similar reaction with succinimide or succinamide were not successful. It has now been found that succin- and glutaramides which bear an alkyl group on the nitrogen atom may be converted successfully at 200–220° over nickel to 2-pyrrolidones and 2-piperidones, respectively.

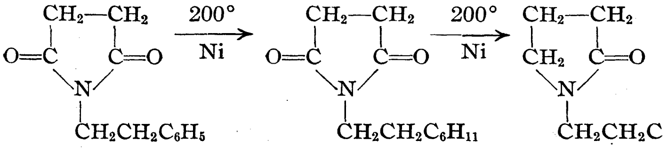




This behavior is similar to that observed in the pyrrole series where the presence of a group on the nitrogen atom greatly facilitates hydrogenation. The resulting pyrrolidones and piperidones are cyclic amides which do not react further under the conditions of the experiments.

As is indicated in Table II three imides were investigated and the yields of products were 46–79%. The reactions were rather slow at 200–220° and would probably have been much more rapid at a higher temperature, but dioxane is the only available solvent which is satisfactory for this type of reaction and it may not be used with Raney nickel above about 220°. The reaction with N-*n*-amylsuccinimide was incomplete after two applications of catalyst. The low yield reported is due to the difficulty of separating the pyrrolidone from the imide. The yields of products from N-phenethylimides were quite satisfactory and no difficulty was encountered in purifying them by fractionation since their boiling points differed much more from that of the starting material than was the case with 1-*n*-amylpyrrolidone-2.

The first reaction in the hydrogenation of the two N-phenethylimides was the saturation of the benzene ring which occurs very rapidly at 200°. It was found possible to isolate 1-β-cyclohexylethylsuccinimide (II) in a yield of 93% when the hydrogenation of N-phenethylsuccinimide (I) was interrupted after twenty minutes. Longer treatment resulted in the removal of one carbonyl oxygen and in the formation of 1-β-cyclohexylethylpyrrolidone-2 (III).



I II III

These reactions are examples of two selective hydrogenations. First, the hydrogenation of a phenyl group in the presence of an imido carbonyl group which is labile to hydrogen under the conditions of the reaction. This is possible because of the difference in rate of reaction. Secondly, we have the hydrogenolysis of an imido carbonyl group while the amido carbonyl remains unchanged.

In the hydrogenation of N-phenethyl-β-methylglutarimide (IV) no attempt was made to isolate the N-cyclohexylethylimide. The reaction was allowed to proceed to completion and the product was 1-β-cyclohexylethyl-4-methylpiperidone-2 (V).

Piperidines from Glutarimides.—In a glutarimide (VI) the ring system of the piperidine

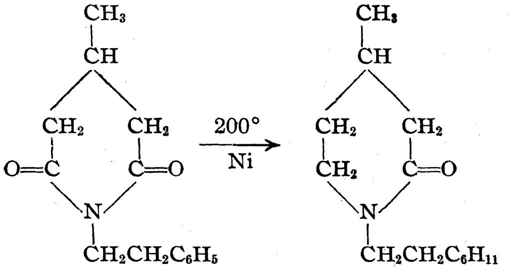
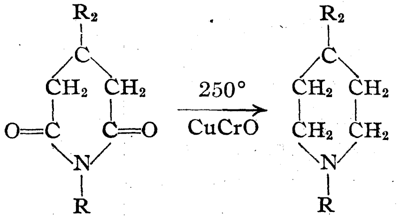
				31 4,4-Dimethylpiperidine



IV V

(VII) is already present, and it might be expected that the yields of piperidine would be somewhat greater than in the case of the amides, due to the lessening of any side reactions which might precede ring closure.



VI VII

Inspection of Table III, however, shows that this is not the case. The yields of the corresponding piperidines from N-benzyl-β-phenyl-, N-*n*-amyl-β,β-dimethyl- and N-phenethyl-β,β-dimethylglutarimide were of the order of 70–75% of ring compounds. The cleavage of the phenethyl and benzyl groups from the nitrogen atom giving the piperidines free from substituents in the 1-position is quite noticeable in these compounds. An attempt to remove the benzyl group to a larger extent was made with N-benzyl-β,β-dimethylglutarimide by running the reaction for a longer time. That much of it was removed is shown by the low yield of 1-benzyl-4,4-dimethyl-piperidine.

The hydrogenation of β-methyl- and β-phenylglutarimides was not very satisfactory. Since the simple amides of glutaric acids are quite insoluble substances and so are difficult to purify by crystallization, it was hoped that the easily purified imides would furnish a convenient method for preparing the piperidines which are unsubstituted in the 1-position. The yields of 4-methyl- and 4-phenylpiperidines from these substances were rather low, however. In both cases the catalyst was found to be red after the reaction was over, indicating that it had been deactivated. This might be due to the hydrolysis of the imide by the

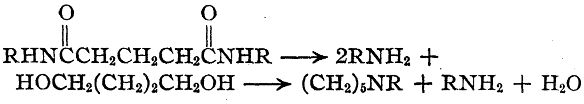
water formed in the reaction, the resulting acid and ammonia deactivating the catalyst. Residues of high boiling material were left after the product had been distilled, amounting to 33% of the starting material in the case of β-methylglutarimide, and 24% with β-phenylglutarimide.

Since the amides of β,β-dimethylglutaric acid are difficult to obtain, and the imides may be prepared in satisfactory yields in most cases (see Table V), the hydrogenation of the imides seems to be the best method of preparing N-alkylated derivatives of 4,4-dimethylpiperidine.

Pyrrolidines and Piperidines from Pyrrolidones and Piperidones.—Three cyclic amides, 1-β-cyclohexylethyl-pyrrolidone-2, 1-*n*-amyl-pyrrolidone-2 and 1-β-cyclohexylethyl-4-methylpiperidine-2, were almost quantitatively converted over copper chromium oxide to pyrrolidines and a piperidine (Table I).

Pyrrolidines, Piperidines and a Hexahydroazepine from Glycols and Amines.—Speculation as to the course of the reaction involved in the formation of piperidines from glutaramides led to the development of another useful method for obtaining piperidines. As indicated in a later section, it seemed possible that the cyclic amines were formed from glycols and amines produced by the hydrogenolysis of the carbon to nitrogen bond in the amides



$$\mathrm{RHN}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{CH_2CH_2CH_2}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\mathrm{NHR} \longrightarrow 2\mathrm{RNH_2} +$$

$$\mathrm{HOCH_2(CH_2)_2CH_2OH} \longrightarrow \mathrm{(CH_2)_5NR} + \mathrm{RNH_2} + \mathrm{H_2O}$$

Since 1,5-glycols may be prepared readily by the hydrogenation of glutaric esters, it was decided to ascertain whether glycols would react with amines to give piperidines. The reactions were carried out under the same conditions as were used for hydrogenation of amides. The results of four such reactions are summarized in Table IV. It is seen that pentanediol-1,5 and its 3-methyl and 3-phenyl derivatives react with *n*-amyl-, benzyl- or phenethylamine to give yields of 70–75% of piperidines. This is the same order of magnitude as the yields obtained from amides or imides (Tables I and II).

The preparation of piperidines from glycols and amines is a rather more convenient method than by the hydrogenation of amides: first, because glycols are in general more easily purified and handled than amides, and second, because only one mole of amine is necessary for this reaction, whereas four moles of amine are necessary to prepare a glutaramide from the corresponding ester.

Pyrrolidines may be prepared in a similar manner. The data in Table IV shows that butanediol-1,4 reacted with phenethyl- and benzylamine to give yields of 71 and 76% of the corresponding pyrrolidines. These yields are similar to those previously obtained by the hydrogenation of N-phenethylsuccinimide and N-*n*-amylsuccinimide.

It was thought that the reaction of glycols and amines might occur under milder conditions than were necessary for the hydrogenation of amides. Consequently, phenethylamine and butanediol-1,4

TABLE IV

REACTION OF GLYCOLS WITH AMINES

Equimolecular amounts of glycol and amine were heated at 250° for one hour under 200–400 atm. of hydrogen, using 600–800 cc. of dioxane and 30–60 g. of CuCrO per mole.

Amine	Glycol	Moles	Yield of products, %
Phenethyl	Pentanediol-1,5	0.25[a]	76 1-Phenethylpiperidine 15 Phenethylamine
Benzyl	Pentanediol-1,5	.4	71 1-Benzylpiperidine
Benzyl	3-Methylpentanediol-1,5	.2	68 1-Benzyl-*d*-methylpiperidine 5.5 4-Methylpiperidine
n-Amyl	3-Phenylpentanediol-1,5	.1	73 1-*n*-Amyl-4-phenylpiperidine 3 4-Phenylpiperidine 14 Di-*n*-amylamine
Benzyl	Butanediol-1,4	.2	76 1-Benzylpyrrolidine 4 Benzylamine
Phenethyl	Butanediol-1,4	.15[b]	71 1-Phenethylpyrrolidine
Phenethyl	Butanediol-1,4	.15[c]	35 4-(N-Phenethylamino)-butanol-1 19 1-Phenethylpyrrolidine 43 Unchanged amine and glycol
Benzyl	Hexanediol-1,6	.22[d]	23 1-Benzylhexahydroazepine

[a] A 25% excess of amine was used, but this is disadvantageous. [b] Time of reaction was three and one-half hours. [c] 200° for half an hour. [d] One and one-half hours.

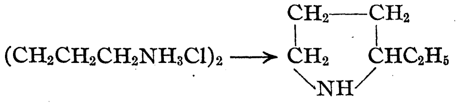
were heated at 200° for one-half hour, but the reaction was not complete. A yield of only 19% of 1-phenethylpyrrolidine was obtained, and 43% of the amine and glycol were recovered. A 35% yield of the amino alcohol formed by reaction at only one end of the glycol, was also obtained: $C_6H_5CH_2CH_2NHCH_2CH_2CH_2CH_2OH$. No more experiments along this line were carried out, but it is quite possible that by modifying the conditions, higher yields of amino alcohols of this type might be obtained.

It was of interest to determine whether or not hexanediol-1,6 would react with an amine to give a hexahydroazepine in the same manner as pentanediol-1,5 gives piperidines. It was found that benzylamine and hexanediol-1,6 reacted (Table IV) to give a 25% yield of 1-benzylhexahydroazepine. The structure of this substance was proved by removal of the benzyl group by treatment with copper–chromium oxide at 275°.

$$(CH_2)_6NCH_2C_6H_5 \xrightarrow[\text{CuCrO}]{H_2} (CH_2)_6NH + C_6H_5CH_3$$

The hexahydroazepine formed was characterized by the preparation of three derivatives which corresponded with those reported in the literature.

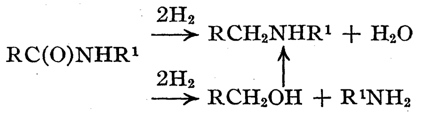
When a reaction should lead to a ring containing more than six atoms, rearrangements frequently occur resulting in the formation of five- or six-membered rings containing the extra atoms in a side chain. Thus Müller and Feld[18] found that on thermal decomposition 1,6-diaminohexane dihydrochloride gave 2-ethylpyrrolidine instead of hexahydroazepine.



Also, a rearrangement to give a 2,3 or 4-methylpiperidine might be possible. All of these possibilities are ruled out by the derivatives of the hexahydroazepine mentioned above. The structure of the 1-amylhexahydroazepine might be assumed to be proved through analogy with the 1-benzyl derivative. It was found to differ in properties from 1-*n*-amyl-4-methylpiperidine which was formed from the corresponding glutaramide. A sample of 1-amyl-2-methylpiperidine was prepared by alkylating 2-methylpiperidine with *n*-amyl alcohol and this was different from the 1-amylhexahydroazepine.

As was mentioned above the same yields of piperidines were obtained whether the glutaramide or an amine and a glycol were used. In the formation of the seven-membered ring, however, a substantially higher yield was obtained from the amide than from the amine and glycol.

Mechanism of Conversion of Amides to Cyclic Amines.—The conversion of an amide to an amine of the same carbon content may proceed either through hydrogenolysis of the oxygen to carbon bond in the amide or through hydrogenolysis of the carbon to nitrogen bond followed by interaction of the alcohol and amine so formed.



$$\begin{tikzcd}[column sep=small] & RCH_2NHR^1 + H_2O \\ RC(O)NHR^1 \arrow[ur, "2H_2"] \arrow[dr, "2H_2"'] & \\ & RCH_2OH + R^1NH_2 \arrow[u] \end{tikzcd}$$

There are no experimental observations available which definitely rule out one of these mechanisms as contrasted with the other. In support of the two-step process may be cited these facts. (1) Alcohols of the type RCH_2OH and amines of the type R^1NH_2 have been obtained as the result of the hydrogenation of amides. (2) Alcohols or glycols and amines react under the conditions used for the hydrogenation of amides to give amines in yields similar to those obtained directly from the amides. (3) Benzoylpiperidine is cleaved completely to toluene, piperidine and water far more rapidly than benzylpiperidine undergoes hydrogenolysis. This indicated that the primary cleavage in benzoylpiperidine is at the carbon to nitrogen rather than at the carbon to oxygen linkage. Against the two-step process may be cited the fact that ammonia does not react with glycols (at 250° over copper–chromium oxide in dioxane) to give good yields of the corresponding amines.

Since the hydrogenolysis of carbon to nitrogen bonds takes place under the same conditions as those effective for the breaking of carbon to oxygen bonds, it seems reasonable to assume that both types of reaction occur. Further studies in the reaction of alcohols and amines and of hydrogen with amides must be made before a definite conclusion can be drawn as to the relative importance of the two types of reactions.

Insofar as the formation of cyclic amines from open chain amides is concerned, it appears that hydrogenation precedes ring closure. There are two pieces of evidence which indicate that N-substituted glutaramides are not converted to imides. In the first place, di-N-*n*-amylglutar-

β,β-Dimethyl	Benzyl	250	9	53[f]	44[f,g]

[a] This product was washed with ethyl acetate, acetone and ether. [b] Recrystallized from 95% ethyl alcohol. [c] Recrystallized from 95% ethyl alcohol to which two volumes of acetone was added. [d] Recrystallized from acetone. [e] Recrystallized from 95% ethyl alcohol to which two volumes of ether was added. [f] The product was fractionated. [g] Recrystallized from a small amount of methyl alcohol.

amide was recovered unchanged after heating at 200° for eight hours, so apparently heat does not cause the formation of imides from glutaramides. Secondly, when one mole of diethyl-β,β-dimethylglutarate was heated with four moles of *n*-amylamine in a bomb at 250° (Table V), the same yields of imide and amide were obtained after heating either for one or for seven hours. Similar results were obtained with the same ester and benzylamine. Evidently none of the amide cyclicized during the extra hours of heating, and it would seem that the two products were probably formed by different reactions.

There appears to be no experimental observation that definitely answers the question as to whether the ring closure involves an aminoamide, an hydroxyamide, a diamine or a glycol and an amine. All of these reactions may occur under the conditions used for the conversion of amides to cyclic amines.

Hydrogenolysis of N-Substituted Piperidines.—The preparation of *pure* primary glutaramides is difficult. The N-monosubstituted glutaramides are readily prepared in high purity. Moreover, primary glutaramides are not as readily hydrogenated as are the substituted amides. Thus it is better to use N-substituted amides even though a piperidine is desired which contains no substituent on the nitrogen. This necessitates using an amine such as benzyl or phenethyl in which the carbon to nitrogen bond has been rendered liable toward hydrogenolysis by the presence of a phenyl group. The tendency of such amides and amines to undergo cleavage is shown in Table I by the formation of 19% piperidine along with 77% 1-phenethylpiperidine, 11% 4-methylpiperidine along with 70% 1-phenethyl-4-methylpiperidine and 16% 4-phenylpiperidine along with 65% 1-benzyl-4-phenylpiperidine.

Data are given in Table VII which indicate the conditions necessary for the cleavage of the amines. A comparison of these data with those in

TABLE VI

PREPARATION OF IMIDES FROM ACIDS

One mole of acid was heated with one mole of amine at 250° under 100–150 atm. of hydrogen using 350–400 cc. of dioxane per mole of acid.

Acid	Amine	Time, hrs.	Yield of products, % Amide	Imide
β-Phenylglutaric	Benzyl	7		62[a,b]
Glutaric	*n*-Amyl	6.5	14[c]	42[a]
β-Methylglutaric anhydride	Phenethyl	4	10[d]	58[d]
Succinic	Phenethyl	5.5		89[b]

[a] This product was fractionated. [b] Recrystallized from 95% ethyl alcohol. [c] Recrystallized from a mixture of equal volumes of 95% ethyl alcohol and acetone. [d] These products were partially separated by fractional crystallization from methyl alcohol. The yields given here are of the pure substances (see Experimental Part).

TABLE VII

HYDROGENOLYSIS OF 1-PHENETHYL- AND 1-BENZYLPIPERIDINES

Forty cc. of dioxane was used as the solvent in each experiment

Piperidine	Moles	Catalyst, g.	Time, hrs.	Temp., °C.	Yields, % Piperidine	Yields, % Unchanged material
1-Phenethyl	0.104	4CuCrO	4.3	250	18	68
1-Phenethyl	.104	4Ni	4	165	7	87
1-Benzyl	.118	4CuCrO	6	250	36	54
1-Benzyl	.149	7Ni	7	170	43	49

Table I would indicate that hydrogenolysis occurred more rapidly with the amides than with the piperidines.

Experimental Part

The reaction products from the hydrogenations were in general centrifuged and fractionated through a Widmer column. Low boiling basic compounds carried over in the dioxane fraction were recovered as hydrochlorides which were recrystallized from ethanol and ether. The various amines were characterized by their neutral equivalents and in most cases by the formation of solid derivatives. The hydrochlorides of all the piperidines and pyrrolidines except 4-phenylpiperidine were prepared. The properties and analyses of those substances which apparently have not been previously reported are given in Table VIII.

In a number of cases where separation could not be effected by fractionation, it was necessary to purify tertiary amines through the use of benzenesulfonyl chloride. In the case of 1-phenethyl-4-phenylpiperidine it was necessary to distil the amine away from the sulfonamide since the hydrochloride of the amine is insoluble in water. In a few cases the yield of secondary amine reported in the tables is based upon the yield of its benzenesulfonamide isolated. 4-Phenylpiperidine was separated from dibenzylamine by cooling the mixture in ice and salt.

The **1-benzyl-4-phenylpiperidine** from **di-N-benzyl-β-phenylglutaramide** gave the correct neutral equivalent of 251 and the hydrochloride gave the correct chlorine analysis, but it was contaminated with some substance apparently of the same molecular weight. The hydrochloride melted at 198–201° and the melting point was lowered by recrystallization. This substance when prepared by hydrogenating N-benzyl-β-phenylglutarimide gave a hydrochloride melting at 210–211°. The 1-benzyl-4-phenylpiperidine was purified by treatment of 8.8 g. with 3.0 g. of $C_6H_5SO_2Cl$ and 20 cc. of 10% sodium hydroxide solution. The benzenesulfonamide of the impurity was a red oil which was insoluble in ether, dilute hydrochloric acid and dilute sodium hydroxide. It was carried through the separation procedure (with appreciable mechanical loss, due to its insolubility) until the piperidine was in solution in dilute hydrochloric acid. At this point, it formed a lower insoluble layer which was separated. It did not crystallize. This treatment gave 7.6 g. of the pure piperidine which corresponded to a yield of 10.6 g. (0.042 mole) in the original fraction of 12.2 g. from 0.065 mole of amide. The yield was thus 65% of the theoretical. The hydrochloride now melted at 211–212°.

The principal fraction from the hydrogenation of di-N-*n*-amyladipamide distilled at 80–88° (9 mm.) and weighed 53.5 g. This was divided for purposes of preliminary investigation into two fractions: (1) 37.3 g., b. p. 80–88° (9 mm.), and (2) 16.2 g., b. p. 88° (9 mm.). Both fractions gave the pure phenyl isocyanate derivative of diamylamine, m. p. and mixed m. p. 78–79°. By titration, it was found that fraction (1) was 36% **1-*n*-amylhexahydroazepine** and 64% diamylamine. Fraction (2) was found to contain 89% of the hexahydroazepine and 11% of diamylamine. These figures indicated that 28.0 g., or 46%, of the hexahydroazepine, and 25.5 g., 45%, of diamylamine were formed in the reaction.

To separate these two substances 50.4 g. of fractions (1) and (2) were combined and treated gradually with 55.0 of benzenesulfonyl chloride and 185 cc. of 10% sodium hydroxide solution. On working up the reaction mixture in the usual manner, there was obtained 19.0 g. of 1-*n*-amylhexahydroazepine b. p. 94–95° (13 mm.). This corresponded to 21.0 g. in the original fraction or 34% of the theoretical. Forty-three and nine-tenths grams of the benzenesulfonamide of diamylamine was obtained which is 41% of the theoretical. That the 1-*n*-amylhexahydroazepine is not identical with either 1-amyl-2- or -4-methylpiperidine is shown by the difference in the refractive indices and the wide divergence in the melting points of the hydrochlorides (see Table VIII). The picrate of 1-*n*-amylhexahydroazepine melts at 109–110° (corr.).

The 25% excess of phenethylamine used in the preparation of 1-phenethylpiperidine[19] from amine and glycol was detrimental since the yield was not increased, and the excess amine contaminated the product.

The fraction from the reaction of **3-phenylpentanediol-1,5** and *n*-amylamine boiling at 133–137° at 2 mm. was found to contain 3% of **4-phenylpiperidine** and 73% of **1-*n*-amyl-4-phenylpiperidine.** Two grams of this fraction was treated with enough benzenesulfonyl chloride to react completely if all the fraction was 4-phenylpiperidine. After reaction was complete, the material was dissolved in ether and the unreacted tertiary amine extracted with dilute hydrochloric acid. The ether solution was dried and the ether evaporated, leaving 0.12 g. of the benzenesulfonamide of 4-phenylpiperidine, m. p. and mixed m. p. 108–109°, after one recrystallization. This amount corre-

sponds to 0.064 g. of 4-phenylpiperidine in 2.00 g. of the mixture, or 3.2%.

The following fractions were obtained from the reaction of **phenethylamine** and **butanediol-1,4** at 200°:

	B. p., °C.	M.	G.	Product
1	79– 81	9	7.8	43% Phenethylamine
2	110–119	9	10.6	1-Phenethylpyrrolidine + butanediol-1,4
3	175–179	9	10.1	35% 4-(N-Phenethylamino)-butanol-1

Fraction 2 was extracted three times with ether (15-cc. portions), the glycol being mostly insoluble. This ether solution of **1-phenethylpyrrolidine** was dried over sodium sulfate and filtered. Into the ether solution a stream of dry hydrogen chloride was passed. A liquid layer separated which solidified in an ice-bath. It was filtered and recrystallized, m. p. and mixed m. p. 159–170°.[11] The yield was 4.3 g. or 14%. This amount of hydrochloride corresponds to 3.8 g. of the free amine so that fraction (2) contained, by difference, 10.8 − 3.6 = 7.2 g. of butanediol-1,4, which would be 55% of the starting amount. Since, however, 35 + 14 = 49% of the glycol is accounted for in the two amines, it is evident that this makes a total of 104% of butanediol. The discrepancy is probably due to incomplete recovery of 1-phenethylpyrrolidine from fraction (2). Assuming that an amount of diol corresponding to the phenethylamine (43%) was unreacted, we obtain a yield of 23% for 1-phenethylpyrrolidine. The average of 14 and 23% is reported as the yield of the pyrrolidine in the table. The hydrochloride of the benzoate of 4-(N-phenethylamino)-butanol-1 was prepared by heating 1.0 g. of the amino alcohol with 1.0 g. of benzoyl chloride at 175° for 1 hour.[20] On cooling, the product was recrystallized from absolute alcohol and ether.

The main fraction from the reaction of **benzylamine** with **hexanediol-1,6** distilled at 119–133° (9 mm.) and weighed 12.5 g. Twelve grams of this fraction was treated with 20.0 g. of benzoyl chloride and 100 cc. of 10% sodium hydroxide and shaken for thirty minutes. It was then warmed on the steam-bath for half an hour to hydrolyze all the benzoyl chloride. On cooling, the alkaline solution was extracted three times with ether, and the unreacted amine extracted from the ether with 5% hydrochloric acid. This solution was made alkaline, the insoluble layer separated and the aqueous layer extracted three times with ether. The ethereal solution of the amine was dried, the ether distilled and the residue fractionated under reduced pressure. Eight and two-tenths grams of **1-benzylhexahydroazepine** was obtained, b. p. 131–134° (13 mm.). This corresponded to 8.55 g. in the original fraction, or a yield of 23% of the theoretical. On refractionation, this substance distilled at 130–132° (12 mm.).

To prove the structure of this substance, the benzyl group was removed by treatment with copper–chromium oxide at 275° for six and one-half hours. Five and three-tenths grams of the material in 9.7 cc. of dioxane was hydrogenated in a small bomb designed for quantitative hydrogenations. One and four-tenths moles of hydrogen per mole of compound instead of the calculated value of 1.0 was absorbed. This excess of hydrogen was undoubtedly due to reaction of the dioxane with hydrogen, which proved to be very detrimental in this case.

After all the material was distilled which would come over at atmospheric pressure (with the oil-bath at 20°), there remained 5.1 g. of high boiling residue, of which 2.0 g. distilled between 130 and 217° at 2 mm. The residue was even higher boiling. This material was probably formed by alkylation of the hydroxyl groups, formed in the reaction of dioxane with hydrogen, with the amino group in the hexahydroazepine formed.

---

(20) McElvain, THIS JOURNAL, **48**, 2182 (1926).

However, when dry hydrogen chloride was passed into the dioxane fraction and the solvent removed under reduced pressure, 0.25 g., 6.6% of **hexahydroazepine** hydrochloride remained. After two recrystallizations it melted at 229–231° (corr.). Müller and Sauerwald give the melting point of this substance as 236° (corr.). Von Braun and Goll give the melting point as 222° while Wallach gives 221–224°. This substance could not be either 2-, 3- or 4-methylpiperidine hydrochloride because samples of the 2- and 4-derivatives were available for comparison and 3-methylpiperidine hydrochloride melts at 171–172°. Also, it apparently is not 2-ethylpyrrolidine hydrochloride because this substance is described as a hygroscopic solid which melts below 100°.

The *p*-toluenesulfonamide melted at 75° in agreement with the value of 75° reported in the literature by Ziegler,[21] and the chloroplatinate melted at 199° (corr.). Müller and Sauerwald[22] gave the melting point at 197° (corr.).

A sample of 2-ethylpyrrolidine was prepared in this Laboratory by Mr. James Rainey, by the hydrogenation of 2-acetylpyrrole. The picrate of this substance melted at 85–86° and the chloroplatinate at 190–191°. Both of these melting points agree with those reported by Müller and Wachs.[23] The chloroplatinate apparently was pure since the melting point was not raised by further recrystallization. The melting point was not depressed by mixing with the chloroplatinate of hexahydroazepine, however. The mixed melting point was 193°.

Preparation of Amides and Imides

In making simple amides, the ester was treated with gaseous ammonia in a bomb at 250° (Table V). The ammonia was introduced into a bomb as a liquid. The ester was placed in a test-tube in a bomb, and the latter was cooled in an ice–calcium chloride bath for about three hours. Then liquid ammonia was run into the bomb slowly until the interior was well cooled. The ammonia was then run in rapidly and the bomb closed immediately. No hydrogen was placed in the bomb in these experiments. When either an amide or imide is prepared (under pressure) from the free acid (Table VI), it is necessary to use dioxane as a diluent for the water formed.

If the amides prepared as above were solids in the bomb they were removed, cooled, filtered and recrystallized from the solvent indicated in Table V. The ethyl alcohol and excess of amine from the filtrate of the reaction product were removed under reduced pressure and the residue purified by recrystallizing. The products which were present as liquids when the bomb was opened were purified by fractionation.

N-Benzyl-β-phenylglutarimide and N-*n*-amylglutarimide were purified by fractionation through a Widmer column. N-Phenethyl-β-methylglutarimide was separated from the amide by fractional crystallization from methyl alcohol. Since the imide is more soluble than the amide it could not be freed entirely from the latter.

The amide present as an impurity was neither converted into the imide nor hydrogenated under the conditions used (Table II), and was recovered unchanged. Some of the amide was insoluble in the dioxane, so when the bomb was opened after hydrogenation of this compound reported in Table II, the catalyst and amide were filtered off. The amide was dissolved immediately in 95% ethyl alcohol and the catalyst filtered off. The two filtrates were combined and fractionated. There was obtained 18.7 g. of 1-β-cyclohexylethyl-4-methylpiperidone-2, b. p. 158–162° (3 mm.). The residue from the first fractionation was 3.9 g. On recrystallization from methyl alcohol it melted at 180–185°, and mixed with di-N-phenethyl-β-methylglutaramide it melted at 186–188°. Since 30.1 g. of the mixture of amide and imide was used, 13% of the mixture was amide. Thus 26.2 g. of imide was present in the mixture, and the yield of piperidone calculated on this basis was 74%.

All the **amides, and the imides of β,β-dimethylglutaric acid,** were prepared by heating the corresponding diethyl ester (1 mol) with four moles of the amine at temperatures of from 180–250° under 125 atm. of hydrogen. Twice the calculated amount of amine is necessary because some of it is alkylated by the ethyl alcohol set free.[24] The esters were previously treated with about 5% of their weight of Raney nickel under 100 atm. of hydrogen at 150° for about six hours to remove any impurities which might poison a catalyst, and to ensure the purity of the amides. It was found that in most cases a temperature of 200° was sufficient for the preparation of amides, but since there were a few exceptions it was considered preferable to carry out the reactions at 250°. Also, most of the reactions were probably complete in much less than the time indicated, but since longer heating does no harm, no particular attempt was made to stop the reactions as soon as they were complete.

β-Phenylglutarimide, m. p. 174–175° (from methanol), was prepared by the method of Vorländer[15] in yields of 62 to 72%. β-Methylglutarimide, m. p. 144–145° (from acetone and ether), was similarly prepared in 72% yield.[13]

Preparation of Acids, Esters and Glycols

Diethyl glutarate was prepared by the hydrolysis of ethyl methylene–dimalonate with 38% sulfuric acid.[25] By this procedure 67–75% of the ester could be obtained directly. Three hundred thirty-two grams (1.0 mole) of the ester and 532 g. of 38% sulfuric acid (prepared from 330 cc. of water and 110 cc. of concentrated sulfuric acid, sp. gr. 1.84) were placed in a 2-liter round-bottomed flask and refluxed vigorously for ten hours. The contents of the flask should be shaken vigorously several times until refluxing starts. Otherwise the bottom layer may become greatly superheated, causing the material to boil out through the condenser. The solution became clear in six hours, but if the reaction was stopped at this point the yields were greatly reduced. When the contents of the flask had cooled to room temperature, the oily layer was separated and the aqueous layer extracted three times with 150-cc. portions of benzene. The benzene and ester were combined, dried over anhydrous sodium sulfate and the benzene distilled at atmospheric pressure. The residue was placed in a flask under a Widmer column and heated in an oil-bath at 150° under reduced pressure until the evolution of carbon dioxide ceased. The ester was then fractionated. This distillation is accompanied by con-

siderable foaming so a column of some sort is necessary. The material boiling at 104–108° (8 mm.) was collected. On refractionation the ester boils at 105–106° (8 mm.). The refractionation of four runs of the size described above gave 563 g. (75% of theoretical) of pure diethyl glutarate, b. p. 105–106° (8 mm.).

β-Phenylglutaric acid was prepared from benzylidenebismalonic ester by hydrolysis with hydrochloric acid.[26] The reaction was carried out in a manner similar to that described in "Organic Syntheses" for the preparation of tricarballylic acid.[27] Three hundred and seventy grams (0.9 mole) of the ester, 125 cc. of water, and 125 cc. of concentrated hydrochloric acid were placed in a 2-liter round-bottomed flask carrying a Widmer column and a condenser set for downward distillation. The mixture was boiled at such a rate that the temperature at the head of the column remained at 80–100°. In this manner the alcohol was removed as formed, but very little water was allowed to distil. This was continued until the solution became clear and no more carbon dioxide was evolved (thirty hours). Twice during this time further 100-cc. portions consisting of 50 cc. of water and 50 cc. of concentrated hydrochloric acid were added.

The flask was cooled in an ice-bath and the crystals were filtered and dried by suction. The dried acid was dissolved in 200 cc. of hot acetone, treated with charcoal and filtered. Half the acetone was distilled and an equal volume of benzene added. One hundred twenty-five grams (67%) of pure β-phenylglutaric acid separated, m. p. 139–140°. (Melting points of 138 and 143° are given in the literature.) The filtrate gave an additional 44.5 g. of acid, m. p. 138–139° (24%). The total yield was 91% of the theoretical.

In preparing diethyl β-phenylglutarate the above procedure was followed except that the crude acid was not purified. Four hundred five grams (1 mole) of benzylidenebismalonic ester was hydrolyzed as above. To the crude, dry acid was added a mixture of 460 cc. of 95% ethyl alcohol and 25 cc. of concentrated sulfuric acid. The mixture was refluxed for six hours on the steam-bath. Then the excess alcohol and the water formed were removed under reduced pressure by warming on the steam-bath until the temperature of the residue was 50° (20 mm.). Then 200 cc. of absolute ethyl alcohol and an additional 10 cc. of concentrated sulfuric acid was added and the mixture refluxed for three hours. The excess alcohol was removed under reduced pressure and the residue poured into water. The oily layer was separated and the aqueous layer extracted twice with ether. The ether solution of the ester was extracted twice with 5% sodium carbonate solution, twice with water and dried over anhydrous sodium sulfate. The ether was removed at atmospheric pressure and the residue distilled *in vacuo*. One hundred sixty grams of ester was obtained (85%) which distilled at 143–145° (1.5 mm.); von Braun and Weissbach[28] report the boiling point of this ester as 148–150° at 0.5 mm.

β-Methylglutaric acid was made as by Boorman, Linstead and Rydon except that the triethyl 2-methylpropanetricarboxylate obtained as an intermediate was purified before hydrolysis. The triester b. p. 117–119° was obtained in 80–85% yield. The yield of acid m. p. 86.5–87.5° was 80%, based on the triester used.[29]

Diethyl-β-methylglutarate was prepared in a manner analogous to that used in the preparation of diethyl-β-phenylglutarate, in a yield of 90% from the pure acid. It boils at 117–118° (13 mm.).

Diethyl-β,β-dimethylglutarate was obtained through the kindness of Dr. Roger Adams.

β-Methylglutaric anhydride was prepared by the method of Darbishire and Thorpe[30] in a yield of 92%, b. p. 141–142° (8 mm.) and m. p. 41–43°.

The glycols were prepared by the hydrogenation of esters.[31]

Summary

Glutaramide gave a 70% yield of piperidine by treatment with hydrogen under 200–400 atm. pressure over copper–chromium oxide at 250° in dioxane solution. Eight N-monosubstituted amides of glutaric, β-methyl-, β-phenyl- and β,β-dimethylglutaric acid in which the substituents on the nitrogen atom were the *n*-amyl, benzyl or phenethyl group, gave 65–80% yields of piperidines substituted in the 1 and 4 positions. Glutarimides gave yields of piperidines of the same order of magnitude. The di-N-pentamethylene amides of glutaric, β-methyl- and β,β-dimethylglutaric acid gave rise to 45–71% yields of di-N-pentamethylenecadaverines.

Under the same conditions two 2-pyrrolidones and one 2-piperidone have been converted to the corresponding pyrrolidines and piperidine in yields of 88–96%.

Primary amines have been found to react with 1,4- or 1,5-glycols under the conditions used for the hydrogenation of amides, to give 68–77% yields of pyrrolidines or piperidines.

The hydrogenation of di-N-*n*-amyladipamide was shown to give a 45% yield of 1-*n*-amylhexahydroazepine. Thirty-four per cent. of this material was isolated in the pure state from the di-*n*-amylamine which was formed to the extent of 41%.

Treatment of hexanediol-1,6 with benzylamine gave a 23% yield of 1-benzylhexahydroazepine which was converted to hexahydroazepine by treatment with hydrogen over copper–chromium oxide at 275°.

Two N-substituted succinimides and one glutarimide have been converted to the corre-

sponding pyrrolidone-2 or piperidone-2 by treatment with hydrogen over Raney nickel at 200–220°.

When diethyl glutarate, or diethyl β-methyl- or β-phenyl-glutarate, was heated with four moles of a primary amine at 250°, amides were formed to the extent of 83–94%. When diethyl β,β-dimethylglutarate was so treated, yields of 39–71% of the glutarimides were formed.

Glutarimides were formed in yields of 42 to 62% by heating glutaric, β-methyl- or β-phenylglutaric acid with one mole of primary amine at 250°. This is appreciably less than the yields of succinimides obtained from succinic acid and primary amines.

An improved method for preparing diethyl glutarate has been developed.

The Rates of Alcoholysis of Acyl Chlorides

G. E. K. BRANCH AND A. C. NIXON

We have recently published the results of a study[1] in which we investigated the effect of the para-substitution of certain groups on the rates of alcoholysis of triphenylmethyl chlorides. In this paper we pointed out that predictions concerning rates in which I and T effects are used merely on the direction of electrical forces tending to prevent or assist the separation of an ion are not necessarily sound, although the actual results we obtained with the trityl chlorides could have been predicted on this basis. As we strongly suspected that this crude method of using I and T effects would be entirely erroneous when applied to the alcoholysis of acyl chlorides, we have used an identical method to measure the rates of alcoholysis of some acyl chlorides. The compounds studied are mainly para substituted benzoyl chlorides but measurements on some aliphatic compounds are also included.

We employed the same solvent as before, namely, a mixture containing by volume at 25°, 60% ether and 40% absolute ethyl alcohol. The reactions were followed by observing the rate of change of the electrical conductivity of solutions containing acid chloride. This method was used on the assumption that the hydrochloric acid produced had a much higher conductivity than any of the other constituents of the solution and hence the concentration of the acid could be determined from the conductivity of the solution by reference to a previously determined conductivity–concentration curve for hydrochloric acid. The concentration of the organic chloride at any time could then be determined as the difference between the hydrochloric acid concentration at that time and the final hydrochloric acid concentration after completion of the reaction. This method is very suitable for measuring low concentrations. We used concentrations around 0.001 *M*, and could follow the reactions accurately to more than 95% completion.

The reaction was found to be irreversible at the concentrations used since the conductivity of a 0.001 *N* hydrochloric acid in the alcohol–ether mixture was found to be unchanged by the addition of an equivalent quantity of ethyl *p*-nitrobenzoate. The irreversibility of the reaction has been shown more definitely by Norris and his co-workers,[2] who showed that ethyl *p*-nitrobenzoate was unaffected when hydrogen chloride gas was bubbled through the molten ester. Their tests also showed the absence of side reactions.

A detailed description of the method and apparatus used is given in our previous communication.[1] The method consisted essentially of mixing 20 cc. (25°) of alcohol with 30 cc. (25°) of an ether solution of the chloride at the bath temperature and then measuring the resistance of the solution at convenient intervals. The cell resistance was determined by means of the usual Wheatstone bridge arrangement, an a. c. galvanometer being used as a null instrument.

Preparation of Materials

(a) Alcohol and Ether.—These were prepared as reported previously and had within limits of error the same physical constants.

[2] J. F. Norris, E. V. Fasce and C. J. Staud, *ibid.*, **57**, 1415 (1935).

(b) Acid Chorides.—These were obtained, whenever available, by distillation and/or crystallization of the Eastman product. In the other cases they were prepared from the pure acids by use of thionyl chloride. The melting and/or boiling points are given below. The boiling points are at 760 mm. unless otherwise specified.

Chloride	°C.
Trichloroacetyl	117–118 (b. p.)
Dichloroacetyl	108 (b. p.)
Chloroacetyl	106 (b. p.)
Acetyl	55 (b. p.)
p-NO_2-benzoyl	71.5 (m. p.)
p-F-benzoyl	70–71 (6 mm.), 8–9 (m. p.)
p-Br-benzoyl	37.5 (m. p.)
p-I-benzoyl	64.5 (m. p.)[a]
p-CH_3-benzoyl	70–71 (4 mm.)
p-CH_3O-benzoyl	21 (m. p.), 144 (b. p.)

[a] The melting points given for this compound in Beilstein range from 71 to 83° but repeated crystallization from hexane and sublimation did not change this value. It was prepared from two different lots of Eastman *p*-I-benzoic acid (m. p. 278°). It yielded 99.9% of the theoretical quantity of the methyl ester (m. p. 114.5–115.5°).

All the acid chlorides gave, within the limits of error, the theoretical quantity of hydrochloric acid upon alcoholysis as measured by conductivity.

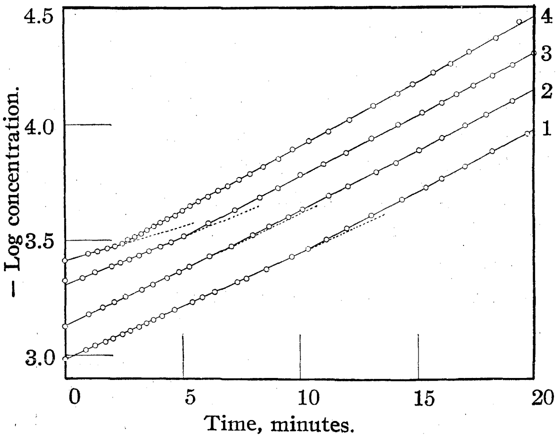

Fig. 1.—The alcoholysis of *p*-nitrobenzoyl chloride. The initial concentrations were (1) 0.00104 *M* *p*-NO_2-benzoyl chloride, (2) 0.000474 *M* *p*-NO_2-benzoyl chloride, (3) 0.000474 *M* *p*-NO_2-benzoyl chloride, 0.000493 *M* HCl, (4) 0.000388 *M* *p*-NO_2 benzoyl chloride, 0.001636 *M* HCl. The points for run (2) have been lowered by 0.2 unit. The curves are ruled lines, the dotted curves being the continuations of the ruled lines through the earlier points.

Kinetics

When the logarithms of the concentrations of the acid chlorides were plotted against the elapsed times, the straight lines characteristic of unimolecular and pseudo-unimolecular reactions were not obtained for the aromatic chlorides. Instead a plot was obtained in which the earlier points fall on one straight line and the later points on another straight line of slightly greater slope, the transition between the two being sharp. The curves in Fig. 1 for *p*-nitrobenzoyl chloride are typical examples. In Fig. 1 the negative logarithms have been plotted, so that the slopes have the same signs as unimolecular rate constants. It would appear that after some time the reaction settles down to a simple pseudo-unimolecular type. We have therefore used the final slopes multiplied by 2.303 for comparing the relative rates of reaction of the various acid chlorides. Norris and his co-workers[2] using 100% alcohol and higher concentrations of acid chlorides found the reactions to be pseudo-unimolecular over their entire course. Our conditions differ from those of Norris and co-workers since we diluted the alcohol with ether and used much smaller concentrations of acid chloride. The difference in the kinetics observed probably arises from the fact that under the conditions employed by Norris considerable hydrochloric acid had already been formed at the time of even the earliest measurements. Thus in the table given by Norris, Fasce and Staud[2] the concentration of hydrochloric acid at the time of the first measurement is 0.005 *N*, while in our experiments the first measurements are only about a hundredth of this value and the final concentrations of hydrochloric acid do not exceed 0.0021 *N*. The conditions used by Norris and co-workers, resulting as they do in simpler kinetics, are better than ours for obtaining relative rates. On the other hand, our conditions might shed some light on the beginning kinetics of the reaction. However, we do obtain approximately the same values for the relative rates of reaction as did Norris for those compounds which are common to both investigations (see Table II).

In seeking an explanation of the effect we must first eliminate the possibility that it is due to experimental error. The most obvious explanation would be that it is due to a lowering of the temperature on mixing the two solutions which would result in a smaller rate at the beginning of the reaction; however, this explanation is not tenable since the effect occurs with compounds whose reactivity is so small that several hours elapse before the final rate is attained. It could be caused by differences between the conductivities of the reaction mixture and those of the standard hydrochloric acid solutions having the same concentrations of hydrochloric acid. These differences might be due either to the conductivities of the acid chloride and ester or, more likely, to their effects on the conductivity of hydrochloric acid. The conductivity of the ester and its effect on the conductivity of hydrochloric acid is easily shown to be quite negligible, at the concentrations we employ, by direct test; but it is impossible to determine directly the effect of the acid chloride since it begins to react immediately. But, irrespective of any effect of this kind, near the end of the reaction the concentration of acid chloride is so small that its effect on the conductivity must be negligible and the observed conductivities must be correct. If the reaction is strictly first order, an extrapolation of the later portion of the curve to zero time should give the initial concentration of the acid chloride, whatever errors had been introduced in the earlier measurements. Such an extrapolation always gives an erroneously high value of the initial concentration. This shows that a real delay in the formation of hydrochloric acid occurs in the earlier stages of the reaction. In the case of acetyl chloride in which no variation from first order was observed, this extrapolation gives the correct value for the initial concentration of acid chloride.

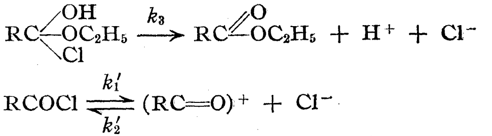
It is unlikely that the delay could be caused by impurities in the solvents such as peroxide or water since runs performed immediately after careful redistillation of the alcohol and ether gave the same results. It is also improbable that it is due to an impurity in the acid chloride since recrystallization produced no change in the effect and the addition of a small amount of the most likely impurity, the organic acid, similarly produced no change.

p-Nitrobenzoyl chloride was selected as a typical compound to use in investigating the rate changing effect and numerous runs were made with this compound under varying conditions. The average value of the constants from the initial slopes for ten runs at concentrations varying between 0.004 to 0.0021 molal was 0.1103 reciprocal minutes, having a mean deviation of 2.5% with a maximum deviation of 4.8%, while the average value for the final constant in 14 runs in the same concentration range was 0.1223 reciprocal minutes, with a mean deviation of 2.0%, the greatest deviation being 3.6%. The position of the transition point decreased from 78% completion in the most dilute solution to 31% completion for the most concentrated solution. The average values of the final constants include those of four runs in which hydrochloric acid was added initially; the values of the initial constants for these runs are not included in the former average. Hydrochloric acid has a slight catalytic effect on the reaction, not noticeable in a single run but appearing as a slight increase in the values of the final rate constants as the initial concentration of either acid chloride or hydrochloric acid is increased. Thus five runs with *p*-nitrobenzoyl chloride at 25° having an average concentration of 0.0008 *M* have an average value for k_f of 0.1205, whereas five runs having an average concentration of 0.0019 *M* show an average value for k_f of 0.1249.

When hydrochloric acid is added initially the initial rate is decreased but the final rate is attained much earlier in the reaction. This is illustrated by plots 2 and 3 in Fig. 1. In run 3 the initial concentration of *p*-nitrobenzoyl chloride was 0.000474 *M* and of hydrochloric acid 0.000493 *M*, which gave an initial constant of 0.088 and a final constant of 0.120, the change occurring at 29% completion, whereas run 2 which started with an identical quantity of acid chloride but no hydrochloric acid gave a value of 0.114 for the initial constant and 0.119 for the final constant, the change occurring at 44% completion. With larger proportions of hydrochloric acid the effect was more pronounced; run 4, in which the initial concentration of *p*-nitrobenzoyl chloride was 0.000388 *M* and of hydrochloric acid 0.001636 *M*, gave 0.069 for the value of the initial constant and 0.127 for the final constant, the transition occurring at 15% completion.

We believe that the results given above may be interpreted on the basis of a mechanism which involves two reaction paths for the acid chloride. This may be expressed as follows

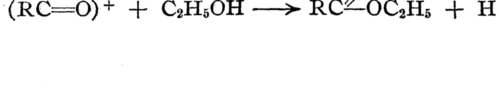
(1)



$$\mathrm{RCOCl} + \mathrm{C_2H_5OH} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{RC}\begin{matrix}\diagup\mathrm{OH}\\ -\mathrm{OC_2H_5}\\ \diagdown\mathrm{Cl}\end{matrix}$$

$$\mathrm{RC}\begin{matrix}\diagup\mathrm{OH}\\ -\mathrm{OC_2H_5}\\ \diagdown\mathrm{Cl}\end{matrix} \xrightarrow{k_3} \mathrm{RC}\begin{matrix}{/\!\!/}\mathrm{O}\\ -\mathrm{OC_2H_5}\end{matrix} + \mathrm{H^+} + \mathrm{Cl^-}$$

(2)



$$\mathrm{RCOCl} \underset{k_2'}{\overset{k_1'}{\rightleftharpoons}} \mathrm{(RC{=}O)^+} + \mathrm{Cl^-}$$

$$\mathrm{(RC{=}O)^+} + \mathrm{C_2H_5OH} \xrightarrow{k_3'} \mathrm{RC}\begin{matrix}{/\!\!/}\mathrm{O}\\ -\mathrm{OC_2H_5}\end{matrix} + \mathrm{H^+}$$

If the reaction follows the mechanism outlined above the rate of formation of products would be given by the equation

$$dP/dt = k_1(A)k_3/(k_2 + k_3) + k_1'(A)k_3'/(k_2' + k_3')(\mathrm{Cl}^-)$$

where (A) represents the concentration of acid chloride at any time after the intermediates have reached a steady state concentration. The first term on the right-hand side of the equation represents rate of formation of products through path (1) and the second term the contribution through path (2). The formation of products through path (1) increases in rate until a steady state concentration ratio of intermediate to reactant is reached, the value being $k_1/k_2 + k_3$. If the reaction forming the intermediate, and its reverse, are catalyzed by hydrogen ion but the change from intermediate to product is not, the period over which the velocity constant for path (1) increases is prolonged. Constancy is reached when k_3 becomes negligible with respect to k_2, and $k_1/k_2 + k_3$ becomes equal to K_e, the equilibrium constant for the change of reactant to intermediate. There is thus a limited catalysis by hydrogen ion as is shown by the trend in the final rate constants with increase in final concentration of hydrochloric acid. The final rates which we have obtained are probably a little lower than the maximum rates beyond which the reaction is not increased by acid. The contribution to the reaction by the second path diminishes with hydrochloric acid, and eventually is negligible. The reaction by path (1), were it the only source of electrolyte, would show a short induction period, followed by a more prolonged approach to a maximum rate. The induction period is masked by the reaction by path (2), which is then at its maximum, and the slow rise to a maximum rate of path (1) is to some extent compensated by the falling off in the rate by path (2). These factors tend to make the change from one value of $d \ln c/dt$ to another abrupt. Further, the vagaries of $d \ln c/dt$ that may exist in the earlier part of the reaction are not observable, as the accuracy is not sufficient to allow its evaluation between adjacent measurements, and one is reduced to using the slopes of the best straight lines drawn through the several points on the curve of $\log c$ against time. The apparent first order character of the earlier portion of the reaction is best considered fictitious. We do, however, believe that the lines shown in the figure are drawn through a sufficient number of points to warrant the statement that the earlier part of the reaction is slower than the later part beyond any reasonable doubt. The first order rate constants, heats of activation and probability factors which we obtain by ignoring the first part of the reaction are those for the reaction by path (1). If our theory is correct, Norris and his co-workers must also have obtained the rate constants for the reaction by path (1).

The Effects of Substituent Groups

The first order final rate constants at 0 and 25° in reciprocal minutes are given in columns 2 and 3 of Table I for all compounds for which these quantities could be obtained. The table also gives the heats of activation and the logarithms of the probability factors in the Arrhenius equation, $k = Ze^{-E/RT}$.

Table I

Reaction Rates and Heats of Activation

The values of $\log Z$ were calculated by the use of the equation $\log Z = \log k^{25} + E/2.3\,KT$, in which k^{25} is in reciprocal seconds.

Chloride	k^0, min.$^{-1}$	k^{25}, min.$^{-1}$	E, cal.	Log Z
Trichloroacetyl	(>5)	.....	....	...
Dichloroacetyl	(>5)	.....	....	...

p-F-benzoyl	1.1	..	.76
Benzoyl	1.0	1.0	1.0
p-CH$_3$-benzoyl	0.60	0.78	4.1
p-CH$_3$O-benzoyl	.49	.81	(>90)

From the data of Table I we have constructed Table II which gives the rates of alcoholysis, at 25°, relative to benzoyl chloride. In column 3 are given the values determined by Norris and co-workers, of the relative reactivities of a number of the same acid chlorides for the reaction in absolute alcohol. It also gives, in column 4, the rates of alcoholysis, relative to triphenylmethyl chloride, of a number of para substituted triarylmethyl chlorides the substituent groups of which are the same as the groups substituted in the benzoyl chlorides, the compounds in each row having the same substituent. Thus the rate of alcoholysis of *p*-nitrotriphenylmethyl chloride relative to that of triphenylmethyl chloride is put in the same row as the relative rate of *p*-nitrobenzoyl chloride. We have taken diphenylmethyl chloride as the analog of acetyl chloride.

It is noticed that the order we have obtained for the relative rates of alcoholysis of the acyl chlorides parallels the order obtained by Norris, except that in our solvent *p*-methoxybenzoyl reacts less rapidly than *p*-methylbenzoyl chloride, while in absolute alcohol the two reactions have approximately the same rate.

A comparison of columns 2 and 4 in Table II shows that a para substituent affects the alcoholysis of aryl acid chlorides and triarylmethyl chlorides in opposite ways. Groups that increase the rates of alcoholysis of the acid chlorides decrease those of trityl chlorides. In our preceding paper we have shown that in the trityl chlorides the influence of the para substituent follows the ability of the group to transfer a positive charge from the methyl carbon atom to the other parts of the molecule. In this way the groups assist the removal of chloride ion, and increase the rates of alcoholysis. The alcoholysis of a chloride involves not only the removal of chloride ion, but also the addition of alcohol. The influence of the group on the addition of alcohol may be opposite to its effect on the removal of chloride ion, and may be the predominant factor governing the relative rates of alcoholysis. The existence of these two factors is obvious in our suggested equation for the rates, rate = $K_e k_3 A$, in which K_e is the equilibrium constant for an addition of alcohol and k_3 the rate constant for the decomposition of the addition compound into hydrochloric acid and ester. The effect of a para substituent group on k_3 must be assumed to be in the same direction as its effect on the alcoholysis of a trityl chloride, though its magnitude may be much less, as the removal of the chloride ion is largely assisted by the tendency of the unshared electrons of the oxygen atoms to relieve the lack of electrons induced on the carbonyl carbon atom by the removal of chloride ion.

The effect of a para substituent group on K_e is best understood if one uses the combination formula,   instead of the classical formula  The above resonance stabilizes the acid chloride, and does so to a greater degree the more stable the internally ionized structures,   etc., are. In this way the resonance decreases K_e, as it is absent or negligible in the addition compound. Any para substituent which by the direction of its group dipole or by a resonance increases the stability of the structure  decreases the value of K_e. Examples of such groups are CH_3 and OCH_3. On the other hand, strongly negative groups increase the value of K_e. In this way the effect of a para substituent on K_e is opposite to its effect on the velocity constant of alcoholysis of a trityl chloride, or on k_3.

Whether the effect of a para substituent on K_e or on k_3 will be the predominant factor in the alcoholysis can only be decided by experiment. Our experiments show that the first factor is predominant for groups having effects within the range studied. Outside of this range it is possible for the influence on k_3 to become the predominant factor, in which case the order of alcoholysis rates of the acid chlorides would follow those of the trityl chlorides. This possibility is suggested in our results. The increase of rate from *p*-methylbenzoyl chloride to *p*-nitrobenzoyl chloride is thirty-fold, the increase in rate from *p*-nitrotriphenylmethyl chloride to *p*-methyltriphenylmethyl chloride is somewhat larger, about four hundred-fold, but the increase of rates from *p*-methoxy to *p*-methylbenzoyl chloride is only 20% which is very much smaller than the twenty-fold increase from *p*-methyltriphenyl chloride to *p*-methoxytriphenylmethyl chloride. Under the conditions used by Norris and his co-workers *p*-methoxybenzoyl chloride reacts as rapidly as *p*-methylbenzoyl chloride.

We have avoided consideration of ortho groups.

In these derivatives the substituent and reacting groups are brought into very close proximity, and what might be called O-effects are introduced. Norris' results and previous work on so-called "steric hindrances" indicate that O-effects are greatly enhanced by duplication. The alcoholysis rates of 2,4,6-trisubstituted benzoyl chlorides[3] have entirely different orders of magnitude to those of the monosubstituted derivatives. These trisubstituted benzoyl chlorides may react either very much faster or very much slower than the monosubstituted compounds.

The work on the trityl chlorides shows that the phenyl group can lower the positive potential of an adjacent atom more than the methyl group can. Assuming that the addition of alcohol is still the predominant factor, the alcoholysis rates of aliphatic acid chlorides should be faster than those of the aromatic. In chloroacetyl chloride the potential energy of the internally ionized form,  $ClCH_2\overset{+}{C}\left\langle\begin{matrix}O^-\\Cl\end{matrix}\right.$, is increased by the dipole of the α-chlorine atom, its + pole being directed toward the carbonyl carbon atom. This decreases the resonance, and increases the rate of alcoholysis. Further introduction of chlorine atoms should still further increase the rate. These relationships were found, except that di- and trichloroacetyl chlorides reacted so rapidly that it was impossible to determine which was the more reactive.

Heats of Activation

The heats of activation given in Table I were calculated from the values of the final rate constants determined at 0 and 25° by solving for E in the equation $\ln k = \ln Z - E/RT$.

There is a rough correlation between low activation energy and rapid reaction in the alcoholysis of the acid chlorides. In the aromatic compounds the differences in the rates cannot be attributed only to the differences in the heats of activation. In general the differences in the rates are much smaller than would be expected from the differences in the activation energies. This can be seen by comparing the probability factors (Z). These show a trend, being higher for the slower reactions. For instance, if we divide the reactions into four classes, (1) the very fast reaction, that of p-nitrobenzoyl chloride, (2) the moderate reactions, those of para Cl, Br and I benzoyl chlorides, (3) the slow reactions, those of p-F and benzoyl chlorides, and (4) the slowest reactions, those of p-CH_3 and OCH_3, the average values of log Z for these classes are 5.5, 6.3, 7.2 and 8.4. Although errors accumulate in the determination of Z, this trend lies well beyond the experimental limits. In the alcoholysis of the trityl compounds this trend is not noticeable, the figures for the corresponding compounds, in that series, being 8.4, 7.5, 7.9 and 8.0. (The value for the methoxy compound was not obtained.) For acetyl chloride the value of log Z is 7.4, that is, the value is much higher than that of the slower reacting p-nitrobenzoyl chloride. The value of E is also greater for acetyl chloride than it is for the nitrobenzoyl chloride, the difference being greater than any likely experimental error.

The values of Z for the alcoholyses of the acid chlorides are much less than those usually found for reactions of ions with neutral molecules. The alcoholyses of acid chlorides belong to Moelwyn-Hughes' class of slow reactions.

Summary

The rates of alcoholysis of several acyl chlorides have been measured, at great dilutions, in a mixture of 60% ether and 40% alcohol.

The kinetics of the reaction and the relative reactivities of the acyl chlorides are discussed.

Thermal Data on Organic Compounds. XVII. Some Heat Capacity, Entropy and Free Energy Data for Five Higher Olefins[1]

BY GEORGE S. PARKS, SAMUEL S. TODD AND C. HOWARD SHOMATE

The heats of hydrogenation of some representative olefins have recently been measured with remarkable accuracy by Kistiakowsky[2] and his collaborators; and in this connection they have kindly loaned us samples of these compounds for the determination of the heat capacities at low temperatures and thereby the calculation of the corresponding entropies and free energies of formation. In the present study we shall present data for *n*-heptene-1, 1,4-pentadiene, tetramethylethylene and the two diisobutylene isomers.

Materials

The preparation and properties of the *n*-heptene-1, 1,4-pentadiene and tetramethylethylene have already been described by Kistiakowsky, Ruhoff, Smith and Vaughan.[2] From the change in melting point during our fusion determinations we have estimated the purity of the heptene-1 to be at least 99.85 mole % and that of the pentadiene 99.90 mole %. While the purity of the tetramethylethylene was probably of a similar high order, a quantitative estimate in this case was prevented by the existence of a transition between its two crystalline forms at a temperature only 1.9° below the melting point, 198.5°K. Incidentally this proximity of the transition and melting points enabled us to perform an interesting qualitative experiment in which a narrow tube containing the olefin was immersed in an alcohol-bath cooled with solid carbon dioxide. By careful maintenance of a suitable temperature gradient in the bath it was then possible to obtain, coexistent in the tube, (1) a supernatant layer of liquid tetramethylethylene, (2) a middle layer of the crystals melting at 198.5° and (3) a bottom layer of the low temperature crystals.

The Harvard investigators also separated the two diisobutylene isomers from a large quantity of commercial material by a series of careful fractional distillations. As they will describe the properties of these compounds in detail in a subsequent paper, we shall simply say here that our fusion determinations indicated a purity of about 99.5 mole % for the low boiling isomer (supposedly 2,4,4-trimethylpentene-1) and about 98 mole % for the high boiling isomer (supposedly 2,4,4-trimethylpentene-2).

Experimental Results

In principle, the method of Nernst was employed with an aneroid calorimeter in determining the "true" specific heats and the fusion data. The apparatus and details of experimental procedure have been fully described in other places.[3] In view of the accuracy of the various measurements involved, the error in the experimental values thereby obtained is probably less than 0.5% at all temperatures.

These heat capacity data, expressed in terms of the defined calorie[4] and with all weights reduced to a vacuum basis, appear in Tables I and II. The specific heat values are also represented

graphically in Figs. 1 and 2. It is interesting to note that the curve for liquid pentadiene shows a marked minimum similar to that found previously with butene-1, *cis*-butene-2 and propylene.[5] Another noteworthy point is that the specific heat curves for both diisobutylene isomers exhibit some sort of minor transition with a slight but appreciable rise at about 101°K. The heat effect associated with this transition seemed almost negligible—1.85 cal. per mole in the case of the low boiling isomer. A sample of diisobutylene, which was in reality a mixture of the isomers with the low boiling predominating, has been studied previously by Parks and Huffman.[6] In the present case our values for the low boiling compound agree for the most part to within 1% with these earlier, less reliable data.

In the calculation of the fusion values, the somewhat more rapid rise in the specific heat of the crystals as the melting point is approached was attributed to premelting; and the heat absorbed in this region in excess of that obtained by extrapolation of the specific heat data at lower temperatures was added to the heat absorbed at the melting point. In the case of tetramethylethylene the transition point in the crystals at 196.6°K. was so close to the melting point that entirely independent determinations of the heat of transition and heat of fusion were impractical. Accordingly the sum of these heat effects was measured and from the relative time intervals for these two steps the fusion results in Table II were then derived. The corresponding values obtained for the heat of transition of tetramethylethylene were: I, 13.00 cal.; II, 13.01 cal.; mean, 13.00 cal. per g.

Entropy Data

Using the heat capacity data contained in the preceding section in conjunction with the third law of thermodynamics, we have calculated the entropies at 298.1°K. for these five substances. The detailed entropy values are given in Table III. In these calculations we have employed the extrapolation method of Kelley, Parks and Huffman[7] for estimating the entropy increases for the crystals (Column 2) from 0 to 80°K. The various increments from 80 to 298.1°K., which appear in the next three columns, were obtained by the usual methods directly from the experimental data. The results for the total entropy in calories per degree per mole are then given in the sixth column under the heading "S°_{298} olefin"; they are probably reliable to within 1.0 e. u. in an absolute sense and to 0.5 e. u. for comparative purposes.

In the seventh column of Table III we have tabulated entropy values,[6,8] derived previously in this Laboratory, for *n*-heptane, *n*-pentane, and 2,2,4-trimethylpentane, the paraffin hydrocarbons produced on the hydrogenation of four of these olefins. The last column then shows the

TABLE III

ENTROPIES OF THE LIQUID OLEFINS PER MOLE

Substance	Crystals		Fusion	Liquid	S°_{298} olefin	S°_{298} paraffin	ΔS paraffin–olefin
	0–80°K.	Above 80°K.					
n-Heptene-1	14.00	14.70	19.71	30.18	78.6	78.8	0.2
1,4-Pentadiene	11.26	7.65	11.80	27.44	58.2	62.0	1.9 × 2
Tetramethylethylene	13.97	23.24	12.13[a]	15.80	65.1	..	.....
Diisobutylene, low boiling	14.28	21.79	11.70	25.44	73.2	75.4	2.2
Diisobutylene, high boiling	14.94	20.10	9.77	29.68	74.5	75.4	0.9

[a] This value includes the entropy of transition (5.56 e. u.) between the two crystalline forms at 196.6°K.

differences between the molal entropies of these corresponding paraffins and olefins or, in other words, the entropy decreases for the formation of the olefin double bond. Undoubtedly this effect depends considerably upon the position of the double bond in the molecule and upon symmetry considerations.[9] In the present case the average entropy decrease per double bond is 1.4 e. u. and this figure, while it cannot be considered very significant, is probably preferable to the decrease of 2.7 e. u. suggested previously by Parks and Huffman[6] from data pertaining mainly to crystalline unsaturated acids and various cyclic compounds.

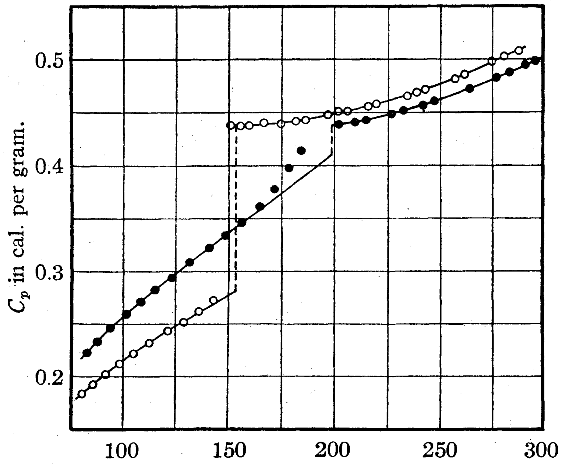

Fig. 1.—The specific heat curves for *n*-heptene-1 (circles) and tetramethylethylene (heavy dots).

Free Energy Data

We have also calculated the free energies of formation of four of these olefins in the liquid state by means of the fundamental equation, $\Delta F = \Delta H - T\Delta S$. The essential thermal data are given in Table IV.

TABLE IV

THERMAL DATA AT 298.1°K. FOR THE OLEFINS

In calories per mole with all weights reduced to a vacuum basis.

Substance	ΔH°_{298}, cal.	ΔS°_{298}, e. u.	ΔF°_{298}, cal.
n-Heptene-1 (l)	−25,520	−149.5	19,050
1,4-Pentadiene (l)	18,060	− 73.5	39,970
Diisobutylene l. b. (l)	−36,360	−187.5	19,530
Diisobutylene h. b. (l)	−35,250	−186.2	20,260

The values for the ΔH°_{298} of formation of these compounds were obtained by a combination of the ΔH°_{298} values for the corresponding or parent paraffins with the heats of hydrogenation of Kistiakowsky and collaborators.[10] The heats of formation of these particular liquid paraffins have already been calculated by Parks[11] with the aid of the highly accurate combustion data obtained in recent years by Rossini and his collaborators at the U. S. Bureau of Standards. To these values for the parent paraffins we have then added

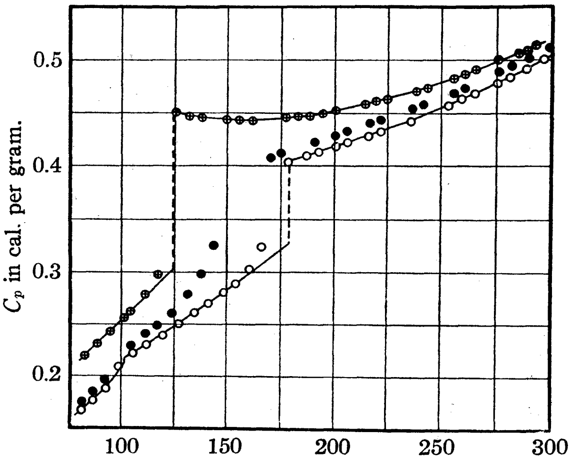

Fig. 2.—The specific heat curves for 1,4-pentadiene (crossed circles) and the low boiling diisobutylene (plain circles). The specific heat values for the high boiling diisobutylene (m. p. 166°) are represented by the heavy dots without a curve.

---

(9) In this connection see Kassel, *J. Chem. Phys.*, **4**, 435 (1936).

(10) The heats of hydrogenation for the diisobutylene isomers have not been published yet. A private communication from the Harvard laboratory gives these as 27,236 cal. per mole for the low-boiling and 28,352 cal. per mole for the high-boiling isomer in the gas phase at 355°K. In the latter case there is considerable uncertainty as to the effect of the impurities on this hydrogenation value. The data for the three other olefins are available in ref. 2.

(11) Parks, *Chem. Rev.*, **18**, 325 (1935).

Kistiakowsky's hydrogenation results, reduced by a uniform 250 cal. (500 cal. in the case of pentadiene) to convert the data from 355 to 298° K. In this connection we have assumed that these heats of hydrogenation, although determined for the gas-phase reaction, can be applied without alteration to the process involving the hydrocarbons in the pure liquid state.

The ΔS°_{298} values represent simply the differences between the S°_{298} for each olefin and the corresponding values for the entropies of the elements contained therein. For this purpose we have used 15.615 e. u.[12] for the entropy of $^1/_2H_2$ and 1.36 e. u.[13] for C (β-graphite).

The molal free energies appear in the last column of the table. The errors in these values are probably within 800 cal. for *n*-heptene-1 and 1,4-pentadiene, within 1500 cal. for low boiling diisobutylene and within 2000 cal. for high boiling diisobutylene.

Comparing the free energy of heptene-1 with that calculated by Parks[11,8] for *n*-heptane, we find $\Delta F^\circ_{298} = 20{,}620$ cal. for the dehydrogenation process

$$n\text{-heptane} \longrightarrow n\text{-heptene-1} + H_2$$

Likewise in the case of 1,4-pentadiene and *n*-pentane the difference is 2 times 21,400 cal. Previously Parks[11] has estimated 21,040 cal. and 21,360 cal., respectively, for the propylene–propane and butene-1–*n*-butane differences. Hence, the free energy change in the formation of a normal α olefin by dehydrogenation of a paraffin is apparently around 21,000 cal. irrespective of the length of the paraffin chain.

The addition of more methyl or other radicals to the carbon atoms adjacent to the double bond, however, leads to definitely lower values for this ΔF°_{298} of dehydrogenation. Thus with branched molecules, such as isobutene and 2,4,4-trimethylpentene-1, the free energy difference drops noticeably, being 18,180 cal. in the latter case. The same trend appears also when the double bond is shifted from the α- to the β-position, as shown by Todd and Parks[5] in the cases of *cis*- and *trans*–butene-2. Next with the trimethylethylene–methylbutane combination, involving three methyl substituents on the ethylene group, we calculate $\Delta F^\circ_{298} = 17{,}360$ cal., using the hydrogenation data of the Harvard laboratory[2] in conjunction with the proper experimental entropy values.[14] Of course, the end-point in this series is the tetramethylethylene–tetramethylethane combination for which an exact calculation of the ΔF°_{298} of dehydrogenation is at present impossible in the absence of an experimental entropy value for the paraffin compound. However, for the dehydrogenation in this case ΔH°_{298} is only 26,380 cal. and, if we assume equal entropies for the olefin and parent paraffin (an assumption that cannot involve us in any serious error), ΔF°_{298} is estimated as approximately 17,100 cal.—a figure about 4000 cal. lower than with the dehydrogenations that yield the normal α olefins. In other words, with additional spatial protection to the ethylene group the olefins become progressively less unstable with reference to the parent paraffin hydrocarbons.

Summary

1. The specific heats of *n*-heptene-1, 1,4-pentadiene, tetramethylethylene and the two diisobutylene isomers have been measured between 80 and 298°K. The corresponding heats of fusion have also been determined.

2. The entropies of these five olefins in the liquid state at 298.1°K. have been calculated from the foregoing heat capacity data.

3. The corresponding free energies (except in the case of tetramethylethylene) have also been calculated. Among the α olefins the free energy difference between an olefin and the corresponding paraffin is uniformly about 21,000 cal. As the number of radicals attached to the carbon atoms of the ethylene linkage increases this free energy of dehydrogenation falls off progressively to about 17,100 cal. as a limit.

Heats of Solution and Heats of Reaction on Liquid Ammonia[1]

BY FREDERIC C. SCHMIDT, JOSEPH SOTTYSIAK AND HERMAN D. KLUGE

In order to study more thoroughly the properties of electrolytes and other compounds in aqueous solution, thermochemical characteristics of these solutions have been examined. Among these, the heats of solution and dilution have been determined experimentally. Such data are scarce in the study of the properties of liquid ammonia solutions.

Kraus and Ridderhof designed a liquid ammonia calorimeter and some heats of solution and reaction were measured.[2]

In the present work the authors have made some measurements of the heats of solution of several electrolytes and non-electrolytes over a fairly wide range of concentrations with this same calorimeter. From the curves obtained the heats of dilution may be calculated.

Experimental Details

The calorimeter described by Kraus and Ridderhof[2] was used and was further improved by silvering, thus making the correction for the heat flow out of or into the instrument practically negligible. The new radiation constant was found to be 0.125 cal./deg./min. The other constants and the experimental procedure were the same as in the earlier investigation of Kraus and Schmidt.[3]

Temperatures were measured by means of a copper–constantan thermocouple (0.0385 mv./deg.) similar to that of Kraus and Prescott,[3] in conjunction with a "Queen" potentiometer and a matched sensitive galvanometer. Temperatures were read directly from the calibration curve of this thermocouple and were accurate to 0.01°; the heat capacity of the calorimeter being 6.73 cal. The error in heat measurement was 0.33 cal. The calorimeter contained 24.89 g. of liquid ammonia.

The heats of solution of ammonium bromide and ammonium chloride; lead iodide and absolute ethyl alcohol were measured over the maximum range of concentration allowed by the construction of the calorimeter. Trial heat effects were made on a few other electrolytes and on pyridine. The ammonium salts were of reagent quality and were recrystallized three times from distilled water. They were pumped and dried at 100° to constant weight. The ethanol was dried over lime and then anhydrous copper sulfate. It was then distilled into weighed bulbs out of contact with the air, and introduced directly into the calorimeter for measurement.

Experimental Results

The heats of solution of ammonium chloride and ammonium bromide are presented in Table I, those for absolute ethyl alcohol in Table II, and those of lead iodide and miscellaneous compounds in Table III.

Pyridine	1.1150	.0000	−17.6	−1250

Discussion

As will be noted on examining Fig. 1, the heats of solution of the ammonium salts vary regularly over the range of concentration measured, increasing with decreasing concentration. These curves are similar to the heat of solution curves of the strong acids in aqueous solution. These results are in accord with the view that the ammonium salts are ammoniated acids in the nitrogen system of compounds.[4]

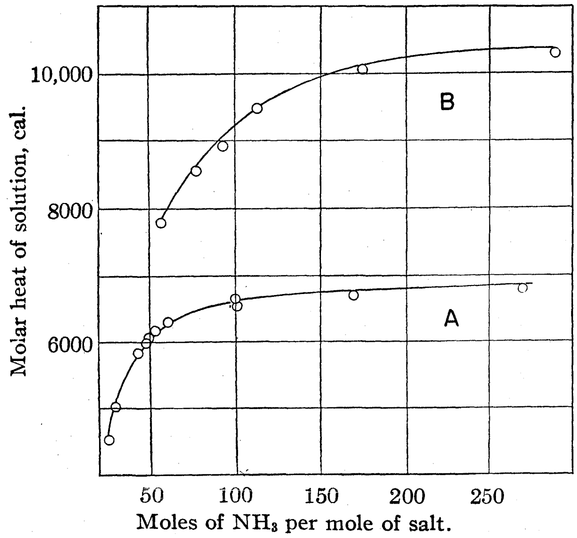

Fig. 1.—Showing variation in the molar heat of solution with concentration: (A) ammonium chloride; (B) ammonium bromide.

From these heat of solution curves it is possible to obtain the heats of dilution of these salts in liquid ammonia. The heat of solution of ammonium chloride in dilute solution is approaching 6800 calories per mole, while that of ammonium bromide at infinite dilution has a value of about 10,500 calories per mole. The absolute ethanol shows also a positive molar heat of solution which varies decidedly with the concentration. The slope of the curve for this compound, as is shown by Fig. 2, is negative. Ethanol has a negative heat of dilution in contrast with the positive dilution heat effect displayed by the ammonium salts. Apparently, energy must be supplied in order to disassociate the ethyl alcohol aggregates as the solution is diluted. The heats of solution of lead iodide, mercuric iodide and the lithium salts are high and are of the order of magnitude of heats of reaction. The lead and mercury salts are known to react with ammonia to form fairly stable ammoniates. The lithium salts, no doubt, show a high heat effect due to the solvation of the positive lithium ion with ammonia molecules. Metallic lithium itself has the highest heat of solution in liquid ammonia of all the alkali metals measured so far.[3]

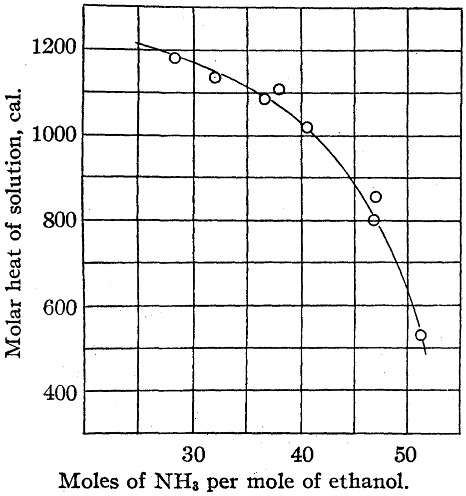

Fig. 2.—Showing variation in the heat of solution of ethanol with the concentration.

The authors wish to thank Dr. C. A. Kraus of Brown University for his kindness in the loan of the liquid ammonia calorimeter.

Summary

The molar heats of solution of ammonium chloride and ammonium bromide have been measured in liquid ammonia over a fairly wide range of concentration and show a marked heat of dilution.

The molar heat of solution of ethyl alcohol has been measured over a range of concentration and it has been shown that this compound has a decided negative heat of dilution.

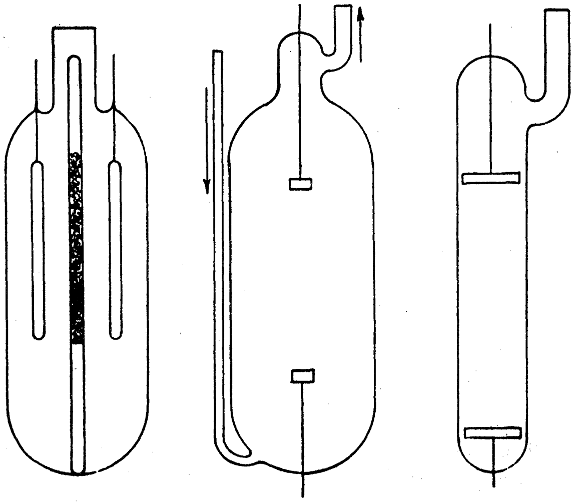
Oxidation of Selenium in the Glow Discharge. II. A Study of Variables and Further Characterization of Product[1]

BY EARL OLSON AND V. W. MELOCHE

In a previous study of the oxidation of selenium in the glow discharge,[2] it was found that a mixture of selenium dioxide and selenium trioxide was produced. Since very little was known concerning the mechanism of the reaction, it was thought that the study could be extended profitably. The present paper includes a description of the effect of variables, pressure, current, electrode distance, shape of tube, and distance of selenium from the electrodes on the production of selenium trioxide, and also gives some general facts concerning chemical action in the glow discharge.



Tube I Tube II Tube III

Fig. 1.

Apparatus.—The apparatus was essentially the same as that used by Kramer and Meloche.[2] A 25,000-volt transformer served as the source of alternating current. For direct current, a single phase full wave rectifier circuit (two RCA-866 tubes) was used. Three types of discharge tubes were used in this investigation.

Materials and Analysis.—The preparation of materials and the methods of analysis are the same as the ones described by Kramer and Meloche. Ordinary analytical methods were later augmented by X-ray examination of the product.

Procedure.—In general, the procedure used was the same as that described by Kramer and Meloche, *viz.*, elementary selenium was supported between the two electrodes of a tube and subjected to the glow discharge at a definite oxygen pressure, the walls of the tube being at the temperature of liquid air. In order to provide a constant pressure for a given experiment, pure dry oxygen was allowed to enter the apparatus through a Hoke micro-valve at such a rate that the inflow of oxygen was balanced by its removal with the pumps. It should be noted that it was possible to pass a current of oxygen into the bottom of tube II by sealing the small side-arm to the micro-valve and sealing the large exit to the pump line of the apparatus. In this manner a current of oxygen passed over the sample whereas in tubes I and III the oxygen reached the sample by diffusion. Other details of procedure will be given in connection with the individual experiments.

Effect of Pressure.—Using tube I, a 25,000-volt transformer and a constant alternating current of 44 m. a., elementary selenium was melted on a rod which was supported in a vertical position between the electrodes and subjected to the action of oxygen at a definite pressure. The curves shown in Fig. 2 represent the analyses of various products which were obtained at various pressures of oxygen.

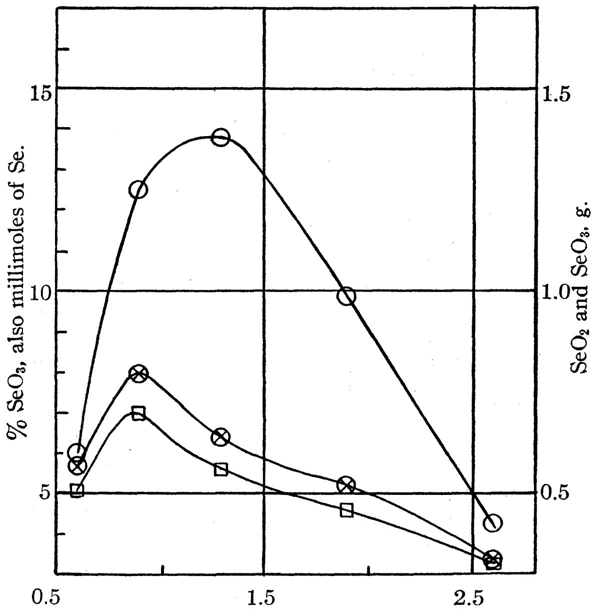


Fig. 2.—○, % SeO_3; ⊗, SeO_2 and SeO_3, g.; □, millimoles of Se.

Kramer and Meloche have reported a maximum in selenium trioxide concentration at a pressure of 1.2 mm. This maximum is shown in Fig. 2 at 1.1 mm. Curves 2 and 3 show the variation of weight of product and the variation of millimoles of selenium in the product with the change in pressure. For these two curves, maxima are found at 0.9 mm. pressure. A difference in the maxima for

(2) Kramer and Meloche, THIS JOURNAL, **56**, 1081 (1934).

curves 2 and 3 as contrasted to curve 1 is to be expected since the weight of product depends primarily upon the vaporization of selenium while the percentage of selenium trioxide depends upon both vaporization and activation of selenium.

Two factors affect the vaporization of selenium, thermal radiation from the cathode and electron bombardment. The percentage of selenium trioxide depends to a large extent upon activation by electron bombardment after vaporization. Using tube I, thermal vaporization of selenium is greatest at 0.9 mm. Maximum activation of the selenium is obtained at 1.1 mm. pressure.

Maxima may also be noted in Fig. 3. In this case tube II was used and selenium was suspended on a glass holder midway between the electrodes. The maximum concentration of selenium trioxide was produced at 0.8 mm. pressure. Since the electrodes were farther apart than in tube I, a lower pressure was required to keep the selenium vapor in the negative glow, which is the most reactive region of the discharge.

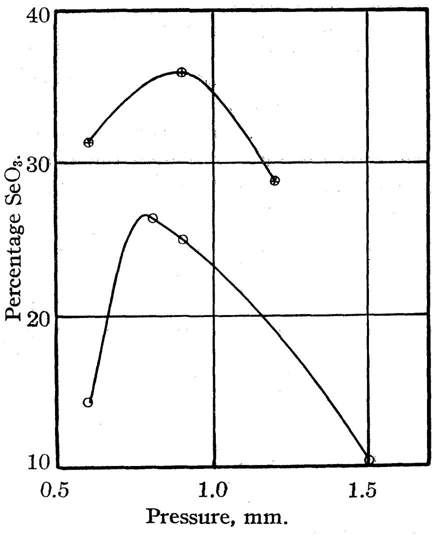

Fig. 3.

Shape of the Tube.—The curves of Fig. 2 using tube I and of Fig. 3 using tube II show that a higher concentration of selenium trioxide was obtained in tube II, identical conditions of current and temperature having been maintained. This was probably due to the fact that the electrodes in tube II were smaller than those in tube I and since the discharge column in tube II was smaller, the current density was higher.

When tube III was used, large amounts of selenium were found mixed with the oxides of selenium. In this tube, the walls were very close to the discharge column. It is therefore likely that some of the deposited product was decomposed or that some elementary selenium condensed on the walls before combination with oxygen could occur.

Still another factor exists other than the proximity of the walls to the region of glow. As has been noted, the small side-arm of tube II could be connected to the Hoke microvalve and the large opening of the tube could be connected to the pump side of the apparatus, thereby making it possible to have a positive flow of oxygen through the tube in the direction of the pumps. It was also possible to seal off the small side-arm and when the large outlet of the reaction tube was sealed to the system, the oxygen reached the sample by diffusion. In Fig. 2, the upper curve shows that a steady flow of oxygen through tube II caused a marked increase in the percentage of selenium trioxide. The lower curve represents results obtained when the oxygen diffused into the tube. If it may be assumed that the flow of oxygen through the tube provides an excess of unactivated oxygen, whereas, in the second case, the oxygen diffuses into the tube and is largely activated, the above results probably indicate that selenium combines more readily with unactivated oxygen than with activated oxygen to form selenium trioxide.

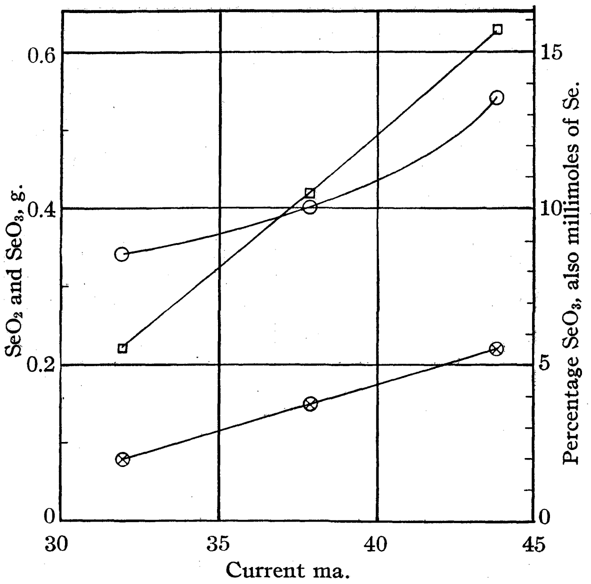

Fig. 4.—○, Percentage SeO_3; ⊗, millimoles of Se; □, SeO_2 and SeO_3, g.

Electrode Distance.—It is well known that the extent of the negative glow is independent of the distance between the electrodes and is dependent on the nature of the gas and the pressure. In tube I a relatively large selenium surface is exposed and the region of negative glow represents a relatively large volume. In contrast the electrodes in tube II are smaller and, therefore, for the same power, the region of negative glow is smaller in volume but more concentrated in electrons for the same current. Results obtained under identical conditions of pressure and current show consistently a larger amount of product for tube I than for tube II and a higher percentage of selenium trioxide for tube II than for tube I. As might be expected, the change of distance between the electrodes of tube II does not affect the percentage of selenium trioxide in the product, pressure and current being the same.

Distance of Selenium from the Electrodes.—It was found that no perceptible reaction took place unless the selenium was in the region of the negative glow. Using direct current, excessive volatilization of selenium took place when the selenium was too near the cathode and selenium was found in the product.

Effect of Current.—The curves of Fig. 3 show distinctly that the percentage of selenium trioxide, the weight of

TABLE I

Pressure, mm.	Current, ma.	Electrode distance, cm.	Distance of Se from cathode, cm.	Wt. of product, g., behind		% SeO_3, behind	
				Anode	Cathode	Anode	Cathode
				Tube I			
1.5	45 d. c.	2	1	0.1169	0.1736	4.66	11.15
1.5	45 d. c.	2	1	.1663	.2996	3.35	7.69
				Tube II			
				Between electrodes	Behind cathode	Between electrodes	Behind cathode
1.0	44 a. c.	6.5	1.2	0.0151	0.1633	16.16	19.9

1.2	45 d. c.	4	1	.0381	.0700	4.47	14.58

product, and millimoles of selenium increase with an increase of current. In these experiments special care was taken to maintain identical conditions, varying only the amperage and voltage. Using the same tube, the voltage must be increased to produce a higher current. Brewer,[3] in his studies of various reactions, also has reported a larger rate with an increase of current. Particularly significant is the relation between percentage of selenium trioxide and current. Evidently the percentage of selenium trioxide is dependent on the power factor, which would lead one to believe that the activation of selenium is an important factor in the production of selenium trioxide. Calculations of m/N ratios have not been attempted because of the complications introduced by the solid reactant and the heterogeneous product.

Deposition of Product.—Using tube I, Kramer and Meloche[2] have reported a higher percentage of selenium trioxide in the product behind the electrodes. Using direct current instead of alternating current, as was the case in the above experiments, a higher percentage of selenium trioxide and a larger weight of product was found behind the cathode. Some typical results, using tubes I and II, as shown in Table I, show conclusively that the product concentrates behind the cathode.

Using tube II, the deposit, in many cases, formed in diffuse rings. The majority of the product was usually concentrated in a ring just below the cathode.

Characterization of the Product.—In the earlier work with alternating current, the products of the oxidation of selenium in the glow discharge were analyzed chemically and reported to be a mixture of selenium dioxide and selenium trioxide. In the present study using direct current the same type of product was obtained. However, since it was realized that chemical analyses could not alone establish the character of the product, X-ray powder photographs were taken of typical samples. A characteristic which interfered with chemical analyses also made the X-ray examination difficult, namely, the strong affinity of the product for water. In the solution of samples for chemical analysis it was necessary to place the weighed dry sample in a weighing bottle and place a drop of water on the wall of the bottle, allowing the sample to stand long enough for the water vapor to reach the product and thus provide slow hydration. When this occurred the sample could be moistened and diluted to the desired volume. If this precaution was not taken and water was added directly to the fresh sample, the reaction was so violent that some sample would be lost.

When samples were prepared for the X-ray examination, the usual thin-walled tubes were filled in a desiccator box to avoid contamination of the sample with water. It was necessary to prepare a standard photograph of selenium dioxide, as there is no X-ray data on this oxide in the literature. A molybdenum target tube was used with a zirconium oxide filter, thereby producing monochromatic light of 0.70997 Å. wave length. An unusually long exposure was required, discernible lines appearing after twenty-four hours.

The data in Table II give the actual diameters of diffraction rings and the calculated interplanar distances of the planes producing these rings.

TABLE II

SeO_2		Discharge product	
Distance between lines, cm.	Interplanar distance, Å.	Distance between lines, cm.	Interplanar distance, Å.
..	....	6.24	1.1560
5.92	1.2164	..	....
5.66	1.2710	5.66	1.2710
5.44	1.3213	5.44	1.3213
5.18	1.3865	5.18	1.3865
4.58	1.5643	4.54	1.5780
..	....	4.00	1.7865
..	....	3.64	1.9602
3.22	2.2163	3.26	2.1889
2.76	2.5773	2.82	2.5247
2.38	2.9909	2.38	2.9909
2.20	3.2350	2.20	3.2350
1.90	3.7375	1.90	3.7375
1.74	4.0864	1.74	4.0864

The above table shows that selenium dioxide crystals are produced by the oxidation of selenium in the glow discharge since selenium dioxide lines are found in the photograph of the glow discharge product. It is doubtful that a double oxide forms, since the selenium dioxide lines on the two photographs were of practically equal intensity (a double oxide would decrease the selenium dioxide percentage). It is more reasonable to suppose that, since there are three additional lines in the selenium dioxide and selenium trioxide photograph, selenium trioxide exists as crystals.

Summary

In the reaction between selenium and oxygen in the glow discharge, the effects of the variables, pressure, current, electrode distance, shape of tubes, were studied. From these studies, optimum conditions for the production of selenium dioxide and trioxide were ascertained. The characterization of these products, by means of chemical analysis, was supplemented by X-ray diffraction studies.

The reaction is best initiated in the negative glow and is completed by the deposition of product on the cold tube walls.

The Oxidation of Selenium in the Glow Discharge. III. Striated Deposits and Possible Mechanism[1]

BY EARL OLSON AND V. W. MELOCHE

Although the glow discharge may be said to comprise a rather complex field for chemical reaction, the use of solid selenium as one of the reactants and the cooling of the walls of the tube in liquid air greatly reduce the complexity of the system. In a homogeneous system, it is difficult to determine the nature of the reaction in the various parts of the discharge column. Since the products of the oxidation of selenium are solids, it has been possible to study the deposits which formed as striations *in the column* and to study the effect of the change of pressure and power on these striations. We propose to describe the results of this study and use these data together with results published in a previous paper in support of a proposed mechanism for the oxidation of selenium in the glow discharge.

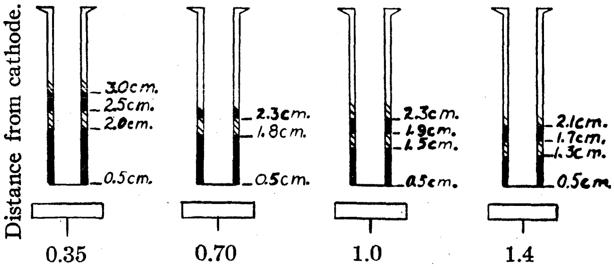

Fig. 1.—▨, Oxides of selenium; █, elementary selenium.

Apparatus.—The apparatus used in this research was the same as that described in previous papers.[2,3] The data to be presented were obtained with the discharge tube III, illustrated in the second paper, having a distance of 10 cm. between the electrodes. Direct current was used.

Striated Deposits in the Discharge

Selenium was fused on the bottom of a glass suspension 0.5 cm. from the cathode as shown in Fig. 1. The basket was suspended in the center of the discharge column. After subjecting the selenium to the glow discharge for an hour and a half, it was found that oxides and elementary selenium deposited not only on the walls of the tube but also on the vertical glass supports directly in the path of the discharge. Distinct striations of white selenium oxide and elementary selenium were sharply defined if the pressure were held constant during the run. The striation dimensions of four constant pressure runs are given in Fig. 1. The lined areas represent deposits of oxides, while the solid black areas represent deposits of elementary selenium. For example, the striations occurring at 0.35 mm. pressure consisted of a 1.5-cm. deposit of black elementary selenium, then 0.5 cm. of white oxide of selenium, 0.5 cm. of red elementary selenium, and above this another selenium oxide deposit of 0.4 cm. No deposit was detectable higher on the glass support. It is well known that red selenium is transformed to the black variety by heat. In agreement with this is the fact that the black selenium deposited close to the cathode where the temperature was relatively high and the red selenium deposited farther away from the cathode where the temperature was undoubtedly lower.

It is believed that this is the first report of striated depositions occurring directly in the discharge column. Brewer[4] has reported a well defined band of deposit on the wall of the tube in the region of the negative glow; also, under special conditions, striated deposits on the wall in the positive column region. The above figure represents striated deposits in the head of the positive column. The lower black area is in the region of the negative glow and Faraday's dark space. The two oxide deposits (lined areas) and the upper black area are in the region of the head of the

positive column. These striated deposits must have been produced by the luminous and non-luminous regions of the discharge. It is well known that these regions move away from the cathode with decreasing pressure. Figure 1 shows that the deposits of selenium and of selenium oxide were affected in a similar manner, supporting the conclusion that the deposits are regulated by the striations of the discharge.

In order to determine whether the oxides of selenium were deposited in a luminous or non-luminous region, the potential drop between two probes was measured with an electrostatic voltmeter. The two probes were placed at distances 2 and 2.5 cm. from the cathode and the discharge moved past them by varying the pressure. Figure 2 shows the variation of potential drop between the probes as the discharge was moved past them.

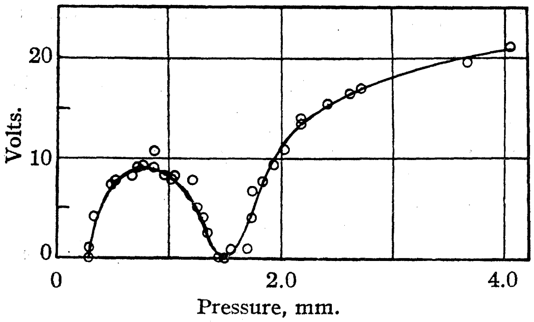

Fig. 2

Figure 3 shows a continuous graph of the striated deposits in Fig. 1.

From the voltage measurements, it can be seen that a non-luminous stratum existed between the probes at pressures of 0.3 and of 1.5 mm. Also, a luminous region filled the space between the probes at a pressure of 0.9 mm. Now, upon inspection of Figure 3, it may be definitely concluded that selenium was deposited in luminous regions and selenium oxide in the non-luminous. This fact gives an indication as to the mechanism of the oxidation of selenium in the glow discharge; the selenium was activated in the negative glow or other luminous regions and then combined with oxygen in a dark space or outside of the discharge column. If any combination of activated selenium and oxygen takes place in a luminous region, decomposition immediately follows.

Facts Pertinent to Mechanism

1. Using a glass suspension located in the d. c. discharge, selenium metal was deposited in luminous portions and selenium oxide deposited in the dark spaces, indicating that selenium was activated in the luminous regions and combined with oxygen in the dark regions.

2. Using a discharge tube with rod electrodes and employing alternating current, higher concentrations of selenium trioxide were found behind the electrodes. This indicated that selenium trioxide was formed near or behind the electrodes; also, the particles were propelled parallel to the electric field.

3. Using the same rod electrodes but employing direct current, larger weights of product and higher percentages of selenium trioxide were found behind the cathode than behind the anode. The larger amount of product behind the cathode indicates that the selenium was attracted toward the cathode and, therefore, was positively charged. Deposition of product in other parts of the tube does not contradict the above for it is certainly feasible that gas neutralization may also take place and, therefore, mere diffusion of product to all parts of the walls.

The higher percentage of selenium trioxide behind the cathode indicates that the selenium was more highly activated in the negative glow, thereby producing a higher concentration of selenium trioxide. This is also indicated by the effect of pressure upon the concentration of selenium trioxide in the product; higher concentrations were obtained at that pressure at which the selenium is in or near the negative glow.

4. A higher concentration of selenium trioxide was produced when a steady current of oxygen was passed through the discharge tube than when oxygen was simply allowed to diffuse into the tube from one opening. (2) This supports the view that the oxides of selenium are formed in the dark spaces or outside the discharge column.

5. Selenium was placed 2 cm. from the cathode and a discharge run at 1.4 mm. pressure; no vaporization or oxidation of selenium occurred. (2) When the pressure was reduced to 0.4 mm. vaporization and the oxidation of selenium took place. Evidently the selenium must be in the region of the negative glow or no appreciable reaction will occur. Brewer[4] has also found the negative glow to be the most reactive region.

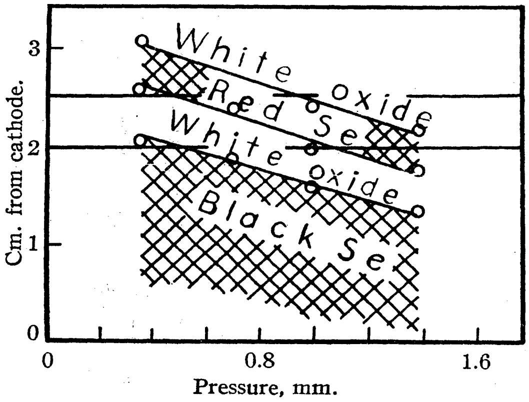

Fig. 3.

6. When pure selenium dioxide was placed in the negative glow, a red coloration developed, indicating reduction to metallic selenium. If selenium dioxide is unstable in the glow, certainly selenium trioxide is unstable and, therefore, only selenium ions exist in the luminous regions, oxides being formed in the dark spaces or outside the discharge column.

7. Increase of power caused an increase of percentage of selenium trioxide and of weight of the product.[2]

8. Previous experiments have shown that selenium trioxide is not formed by the action of ozone on selenium. This fact supports our belief that activated selenium is necessary for the formation of selenium trioxide.

The Mechanism

The selenium is vaporized and activated in the luminous portions of the discharge, the rate being at a maximum in the negative glow. It is highly probable that positive ions are formed and propelled toward the cathode. Once outside the region of the discharge, the activated selenium combines with oxygen forming either the dioxide or trioxide; more trioxide is formed at higher activations of the selenium, as indicated by the effect of current and voltage on the per cent. of selenium trioxide in the product. The particles are positively charged, gas or wall neutralization taking place. Undoubtedly there is decomposition of selenium trioxide occurring. It seems logical that there will be less decomposition of a selenium trioxide particle if it is neutralized on the wall, which is at a low temperature and will take up the heat of neutralization. On the other hand, if gaseous neutralization takes place, the heat cannot be dissipated and therefore might decompose the selenium trioxide molecule. It may be mentioned that only very low percentages of selenium trioxide were found when the tube was at room temperature during the reaction.

Summary

1. Banded deposits of selenium metal and selenium oxide were obtained in the glow discharge column. This afforded a means of determining the region in which the oxidation of selenium takes place. A correlation of voltage measurements and the character of the striated deposits shows that vaporization and activation of selenium takes place in the luminous regions. Combination with oxygen takes place in the dark regions.

2. After considering the experimental facts, a mechanism is suggested.

The CN Bond in Methyl Cyanide and Methyl Isocyanide

BY L. O. BROCKWAY

The bond between the carbon and nitrogen atoms in methyl cyanide and other organic nitriles has long been regarded as a triple electron pair bond, the structural formula for these compounds, $R{-}C{\equiv}N$, being considered satisfactory because in it carbon shows its normal valence of four and nitrogen one of its two normal valences, three. The isocyanides, on the other hand, according to the same considerations might have either one of two formulas, $R{-}N{\equiv}C$ and $R{-}N{=}C$. In the former the carbon atom is again quadrivalent while the nitrogen is quinquivalent; the latter formula is distinguished by the bivalent carbon atom. This formula, suggested by Nef, was favored because it was thought that the unusual chemical reactivity of the isocyanides was perhaps due to the "unsaturated" bivalent carbon atom.

In 1919 Langmuir[1] considered the possibility of a third formula for the CN radical on the basis of the Lewis theory of valency, namely, $R{-}C{\equiv}N$. Langmuir, however, noted the isosterism of cyanide ion and nitrogen molecule and rejected the triple bond structure because of the pronounced chemical differences between nitrogen molecule and acetylene, for which a triple bond structure was accepted. He proposed a structure in which one pair of electrons was shared between the two atoms and the remaining eight formed an octet around the two atoms together. This structure was not generally accepted and Lewis in 1923[2] supported the validity of the triple bond formulation for the cyano radical. In accordance with the octet theory this formula originally considered by Langmuir is preferable to the first two mentioned above since it is the only one of the three in which each of the atoms is surrounded by four electron pairs. This is evident when the formulas are written to show both the shared and the unshared electrons, as follows

$$\mathrm{R:N::::C} \qquad \mathrm{R:\ddot{N}::C:} \qquad \mathrm{R:N:::C:}$$

The interpretation of the octet theory by quantum mechanics in terms of the application of the Pauli exclusion principle to the elements of the first row of the periodic table still excludes the first but admits the second and third structures.

The first direct attempt to decide among these three bond types for methyl isocyanide was made

---

[2] G. N. Lewis, "Valence and the Structure of Atoms and Molecules," Chemical Catalog Co., New York, 1923, p. 127.

in 1930 by Lindemann and Wiegrebe,[3] who concluded from a determination of the parachor that only the triple bond structure was correct. Hammick, New, Sidgwick and Sutton[4] measured the parachor of ethyl isocyanide and decided on the same bond type. These authors also measured the dipole moment of several para-substituted aromatic cyanides and isocyanides. By a comparison of the moments they showed that the direction of the moment in the C–N link is different for the two classes of compounds; the nitrogen is negative with respect to the carbon in the cyanides and positive in the isocyanides. Nitrogen in isocyanide with a double bond would be negative but in the triple bond structure nitrogen has become positive by the loss of an electron to the carbon atom, the electron transfer being compensated energetically by the formation of the third electron pair bond. The positive nitrogen in the isocyanide accordingly supports the triple bond structure.

Dadieu,[5] who regarded the foregoing evidence as "indirect," found support for the triple bond structures of both methyl cyanide and isocyanide in the Raman spectra of the two compounds. According to Dadieu every compound which is definitely known to contain a triple bond shows a strong Raman line in the range between 1960 and 2400 cm.$^{-1}$. Each of these compounds shows a strong line in this region; therefore, each has a triple bond structure. Professor R. M. Badger of this Laboratory is making an analysis of the normal vibrations of these molecules in interpreting their infra-red absorption spectra. The evaluation of the force constants of the individual bonds will make the spectral evidence somewhat more satisfactory.

Another test for bond type in covalent compounds is found in the relation between bond type and internuclear distance. The bond distances for single, double and triple bonds are known quite accurately from the table of covalent radii due to Pauling and Huggins.[6] The distances for bonds of intermediate types are known from investigations[7] of the effect of resonance on bond distances.

In the present investigation I have measured the internuclear distances in methyl cyanide and isocyanide by electron diffraction of the vapors. The experimental procedure and methods of interpreting the diffraction patterns have been described in detail.[8]

Methyl Cyanide.—Eastman methyl cyanide was fractionated and a sample boiling at 80.4–80.5° (uncorr.) was used at room temperature for the electron diffraction. The camera distance was 10.85 cm. and the electron wave length was 0.0611 Å. The photographs show five rings of a very characteristic appearance. The first is strong and diffuse, the second weak and sharp, the third strong and sharp with a shelf on the outside edge, the fourth diffuse and the fifth sharp. Reproducible measurements of the diameters could be made only on the sharp rings, *i. e.*, the second, fourth and fifth.

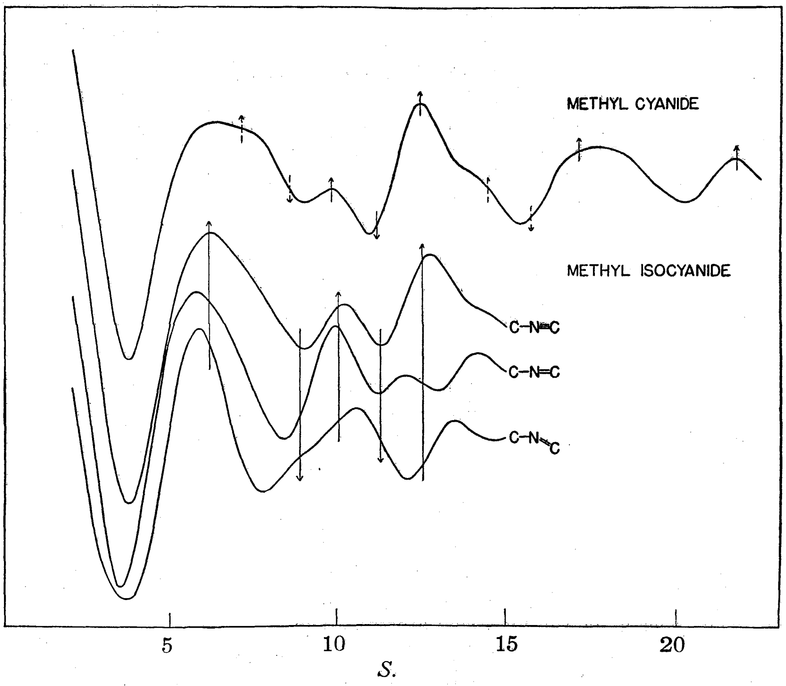

Fig. 1.—Theoretical electron diffraction curves for methyl cyanide and isocyanide with the positions of the maxima and minima measured on the photographs indicated by arrows.

The theoretical curve (Fig. 1) was calculated for a linear arrangement of two carbon atoms and a nitrogen atom with distances of 1.54 and 1.16 Å. for the carbon–carbon and carbon–nitrogen bonds, respectively. The distance 1.06 Å. was used for the carbon–hydrogen bonds in the

methyl group, with H–C–H angles of 109°28′. The linear configuration is supported by the known linear form of HCN[9] and by preliminary results of the analysis of the infra-red absorption spectrum of methyl cyanide now in progress. Non-linear models were not considered.

The characteristic qualitative features observed in the photographs are well reproduced in the curve. The positions of the observed maxima and minima are indicated by the arrows; the points which did not afford reproducible measurements are shown by dashed arrows and were not used in the quantitative comparison in Table I. The final values observed, 1.54 ± 0.02 Å. and 1.16 ± 0.02 Å., are exactly those for a single carbon–carbon bond and a triple carbon–nitrogen bond, respectively.

TABLE I

METHYL CYANIDE

Max.	Min.	s, obsd.	s, calcd. for C–C = 1.54 and C–N = 1.16	C–C, Å.	C–N, Å.
1		7.19	(6.20)		
	2	8.60	9.00	(1.613)	
2		9.84	9.78	1.530	1.152
	3	11.17	10.88		
3		12.44	12.43	1.539	1.159
Shelf		14.53			
	4	15.75	15.40	1.507	1.135
4		17.16	17.65	1.584	1.193
5		21.77	21.68	1.533	1.155
			Average	1.539 Å.	1.159 Å.
			Av. dev.	0.018	0.014

Final value: C–C = 1.54 ± 0.03 Å.; C–N = 1.16 ± 0.02 Å.

Methyl Isocyanide.—Methyl isocyanide was prepared by Dr. C. E. Wilson using methylamine, chloroform, and alcoholic potash. The electron diffraction photographs were taken with a camera distance of nearly 20 cm. and the three rings observed covered the negative. Of these three rings the third is considerably stronger than the second although weaker than the first.

Three molecular models were considered. The first corresponds to the triple bond structure of isocyanide and is linear (except for the hydrogen atoms). The second is also linear but has the double bond N–C distance, 1.31 Å. For the third model a CNC angle of 125° was chosen with the double bond distance since the angle between a single and a double bond is usually observed to have about this value.

The second and third models are quite definitely eliminated. The third maximum in these curves is weaker than the second whereas it is observed to be stronger. In the case of the third curve the second and third maxima both appear to be somewhat asymmetric but in the photographs they are sharply defined. The positions of the outer rings are not correct in either curve as indicated by the arrows showing the observed *s* values.

Model I corresponding to a single and a triple bond in the molecule shows good qualitative and quantitative agreement with the photographs. The quantitative comparison of Table II leads to a CH_3–N distance of 1.48 ± 0.03 Å. and a N–C distance of 1.17 ± 0.02 Å.

TABLE II

METHYL ISOCYANIDE

Max.	Min.	s, obsd.	s, calcd. for C–N = 1.46 and N–C = 1.16	CH_3–N, Å.	N–C, Å.
1		6.17	6.24	1.476	1.173
	2	8.88	9.00	1.480	1.176
2		10.04	10.21	1.485	1.180
	3	11.27	11.26	1.459	1.159
3		12.51	12.73	1.485	1.180
			Average	1.477 Å.	1.173 Å.
			Av. dev.	0.008	0.006

Final value: CH_3–N = 1.48 ± 0.03 Å.; N–C = 1.17 ± 0.02 Å.

Discussion.—The bond distances for single, double and triple carbon–nitrogen bonds are 1.47, 1.32 and 1.16 Å., respectively. The distance 1.16 Å. observed in methyl cyanide supports the triple bond structure and the structure represented by the formula $CH_3—C\equiv N:$ is now well substantiated.

The observed distance of 1.17 Å. in the isocyanide is also very close to the triple bond distance, but the apparent discrepancy of 0.01 Å. suggests the possibility of resonance with the double bond structure. A 60% contribution of this structure would increase the observed bond distance by only 0.02 Å. above the value for a triple bond so that the double bond structure may well be important in the normal state of the isocyanide molecule. The linear configuration indicates, however, that the triple bond structure predominates in determining the properties of methyl isocyanide.

I wish to thank Dr. Chester Wilson for the preparation of the isocyanide and Professor Linus Pauling for his kindly criticism of the investigation.

Summary

The electron diffraction determination of the molecular structures and bond distances of methyl cyanide and isocyanide shows that a triple bond exists in the cyano group of each compound. The observed distances in the first are CH_3–C = 1.54 ± 0.02 Å., C–N = 1.16 ± 0.02 Å.; in the second CH_3–N = 1.48 ± 0.03 Å., N–C = 1.17 ± 0.02 Å. Both compounds are linear except for the hydrogen atoms.

The Separation of Lithium Isotopes

BY GILBERT N. LEWIS AND RONALD T. MACDONALD

Except in the case of hydrogen the separation of isotopes will always be a laborious and expensive undertaking. However, even a partial separation will in many cases permit an answer to important questions relating to the difference between isotopes in chemical behavior, in spectra, and in nuclear transformations. The methods leading to effective separation will also be interesting in themselves; for even a casual inspection of the literature shows how unsystematic has been the exploration of the methods of separating similar substances.

Most chemical separations have depended upon a difference in the solubility of solids or in the vapor pressure of liquids. Fractionation by selective distribution between two liquid phases is only now being developed in some important industrial processes. The method which we have chosen for the separation of lithium isotopes involves a system of two liquids, but it is not a simple case of selective distribution. In principle it depends, as the first separation of hydrogen isotopes chiefly depended, upon the difference in electrode potentials between the two isotopes.

If a solution of a lithium salt is shaken with an amalgam of lithium, the ratio of Li^7 to Li^6 will not in general be the same in the two phases. The quotient of the two ratios, α, is the fractionating factor. If we use such a system in a continuously operating column of n cells, and equilibrium is established in each cell, then the maximum fractionating effect which can ultimately be obtained from the column is α^n. However, as in the similar case of distillation, when only small quantities of material are employed it is simplest to use a column without definite separation into cells, so that the number of theoretical cells or "plates" depends upon the conditions of operation and can only be determined experimentally.

In our column in which small drops of lithium amalgam fell through a long column containing a solution of lithium salt, we were never able to determine the actual plate efficiency, but several preliminary experiments indicated that the efficiency would be high. For example, when the fine drops of lithium amalgam such as we have used in our experiments fell through one meter of aqueous sodium chloride, analysis of the amalgam which had passed through showed that 96% of the alkali metal in the amalgam was sodium and only 4% lithium. We may assume that this rapid interchange between lithium and sodium indicates a similar rapid interchange between lithium and lithium in our actual column.

The stocks of lithium amalgam, containing from 0.5 to 0.7 mole per liter, were prepared by electrolyzing a saturated aqueous solution of lithium carbonate, in the presence of excess solid carbonate, between platinum and mercury electrodes. The mercury was placed in flat crystallizing dishes, covered with about 2 cm. of water containing powdered lithium carbonate. Horizontal disks of platinum served as anodes. Four such cells were operated in series and these were placed in a trough of ice water to diminish the reaction between the water and the lithium amalgam already formed. Using a cathode current density of about 0.1 amp./sq. cm., the amalgams reached the desired concentration in six or eight hours, provided that reasonable care was taken to exclude such impurities as catalyze the reaction between water and amalgam. The process required little attention, but nevertheless was one of the more onerous parts of the investigation, during which over half a ton of the lithium amalgam was prepared.

The Column

The fractionating column consisted of a vertical glass tube 18 meters high and 4 mm. in internal diameter, which was filled with a solution of lithium salt. Through this solution a fine spray of lithium amalgam fell. It might be thought that the falling drops of mercury would cause serious mixing of the solution at top and bottom, but, on the contrary, when the stream of droplets is properly regulated they actually prevent such mixing. If the drops are of the right size and number they produce a condition of complete turbulence. Each drop of amalgam, as it passes down through the electrolyte, which is itself rising through the tube, assumes a zig-zag course, so that it takes four or five minutes to fall through the length of the column. This condition of turbulence, while causing intimate local mixing, prevents the mixing of the solution in one section of the column with that in another.

A state of turbulence is always very sensitive to slight changes in conditions and if the number of falling drops is increased much above that required for turbulence, the drops begin to pile up, with or without coalescence, thus ruining the whole experiment. In order to avoid dangerous spots it was necessary that the sections of glass tubing used in building the column be welded together with care to prevent any constriction or irregularity.

The top of the column, as shown in Fig. 1, is a continuation and enlargement of the main column, L. The shape of the funnel between L and M is important, since any discontinuity in the stream line causes too great an accumulation of amalgam drops. There is always some accumulation of these drops from the bottom of the funnel to a point which varies with the rate of production of drops at the source M. If the accumulation rises as high as M, or in any case if the droplets remain long enough in the top to coalesce into larger drops, the result is fatal and the whole experiment must be begun anew.

Each experiment was carried out with 10 liters of lithium amalgam, stored in a carboy, and protected against air and moisture. From this carboy the amalgam entered the tube P through a rubber tube fitted with a stopcock, so mounted that the rate of flow of the amalgam could be regulated carefully. Except in one case when a new rubber tube contaminated the amalgam this cock gave a nearly constant rate of flow, although it was customary to make a fine regulation about once an hour.

The amalgam entered the column at M through a fine silk fabric tied at the end of the glass tube. Drops of amalgam about 0.1 mm. in diameter were desired, and many kinds of silk were tried before one was obtained which gave drops of the necessary size and uniformity. As the amalgam falls through the column it displaces an equal volume of the solution which leaves by the overflow at N.

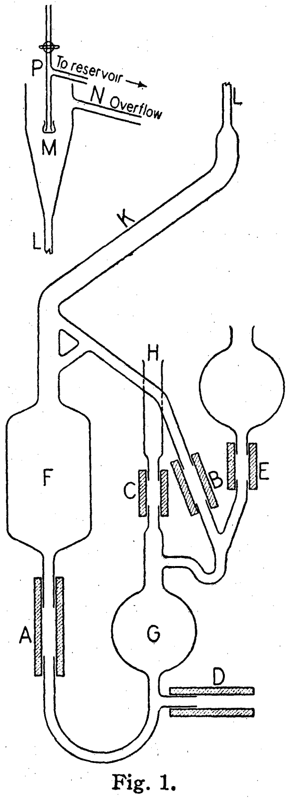

Fig. 1.

The lower end of the column is also shown in Fig. 1. In this part of the apparatus there are five cocks, A, B, C, D and E. The pressure at the bottom is about 2 atmospheres when the whole column is filled with the solution of lithium salt, and this pressure is approximately doubled when the amalgam is streaming down. Pressure stopcocks of glass were tried but it was found that the best cock for our purposes was afforded by a heavy walled rubber tube reinforced on the outside with adhesive tape and closed by a simple screw clamp (not shown in the diagram). The rubber tubing used in the cocks was boiled first with alkali and then with the solution which was to be used in the system. The cocks so prepared caused no appreciable contamination of the mercury and showed no evidence of any rapid deterioration.

At the beginning of the experiment the solution of lithium salt fills the whole column, the bulbs F and G, and connecting tubes as far as the cocks C, E and D. Then, all cocks being closed, the amalgam spray is started at the top of the column. The droplets fall without coalescence as far as the diagonal tube K, which is sealed to, and is larger than, the main column L. Here the coalescence begins and continues as the mercury accumulates in F so that under satisfactory working conditions the amalgam in F becomes a single mass except for a small layer of individual drops at the top. A great deal of time was spent in finding the proper conditions for the coalescence. In one experiment with a solution of lithium chloride in amyl alcohol which was supposed to be ready for a complete run, the drops formed an emulsion in F and no simple method was found which would make the drops coalesce. On the other hand, in some solutions there is danger of too rapid coalescence, for if it begins in the vertical column the experiment is also ruined.

Our present system has one valuable characteristic which is unique. Ordinarily if a material is distributed between two liquid phases the concentration is different in the two, and if a fractionating column is set up it requires a complicated feeding device to ensure that the amount of material rising through the column is just equal to that which is descending. In our present case the concentrations of lithium in the amalgam and in the other phase are independent. We therefore make the concentration of lithium the same in the two phases, and since the falling amalgam displaces an equal volume of the other phase, there is exact equality in the amount of lithium ascending and descending.

The remaining problem is to withdraw a certain volume of amalgam from the bottom of the column, extract its lithium in the form of a salt, dissolve this salt in the same volume of the other solvent, and return this solution to the column without disturbing its operation.

Starting with all the stopcocks closed, the amalgam is allowed to accumulate in the bulb F until it exceeds 100 cc. Stopcocks A and B are then opened until 100 cc. of amalgam flows into the bulb G, being replaced by an equal volume of the solution rising through B. The cocks A and B are now closed, and the cock C is opened to the air, the standpipe H serving to catch any liquid which may be carried up by hydrogen that has been evolved. The cock D is then opened until the amalgam is withdrawn from G. The lithium must now be extracted rapidly from the amalgam, converted into the salt which is being used, and this salt dissolved in 100 cc. of the solvent. The resulting solution is introduced into the system through the cock E, after which, closing E and C, the system is in its original state. This whole maneuver must be executed before the next 100 cc. of the amalgam is collected in the bulb F. This took in our various experiments from thirteen to fifteen minutes.

Attempts were made to find some automatic method of effecting, at the bottom of the column, the exchange from lithium amalgam to a solution of lithium salt. One method which seemed promising was to allow the amalgam drops to fall through a saturated solution of the corresponding salt of a heavy metal such as zinc. In such experiments, however, the zinc, instead of entering the amalgam, often formed a precipitate in the solution itself. Such methods were finally abandoned and we returned to the laborious but reliable methods of hand control.

If we are using, for example, a solution of lithium chloride in one of the alcohols, the simplest plan would be to treat the amalgam with an equivalent amount of an alcoholic solution of hydrochloric acid, but this process proved to be too slow. The reaction is rapid as long as the concentration either of lithium in the amalgam or free acid in the solution is high, especially when the system is kept at the boiling point of the solvent. However, even with amyl alcohol boiling at 130° it was found impossible to remove all the lithium from the amalgam by an equivalent amount of the acid solution during the fourteen or fifteen minutes available. Even a slight excess of acid could not be tolerated as it caused a violent evolution of hydrogen from the stream of amalgam drops. This evolution of hydrogen occurred to some extent in all of our experiments, but every effort had to be taken to keep it at a minimum.

The method finally employed is illustrated in Fig. 2. Two vessels A and B, operating on the counter current plan, are provided with small centrifugal stirrers which draw in amalgam at the bottom and spray it violently into the acid solution through a number of small openings. The burets C and D permit the introduction of measured volumes of a molal acid solution in the chosen solvent. In the vessel B, amalgam, from which most of the lithium has been removed in the vessel A, comes in contact with fresh acid until the last trace of lithium is removed. Through the stopcock F the mercury is withdrawn and discarded while the still acid solution is transferred to vessel A. Here 100 cc. of fresh amalgam enters directly from the column through the tube G.

The stirrer is then set in motion and a certain volume of acid introduced from the buret C. After a few minutes this acid is used up, as shown by an indicator, more acid is added, and the process repeated as long as time permits. The indicators used were phenolphthalein and chlorphenol red. Both are destroyed by violent agitation with lithium amalgam, so that they must be added near the end-point. At one of these end-points the stirrer is stopped, the nearly spent amalgam is transferred to vessel B, and the neutral solution is made up to 100 cc. and introduced into the column. The whole operation with both stirrers operating simultaneously took about ten minutes, leaving three or four minutes for the handling of the material at the bottom of the column.

All these operations had to be continued on schedule time and without the slightest departure from routine throughout the twenty-four hour run. At the end of each run, when the whole 10 liters of original amalgam had passed through the column, the two last samples of amalgam were withdrawn for analysis, as well as the solution which remained in the bottom of the apparatus and the lower end of the column.

The Isotopic Analysis

After the method of fractionating lithium isotopes had been developed it became an equally difficult task to ascertain the degree of enrichment of the light lithium isotope in the samples obtained from the column, for it is necessary to determine the atomic weight in a sample which contains originally only about 0.4 g. of lithium even before the processes of purification are begun.

Formerly, in an entirely different attempt to separate the isotopes of lithium, we had met the problem of determining the atomic weight in a sample containing less than a milligram of lithium, and we used a simple method which would only be able to show a large change in the isotopic ratio. In that method the sample was purified as lithium fluoride and the fluoride was fused on a platinum foil in an inert atmosphere. The drop of fluoride, on freezing, was usually transparent in the center with some opacity at the edges. By breaking the crystal into small pieces and selecting the transparent ones, it was possible to determine their density by a flotation method, using a mixture of a heavier and a lighter organic liquid. The reproducibility thus obtained was about 0.1%. With the larger samples available in the present research a higher degree of accuracy was sought by some more conventional method of atomic weight determination.

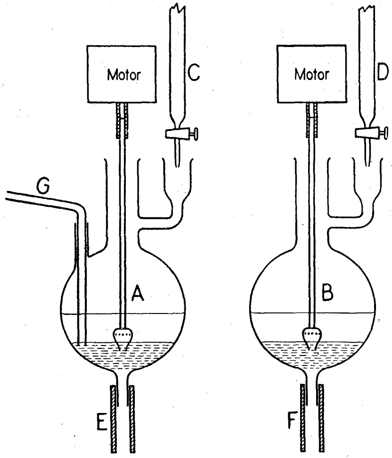

Fig. 2.

The method chosen consisted in titrating a weighed quantity of pure dry lithium carbonate against a solution of hydrochloric acid about 1.8 *N*. Since it was desired to obtain results reproducible to 0.01% it was necessary to take special precautions in the purification, the drying and the titration.

In order to test the method three samples of ordinary lithium carbonate containing 3 or 4 g. each were independently purified in the following manner. Each sample was dissolved in the requisite amount of pure water in a quartz flask. The solution was filtered through a small fine hardened filter paper, fastened by a clean rubber band to the end of a quartz tube. The filtrate was placed in a platinum flask of 900-cc. capacity and was then boiled until only 10 cc. of liquid remained. Most of the lithium carbonate was now in the form of a granular solid or a coherent layer on or near the bottom of the flask. The liquid was poured off and the remaining solid was rinsed with 10 cc. of pure water. The flask was next refilled with water to dissolve the carbonate and again boiled down for a second recrystallization. Each sample was crystallized three or four times. After two or three crystallizations the material gave every evidence of purity. It showed no flame test for sodium and in certain other experiments in which Br^- and SO_4^{--} were originally present, these ions could no longer be detected. All of the water used in these recrystallizations was prepared in a still of block tin and was free from non-volatile impurities.

The purified sample consisting of 1 or 2 g. of lithium carbonate was dried in a platinum crucible at 200°. It was then transferred to a weighed crucible and heated in an electric furnace for thirty minutes at a temperature about 50° below the melting point. The drying and heating were both carried out in an atmosphere of pure carbon dioxide. Previous experiments had shown that without this precaution some of the carbonate is converted into oxide and causes etching of the crucible. If the carbonate is heated to fusion the crucible is always slightly etched, even in an atmosphere of carbon dioxide. Our method proved to be the only one leading to strictly reproducible weighings.

After the carbonate was so prepared and weighed it was titrated against the standard solution of hydrochloric acid. Aside from the ordinary difficulties inherent in such a titration, the chief source of error lies in the carrying away of carbonate or acid by the spray resulting from the evolution of carbon dioxide. This danger was avoided by allowing the reaction to occur in a closed vessel. The crucible containing lithium carbonate was lowered until it stood upright at the bottom of a 1-liter quartz flask. A small excess of the standard acid was then introduced from a weight buret so as to flow around the crucible without meeting its contents. The flask was then closed with a rubber stopper through which passed a glass tube fitted with a rubber tube and a pinchcock. The flask was exhausted until the first bubbles of air began to rise from the acid. The cock was then closed, the crucible overturned, and the flask gently agitated until the carbonate was dissolved entirely. The cock was now opened and the stopper removed and tested for traces of acid or alkali. This test was always negative if the flask was so tilted during the neutralization that there was no direct path from the effervescing liquid to the stopper. The drops adhering to the sides of the flask were washed down and the small excess of acid remaining was now titrated with no more than ordinary precautions, the carbon dioxide being boiled off from the acid solution and phenolphthalein being used as indicator. Dilute solutions of barium hydroxide and hydrochloric acid, standardized with respect to the standard solution of concentrated hydrochloric acid, were used.

The titration of the three samples gave as the ratio of the weight of the standard acid solution to the weight of the lithium carbonate the three values 13.129, 13.127 and 13.128. In later experiments the standard acid was checked against ordinary lithium carbonate prepared from ordinary lithium amalgam, in order to follow the exact procedure used in preparing the samples of lithium carbonate of unknown isotopic composition from the amalgam taken at the bottom of the column. The procedure was as follows. The lithium amalgam was treated with pure distilled water in a wax bottle. After a day or two the reaction was complete and the solution of lithium hydroxide was filtered into a quartz flask through fine hardened filter paper attached to the end of a quartz tube. This treatment will remove any impurity of magnesium, which is the hardest element to separate from lithium. The filtrate was then immediately transferred to the platinum flask, converted into carbonate by a stream of carbon dioxide, and recrystallized by the method that we have already described.

The Three Operations of the Column

The First Run.—We first operated with half normal lithium amalgam and the same concentration of lithium chloride in ethyl alcohol. The method of transferring lithium from the amalgam to the electrolytic solution was in an experimental stage and broke down early in the run. In consequence a very crude and laborious method was necessary. The amalgam was treated with an excess of concentrated hydrochloric acid in a casserole which was heated until the excess acid had been driven off and the alcohol was added while the material was still hot and then brought to the proper concentration. About half way through the run one of the amalgam samples was lost completely. In addition to these difficulties the alcohol was not entirely free from water and there was therefore a large evolution of hydrogen in the column. This evolution of hydrogen does not seriously disturb the lower part of the column, for here the gas is under pressure and rises as small bubbles with the ascending solution, but as the bubbles rise they not only expand, but coalesce to form larger bubbles which produce much irregularity in the falling of the amalgam drops. In spite of these vexations the experiment was continued until the whole 10 liters of amalgam had passed through the column and the final amalgam at the bottom was analyzed. This analysis showed that Li^6 was being carried preferentially by the amalgam and that the ratio of Li^6 to Li^7 had approximately doubled. We were therefore encouraged to continue the experiments, avoiding as far as possible the difficulties of this run.

The Second Run.—Many experiments were now made with a variety of solvents and lithium salts, chiefly with the purpose of limiting the evolution of hydrogen. It was found in general that a solution which could be kept for hours in contact with lithium amalgam without appreciable reaction would react rapidly with the amalgam in the form of a fine spray. The rate of this reaction proved to be nearly independent of temperature, but depended markedly upon the presence of water and other impurities in the solvent, and was greatly increased by even a slight acidity.

Pure dioxane, which we prepared by a method similar to that of Kraus,[1] gives no reaction with lithium amalgam, but it is too poor a solvent to give the desired concentration of lithium salt. The system which seemed to suit our purpose best was a solution of lithium bromide in a mixture of four parts dioxane to one of ethyl alcohol, and our second run was started with this solution. However, the amalgam drops would not coalesce at the bottom of the column and it was necessary to begin anew with a solvent composed of two parts of dioxane and one of ethyl alcohol. This caused a somewhat greater evolution of hydrogen but not enough to cause serious trouble. One reason for using dioxane was that it seemed likely, on theoretical grounds, that it would enhance the separation of the two isotopes

---

(1) Kraus, THIS JOURNAL, **55**, 21 (1933).

We shall see, however, that this proved not to be the case.

At the bottom of the column the lithium was transferred from the amalgam to the electrolytic solution by the new method which we have already described. The stock acid solution was made by passing dry gaseous hydrogen bromide into absolute alcohol at −40° and this solution was then mixed with dioxane and kept at 0°, since at higher temperatures the hydrogen bromide reacts rapidly with both dioxane and alcohol. The run was satisfactory in every respect and two samples of amalgam were obtained at the end. These were purified carefully.

The pure lithium carbonate obtained in this experiment was titrated against our standard acid and its weight was compared with the weight of lithium carbonate of ordinary isotopic composition neutralizing the same amount of standard acid. For the ratio of the equivalent weight of the latter to the equivalent weight of the former we found in the first sample 1.0015, and in the second sample 1.0014. The calculation of the isotopic composition from these figures will be made presently.

The Third Run.—Since we found that contrary to our expectations the dioxane–alcohol mixture gave less fractionation than pure alcohol, it was decided to make one more run with lithium chloride in absolute ethyl alcohol, although the evolution of hydrogen is greater in this solvent. In the third run ten liters of 0.6 *N* amalgam were passed through the column in twenty-three hours. At the end, two 100-cc. samples of amalgam were obtained, and also a third sample containing the alcohol solution remaining in the bottom, together with some from the column itself.

The lithium carbonate from the first sample of amalgam was purified and at the end of the recrystallization 1.37 g. was left. The ratio of the weight of ordinary lithium carbonate to the equivalent weight of this sample was 1.0022. With the second sample of amalgam the process of recrystallization was carried further than we intended, leaving only 0.69 g., which gave 1.0026 as the ratio of equivalent weights.

On account of the small amount of the second sample a new determination seemed desirable. Therefore the material left from the titration of these two samples, containing chiefly lithium chloride and barium chloride, was treated with sulfuric acid and evaporated nearly to dryness. To the residue, water and an excess of barium carbonate were added, and carbon dioxide was bubbled through overnight. The solution was boiled, filtered and subjected to the usual recrystallizations. The resulting carbonate gave the lower ratio 1.0016. It is to be noted that every impurity that can be imagined to be present will diminish the value of the ratio. It seems probable that this sample, which was obtained by a different procedure from the others, still contained some impurity.

Finally, the lithium chloride which was present in the electrolytic solution at the bottom of the column was purified by the following method. An aqueous solution of the lithium chloride was treated with an excess of silver oxide, and carbon dioxide was bubbled through for many hours. The solution was then filtered, boiled and refiltered. To remove the last traces of silver carbonate 2 cc. of 0.01 *N* hydrobromic acid was added. After filtration the treatment was continued as in previous cases through four recrystallizations, during which all traces of Br^- disappeared. This carbonate gave, for the ratio of equivalent weights, 1.0019. Since this sample contained some liquid from the column where there would be less separation of the isotopes, this experiment tends to confirm the higher ratio obtained in the first two analyses.

Unfortunately at this point it was necessary to discontinue the experiments owing to the departure of one of the authors, but it seems that we can make no great error in taking as our final ratio for this run the weighted mean of the first two ratios, namely, 1.0023.

Interpretation of the Results

The ratio of Li^7 to Li^6 in ordinary lithium is 11.6, according to the most recent work of Brewer.[2] This identical value is also obtained by comparing the accepted atomic weight of lithium, 6.940, with the values 7.0182 for Li^7 and 6.0170 for Li^6, obtained from mass spectra and nuclear disintegrations.[3]

In our third run, in which the highest concentration of Li^6 was obtained, we found the value 1.0023 as the ratio between the equivalent weights of ordinary lithium carbonate and of that from the column. Using the latest International atomic weights, we thus find that in our experiment the atomic weight of lithium was brought from 6.940 to 6.855. This means that the concentration of Li^6 has been raised from 8% in the original lithium to 16.3% in our new material. In other words, the ratio of Li^7 to Li^6 in our sample has been reduced to 5.1.

In our second run, using lithium bromide in a solvent containing one part of ethyl alcohol to two parts of dioxane, the ratio of Li^7 to Li^6 was brought to the value 6.6. Whether the smaller fractionation in this case was due to a smaller fractionating factor or to a lower efficiency in the column we cannot state.

Concerning the theory of the fractionation in our column, there is little to be said. In some experiments on the separation of the nitrogen isotopes, which will shortly be published by Lewis and Schutz, it was found possible to make in advance a rough calculation of the sign and the magnitude of the fractionating effect. In the present case there was no sure way even of predicting whether Li^6 would be concentrated at the top or bottom of the column. Since the fractionation must depend chiefly upon differences in zero-point energy, the zero-point energy always being greater in a substance containing a heavier isotope,

---

(3) See, for example, Bonner and Brubaker, *ibid.*, **50**, 308 (1936).

our experiments indicate that lithium is held more tightly to oxygen in the electrolytic solution than it is to mercury in the amalgam. Since, presumably, in alcohol the lithium is held between two or more atoms of oxygen and attached ordinarily to only one oxygen in dioxane, it seemed likely that the fractionating effect would be higher with dioxane than with alcohol; but, as we have seen, this proved not to be the case.

Our experiments did not proceed far enough to enable us to determine either the exact fractionating factor or the number of theoretical plates in our column. We can, however, obtain a minimum value for the fractionating factor, as follows. We estimate that in our last run 0.012 equivalent of Li^6 accumulated at the bottom of the column in excess of the amount present in ordinary lithium. This figure is to be compared with the total of 0.48 equivalent of Li^6 which was present in the original ten liters of amalgam. If the column is assumed to have an infinite number of theoretical plates, the fractionating factor is then 1.025. If, on the other hand, the column was less efficient, and some of the excess Li^6 found its way to the overflow at the top of the column, then the fractionating factor is larger. Corresponding to a fractionating factor of 1.025, the electrode potential between lithium amalgam and a solution of lithium chloride in alcohol would, at room temperature, and under equivalent conditions, be 0.0006 volt higher for Li^7 than for Li^6. Hence we may conclude that the difference in potential is at least as great as this.

The material obtained in this investigation will be used in several experiments to determine the difference in physical and chemical properties of the two lithium isotopes. Recently Mr. Brewer,[2] studying positive rays, has obtained indications of the existence in ordinary lithium of the isotope Li^5. If we attribute the concentration of Li^6 in our experiments mainly to differences in zero-point energy, a simple calculation shows that if Li^5 exists in the original lithium, it would be concentrated five-fold by our fractionation. We have, therefore, sent a sample of material from our third run to Mr. Brewer, who has been kind enough to examine it. He writes that in his first experiment conditions were unfavorable for observing Li^5, but it is interesting that he finds in this sample exactly the same ratio of Li^7 to Li^6 which we found by the atomic weight method, namely, 5.1.

Summary

From the ordinary mixture of lithium isotopes, Li^6 has been enriched in an 18-meter column, where fine drops of lithium amalgam fall through a solution of lithium chloride in absolute ethyl alcohol or of lithium bromide in a mixture of alcohol and dioxane. At the bottom of the column, the lithium is extracted from the amalgam and added as lithium salt to the ascending electrolytic solution. After the passage of 10 liters of amalgam through the solution, the material at the bottom of the column is removed for the analysis, which consists in determining the atomic weight of this lithium relative to that of ordinary lithium. This was accomplished by the exact titration of dry lithium carbonate against a solution of hydrochloric acid. In the final experiment, the isotopic ratio Li^7 to Li^6 was changed from 11.6 in ordinary lithium to 5.1 in our material. The results show that, under equivalent conditions, the electrode potential between amalgam and alcohol solution is greater for Li^7 than for Li^6 by at least 0.0006 volt.

The Reaction of Hydrogen Peroxide with Chromic Anhydride in Dry Ethyl Acetate

BY DOUGLAS G. NICHOLSON

The chemical literature contains many references to the deep blue colored metastable compound formed when acidified chromate solutions are treated with hydrogen peroxide. Many of these references[1–6] imply that the chromium in this compound is in a valence state higher than six; while others[7–10] show quite conclusively that the chromium is present in the hexavalent state.

An investigation was undertaken to prepare and, if possible, study the properties of this peroxychromic compound in a non-aqueous medium. The solubility of chromic anhydride and hydrogen peroxide in dry ethyl acetate led to the selection of this material as the solvent for this work.

Experimental

A solution of hydrogen peroxide in ethyl acetate was prepared by shaking a mixture of 100 ml. of 30% hydrogen peroxide, 3–5 ml. of water, and 900 ml. of ice cold ethyl acetate for about fifteen minutes, allowing the liquids to separate, then carefully pouring off the acetate layer. This acetate solution of hydrogen peroxide was then dried over anhydrous copper sulfate for at least thirty minutes. After filtration, to remove the cupric sulfate, a small portion of this solution was titrated (in dilute aqueous sulfuric acid solution) with standard permanganate solution. This titration showed the peroxide content of the ethyl acetate solution to be between 0.95–0.99 normal. Upon standing for several days this solution showed no material loss in peroxide content.

From one-half to one gram of solid chromic anhydride was added to the remaining bulk of the ethyl acetate peroxide solution. The resulting intensely blue colored solution was maintained at the temperature of the ice-bath, while a solution of ammonia in absolute alcohol was added in slight excess. This alcoholic ammonia solution was prepared by adding liquid ammonia to absolute alcohol. Upon the addition of the ammonia, the intensely blue color faded leaving a water clear solution and a tan colored precipitate.

The peroxide solution was maintained in excess at all times in order to retain the chromic anhydride in combination as the blue colored peroxy compound.

The tan precipitate was carefully washed with cold ethyl acetate and dried in an atmosphere of nitrogen while retained in a vessel jacketed with dry ice. Samples of the dry material were analyzed for ammonia as well as for the chromium content.

Discussion

Since chromic anhydride unites with water forming chromic acid, it seems likely that the anhydride may unite with hydrogen peroxide in a non-aqueous medium to form a peroxy acid analogous to Caro's acid in the case of sulfur trioxide. Addition of the alcoholic ammonia solution should form an ammonium salt of this acid. The tan precipitate which formed upon addition of the ammonia was studied to evaluate some of its physical and chemical properties.

The ammonia content of the tan precipitate was determined using the standard method of absorbing the ammonia in a known volume of standard acid, then back titrating with standard alkali solution.

The chromium was determined by reduction and precipitation of chromic hydroxide, with subsequent ignition to chromic oxide; as well as by oxidation to chromate, precipitation of mercurous chromate, and ignition to chromic oxide.

On the basis that hydrogen peroxide would unite with chromic anhydride forming a peroxychromic acid thus: $H_2O_2 + CrO_3 \longrightarrow H_2CrO_5$, and that the tan precipitate would have the formula $H_2CrO_5 \cdot 2NH_3$, the calculated chromium content would be 30.95% while the ammonia content would be 20.23%. The average chromium content found by analysis was 30.93%, and the average ammonia content 20.15%.

Considerable difficulty was encountered in the analysis of the tan material due to its extremely unstable nature. Several samples took fire spontaneously during the course of weighing. Other samples gave poor results due to absorption of moisture and subsequent decomposition.

The tan colored ammonium salt dissolves in water with evolution of oxygen, forming a yellow-orange chromate solution. When added to acidic solutions it evolves oxygen with the formation of the unstable blue peroxychromic acid, and the resulting decomposition gives rise to a green chromic salt. At temperatures slightly above room temperature, the salt decomposes spontaneously

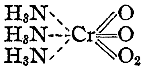
and bursts into flame. This decomposition takes place in two stages—swelling and ignition. The particles appear to swell considerably, and finally flash rapidly leaving a residue of finely divided chromic oxide. If struck a sudden blow the material decomposes with explosive violence. If allowed to remain for some time below, or at room temperature, the material becomes more stable and behaves in much the same manner as does ammonium dichromate. X-Ray diffraction patterns show the tan colored material to have a structure quite different from that of ammonium chromate or ammonium dichromate.

The physical and chemical properties of this material resemble those described by Riesenfeld[11] for the compound chromic tetroxide triammine. The formula given this compound is



$$\begin{matrix} H_3N\searrow & & \nearrow O \\ H_3N\rightarrow & Cr & = O \\ H_3N\nearrow & & \searrow O_2 \end{matrix}$$

Since the molecular weight of this material would be 167, and that of $H_2CrO_5 \cdot 2NH_3$ 168, it follows that the chromium content would not be a deciding factor in the determination of structure. Since but two ammonia groups could be accounted for by accurate ammonia analysis in the case of the material prepared in this study; it is assumed that these compounds are different in chemical constitution although very similar in chemical properties.

Summary

The reaction between hydrogen peroxide and chromic anhydride has been studied using dry ethyl acetate as the solvent. A tan ammonium salt of the blue colored peroxychromic acid has been prepared. Analyses of this salt are in accord with the formula $H_2CrO_5 \cdot 2NH_3$. From this information the formula of the blue peroxychromic acid probably is H_2CrO_5 or $CrO_3 \cdot H_2O_2$. Some physical and chemical properties of the ammonium salt have been determined.

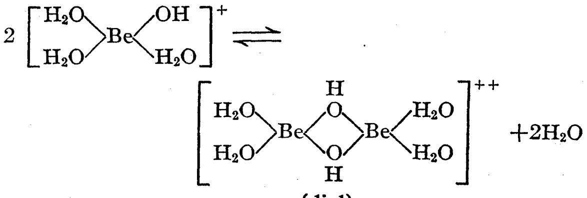
Basic Beryllium and Complex Beryllate Hydrosols; an Additional Contribution to the Concept of Polyolated and Polyoxolated Structures

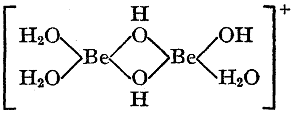
By Arthur W. Thomas and Hoke S. Miller

In previous publications from this Laboratory the properties of certain colloidally dispersed metallic "oxides" have been readily explained according to the concept that the micelles are polyolated and/or polyoxolated structures.[1] Application of this theory which involves the Werner–Pfeiffer ideas of hydrolysis and olation together with Stiasny's concept of the oxolation of ol groups, has produced a new and fundamental knowledge of beryllium "oxide" hydrosols.[2] Accepting the coördination number of 4 usually assigned to beryllium, the formation of a diol from triaquo monohydroxo beryllium ion would be



(diol)

The dissociation of an aquo group in this dinuclear diol ion, or the replacement of one of its aquo groups by OH would produce an ion such as



According to the theory, two of these in turn can olate, the result in this case being a tetranuclear olated ion. Since removal of H^+ ion favors olation, one would expect increase in size of the olated ions when a solution of a beryllium salt is made increasingly basic. Increases in basicity, however, and especially elevation of temperature

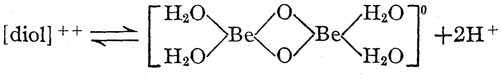
(2) For convenience, those hydrosols in which the beryllium is in the cationic micelle will be called *basic beryllium* hydrosols and the name *complex beryllate* will signify hydrosols in which the beryllium exists in the form of an anionic micelle.

favor oxolation, which, taking the diol for simplicity, is represented by the reaction



the intermediate product, containing one ol and one oxo group being omitted to save space. Quite unlike metals having coördination numbers of 6 and 8, it is seen that the complete oxolation of a diol structure of beryllium with its coördination number of 4 produces a complex without a charge. This would suggest that oxolation of colloidal basic beryllium complexes would result in precipitation of the micelles. This prediction has been found to be correct because our basic beryllium hydrosols precipitate immediately when boiled, and in about two hours at 60°.[3]

According to the polynuclear theory proposed at this Laboratory, the formation of a hydrosol by peptization of the hydrous oxide with the acid, HA, consists in the interaction between the H^+ ion of the peptizing acid with OH groups of the hydrous oxide gel, thus converting the polynuclear olated hydrous oxide to a polynuclear cationic micelle. A cationic micelle arises, however, only when the anion, A^- of the acid is not a strong coördinative binder. If it, by displacing aquo groups, becomes coördinatively bound to the same extent that the H^+ ion reacts with the OH groups of the gel, then no colloidal dispersion occurs. However, if A^- has great tendency to displace aquo groups, it may actually produce anionic micelles, and in the case of even neutral salts of such anions, an anionic micelle arises by peptization of the oxide.[1e] Such phenomena previously reported for zirconium and thorium "oxide" hydrosols have also been found in the case of beryllium "oxide" hydrosols.

Preparation of Basic Beryllium Hydrosols.—Three methods were employed as follows:

(a) Sodium hydroxide was added dropwise to a mechanically stirred aqueous solution of beryllium nitrate until a decided turbidity was produced. The stirring was continued for about twenty hours, after which the hydrosol was dialyzed against running distilled water, using nitrocellulose membranes.

(b) Beryllium hydroxide was precipitated from aqueous beryllium nitrate solution, washed by centrifuging and peptized with tenth molar beryllium nitrate solution. During the peptization the system was stirred mechanically. The stirring was continued for twenty hours after the beryllium nitrate was added. The hydrosols thus formed were dialyzed as previously mentioned.

(c) Beryllium hydroxide precipitated by ammonium hydroxide from beryllium nitrate solution was washed by centrifuging until the supernatant liquid no longer gave the ferrous sulfate ring test for nitrate. A known amount of 0.05 *N* hydrochloric acid was added while the solution was stirred mechanically. It was observed that the ratio of equivalents of beryllium as the hydroxide, to the equivalents of chloride, as the acid, should be approximately 50:1. When too much acid was added, deolation seemed to occur. After peptization had continued for about twenty hours the hydrosols were dialyzed against distilled water.

In all cases, the dialysis was carried out by allowing distilled water to flow through nitrocellulose bags which were immersed in the colloidal solutions, the latter being stirred mechanically. All sols were centrifuged after dialysis to remove coarse suspended matter.

Table I summarizes briefly some of the properties of these hydrosols.

TABLE I

DATA CONCERNING HYDROSOLS[a] CONTAINING CATIONIC BERYLLIUM MICELLES

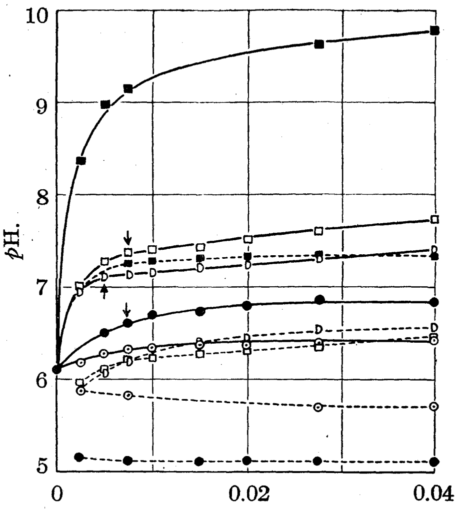
[a] All the hydrosols displayed particles in lively Brownian motion in a brilliant Tyndall cone. They were cloudy in appearance. [b] The initial letters (c) and (a) are used in Tables I and III to signify that the beryllium is in the cationic (c) or in the anionic (a) micelle. [c] In milliequivalents per liter. [d] *p*H values were measured immediately after centrifuging the dialyzed hydrosols. [e] 500 cc. of sol cC when decomposed with nitric acid gave no test for chloride with silver nitrate, nor did a portion of it give the ferrous sulfate ring test for the nitrate ion.

Effect of Neutral Salts upon Hydrosols.—In previous publications[1] it was shown that neutral salts raise the *p*H values of certain metallic

---

[3] Some of our basic beryllium hydrosols precipitated after storage for two months at room temperature.

"oxide" hydrosols, the action being ascribed to the displacement of OH groups in the micelle by the added neutral salt anions. The relative potencies of neutral salt anions to raise the *p*H value have been ascribed to their relative coördinative binding tendencies.



Final salt concentration in equivalents.

Fig. 1.—Effect of potassium salts on the *p*H of sol cA. Sol six days old. Broken lines represent *p*H values of pure aqueous salt solutions. Continuous lines record *p*H values of sol-salt mixtures. ■, Citrate; ⊙, chloride; □, oxalate; ●, sulfate; D, tartrate.

In the experimental work, with the exception of all the data given in Fig. 1 and that for the potassium citrate solution in Fig. 3, 0.08 *N* stock solutions of the salts were adjusted to *p*H values below 7 and above 6 by the addition of potassium hydroxide or of the appropriate acid. The *p*H values of these stock solutions are recorded in Table II. These solutions with added water, when necessary, were added to equal volumes of the hydrosol in small bottles and rotated at 7 r. p. m. for twelve to twenty hours at 25°.[4] The hydrogen ion activity was then measured by the quinhydrone electrode if the *p*H value was less than 7.5 and by the hydrogen–platinized-platinum electrode when it was above 7.5.

Table II

*p*H Values of 0.08 *N* Potassium Salt Solutions

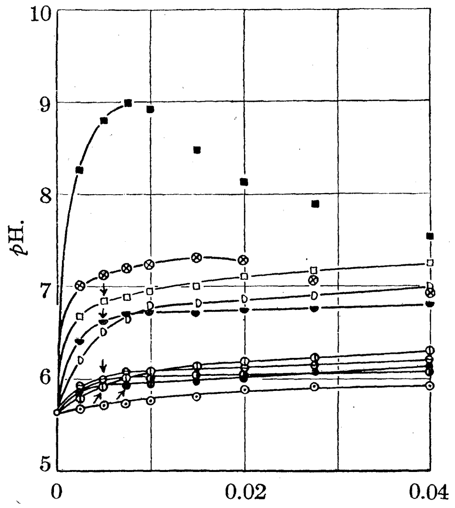
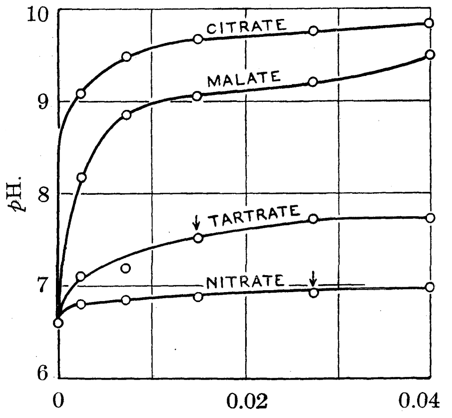
Lactate	6.7	Tartrate	6.4
Malate	6.4		



Final salt concentration in equivalents.

Fig. 2.—Effect of potassium salts on *p*H of sol cE. Sol one day old. Salt solutions were those described in Table II. ⦶, Acetate; ■, citrate; ⊙, chloride; ⊖, formate; ◑, fumarate; ⊗, malate; ▾, maleinate; □, oxalate; ●, sulfate; D, tartrate.



Final salt concentration in equivalents.

Fig. 3.—Effect of potassium salts on *p*H of sol cC. Sol one day old and apparently devoid of chloride or nitrate ion. Salt solutions used were those described in Table II with exception of the citrate solution which in this instance was at *p*H = 6.9.

Figures 1 to 3 provide some typical results. In Fig. 1, the broken curves show the *p*H values of pure aqueous solutions of the salts while the continuous curves represent the *p*H values of the salt–hydrosol mixtures. There can be no doubt concerning the *p*H increasing effect of the added anions. The marked buffer effect of the *p*H =

---

[4] The reaction is practically complete in one to three hours.

6.3 citrate solution used in the experiments plotted in Fig. 2 led us to use a stock citrate solution of $p\text{H} = 6.9$ in the work recorded in Fig. 3. The arrows on Figs. 1, 2, 3 and 7 indicate where precipitation was observed. In the cases of added citrate and malate, precipitation occurred at extremely low concentrations of the added salt, higher concentrations of these salts producing no precipitate but having converted the cationic beryllium micelles to anionic citrato (or malato) beryllate micelles. A summary of all of our measurements showed that the pH raising order for the anions upon cationic beryllium hydrosols is citrate $>$ malonate $>$ oxalate $>$ malate $>$ tartrate $>$ maleinate $>$ acetate $>$ formate $\geqq$ fumarate $\geqq$ sulfate $>$ chloride $\geqq$ nitrate. This series resembles that found in this Laboratory for thorium oxychloride sols[1e] and for zirconium oxychloride sols.[1f]

With the *cis-trans* isomers, potassium maleinate proved to be more effective than potassium fumarate. This is in agreement with the action of these salts on thorium oxychloride sols as reported by Thomas and Kremer.[1e]

One might ask whether there is any relationship between the pH raising effect of the added salts and their precipitating potencies upon basic beryllium hydrosols. A few experiments were performed to throw light upon this question.

Liminal Values[5] of Salts.—The procedure adopted for the measurement of liminal values was as follows. Into each of four 30-cc. volume test-tubes was placed 5 cc. of the hydrosol. Five cubic centimeter portions of varying concentrations of the salt were placed in four other tubes. The salt solution was poured into the hydrosol; the contents were poured back into the salt solution tube; then back to the hydrosol tube, after which they were centrifuged for two minutes at 1000 r. p. m. (radius, 21 cm.). This procedure was repeated until the liminal value was finally obtained.

From the results given in Table III it can be seen that the effectiveness of certain potassium salts as precipitants of cationic basic beryllium hydrosols is in general: citrate $>$ malate $=$ tartrate $>$ oxalate $>$ sulfate $>$ fumarate $>$ maleinate $>$ chloride. It is interesting to note that tartrate is a more powerful precipitant than oxalate although the reverse is true for their pH raising potencies. Inasmuch as inorganic micelles are, in general, precipitated when the charge is reduced to a certain extent, and since in this instance the positive charge must be reduced by displacement of aquo groups of negatively charged ions, it would seem that tartrate is a more potent displacer of aquo groups than is oxalate. The same may be said for sulfate as compared with maleinate where the precipitating potency is sulfate $>$ maleinate, the reverse of the pH raising tendency.

TABLE III

LIMINAL VALUES

Sol	Citrate	Tartrate	Malate	Oxalate	Sulfate	Fumarate	Maleinate	Chloride

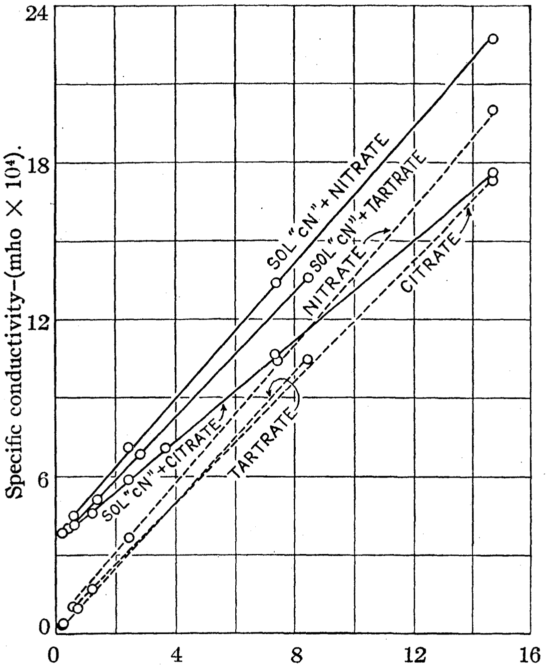
Conductance Titrations.—Another means of comparing the tendencies of anions to displace aquo groups from the central metallic ions of the micelle is offered by measurement of changes in conductivity resulting upon addition of very small amounts of salts to the hydrosol and to water. Such measurements are shown in Fig. 4 where the conductivities of mixtures of hydrosol "cN" and potassium salts (solid lines) are compared with the conductivities of the pure salt solutions (broken lines). If the anion of an added salt enters the micelle, displacing an aquo group therefrom, the conductivity of the salt–hydrosol mixture will obviously be less than if there were no reaction between the added anion and the colloidal micelle. Convergence of the solid line and broken line curves in Fig. 4 is evidence for such displacement, while parallelism of the solid and broken lines for a given salt means no such reaction. Inspection of the figure reveals that the nitrate curves have practically identical slopes and hence at the low concentrations used, nitrate has only a negligible (if any) effect in replacing aquo groups from the central beryllium ions of the micelle. The tartrate curves are not of the same slope, showing that tartrate has an aquo group replacing tendency which is, however, less than that of citrate where the curves converge at the concentration of 15 milliequivalents of potassium citrate per 50 cc. of solution. It must be remembered that some replacement of OH groups also is effected by an ion such as citrate (and to a less extent by tartrate). This

---

[5] "Liminal value" as used in this paper is defined as the lowest concentration of salt, expressed in millimoles per liter of final mixture, that just completely precipitates the micelles under the described procedure.

would cause the curves to diverge with increasing concentration, however. In view of the fact that both OH replacement and aquo group replacement may occur, one is obliged to be content with the solely qualitative nature of the evidence given in Fig. 4, namely, aquo group replacement potency is citrate > tartrate > nitrate.[6]



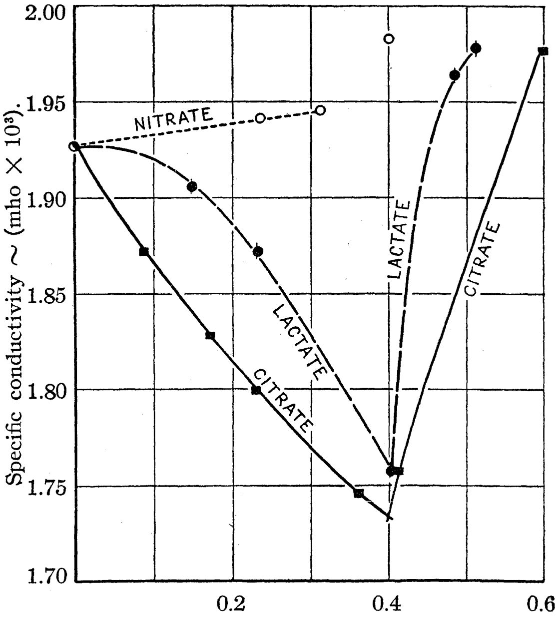
Milliequivalents of salt in final solution, 25 cc. sol "cN" + 25 cc. salt.

Fig. 4.—Potassium salt conductivity titrations of sol cN. Sol three days old. Continuous lines represent mixtures of sol and salt solutions. Broken lines represent salt solutions diluted with water.

Another method of measuring the tendency of anions to replace aquo groups is by means of the observation of the effect of added silver salts upon the conductivity of the hydrosol. By means of a technique previously described[1b] the results shown in Fig. 5 were given by sol "cM."

All the chloride in the hydrosols was precipitated by each of the silver salts added since the value of the chloride content determined by the conductivity method agreed with the gravimetric results. When an amount of silver salt just in excess of equivalence to the chloride content of the hydrosol was added, a sharp change in direction of the curve occurred.

It is seen that added amounts of silver nitrate caused an increase in conductivity in the first segment of the curve, while the reverse was found true for lactate and citrate. These experimental data may be explained as follows. When silver ion is added to the hydrosol it combines with the unbound chloride ion to form silver chloride. As the chloride ion is removed from solution, any coördinatively bound chloride moves out of the micelle. This reaction continues until all the chloride has been converted to silver chloride, when the inflection point occurs; further additions of silver salt obviously increase the conductivity of the system. Since the nitrate ion has only a very feeble tendency to become coördinatively bound, we may assume that as the chloride groups move out of the micelle, aquo groups enter to satisfy the coördination number of the beryllium atom, thus the positive charge of the micelle increases, and consequently the conductivity increases also. This is, of course, superimposed upon the increase in conductivity resulting from the addition of silver and nitrate ions.



Milliequivalents of silver salts added.

Fig. 5.—Conductivity titrations of sol cM with silver salts. Sol three days old.

The decrease in conductivity when either silver lactate or silver citrate is added may be explained in the following manner. As the coördinatively bound chlorido groups move out of the complex they are replaced by negatively charged lactate or citrate ions as the case may be. The combination between chloride and silver ions reduces the

---

(6) The reaction between citrate ion and the micelle was rather slow, four hours being required for attainment of equilibrium at the highest concentration of added citrate.

conductivity of the system as in the first instance. At the same time, since lactate or citrate ions displace aquo groups, the charge of the micelle is reduced. These ions no longer contribute to the conductivity of the system and hence there are introduced two additional conductivity-lowering factors.

The steeper slope for citrate is ascribed to its greater tendency than lactate to become coördinatively bound to the central beryllium ions and to replace aquo groups therefrom.

A similar series of titrations of sol "cO" is given in Fig. 6. This sol differed from "cM" in its lower basicity or higher ratio of chloride to beryllium. It is noted that nitrate ion showed a slight tendency to combine with the micelles.

Complex Beryllate Hydrosols

Thomas and Owens[1f] and Thomas and Kremer[1e] found that a reversal of the sign of charge of cationic zirconium "oxide" and thorium "oxide" micelles occurred upon the addition to the hydrosols of specified concentrations of salts and acids of strong coördinative binding anions. These authors also demonstrated that upon direct peptization of zirconium or thorium hydrous oxides with certain salts or acids, anionic basic "oxide" sols were produced. Thomas and Owens reported also that anionic zirconium micelles could be produced by boiling a crystalloidal solution of a complex zirconeate.

Search of the literature failed to locate any statement concerning the reversal of the sign of the charge of cationic beryllium "oxide" micelles other than the report that attempts to accomplish such a result by use of potassium ferrocyanide[7] did not meet with success. Following the theoretical prediction that anions which are powerful coördinative binders should produce anionic micelles provided that they replace a sufficient number of aquo groups from the cationic micelle or from the hydrous oxide, it was found that stable hydrosols of anionato complex beryllate micelles could be produced. Some remarks concerning these systems follow.

Preparation of Complex Beryllate Hydrosols.—These hydrosols can be prepared by either of the following methods: (1) by the addition of either potassium citrate, malate or tartrate to a cationic beryllium hydrosol, producing a precipitate which redisperses;[8] (2) by the peptization of freshly precipitated hydrous beryllium oxide with an aqueous solution of either potassium citrate or malate, or tartrate; (3) by dropwise addition of ammonium hydroxide solution to a complex crystalloidal beryllate, prepared by adding potassium tartrate to beryllium nitrate solution, with immediate and subsequent dialysis. Care must be exercised not to add too much ammonium hydroxide. An excess of this reagent precipitates the beryllium as hydroxide.[9]

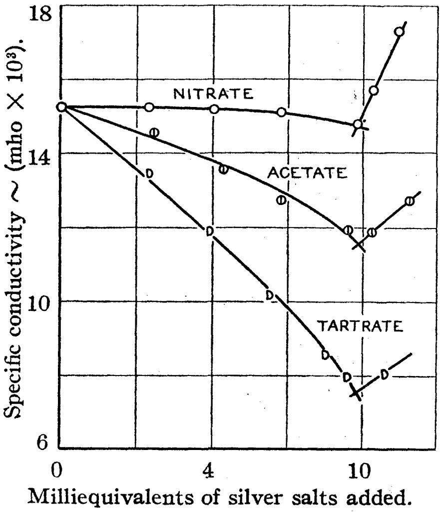


Fig. 6.—Conductivity titration sof sol cO with silver salts. Sol three days old.

A description of a few of these sols is given in Table IV.

TABLE IV

DATA CONCERNING COMPLEX BERYLLATE HYDROSOLS[a]

Designation	Method of preparation	Hours dialyzed	Be[b]	pH[c]
aJ	3	186	40.1	7.8
aK	2 (citrate)	237	19.5	6.3
aH	2 (tartrate)	113	41.6	6.4
aL	2 (malate)	223	29.1	6.9
aQ	2 (tartrate)	77	74.5	6.9

[a] These hydrosols were cloudy in appearance, displaying particles in lively Brownian motion in a brilliant Tyndall cone. [b] In milliequivalents per liter. [c] The pH values were measured immediately after centrifuging the dialyzed hydrosols.

Some Properties of Complex Beryllate Hydrosols.—It was found that addition of potassium salts to these hydrosols results in an increase in pH value. A typical result is shown in Fig. 7

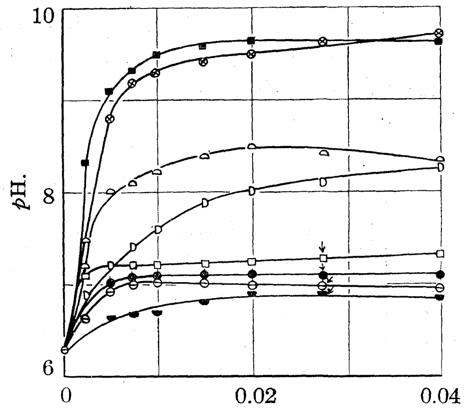
---

(7) W. H. Madson and F. C. Krauskopf, *J. Phys. Chem.*, **35**, 3237 (1931).

(8) The redispersion of the precipitate with potassium tartrate is slow, several days being necessary for the formation of a hydrosol.

(9) This affords a means for the separation of beryllium from certain other metals which is to be described by one of us (H. S. M.) in a subsequent paper.

where the effectiveness of the anions is seen to be citrate > malate > malonate > tartrate > oxalate > lactate > formate > maleinate. In the concentration range shown in Fig. 7, precipitation of the micelles occurred only with the last four salts mentioned and then only slightly at a concentration of 0.028 milliequivalent.

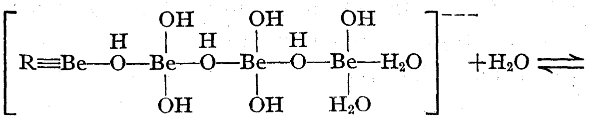


Final salt concentration in equivalents.

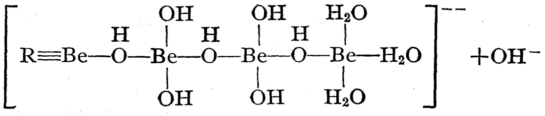
Fig. 7.—Effect of potassium salts on the pH of sol aK. Sol five days old. Salt solutions used were those described in Table II. ■, Citrate; ⊖, formate; ●, lactate; ⊗, malate; ▾, maleinate; ⌓, malonate; □, oxalate; D, tartrate.

It will be recalled that hydrosols of the cationic metallic micelles become more acid on storage at room temperature owing to oxolation and possibly to dissociation of aquo groups. The complex beryllate hydrosols, on the contrary, become less acid on aging at 25°. The pH value of sol "aK" which was 6.3 at the conclusion of dialysis rose to 7.2 in one month. Six weeks later it was 7.4. Sols "aL" and "aQ" also increased in pH value but to a less extent.

This increase in pH might be ascribed to the action of free citrate, malate or tartrate ions (possibly present) in replacing coördinatively bound OH groups. But the phenomenon of aquotization would seem to offer a more plausible explanation. An aquotization reaction of a hypothetical basic citrato beryllate[10] may be illustrated as follows, where R = $C_6H_5O_7^{---}$



$$\left[\mathrm{R{\equiv}Be{-}\overset{H}{O}{-}\underset{OH}{\overset{OH}{Be}}{-}\overset{H}{O}{-}\underset{OH}{\overset{OH}{Be}}{-}\overset{H}{O}{-}\underset{H_2O}{\overset{OH}{Be}}{-}H_2O}\right]^{---} + H_2O \rightleftharpoons$$



$$\left[\mathrm{R{\equiv}Be{-}\overset{H}{O}{-}\underset{OH}{\overset{OH}{Be}}{-}\overset{H}{O}{-}\underset{OH}{\overset{OH}{Be}}{-}\overset{H}{O}{-}\underset{H_2O}{\overset{H_2O}{Be}}{-}H_2O}\right]^{--} + OH^-$$

As a precedent for this type of reaction we would cite Sandved's[11] measurements of the equilibrium constants of the reversible aquotization reactions

$$\left[\mathrm{Co}^{\chi}_{(NH_3)_5}\right]^{++} + H_2O \rightleftharpoons \left[\mathrm{Co}^{H_2O}_{(NH_3)_5}\right]^{+++} + \chi^-$$

where χ = Cl or NO_3

Heating of beryllate sols produced an unexpected change in that cationic beryllium micelles arose. Sols "aK" and "aL" were heated at 95° in sealed containers for ninety-six and fifteen hours, respectively. As a result of the heating, the conductivities rose in the case of "aK" from 4.24×10^{-5} to 5.84×10^{-5} mho and in the case of "aL" from 13.76×10^{-5} to 13.98×10^{-5} mho.

Upon electrophoresis of the sols which had been heated, it was observed that about half the beryllium in the case of sol "aK" and about four-fifths in the case of "aL" migrated to the anode, the remainder being cationic.[12] These results may be explained on the assumption that heating causes some of the citrato or malato groups to move out of the micelles, thus reducing the negative charge and even reversing it on some of the particles. The citrato or malato groups which move out of the micelles cause an increase in conductivity, the increase depending upon the length of time of heating the hydrosols. Thus, oppositely charged micelles may exist in basic beryllium hydrosols as previously mentioned for basic zirconium complexes.[1f]

Action of Acids upon Hydrous Beryllium Oxide.—It was shown previously that acids containing weakly coördinative binding anions peptize hydrous alumina at room temperature to the colloidal state while those whose anions have powerful coördinative binding tendency do not.[1d] The following experiment was performed in order to see whether hydrous beryllium oxide acted similarly. A suspension of freshly precipitated and washed hydrous beryllium oxide (precipitated from the nitrate with ammonium hydroxide) equal to 0.1 g. equivalent of beryllium oxide was agitated for forty-eight hours at 25° with 195 cc. of water containing 0.005 g. equivalent of acid. The reaction mixtures were filtered and examined.

---

(10) It is to be understood that the hypothetical compound formulated is not intended to describe the structure of a complex beryllate micelle.

(11) K. Sandved, *Tids. Kjemi Bergvesen*, **15**, 21 (1935).

(12) The colloidal nature of the migrating particles was evidenced by the turbid appearance of the contents of both arms of the electrophoresis U-tube.

In the cases of citric and malic acids (citrate and malate ions have powerful coördinative binding affinity for beryllium) the filtrates contained some beryllium ion but no colloid. In the case of tartaric acid (tartrate ion is not so powerful a coordinative binder as citrate or malate), the slightly turbid filtrate was found to consist of a dispersion of colloidal complex beryllate micelles ("negatively charged beryllium oxide"). In the case of lactic acid (lactate ion is not a strong coordinative binder to beryllium), the very turbid filtrate was a dispersion of cationic basic beryllium micelles ("positively charged beryllium oxide").

Thus, it is indicated that the reaction of hydrous beryllium oxide to acids can be included under the same theoretical treatment as aluminum oxide. More will be reported on this topic in a subsequent publication.

Summary

For convenience of expression the term "beryllium hydrosol" will be used to designate hydrosols wherein the beryllium is in the complex cationic micelles; and the term "beryllate hydrosol" will refer to those hydrosols wherein the beryllium is in the anionic micelles.

1. Some methods for the preparation of beryllium and beryllate hydrosols have been described.
2. Addition of neutral salts to beryllium and to beryllate hydrosols produces marked decreases in hydrogen ion activity, the decrease being dependent upon the nature and concentration of the anion of the salt added.
3. The effectiveness of potassium salts in decreasing the hydrogen ion activity of beryllium hydrosol–salt systems was in general: citrate > malonate > oxalate > malate > tartrate > maleinate > acetate > formate ≧ fumarate ≧ sulfate > chloride ≧ nitrate; while that for a beryllate hydrosol–salt system was: citrate > malate > malonate > tartrate > oxalate > lactate > formate > maleinate.
4. Heating to 60° precipitated the beryllium hydrosols, whereas the beryllate hydrosols did not precipitate[13] when raised to 100°.
5. Aging at 25° caused an increase in hydrogen ion activity of the beryllium hydrosols, while in case of the beryllate hydrosols a decrease in hydrogen ion activity was noted on aging.
6. The order of silver salts in decreasing conductivity is: nitrate < lactate < citrate; and nitrate < acetate < tartrate.
7. Conductance titrations of beryllium hydrosols with potassium salts indicate the following order with respect to the tendency of the anions of the salts to become coördinatively bound to the beryllium atom: citrate > tartrate > nitrate.
8. It has been shown that heat increases the conductivity of beryllate hydrosols, converting some of the anionic beryllium to the cationic state.
9. It is evident that the order of peptization of hydrous beryllia with acids is the reverse of the *p*H raising potencies of the corresponding neutral salts of the acids.

NEW YORK, N. Y. RECEIVED JUNE 24, 1936

---

(13) After standing for two months at room temperature tartrato beryllate began to precipitate, while the citrato and malato beryllates were still stable.

The Rearrangement of Sugar Acetates by Aluminum Chloride. Crystalline Celtrobiose and Some of its Derivatives[1]

BY NELSON K. RICHTMYER AND C. S. HUDSON

Although it is stated in well-known texts[2] that celtrobiose is *d*-glucosido-*d*-altrose, the evidence rests on the single observation[3] that after hydrolysis of acetochloroceltrobiose with 0.5 *N* hydrochloric acid for two and a half hours at 98° the solution is levorotatory. By analogy with neolactose (*d*-galactosido-*d*-altrose),[4] both in its preparation through the rearranging action of aluminum chloride, and in its behavior on hydrolysis, whereby a levorotatory solution also is obtained, such a formulation seemed probable. We now know that this negative rotation is due, not to *d*-altrose itself which rotates[4c,5] +32.6°, but to a non-reducing derivative, and that the rotation −98° originally ascribed to *d*-altrose[4b] refers to the equilibrium mixture of *d*-altrose and its anhydro form that results from sufficiently strong acid conditions. The present report, dealing with celtrobiose and some of its derivatives, proves conclusively that celtrobiose is *d*-glucosido-*d*-altrose.

Acetochloroceltrobiose has now been obtained in yields of 40–45% by the action of a mixture of aluminum chloride and phosphorus pentachloride on a chloroform solution of cellobiose octaacetate. From this acetochloro compound with acetic anhydride and sodium acetate the α-octaacetate was prepared; by converting the acetochloro derivative to the β-heptaacetate with silver carbonate and aqueous acetone, and then acetylating with acetic anhydride and pyridine the β-octaacetate was prepared. The rotations of these carefully purified substances are recorded in Table I, and from them values for the rotations of the end asymmetric carbon atoms (A_{Ac} and A_{Cl}) have been obtained in the usual way.[6]

It is noted that the value for A_{Ac} is in agreement with those obtained for cellobiose, lactose, and neolactose, and the two octaacetates may be assumed to represent a normal α,β-pair. The value for A_{Cl} is much smaller than in the case of cellobiose and lactose, but agrees closely with that found for neolactose; it seems probable that this A_{Cl} value is a characteristic of the acetochloro-*d*-altrose portion of the disaccharide derivative, and that the A_{Cl} value for acetochloro-*d*-altrose itself will be of the same magnitude, namely, about 30,000.

Although aluminum chloride was originally suggested as being the reagent which causes the double epimerization at the second and third carbon atoms, the best yields of rearrangement products have been obtained by using a mixture of aluminum chloride and phosphorus pentachloride. On the other hand, the use of aluminum chloride alone is recommended for the preparation of the normal chlorination product; for example, acetochloroceltrobiose has been obtained in 90% yield by warming a chloroform solution of celtrobiose octaacetate with twice its weight of commercial aluminum chloride.

In our study of the α- and β-octaacetates of celtrobiose six different crystalline modifications were isolated. The α-octaacetate separates from alcohol in large prisms which melt at 130°, or in prisms which melt at 112°, then resolidify and melt at 130°; either form can be obtained at will. The β-octaacetate crystallizes from aqueous alcohol in prisms as a monohydrate melting at 87–93°, or as solvent-free needles melting at 114°; from ether it separates in fine needles melting at 103-105°. Here also any of the three forms is obtainable as desired. In addition to the pure α- and β-forms, a double compound is known, and serves to identify readily one octaacetate in the presence of the other. It crystallizes from ether in typical rectangular plates melting at 70° with evolution of gas; it has the composition 2α-octaacetate·1β-octaacetate·3ether, as shown by analysis, and rotation of +24.9° as compared with the value +25.0° calculated from the known rotations of the two octaacetates. This appears

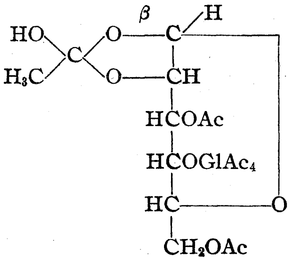
	Lactose	19,800[d]		38,400[e]

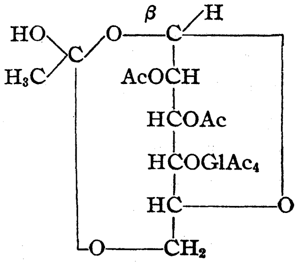
[a] Hudson and Johnson, THIS JOURNAL, **37**, 1276 (1915). [b] Calculated from the rotation +71.7° for acetochlorocellobiose, found by Brauns, *ibid.*, **48**, 2776 (1926). [c] Kunz and Hudson, ref. 4a. [d] Hudson and Johnson, THIS JOURNAL, **37**, 1270 (1915). [e] Kunz and Hudson, *ibid.*, **47**, 2052 (1925).

to be the first example of a double compound of two octaacetates, and indicates that considerable caution is required lest two isomers crystallizing together be mistaken for a pure chemical individual. Similar molecular compounds reported from this Laboratory include the novel modifications of methyl-*d*-xyloside,[7] lactose,[7] anhydrous *l*-rhamnose,[8] and the so-called neolactose "α"-heptaacetate.[4c] Also, Fischer's rhamnose β-triacetate rotating −19.4° was considered by him to represent a mixed compound.[9]

Exchange of the Cl atom in acetochloroceltrobiose by an OH group leads to the formation of celtrobiose β-heptaacetate which has been crystallized only in combination with one mole of ether; on a solvent-free basis the β-heptaacetate in chloroform rotates +3.9° changing to +15.1°. The α-heptaacetate crystallizes as a dietherate and also solvent-free; it mutarotates downward in chloroform from +22.3 to +15.1°.

Another heptaacetate of celtrobiose has been obtained, in very small yield, through the silver carbonate–aqueous acetone reaction with the chloro compound; it melts considerably higher than the other acetates, rotates +1.0° in chloroform without mutarotation, and on cautious acetylation with acetic anhydride and pyridine is transformed quantitatively to celtrobiose β-octaacetate. These properties, combined with the fact that the normal α- and β-heptaacetates are known, lead to the belief that this acetate may well have an ortho ester structure involving the 1,2- or even the 1,6-positions of the altrose molecule which are spatially much closer than the customary formula would indicate.





The previously known ortho esters of the sugar series in which one hydroxyl group remains unsubstituted appear to be limited to the heptaacetate of the ketone sugar turanose described by Pacsu[10] and to a tetraacetate of glucose described by Helferich and Klein[11] as 1,2,3,6,(?)-tetraacetyl-β-*d*-glucose, but to which Haworth, Hirst and Teece[12] have assigned a 1,6-ortho ester structure. Reactions which were expected to prove an ortho ester linkage in these compounds were disappointing because derivatives of the normal form were usually obtained. Methylation with silver oxide and methyl iodide produced the normal acetylated β-glycoside in each case. Acetylation of the glucose tetraacetate did not lead to a new glucose pentaacetate but only to the well-known β-pentaacetate. In these reactions it has been assumed that a facile rearrangement from the ortho ester to the normal form has been brought about by the reagents employed. The lack of reactions suitable for proving an ortho ester structure together with the scarcity of our own extra heptaacetate make necessary a postponement of its further study.

Deacetylation of the hepta- or octaacetates with barium methylate solution resulted in crystallization of the parent disaccharide. Celtrobiose monohydrate, well-formed prisms from 75% alcohol, rotates +13.6° in water; although mutarotation was not observed the sugar is undoubtedly the β-form since on cautious acetylation it produced an 85% yield of celtrobiose β-octaacetate. The component hexoses liberated from celtrobiose by hydrolysis with dilute hydro-

chloric acid at 100° had a rotation of −22.8°; the value −22.7° would be expected from an equilibrium mixture of *d*-glucose (+52.5°) and *d*-altrose (−98° in acid solution).[4c] The oxidation of celtrobiose with bromine water, followed by acid hydrolysis of the bionic acid, yielded crystalline *d*-glucose, and *d*-altronic acid which was isolated as the crystalline calcium salt. Since the biose linkage should not be affected by the aluminum chloride rearrangement of cellobiose octaacetate, these data prove conclusively that celtrobiose is 4-β-*d*-glucosido-*d*-altrose.

Preliminary experiments have shown that calcium *d*-altronate, obtainable through the aluminum chloride rearrangement of lactose or cellobiose octaacetates, is a convenient source for the preparation, by degradation, of *d*-ribose.

Experimental

α-Acetochloroceltrobiose.—The modified procedure is as follows. To a solution of 50 g. of recrystallized cellobiose octaacetate[13] in 400 cc. of alcohol-free dry chloroform in a one-liter flask is added 100 g. of powdered commercial aluminum chloride and 50 g. of powdered phosphorus pentachloride. The flask is shaken for a few minutes to ensure thorough mixing, then heated for one hour in a bath at 60–63°. The granular mixture is decomposed carefully with ice and water, the resulting solution extracted with chloroform, and the chloroform extracts washed several times with water, dried with granular calcium chloride and concentrated *in vacuo* to a thin sirup. Dry ether is then added cautiously in order to obtain a small crop (*ca.* 10 g.) of acetochlorocellobiose which carries down most of the colloidal impurities derived from the cellulose. After a few minutes the solid is removed by filtration, and the mother liquor diluted to 500 cc. with dry ether. Crystallization is allowed to proceed overnight at room temperature and then for a week in the refrigerator. The mixture of acetochloro derivatives thus obtained is separated mechanically; partial disintegration of the crystals with a spatula allows the fine needles of acetochlorocellobiose to be floated away in ether suspension, leaving the heavier prismatic crystals of the celtrobiose compound. A small additional crop of the latter may be obtained by combining the two fractions of crude acetochlorocellobiose and shaking them with ether for several hours at room temperature; the more soluble celtrobiose derivative is dissolved, together with some of the cellobiose compound, and the two are separated by crystallization. The yield of crude acetochloroceltrobiose is 19–22 g. (40–45%). Two recrystallizations from chloroform–ether give a product, rotating about +61°, which is pure enough for subsequent transformations. However, thirteen recrystallizations brought the rotation to +63.9°, a figure which was not appreciably changed by eight additional recrystallizations, and the value +64.2°, obtained after the twenty-first recrystallization is accepted for the rotation of α-acetochloroceltrobiose in U. S. P. chloroform (*c*, 4). The m. p. is 141–142°, with no visible decomposition.

α-Acetochloroceltrobiose from Celtrobiose α-Octaacetate.—A solution of 25 g. of pure α-octaacetate (see below) in 200 cc. of alcohol-free dry chloroform was heated with 50 g. of powdered commercial aluminum chloride for two hours at 60–63°, then decomposed carefully with ice and water. The chloroform extracts, after being washed with water and dried with calcium chloride, were concentrated *in vacuo* to a thin sirup. Upon the addition of dry ether the solution deposited typical hexagonal plates of acetochloroceltrobiose in a yield of 21.6 g. (90%) plus a few centigrams of the acicular crystals of acetochlorocellobiose. After five recrystallizations the acetochloroceltrobiose melted at 141–142°, and rotated +64.2° in U. S. P. chloroform (*c*, 4); these values were unchanged by five additional recrystallizations.

Celtrobiose α-Octaacetate.—A mixture of 25 g. of acetochloroceltrobiose, 25 g. of fused sodium acetate and 200 cc. of acetic anhydride was heated on the steam-bath for two hours, then boiled gently for five minutes and poured into two liters of ice and water. The solution was neutralized by adding solid sodium bicarbonate, whereupon most of the octaacetate separated as a spongy, light brown mass. This was extracted with chloroform, and the chloroform solution washed with water, dried with granular calcium chloride, and concentrated *in vacuo.* The resulting sirup was dissolved in alcohol and the solution, inoculated with a crystal already obtained, deposited 22.1 g. of heavy clusters of prisms, melting at 127–129°. Recrystallized from three volumes of warm alcohol, it melted at 129–130° and rotated +48.0° in U. S. P. chloroform (*c*, 4); these values were unchanged by eight additional crystallizations.

A second modification of the α-octaacetate, melting at 112°, was obtained in a preliminary experiment; the same form appeared during recrystallizations when the 130° form was left in contact with its mother liquor, especially in a cool place, the original sharp-edged prisms assuming a "weather-beaten" appearance and showing the lower melting point. It was later discovered that either the 112° or the 130° modification could be obtained at will by seeding an alcoholic solution of the octaacetate with a crystal of the desired form. This second modification crystallizes in prisms which melt at 112°, then resolidify and melt again at 129–130°; it contains no solvent of crystallization, and its melting point was unchanged after four hours of heating at 100° *in vacuo.* After five recrystallizations it rotated +48.0° in U. S. P. chloroform (*c*, 4).

Anal. Calcd. for $C_{28}H_{38}O_{19}$: C, 49.54; H, 5.65; acetyl, 11.79 cc. of 0.1 *N* NaOH per 100 mg. Found: (130° form) C, 49.39; H, 5.64; acetyl, 11.83 cc.; (112° form) C, 49.31; H, 5.63; acetyl, 11.84 cc.

Celtrobiose β-Octaacetate.—A mixture of 50 cc. of acetic anhydride and 125 cc. of pyridine, cooled to −10°, was added to 25 cc. of twice recrystallized celtrobiose β-heptaacetate monoetherate (see below), also at −10°. The solution was kept in the refrigerator overnight, then poured into ice water and extracted with chloroform. The chloroform solution was washed in succession with water, cold dilute hydrochloric acid until free from pyridine, water,

---

[13] Prepared in about 30% yield by the acetolysis of alpha sulfite, soda, or kraft paper pulp which had been furnished through the courtesy of Mr. Warren E. Emley of the Division of Organic and Fibrous Materials of the National Bureau of Standards.

aqueous sodium bicarbonate, and water, dried with granular calcium chloride, and the chloroform evaporated *in vacuo*. The thick sirup was dissolved in 75 cc. of warm alcohol and treated with a little activated carbon, filtered, and diluted with an equal volume of water. After being inoculated with a crystal obtained in a preliminary experiment the solution deposited 21.9 g. of β-octaacetate rotating $-10°$. This material was recrystallized once from dry ether, then four times from 50% alcohol; the rotation in U. S. P. chloroform (c, 6) was $-13.0°$, and was unchanged by four additional crystallizations from 50% alcohol.

The β-octaacetate, like the α-octaacetate, may crystallize in more than one form. Originally it separated from the aqueous alcohol solution in prisms melting at 87–93°; analyses showed it to be a monohydrate. Upon recrystallization from ether it crystallized in solvent-free needles melting at 103–105°. Recrystallization from 50% alcohol then produced a third modification, anhydrous needles melting at 113–114°. Any of the three forms can be obtained as desired, by suitable manipulation.

Anal. Calcd. for $C_{28}H_{38}O_{19}\cdot H_2O$: C, 48.25; H, 5.79; H_2O, 2.59. Found (87–93° prisms): C, 48.36; H, 5.85; H_2O (4 hours in pistol at 100°), 2.49. Calcd. for $C_{28}H_{38}O_{19}$: C, 49.54; H, 5.65; acetyl, 11.79 cc. of 0.1 N NaOH per 100 mg. Found (103–105° needles): C, 49.30; H, 5.83; (113–114° needles): C, 49.36; H, 5.68; acetyl, 11.88 cc.

The Double Octaacetate: 2α-Octaacetate$\cdot 1\beta$-Octaacetate$\cdot 3(C_2H_5)_2O$.—In the preparation of celtrobiose β-octaacetate just described the original alcoholic mother liquor was evaporated *in vacuo* to a thick sirup which was dissolved in the mother liquor from the crystallization from ether, and the solution concentrated. In addition to needles of β-octaacetate it deposited 1 g. of rectangular plates which, after one recrystallization from ether, melted with decomposition at 70°, and rotated $+24.9°$ in U. S. P. chloroform (c, 4). From the known rotations of the α- and β-octaacetates the rotation calculated for a double octaacetate of celtrobiose having the composition 2α-octaacetate$\cdot 1\beta$-octaacetate$\cdot 3(C_2H_5)_2O$ is $+25.0°$. The compound was then synthesized by mixing pure α- and β-octaacetates in the proportions indicated and crystallizing from ether; the product formed in plates melting at 70° with evolution of gas, rotated $+25.8°$ and lost the calculated amount of ether when heated for several days at 56° in a Fischer pistol; the ether-free compound melted over the range 70–85°.

Anal. Calcd. for $C_{28}H_{38}O_{19}\cdot C_4H_{10}O$: ether, 9.85%; acetyl, 10.63 cc. of 0.1 N NaOH per 100 mg. Found: ether, 9.80%; acetyl, 10.66 cc. For the ether-free compound, calcd. for $C_{28}H_{38}O_{19}$: C, 49.54; H, 5.65. Found: C, 49.30; H, 5.66.

Celtrobiose β-Heptaacetate Monoetherate.—The heptaacetates of celtrobiose were prepared by shaking 10 g. of acetochloroceltrobiose with 5 g. of silver carbonate in 190 cc. of acetone and 10 cc. of water for twelve hours. The silver salts were removed by filtration and the clear solution concentrated *in vacuo* at 25° to a sirup from which the crude heptaacetate could be obtained in nearly quantitative yield by adding ether and cooling. The product could not be purified by simple recrystallization, and from a mixture of acetone and ether there usually separated at the same time four crystalline forms melting, when pure, at 60° (dec.), 80° (dec.), 131, and 216°, respectively. However, the several heptaacetates were finally isolated and purified by the following procedure. The crude product was packed into the thimble of a Soxhlet apparatus and extracted with boiling anhydrous ether for two or three hours. The ethereal solution was set aside, and the undissolved residue, containing mostly 80° heptaacetate, was then extracted with fresh ether for six or eight hours; during this extraction the 80° compound crystallized slowly from the warm ether solution in the form of rectangular plates. By decanting the ether while still warm the plates could be separated from the more soluble α-forms which stayed in solution and from the tiny needles of the 216° compound which floated away with the ether. From 50 g. of acetochloroceltrobiose there was thus obtained 25 g. of plates which were purified by two additional crystallizations in the same manner. Analyses showed the substance to be a heptaacetate which contained one mole of ether of crystallization. The rotation of the monoetherate in U. S. P. chloroform (c, 10) was $+3.5°$, changing in the course of a week at 20° to $+13.5°$; calculated for the solvent-free heptaacetate these values become $+3.9°$ changing to $+15.1°$. It could not be obtained crystalline in the absence of ether, and the ether of crystallization could be removed completely only by melting the substance at 80° *in vacuo;* during this process mutarotation took place and the glassy solid when dissolved in chloroform rotated $+14.5°$ changing overnight to $+15.0°$.

Anal. Calcd. for $C_{26}H_{36}O_{18}\cdot C_4H_{10}O$: ether, 10.43%; acetyl, 9.85 cc. of 0.1 N NaOH per 100 mg. Found: ether, 10.19, 10.30%; acetyl 9.95 cc. For the ether-free compound, calcd. for $C_{26}H_{36}O_{18}$: C, 49.03; H, 5.70; acetyl, 11.00 cc. of 0.1 N NaOH per 100 mg. Found: C, 48.84; H, 5.70; acetyl, 10.99 cc.

Celtrobiose α-Heptaacetate.—The ethereal solutions left after isolation of the β-heptaacetate monoetherate as described above were united, concentrated and a mixture of crystalline heptaacetates obtained in which the α-form predominated. The material was placed in the Soxhlet thimble and extracted with ether; this time, after one or two hours of boiling, the α-heptaacetate began to separate in tiny crystals which united to form small granules. By filtering the warm solution most of the β-heptaacetate which had been extracted remained in the mother liquor. Five recrystallizations by this method were carried out, the final product melting at 130–131° and rotating in U. S. P. chloroform (c, 5) $+22.3°$, changing in the course of five days at 20° to $+15.1°$.

Anal. Calcd. for $C_{26}H_{36}O_{18}$: C, 49.03; H, 5.70; acetyl, 11.00 cc. of 0.1 N NaOH per 100 mg. Found: C, 48.83, 48.67; H, 5.83, 5.68; acetyl, 11.07 cc.

Celtrobiose α-heptaacetate may be converted to celtrobiose β-heptaacetate, or *vice versa*, by allowing a chloroform solution to mutarotate until equilibrium is reached, concentrating to a sirup, and isolating the mixture of heptaacetates with ether. Extraction in a Soxhlet with dry ether according to the procedures outlined above will then furnish the desired form.

Celtrobiose α-Heptaacetate Dietherate.—In the ordinary crystallization of the α-heptaacetate there is formed not the 130–131° compound just described but transparent elongated prisms which melt at 60° with the evolution of gas, then resolidify, and melt again at 130–131°. Upon standing in the air, or more rapidly *in vacuo* below 60°, the prisms lose their transparency while retaining their crystalline structure and then show the higher melting point 130–131°. Analyses show the loss of two moles of ether of crystallization from each mole of the heptaacetate (calcd. for $C_{26}H_{36}O_{18}\cdot 2C_4H_{10}O$: ether, 18.89%. Found: ether, 18.79, 18.80%). Crystallization from a warm ethereal solution, as shown above, produces the solvent-free form, but left overnight in the presence of ether at 20°, or below, the granular heptaacetate disappears and beautiful prisms of the dietherate modification are deposited. Under certain intermediate conditions both forms thus are present at the same time.

Celtrobiose β-Heptaacetate with Ortho Ester Structure.—In addition to the α- and β-heptaacetates described above, there always appeared a small amount (5%) of another substance, melting at 216°, which also had the composition of a heptaacetate. It was obtained by the action of silver carbonate in aqueous acetone even from acetochloroceltrobiose which had been subjected to twenty-one recrystallizations, and from acetochloroceltrobiose recrystallized ten times after being prepared by the action of aluminum chloride on purest celtrobiose α-octaacetate. This new heptaacetate is very sparingly soluble in ether, and was recovered from the material left in the Soxhlet thimble after extraction of the more soluble α- and β-forms, or filtered from the ethereal solutions which were decanted during recrystallization of the 80° β-heptaacetate monoetherate. From a mixture of chloroform and ether it separated in small needles, melted at 216°, and after three recrystallizations showed the constant rotation of +1.0° in U. S. P. chloroform (using a 4-dm. tube; *c*, 1). Unlike the normal α- and β-heptaacetates of celtrobiose, which in chloroform solution mutarotate to the equilibrium value +15.1°, this β-heptaacetate showed no evidence of mutarotation on standing eight days. It reduces Fehling's solution readily at 65°. An alkoxyl determination was negative.

Anal. Calcd. for $C_{26}H_{36}O_{18}$: C, 49.03; H, 5.70; acetyl, 11.00 cc. of 0.1 *N* NaOH per 100 mg. Found: C, 48.81; H, 5.74; acetyl, 11.04 cc.

Acetylation of the Heptaacetates.—In order to relate the normal α- and β- and the ortho ester β-heptaacetates with the corresponding α- and β-octaacetates, a 1-g. sample of each of the five compounds was cooled to −10°, and to it was added a mixture of 5 cc. of acetic anhydride and 15 cc. of pyridine, also at −10°; the solution was kept at −10° for one hour, then at 4° overnight. The next morning the temperature was allowed to rise to 20°, the volume adjusted exactly to 25 cc., and the rotation observed. After twenty-four hours a second reading of the rotation showed no change in any case.

Acetylation of the normal α-heptaacetate (m. p. 130–131°) gave a solution of specific rotation +33.3°, as compared with the rotation +38.3° for pure α-octaacetate and −18.6° for pure β-octaacetate in the same acetylating solvent (all rotations calculated on the basis of the amount of octaacetate present). The rotation +33.3° thus corresponds to a mixture containing 91% α-octaacetate and 9% β-octaacetate. By working up the acetylation mixture from 2.09 g. of α-heptaacetate in the usual way and crystallizing from ether there was isolated 1.84 g. of α-octaacetate and 0.20 g. of the 2α-·1β-octaacetate trietherate described above. One recrystallization from alcohol yielded 1.58 g. of α-octaacetate with the correct melting point, and rotating in chloroform +47.4° as compared with +48.0° for the pure compound.

Acetylation of the β-heptaacetate monoetherate (m. p. 80° with decomposition), a method already used in the preparation of celtrobiose β-octaacetate, gave a solution of specific rotation −13.9°, corresponding to a mixture of 92% β-octaacetate and 8% α-octaacetate. How much of this α-octaacetate is derived from α-heptaacetate present as an impurity, and how much is due to mutarotation preceding the acetylation is difficult to estimate; a similar problem arises in considering the acetylation of the α-heptaacetate.

Acetylation of the β-heptaacetate with ortho ester structure (m. p. 216°) produced a solution having the rotation −18.3°, as compared with the value −18.6°, for the pure β-octaacetate; these figures are identical within the limits of error and represent a quantitative transformation to the β-octaacetate. When isolated in the usual way, the product from 2.01 g. of heptaacetate consisted of 2.05 g. of octaacetate (theoretical 2.14 g.). After recrystallization from 50% alcohol it was identified completely as the β-octaacetate by its melting point and mixed melting point of 113–114°, by its rotation in U. S. P. chloroform (−13.2° as compared with −13.0° for the known β-octaacetate), and by its characteristic change of melting point to 103–105° when crystallized from ether and back to 113–114° again on crystallization from 50% alcohol. In addition, a small sample was mixed with twice its weight of pure α-octaacetate and crystallized from ether; typical plates of the double octaacetate etherate were obtained, melting at 70° (dec.), having the rotation +24.9° (calcd. +25.0°) and losing the theoretical amount of ether at 65° *in vacuo* (calcd. 9.85%; found 9.81%).

Celtrobiose Monohydrate.—Deacetylation of any of the hepta- or octaacetates with barium methylate as catalyst in absolute methyl alcohol, followed by removal of the barium by adding the exact amount of dilute sulfuric acid required, led to the isolation of the parent disaccharide in practically quantitative yield. Celtrobiose crystallizes readily as a monohydrate from water, or better by adding three volumes of alcohol to its aqueous solution. The monohydrate is the stable form, and a dehydrated sample quickly reverts to the hydrate on exposure to moist air. It forms large well-shaped prisms which begin to soften at 133°, then slowly melt to a thick sirup which evolves gas at 148°. The rotation was unchanged by three recrystallizations, and the accepted value is +13.6° in water (*c*, 5). No mutarotation was observed in twenty-four hours, the first reading being taken five minutes after adding the water to dissolve the sugar.

Anal. Calcd. for $C_{12}H_{22}O_{11}\cdot H_2O$: C, 39.98; H, 6.72; H_2O, 5.00. Found: C, 39.93; H, 6.88; H_2O, 4.98 (six hours in pistol at 110°).

Acetylation of Celtrobiose.—Since celtrobiose shows no mutarotation, evidence for its designation as the α- or β-form was sought by acetylation studies. To this end a cooled mixture of 5 cc. of acetic anhydride and 15 cc. of pyridine was added to one-half gram of the monohydrate. Most of the sugar dissolved when shaken for an hour at room temperature. After standing overnight the solution was diluted with pyridine to 25 cc. and found to rotate, in duplicate experiments, −11.9° and −11.4°; this corresponds to a mixture containing 88% of the β-octaacetate and 12% of the α-octaacetate. When the solution was poured into ice water and examined in the usual way it yielded 85% of the theoretical amount of octaacetate as the β-form (identified by melting point, mixed melting point and rotation) and about 2% as the double octaacetate etherate.

Hydrolysis of Celtrobiose.—After 0.2594 g. of celtrobiose hydrate was heated with 8 cc. of 1 *N* hydrochloric acid for two and one-half hours at 100° and the solution diluted exactly to 10 cc. at 20°, it rotated −22.8° and did not change when heated for another hour. This rotation is in agreement with the value −22.7° calculated for an equimolecular mixture of *d*-glucose (+52.5°) and *d*-altrose (−98°) under the same conditions.

Oxidation to Celtrobionic Acid and Subsequent Hydrolysis to *d*-Glucose and *d*-Altronic Acid.—The method of Hudson and Isbell[14] was adopted. Thus, to 9.2 g. of benzoic acid and 11.8 g. of barium hydroxide octahydrate, combined by dissolving in 350 cc. of hot water, and cooled, was added 9 g. of the crystalline sugar and 2 cc. of bromine. The solution was kept in the dark, with occasional shaking, for forty-four hours. Excess bromine was expelled with a current of air; precipitated benzoic acid was removed by filtration; the barium ions were completely precipitated by adding a slight excess of sulfuric acid; bromide ions were removed by shaking the solution with 10 g. of silver carbonate; the filtered solution was freed from silver ions with hydrogen sulfide, and the excess hydrogen sulfide blown out with air. The dissolved benzoic acid was completely removed by extraction with chloroform and the solution concentrated to about 240 cc. No attempt was made to isolate the celtrobionic acid, but instead it was hydrolyzed by adding 6.7 cc. of concentrated sulfuric acid to make the solution about 1 normal, and refluxing gently for three hours. To the pale yellowish solution was added 38 g. of barium hydroxide octahydrate, the barium sulfate removed by filtration, and the slight excess of barium precipitated by titration with 0.5 *N* sulfuric acid, using sodium rhodizonate as an external indicator.[15]

The solution should now contain only *d*-glucose, and *d*-altronic acid and its lactone. The acid and lactone were neutralized by adding lime water until the solution would remain faintly alkaline to phenolphthalein for one hour. By concentrating to a small volume and adding alcohol there was obtained 4 g. of crystalline calcium *d*-altronate which was identified completely as described below.

The mother liquor was freed from the remaining calcium altronate by concentrating to a thin sirup and adding methyl alcohol, filtering the granular salts, and repeating the operations. The methyl alcoholic solution of glucose was then evaporated *in vacuo* to a very thick sirup which was extracted with 250 cc. of hot 95% alcohol; from this extract, upon concentrating and inoculating, was obtained 2.2 g. of fine needles. The product was identified as *d*-glucose through the melting point and mixed melting point 146–147°, through its phenylosazone with melting point and mixed melting point 208° (dec.), and finally by a study of its mutarotation. At 23° the initial rotation +70.3° in water (*c*, 5) showed it to be a mixture of the α- and β-forms; the equilibrium rotation +53.0° is in accord with the known value +52.5° for *d*-glucose; and the mutarotation constant 0.0087 is in excellent agreement with the value 0.0085 for 23°, as calculated from the equation $\log (k_1 + k_2) = 11.0198 - (3873/T)$ given by Hudson and Dale.[16]

Identification of Calcium *d*-Altronate·3.5H$_2$O.—The calcium altronate obtained above was recrystallized twice from water, and then found to be identical in its properties with a sample of calcium *d*-altronate prepared from neolactose by oxidation and hydrolysis in the same manner. The air-dried calcium salt contains three and one-half moles of water of crystallization[17] which it loses on heating one hour at 110° *in vacuo;* upon exposure to the moist air of the laboratory it quickly regains its original water content. This property of losing and regaining 3.5H$_2$O as described can be used to distinguish calcium *d*-altronate (and presumably calcium *l*-altronate) from the known calcium salts of other aldohexonic acids except possibly gulonic.[18]

Anal. Calcd. for $(C_6H_{11}O_7)_2Ca\cdot3.5H_2O$: H$_2$O, 12.78. Found: 12.79 for calcium altronate from celtrobiose, 12.78 for calcium altronate from neolactose.

The solubility of hydrated calcium *d*-altronate in water at 20° is very nearly 2 g. in 100 cc Its rotation in water (*c*, 1.8; 4-dm. tube) was determined as −2.36° from celtrobiose and −2.35° from neolactose, as compared with +2.08° for calcium *l*-altronate.[17c]

TABLE II

ROTATION OF CALCIUM *d*-ALTRONATE·3.5H$_2$O IN 1 *N* HCl (*c*, 3)

Time, min.	From celtrobiose	From neolactose	Steiger and Reichstein From *d*-ribose	From "levo-lactone"
5	+11.7	+11.1		
10	14.0	13.8	+14.1	+14.6
15	15.7	16.1		
20	17.5	17.8		
30	20.1	19.4		19.8
45	22.4	21.7	22.3	22.3
60	23.2	23.6		
90	24.3	24.4		
Constant	24.8	24.9	24.7	24.3
Final Rotation, Calculated as Lactone				
	+34.4	+34.5	+34.2[a] 35.1[b]	+33.7[a]

[a] These values have been recalculated from the data given by Steiger and Reichstein.

(16) Hudson and Dale, THIS JOURNAL, **39**, 320 (1917).

(17) (a) Levene and Jacobs, in *Ber.*, **43**, 3142 (1910), reported 3.5 H$_2$O for calcium *d*-altronate; (b) Austin and Humoller, THIS JOURNAL, **56**, 1152 (1934), reported 3.5H$_2$O for calcium *l*-altronate; (c) Isbell, however, in *Bur. Standards J. Research*, **14**, 308 (1935), wrote calcium *l*-altronate·3H$_2$O.

(18) *Cf.* Fischer and Stahel, *Ber.*, **24**, 528 (1891).

Very convincing evidence of the identity of calcium altronate from celtrobiose with the calcium altronate from neolactose, as well as for their identity with samples of calcium altronate from *d*-ribose and from the 1,4-lactone of *d*-talomucic acid[19] is given in Table II. Here are recorded the changes in rotation which occur when calcium altronate is dissolved in 1 *N* hydrochloric acid and the liberated altronic acid undergoes lactone formation.

This work has been materially aided by a grant to one of us (N. K. R.) from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

Summary

1. Acetochloroceltrobiose has been obtained in 40–45% yield by the action of a mixture of aluminum chloride and phosphorus pentachloride on cellobiose octaacetate in chloroform.

2. Both the α- and the β-octaacetates of celtrobiose have been prepared. A double compound of the two acetates crystallizes with the composition 2α-octaacetate·1β-octaacetate·3-ether.

3. Both the α- and the β-heptaacetates of celtrobiose have been prepared. A third heptaacetate is believed to possess an ortho ester structure.

4. Celtrobiose monohydrate has been obtained in crystalline form. It has $[\alpha]^{20}\text{D} + 13.6°$, without mutarotation. Acetylation shows it to be the β-form.

5. Acid hydrolysis of celtrobiose indicates that the component hexoses are *d*-altrose and *d*-glucose. Oxidation to celtrobionic acid, followed by acid hydrolysis, yielded *d*-glucose, and *d*-altronic acid which was identified as calcium *d*-altronate·$3.5H_2O$. These data lead to the conclusion that celtrobiose is 4-β-*d*-glucosido-*d*-altrose.

The Asymmetric Oxidation of Sugars by Optically Active Alkaline Copper Solutions[1]

By Nelson K. Richtmyer and C. S. Hudson

In a recent paper dealing with neolactose and *d*-altrose[2] we had occasion to compare the reducing powers of the *d*- and *l*-forms of altrose toward the alkaline copper reagent of Shaffer and Hartmann.[3] The *d*-altrose was found to have only about 56% the reducing power of *l*-altrose; similarly, *d*-arabinose was found to have only 76% the reducing power of *l*-arabinose. The suggestion was made that, since the copper carbonate reagent contains an optically active substance, namely, *d*-tartaric acid, the *d*- and *l*-forms of the reducing sugars may behave differently in its presence.

A number of investigators[4] have compared the reducing powers of various sugars as determined by the methods of Hagedorn–Jensen, Folin–Wu, Shaffer–Hartmann, and others, but the behavior of a pair of antipodal sugars toward these reagents, and toward copper reagents containing other than the ordinary *d*-tartaric acid, has not been studied previously. The results of our experiments, in which *d*-glucose, *d*- and *l*-altrose, and *d*- and *l*-arabinose were compared by oxidation with the Hagedorn–Jensen–Hanes ferricyanide reagent, and with four modifications of the Shaffer–Hartmann–Somogyi Reagent 50 with 1 g. of potassium iodide, containing the *d*-, *l*-, racemic, and *meso* tartaric acids, respectively, are shown in Tables I and II.

The first three columns of figures in Table I show clearly that with the ferricyanide reagent, and with the alkaline copper reagents containing *meso* and racemic tartaric acids, the *d*- and *l*-forms of altrose have identical reducing powers, and the same is true of the *d*- and *l*-forms of arabinose, within the limits of experimental error. In the fourth and fifth columns, however, striking differences appear between *d*- and *l*-altrose in their behavior with the alkaline copper solutions containing *d*- and *l*-tartaric acids, respectively. Thus, *d*-altrose (1.2 mg.) requires 5.82 cc. of

TABLE I

CC. OF 0.005 N THIOSULFATE EQUIVALENT TO AMOUNT OF REAGENT CONSUMED IN 15 MINUTES

	Reagent				
Sugar 1.20 mg.	Ferri-cyanide	Meso tartaric	Racemic tartaric	*d*-tartaric	*l*-tartaric
d-Glucose	7.12	10.50	10.97	10.94	10.82
d-Altrose	5.67	8.44	7.34	5.82	9.47
l-Altrose	5.63	8.34	7.26	9.41	5.78
d-Arabinose	6.58	8.07	8.42	8.00	9.18
l-Arabinose	6.56	8.03	8.29	9.09	7.89

TABLE II

RELATIVE REDUCING POWERS TOWARD VARIOUS REAGENTS, WITH GLUCOSE AS STANDARD IN EACH CASE

	Reagent				
Sugar	Ferri-cyanide	Meso tartaric	Racemic tartaric	*d*-tartaric	*l*-tartaric
d-Glucose	100	100	100	100	100
d-Altrose	79.6	80.4	66.9	53.2	87.5
l-Altrose	79.1	79.4	66.2	86.0	53.4
d-Arabinose	92.4	76.9	76.7	73.1	84.8
l-Arabinose	92.1[a]	76.5	75.6	83.1	72.9

[a] This is in accord with the value of 92 found by Pucher and Finch, ref. 4, and the value of 94 found by the ferricyanide gasometric method of Hawkins, ref. 4.

0.005 N thiosulfate, which is a measure of the amount of oxidation brought about by the reagent containing *d*-tartaric acid, whereas the same amount of *l*-altrose requires 9.41 cc. of thiosulfate; the ratio 5.82:9.41 indicates that toward the *d*-tartaric reagent the *d*-altrose has only 61.8% the reducing power of its *l*-isomer. On the other hand, using the copper reagent containing *l*-tartaric acid, the relations are reversed, the *l*-altrose requiring 5.78 cc., and the *d*-altrose 9.47 cc. of thiosulfate; the ratio of these values shows that toward the *l*-tartaric acid reagent the *l*-altrose has only 61.0% the reducing power of its *d*-isomer. It is noted that the figure for the *d*-sugar with the *d*-reagent, 5.82 cc., is identical, within the experimental limits, with the value 5.78 cc. for the *l*-sugar plus the *l*-reagent; likewise, the *d*-sugar with the *l*-reagent, and the *l*-sugar with the *d*-reagent, give practically identical values of 9.47 and 9.41 cc., respectively.

In the case of the arabinoses, the differences in behavior are strictly parallel, although not so marked. Using the *d*-reagent, the ratio 8.00:9.09 gives the *d*-arabinose 88.0% the reducing power of the *l*-arabinose,[5] with the *l*-reagent the situation is reversed, and the ratio 7.89:9.18 shows *l*-arabinose to have 86.0% the reducing power of its *d*-isomer. For both the altroses and the arabinoses, with the reagent containing racemic tartaric acid, the values lie between those found for the *d*-reagent and those for the *l*-reagent.

In the case of *d*-glucose, the values in Table I show no difference, within the experimental limits of accuracy, between its behavior with the copper reagents containing the *d*-, *l*- and racemic tartaric acids. The value obtained with the *meso* tartaric acid is somewhat smaller; this is not unexpected, since *meso* tartaric acid differ from the other tartaric acids in chemical and physical properties, and a reagent containing it might be expected to differ as much as would a reagent containing citric, trihydroxyglutaric, or other hydroxy acid which might be used to prevent precipitation of the copper hydroxide.

Table II shows the relative reducing powers found for the pairs of altroses and arabinoses, compared with glucose as a standard with each of the five oxidizing agents. The relationships are similar to those already discussed, and show, for example, that each of the two altroses has about 80% the reducing power of *d*-glucose toward the ferricyanide reagent and toward the copper reagent containing meso tartaric acid, and about 66.5% of the reducing power of *d*-glucose toward the racemic tartaric acid reagent. However, toward the *d*-tartaric reagent the *d*-altrose has 53% the reducing power and *l*-altrose 86% the reducing power of *d*-glucose, while toward the *l*-tartaric reagent the reverse situation exists, the *d*-altrose having 87% and the *l*-altrose 53% the reducing power of *d*-glucose.

Having accomplished the primary objects of the research, and having a certain amount of copper reagents on hand, we decided to examine the behavior of other available sugars as far as the supply of reagents would permit. These additional results are presented in Table III. In the last three columns are compared the reducing powers of a single sugar against each of the three alkaline copper reagents employed, which is a somewhat different method of interpreting a portion of the data previously discussed.

The most striking examples were found in the cases of *d*- and *l*-altrose and *l*-allose. For example, *d*-altrose reduces the copper reagent containing *l*-tartaric acid 163% as much as it does the reagent containing *d*-tartaric acid; on the other hand, *l*-altrose reduces the *l*-tartaric reagent

---

(5) The discrepancy between the value 88% and the value 76% previously reported may be due in part to the fact that the samples of arabinose used earlier were not purified by us, and in part to the difference in composition of the alkaline copper reagents as used in the two sets of experiments. The present values are believed to be correct at least to within ±2%.

TABLE III

COMPARISON OF SUGARS

Sugar	Time of heating, min.	Cc. of 0.005 N thiosulfate equivalent to amount of reagent consumed by 1.20 mg. of sugar			Relative reducing powers of the sugar toward the three copper reagents, with the *d*-tartaric acid reagent as standard		
		Reagent			Reagent		
		d-tartaric	*l*-tartaric	Racemic	*d*-tartaric	*l*-tartaric	Racemic
d-Glucose	15	10.94	10.82	10.97	100	99	100
d-Mannose	15	8.21	8.69	9.01	100	106	110

only 61% as much as it does the *d*-tartaric reagent; yet the fourth column shows that the *d*- and *l*-altrose solutions reduce to the same extent the reagent containing racemic tartaric acid. The *l*-allose also reduces the *l*-tartaric reagent only 61% as much as it does the *d*-reagent.

The arabinose pair of sugars behaves like the altrose pair, although to a lesser extent, the values being 115 and 87%, respectively, for the *d*- and *l*-sugars. *d*-Galactose and *l*-fucose also showed very marked differences in their behavior toward the copper reagents, with values of 83 and 113%, respectively. *l*-Rhamnose, the ketone sugar *d*-mannoheptulose, and the disaccharides lactose, neolactose, and celtrobiose all show differences well outside the limits of error.

The time of heating was varied in several cases, since Shaffer and Somogyi[6] have found that with their Reagent 50, glucose and fructose are oxidized completely in fifteen minutes, while mannose and xylose require thirty-five and thirty minutes, respectively. With the altroses, fructose and mannoheptulose the reaction appeared to be complete within fifteen minutes; with the two arabinoses, and *d*-mannose, a longer period was required, the time of thirty-five minutes being chosen arbitrarily. For the three disaccharides the fifteen-minute period only was tried, while for *d*-xylose, *l*-rhamnose and *l*-fucose a thirty-five minute heating was allowed.

Certain correlations between the configurations of the sugars and the relative reduction of the *d*-, *l*- and racemic reagents may be cited. *d*-Xylose and *d*-glucose, each with the *d*-xylose configuration on the second, third, and fourth carbon atoms, show practically no difference in their behaviors, the ratios being 100:99:101 and 100:99:100, respectively. *d*-Arabinose, *d*-altrose, and *l*-fucose, each with the *d*-arabinose configuration on the second, third and fourth carbon atoms, form a series with the ratios 100:115:105, 100:163:126, and 100:113:109, while *l*-arabinose, *l*-altrose and *d*-galactose, each with the *l*-arabinose configuration, form another series with the ratios 100:87:91, 100:61:77, and 100:83:94, respectively. The other aldoses including lactose, and the two ketoses, are not closely related to themselves or any of the foregoing series, so a further and complete correlation will require more data. All the facts given, however, are in full accord with the recognized theories of stereochemistry.

The above examples of asymmetric oxidation may be considered as belonging to the larger group of phenomena called asymmetric degradations. Pasteur's classical experiment on the preference of *Penicillium glaucum* for the *d*- over the *l*-form of tartaric acid, the selective fermentation of the *d*- but not the *l*-forms of glucose, mannose and fructose, and the peculiarities of other enzymes and micro-organisms in their behavior toward optical antipodes, are well known. A purely chemical asymmetric degradation was first studed by Bredig and his associates.[7] They were able to show that the rates of decomposition of the *d*- and *l*-forms of camphor- and bromocamphor-carboxylic acids were unequally accelerated by the addition of a small amount of optically active base as catalyst; for example, the *l*-camphor carboxylic acid in acetophenone at 75° decomposed about 46% faster than did the *d*-acid

when quinine was added, while the reverse effect was produced when quinidine was added.

Recently Y. Shibata and his co-workers[8] have described the asymmetric oxidations brought about by the oxidase-like action of ammonochlorodiethylenediamine cobaltic bromide $[Co-en_2NH_3Cl]Br_2$. Their experiments have led to the conclusion that the *l*-form of 3,4-dihydroxyphenylalanine is oxidized more rapidly than the *d*-form by the *l*-cobalt complex; and that *d*-catechin is oxidized more rapidly by the *d*-cobalt than by the *l*-cobalt complex.

To return to the data in Table III, we find that in the members of the *d*- and *l*-arabinose series, and also in the case of *l*-allose, the reducing power of each sugar toward the racemic tartaric acid reagent was intermediate between the value found for the *d*-reagent and that found for the *l*-reagent. In other cases, notably those of *d*-fructose, *l*-rhamnose, *d*-mannoheptulose and the three disaccharides, the reducing power was not intermediate in value, but was equal to or even greater than the reducing power toward either the *d*- or the *l*-reagent. The reason for this might be learned if we knew more about the mechanism underlying these sugar oxidations. Nef[9] states that the oxidation of *l*-arabinose by alkaline copper hydroxide solution leads to the formation of carbon dioxide, formic and glycolic acids and the optically active arabonic, ribonic, erythronic, threonic and glyceric acids. Thus are produced a number of other optically active acids which would intensify or mitigate the effects already initiated by the tartaric acids, and the reaction becomes so complex that almost any final result would be conceivable.

Similarly, Shibata reports that the oxidation of *d*-catechin by the *d,l*-cobalt complex takes a course closely resembling that of the system *d*-catechin plus *l*-complex as if there were no *d*-complex salt in the solution. Willstätter, Kuhn and Bamann[10] found that if racemic mandelic ester is subjected to the action of an esterase extracted from liver, the (+)-ester is hydrolyzed more rapidly than the (−)-ester, but the relation is reversed if the two forms are examined separately: here the (−)-ester is hydrolyzed faster. This is explained by assuming that the ratio of reaction velocites with which the *d*- and *l*-forms in the racemate are cleaved is conditioned by (1) the ratio of affinities of the esterase for the *d*- and *l*-forms, and (2) the ratio of the velocities at which the esterase—*d*-ester complex and the esterase—*l*-ester complex are hydrolyzed.

It is possible that the asymmetric oxidation of sugars by alkaline copper solutions containing optically active tartrates, or even by alkaline ferricyanide reagents to which tartrates have been added, may become a practical method for identifying sugars, especially in working with very small amounts and before isolation of the crystalline material. The behavior of a *d*-galactose solution toward the *d*- and *l*-reagents would clearly distinguish it from solutions containing *d*-glucose, *d*-mannose, *d*-fructose, *d*-xylose, *l*-rhamnose and *d*-arabinose, although *l*-arabinose would remain a possibility. Because of the difficulties involved in preparing *l*-tartaric acid from the common *d*-acid, it might be advantageous to use other antipodal acids, such as the *d*- and *l*-araboglutaric acids which may be prepared by oxidation of the now readily procurable *d*- and *l*-arabinoses. The use of *d*- and *l*-alanine might also be suggested, since Benedict[11] has substituted alanine for tartaric acid, in part at least, in his sugar reagent.

Experimental

Tartaric Acids.—The **racemic** and **meso tartaric acids** were Eastman Kodak Co. products; the former had no detectable optical activity, while the latter appeared to have the very slight specific rotation of +0.07°. The ***d*-tartaric acid** was a commercial brand, thrice recrystallized from water, having $[\alpha]^{20}D$ +13.5° in water (*c*, 10.1). The ***l*-tartaric acid** was obtained by resolving racemic tartaric acid with cinchonine according to Marckwald.[12] The recrystallized cinchonine *l*-acid tartrate monohydrate was decomposed with excess ammonia and the cinchonine removed by filtration. The filtrate was made barely acid with acetic acid, and lead acetate solution added until no further precipitation occurred. Upon standing overnight the amorphous lead tartrate changed to fine needles which were filtered, washed, suspended in water and the lead removed by hydrogen sulfide precipitation. The clear solution was evaporated *in vacuo* to a small volume and the *l*-tartaric acid allowed to crystallize slowly in a desiccator. After several recrystallizations from water it showed $[\alpha]^{20}D$ −13.5° in water (*c*, 10.3).

Sugars.—The *l*-altrose and *l*-allose were samples kindly supplied by the late Dr. W. C. Austin.[13] The *d*-altrose and the disaccharides neolactose and celtrobiose have been

described by the present authors.[14] The *d*-arabinose, prepared in this Laboratory by the method of Hockett and Hudson,[15] showed $[\alpha]^{20}{}_{\mathrm{D}}$ −103.4°; the *l*-arabinose, from the Difco Laboratories in Detroit, after one recrystallization, rotated +104.2° in water (*c*, 6). The other sugars were either high grade commercial products or prepared by other workers in this Laboratory. All sugar solutions were made up to contain 1.20 mg. of anhydrous substance in each 5 cc. of solution.

The Alkaline Ferricyanide Reagent.—The procedure of Hagedorn and Jensen[16] as modified by Hanes[17] was used, except that the oxidizing solution contained 6.60 g. instead of 8.25 g. of potassium ferricyanide per liter; thus 5 cc. of this solution was equivalent to 5 cc. of the alkaline copper solutions, each requiring about 20 cc. of the same 0.005 *N* thiosulfate solution in the blank determinations.

The Alkaline Copper Reagents.—According to the latest procedure of Shaffer and Somogyi,[6] four solutions were prepared, the only variation being in the use of an equivalent amount of the sodium tartrates instead of the sodium potassium tartrate (Rochelle salt) recommended. Thus, 3.32 g. of *d*-tartaric acid (or 3.32 g. of the *l*-acid, or 3.72 g. of the *meso* or racemic acid monohydrates) was dissolved in 50 cc. of water, and neutralized with *N* sodium hydroxide, with phenol red as indicator. Then were added in succession 6.25 g. of anhydrous sodium carbonate, 1.875 g. of copper sulfate pentahydrate in 20 cc. of water, 5.00 g. of sodium bicarbonate, 0.25 g. of potassium iodide and 50 cc. of standard potassium iodate solution, 0.1 *N* as to iodine. The mixture was diluted exactly to 250 cc., and allowed to stand for several days before filtering through washed and dried filter paper into a Pyrex flask. This reagent should be the exact equivalent of the "Shaffer–Somogyi Copper Iodometric Reagent 50 with 1 g. KI;" 5 cc. of it required about 20 cc. of 0.005 *N* thiosulfate in a blank determination. The preparation and standardization of the solutions, and the oxidations of the sugars, were carried out as directed, observing all the precautions noted by the original writers. The solutions were kept, and the titrations performed, in a room equipped with a white light and kept constant at 20°.

Summary

1. A study of the oxidation of the *d*- and *l*-forms of altrose and of arabinose by an alkaline ferricyanide reagent and by four modifications of an alkaline copper reagent containing the *d*-, *l*-, racemic and *meso* forms of tartaric acid, respectively, has been made.

2. The reagents which are optically inactive show no difference in their relative oxidizing power on the *d*- and *l*-forms of the sugars.

3. The reagents which are optically active oxidize the *d*- and *l*-forms of the sugars asymmetrically. Striking relationships have been noted in the four systems composed of the *d*- and *l*-sugars with the *d*- and *l*-reagents. The results are in full accord with the classical theories of stereochemistry.

4. The behavior of twelve other sugars toward the *d*-, *l*- and racemic copper reagents has been studied.

5. The practical adaptation of this asymmetric oxidation for the identification of sugars has been suggested.

On the Formation and Reactions of the Substituted Thiazolidones. IV

BY FLOYD A. EBERLY AND F. B. DAINS

Previous papers from this Laboratory[1] have shown that the alkylation of the 2-arylthiazolidones gave both the 2-aryl-2-alkyl and the 2-aryl-3-alkyl derivatives. This paper is a study of the influence of allyl groups, of acyl groups and of phenyl and diphenylchloroacetyl chlorides in the formation and properties of such thiazolidones. Thus from mono-allylthiourea was obtained the 3-allyliminothiazolidone (the unstable form of Wheeler and Johnson) which did not rearrange; while allylphenylthiourea formed a thiazolidone in which the allyl group assumed position 2 with the phenyl at 3. Allyl iodide and the sodium salt of monophenyl thiazolidone gave the two remaining isomers of phenylallylthiazolidone.

The symmetrical benzoyl and carbethoxyphenylthiourea yielded thiazolidones with the acyl radical at 2. Dixon had erroneously assigned the reverse formula to his carbethoxyphenylthiazolidone.

Our work also indicated that the stable form of phenyl-5-phenylthiazolidone is the 2-phenyl isomer and not the 3-phenyl as was suggested by Wheeler and Johnson since it gave alkylation

---

products with the phenyl group at 2 and the alkyl radical entering at either 2 or 3.

The 2-arylthiazolidone from diphenylchloroacetyl chloride was obtained by the action of aniline upon thiocyanodiphenylchloroacetic ester, and not from the acid chloride and phenyl thiourea. The isomeric 2-thio-3-phenyl-5-diphenyl-4-imidazolone unexpectedly resulted from the action of ammonium thiocyanate upon diphenylchloroacetanilide.

Symmetrical phenylmethylthiourea and diphenylchloroacetyl chloride gave the two possible isomeric thiazolidones, the only case noted thus far.

Experimental

1. 2-Imino-3-Allyl-4-Thiazolidone HCl I,

$\overline{\mathrm{SC(NH)NC_3H_5COC}}\mathrm{H_2\cdot HCl}$.

Allyl thiourea and chloroacetic acid on warming, either in water or in alcohol solution, gave an oil, the above labile form of Wheeler and Johnson, which is very easily hydrolyzed to the 2,4-diketo compound II with loss of ammonia. Benzaldehyde condensed with II under the influence of alkali or piperidine yielding 5-benzal-3-allyl-2,4-thiazoledione III, colorless needles melting at 88°. The constitution of III was shown as follows: 2,3-diallyl-thiazolidone, an oil at −10°, prepared from chloroacetyl chloride and diallyl thiourea in acetone and pyridine solution, gave a 5-benzal derivative V, m. p. 53°, which on hydrolysis with hot 50% sulfuric acid yielded allylamine and the diketo compound III.

N-Phenyl-N′-Allyl Thiourea and Chloroacetyl Chloride.—These compounds were refluxed in acetone solution with two moles of pyridine for thirty minutes. The 2-allyl-3-phenyl-4-thiazolidone VI melted at 151° and was soluble in dilute hydrochloric acid. In the majority of cases previously the alkyl group has been found at position 3 and the aryl group at 2. The ring was easily ruptured with alkali but heating with benzaldehyde, sodium acetate and acetic anhydride gave a 5-benzal compound VII (m. p. 141°).

Heating VII with 50% sulfuric acid at 140° gave 5-benzal-3-phenyl-2,4-thiazoledione VIII (m. p. 208°),[2] thus proving the structure.

Further evidence was obtained by the synthesis of the two possible isomers. When the sodium salt of 2-phenylthiazolidone was treated with allyl iodide in absolute alcohol solution, two compounds were isolated: (A) 2-phenyl-2-allylaminothiazolidone IX (95% yield), soluble in dilute acid and melting at 92°; and (B) 2-phenylimino-3-allyl-4-thiazolidone X (5% yield), an oil insoluble in acid which gave a 5-benzal derivative XI (m. p. 106.5°). Hydrolysis of XI with acid yielded the diketo compound III and aniline. The isomeric benzal derivative XII melted at 165°.

2. The Benzoyl and Carbethoxy Thiazolidones.—In these cases it is noteworthy that ring closure occurred with the acyl group at position 2.

2-Benzoylimino-3-*p*-bromophenyl-4-thiazolidone XIII, $\overline{\mathrm{SC(NCOC_6H_5)NC_6H_4BrCOC}}\mathrm{H_2}$, m. p. 213°, was made by heating N-benzoyl-N′-*p*-bromophenylthiourea[3] in acetone solution with chloroacetyl chloride and two moles of pyridine.

Alkaline Hydrolysis.—The compound dissolved in dilute alkali on boiling due to the formation of a thiohydantoic acid, but on continued heating there was deposited N-benzoyl-N′-*p*-bromophenyl urea XIV which melted at 233–234° with decomposition.

Acid Hydrolysis.—The benzoyl compound XIII was treated with boiling concentrated hydrochloric acid for three hours. Benzoic acid and ammonia were split off with traces of *p*-bromoaniline. The residue (m. p. 163°) gave figures on analysis corresponding to 3-*p*-bromophenyl-2,4-thiazoledione, XV. The 5-benzal derivative XVI crystallized from dioxane in needles melting at 253°. Hydrolysis with 60% sulfuric acid at 160° gave 5-benzal-3-*p*-bromophenyl-2,4-thiazoledione XVII (m. p. 247°).

2-Carbethoxy-3-phenyl-4-thiazolidone, XVIII, is best prepared by heating phenylthioallophanic ester with chloroacetyl chloride and pyridine in benzene solution.[4] The plates from dioxane decomposed slowly above 230° and melted completely at 256°. Dixon had formulated it as a 2-phenylimino-3-carbethoxy compound and stated that on hydrolysis it gave phenyl "dioxy thiazole," $\underline{\mathrm{SC(NC_6H_5)OCOC}}\mathrm{H_2}$.

Alkaline hydrolysis disrupted the ring completely but acid treatment gave the known 3-phenyl-2,4-thiazoledione (m. p. 146°), identical with a synthetic preparation. Additional evidence for our structure was afforded by the hydrolysis of its benzal derivative XIX (m. p. 225°), which gave the known 5-benzal-3-phenylthiazoledione, VIII.

Heating the carbethoxy compound XVIII with aniline at 150° or at 180–200° gave only diphenyl urea.

3. Derivatives of 5-Phenyl Thiazolidones

2-Phenylimino-5-phenyl-4-thiazolidone, XX.[5]—Wheeler and Johnson had prepared a diphenylthiazolidone (m. p. 185–186°), by the action of phenylchloroacetic ester on phenylthiourea, to which they assigned a 2-imino-3-phenyl structure since it gave a 3-phenyl-2,4-diketo compound (m. p. 173°) on hydrolysis. This work was repeated and the thiazolidone (m. p. 185°), XX, hydrolyzed by heating with 40% sulfuric acid at 140° for four hours. The acid solution contained both aniline and ammonia while from the solid residue were isolated two compounds; one, soluble in dilute alkali and in cold alcohol, proved to be 5-phenyl-2,4-thiazoledione XXI (m. p. 130°), obtained also by the hydrolysis of 5-phenylthiazolidone (m. p. 233–234°); the other compound was Wheeler's product (m. p. 173°), 3,5-diphenyl-2,4-thiazoledione, XXII. These results are due to the formation of the thiohydantoic acid, loss of either ammonia or aniline and subsequent ring closure. Approximately one part of XXI and two parts of XXII were found.

The original compound XX has the phenyl group at position 2. This was shown by the fact that its sodium salt

XXXI	2-Methyl-3-phenyl-5-diphenyl	$C_{22}H_{18}N_2OS$	119	7.82	7.77
XXXII	3-Phenyl-5-diphenyl-2,4-diketo	$C_{21}H_{15}N_2OS$	150	9.27	9.25

on methylation gave a 2-phenyl-2-methylaminothiazolidone XXIII (m. p. 144°), soluble in dilute acid and identical with the product from phenylbromoacetic ester and unsymmetrical phenylmethylthiourea.

4. Derivatives of Diphenyl Chloroacetyl Chloride[6]

The acid chloride failed to give a thiazolidone with phenylthiourea by the usual methods. However, 2-thio-3-phenyl-5-diphenyl-4-imidazolone, $HNCSN(C_6H_5)COC(C_6H_5)_2$, XXIV, was the unexpected product resulting when diphenylchloroacetanilide[7] was refluxed one hour in dry acetone solution with ammonium thiocyanate, and its formation would seem to be due to the rearrangement of the —SCN grouping in the initial product to —NCS and subsequent ring closure. It was soluble in dilute alkali and crystallized from alcohol in thick needles melting at 254°. It was desulfurized by heating with concentrated nitric acid for thirty minutes, yielding 3-phenyl-5-diphenyl-2,4-imidazoledione, XXV, prisms from alcohol (m. p. 203.5°).

The structure of the 2,4-imidazoledione was proved by its synthesis from monophenyl urea and benzilic acid[8] which were fused together one hour at 180–190°.

2 - Methylmercapto - 3 - phenyl - 5 - diphenyl - 4 - imidazolone, XXVI.—Methylation of the 2-thioimidazolone, either alone or with the aid of potassium hydroxide, gave the thio ether, soluble in acid and melting at 143°. Hydrolysis with 50% sulfuric acid at 150° yielded XXV.

2-Phenylimino-5-diphenyl-4-thiazolidone, XXVII (m. p. 253°).—This compound, prepared according to the method of Wheeler and Johnson,[9] is an isomer of XXIV but mixed melting point and properties showed that they are not identical. This compound behaved as a normal thiazolidone, the sodium salt yielding: (a) 2-methylphenylamino-5-diphenyl-4-thiazolidone XXVIII (m. p. 191°) and (b) 2-phenylimino-3-methyl-5-diphenyl-4-thiazolidone XXIX (m. p. 134°).

The constitution of XXVIII was shown by its synthesis from unsymmetrical methylphenylthiourea and that of XXIX proved by its synthesis from symmetrical methylphenylthiourea and to the fact that it hydrolyzes to give 3-methyl-5-diphenyl-2-4-thiazoledione, XXX (m. p. 102°). The synthesis of XXIX from methylphenylthiourea and diphenylchloroacetyl chloride in benzene solution with two moles of pyridine resulted in the formation in 25% yield of the 2-phenyl-3-methyl compound, insoluble in dilute acid, while the isomeric 2-methyl-3-phenyl derivative, XXXI (m. p. 119°), soluble in dilute acid, was formed in 75% yield. XXXI on hydrolysis gave methylamine and 3-phenyl-5-diphenyl-2,4-thiazoledione, XXXII (m. p. 150°).[10] The isolation of the two isomers is of

special interest since in the previous cases, doubtless due to the selective action, only one compound has been isolated from such reactions.

Summary

A study has been made of allyl and acyl substituted thiazolidones and of the use of mono- and diphenyl halogen acetyl chlorides and esters in the synthesis of thiazolidones and in one case of an imidazolone.

The diphenylchloroacetyl chloride gave with methylphenyl thiourea the two possible thiazolidones. It was noted also that the two phenyl groups at position 5 stabilize the thiazolidone ring toward hydrolysis as does the benzal group at the same position.

Ethyl Imidocyclopropanecarboxylate Hydrochlorides[1]

BY JOHN B. CLOKE, EDWIN C. KNOWLES AND RAYMOND J. ANDERSON

Preparation.—The imido ester salts were prepared by the general method of Pinner.[2] Thus, the ethyl imidocyclopropanecarboxylate hydrochloride (I) was obtained by the action of dry hydrogen chloride on an ether solution of ethanol and cyclopropyl cyanide as follows

$$\underline{CH_2CH_2CH}CN + HOC_2H_5 + HCl \longrightarrow \underline{CH_2CH_2CH}—C(=NH_2Cl)OC_2H_5 \quad (I)$$

Similarly, the ethyl imido-1-phenylcyclopropanecarboxylate hydrochloride

$$\underline{CH_2CH_2C}(C_6H_5)—C(=NH_2Cl)OC_2H_5 \quad (II)$$

was obtained from 1-phenyl-1-cyanocyclopropane.[3]

Decomposition by Heat.—Pinner[4] many years ago found that the ordinary alkyl imido ester hydrochlorides are decomposed by the action of heat to give an amide and an alkyl chloride. His equation for the pyrolysis was

$$R—C(=NH_2Cl)OR' + \text{heat} \longrightarrow R—CO—NH_2 + R'Cl$$

Several years later, however, Stieglitz[5] in a much more critical study of this reaction pointed out that certain facts are more in harmony with the carbonium, $(R)(NH_2)(OR')CCl$, than with the enammonium structure for the pyrolyzing imidoester salt. His present view, which differs from this one, will be considered in a subsequent communication on this problem.

Following the observation[6] that a cyclopropyl ketimmonium chloride $\underline{CH_2CH_2CH}—C(=NH_2Cl)—R$, rearranges when heated to give the isomeric pyrrolinium chloride, $\underline{CH_2CH_2CH=C(R)NH_2Cl}$, it appeared to be quite possible that the analogous imido ester derivatives such as (I) and (II) might likewise undergo a ring rupture in addition to the Pinner–Stieglitz reaction. However, the work reported in this paper, which was undertaken largely to provide an answer to this question, has demonstrated that (I) and (II) decompose normally according to the Pinner–Stieglitz reaction to give cyclopropanecarbonamide, $\underline{CH_2CH_2CH}—CONH_2$, and 1-phenylcyclopropanecarbonamide

$$\underline{CH_2CH_2C}(C_6H_5)—CONH_2,$$

respectively. No ethoxypyrrolinium salts were detected in the cases thus far investigated. In future work an effort will be made to obtain a definite explanation of this notable ring stability.

Decomposition by Water.—In aqueous solution the imido esters undergo two concurrent reactions. In the first place, they decompose into a nitrile and an alcohol or phenol; and, in the second, they react with water to give the ordinary ester and ammonia, $R—C(=NH)–OR' + H_2O = RCOOR' + NH_3$. The first of these reactions is accelerated by bases, whereas the second is favored by acids. The imido ester hydrochlorides, therefore, are normally decomposed by water to give the ordinary ester and ammonium chloride in accordance with the monomolecular law, although some of them undergo a significant decomposition into nitrile, hydrochloric acid and an alcohol or phenol. Many years ago Stieglitz

and his collaborators[7] made an extensive study of the decomposition of a variety of imido ester salts. The measurements reported in this paper were made in order to compare the characteristics of the cyclopropyl radicals with the alkyl and aryl radicals previously investigated. Upon the basis of these results, the cyclopropyl radicals would be classified with the so-called electronegative aryl radicals.

Experimental Part

Ethyl Imidocyclopropanecarboxylate Hydrochloride.—A solution of 0.2 mole of cyclopropyl cyanide[8] and 0.205 mole of absolute alcohol in four volumes of absolute ethyl ether in a moisture-proof vessel was then cooled in an ice-bath, when a current of carefully dried hydrogen chloride was passed in until no more gas was absorbed, which required about three hours. The solution was then allowed to stand overnight, which led to the separation of a crop of white crystals. These were collected on a filter, which was supported in a moisture-proof housing, when they were washed with anhydrous ether, dissolved in anhydrous acetic acid and reprecipitated therefrom by the addition of anhydrous ether. These crystals, which again were collected on a filter and dried under diminished pressure, melted at 120°, which, however, is actually the melting point of the pyrolysis product, *viz.*, the cyclopropanecarbonamide.[9]

Anal. Calcd. for $C_6H_{12}ONCl$: N, 9.36. Found: N, 9.43, 9.47.

Pyrolysis of Ethyl Imidocyclopropanecarboxylate Hydrochloride.—The imido ester hydrochloride was heated in a test-tube, whereby a white solid condensed on the walls of the tube. The solid melted at 120°, which corresponds to the melting point of the cyclopropanecarbonamide.

Anal. Calcd. for C_4H_7ON: N, 16.45. Found: N, 16.31.

Ethyl Imido-1-phenylcyclopropanecarboxylate Hydrochloride.—A solution of 13.72 g. of 1-phenyl-1-cyanocyclopropane[3] and 4.45 g. of absolute alcohol in 80 cc. of anhydrous ether was treated on several successive days with carefully dried hydrogen chloride. Since only a small amount of white solid had separated at the end of ten days, about 300 cc. of anhydrous ether was added to the mixture, whereby a voluminous white precipitate separated. The crystalline mass was collected on a filter under anhydrous conditions, washed with anhydrous ether and dried in a vacuum desiccator over phosphorus pentoxide for several hours. In view of the fact that the substance, which weighed 11 g., contained 17.6% chlorine as compared with a theoretical value of 15.8%, it was dissolved in warm glacial acetic acid and reprecipitated by the addition of anhydrous ether and petroleum ether. The purified compound was collected and dried as before.

Anal. Calcd. for $C_{12}H_{16}ONCl$: N, 6.21; Cl, 15.72. Found: N, 6.51, 6.37; Cl, 16.1, 15.88.

Action of Heat on above Hydrochloride.—The ethyl imido-1-phenylcyclopropanecarboxylate melted in the vicinity of 110° with some effervescence. When the residue was recrystallized from boiling water and then thoroughly dried, it melted from 98.5–99.5°, which is the melting point of the 1-phenylcyclopropanecarbonamide.

Ethyl Imido-2-methyl-1-phenylcyclopropanecarboxylate Hydrochloride.—A mixture of 7.83 g. of 2-methyl-1-phenyl-1-cyanocyclopropane and 2.3 g. of absolute alcohol was saturated at 0° with dry hydrogen chloride and allowed to stand in a stoppered flask for eight days. The addition of 200 cc. of anhydrous ether to the solution gave 1.5 g. of white crystals, which were washed with dry ether and dried under diminished pressure.

Anal. Calcd. for $C_{13}H_{18}ONCl$: Cl, 14.8. Found: Cl, 15.93.

Reaction Rates of Imido Ester Hydrochlorides with Water.—The velocity with which the imido ester hydrochlorides reacted with water, $R—C(=NH_2Cl)OR' + H_2O = RCOOR' + NH_4Cl$, was ascertained by the method of Stieglitz and Derby[10] for analogous compounds. This method is based upon the fact that an imido ester can be liberated from its hydrochloride by the action of sodium hydroxide and that the free ester is much more soluble in carbon tetrachloride than it is in water, whereas the reverse solubility behavior holds for ammonia. The reaction velocity constant, *k*, was calculated from the equation for a monomolecular reaction

$$k = \frac{2.303}{t_2 - t_1} \log \frac{v_1}{v_2}$$

where v_1 and v_2 represent the relative concentrations of the imido ester hydrochloride at times t_1 and t_2.

In the work which is recorded in the following tables, a 0.05 molar aqueous solution of the imido ester salt was prepared and maintained at a definite temperature in a thermostat. Without delay a 10–20 cc. volume of the reacting solution was pipetted into a Squibb funnel which contained a carefully measured volume of 0.1 *N* sodium hydroxide and a suitable quantity of carefully purified carbon tetrachloride. At once the mixture was well

shaken, the carbon tetrachloride layer was drawn off, and the extraction was repeated twice with fresh portions of this solvent. Finally the residual aqueous alkaline solution was titrated with 0.1 N hydrochloric acid. Table I gives the data for a typical run.

Table II presents a summary of runs similar to that recorded in Table I.

In view of the fact that compound (II) appeared to be relatively pure, the drift in the values of the constants of runs 4, 5 and 6 suggests a secondary concurrent reaction, although this has not been ascertained experimentally. Runs 7 and 8 on the methylated derivative are of qualitative value only.

Summary

1. The hydrochlorides of ethyl imidocyclopropanecarboxylate and ethyl imido-1-phenylcyclopropanecarboxylate are pyrolyzed normally according to the Pinner–Stieglitz reaction to give the corresponding amides and ethyl chloride. No evidence was obtained of a ring rupture to give pyrrolinium salts.

2. A study of the reaction velocity constants of our imido ester salts with water and those previously determined by Stieglitz and his collaborators for other compounds shows that by this criterion the cyclopropyl radicals should be classified with the electronegative aryl radicals.

Unfinished work on the free esters and amidines will be completed and reported at a later date.

Acetyl Derivatives of the Monobasic Sugar Acid Lactones

BY FRED W. UPSON, JOHN M. BRACKENBURY AND CARL LINN

The preparation of a number of acetyl derivatives of the monobasic sugar acid lactones is described in this paper and their properties are compared with those of the parent lactones. Since these derivatives are easily prepared, they are useful in identifying the lactones and in synthesizing other compounds.[1] Furthermore, since no other derivatives have been prepared directly from the δ-lactones the preparation of the acetyl derivatives of these lactones is of interest.

It has been shown[2] that the monobasic lactones having an amylene oxide structure, the δ-lactones, are rapidly hydrolyzed in water solution. Loder[3] found that methylation of *d*-mannonic δ-lactone yielded a derivative having the properties of the γ-lactone. A study of the acetyl compounds was undertaken in an effort to prepare derivatives directly from the δ-lactones[4] and this paper is a continuation of the earlier work of Upson and Bartz. A non-crystalline substance identified as the 2,3,4,6-tetraacetyl derivative was obtained by direct acetylation of *d*-gluconic δ-lactone. This compound though non-crystalline, showed a very rapid mutarotation in 80% acetone–water solution, and was otherwise characterized as a derivative of a δ-lactone.

The acetyl derivatives of thirteen sugar acid lactones have been prepared and their specific rotations have been determined in comparison with those of the parent lactones. The following compounds prepared for this study are already described in the literature: 2,3,5-triacetyl-*d*-xylonic[5] and *l*-arabonic,[6] γ-lactones; the 2,3,5,6-tetraacetyl derivatives of the γ-lactones of *d*-gluconic,[4] *d*-mannonic,[4] α-*d*-glucoheptonic,[4] and α-*l*-rhamnohexonic acids;[7] and 2,3,4,6-tetraacetyl-*d*-gluconic δ-lactone.[4] In addition the following

new compounds have been synthesized: the 2,3,5,6-tetraacetyl derivatives of the γ-lactones of *d*-galactonic, *d*-gulonic, *d*-talonic and *l*-rhamnonic acids and the 2,3,4,6-tetraacetyl derivatives of the δ-lactones of *l*-rhamnonic and *d*-mannonic acids.

Experimental

Acetylation was accomplished by means of acetic anhydride in the presence of a catalyst. Anhydrous zinc chloride, pyridine and sulfuric acids have been used. The acetylated product is separated from the catalyst by means of water, a process which tends to cause hydrolysis of the lactones. Dry hydrogen chloride in acetic anhydride was found to be a suitable acetylating agent and the possibility of hydrolysis is avoided since excess reagent may be removed by distillation under reduced pressure.

Preparation of the Acetyl Derivative.—Dry hydrogen chloride was passed into acetic anhydride for several minutes. After cooling to 0° the pure lactone was added, 5 cc. of acetic anhydride being used for each gram of lactone. The lactone went into solution at room temperature, the time required varying from a few hours to two weeks, depending upon the lactone used. After the substance had been completely in solution for at least one day the solution was transferred to a distilling flask of appropriate size and the acetic anhydride excess removed under 15–20 mm. pressure. During this distillation the temperature was controlled by a water-bath, the temperature of which was raised slowly to a maximum of 80°. Occasionally the derivative would crystallize during this process. After all acetic anhydride had been removed, the residue was dissolved in chloroform, filtered and the product finally thrown out of solution by the addition of petroleum ether. The product in most cases was solid at this point and was filtered off, dried in vacuum over potassium hydroxide and finally recrystallized from absolute ethanol. Butanol was usedf or the derivatives of *l*-rhamnonic and α-*l*-rhamnohexonic lactones since these are very soluble in ethanol. If the product thrown down by the petroleum ether was non-crystalline, it was washed several times with petroleum ether, the latter removed by heating at 40° under 20 mm. pressure and the resulting liquid kept in a vacuum over potassium hydroxide, with frequent stirring. Various solvents were tried when the product was persistently non-crystalline.

The following new acetylated lactones were prepared using the method above described. In each instance the corresponding pure lactone was used and the acetylated products were characterized by analyses for carbon and hydrogen as well as by their optical properties.

The acetylation of *d*-gluconic δ-lactone using zinc chloride as the catalyst gives a tetraacetylgluconic acid monohydrate as shown by Upson and Bartz.[4] This possesses a melting point of 114–117° and the specific rotation is very nearly zero. On heating in vacuum for some hours at 100° water is given off and there remains a colorless glass-like solid which analyzes correctly for a tetraacetylgluconic lactone. Furthermore, it exhibits the very rapid mutarotation characteristic of δ-lactones. Acetylation according to the method described in this paper using hydrochloric acid as the catalyst produced the same non-crystalline solid which checked in every particular with the 2,3,4,6-acetylated lactone described by Upson and Bartz. The rotation of this substance is recorded in this paper. The acetyl derivatives of γ-gluconic, γ-talonic and γ-rhamnonic lactones are also liquid, but the non-crystalline character of these compounds does not appear to be related to asymmetric structure.

Two acetyl derivatives prepared in this study, namely, 2,3,5,6-tetraacetyl-γ-*l*-rhamnohexonic lactone and 2,3,5,6-tetraacetyl-*d*-talonic γ-lactone possess unusually low initial rotations, and there is little change in the rotation with time. These low rotations are characteristic of free acids rather than of lactone derivatives. Nevertheless, analyses show that these two compounds are acetylated lactones. Of the remaining compounds the acetyl derivatives of galactonic and glucoheptonic lactones are the only ones which possess significantly lower rotations than do the parent lactones. The acetylated *l*-rhamnonic, γ and δ-lactones have rotations somewhat higher than those of the parent lactones whereas the remaining lactones and acetylated derivatives correspond fairly closely as regards specific rotation.

The mutarotation of the lactones and their acetyl derivatives is recorded by means of graphs in Figs. 1 and 2. The graphs in Fig. 2 are plotted without reference to the sign of rotation. The sign of rotation is negative in the case of rhamnonic lactone and its acetyl derivative and is positive for the mannonic and gluconic derivatives.

Time is plotted in *days* in Fig. 1 and in *hours* in Fig. 2 because of the more rapid change of rotation with time in the case of the delta lactones. Polariscopic readings were taken at intervals during a period of several days and the solutions of the various lactones were maintained at a temperature of 25° during this period. Water was the solvent used in the case of the lactones whereas the solvent for the acetyl derivatives was a mixture of acetone and water in the proportions of 80 and 20%.

An inspection of Fig. 1 brings out a number of points. In all cases the sign of rotation of the lactone and its acetyl derivative is the same. In a number of instances the specific rotation of the acetyl derivative is notably less than that of the parent lactone. The derivatives of galactonic (1 and 1a), gulonic (2 and 2a), talonic (4 and 4a) and rhamnohexonic (10 and 10a) fall in this group. In the case

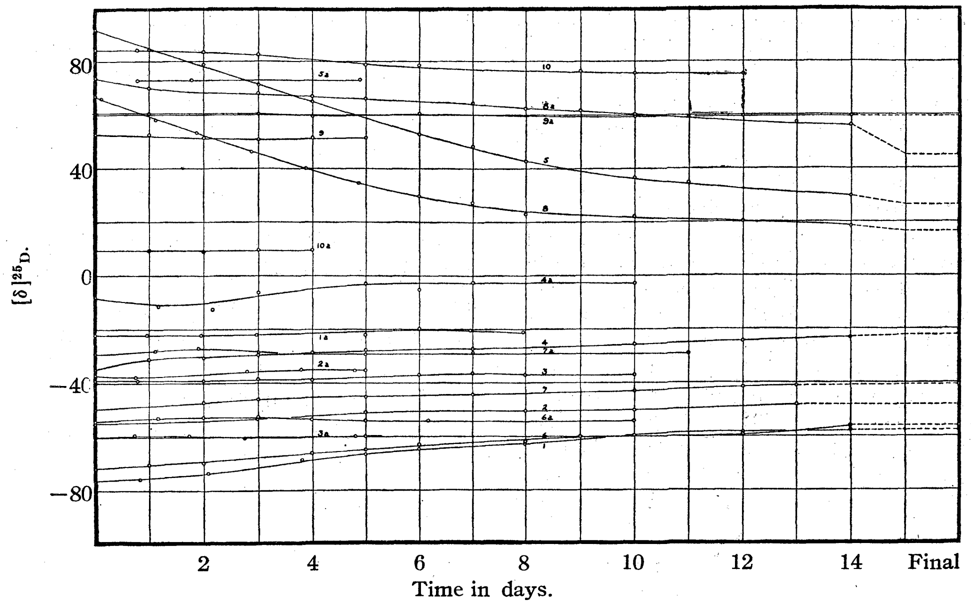

Fig. 1.—Gamma lactones and their acetyl derivatives: 1, 1a, *d*-galactonic; 2, 2a, *d*-gulonic; 3, 3a, *l*-rhamnonic; 4, 4a, *d*-talonic; 5, 5a, *l*-xylonic; 6, 6a, *l*-arabonic; 7, 7a, α-*d*-glucoheptonic; 8, 8a, *d*-gluconic; 9, 9a, *d*-mannonic; 10, 10a, α-*l*-rhamnohexonic.

of xylonic (5 and 5a), gluconic (8 and 8a) and mannonic (9 and 9a) the acetyl derivatives possess specific rotations somewhat higher than their lactones. In all cases there is a relatively slow change in rotation with time, the lactones and their acetyl derivatives showing a similar behavior. The only exceptions are found in the case of xylonic (5 and 5a) and gluconic (8 and 8a) where the rotation of the lactone changes somewhat more rapidly than that of the acetyl derivative. It is to be noted, however, that in all cases the mutarotation is relatively small in the first forty-eight to seventy-two hours.

In marked contrast is the behavior of the delta lactones and their acetyl derivatives as illustrated in Fig. 2. As has been noted in numerous investigations the specific rota-

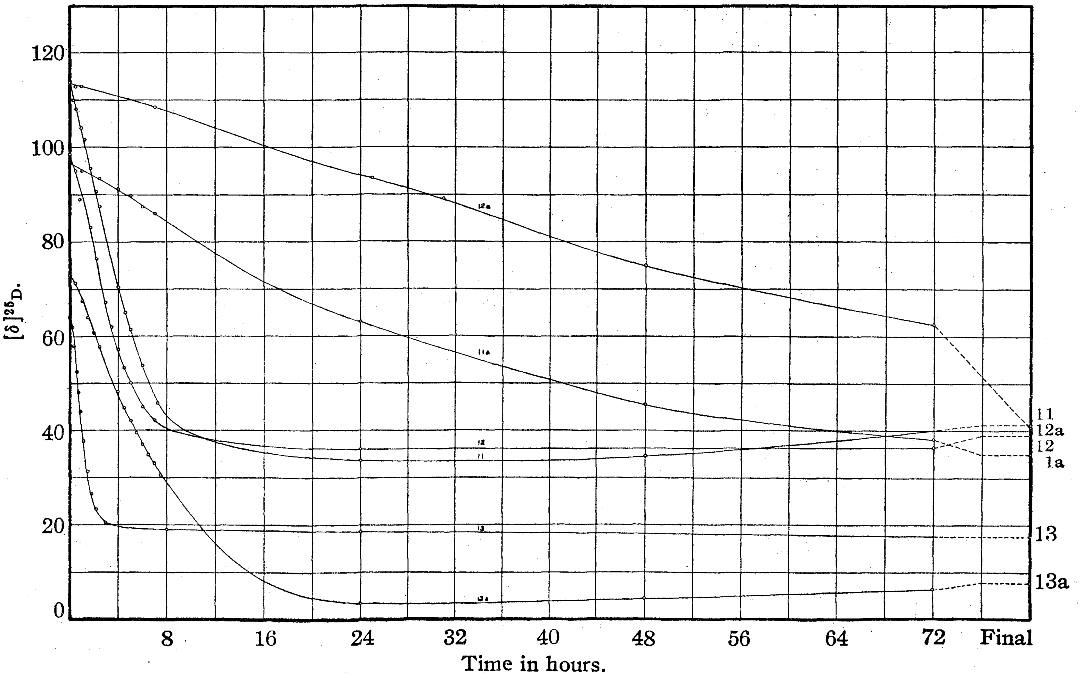

Fig. 2.—Delta lactones and their acetyl derivatives: 11, 11a, *d*-mannonic; 12, 12a, *l*-rhamnonic; 13, 13a, *d*-gluconic.

tions of the δ-lactones of gluconic (13), mannonic (11) and rhamnonic acids (12) are relatively high initial specific rotations which show rapid diminution in value during the first few hours after solution. In comparison with the parent lactones, the acetyl derivatives of mannonic (11a) and rhamnonic (12a) do not show as rapid diminution of specific rotation. The behavior of acetyl δ-gluconic lactone, however, parallels very closely that of the parent lactone. In comparison with the corresponding acetyl γ-lactone derivatives these acetylated δ-lactones all show a much more rapid rate of mutarotation and the initial rotations are all very close to those of the parent lactones. Thus the acetylated δ-mannonic lactone (2–11a) changes in rotation from +97 to +63° in twenty-four hours, whereas the corresponding gamma derivative (1–9a) has an initial specific rotation of +60° which shows no change even after ten days. In like manner the rotation of acetylated γ-rhamnonic lactone (2–12a) has an initial value of −114° which changes to −94° in twenty-four hours, while the acetyl derivative of the corresponding γ-lactone (1–3a) exhibits an initial specific rotation of −60° which shows no change even after five days. These acetylated δ-lactones are of special interest since they are the first derivatives to be prepared directly from the delta lactones themselves.

Summary

1. Thirteen acetylated monobasic sugar acid lactones have been prepared, ten of the γ-variety, and three of the δ-configuration.

2. The change in specific rotation with time at 25° has been determined.

3. It has been shown that the acetylated lactones parallel rather closely the parent lactones as regards change of rotations with time.

Deuterium Abundance Ratios in Organic Compounds. III. Cholesterol

BY MALCOLM DOLE AND ROBERT B. GIBNEY

The interesting possibility of variations in the isotopic abundance ratios of deuterium in naturally occurring organic compounds as compared to the value of this ratio in normal water has been realized and investigated by a number of workers,[1] but there has not yet been published definite proof of an abnormal deuterium content in any organic compound. The hydrogen of benzene has been analyzed by one of us using a method presumably free of isotopic error[1] but its deuterium content is practically normal. In this paper we report data for the abundance of deuterium in cholesterol which appear to demonstrate the existence of a compound containing a slightly low abundance of deuterium although the observed effect is scarcely greater than the experimental error.[2] We chose cholesterol for this study because it is definitely an animal product,[3] and because its high molecular weight and complexity of structure led us to believe that if any animal product would be abnormal in its deuterium content, cholesterol would be that compound. Cholesterol is also interesting because of its apparently important relations to the hormones and other physiologically active substances. As compared to benzene cholesterol has a relatively high percentage of hydrogen; the small amount of oxygen present introduces a negligible error.

Experimental

Combustion of the Cholesterol.—The method of determining the deuterium content previously used was followed here. The source of the cholesterol was the Wilson Laboratories, Chicago, highest grade "Cholesterin" which comes 95% from the spinal fluid of cattle and 5% from the brains of pigs. The purity of this product was claimed by the manufacturers to be 99.9%, but Fieser states[3] (p. 113) that commercial cholesterol contains small amounts of closely related substances which cannot be eliminated by repeated crystallization, to the extent perhaps of 1 to 2%. Since these related compounds would probably contain similar isotopic proportions of deuterium, this small impurity can be neglected. The melting point temperature of the cholesterol was 149°. The combustion of the cholesterol was carried out using four different methods in order to make it fairly certain that the water obtained contained a representative sample of the hydrogen. Deuterium containing substances apparently burn more slowly than similar compounds made of protium, so that unless all or practically all the cholesterol suffers combustion, the

(2) See M. Dole, *Science*, **83**, 31 (1936), for calculations showing that the work of Washburn and Smith apparently indicated a smaller than normal abundance of deuterium in dry wood of the willow tree after proper allowance had been made for the difference in atomic weights of oxygen of the air and of water. However, the isotopic composition of the oxygen in the willow tree water is still uncertain even after this correction has been made.

(3) L. F. Fieser, "The Chemistry of Natural Products Related to Phenanthrene," Reinhold Publishing Corporation, New York, 1936, states, p. 122: "Although the evidence is conclusive that the cholesterol present in higher animals is synthesized in the animal organism, the site and mechanism of cholesterol formation are unknown."

resulting water might not contain all the deuterium it should contain.

The first combustion of cholesterol was carried out by one of us in 1934 by heating the cholesterol to 350° in a Pyrex flask and leading the vapors over hot copper oxide by means of a stream of air which was passed over the surface of the hot cholesterol.[4] The cholesterol burned on the catalyst and tank oxygen of an unknown source (probably Linde oxygen) was added in relatively small amounts whenever the oxygen in the air was insufficient to keep the catalyst in the oxide form. The burning of the cholesterol was repeated by this method in 1936 using air to sweep the vapors of the cholesterol over the copper oxide. Air was also admitted to the middle portion of the combustion tube in just sufficient quantities to maintain the catalyst in the oxide form. An excess of air was avoided in order to prevent a separation of the isotopes of water by a fractional condensation of its vapors. In the case of this second combustion a large charred residue remaining in the cholesterol flask was removed, ground fine and burned in a modified apparatus using air. The yield of water was approximately 75% of the theoretical.

The third combustion of the cholesterol was carried out in a specially designed apparatus using instead of air Airco oxygen, whose isotopic composition in reference to that of atmospheric oxygen was known. The cholesterol burned at a jet made out of capillary tubing in a chamber 6.4 cm. in diameter, 10.2 cm. long which was sealed onto the combustion tube containing the copper oxide catalyst. Oxygen was supplied through a side arm. The cholesterol was kept in a liquid state in a flask by means of a cottonseed oil-bath heated to 180°. Nitrogen forced the cholesterol from the flask into the combustion system through a glass tube while more nitrogen entering into the tube halfway to the combustion chamber, broke the stream of cholesterol into bubbles and blew the cholesterol vapor which was now formed from the heat of the combustion furnace through the jet where the cholesterol burned in a flame steadily and brilliantly. Sometimes it was found unnecessary to add nitrogen at the half-way point. Oxygen was added just rapidly enough to keep the copper oxide catalyst in the oxide form. The yield of water was about 75%. Some of the cholesterol was occasionally blown through the apparatus unburnt due to slight explosions which occurred when the flame went out. Considerable attention was required to maintain a flame at the jet; the flame was lighted by explosions of the oxygen–cholesterol vapor mixture traveling back to the capillary tip.

The fourth method of burning the cholesterol (number III of Table I) consisted in dropping liquid cholesterol onto a copper oxide catalyst heated to about 500°. Air was admitted into the tube to keep the copper catalyst oxidized, and the water formed in the combustion was partially condensed in a water condenser, and the uncondensed residue completely frozen out in a dry ice–acetone trap. This trap was quite necessary as the condensing water was so warm due to the fact that the experiment was done in the summer that only 66% of the water was collected in the water condenser. This method of combustion produced about 75–80% of the theoretical yield.

Measurement of the Density.—The water was distilled from alkaline permanganate over hot copper oxide until all odor disappeared. It was then purified according to our previous method. The method of measuring the density was also the same as previously described except that the apparatus was rebuilt to accommodate smaller volumes of water, a smaller float was made and the motion of the float was observed with the aid of a cathetometer. The temperature measurements and corresponding values of γ are given in Table I where γ is the density of the water under investigation less the density of normal water at the same temperature, the difference expressed in parts per million.

TABLE I

DENSITY OF WATER OBTAINED IN THE COMBUSTION OF CHOLESTEROL

		Cholesterol + air Δt	γ
I		+0.007	
		+ .004	
	Av.	+ .005	+1.1
II		+ .005	
		+ .004	
	Av.	+ .004	+0.9
III		+ .005	
		+ .003	
	Av.	+ .004	+1.2
		Cholesterol + Airco oxygen Δt	γ
IV		(+0.019)	
		+ .008	
		+ .009	
	Av.	+ .008	+1.8
Corr. for oxy:		− .002	−0.5
Final result:		+ .006	+1.3

The method of measuring and the value for the correction to Airco oxygen to bring its atomic weight to that of atmospheric oxygen have already been published.[1] Oxygen from the same Airco tank was used in this experiment.

The density measurements for the combustion number III of Table I were made at 29.9° which accounts for the different relation between Δt and γ.

Interpretation of the Results

In interpreting the very slight difference between the density of the cholesterol–water and normal water calculated from the data of the first combustion, one of us[4] originally concluded that the deuterium content of cholesterol was normal, but at that time we were ignorant of the relatively large difference between the atomic weight of atmospheric oxygen and oxygen of water which has since been observed.[5] In order to correct for this effect 6.0 γ must be subtracted from 1.1 γ, the average of the four data from the three combustions, yielding -4.9 γ as the apparently correct value for the difference in density between

water made from the hydrogen in cholesterol and normal water. However, there is the possibility that the oxygen isotopes may have separated during the combustion of the cholesterol as one of us has already pointed out.[1] We have investigated this source of error by electrolyzing the cholesterol water along with normal water, combining the liberated oxygen with the same tank hydrogen in both cases and comparing the density of these waters. Two independent experiments were carried out, the second series being the more reliable since more measurements were made in determining the density. Much to our surprise we found that the oxygen in the cholesterol which originally came from the air was not as heavy as we had suspected so that instead of subtracting 6.0 γ from the value of 1.1 γ given in Table I we should subtract only 2.5 γ (the average of the results given in Table II, giving double weight to the more accurate value of the second series) which is the extent in p. p. m. to which the density of water made from the oxygen in the cholesterol water exceeds the density of water made from the oxygen in normal water, the hydrogen in the two waters being identical. The result of this calculation is -1.4 γ which is the extent in p. p. m. to which the density of water made from the hydrogen in cholesterol is lighter than water made from normal hydrogen, the oxygen in the two waters being identical in isotopic composition. Considering all the corrections which must be made to the measured values in addition to the errors which are inherently present in the measurements themselves, we cannot consider this value of -1.4 γ as proving definitely that the isotopic abundance of deuterium in cholesterol is lower than normal. Indeed, when one considers the complicated nature of cholesterol, it is surprising that the hydrogen is not more abnormal.

TABLE II

DENSITY DATA OBTAINED IN THE ANALYSIS OF THE OXYGEN CONTAINED IN THE CHOLESTEROL WATER

		$-$ .032	$-$ 9.6
		$-$ .0315	$-$ 9.5
Average		$-$ .032	$-$ 9.5
Difference		$-$ .009	$-$ 2.7
Average of both series			$-$ 2.5

We have also burned halibut liver oil residues in the same way that combustion III of Table I was carried out using Airco oxygen, however, instead of air. The water, after correcting for the Airco oxygen as in Table I, was 3.6 γ heavier than normal. The volume of the water obtained, however, was so small because of the limited amount of the oil at our disposal that we were unable to analyze the oxygen in the water with respect to its isotopic composition. Assuming that the oxygen behaved in this combustion similarly to the cholesterol combustion, and subtracting 2.5 γ for the excess density because of the different oxygen present, we obtain only $+1.1$ γ for the excess density of water made from the hydrogen in the halibut liver oil residues over normal water, the oxygen in each water being of identical isotopic composition. Once again we find the hydrogen to be surprisingly normal in its isotopic composition.

Since we have now analyzed benzene, a plant product, cholesterol, an animal product, and halibut liver oil residues, a fish product, without finding the hydrogen isotopic composition to be definitely abnormal, we are forced to the conclusion that the role of heavy hydrogen in nature cannot be very significant. There is definitely no indication here of the accumulation or rejection of deuterium in the building of these compounds utilizing hydrogen from the ultimate source of water.

In the combustion of the benzene one of us found no separation of the oxygen isotopes,[1] but the benzene burned in a blue flame at a much higher temperature than the temperature at which the cholesterol burned. The cholesterol burned at a catalyst about 500–600°, but even this temperature is so high that one would not expect an appreciable fractionation of the oxygen isotopes, at least from equilibrium theory, since the fractionation factor for the isotopic equilibrium reaction

$$CO_2^{16} + 2H_2O^{18}(g) \rightleftarrows CO_2^{18} + 2H_2O^{16}(g)$$

falls from 1.054 at 25° to 1.014 at 323°.[6] At 600° it would probably be even smaller. Perhaps an isotopic exchange takes place at lower temperatures before the carbon dioxide and steam are separated, but if such an exchange takes place, it would have to be catalyzed by products formed in the combustion since a simple mixing of carbon dioxide and steam for a short period of time produces no isotopic exchange.[1] The magnitude of the effect, about 4 p. p. m. in terms of water density, is small enough to be accounted for by such an exchange and it is in the direction expected.

Acknowledgments.—We are greatly indebted to Dr. D. L. Tabern of the Abbott Laboratories for supplying the halibut liver oil residues, to Mr. Stanley Cristol for carrying out the combustion of the oil, to Mr. J. L. Gabbard for the loan of the electrolysis cells, and to Mr. B. Z. Wiener for carrying out the second electrolysis mentioned in Table II.

Summary

Cholesterol has been examined for its deuterium content, but after all the necessary corrections have been applied to the data it appears that the deuterium content of cholesterol is normal. The measurements indicate a slight deficiency of heavy hydrogen, but the magnitude of the deficiency is hardly greater than the experimental error. Halibut liver oil residues have also been analyzed isotopically, but again the hydrogen appears to be normal in its deuterium content.

We have found, however, that there is a marked fractionation of the oxygen isotopes on combustion of the cholesterol.

The Reactivity of Hydrogen Peroxide in Bromine–Bromide Solutions

BY ROBERT OWEN GRIFFITH AND ANDREW MCKEOWN

A recent paper by Livingston and Schoeld[1] on the photochemical behavior of H_2O_2–HBr–Br_2 mixtures in aqueous solution prompts us to communicate briefly the results of some experiments which we carried out in 1933–34 on this same system, especially as (a) our conclusions regarding the photochemical reaction are diametrically opposed to those of Livingston and Schoeld, and (b) our observations on the thermal reaction differ in some respects from those of Bray and Livingston.[2]

Dealing first with the thermal reaction, we find that H_2O_2–HBr–Br_2 systems at constant temperature and in the dark never attain "steady state" conditions as defined by Bray and Livingston, that is, the concentration of bromine $[\Sigma Br_2]$, and correspondingly that of hydrobromic acid, never reach stationary values so long as any hydrogen peroxide remains undecomposed. According to our measurements, if no bromine is originally present in the system, $[\Sigma Br_2]$ at first rapidly increases toward a pseudo-stationary value, but instead of remaining at this value it then slowly but progressively increases with diminishing concentration of hydrogen peroxide. If excess of bromine is originally present, $[\Sigma Br_2]$ at first rapidly falls to a pseudo-stationary value, passes through a minimum, and then as before slowly increases. In either case, provided the sum $[HBr] + {}^1/_2[\Sigma Br_2]$ has the same value and provided enough hydrogen peroxide be present initially, the concentration of bromine becomes after a sufficient lapse of time the same function of the hydrogen peroxide concentration, independent of the previous history of the system.

For our experiments we have employed, with identical results, hydrogen peroxide from the following sources: (1) Merck 30% Perhydrol free from preservatives, (2) a preparation from sodium peroxide following the method of Rice, Rieff and Kirkpatrick,[3] and (3) a sample obtained from an A. R. hydrogen peroxide by distillation under reduced pressure. Our measurements of bromine concentration were carried out (α) analytically by the method described by Bray and Livingston,[2] and (β) spectrophotometrically.

Table I gives the results of four typical experiments. It will be noted that, after the attainment of pseudo-stationary conditions, the con-

.017	.00153	

centration of bromine steadily increases in every case; in some of our experiments the increase in $[\Sigma Br_2]$ amounts to more than 100%. The rate of increase of $[\Sigma Br_2]$ with time (beyond the pseudo-stationary state) is practically a constant in each experiment while the hydrogen peroxide concentration changes over the range $0.3 \longrightarrow 0.03$ *M*. When the hydrogen peroxide becomes very weak, however, $d[\Sigma Br_2]/dt$ falls off in each case. For the two concentrations of hydrobromic acid in Table I the constant rate $d[\Sigma Br_2]/dt$ equals 31 and 9.3×10^{-8} moles per minute, respectively, and from other experiments not listed this rate appears to be roughly proportional to the fifth power of [HBr].

Attention may also be directed to a further point. The last column for each experiment gives values of $k_{uni.}$ (natural logs; time in minutes) for the rate of disappearance of hydrogen peroxide, *viz.*, $-d[H_2O_2]/dt = k_{uni.}[H_2O_2]$. It will be seen that $k_{uni.}$ falls with time, that is, with diminishing $[H_2O_2]$. The fall is considerably greater than that which might be due to the slight decrease in the concentration of hydrobromic acid resulting from the increasing concentration of bromine. Thus in the first experiment [HBr] decreases about 1%, but $k_{uni.}$ falls by 8%. We have observed this fall in $k_{uni.}$ in all our experiments and we believe it to be real and of significance for the mechanism of the reaction.

We have also studied the photochemical behavior of H_2O_2–HBr–Br_2 systems from various aspects. One of the methods employed was to allow a H_2O_2–HBr–Br_2 mixture to attain, at constant temperature and in the dark, a pseudo-stationary state in which under our experimental conditions $[\Sigma Br_2]_d$ is changing but slowly, then illuminate with monochromatic light and measure by photometric means (thermopile–galvanometer) the *initial* rate of disappearance of bromine. The apparatus used was similar to that of Griffith, McKeown and Winn[4] the main difference being that e. m. fs. generated in the thermopile were balanced by a compensator, similar to that described by Goodeve and Nagai,[5] and recorded on a Weston precision millivoltmeter used in conjunction with a Zernicke *Zc* galvanometer. The thermopile was standardized by means of the uranyl oxalate reaction and checked with a carbon filament lamp standardized by the N. P. L. Table II gives the results (γ = quantum yield, molecules of bromine disappearing per quantum absorbed) of six experiments using blue light ($\lambda = 436$ mμ).

TABLE II

$[H_2O_2]$	$[\Sigma Br_2]_d$	Quanta absorbed per minute	Molecules of Br_2 disappearing per minute *initially*	γ
Temp. = 20°; $[HBr]_{init.} = 0.1437$; $[\Sigma Br_2]_{init.} = 0$; 2-cm. cell				
0.15	0.000523	2.04×10^{16}	1.61×10^{17}	7.9
.15	.000523	4.14×10^{15}	4.74×10^{16}	11.5
.042	.000714	2.17×10^{16}	4.42×10^{16}	2.0
.042	.000714	4.67×10^{15}	1.53×10^{16}	3.3
Temp. = 17°; $[HBr]_{init.} = 0.1071$; $[\Sigma Br]_{init.} = 2 \times 10^{-4}$; 10-cm. cell				
0.19	0.0001194	2.57×10^{16}	4.4×10^{17}	17
.19	.0001194	5.66×10^{15}	1.9×10^{17}	34

The data show that quantum yields considerably in excess of unity are obtained, and that γ is roughly proportional to $[H_2O_2]$ and increases with decreasing light intensity. On these grounds there appears therefore to be no doubt that the photochemical action between hydrogen peroxide and bromine is a chain reaction.

---

(4) Griffith, McKeown and Winn, *Trans. Faraday Soc.*, **29**, 369 (1933).

(5) Goodeve and Nagai, *ibid.*, **27**, 508 (1931).

Results analogous to the above were also obtained by a method similar to that used by Livingston and Schoeld. A photostationary state (denoted by suffix l) was attained from a given pseudo-stationary state in the dark (suffix d) by illumination with monochromatic light of constant intensity. Both $[\Sigma Br_2]_d$ and $[\Sigma Br]_l$ were measured photometrically. On the basis of the Bray–Livingston mechanism for the thermal reaction, it can easily be shown, from the condition that the rate of formation of bromine equals its rate of disappearance both for the thermal and for the photostationary state, that the purely photochemical reaction of hydrogen peroxide and bromine is given by

$$\left\{-\frac{d[\Sigma Br_2]}{dt}\right\}_{\text{phot.}} = \frac{1}{2}k_{\text{uni.}}[H_2O_2]\left\{\frac{[H^+]_l[Br^-]_l}{[H^+]_d[Br^-]_d} - \frac{[H^+]_d[Br^-]_d[\Sigma Br_2]_l\{K_3 + [Br^-]_d\}}{[H^+]_l[Br^-]_l[\Sigma Br_2]_d\{K_3 + [Br^-]_l\}}\right\} \quad (1)$$

where K_3 is the equilibrium constant of tribromide formation. From a knowledge of the energy absorbed in the photo-stationary state the quantum yield can therefore be calculated. Table III gives the results of a few experiments of this type.

TABLE III

Temp. = 17°; λ = 436 mμ

$[\Sigma Br_2]_d$	$[\Sigma Br_2]_l$	Quanta absorbed per minute	Molecules of Br_2 disappearing per minute	γ
$[H_2O_2]$ = 0.167; $[HBr]_{\text{init.}}$ = 0.149; $k_{\text{uni.}} = 2.9 \times 10^{-4}$; 2-cm. cell				
0.000715	0.000088	5.41×10^{15}	4.33×10^{16}	8
.000715	.000231	2.81×10^{15}	3.36×10^{16}	12
$[H_2O_2]$ = 0.19; $[HBr]_{\text{init.}}$ = 0.1071; $[\Sigma Br_2]_{\text{init.}} = 2 \times 10^{-4}$; $k_{\text{uni.}} = 1.53 \times 10^{-4}$; 10 cm. cell				
0.0001194	0.0000179	4.59×10^{15}	1.18×10^{17}	26
.0001194	.0000414	2.25×10^{15}	0.91×10^{17}	40

It will be remarked that at the bromine concentrations and light intensities employed, the photostationary concentration of bromine has been reduced as much as eight-fold below the thermal value. This is in marked contrast with the much smaller relative changes in bromine concentration effected by Livingston and Schoeld, these authors using higher concentrations of bromine and green light which is less strongly absorbed than blue. However, the much smaller quantum yields recorded by them are not wholly to be ascribed to these differences. Our method of calculating the photochemical action at the photostationary state is quite different from that used by Livingston and Schoeld, who write

$$\{-d[\Sigma Br_2]/dt\}_{\text{phot.}} = (k_l - k_d)[H_2O_2] \quad (2)$$

where k_l and k_d are the (measured) unimolecular constants of decomposition of hydrogen peroxide in the light and dark, respectively. There appears, however, to be no theoretical justification for this relation even as an approximation, and indeed a closer scrutiny of their data shows that equation (2) must give far too low an estimate of the photochemical action. Thus, in their experiment 2 where $[\Sigma Br_2]$ has been reduced by the light from 0.0008 to 0.0005, that is, by 38%, it is obvious that approximately this same fraction of that reaction which uses up bromine in the thermal stationary state must now in the light be replaced by photochemical action. The reaction forming bromine in the dark is given by $^1/_2k_d[H_2O_2]$, hence the photochemical action is, at least as regards order of magnitude, about 19% of $k_d.[H_2O_2]$ and not 2% as taken by Livingston and Schoeld. Recalculation of their data for experiments 2, 4, 7, 10, 13 and 16 on the basis of equation (1) leads to γ = 5.1, 1.9, 1.8, 1.8, 2.4 and 0.46, respectively, in place of the recorded values 0.68, 0.34, 0.48, 0.26, 0.70 and 0.34. There seems little doubt therefore that, even with green light as used by Livingston and Schoeld, quantum yields greater than unity can be obtained, especially for low values of the energy absorbed.

The evidence presented above shows that under both thermal and photochemical conditions the kinetics of H_2O_2–HBr–Br_2 mixtures are likely to be of complex character. Photochemically, chain reactions must occur involving Br atoms and probably radicals such as HO_2 and OH. Under thermal conditions, while doubtless the excellent work of Bray and his co-workers has elucidated the main outlines of the kinetics, additional processes must be assumed to occur in order to explain the absence of a true stationary state. It seems likely that it is the reaction between hydrogen peroxide and bromine which—thermally as well as photochemically—is of complex nature. We do not wish, however, to discuss the mechanism further at present, as we are continuing our study of these reactions and hope to be able to publish a more detailed report in the near future.

Summary

1. Data are presented to show that for H_2O_2–HBr–Br_2 mixtures in aqueous solution, the "stationary state" characteristic of the Bray–Livingston mechanism for the thermal reaction does not in fact occur.

2. The photochemical reaction of hydrogen

peroxide and bromine under the influence of blue light gives quantum yields considerably in excess of unity. A recalculation of Livingston and Schoeld's data gives quantum yields greater than unity for green light also. A chain mechanism is indicated, contrary to the conclusion of Livingston and Schoeld.

The Viscosity of Aqueous Solutions of Electrolytes as a Function of the Concentration. IV. Potassium Ferrocyanide

BY GRINNELL JONES AND ROBERT ELIOT STAUFFER

Introduction

This paper describes a continuation of the earlier researches[1] carried out in this Laboratory on the viscosity of solutions of electrolytes. An historical introduction and a discussion of the general objects of the investigation and the progress already made will be found in the earlier papers of this series and is therefore omitted here. In this paper the investigation is extended to a salt of a higher valence type and measurements are made at both 25 and 0° on the same solution in order to permit the study of the influence of temperature on the phenomena. Potassium ferrocyanide was selected as the most suitable uni-tetravalent salt since it is sufficiently soluble and stable and is only slightly hydrolyzed. Moreover, measurements on viscosity were needed for use in the interpretation of data on the conductance of this salt which were being obtained in this Laboratory (see the following paper).

Experimental

The apparatus and experimental procedure was the same as that described in the earlier papers with some modifications and improvements in detail. The most important innovation was the construction of an ice thermostat permitting the viscometer to be placed in succession in the 25 and 0° thermostats so that measurements could be made in succession on the same solution.

The ice thermostat consisted of a tank of about 180-liter capacity firmly supported on a three-point support of Monel metal and surrounded on all sides except the top with diatomaceous earth at least 8 cm. thick. The top had insulating covers built in sections permitting temporary removal in parts when necessary to insert the viscometers or to add fresh ice. The tank had small double windows of plate glass in front and rear to permit observation and operation of the optical system necessary for the automatic timing described in the earlier papers. The thermostat when in use was filled with a well-stirred mixture of ice and water. Wire screens of 14-mesh were arranged as near to the viscometer as possible to protect the fragile instrument from fracture by the moving ice and also to keep open narrow paths for the beam of light needed for operation of the automatic timing system and for inspection of the upper bulb of the viscometer. Water was kept circulating vigorously through the ice and around the viscometer by three motor-driven stirrers. A very good thermometer having an open scale 6 cm. long per degree was mounted totally immersed near the viscometer and read through the window to thousandths of a degree by a telescope. The readings of the thermometer and the consistency of the viscometric data prove that our thermostat can maintain a temperature safely within 0.003 of 0°. It requires about 50 pounds (25 kg.) of ice per day in hot summer weather.

Our old instrument has an inconveniently long period at 0° and therefore a new viscometer of vitreous silica was constructed with a slightly wider capillary (0.052 cm. diameter and 17.9 cm. long) and therefore a shorter period (428.7 sec. for water at 25° and 862.9 sec. for water at 0°). The ice thermostat had its own optical system, photoelectric cell and amplifiers but the same chronograph and clocks served both thermostats. Three different viscometers could be used interchangeably in either thermostat and measurements with different instruments could be going on simultaneously in both thermostats if desired.

The best potassium ferrocyanide available by purchase was twice recrystallized by dissolving in water at 60°, cooling and adding ethyl alcohol, followed by centrifugal drainage. It was dried by heating to 90° in nitrogen at low pressure for several hours. The solutions were made up by weight.

The experimental data at 25 and at 0° are recorded in Tables I and II, respectively. The values for the density given in parentheses were not actually measured but were computed by the formula given below. The third column gives the relative viscosity before applying the kinetic energy correction, which is shown in column 4. The relative viscosity after applying the kinetic energy correction is given in column 5. In some cases a small correction was necessary to bring the data to a round concentration. The results after applying this correction are shown in the last column.

Interpretation of the Data.—The experimental data given below on the density of potassium

ferrocyanide solutions may be expressed with an average deviation of 0.003% by the equations

$$d^{25}_4 = 0.99707 + 0.25074c - 0.02776c^{3/2}$$
$$d^{0}_4 = .99987 + .26836c - .04313c^{3/2}$$

The agreement with the Root equation is not quite so good as has been found for other salts of simpler valence type in previous work in this Laboratory. The deviations although small are apparently systematic in this case and greater than the experimental error.

Column 4 of Tables III and IV shows that the "Grüneisen Effect" is more pronounced than for the salts of lower valence type which have been studied in this Laboratory.

The results at 25° can be expressed in terms of relative fluidity by the equation having the form proposed by Jones and Dole, namely

$$\varphi = 1/\eta = 1 - 0.03995\sqrt{c} - 0.33518c$$

up to 0.1 molar (or 0.4 N) with an average deviation of only 0.004% as is shown in column 5 of Table III. The extended form of the equation $\varphi = 1/\eta = 1 - 0.03995\sqrt{c} - 0.32859c - 0.0639c^2$ fits the data over the entire range up to and including 0.5 molar (or 2 N) with an average deviation of only 0.006% as is shown in column 6

TABLE III

RELATIVE VISCOSITY AND RELATIVE FLUIDITY OF POTASSIUM FERROCYANIDE SOLUTIONS AT 25°

				Jones and Dole equation	
c	η	φ	$\frac{\eta - 1}{c}$	Simple $\Delta\varphi \times 10^5$	Extended $\Delta\varphi \times 10^5$
0.00020	1.00053	0.99947	2.65	+ 10	+10
.00035	1.00079	.99921	2.26	+ 7	+ 7

.00075	1.00138	.99862	1.84	− 3	− 4
.001	1.00163	.99837	1.63	− 3	− 1
.002	1.00244	.99757	1.22	+ 3	+ 1
.005	1.00451	.99551	0.90	+ 1	− 2
.01	1.00744	.99261	.744	− 4	−10
.02	1.01255	.98761	.628	− 4	−14
.05	1.02632	.97435	.526	+ 4	−13
.1	1.04839	.95384	.484	− 1	− 3
.2	1.09414	.91396	.471	− 114	+10
.5	1.26347	.79147	.527	−1270	− 1

Jones and Dole equations	Range of validity	Average % deviation
$\varphi = 1 - 0.03995\sqrt{c} - 0.33518c$	0.1	0.004
$\varphi = 1 - .03995\sqrt{c} - .32859c - 0.0639c^2$	.5	.006
$\eta = 1 + .03695\sqrt{c} + .3660c$	.1	.008
$\eta = 1 + .03695\sqrt{c} + .33538c + 0.27832c^2$	.5	.023

of Table III. If the results are expressed in terms of relative viscosity instead of relative fluidity the agreement is not quite so good. The equation $\eta = 1 + 0.03695\sqrt{c} + 0.3660c$ fits the data up to 0.1 molar with an average deviation of 0.008% and the equation $\eta = 1 + 0.03695\sqrt{c} + 0.33538c + 0.27832c^2$ fits the data up to 0.5 molar with an average deviation of 0.023%.

After our experimental work was completed Hood and Williams[2] published measurements of the viscosity of solutions of potassium ferrocyanide at 18 and 25°. Their results for the viscosity at 25° are slightly lower than ours. They state that their results at 25° are in agreement with the equation $\varphi = 1 - 0.0245\sqrt{c} - 0.3720c$.

Our results show that as usual the relative viscosity at 0° is lower than at 25°, the difference being mainly in the effect responsible for the linear term. At 0° both the simple and extended forms of the Jones and Dole equation seem to be equally good whether expressed in terms of viscosity or of fluidity. At 0° the simple form only holds up to 0.02 molar, whereas at 25° the simple form holds up to 0.1 molar. These equations are given below Table IV.

TABLE IV

RELATIVE VISCOSITY AND RELATIVE FLUIDITY OF POTASSIUM FERROCYANIDE SOLUTIONS AT 0°

c	η	φ	$\frac{\eta - 1}{c}$	Jones and Dole equation Simple $\Delta\varphi \times 10^5$	Jones and Dole equation Extended $\Delta\varphi \times 10^5$
0.0002	1.00053	0.99947	2.6	− 3	− 3

$\eta = 1 + .03508\sqrt{c} + .02123c + 0.4778c^2$	.2	.004

An attempt was made to fit an equation of the form suggested by Onsager and Fuoss[3] to the data without success. In previous papers of this series it has been shown that the Onsager–Fuoss equation is useful for solutions of several salts in methanol but that it failed for aqueous solutions of potassium permanganate and of cesium iodide.

It now remains to compare the values of the coefficient of the square root term (A) determined by experiment with that computed by the Falkenhagen and Vernon equation.[4] Although we can probably estimate the equivalent conductance of the ferrocyanide ion at infinite dilution more accurately than that of any other tetravalent ion, nevertheless the difficulty of extrapolating the conductance of a 1–4 salt is so great that this equivalent conductance is not known as well as for ions of lower valence (see the following paper). If the equivalent conductance of the ferrocyanide ion at 25° is assumed to be 117, the value of A computed by Falkenhagen and Vernon's equation is 0.033. If the equivalent conductance is assumed to be 122 (which is probably too high), then the computed value comes out to be 0.032. The experimentally determined value is 0.037. At 0° the computed value of A (based on the equivalent conductance of the ferrocyanide ion of 64) is 0.030, whereas the experimental value is 0.035. Although the agreement is not perfect, nevertheless the experimental results do harmonize with the prediction of the theory that increasing the valence of the ions involved should increase greatly the value of A and that raising the temperature should cause a moderate increase in A.

Summary

1. The absolute density and relative viscosity of many solutions of potassium ferrocyanide have been determined at 0 and 25°, covering a range of concentration from extreme dilution nearly to saturation.

2. The "Grüneisen Effect" is especially pronounced in this salt of high valence type.

3. The Jones and Dole equation is found to fit our data.

4. The results confirm approximately the equation of Falkenhagen for the computation of the influence of interionic attraction on the viscosity.

The Conductance of Aqueous Solutions as a Function of the Concentration. II. Potassium Ferrocyanide

BY GRINNELL JONES AND FREDERIC C. JELEN

Introduction

The conductance of solutions is greatly influenced by the valence type of salt and therefore data on salts of a high valence type may serve as a severe and useful test of the validity and generality of the various equations which have been proposed for the conductance as a function of the concentration. For an historical review of the more important of these equations and the background of the problem the reader is referred to a recent paper by Jones and Bickford.[1] Potassium ferrocyanide seemed to be the most suitable salt of the 1–4 valence type because it is only very slightly hydrolyzed and is sufficiently soluble and stable and was therefore selected for this investigation.

Experimental

Potassium ferrocyanide was prepared for this investigation by two different methods. The best material available by purchase was twice recrystallized from conductivity water by dissolving at 60°, filtering through a sintered glass filter and cooling to 0°, followed by centrifugal drainage. Since there was a slight indication of instability of these solutions at 60°, we also prepared other samples by dissolving the salt in cold water and precipitating it by adding redistilled ethyl alcohol followed by centrifugal drainage. The entire process was then repeated. This method gave small crystals which were almost white in color. No difference in the conductivity could be detected between the salt prepared by the two methods of purification.

The salt was then placed in a platinum boat in a tube and heated at 90° in a stream of dry nitrogen for about two hours. The salt was cooled in nitrogen and the nitrogen replaced by dry air. The boat and salt was then bottled without exposure to the moist air of the laboratory in a Richards bottling apparatus. Repeated experiments demonstrated that a repetition of the heating and drying process did not change the weight by as much as 0.01%. The preparation of the solutions and the measurement of their conductivity at 25 and 0° were so similar to the procedure used by Jones and Bickford that no further description is needed. The cell constants were determined by the use of the values for the conductance of standard potassium chloride solutions determined by Jones and Bradshaw.[2] The density of each solution was determined by means of a large (65 cc.) pycnometer at both 25 and 0°. At each concentration at least two but sometimes three or four independent solutions were prepared. The actual concentrations were commonly slightly different from the round concentrations desired. Slight corrections were applied to bring the results for the conductivity to the round concentration. These corrections were rarely more than 0.01% and in only one case more than 0.05%. The detailed data on each solution and the corrections to round concentration are omitted to save space in printing.

No corrections have been applied for hydrolysis because tests made by indicators and a quinhydrone electrode on a 0.01 molar solution gave a pH of 7.5, from which it may be inferred that the effect of hydrolysis would be negligible. The results are shown in Tables I and II, in which c is the concentration in moles per liter and Λ is the molar conductance.

Interpretation of the Data

Figure 1 is a plot of the molar conductance against the square root of the concentration. The experimental data at 25° are represented by the centers of the circles. This gives a curve which is similar to the curves given by salts of lower valence types except that the slope and curvature in the dilute end are greater than has been found for salts of lower valence type. The curve is nearly straight at the dilute end but there is evidently some curvature even below 0.001 molar. Putting a straight line through the four lowest concentrations gives the equation $\Lambda = 741.9 - 4637\sqrt{c}$ (line K in Fig. 1). This method of extrapolation must give a value for the limiting conductance and limiting slope at infinite dilution which is too low unless there is a change in curvature at extreme dilution for which there is no experimental evidence or theoretical warrant. This equation, which has the form suggested by Kohlrausch, fails completely above 0.001 molar as is evident from the figure.

The coefficients of the Jones and Dole equation were determined by the method of least squares using all the experimental points including c = 0.5 molar or 2 N, giving the equation

$$\Lambda = 785.16 - \frac{9171.38\sqrt{c}}{1 + 17.106\sqrt{c}} - 12.84c.$$

The curve marked J in Fig. 1 is the plot of this equation and as will be seen it agrees with the experimental data so closely that the deviations are not apparent on the scale that can be printed.

Equations: Jones and Dole

$$\Lambda = 420.40 - \frac{4768.73\sqrt{c}}{1 + 16.4586\sqrt{c}} + 33.87c$$

Jones and Dole; column 6,

$$\Lambda\eta = 418.79 - \frac{4635.89\sqrt{c}}{1 + 16.0335\sqrt{c}} + 68.40c$$

Nevertheless, an examination of column 3 in Table I indicates that there are deviations which are probably greater than the experimental error. These deviations are substantially greater than were found for lanthanum chloride, and barium chloride and potassium bromide. This equation is clearly the best formula known to us for the more concentrated solutions of salts of all valence types but there are indications that it gives too great a curvature in the dilute end and too high a value of the limiting conductance and limiting slope.

Since the concentrated solutions of this salt are exceptionally viscous, the effect of applying a viscosity correction is of special interest. The viscosities of these solutions, η, have been determined for this and other purposes (see the preceding paper) as is shown in column 4 of Table I and the values of $\Lambda\eta$ are shown in column 5 and are plotted as the points within the triangle in Fig. 1. The Jones and Dole equation was then fitted to these values, giving

$$\Lambda\eta = 783.75 - \frac{9000.35\sqrt{c}}{1 + 16.8424\sqrt{c}} + 133.9c$$

The upper curve in Fig. 1 is the plot of this equation and, as will be seen, the deviations are so slight that they are not apparent on the scale that can be printed. Column 6 in Table I shows the computed deviations. The application of the viscosity correction substantially reduces the deviations in the more concentrated solutions but has little effect in the dilute range where the viscosity correction is small. It should be noticed that the curve depicting $\Lambda\eta$ has a flat minimum at about 0.2 molar.

It is next of interest to apply the Onsager–Shedlovsky method of extrapolation to the data. If the Onsager equation is transformed by using molar concentrations (gram molecules per liter) and molar conductances, and by introducing the appropriate numerical values for water at 25°, namely, $\eta = 0.008949$ and $D = 78.57$ and $T = 298.1$, the Onsager equation becomes

$$\Lambda = \Lambda_0 - [0.27446 w \Lambda_0 + 21.138 z_1 z_2 (z_1 + z_2)] \sqrt{z_1 z_2 (z_1 + z_2) c}$$

where $w = 2qz_1z_2/(1 + \sqrt{q})$

and $q = \dfrac{z_1 z_2 \Lambda_0}{(z_1 + z_2)\ \{\Lambda_0 + (z_2^2 - z_2)\Lambda_1^0 + (z_1^2 - z_1)\Lambda_2^0\}}$

for potassium ferrocyanide we substitute $z_1 = 1$ and $z_2 = 4$ giving $\Lambda = \Lambda_0 - (1.22742\ w\ \Lambda_0 + 1890.64)\sqrt{c}$

$$w = \frac{8q}{1 + \sqrt{q}}$$

$$q = \frac{4\Lambda_0}{5(\Lambda_0 + 12\Lambda_K^0)}$$

It is evident that the limiting slope cannot be computed from these equations without first assuming that the values of the limiting conductances of the two ions are known because the value of w depends on Λ_0 and Λ_K^0 in the complicated manner indicated by the equations. However, the value of w is rather insensitive to the value of Λ_0 so that we may proceed by a method of successive approximations and obtain a result if the equations are really valid.

If we take as a first approximation the value of $\Lambda_0 = 741.9$ obtained by putting a straight line through the four lowest points and assume that the limiting conductance of the potassium ion is 73.5 then $q = 0.36549$ and $w = 1.82226$ and the Onsager equation becomes $\Lambda = \Lambda_0 - (2.23668\ \Lambda_0 + 1890.64)\sqrt{c}$ or $\Lambda_0 = (\Lambda + 1890.64\sqrt{c})/(1 - 2.23668\sqrt{c})$.

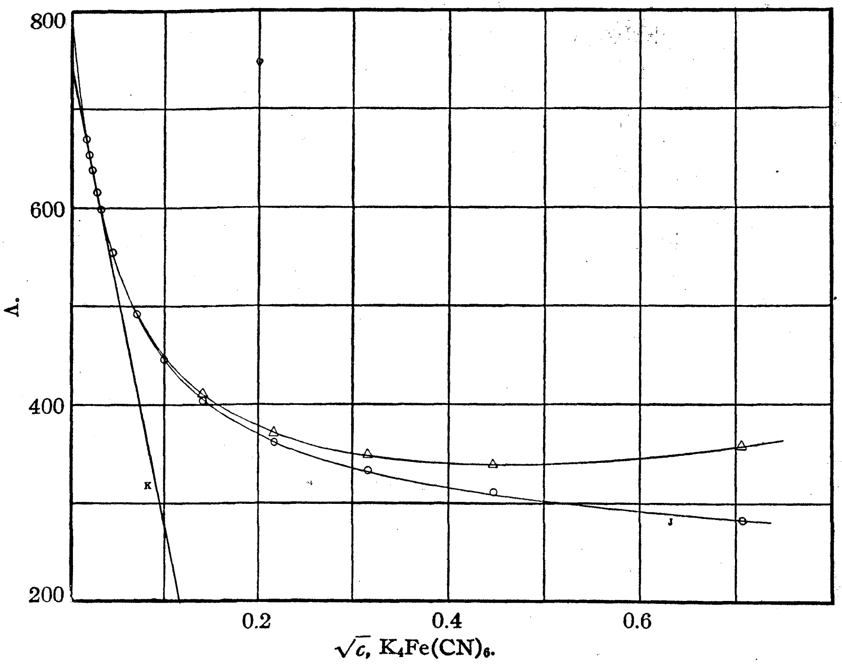

Fig. 1.

If the Onsager equation were valid over any range accessible to experimentation, the values of Λ_0 computed from this equation should be a constant over the range of validity of the equation. The values of Λ_0 computed by this equation are given in column 7 of Table I. As will be evident from the table, the values of Λ_0 are far from being constant. Attempts were made to obtain constancy by varying the value of Λ_0 assumed in the computation of w but no appreciable improvement could be obtained in this manner. This proves that Onsager's equation is not valid for potassium ferrocyanide even up to 0.001 molar.

It has been demonstrated previously that the values of Λ_0 computed by this method are not constant for salts of any valence type. Shedlovsky[3] found for many uni-univalent salts that if the values of Λ_0 computed by the Onsager formula were plotted against c a straight line was obtained up to about 0.1 molar and he proposed to use this method to obtain Λ_0 by extrapolation and also suggested a modified Onsager equation $\Lambda_0 = \dfrac{\Lambda + \beta\sqrt{c}}{1 - \alpha c} + Bc$ which fitted the data up to about 0.1 N. In this Shedlovsky equation definite numerical values can be assigned to α and β from the Onsager theory and only Λ_0 and B are arbitrary parameters selected to fit the data for each salt. Some uni-univalent salts did not obey this equation. Shedlovsky suggests that this exceptional behavior is due to association.

Jones and Bickford applied Shedlovsky's method to lanthanum chloride, obtaining a curve which was approximately straight between 0.0025 and 0.01 molar but had a definite positive curvature in the more dilute range and a negative curvature between 0.01 and 0.1 molar. At the dilute end the plot appeared to be curving so as to enter the axis horizontally, which is the behavior to be expected if Onsager's law is valid as a limiting law. However, Shedlovsky's method

---

[3] T. Shedlovsky, THIS JOURNAL, **54**, 1405, 1411 (1932).

of straight line extrapolation could not be applied to this tri-univalent salt.

Shortly afterward Shedlovsky and Brown[4] reported measurements on the chlorides of four divalent metals which when plotted gave a similar curvature at the dilute end. They, therefore, abandoned extrapolation along a straight line and recommended extrapolation along a curve and thus in effect for divalent salts abandoned the Shedlovsky equation, although they are not clear as to whether or not this curve is assumed to enter the axis horizontally. They propose a modification of the original Shedlovsky equation by the addition of two more terms each containing an arbitrary parameter giving the equation

$$\Lambda_0 = \frac{\Lambda + \beta\sqrt{c}}{1 - \alpha\sqrt{c}} + Bc + Dc \log c - Ec^2$$

This equation, of course, can be made to fit the data better than the original Shedlovsky equation because it contains two more parameters selected to fit the data for their four divalent salts. But they do not give a detailed comparison of the data for the four divalent salts with the results computed by their equation.

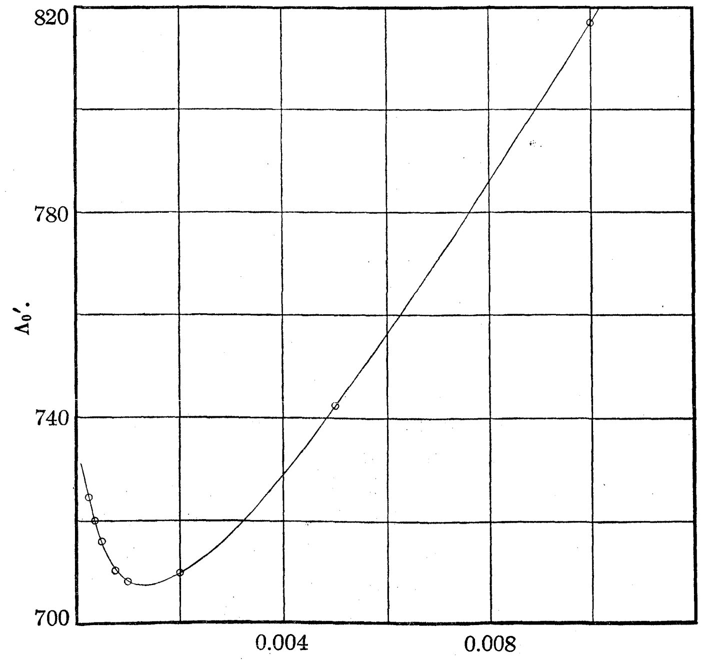

Fig. 2.

Shedlovsky, Brown and MacInnes[5] have shown that this equation may be applied successfully to potassium chloride up to 0.12 *N*.

The results of an attempt to apply the Shedlovsky method of extrapolation to obtain Λ_0 by plotting $\Lambda_0' = \frac{\Lambda + \beta\sqrt{c}}{1 - \alpha\sqrt{c}}$ against c with our data on potassium ferrocyanide are shown in Fig. 2. In this case the plot has a very definite minimum and the portion of the curve which must be extended for extrapolation has a pronounced curvature. Any attempt to extrapolate such a curve depends too much on a guess as to the curvature to have much value. The influence of making other assumptions as to the value of Λ_0 in the computation of w and hence of Λ_0' was tried but there was no change in the character of the curves. These curves are so close together that only one can be shown without confusion on the scale which can be printed and, therefore, only one curve is shown in Fig. 2.

Onsager and Fuoss[6] have suggested a generalized equation for the properties of solutions of the form $F(c) = F(o) - A\sqrt{c} + Bc - Dc \log c + \ldots$. It seemed worthwhile, therefore, to attempt to apply this generalized equation to conductance in the form $\Lambda = \Lambda_0 - A\sqrt{c} + Bc - Dc \log c$. Although in principle the value of A might be computed theoretically if the value of Λ_0 were known, yet since Λ_0 is not known and the results depend so greatly on the value of A, it seemed best to treat A as a parameter and evaluate it from the data by the method of least squares. The result is $\Lambda = 709.96 - 3954.98\sqrt{c} + 3063.41\,c - 5542.92\,c \log c$. The values computed by this equation and the deviations between the experimental and computed results are shown in column 8 of Table I. As will be seen, the results are disappointing. The average deviation is more than eight times as great as for the Jones and Dole equation, although both are four parameter equations. The value of Λ_0 is substantially below that given by Kohlrausch's method of extrapolation (741.9), although there is strong reason for believing that the Kohlrausch method gives too low a result. Moreover, the equation gives a curve having a minimum at about 0.1 molar and a maximum at about 0.25 molar whereas

the experimental data show no such minimum and maximum in this or other cases.

The data for 0° are given in Table II. These data cover a smaller range of concentration than for 25°, and therefore give a less severe test of the equations. The solubility is not great enough at 0° to make it possible to work with 0.5 molar solutions and the data below 0.001 molar were not obtained. These data are probably not quite so reliable as the data at 25°, because it is harder to control the temperature inside an oil bath at 0 than at 25°. The Kohlrausch method of extrapolating to infinite dilution using the data from 0.001 to 0.01 molar gives $\Lambda_0 = 353$ but this figure is undoubtedly much too low. The Jones and Dole equation for this case is $\Lambda = 420.40 - 4768.7\sqrt{c}/(1 + 16.459\sqrt{c}) + 33.87c$. The differences between the observed results and the results computed by this equation are given in column 3 of Table II. The deviations are much less than were found at 25°, but this is probably due to the fact that the data cover a smaller range of concentration and are therefore easier to fit to an equation. The deviations are probably somewhat greater than the experimental error.

By the use of the values of the relative viscosity given in the preceding paper we have computed the values of $\Lambda\eta$ given in column 5 of Table II. With the viscosity correction applied the Jones and Dole equation becomes $\Lambda\eta = 418.79 - 4635.89\sqrt{c}/(1 + 16.0335\sqrt{c}) + 68.40c$. As will be seen by a comparison of columns 3 and 6 the deviations are substantially reduced by the application of the viscosity correction especially in the more concentrated solutions.

The last column in Table II gives the ratio between the conductance at 25 and at 0°. As will be seen the temperature coefficient of the conductance decreases with increasing concentration.

Summary

1. The conductance of potassium ferrocyanide solutions has been determined at 25 and at 0° from great dilution up to nearly saturation.

2. The data have been used to test various equations which have been proposed to express the conductance as a function of the concentration.

The Palladium–Hydrogen Equilibrium and New Palladium Hydrides[1]

BY LOUIS J. GILLESPIE AND LIONEL S. GALSTAUN

The early work of Troost and Hautefeuille, Hoitsema, Sieverts, Lambert and Gates and others was reviewed in the paper of Gillespie and Hall. It may be remembered that Troost and Hautefeuille[2] claimed the existence of Pd_2H on the basis of evidence just short of that demanded by the phase rule, which was about to be announced by Gibbs, and that this claim was usually disallowed after the paper of Hoitsema,[3] although Lambert and Gates[4] pointed out that their descending isotherms show "breaks" at approximately the same composition (about $Pd_{1.9}H$) at 75, 103 and 120°. Gillespie and Hall[5] worked with finely-divided palladium, allowed much time —often one to three days or longer—to elapse before recording pressures, and obtained for the first time a phase diagram for the system in obvious conformity with the phase rule. This diagram indicates the existence of Pd_2H capable of formation in definite proportions from about 80 to 180° or higher; at lower temperatures the phase contains a progressively greater excess of hydrogen.

In their first work at 0° they established the first break between the first rising isotherm and the relatively horizontal one as a sharp angle, which could be demonstrated reversibly at constant temperature. Large additions of hydrogen produced hysteresis effects. They discovered that if some hydrogen were withdrawn and the

system heated for a short time to 360° and exposed again to 0°, the pressure returned to the same level as that of the first break. They were able by the use of this "heat treatment" to follow along a truly horizontal isotherm. Now the pressure at the first break was proved by the classical method, and the results of the heat treatment must be correct—so long at least as the isotherm remains horizontal—as they maintained in an extended discussion. This method was then used for other temperatures, and for the second rising isotherms.

Some writers have since felt misgivings because of this use of heat treatment, yet no one has tried unsuccessfully to reproduce the results. No theoretical objection to the heating has been presented, except that Gillespie and Hall pointed out that the results refer palladium that has recently been heated and that this must in any case be so, as heating *in vacuo* is a necessary preliminary to the experimentation. This being granted, it cannot be admitted further that there is any theoretical advantage in conducting the additions of hydrogen isothermally. A practical advantage is that of greater consistency of data at a given temperature.

Since the work of Brüning and Sieverts,[6] who established the existence of a critical solution temperature at about 300° and found that equilibrium is very quickly reached above this even in the case of wire, it is possible to understand why the heat treatment was beneficial in the case of large additions of hydrogen.[7] The heating to 360° must have brought about uniformity of composition throughout the mass. On cooling, the mass had to separate into two phases, but these phases could form equally well at all points in the mass, whereas a crust may form on direct isothermal addition. There is still of course a difficulty due to the necessary exchange of gas between solid and dead space, which would make the treatment nearly or quite useless for small additions.

Linde and Borelius[8] obtained very exact X-ray data that show at 100, 150 and 200° the presence of two mutually saturated solid solutions. The lattice constant of that richer in hydrogen is about the same at all three temperatures, and they suggested without further evidence that perhaps Gillespie and Hall were mistaken in supposing the richer phase to contain, at temperatures below 80°, an excess of hydrogen over the composition of Pd_2H. This appears impossible, however, as the proof of the excess seems to be perfect, according to the discussion above. Linde and Borelius found the lattice constant practically the same at the two higher temperatures for the hydrogen-weak phase. This is quite consistent with the original data plotted in the Fig. 3 of Gillespie and Hall (though not consistent with the broken line that interprets the compositions of this phase). This fact indicates the existence of Pd_8H, which will be discussed later in connection with new data.

Brüning and Sieverts[6] have studied the pressures, compositions and electrical resistance of palladium wire containing hydrogen. In their work at 210 to 310° the compositions were estimated from the resistances with the aid of extrapolated relations determined at lower temperatures. Thus no great accuracy can be claimed for the calculated compositions, particularly in some cases where the relations involved an angle whose magnitude must change with the degree of hysteresis (see their Fig. 9), since the hysteresis vanishes at the highest temperatures. Nevertheless they found with certainty that there is a cirtical solution temperature between 290 and 310°, estimated at about 300°.

In their work at 160, 180 and 200° they measured the compositions directly. Hysteresis was very marked when two solid phases were obviously present. They forebore to compare their results with those of Gillespie and Hall at the two lower temperatures on the grounds that the latter used finely divided palladium heated to 400° in a vacuum and did not carry out the measurements isothermally. But along the first rising isotherm there was no hysteresis; their results with wire should not differ from the results in this Laboratory. Figure 1 shows one of their two series at 180°, their points being joined with broken lines, and the final results of Gillespie and Hall being shown by a solid line. The agreement along the first rising isotherm is not bad; in the case of their other series at 180° it is better; at 160°, as also shown in Fig. 1, it is very good; and at 200° the agreement is equally good, when in this case the data presented below are used for comparison. Although Gillespie and Hall believed they reached the second rising isotherm, it is doubtful whether Brüning and Sieverts did so, except prob-

---

(6) Brüning and Sieverts, *Z. physik. Chem.*, **163A**, 409 (1933).

(7) We cannot say it was really beneficial for small additions.

(8) Linde and Borelius, *Ann. Physik*, [4] **84,** 747 (1927).

ably at 160°. Only in this case is there a hint of agreement along the second rising isotherm, and here their break is estimated at the atomic ratio H:Pd = 0.49—nearly at Pd_2H. Figure 1 indicates very clearly that the experiments at 180° were not carried along with sufficient addition of hydrogen to convert the whole of the wire into the second solid phase. For, if from the point A hydrogen had been subtracted instead of added a false break at a ratio of 0.4 or less would probably have been obtained; whereas if from B hydrogen had been added again instead of withdrawn it appears entirely possible that another hysteresis loop might have been observed, followed by a break at a ratio greater than 0.49. Figure 1 shows that at 160° the rising and falling isotherms at the top of the figure nearly coincide, and therefore complete conversion, or nearly so, may have been obtained at the point D. Even here, all that can be concluded is that the second break lies somewhere within the area of hysteresis, probably at a level higher than the line EC. In short, Fig. 1 indicates a complete confirmation of the 160° isotherm of Gillespie and Hall within the error of hysteresis. In the other three cases not enough hydrogen was ever added to produce rising and falling isotherms at the top of the diagrams in approximate coincidence and the results do not really speak against the existence of Pd_2H.

This matter has been discussed at length because, interpreting the phase relationships for this system, Brüning and Sieverts allow the picture in their Fig. 13 to be obscured by the inclusion of the unexplained early results of Hoitsema and some irrelevant data[9] concerning palladium charged with hydrogen by electrolysis and draw their temperature–composition line in disregard to data of Lambert and Gates and of Gillespie and Hall (particularly at 80°) and of the existence of Pd_2H.

It seems significant that when they draw the locus of the resistance of mutually saturated solid phases as function of the pressure in their Fig. 11 they avoid the second break-points plotted at 180 and 200° to prevent an unnatural change of curvature. We think the corresponding points should be similarly avoided in the composition–pressure locus of their Figs. 12 and 13.[10]

Ipatieff and Tronow[11] have measured some rising isotherms at various temperatures and at pressures up to about 25 atm. Hysteresis was not discussed but was evidently great. Thus at 150° the pressure could be reduced from 3.5 atm. (at the atomic ratio 0.79) to 1 atm. without changing the amount of hydrogen absorbed by more than about 1 part in 250. The object of the authors was not to study the phase diagram and they do not refer to recent work on it.

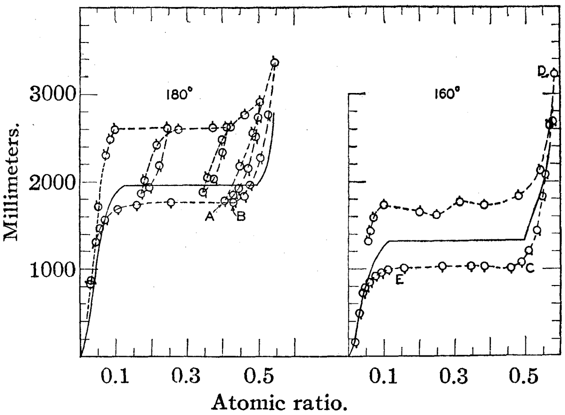

Fig. 1.—Comparison of previous data.

Tromp and De Loor[12] criticize the interpretation of Gillespie and Hall, but the criticism is really not specially directed against them, being a general attack on orthodox interpretations of phase diagrams, and is based on a misunderstanding of the mass action law.[13]

Hüttig[14] has given a general review of hydrides.

Valensi[15] has given a general discussion of the action of gases on metals and has pointed out the similarity of the chromium–nitrogen diagram studied by him—with its compound CrN and critical solution temperature—to the palladium–hydrogen system.

---

(9) We do not call these data irrelevant simply because hydrogen was added by a special method (electrolysis), but because the line in question is supposed by phase theory to be the locus of compositions of mutually saturated solid phases There appears not the slightest reason to suppose that the substance prepared by electrolysis is a pure phase in equilibrium with the so-called first, hydrogen-poor phase. It is probably not even in internal equilibrium.

(10) Their reference to the material of Gillespie and Hall as *gesinterter Mohr* is not understood by us. Our palladium black will undergo great volume contraction and sinter when heated in air or oxygen, but nothing like this happens when it is heated much over 400° *in vacuo*, in carbon dioxide or in hydrogen, and sintered material has not been used by us for absorption experiments.

Experimental

Apparatus.—The apparatus for the generation, measurement and confinement of hydrogen is shown schematically, not to scale, in Fig. 2. Hydrogen is made by electrolysis of 10% NaOH containing some barium hydroxide between nickel electrodes, the generator being run continually to keep out air. It can be passed through a heated platinized-asbestos tube M, but in the present experiments it has been passed through a thin palladium tube, L heated to about 300°. Some is rejected through H, the rest is passed through two phosphorus pentoxide tubes, one of which is shown at J, and hence to the storage bulb K or the gas buret E. From this a measured portion can be passed into the steel-protected glass bulb B by means of a mercury compressor G. By closing the stopcock 2 and opening 1 the gas can then be compressed into the heavy Pyrex reaction bulb A until the mercury stands in the glass capillary tube at the level of the dotted line above B.

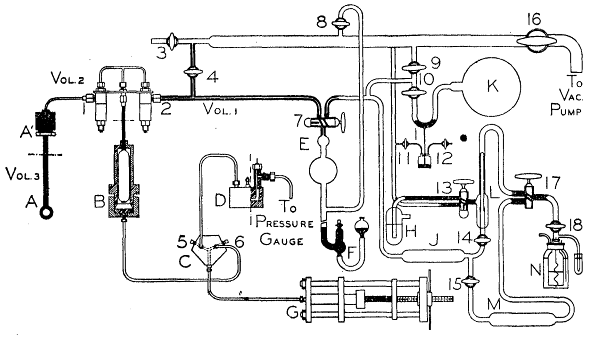

Fig. 2.—Apparatus.

The stopcocks 1 and 2 are of steel, worked from below, and are provided with mercury seals to keep gas from the waxed packing gland. The volumes 1, 2 and 3 were determined by expanding dry hydrogen from the gas buret in a series of experiments, volume 3, extending to the dotted line, having first been determined by weighing water. Stopcock 1, when opened, is open always to the same extent, likewise stopcock 2. In this case the change of volume on closing is 0.02 cc. The volumes 1, 2 and 3 contain 2.4383, 1.5834 and 0.8906 cc., respectively, the last without palladium. 0.96670 g. of palladium was added to the bulb and the capillary resealed without appreciable change of volume. Assuming the density of palladium to be 11.78, we find the free volume 3 to be 0.8085 cc. This is assumed to be at the temperature of the palladium in the thermostat, as the level of demarcation was suitably chosen after exploration with a thermocouple.

The riser block D contains the junction between mercury on the left and oil on the right. The oil line leads to a dead-weight pressure gage. The junction can be maintained at a known level at the end of a steel needle, by means of a vacuum tube circuit which requires only a grid current across the junction. Corrections were made for all oil and mercury columns and the barometric pressure exerted on the gage and the pressures are reported in international atmospheres.

The glass-to-steel joint A′ is shown in detail in Fig. 3. A small steel baffle A, slightly greased, is used to catch and detect any chance droplet of mercury from the stopcocks, but none was found at the end of the experiments.

The thermostat is of steel, provided with an efficient stirrer and wells of steel for the reception of two platinum thermometers, a knife-blade heater and the reaction bulb. Steady heating is provided by an external coil, operated through a Raytheon voltage regulator of 250 watts, working at full load by means of an adjustable shunt load. One of the platinum thermometers is used for measuring the temperature, having been carefully calibrated and compared with other good thermometers. The other is part of a bridge circuit, the galvanometer in which actuates a selenium cell controlling, in a "phase-shift" circuit, a thyratron tube which furnishes the auxiliary current for the knife-blade heater. The thyratron furnishes about 15 to 20% of the total heat. The bath is a mixture of sodium, lithium and potassium nitrates. Under favorable circumstances of room temperature, regulation to better than 0.001° is obtained at the experimental temperatures.

The dead space at room temperatures is protected by the use of aluminum foil and the temperature measured.

Materials.—The hydrogen was purified by diffusion through a hot palladium tube as described above. In some preliminary work at 310° such hydrogen was found to give the same isotherm as hydrogen passed over platinized asbestos (and in either case, over phosphorus pentoxide).

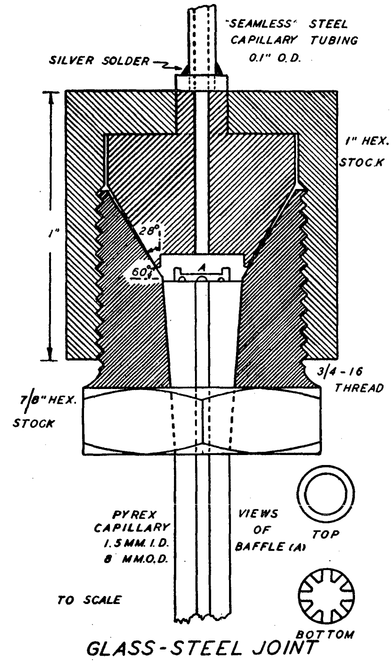

Fig. 3.—Detail of glass to metal joint.

Ammonium chloropalladate was obtained through the kindness of the National Bureau of Standards. It was stated to be free of other metals, particularly platinum-like metals, though not of alkali metals. From this the yellow palladosammine chloride was prepared, reprecipitated twice from ammoniacal solution with hydrochloric acid, thoroughly washed in conductivity water and dried at 100°. A weighed sample was reduced in a stream of hydrogen at 150°, the temperature then slowly raised to a maximum of 500° and a stream of carbon dioxide substituted for the hydrogen. After ten minutes at 500° it was then slowly cooled in the stream of carbon dioxide and weighed. Vacuum corrections were applied. Palladium found, 50.353 and 50.344%; calculated by 1935 atomic weights 50.407%.

Palladium reduced in this way was placed in a Pyrex bulb, and the bulb was evacuated and heated with a hand torch until it partly collapsed. This was an effort to remove any trace of ammonium chloride. The material was allowed to cool in a vacuum, weighed and transferred to the reaction bulb.

In this type of experiment the palladium is easily contaminated with mercury through accident. Furthermore, mercury may be transferred with hydrogen to the palladium, or may distil to it during evacuation. We have not introduced a liquid air-bath to prevent this because of the damaging increase of dead-space corrections and increased liability of accident to the glass apparatus. A palladium mercuride occurs naturally in British Guiana, containing 54.4 to 65.2% Hg.[16] An excess of mercury can react with palladium, especially readily if the palladium contains hydrogen and if heated. After driving off mercury with a fairly strong Bunsen flame we have found to remain 58.2 and 59.1%, most of which could be removed by the strongest Bunsen flame on a small crucible. The formula Pd_4Hg_3 corresponds to 58.5% Hg. Our preparation was hard, sank in the excess of mercury and appeared to have a very low solubility in it. The natural mercuride is hard and denser than its elements.

If the hydrogen which actually entered the palladium during our experiments had been saturated with mercury at 1 atmosphere total pressure, the palladium would have contained about 0.01% of mercury at the end of the experiments. Even ten times as much would not—we have reason to suppose—influence the pressures seriously, though it might hinder equilibrium.

After the last pressure measurement the palladium was exhausted at 290°, cooled in a vacuum and exposed to air. It was then weighed in a porcelain boat with a suitable tare. Then it was conditioned at about 370° in hydrogen, followed by carbon dioxide for half an hour and finally cooled in carbon dioxide, conditioned in the balance case and weighed again with undisturbed weights and rider. The loss of weight was only 0.03 mg. on 942 mg. of sample. Such heating will not remove small amounts of mercury. The boat was placed in a narrow quartz tube and strongly heated with a Meker burner to bright red heat in a current of carbon dioxide, the palladium conditioned with hydrogen and carbon dioxide, cooled in carbon dioxide and weighed as before. The loss of weight was about 2 mg. The palladium was then heated again in the quartz tube in a current of oxygen, followed by hydrogen and carbon dioxide as before. The further loss of weight was about 0.3 mg. The total loss of weight was 0.26% of the weight of the palladium. Previous experience with the elimination of known quantities of mercury showed that this procedure is sufficient.

The loss in weight in this case cannot be due mainly to mercury, as this should have been collected in a narrow water-cooled part of the quartz tube, and none could be found by inspection with the low-power microscope. As the tube at this place appeared etched, about 2 mg. of mercury was intentionally distilled and collected in this part, without cleaning it. Under the low power, the mercury made a striking display, no substantial fraction of which could have been missed in the analysis. In the analysis the gas was passed into a test-tube of water for cooling, and this gave a test with Nessler's reagent.

We conclude that part of the loss of weight was due to elimination of ammonium chloride, and that the amount of mercury in the palladium was much less than 0.2%.

Measurements of Equilibrium Pressure.—We considered the pressure worthy of record as equilibrium pressure when it remained constant for one-half hour. Weighings of the pressure were made to 1 g., corresponding to about 1 mm., though in most cases not reported so precisely in the table. At the higher temperatures equilibrium was evidently reached very quickly, and this was confirmed by coincidence of the rising and falling isotherms. In the two-solid-phase region hysteresis was increasingly evident as the temperature was lowered, until it was very serious at 200°. The "heat treatment" of Gillespie and Hall was not used at all in this work, as it was very inconvenient with the new apparatus. The mercury compressor allowed of a withdrawal of hydrogen followed by return of the same amount to the palladium plus dead space. This seems to be of some assistance in gaining proper equilibrium, but proof of this is lacking, and in the interpretation of the measurements no particular weight has been given to data secured in this way. Such points are shown in the diagrams by circles without tails—they should in most cases be regarded as additions. Additions are shown by tails pointing upward; subtractions, by tails pointing downward.

Calculation of Concentrations.—The hydrogen admitted to the apparatus during an experiment is partly in the palladium and partly in the dead space. Frequently only one-fourth of it was in the palladium. The dead space is in two parts, one at bath temperature and one at room temperature. The density of palladium with adsorbed hydrogen is not well known, and perhaps cannot be. Measurements of Wolf[17] on palladium wire show marked hysteresis and lack of reproducibility. However, they lead us to believe that the error we make in assuming constant density is not serious. We have given above enough apparatus constants to allow of easy correction of our concentrations, if better density data become available. The error of neglecting the thermal and pressure expansion of the glass reaction bulb should be much smaller. At the higher pressures it is necessary to correct for the non-ideality of hydrogen and this correction has been made throughout. It amounted to an increase of 0.0086 in the atomic ratio at 32 atm. and 310° and was a strong function of the pressure and a weak function of the temperature.

The concentration is reported throughout as the atomic ratio: atoms hydrogen per atom palladium.

Experimental Results.—The data are presented in Table I in the order in which they were taken, except for some measurements at 0°, made

between those at 200° and those at 280°. When the mercury compressor was used as described above to withdraw and return hydrogen the ratio is followed by an asterisk. In the last few cases the entries do not begin with zero pressure. This means that the preceding experiment was continued at a new temperature without exhaustion.

At 0° no attempt was made to investigate the whole curve, or to find again the first break, but we have tried to find the pressure of the horizontal isotherm more accurately than did Gillespie and Hall, who found the average 3.95 mm. by the use of capillary tubes and a meter stick. In this case we have used wide tubes and a good cathetometer. We find that the equilibrium pressure cannot be greater than about 3.56 mm. "Heat treatment" was not used, but the palladium was heated *in vacuo* at 360° before the experiments. The material absorbed hydrogen over a wide range of composition at much lower pressures than in the former investigation, as did the material used by Gillespie and Ambrose.[18] For instance, when the atomic ratio was increased from 0.047 to 0.408 the pressure fell in twelve and a half hours to only 4.03 mm. This is probably a result of the better elimination of ammonium chloride. On withdrawing hydrogen, however, even from the ratio 0.07, the material showed hysteresis, the pressure falling to 3.0 mm. with a decrease of only 0.002 in the ratio.

The last entry of Table I is for a check on the condition of the palladium in comparison with the earlier 290° isotherm. It is not plotted in the diagrams. This result is about 1% lower than the curve at 290°. If plotted in Fig. 5 the center of its circle would lie on the circumference of one of the circles shown. This result points to some small change in the material. The palladium was found to be packed together after the experiments. The mass could be broken up almost entirely by shaking the container so that most of it was removed through the capillary tube. Care was taken to include all of the packed material for the test for mercury.

Discussion

The data cannot be properly judged by a single diagram of constant scale. Hence the experimental points in the neighborhood of the heterogeneous region are plotted in Fig. 4 with different pressure scales for the different isotherms. Even here, the magnification is not quite sufficient to make evident the horizontal portion at 295°, and one must examine the numbers. The scale at 300° is the same as at 295°, though displaced, and the difference between these isotherms, one above the critical point, and one just below it, is very clear. The isotherm at 285° is the last one obtained. It is not so consistent as the others—indeed, taken by itself, it suggests a continuous curve. In order to locate the breaks as well as possible in this and some other cases, we have sought to take advantage of the fact that the pressure level of the horizontal portion is very well defined at some temperatures. A plot was made of log p against $1/T$ for the horizontal portions, and the doubtful levels were chosen so that all the pressures lie within 0.2% of the pressure given by the equation

$$\log p = 4.6018 - 1877.82/T$$

At the seven temperatures increasing from 200 to 295° the pressures chosen differ from those given by this equation by the respective percentages: 0, +0.24, −0.11, 0, −0.06, 0, 0. This equation prescribes a pressure of 4.05 mm. at 0°, which is too high. It agrees with the experimental value 3.56 mm. about as well as any linear equation can, the true equation being that of a curve. On this

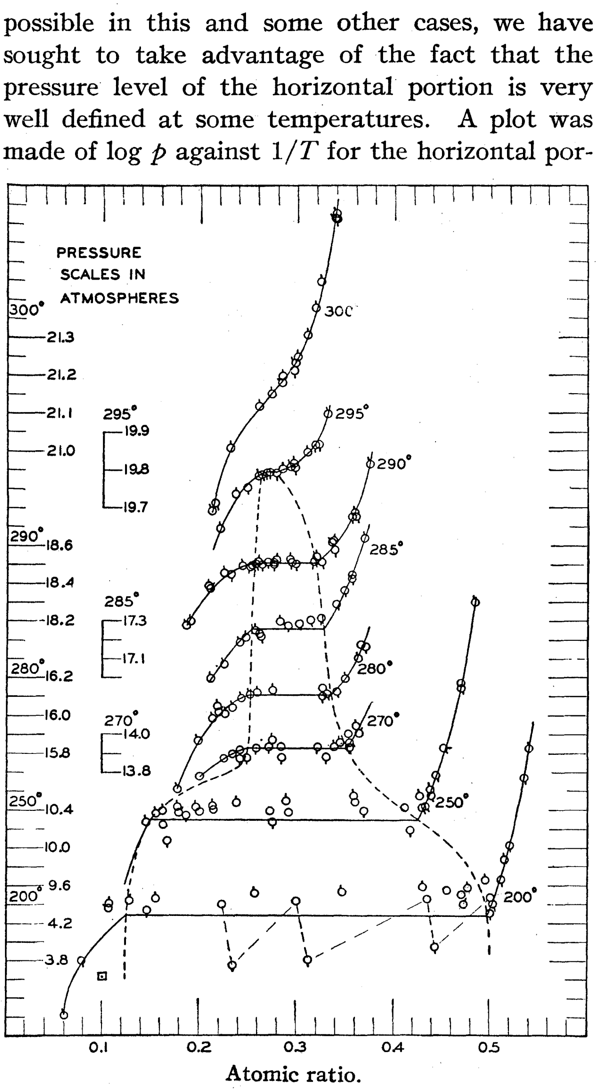

Fig. 4.—Detail of breaks. The square denotes a point in the 250° isotherm. All other points belong on the nearest curve.

---

(18) Gillespie and Ambrose, *J. Phys. Chem.*, **35**, 3105 (1931).

plot the results of Gillespie and Hall at the higher temperatures, particularly 180°, appear too low.

The breaks may be sharper than we have drawn them, but it would seem that the heat of absorption per mole of hydrogen is nearly the same at a given temperature, whether the palladium is nearly saturated or whether it is already a two-phase mixture and hydrogen is being used for compound formation. One would therefore expect it legitimate to use a continuous function for smoothing in the manner just described.

The main results of the measurements are shown in summary in Fig. 5, a diagram of uniform scale. Although the exact location of the breaks is very difficult, requiring a smoothing in two variables, yet we think it certain that the boundary of the two-solid-phase region is substantially as shown in Figs. 4 and 5 and that the boundary has steep tangents at ratios 0.125, 0.250, 0.333 and 0.5, corresponding to the compounds Pd_8H, Pd_4H, Pd_3H and Pd_2H. The existence of the first and last of these depends in part on the results of Gillespie and Hall, which are likewise shown in Fig. 5, and is supported in both cases by the X-ray diagram of Linde and Borelius.[8] The short vertical lines across the isotherms at 160 and 180° show the limits allowed by the original data.

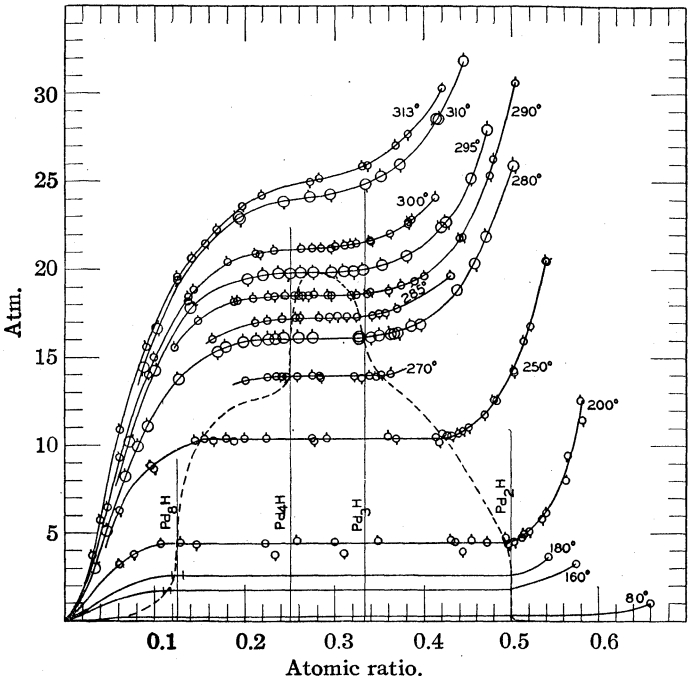

Fig. 5.—Pressure–concentration diagram of palladium–hydrogen system.

We have drawn the tangent much steeper at Pd_4H than at Pd_3H, but such comparisons depend upon the smoothing and are perhaps not fully justified. We think it possible that the tangents are vertical in all cases except Pd_3H, which would mean that the corresponding compounds follow the law of definite proportions. In such a case as shown for Pd_3H there is evidence of chemical individuality, even if the law of definite proportions seems to hold only at a point—*i. e.*, not at all from a practical standpoint. The curve for it is like the curve for FeO in the Fe–H–O system shown by Eastman and Evans,[19] and Pd_3H seems to have as great a claim for existence as FeO.

It may be noted that the tangent cannot be assumed vertical at Pd_7H or Pd_9H. The next compound in the obvious series would be $Pd_{16}H$. This was not observed by Gillespie and Hall, and their data in the neighborhood of 80° are not sufficient to give any information about its possible existence.

The critical solution temperature is estimated by us to be 295.3°, the corresponding pressure 19.87 atm. and the atomic ratio, 0.270.

No compound PdH has ever been shown, nor any phase diagram presented that gives evidence of it. Palladium has been heavily loaded with hydrogen by electrolysis by Fischer[20] to an atomic ratio of 0.84. On standing, hydrogen was lost until the ratio was 0.81. Paal and Gerum[21] report a single experiment in which hydrogen was absorbed by palladium black suspended in water and shaken until the ratio reached 0.98, indicating PdH. But when their absorptions are plotted against the time, a curve is obtained which suggests that further absorption might have been observed in a longer time. Thus there is no evidence here of the existence of PdH even if one grants the enormous absorption, which appears quite inconsistent with the results of electrolysis. This process ought to be capable of saturating palladium under virtually very great pressure—indeed, von Samson-

---

(19) Eastman and Evans, THIS JOURNAL, **46**, 888 (1924). In this case the temperature is replaced with per cent. of H_2 in the gas phase as variable, the temperature and partial pressure of water being held constant in the 3-component system, but the curves are analogous.

(20) Fischer, *Ann. phys.*, [4] **20**, 503 (1906).

(21) Paal and Gerum, *Ber.*, **41**, 818 (1908).

Himmelstern[22] has found an increase of pressure from 1 to 968 atm. to increase the atomic ratio found on electrolysis by a negligible amount (from 0.7 to not more than 0.707).

Summary

Seven isotherms, from 200 to 313°, have been traced on the pressure–composition diagram for palladium and hydrogen, in most cases from zero pressure through the heterogeneous region and well into the second homogeneous solid phase. The diagram, including the previous results at lower temperatures of Gillespie and Hall, indicates that the compounds Pd_2H, Pd_3H, Pd_4H and Pd_8H have chemical individuality, even though in the second case, and possibly others, the tangent to the boundary curve is not vertical, the curve then resembling the analogous curve for FeO in the Fe–H–O system. In all cases the compound is to be regarded as a solid solution that has a stoichiometrical composition over a limited range of temperature. The finding of Brüning and Sieverts of a critical solution temperature for the solid phases near 300° is confirmed, and the critical constants are found to be: temperature, 295.3°; pressure, 19.87 atm. and atomic ratio H:Pd, 0.270.

In the discussion the validity is denied of (1) certain evidence against the existence of Pd_2H, and (2) certain evidence in favor of the existence of PdH.

Mention is made of palladium mercuride, probably Pd_4Hg_3, of very low decomposition pressure. The palladium investigated was found at the conclusion of the experiments to contain a presumably harmless amount of mercury, much less than 0.2%.

The Extraction of Ferric Chloride from Hydrochloric Acid Solutions by Isopropyl Ether

BY RICHARD W. DODSON, GERARD J. FORNEY AND ERNEST H. SWIFT

Introduction

The extraction of ferric chloride from solutions approximately 6 formal in hydrochloric acid by ethyl ether has been studied repeatedly,[1–5] but, although such an extraction process offers obvious advantages over precipitation methods, this separation has not been used as widely in general qualitative and quantitative procedures as would seem justified. This has been due to several factors: the efficiency of the extraction process is critically dependent on the hydrochloric acid concentration; the solubility of ether in the acid is of such magnitude that the volume of the aqueous phase is increased by as much as 25%, making the concentration of the acid after an extraction uncertain or requiring the use of acid previously saturated with the ether; it has been feared that peroxide or alcohol which are frequently present in ether would reduce the iron to the ferrous state, in which form it is not extracted; finally, the volatility of ethyl ether makes the quantitative technique of the extraction somewhat difficult at room temperatures, and especially for student use, involves a serious fire hazard. Because of these facts, it has seemed worth while to investigate the use of other, less volatile ethers for this separation, and this paper presents the results of experiments with isopropyl ether. This ether is readily available, and the present cost of the best technical grade is somewhat less than that of ethyl ether of a comparable grade.

The Experimental Method

Materials.—Concentrated hydrochloric acid, C. P. grade, was standardized against sodium carbonate. Ferric chloride solutions were prepared and standardized, by permanganate, using the Zimmermann–Reinhardt method, or by thiosulfate, using the iodometric method.[6] In every case the ferric chloride used was shown to be free from ferrous salt by testing with ferricyanide. Except when testing the suitability of the technical product for routine analyses, the isopropyl ether used was prepared from a technical grade by fractional distillation, the fraction

[6] E. H. Swift, THIS JOURNAL, **51**, 2682 (1929).

taken distilling over a temperature range of 0.1°. The ethyl ether used had been distilled over sodium, and before use was shaken with mercury to remove peroxide. Solutions of the chlorides of copper, cobalt, manganese, nickel, aluminum, chromium and zinc were prepared by dissolving appropriate amounts of these substances in distilled water, and adding such amounts of concentrated hydrochloric acid and water that the final acid concentration was 7.75 *f*, and the metal ion was present in the desired concentration. Hydrochloric acid solutions were prepared similarly of technical titanic sulfate solution, vanadol and vanadyl ions (from ammonium vanadate), sodium molybdate, sodium hydrogen sulfate and sodium dihydrogen phosphate.

Extraction Technique.—Twenty-five ml. of a solution of hydrochloric acid and ferric chloride in definite concentrations was introduced into a 50-ml., glass-stoppered, graduated cylinder, 25.0 ml. of ether added and the mixture shaken vigorously 500–1000 times. After a separation of the layers was obtained, the phase volumes were read and the mixture transferred to a dry separatory funnel. Portions for analysis were withdrawn from each phase. Except where otherwise stated, the extractions were performed at room temperatures. The same technique was used in the extractions of the other substances tested.

Analytical Procedure.—Small amounts of iron were determined colorimetrically with thiocyanate, larger amounts either by the Zimmermann–Reinhardt method or by the iodometric method. The peroxide content of the ethers used was estimated colorimetrically by means of titanium sulfate. In studying the reducing effect of peroxide and alcohol, ferrous iron was estimated by adding ferricyanide to the solution to be tested and comparing the precipitate so obtained with the precipitate obtained under similar conditions with known amounts of ferrous iron, also by the difference between thiocyanate determinations of ferric iron and, after permanganate oxidation, of total iron.

The Experimental Results

Effect of Varying the Acid Concentration.—Since the efficiency of the extraction with ethyl ether is known to be very dependent on the acid concentration, extractions using isopropyl ether were performed with 125 and 250 mg. of ferric iron over a wide range of acid concentrations. The results of these extractions are recorded in Table I. As noted, with these amounts of iron, three phases appear at hydrochloric acid concentrations above 7.5 formal. In these cases, the two upper layers are considered as ether phases, and the sum of their volumes is recorded. The volumes of these two phases at acid concentrations of 7.5–8.0 formal are approximately equal and the distribution ratio for iron between them varies from about 2.5 to 7.5, the ratio favoring the bottom layer of the two and increasing with increase in hydrochloric acid concentration.

For purposes of comparison there are recorded in Table II values obtained under similar conditions for the distribution of ferric iron between aqueous hydrochloric acid solutions and ethyl ether.

[a] Separate ether phase metastable.

Values for the phase volumes and extraction percentages with ethyl ether at acid concentrations of 8.6 and 9.3 formal are recorded in Table II. In subsequent experiments it was found that at these concentrations the ether phase very slowly but completely dissolves in the other phase on continued shaking. The values given for these concentrations represent, therefore, extraction under metastable conditions.

In Fig. 1 are plotted the extraction percentages given in Tables I and II.

In order to determine the suitability of the technical grade of isopropyl ether for this extraction, experiments similar to those previously described were made using commercial isopropyl ether. The results of these experiments are given in Table III.

TABLE III

THE DISTRIBUTION OF FERRIC IRON BETWEEN TECHNICAL ISOPROPYL ETHER AND AQUEOUS HYDROCHLORIC ACID SOLUTIONS

Initial HCl concn., moles per liter	Volume after shaking, ml. Ether layer	Water layer	Iron found, mg. Ether layer	Water layer	% extracted	Distribution ratio $(\mathrm{Fe}_{ether})/(\mathrm{Fe}_{water})$
6.0	24.7	25.0	244.0	7.76	96.9	31.8
8.0	23.5	26.1	251.5	0.52	99.8	540

Effect of Varying the Iron Concentration.—In order to determine the effect on the distribution of varying the iron concentration, a series of extractions were made with isopropyl ether in which the acid concentration was kept constant and the amount of iron was varied. In these experiments the solutions were kept at 25° during the extraction process. A hydrochloric acid concentration (5.0 formal) below that for optimum extraction was selected in order that more accurate values for the distribution ratio might be obtained. The results of these experiments are given in Table IV. The isopropyl ether used in obtaining the data presented in Table IV was found to be 0.03 *N* in peroxide.

Because it was seen from the data recorded in Table IV that the distribution varies with the total amount of iron, extractions were performed with one milligram of iron with both ethyl and isopropyl ethers. The results are given in Table V.

The Effects of Peroxide and Alcohol.—To determine the reducing effects of peroxide and alcohol, extractions were made with ethers containing known amounts of these impurities. A thirty-minute extraction of 250 mg. of ferric iron was performed with ethyl ether from hydrochloric

acid 6.0 *f* and with isopropyl ether from hydrochloric acid 8.0 *f*. A small amount of ferrous iron was found in the aqueous layer after the ethyl ether extraction, less than 0.3 mg. when the ether was 0.003 *N* in peroxide and contained ethyl alcohol 4% by volume, and a like amount when no alcohol was present. With isopropyl ether, 0.1 *N* in peroxide, both with and without isopropyl alcohol present 4% by volume, no test for ferrous iron was obtained, or less than 0.0 mg. was formed.

The Behavior of Elements Other than Iron.—In order to determine the behavior of other elements with isopropyl ether, extraction experiments were performed with copper, cobalt, nickel, manganese, aluminum, chromium, zinc, molybdenum, vanadium, titanium, sulfur and phosphorus.

TABLE VI

THE EXTRACTION OF ELEMENTS OTHER THAN IRON FROM 7.75 *f* HYDROCHLORIC ACID SOLUTIONS BY AN EQUAL VOLUME OF ISOPROPYL ETHER

Element taken	Amount, mg.	Amount found in ether, mg.	% extracted
Cu^{II}	500	0.0	0.0
Co^{II}	500	.0	.0
Mn^{II}	500	.00	.00

P (as H_3PO_4)	125	.1	.1
P (as H_3PO_4)	62.5	39	62
Fe^{III}	250		

These extractions were performed at an initial hydrochloric acid concentration of 7.75 formal. The results are given in Table VI.

Discussion

It is to be seen from Tables I and II and from Fig. 1 that with 250 mg. of iron the extraction with ethyl ether reaches an efficiency of 99% or slightly greater at an initial hydrochloric acid concentration of 5.5–6.5 formal. Above 6.5 formal the efficiency of extraction falls off quite rapidly. With isopropyl ether the efficiency of extraction reaches 99% at an initial acid concentration of 6.5 formal, rises above the curve for ethyl ether, and does not fall off appreciably until an acid concentration of 8.5 formal is reached. Under optimum conditions (acid 7.75–8.0 formal) the extraction is 99.9% complete. From the standpoints both of maximum efficiency of extraction and of range of acid concentration over which a favorable extraction is obtained, isopropyl ether is seen to be markedly superior to ethyl ether.

Technical isopropyl ether was found to give an extraction almost as efficient as that obtained with the redistilled ether.

Tables IV and V show that, with both ethers, the percentage extraction decreases with decrease in total iron. However, as for the extraction of large quantities, isopropyl ether is also found to be superior for the extraction of small quantities of iron, the extraction of one milligram under optimum conditions being 96% with isopropyl ether as compared with 80% with ethyl ether. In view of the completeness of extraction of quantities of iron as small as one milligram it can be said that with isopropyl ether a very satisfactory separation of iron is possible. Shaking with three successive portions of isopropyl ether should give a separation that is practically quantitative.

Under conditions of maximum extraction the volume changes of the ether and aqueous layers are considerably less with isopropyl than with ethyl ether. This is an advantage in analytical separations in which it is desired to know the approximate acid concentration after an extraction. An optimum final acid concentration corresponding to an initial concentration of 8.0 *f* is calculated to be 7.4 *f*. (The assumption is made that the formula of the extracted complex is approximately $HFeCl_4$; the concentration of hydrochloric acid in isopropyl ether saturated from aqueous 7.5 *f* solution has been determined by us to be 0.0246 mole per liter at 25°.)

The reduction of ferric iron in the ether layer does not occur even when isopropyl alcohol and peroxide are both present in moderate amounts. With ethyl ether, reduction is slight.

The data recorded in Table VI indicate that a very satisfactory separation of iron from copper, cobalt, manganese, nickel, aluminum, chromium, zinc, quadrivalent vanadium, titanium and sulfur is to be obtained. Large amounts of pentavalent vanadium are extracted; phosphoric acid and molybdenum pass into the ether layer with ferric iron.

Experiments are in progress to determine the formula of the iron compound in the ether phase, and to study the factors affecting the distribution between phases and the formation of two ether phases under certain conditions. Experiments are planned to determine the efficiency of isopropyl ether in the separation of other elements, such as gallium and thallium.

Summary

It has been shown that isopropyl ether offers marked advantages over ethyl ether for the extraction of ferric iron from aqueous hydrochloric acid solutions, giving a more efficient extraction over a wider range of acid concentrations than does ethyl ether. Data are given which show the effect of varying the hydrochloric acid concentration, the amount of ferric iron, the effect of the presence of alcohol and peroxide and the behavior of other elements commonly occurring with or alloyed with iron.

PASADENA, CALIF. RECEIVED SEPTEMBER 22, 1936

[CONTRIBUTION FROM THE PHYSICAL CHEMISTRY INSTITUTE OF THE UNIVERSITY OF COPENHAGEN]

The Strength of Acids in Formamide

BY FRANK H. VERHOEK

As a part of the study of the behavior of acids and bases in various solvents being carried on in this Institute, it was undertaken to investigate the strengths of acids in formamide. This substance is particularly interesting in that it is reported by Walden[1] to have a dielectric constant greater than that of water. It is a colorless, odorless, hygroscopic liquid, denser and more viscous than water, freezing at +2.55°, and it is a good solvent for both inorganic and organic salts. The study is concerned with the determination of the strength constants of representative groups of acids in formamide, from measurements of the conductivity of acid–base mixtures in that solvent, and from measurements of the potential differences set up between a standard buffer solution and buffer solutions made up with the different acids.

Purification of the Solvent.—Formamide obtained commercially is frequently acid and contains ammonium formate. The latter is volatile enough so that it is not readily removed by distillation at reduced pressure; further, it is so largely solvolyzed that the ammonia is pumped off in the distillation, leaving formic acid, which then appears in the acid distillate. Any water present in the solvent during the distillation reacts with the formamide to form ammonium formate. Formamide reacts with strong bases and with phosphorus pentoxide. The method adopted finally for the purification was to add solid brom thymol blue directly to the formamide, and neutralize with sodium hydroxide, avoiding an excess. The neutral liquid is heated at 80–90° under an oil pump vacuum until distillation is about to begin, ammonia and some of the water formed by the neutralization being pumped off. During this time the formamide has turned acid again, by loss of ammonia both from the ammonium formate originally present and from that formed by reaction with the water from the neutralization. The neutralization with sodium hydroxide is repeated, and the liquid heated in a vacuum to incipient distillation. This time less water is formed by the neutralization, and consequently less acid from the reaction *water* ⟶ *ammonium formate* ⟶ *formic acid.* With a repetition of the process four or five times, even quite impure samples will remain neutral when distillation begins. The whole of the formamide is now distilled from the sodium formate by evaporation from the surface at 80–90° in a vacuum, neutralized again with sodium hydroxide and redistilled in the same fashion, collecting the last four-fifths. This material is neutral, melts at about 2.2°, and has a specific conductance of about 5×10^{-5}. The neutral distillate is now further purified by fractional crystallization in a water- and carbon dioxide-free atmosphere. From 400–500 cc. five or six fractions are removed, giving a final 100 cc. with a specific conductance of 1 or 2×10^{-6}. The fractions removed, together with the first portion from the distillation, are returned again for treatment with sodium hydroxide, distillation, and recrystallization.

Residues were recovered by the same method as that for the purification of the original substance.

The pure material is not stable; the conductance increases by a factor of eight or ten in ten days or two weeks. It was found, however, that if a stream of air, purified by passing through a train containing soda lime, calcium chloride, phosphorus pentoxide and cotton, was bubbled rapidly through the liquid, the conductance would remain low for a longer period. With certain samples a decrease of conductance occurred at first on bubbling air through the formamide, followed by an increase. The solvent was considered still sufficiently pure for use when the specific conductance was less than 3.5×10^{-6}; the large majority of the experiments, however, were made on material having

---

[1] Walden, *Z. physik. Chem.*, **46**, 175 (1903).

a conductance between 1.0×10^{-6} and 2.0×10^{-6}. The lowest value found for the conductance in the course of the work was 6.2×10^{-7}; already the next day, however, the conductance of this sample had risen to 1.17×10^{-6}. The best previously reported value[2] is 1.58×10^{-6}. Data reported below indicate that the specific conductance of pure formamide is in the neighborhood of 10^{-10}.

The hygroscopic nature of formamide was tested by exposing 5.6 g. in a small beaker to the room atmosphere, the liquid having a free surface of about 9 sq. cm. There was a gain in weight of 0.2% in one hour, 1% in five and one-half hours, and 10% in one hundred and forty-one hours. It was found, however, that amounts of water even up to 1% had no large effect in either the conductance or potentiometric experiments, so no special precautions, beyond a reasonable care in preventing unnecessary exposure to air on transferring and pipetting, were taken to prevent contamination with moisture.

Conductance Experiments.—By measuring the conductivity of a solution containing an acid and a base, and knowing the equivalent conductance at various concentrations of the salt formed by the reaction between the acid and the base, the amount of salt present in the acid–base mixture can be calculated. Using the same base and several different acids, the amount of salt formed with the several acids will depend upon the strengths of the acids, so that the relative strengths of the acids with respect to that base may be obtained. With the help of suitable transition systems the strengths of another group of acids with respect to another base may be referred back to the first group and a continuous scale of acid strengths set up over the whole range. If the solvent is itself basic or acidic, a detectable part of the conductivity of the acid–base mixture may be due to the free acid or base still present, so that the measured value must be corrected for this in order to get the true value for the salt.

In the case of formamide the bases used were the solvent itself, pyridine, and α-picoline, covering a range of acids from the strongest down to *p*-nitrophenol. To study still weaker acids, stronger bases would be required; piperidine and benzylamine, however, were found to react with formamide, forming ammonia and a substituted formamide, while the strong tertiary amines, which would not be expected to react, were too insoluble, except for triethylamine, which volatilized so rapidly from the solution that the data were not reliable. The equivalent conductances in formamide of the salts formed by the acid–base reaction are not known; since the formamide could not be obtained in a really pure state, these values could not be obtained accurately. Extrapolation to infinite dilution of the equivalent conductances of potassium dichloroacetate, potassium benzenesulfonate and potassium picrate solutions, using the Onsager equation with an assumed dielectric constant of 90 and making no corrections for the self-conductance of the solvent, gave the values 22.1, 20.7 and 19.8. Davis, Putnam and Jones[3] report for the equivalent conductance at infinite dilution for tetramethylammonium iodide 24.3, and for sodium iodide 24, the lowest concentration observed being only 0.1 *M* in the first case and 0.02 *M* in the second. The value 22 has then been chosen as reasonable for the equivalent conductance; it has been taken the same for all the salts, and it has been assumed to be unchanged with change in concentration. The protolysis constants are increased by a factor of two by changing the value of the equivalent conductance used in calculating them from 25 to 20; no accuracy greater than, say, 0.2 *pK* unit can therefore be claimed for the results.

Since formamide is itself both an acid and a base, an acid or a base alone dissolved in formamide gives an appreciable increase in conductivity, so that the measured conductance of the acid–base mixture is not that due to the presence of the salt alone. To get the true value the increase in the conductance of the solvent due to the addition of acid alone was added to the increase in conductance due to the addition of base alone, and the sum subtracted from the increase in conductance when both acid and base were present at the same concentrations as in the first two cases. From these values of the conductance at the various concentrations, and the assumed value for the equivalent conductance, the concentration of the ions may be obtained; subtraction of this value from the stoichiometric concentrations of the acid and base added gives the concentration of the free acid and base present, so that the protolysis constant for the reaction

$$A_1 + B_2 \longrightarrow A_2 + B_1$$
$$K_{A_1B_2} = \frac{[A_2][B_1]}{[A_1][B_2]}$$

may be calculated. If the extent of salt formation is large, as with strong acids, the value obtained in this manner is a first approximation, since in correcting for the conductance due to the addition of acid alone and base alone, values have been used corresponding to concentrations of acid and base higher than those actually present in the final solution. A second approximation using values for the acid and base concentrations found in the first approximation could be made, but the difference between the first and second approximations amounts at the most to 0.03 *pK* unit; the error introduced by virtue of the uncertainty in the value for the equivalent conductance is greater than this, and such a second approximation has been omitted. In general, equivalent amounts of acid and base were used; in representative cases, an excess of one of the components was introduced. The protolysis constants for those experiments containing an excess checked with those in which equivalent amounts were present. The detailed data for an experiment with benzoic acid and picoline are given in

.1	361.0	10.17	4.51	359.2	8.29	2.61	348.3	.01583	3.53

Table I. It is evident that a possible increase in the protolysis constant with increasing salt concentration is not greater than the experimental error.

For the strong acids, where formamide itself acts as the base, a conventional dissociation constant was calculated, using Ostwald's dilution law and the value 22 for the equivalent conductance. There was some indication, from a comparison of the equivalent conductance–concentration curves for the strong acids benzenesulfonic and picric with those for the corresponding potassium salts, that the equivalent conductance at infinite dilution of an acid is two units less than that of its potassium salt, but no account has been taken of this difference. Table II gives the data for *o*-nitrobenzoic acid dissolved in formamide. The constants at lower concentrations are inaccurate, since the solvent itself has such a high conductivity that it amounts to a large fraction of the total.

TABLE II

THE DISSOCIATION CONSTANT OF *o*-NITROBENZOIC ACID IN FORMAMIDE

$pK_{0.05} = 4.26$

The conductivity experiments were carried out at 20° in a small narrow cell of 15-cc. capacity with platinized electrodes, and a constant of 0.3827. To 5 cc. of solvent was added from a weight buret a solution roughly 0.2 *M* in acid and base, giving concentrations in the cell from slightly less than 0.001 up to 0.1 *M*. In the particular case of trichlorophenol a saturated solution of the acid is only 0.06 *M*, putting an upper limit to the concentration at which the experiments could be carried out. The density of the final solution in the cell was measured at the end of the experiment, and the density assumed to vary linearly with the concentration in calculating the concentrations from the weight data. Values at round concentrations for correcting for the conductances of the free acid and base were obtained from these original data by straight line interpolation. The three experiments required for the determination of the protolysis constant of an acid–base pair, namely, an experiment with both acid and base, one with acid alone and one with base alone, were always made on the same day, so as to have the solvent as nearly identical for the three as possible.

The negative logarithms of the strength constants determined from the conductance measurements are given in the second, third and fourth columns in Table V. The values given are those for the arbitrarily chosen stoichiometric concentration of acid or of acid and base 0.05 *M*. Picric acid and trichloroacetic acid are so strongly dissociated in formamide that the values given for them are uncertain; benzenesulfonic acid appears to be dissociated completely at all concentrations up to 0.1 *M*. The values in the third column have been obtained from the protolysis constants of the acids reacting with pyridine by the relation

$$pK_{\mathrm{AM}} = pK_{\mathrm{AP}} - pK_{\mathrm{SP}} + pK_{\mathrm{SM}}$$

where pK_{AM} is the negative logarithm of the conventional dissociation constant given in that column, K_{AP} is the protolysis constant for acid A reacting with the base pyridine, K_{SP} is the constant for salicylic acid and pyridine, and K_{SM} is the constant for salicylic acid and the pure solvent. An extension of this equation through benzoic acid chosen as a standard connects the data for pyridine with that for α-picoline, and so back to the pure solvent.

Potentiometric Experiments.—The potentiometric experiments were carried out with hydrogen electrodes in each of two compartments connected through stopcocks to a narrow U-tube filled with saturated potassium chloride (0.88 *M*) as a bridge. The potential was found to depend in part upon the rate at which the hydrogen was bubbled through the solutions in the two compartments. If the rate of bubbling was the same in the two compartments, a value of the potential difference constant over several hours was obtained; if the rate at which the hydrogen passed through one solution was greater than that in the other the potential difference rose or fell at a constant rate, but would return to a value near to the original value when the rate of bubbling was made equal in the two compartments again. The experiments were made using the same constant and equal rate for all. The substitution of quinhydrone for the hydrogen electrode proved to be of no advantage, since quinhydrone gradually darkens on standing with formamide, and there is a slow change in the potential difference. It is possible, however, to extrapolate back to an initial value, and a dissociation constant determined with the quinhydrone electrode in a case where hydrogen would have been unsuitable is included in the data reported. Junction potentials were neglected in all cases.

The standard buffer was a solution 0.05 *M* in potassium chloride, 0.05 *M* in anhydrous potassium salicylate and 0.05 *M* in salicylic acid. The *p*H of the salicylic acid–salicylate buffer was determined by measuring against benzenesulfonic acid, assuming complete dissociation of the latter. With this strong acid there was a slow decrease in potential with time, and the value used in calculating the *p*H is that obtained by extrapolating to zero time. The average of three experiments for which the maximum difference was 0.071 unit gave 4.358 for the *p*H of the standard buffer. The standard salicylate solution was made up anew for each experiment at the same time as the test solution, so as to have the two solutions as nearly comparable as possible. The test buffers in the case of the carboxylic acids were 0.05 *M* in potassium chloride, and 0.05 *M* in the potassium salt of the particular acid; they were made 0.02, 0.05 and 0.1 *M* in the acid by adding weighed amounts of acid to 5 cc. of salt solutions in the apparatus. The hydrogen ion concentrations in the test solutions were calculated from

$$\log [\mathrm{H}^+] = E/0.05814 + \log [\mathrm{H}^+]_{\text{salicylic–salicylate}}$$

where $\log [\mathrm{H}^+]_{\text{salicylic–salicylate}}$ is -4.358. The *pK* for the acid is then found from

$$pK = -\log K = -\log [\mathrm{H}^+] - \log [\text{base}] + \log [\text{acid}]$$

the stoichiometric concentrations of the acid and base present being corrected where necessary for the dissociation of the acid. The constants calculated for the three buffer ratios checked to about 0.1 logarithmic unit, and duplicate experiments checked with the same accuracy. An experiment with salicylic and benzoic acid buffers in which the buffer ratio was changed by adding salt to a 0.05 *M* acid solution showed that the effect of changing ionic strength on the dissociation constant is not greater than the experimental error. Table III gives the results for measurements on salicylic acid–benzoic acid buffer pairs under various conditions.

For the anilinium acids, the test solutions were made 0.05 *M* in potassium chloride, and 0.1 *M* in the anilinium chloride or benzenesulfonate; to a known volume of this solution in the electrode compartment was added one, two, or three drops of piperidine from a weight pipet, forming free base by the reaction

$$\mathrm{RNH_3^+ + C_5H_{11}NH \longrightarrow C_5H_{11}NH_2^+ + RNH_2}$$

This reaction is complete with the strong acids and piperidine, and the piperidinium ion plays no part in determining the hydrogen ion concentration of the solution in the presence of the strong acids. Addition of piperidine in excess of 0.1 *M* gave a buffer solution in piperidine–piperidinium ion, from which the acid strength of piperidinium ion could be obtained. For benzylamine, triethylamine, and pyridine, the pure bases were added from a weight buret to solutions 0.05 *M* in potassium chloride and 0.05 *M* in the amine salt. With the amine bases present there is a change in potential difference with time due to the reaction with formamide. This change is not great; even with the strongest base piperidine it amounts only to one and one-half or two millivolts an hour, so that an extrapolation to the initial time is carried out easily. Readings were taken at fifteen-minute intervals until the rate of change remained constant for an hour, and the value obtained by extrapolating to zero time used in the calculations. About one-half hour was usually required for the system to come to equilibrium. With triethylamine, the triethylamine was bubbled out by the hydrogen so rapidly that the potential difference decreased by 10 mv. an hour. The correctness of the value reported for this substance, however, is indicated by the fact that the addition of further triethylamine to the solution, and extrapolation back to the moment of addition, gave values for the dissociation

TABLE III

pK	1.566	1.527

constant of the triethylammonium ion which agreed with the first, when the concentration of triethylamine added the first time was corrected for the amount which had bubbled away. Table IV gives the data for an experiment in which the dissociation of *o*-chloroanilinium ion was studied. To a solution 0.1 *M* in *o*-chloroanilinium chloride was added in the first half of the experiment piperidine corresponding to 0.04371 *M* per liter; to this solution was later added piperidine corresponding to 0.03267 *M* per liter. No correction was applied for the reaction of the amine with the formamide during the first half of the experiment in calculating the concentrations in the second half.

The *pK* values from the electrometric measurements are included in Table V. The values given for the carboxylic acids in the table are those for buffer solutions containing equal quantities of acid and salt; for the cation acids the values are those obtained from the first addition of piperidine or other amine.

TABLE V

THE DISSOCIATION CONSTANTS OF ACIDS IN FORMAMIDE

Acid	*pK* in H_2O	*pK* in formamide Solvent

The Ion Product of Formamide.—The ion product of the solvent, $K_M = [M^+] [M^-]$, was determined directly by measuring the potential difference between a solution of potassium hydroxide and the standard salicylate buffer, and combining these data with those for benzenesulfonic acid measured against the standard buffer. The reaction between potassium hydroxide and formamide does not have such a great effect on the potential difference as might be expected; the potential dropped at a steady rate of about 8 mv. an hour, and a value extrapolated back to the moment at which the solution was made was easily obtained. The potential difference between 0.0976 *M* KOH and the salicylate buffer was 669.7 mv.; between 0.0303 *M* KOH and the buffer 632.2 mv. For 0.02498 *M* benzenesulfonic acid against the buffer the potential difference was 157.6 mv.; for 0.06956 *M* benzenesulfonic acid 187.0 mv. These data make possible two independent calculations of the ion product. Even combining them to pairs in such a way that the difference between the two values of the ion product is greatest, the values obtained for pK_M

are: for 0.0303 M KOH and 0.02498 M $C_6H_5SO_3H$: 16.70; for 0.0976 M KOH and 0.06956 M $C_6H_5SO_3H$: 16.90. The agreement is good.

If $pK_M = 16.8$, and the equivalent conductance of a mixture of M^+ and M^- ions is 22, the value calculated for the specific conductance of the pure solvent is 9×10^{-11}.

Discussion

The data of Table V are plotted against the corresponding pK values for water in Fig. 1. Except as otherwise noted, the pK values for water for the carboxylic and cation acids are taken from the paper of Brønsted, Delbanco and Tovborg-Jensen;[4] the values for the phenols are from the Landolt–Börnstein "Tables." Some of the values for acids not included in the paper cited are for temperatures other than 20°. The slope of the curves as drawn is 1.19, *i. e.*, greater than unity. The slope usually found on plotting the logarithm of acid or basic dissociation constants in a non-aqueous solvent against the corresponding values in water is unity, and the latter slope is also predicted theoretically if the assumption is made that the effect of changing the medium is only to change the activity coefficients of the ions by virtue of the change in dielectric constant. It has been difficult to decide whether the unusual slope found in the formamide–water diagram is the result of experimental error. For the carboxylic acids, the only point which is greatly in doubt is that for trichloroacetic acid. The pK value for trichloroacetic acid in water is not too well known. The value given for formamide is probably too high rather than too low, since the change in the equivalent conductance with concentration has not been considered; consideration of this change would give the acid a larger dissociation constant. A determination of the potential difference between a trichloroacetic acid solution and the standard salicylate buffer using quinhydrone indicated that trichloroacetic acid is completely dissociated at 0.02 M, but as stated previously, the potential values with quinhydrone are not dependable. Consideration only of the pK values of the carboxylic acids obtained by potentiometric measurements would definitely give a curve with a slope greater than unity. For the phenols, the data are perhaps not numerous enough to serve as a basis for discussion; a curve drawn through the points with the same slope as for the other two acid types is at least not inconsistent with the positions of the points, with the exception of the point plotted for picric acid. A valid dissociation constant for picric acid cannot be calculated from conductivity data, since the degree of dissociation is too large. Direct comparison of the equivalent conductances at various concentrations of the three acids picric, trichloroacetic and benzenesulfonic given in Table VI shows picric acid to be much stronger than trichloroacetic acid, and nearly completely dissociated. In comparing the data it should be noted that the equivalent conductance at infinite dilution is evidently greater for trichloroacetic acid than for picric and benzenesulfonic acids. The value of pK actually calculated from the data for picric acid is given in Table V and plotted in the figure, but it is evident that it should be much less. In the curve for the cation acids, only the points for the primary amines can properly be compared, that is, the curve must be drawn through the points for the substituted anilines and benzylamine. One would of course expect a difference in slope if primary are compared with secondary or tertiary amines. A curve drawn through the points for the anilines and benzylamine must have a slope greater than unity.

TABLE VI

CONDUCTANCE OF STRONG ACIDS IN FORMAMIDE

Benzenesulfonic acid Sp. cond. of solvent 1.62×10^{-6}		Picric acid Sp. cond. of solvent 2.31×10^{-6}		Trichloroacetic acid Sp. cond. of solvent 2.87×10^{-6}	
Concn.	Equiv. cond.	Concn.	Equiv. cond.	Concn.	Equiv. cond.
0.000938	18.93	0.000789	18.58	0.000880	19.67
.001979	18.23	.001360	18.04	.001742	18.86
.002928	18.00	.002114	17.60	.002603	18.43
.006031	17.69	.004509	17.12	.005235	17.57
.01298	17.20	.009988	16.33	.01127	16.25
.02658	16.52	.02137	15.85	.02240	14.64
.05935	15.59	.04205	14.98	.04828	12.35
.1170	14.52	.09118	13.60	.1026	9.90

One is inclined to believe, then, that the anomalous slope of the curves is real. The curves have been drawn in such a way as to give all three the same slope; the possibility of some variation in slope in the three cases is not, however, excluded. The literature records another case in which the slope of a curve in a plot similar to that in Fig. 1 differs from unity, namely, the case of the singly charged cation acids in acetonitrile,[5] where the slope is only 0.47. The reason for this deviation is probably to be sought in a consti-

tutional effect on the activity coefficients of the components of the solution. Such effects of structural differences in changing from one solvent to another are quite common, and must in any case be adduced to explain the difference between the carboxylic acids and the phenols. The unexpected in the case of formamide and acetonitrile is that such an effect should be operative over such a large range, and so consistently parallel to the acid strength. One usually finds a scattering of points on both sides of a line of the predicted unit slope, rather than a single line of a different slope. It is possible, of course, that the inclusion of more acids would give such a chance scattering about curves of unit slope.

The figure shows that if a carboxylic acid, a phenol, and a singly charged positive acid have the same strength in water, the phenol will be twenty-five times stronger than the carboxylic acid in formamide, and the cation acid five hundred times stronger. The difference between the carboxylic acids and the phenols must be due, according to the equation of Brønsted[6] $K_A = K_a f_A/f_B$ where K_a is a thermodynamic dissociation constant independent of the medium, K_A is the dissociation constant in the solvent concerned, and f_A and f_B are activity coefficients of the acid and the base in that solvent, to a change in the ratio of the activity coefficient of the acid to that of the base to a different extent for the two sorts of acids on passing from water to formamide. This change must be due to influences other than those of electric charge and dielectric constant, since, as far as the latter forces are concerned, the system is the same for carboxylic acids and phenols. An increase in the strength of certain phenols relative to carboxylic acids has been found for several other solvents—ethyl and methyl alcohols, *n*-butyl alcohol, acetonitrile—and has been attributed by Wynne-Jones[7] in the case of picric acid to the greater effective radius of the picrate ion compared to a carboxylate ion. The same treatment applied to the data in formamide, however, would require the phenolate ions to be smaller than the carboxylate ions.

In passing from an uncharged to a charged acid, the effect of the electric charge and dielectric constant should ordinarily become noticeable. In the particular case of a change from water to formamide, however, comparatively little effect resulting from the change in the dielectric constant should be observed. If the dielectric constant of formamide is taken as 100, the strength of a cation acid relative to an uncharged acid should be decreased by 0.125 logarithmic unit on passing from water to formamide, the calculation being made according to the equations developed by Brønsted,[6] using 5×10^{-8} cm. as the ionic radius. The actual difference found between the anilinium ions and the carboxylic acids is an increase of 2.7 units, which would correspond to a value of 15 for the dielectric constant of formamide. The dielectric constant of formamide has not been measured in this investigation, but it is hardly likely that it can be as low as this. Salts are, in general, easily soluble in formamide—simple salts such as potassium and sodium chloride are about one-fifth to one-sixth as soluble in formamide as in water, while the cobaltammines are either as soluble or often much more soluble in formamide than in water—which would indicate that it has a high dielectric constant. Experiments on the change of solubility with ionic strength of the 2–1 salts chloropentammine cobalt chloride, bromopentammine cobalt bromide and *trans*-dinitrotetrammine cobalt sulfate in solutions of potassium thiocyanate and sodium formate gave limiting slopes at infinite dilution of 0.7, 0.6 and 0.9. The results are obscured by the initial contamination of the solvent with salt, as observable in its high conductivity, but the slopes are in all three cases less than the value 1.0 calculated for a 2–1 salt in water, indicating that the dielectric constant is higher than that of water. At concentrations above 0.005 *M*, where the conductivity of the solvent is no longer such a disturbing factor, the change of conductance with concentration of the three salts potassium dichloroacetate, potassium benzenesulfonate and potassium picrate is in fair agreement with that to be expected from the Onsager equation, assuming the dielectric constant to be 90. From cryoscopic measurements Walden[8] concluded that potassium iodide, tetramethylammonium iodide, and other alkyl ammonium salts are as highly ionized in formamide as in water, indicating a high dielectric constant. The dielectric constant of formamide's nearest homolog, acetamide, is 60 in the liquid phase, and it is reasonable to expect that that of formamide should be at least as great. The increase in the strength of a cation

acid with respect to a carboxylic acid in passing from water to formamide must then be attributed to a more marked effect of the same influence which causes the increase in strength of a phenol as compared to a carboxylic acid, and to be not at all the result of a change in the dielectric constant. If the change in structure represented by a change from benzoic acid to 2,4-dinitrophenol, which have nearly the same strength in water, causes the strength to change by a factor of 25, it is evident that one cannot exclude the possibility of a further change by a factor of 20 on passing from 2,4-dinitrophenol to *p*-chloroanilinium ion.

Further light on this question would be given by a study of negatively charged acids such as acid salts of dicarboxylic acids. The theoretically predicted effect of the change in dielectric constant on the relative strengths of monocarboxylic acids and the acid salts of dicarboxylic acids is of the same (small) magnitude but opposite in sign to that predicted for a change to a cation acid. Further, one would not expect any enormous change in activity coefficient ratios in going from a mono- to a dicarboxylic acid, since these two are in any case more nearly similar than a carboxylic acid and a phenol or a carboxylic acid and an amine ion. The prediction would be, then, that a group of acids including both monocarboxylic acids and acid salts of dicarboxylic acids would show nearly the same relative strengths in formamide as in water. Unfortunately, of the normal salts of dibasic acids which were available—sodium and potassium oxalate, sodium tartrate, sodium malonate and sodium succinate—only the last named was sufficiently soluble for use in an acid salt–normal salt buffer, and the short time left did not permit the preparation of other salts. Values for the somewhat "overlapping" strength constants for succinic acid were calculated by the method of Simms[9] from the potential difference between sodium succinate–succinic acid mixtures and the standard buffer, and are given in Table V. On plotting the value for the second dissociation constant of succinic acid, the point is found to lie directly upon the curve for the other carboxylic acids, in agreement with the above prediction.

The observed difference between the carboxylic acids, the phenols and the cation acids in formamide shows that extreme care is necessary when attributing solely to a difference in charge type effects which may be due to the change in chemical type which is inextricably connected with the change in charge type.

The author wishes to express his gratitude to Professor J. N. Brønsted for help and criticism in the course of the work.

Summary

1. A simple method for the preparation of formamide having a specific conductance of 10^{-6} has been described. It consists in the distillation of formamide treated with sodium hydroxide, followed by a fractional crystallization.

2. From measurements of the conductivity of formamide solutions of free carboxylic acids and of mixtures of acids with pyridine and α-picoline, and the assumption of certain values for the equivalent conductances of the salts formed in the solutions, dissociation constants of the acids in formamide have been calculated.

3. Dissociation constants of a group of phenols in formamide have been obtained by the same procedure.

4. From measurements of the potential difference between buffer solutions of various carboxylic acids and a standard potassium salicylate–salicylic acid buffer, which was in turn compared with a benzenesulfonic acid solution, a scale of acid strengths in formamide independent of the conductivity measurements has been obtained. The dissociation constants obtained by the two methods are in agreement within the experimental error.

5. Dissociation constants of a group of singly charged cation acids have been obtained by the potentiometric method.

6. The value 10^{-17} has been found for the ion product of formamide by measurements of the potential difference between solutions of potassium hydroxide and benzenesulfonic acid and the standard buffer.

7. On plotting the negative logarithms of the dissociation constants of acids in formamide against the corresponding values in water, three straight lines of slope greater than unity, corresponding to the carboxylic acids, the phenols and the cation acids, have been obtained. The relative positions of the lines indicate that if a carboxylic acid, a phenol and a singly charged cation acid have the same strength in water, the phenol will be 25 times stronger than the carboxylic acid in formamide, and the cation acid 500 times stronger.

The Molecular State of the Vapor of Acetic Acid at Low Pressures at 25, 30, 35 and 40°

BY F. H. MACDOUGALL[1]

Introduction

In a previous publication[2] it was pointed out that our knowledge of the equilibrium between single and double molecules of acetic acid in the vapor phase at room temperatures was far from being exact. The published data were discordant and could lead to only a very rough estimate of the equilibrium constants. It seemed desirable to undertake an accurate investigation of the behavior of acetic acid vapor at room temperatures and under pressures ranging from that of the saturated vapor to three or four millimeters of mercury.

The Preparation of Acetic Acid

The method of Chandlee and Hutchison[3] was employed in the purification of glacial acetic acid. A tail fraction from the final distillation was further purified by fractional crystallization until an acid melting at 16.60 ± 0.01° was obtained. Two samples prepared by Dr. Fuller had melting points of 16.612° (sample A) and 16.616° (sample B), respectively. These were used in the final measurements. The "International Critical Tables"[4] give 16.60° as the melting point of the pure acid.

In order to free the acid from dissolved gases, a 200-ml. sample was introduced into a small flask, which had been cleaned previously, dried and filled with dry nitrogen. The flask was fitted with two glass break-off seals. After the introduction of the acid, the flask was sealed and was then attached to the distillation system shown in Fig. 1 by means of one of the break-off joints. The flask in question is shown at A, Fig. 1. When the entire system had been evacuated and flamed out, so that over a period of twenty-four hours it was able to maintain a vacuum of the order of 10^{-5} mm. of mercury as read on the McLeod gage G, the break-off seal was broken, and the acid was distilled into one of the bulbs B. The distillation was accomplished by freezing the acid into B by means of a bath of ether and solid carbon dioxide. After the residual nitrogen had been pumped off, the acid was sublimed repeatedly in the evacuated system back and forth between the two bulbs B. After each sublimation the residual pressure due to permanent gases was read on the McLeod gage, and the system was again exhausted to 10^{-4} mm. This procedure was repeated until the residual pressure after a sublimation did not exceed 10^{-5} mm. Finally about one-half of the sample was collected in the original flask and sealed off from the distillation system. It was then ready to be connected by means of the second break-off joint to the apparatus for determining the pressure-volume data, Fig. 2.

The Experimental Apparatus for Obtaining the Density Data

The Specific Information to be Obtained.—By a suitable manipulation of this apparatus and by means of certain auxiliary operations it was possible to obtain the following three pieces of information about each sample of acetic acid employed in these experiments: (1) the pressure and (2) the volume at three different pressures at a given constant temperature and (3) the absolute quantity of acetic acid in the sample.

General Plan of the Apparatus.—In Fig. 2 there is a diagrammatic sketch of the apparatus used in making the density measurements. The three glass bulbs, A, B, C, of known volume, part of one of which, A_1, also served as one arm of a U-type differential mercury manometer, were connected to each other in series by mercury Y-seals of the usual type. Thus if B were evacuated and if A contained a sample of gas, the opening of the seal between A and B would allow free expansion of the gas from A into B. These bulbs were set into a water-bath in which the temperature could be controlled to within 0.05° between 25 and 40°. The water-bath, which was 36″ × 18″ × 18″ (91 × 46 × 46 cm.) and was made of galvanized iron, contained a large glass window on one side, through which the operation of the mercury seals could be observed. Holes were punched in the bottom of the bath for the tubes for the control of the mercury seals and for the manometer, the other arm of which was outside of the bath, and the cracks about these holes were sealed with picein wax. The metal walls of the bath were insulated with heavy felt.

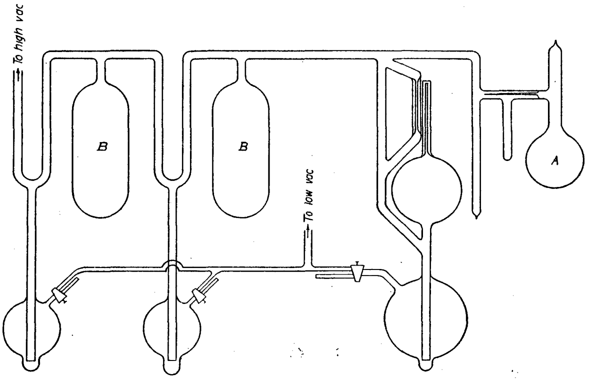

Fig. 1.—Distillation system.

The manometer used to obtain the pressure data was of the differential U type. One arm, A_1, was inside the bath,

---

(1) This research has been made possible by grants from the Research Fund of the Graduate School of the University of Minnesota. Credit for the devising, constructing and testing of the apparatus should go chiefly to Dr. C. P. Roe. Dr. Donald Fuller prepared several samples of very pure acetic acid. Mr. Herbert Sargent carried out the final series of measurements.

(4) "International Critical Tables," Vol. IV, p. 6.

and the other arm, M, was outside. The inside arm was considerably larger than the outside one, so that most of the movement took place in the outside arm. The reading of the mercury level in the latter was accomplished by means of a traveling microscope which could be focused alternately on the meniscus or on a steel meter bar which was graduated in 0.5-mm. divisions and which was rigidly fixed with respect to the manometer. The microscope also contained a scale on which it was found that 13.3 divisions were equal to 0.5 mm. on the steel meter bar. Thus the position of the meniscus could be estimated to 0.004 mm., but in practice it was found that results which were reproducible to 0.01 mm. were the best that could be obtained. In order to obtain consistent results with the manometer it was found necessary to surround the greater part of the outside arm with a wooden jacket lined with wax, through which a stream of water from the bath was kept moving by means of a circulating pump. In this way the temperature of the manometer was kept constant. The manometer was calibrated for the reading of absolute pressures against the McLeod gage, G, with help of pure nitrogen as a permanent gas.

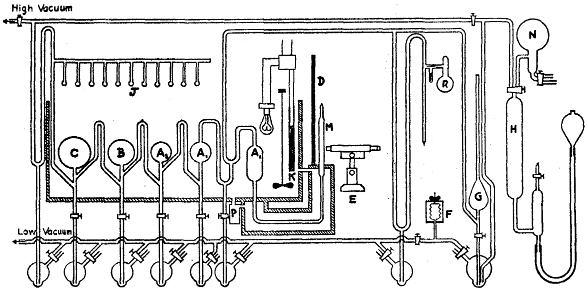

Fig. 2.

Between the bulb C and the pumps there was inserted a line of small sample bulbs of 1 to 2 ml. each. These bulbs were blown on the ends of stubs of heavy-walled Pyrex tubing of about 4 mm. inside diameter. A sample of acetic acid, following the taking of pressure readings on it, was frozen into one of the sample bulbs, sealed off from the line and subsequently analyzed for its acetic acid content by titrating with a standard barium hydroxide solution.

The remainder of the apparatus consisted of a mercury condensation pump, an oil pump, a glass reservoir *N* for nitrogen and the necessary mercury traps for the control of the McLeod gage and the mercury seals.

Details of the McLeod Gage.—This instrument, shown at G in Fig. 2, served the two-fold purpose, (1) of testing the state of evacuation of the entire density apparatus, and (2) of calibrating the differential manometer so that readings taken directly from the manometer could be converted to absolute pressure. In order to gain the necessary precision for the latter purpose, two unusual features in the construction of the gage were introduced.

The first was that the capillary tube of the ordinary McLeod gage was replaced by a tube some 30 cm. long and of approximately 6 mm. inside diameter. By means of hydrofluoric acid three fine scratches were etched on this tube, and the volume from each scratch to the sealed-off end of the tube was determined by finding its mercury capacity. The total volume of the gage was also determined with mercury. The scratches were so located that when the instrument was in use for the measurement of pressures lying in the range from 1–15 mm., the meniscus in the gage could always be set on one of the scratches and the pressure could then be read on the special comparison barometer for the gage, which was taken from the same piece of stock as the etched tube. A cathetometer with scale and vernier attached was used for this purpose. It should be noted that the special barometer, although drawing on the same mercury well as the gage, had no connection with the gage. The necessity for this arrangement is obvious when one considers the magnitude of the pressures to be measured. The high pressure readings on the gage always lay in the range from 8 to 45 cm., and it is to be noted that the precision of the gage was always much greater than that of the manometer.

The second unusual feature of the gage was an arrangement for making fine adjustments of the meniscus near the scratches. Credit is due to Dr. George Glockler for suggesting the method of doing this. The essential part of this arrangement was a short length, 13 cm., of semi-collapsible corrugated brass tubing about 2.5 cm. in diameter which was mounted between two rigidly connected brass plates. One end of the tube was soldered to one of the plates, while the other end was closed up and attached to a screw which operated in the other plate as a base. A small outlet tube, which was cemented to a suitable glass connection, was inserted in the brass plate which was fixed to the collapsible tube. This arrangement was sealed to the low vacuum side of the mercury well controlling the gage. By suitable operation of the screw, the brass tubing could be expanded or collapsed within certain limits, and corresponding changes could thus be produced in the menisci of the gage and its barometer.

In the calibration of the etched tube on the gage it was necessary to hold the tube in a position which was just inverted from that which it occupied when in use. Thus each of the volumes determined from the mercury calibration had to be given a positive correction of twice the volume of the meniscus. The data on this point were obtained in the "International Critical Tables."[5]

Details of Calibration and Use of Manometer.—The manometer, the arms of which are shown at A_1 and M in Fig. 2, was of the differential U-type; but it was unusual in that the two arms were of different diameters. This had the effect of confining the movement resulting from changes in pressure on the meniscus in the larger arm, A_1, largely to the meniscus in the smaller arm, M. The diameter of the larger arm was approximately 6 cm., while that of the smaller arm was 16 mm. The considerable size of the larger arm had the advantage of reducing the relative importance of edge effects, which presumably varied with varying conditions, to a negligible order of magnitude. The manometer was prepared by evacuation and suitable flaming out of the glassware, and subsequent vacuum distillation of the mercury into the U. When the distillation had proceeded far enough, the arm M was sealed off permanently from the still and from the high vacuum system.

Since the position of the meniscus in the smaller arm had to be read with an accuracy of 0.01 mm., if possible, a

(5) "International Critical Tables," Vol. I, p. 72.

small traveling microscope which magnified to the extent of about twenty-five diameters was mounted on a wooden frame at a convenient place in front of M. The immediate standard of comparison in the reading of heights with microscope was a steel meter bar prepared by the Gaertner Scientific Corporation of Chicago, and graduated in 0.5-mm. divisions. This was mounted rigidly just behind the smaller manometer arm as referred to the microscope. The microscope could be focused either on the meniscus or on the steel meter bar by means of a screw adjustment, and the vertical motion was controlled by a similar device.

The calibration of the manometer between 1 and 15 mm. was accomplished by admitting pure nitrogen to the system up to the desired pressure and then reading both the rise in the manometer column and the absolute pressure as indicated by the McLeod gage. The upper reaches of the manometer were calibrated after the volumes of the density bulbs had all been determined. When these volumes were known, it was necessary only to allow a sample of nitrogen to expand from one bulb to another and measure the change in the manometer and repeat the process as often as it seemed desirable in order to complete the calibration.

In the manipulation of the manometer the following procedure was used. The microscope was first set at approximately the level of the meniscus and was then focused on the steel scale. A given mark on the microscope scale, in practice 6.00, was set on the nearest scratch on the steel scale. The microscope was then focused on the meniscus. In order to get a sharp image of the latter the aid of a strip of black paper with a slit in it was required. The paper was wrapped and pasted about the tube M so that the slit was in a horizontal position and so that the whole strip could be moved up and down the tube at will. When the meniscus was under observation, the slit, which was about 2 mm. in width, was so placed with respect to the meniscus that the band of light between the meniscus and the upper edge of the slit as seen in the field of the microscope always had the same width. The position of the meniscus could then be read, and its displacement from the zero position, which was determined in the same manner, could be calculated from a direct count of the number of scratches on the steel scale past which the reference mark on the microscope scale had been moved and from the displacements of the meniscus from the reference mark. It should be mentioned that the vertical carriage of the microscope carried a small light, so that optical effects in the microscope were always the same.

Details of Temperature Control.—The temperature of the water thermostat was controlled by the suitable turning on and off of a bank of several 100-watt light bulbs, connected in parallel and immersed in the water. A small telephone relay was used to open and close the tilting mercury switch which controlled the power circuit upon which the heater lamps drew. The relay was in turn operated by the grid circuit of a Commander 71a power vacuum tube, the circuit being opened and closed by the thermal contraction and expansion of a standard mercury control placed in the bath.

Calibration of the Density Bulbs.—The final calibrations of the bulbs A_2, B, C, were made during a period when the apparatus was temporarily dismantled, but after it had once been set in place. Hence the validity of the various water and mercury calibrations was only negligibly affected by subsequent glass blowing operations which were necessary to make the seals between the various parts of the apparatus. The explanatory material in connection with the presentation of the data is sufficient to indicate the details of these calibrations.

Since the volume of A_1 or of A taken as a whole could be found only after the whole system was in place (this was on account of the impossibility of controlling precisely the amount of mercury distilled into the manometer) it was necessary to resort to the use of the expansion of pure nitrogen for this purpose. The procedure was as follows. A sample of nitrogen was admitted to A_1, the seal between A_1 and the nitrogen reservoir was closed and the pressure was read by means of the manometer. Then the seal between A_1 and A_2 was opened, and the pressure was again read. It was necessary in making calculations to take account of the change in capacity of A with pressure. This change was due to the vertical movement of the large meniscus in the manometer, and could be found directly from the movement in the small one, the diameter of which was known to be 16 mm. Now let R_1 and R_2 be the rises observed on the manometer when the gas occupies A_1 and the whole of A, respectively. From the known diameter of the outside manometer tube, a 1-mm. rise produces an increase in the volume of A of 0.2 ml. Let V_{A_2} and V_A be the zero pressure volumes of A_2 and A, respectively. Then

$$V_A = V_{A_2}\left(\frac{R_1}{R_1 - R_2}\right) - 0.2(R_1 + R_2)$$

The Experimental Procedure

The entire system was exhausted to a point where no pressure could be detected on the McLeod gage. A sample of acetic acid vapor from the reservoir of liquid acid at R was then admitted to the bulb A, and when the desired pressure was approximately reached, the mercury seal between A and R was closed. The mercury levels in the seals confining the vapor to the bulb A were adjusted to their proper marks, and after sufficient time had elapsed to ensure that the vapor had come to the temperature of the bath, the change in the manometer meniscus from its zero position was read and recorded. The seal between bulbs A and B was then opened, so that the vapor occupied the combined volumes of these two bulbs. The manometer was again read and recorded. When this procedure had been repeated for the bulb C, the seal leading to the line of sample bulbs was opened, and the vapor in the apparatus was condensed into one of them by means of liquid air. The liquid air was allowed to remain on the sample bulb for at least fifteen minutes after the meniscus in the manometer had returned to its zero position. The sample bulb was then sealed off and detached from the line. The bulb was broken while submerged in a weighed amount of barium hydroxide solution. The broken bulb was then rinsed with distilled water and the acid yet unneutralized was titrated with standard base using phenol red as indicator. The solution was boiled when near the end-point and was then cooled to room temperature under a soda–lime tube. The titration was completed under a stream of nitrogen.

Barium acetate, purified by recrystallization, was dissolved in carbon dioxide-free water, phenol red was added and the volume and concentration were adjusted to the conditions obtaining at the end-point of the titrations. This solution was stored under carbon dioxide-free air and was used in estimating end-points.

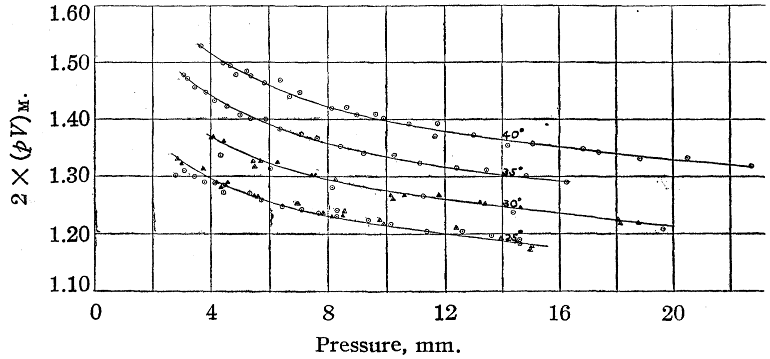

Fig. 3.—Isothermals of acetic acid vapor.

Calibration of the McLeod Gage

V_4 = total volume

V_1 = volume from uppermost scratch to the top

V_2 = volume from middle scratch to the top

V_3 = volume from lowest scratch to the top

These volumes were determined with mercury at 25°. The values obtained (corrected for inversion of meniscus by adding 0.023 ml.) were $V_4 = 326.4$, $V_1 = 3.804$, $V_2 = 7.700$, $V_3 = 11.734$ ml. The factors, $V_1/V_2 = 0.01165$, $V_2/V_4 = 0.02359$ and $V_3/V_4 = 0.03595$ are needed. These factors are represented by the symbol F.

Calibration of Manometer by Means of the McLeod Gage at 25° Using Nitrogen

R = manometer rise in millimeters

P' = pressure observed on McLeod gage in millimeters of mercury at 25° after the nitrogen in the gage had been compressed from the volume V_4 to the volume V_3 or V_2

F = V_3/V_4 or V_2/V_4 (see preceding section)

P = pressure of the gas in the system in mm. at 0° before being compressed in the gage. $P = P' \times F \times 0.9955$

f = P/R = factor used to convert manometer rise to pressure in mm. at 0°

From seventeen determinations of the value of the factor f at 25°, we obtain an average value of 1.0956. The average value of the deviations was ±0.0014. The accepted value of f at 25° was 1.096. The values of f at 30, 35 and 40° are calculated to be 1.095, 1.094 and 1.093, respectively.

Experimental Data

In the following tables, R is the rise in the manometer, p is the pressure in mm., V is the volume in ml. of the bulb or bulbs containing the acetic acid vapor, g is the weight in grams of barium hydroxide solution (0.007925 equivalent per kilogram of solution) required to neutralize the sample of acetic acid, and $(pV)_M$ is the pressure–volume product for 60.03 g. of acetic acid when 760 mm. × 22,414 ml. is taken as unity. It will be evident that

$$2(pV)_M = (1 + \alpha)T/273.1 \quad (1)$$

where α is the degree of dissociation of $(HOAc)_2$ into HOAc.

In Table I are given the complete data for two runs, one at 25° and the second at 35°. In the presentation of the rest of the experimental results we give the number of the run, the temperature, the pressure and the value of $2(pV)_M$. The work at 25 and at 35° was carried out with sample A, that at 30 and 40° with sample B of the acid prepared by Dr. Fuller.

Table I

Run	t, °C.	R	p	V	g	$2(pV)_M$
I	25	10.38	11.38	652.5	91.32	1.204
		5.88	6.44	1194		1.248
		3.16	3.46	2315		1.300
VIII	35	11.32	12.39	652.8	91.14	1.314
		6.47	7.08	1194		1.374
		3.52	3.85	2315		1.448

In Fig. 3 we have plotted the experimental values of $2(pV)_M$ against p for each of the four temperatures, 25, 30, 35 and 40°. Included in the figure are values (indicated by triangles) obtained by Dr. Roe at 25 and 30°. From curves drawn on a large scale plot, we have read off the "best" values of $2(pV)_M$ for integral values of the pressure. These values are given in Table IV.

From the chemical equation $(HOAc)_2 = 2HOAc$ we find for the dissociation constant, K_p

$$K_p = 4\alpha^2 p/(1 - \alpha^2) \qquad (2)$$

where α, the degree of dissociation, is given by the equation

$$\alpha = 2(pV)_M \times (273.1/T) - 1 \qquad (3)$$

In Table V are given values of α corresponding to the data of Table IV and the values of X_p calculated by means of equation 2.

Since the saturated vapor pressures of acetic acid (see a later section of this paper) are 15.5 at 25°, 20.6 at 30°, 27.0 at 35° and 35.2 at 40°, it will be observed that the pressures recorded in Tables II and III for 25 and 30° approach quite closely the saturation pressures whereas for 35 and 40° the highest pressures measured are approximately 60% of the saturation pressures. It will be noticed that at 25 and 30° the calculated values of K_p fall off rapidly as the saturated pressure is approached. This may be due to an increasing deviation from ideal behavior, but whatever the reason may be, it seems plausible to derive the best value of K_p for 25° from the values for pressures in the range 3 to 9 mm. and the best value of K_p for 30° from the values for pressures in the range 4 to 11 mm. For 40° the best value of K_p was taken to be the average of the values corresponding to pressures from 10 to 23 mm. On this basis, we obtain

K_p at 25° = 0.547 mm. K_p at 35° = 1.37 mm.
K_p at 30° = 0.909 mm. K_p at 40° = 2.08 mm.

When $\log_{10} K_p$ is plotted against $1/T$, the points obtained fall, within the experimental error, on a straight line given by the equation

$$\log_{10} K_p = 11.789 - (3590/T) \qquad (4)$$

The values of K_p calculated by means of equation (4) for 25, 30, 35 and 40° are, respectively, 0.557, 0.881, 1.37 and 2.10 mm.

The Measurement of the Saturated Vapor Pressure of Acetic Acid

The density bulbs and the line leading to the mercury seal separating the reservoir R from the density bulbs were exhausted as completely as possible. After the temperature of the bath had been constant for fifteen minutes, the height of the mercury meniscus in the manometer was read. With the pump going, the mercury seals separating

(1) the line of sample bulbs from the high vacuum line, and (2) the line of sample bulbs from density bulb C, were closed. Acetic acid vapor from the reservoir R was admitted to the bulbs by opening the seal between the reservoir and the line leading to the density bulbs. Cold water was allowed to run over bulb C until a sufficient amount of acetic acid had condensed and collected above the mercury surface of the seal separating bulb C from the line of sample bulbs. The seal between the line leading to the reservoir and the bulb A_1 was then closed. The bath was again brought to the original temperature, and, after thirty minutes had elapsed to allow the system to become uniform and constant in temperature, the height of the manometer meniscus was read.

The seal separating the line of sample bulbs from the bulb C was opened and the acetic acid in the bulb system was frozen into one of the sample bulbs by means of liquid air. After the sample bulb had been cooled for fifteen minutes the height of the manometer meniscus was again read as a check on the original reading.

Subsequent runs were made using this same sample of acid. The acid was frozen into a sample bulb and, while it remained cooled by the liquid air, the seal separating the system from the high vacuum line was opened and the entire sample bulb and density bulb system was subjected to evacuation for thirty minutes, although the manometer readings taken during this time showed negligible changes. The seal separating the system from the vacuum line was closed, and the sample of acid was transferred from the sample bulb to the density bulbs by removing the liquid air and running cold water over one of the density bulbs. The seal between the density bulb system and the sample bulbs was then closed, confining the vapor to the bulbs inside the water bath.

In each run enough acid was condensed into the system so that a visible amount of liquid was present after equilibrium had been established. In practice it was found that liquid acetic acid collected on the surface of the mercury in the inner manometer arm, causing an indeterminate error in the manometer reading. It was impossible to avoid this entirely, although it was minimized by using as little excess acid as possible. The maximum thickness of this layer of liquid on the surface of the mercury was estimated to be 1 mm. and the usual thickness much less than 1 mm.

The thermometer used in these experiments was compared with thermometer 40316 in Bureau of Standards set 19691, marked C343, and was found to require a correction of −0.06° at 25 and 30°, of −0.03° at 35° and of −0.07° at 40°.

Table VI

Data on Vapor Pressure of Acetic Acid

t = 24.94

32.19	35.18
31.95	34.92
31.95	34.92
Average	35.05

In Table VI are given the results obtained for the vapor pressure of acetic acid at 24.94, 29.94, 34.97 and 38.93°. We readily obtain for 25.00°, 15.54 mm., for 30.00°, 20.64 mm., for 35.00°, 26.98 mm. and for 40.00°, 35.18 mm. The "International Critical Tables"[6] give for these temperatures 15.6, 20.6, 26.9, 34.8. The equation

$$\log_{10} p_s(\text{in mm.}) = 8.5723 - (2200/T) \qquad (5)$$

reproduces our results very accurately, the average deviation corresponding to ±0.04 mm., which is well within the experimental error.

Thermochemical Calculations

Heat of Dissociation.—Representing by ΔH the heat absorbed in the dissociation of a mole of $(HOAc)_2$ into two moles of HOAc, we find from equation (4) for a temperature between 25 and 40°

$$\Delta H = 16{,}400 \text{ cal.} \qquad (6)$$

We judge that this value may be in error by as much as 800 cal.

Heat of Vaporization.—If we assume that the saturated vapor of acetic acid does not deviate much from an ideal gas, we can calculate the latent heat of vaporization of one mole (120 g.) of acid by means of the equation

$$L = -(1 + \alpha)R\frac{\mathrm{d}\log_e p_s}{\mathrm{d}\,(1/T)} \qquad (7)$$

In view of equation (5), we obtain

$$L = 10{,}060(1 + \alpha) \qquad (8)$$

Inserting in equation (2) the measured values of K_p and of p_s, we find for 25°, $\alpha = 0.093$; for 30°, $\alpha = 0.104$; for 35°, $\alpha = 0.112$ and for 40°, $\alpha = 0.121$. From equation (8) we obtain

L at 25° = 11,000 cal.
L at 30° = 11,110 cal.
L at 35° = 11,190 cal.
L at 40° = 11,270 cal.

Brown[7] obtained by direct measurement at 117.4° a value of 97.05 calories per gram, equivalent to 11,650 calories per 120 g. of the acid.

From Ramsay and Young's[8] measurements of the saturated vapor pressure, p_s, at 100, 110, 120 and 130°, we readily find for 118°, assuming the vapor to be ideal, $L = 9344\ (1 + \alpha)$. Combining this result with that of Brown we infer that at 118° and 1 atm. the value of $(1 + \alpha)$ is 1.247. On the other hand, the value of pV at 118° and 1 atm. obtained by Ramsay and Young[9] is about 0.319 liter-atm. per gram which leads to a value of $(1 + \alpha)$ equal to 1.194. The difference in the calculated values of $(1 + \alpha)$ is probably due to an appreciable departure from ideal behavior when the vapor is saturated.

Summary

1. Values of pV have been determined for the vapor of very pure acetic acid at 25, 30, 35 and 40° and at pressures as low as 3 mm.

2. The equilibrium constant for the reaction: $(HOAc)_2 \rightleftharpoons 2HOAc$, has been determined for 25, 30, 35 and 40°. The heat of dissociation is calculated to be about 16,400 cal.

3. The vapor pressure of acetic acid has been measured at 25, 30, 35 and 40°. The heat of vaporization per 120 g. of acid at these temperatures is calculated to be 11,000, 11,110, 11,190 and 11,270 cal.

The Use of Chromous Sulfate in the Removal of Oxygen from a Stream of Gas. A Comparison with Other Oxygen Absorbents

BY HOSMER W. STONE

The frequent need of a stream of inert gas of low oxygen content led the author to the observation that not only did the commercial nitrogen contain appreciable quantities of oxygen, but even the gas from the liquid carbon dioxide was contaminated. The usual methods of purifying the nitrogen proved unsatisfactory. This, together with the lack of data on the relative effectiveness of oxygen-absorbing reagents, led to the work reported in this paper.

A cylinder of commercial nitrogen, containing 0.3% oxygen, was chosen for reference. This gas was passed through the apparatus containing the absorbent to be tested, at a constant rate. The time which elapsed before sufficient oxygen escaped the absorbing reagent to color a very sensitive oxygen indicator has been taken as a measure of the effectiveness of that absorbent for removing oxygen from the stream of nitrogen. All of the reagents allowed detectable quantities of oxygen to pass, but in the case of the chromous solution the amount was so small that this reagent was selected as a standard for the comparison of the others. If the time required to color the indicator by the oxygen escaping the chromous sulfate absorbent is taken as 100%, then under the conditions used, none of the other reagents investigated exceeded 4% in their relative efficiency. The work deals with the relative rates of oxygen absorption and makes no attempt to compare the completeness of the reaction at equilibrium conditions.

Apparatus and Reagents

The illustration of the apparatus used requires some explanation. A single cylinder of commercial nitrogen, containing 0.3 volume percentage of oxygen, was used throughout the investigation. The flow of gas through the apparatus was maintained at a rate of 300 ml. per minute by the adjustment of a pressure reducing valve at the nitrogen cylinder. A pressure of about eight pounds per square inch (414 mm.) was required to produce the desired rate of gas flow. This rate refers to that which was measured on the flowmeter after the oxygen had been absorbed.

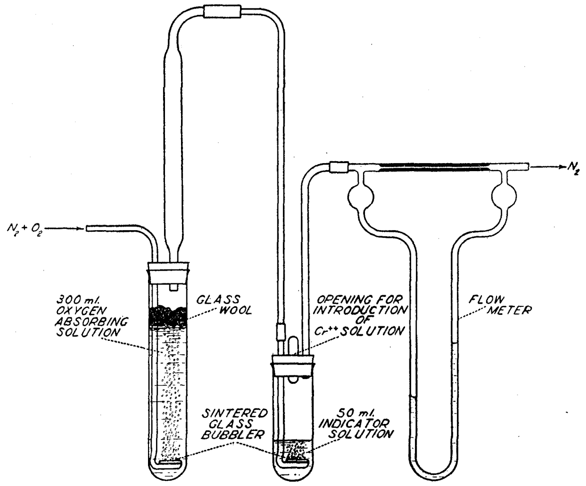

Fig. 1.—Apparatus for the determination of the efficiency of oxygen absorption.

The nitrogen entered the absorbing solution through a sintered glass bubbler. The bubbler, a product of the Jena Glass Works, catalog number 33cG4, was listed as having a pore size to from five to ten microns. The glass wool above the absorbing solution was introduced to overcome the troublesome foaming which occurred when the pyrogallate and the hyposulfite reagents were used as absorbents. The glass wool, together with the tower above it, prevented appreciable amounts of the absorbing solution from being carried into the indicator. The ammoniacal cuprous ammonium chloride reagent liberated so much ammonia gas that it was necessary to introduce a wash bottle containing 2 *N* sulfuric acid between the absorbing solution and the indicator when this reagent was used. When this was not done the basic effect of the ammonia changed the indicator from red to amber at a *p*H of from 6 to 7 and precipitated the hydroxides of the chromium ions.

The Jena glass bubbler in the indicator tube was listed as having pore sizes varying from 100 to 120 microns in diameter. A coarser pore size was used here than in the absorbing tube to reduce the amount of back pressure.

The indicator solution was 0.05 *M* in sulfuric acid and about 0.00025 *M* in the *o*-semidine indicator. The *o*-semidine used in the preparation of the indicator was *o*-amino-*m*-ethoxydiphenylamine and was prepared as described by Jacobsen.[1] A hydrochloric acid solution of this *o*-semidine[1] was oxidized by ferric chloride and the oxidation product recrystallized and thoroughly dried. A stock solution of this oxidation product dissolved in glacial acetic acid was used in making the indicator solution. The properties of this oxidation–reduction indicator were discussed by the author before the Division of Physical and Inorganic Chemistry at the 90th meeting of the American Chemical Society, San Francisco, California, August 19 to 23, 1935. This work has not yet been published.

The indicator was decolorized by the addition of 0.023 *N* chromous sulfate solution. (This chromous sulfate reducing reagent was used to decolorize the indicator in all of the experiments and should not be confused with the chromous reagent used as an oxygen absorbent.) At the end-point of the reaction in which the indicator was reduced by the chromous ion, one drop of the reducing reagent was sufficient to remove the last trace of indicator red and leave a slight excess of unoxidized chromous ion. This excess of chromous ion had to be oxidized by oxygen escaping the absorbing reagent before an indicator color change could appear.

The sensitivity of the indicator was determined by measuring the amount of distilled water, saturated with air, which was required to oxidize the slight excess of chromous ion at the end-point and to produce a distinct color change in the indicator. It required 0.2 ml. of this water which was 0.001 *N* in dissolved oxygen.

Procedure

The following method was used in testing each of the oxygen absorbing reagents. (1) 300 ml. of the reagent to be tested was placed in the absorbing tube. (2) The pressure of the nitrogen gas entering the apparatus was regulated to produce a flow of 300 ml. per minute as indicated on the flow meter. (3) After fifteen minutes of gas flow at this rate and with the gas still flowing the plug in the stopper of the indicator tube was removed and the indicator reduced by a dropwise addition of the 0.023 *N* chromous sulfate solution. Contamination by oxygen of the air during this operation was prevented by the gas which escaped from the opening.

(4) The opening in the stopper of the indicator tube was then closed and the gas allowed to flow through the system until the oxygen escaping the absorbing reagent was sufficient to produce a faint color change in the indicator. This first faint color change was the starting point in all of the runs at which the recorded number of

---

[1] Paul Jacobsen, *Ann.*, **287**, 145 (1895); *ibid.*, **427**, 76 (1922).

drops of the reducing agent were added to the indicator solution. The desired number of drops of the 0.023 *N* chromous sulfate reagent were then added to the indicator and the time interval before the first faint color appeared in the indicator determined. From this observation, the time required to color the indicator, per drop of chromous reagent, was calculated.

(5) The indicator was again decolorized by the addition of a recorded number of drops of the chromous reducing agent and the time interval again determined. This operation was repeated until a nearly constant time interval was obtained. It usually required at least forty-five minutes of gas flow at 300 ml. per minute before this nearly constant value was reached. Up to this time, the intervals were shorter, due to the necessity of removing the air from the system. The data reported represent successive experiments on a single solution of the reagent, obtained after the nearly constant interval had been reached.

The potassium pyrogallate solution which was tested was prepared according to the specifications of Wolf and Krause,[2] who recommend a solution containing 18% potassium hydroxide, 15% pyrogallol and 67% water as absorbing oxygen most rapidly. The reagent containing 50% potassium hydroxide is the approved reagent for absorbing oxygen because it yields less carbon monoxide during its oxidation, even though it is slower in its absorption of oxygen.

The pyrogallate solutions gave trouble by foaming, by forming a precipitate in the glass filter plates, and by yielding a gaseous decomposition product which modified the indicator change. The foaming was overcome by the use of the glass wool. The clogging of the filter plate and the resulting diminution in the flow of gas was taken care of by increasing the nitrogen pressure. The undesirable effect of the decomposition gases on the indicator was minimized by using freshly prepared pyrogallate solution.

The interval of time required to bring back the color to the indicator was 0.30, 0.325, 0.325, 0.28, 0.33, 0.30, 0.28, 0.28 minute per drop of 0.023 *N* chromous sulfate solution. These values represent successive determinations on the same solution after the time interval had become nearly constant.

The oxygen-absorbing sodium hyposulfite reagent recommended by L. F. Fieser[3] consisted of 48 g. of sodium hyposulfite, 12 g. of β-anthraquinone–sodium sulfonate, 40 g. of sodium hydroxide and 300 ml. of water. He states that a train of three Friedrichs bottles containing this solution removed all traces of oxygen gas, even when the velocity was at its maximum. He also reported that, in a bubbling pipet, the absorption of oxygen by this reagent was more rapid than by the pyrogallate reagent.

This reagent, as the oxygen absorbent in a series of successive experiments on the same solution and using from six to fifteen drops of 0.023 *N* chromous reagent, showed the following time intervals in minutes per drop: 0.50, 0.50, 0.50 and 0.47.

The ammoniacal cuprous ammonium chloride reagent used to absorb the oxygen was prepared as directed by Badger.[4]

Five hundred ml. of 15 *N* ammonium hydroxide was mixed with an equal volume of ammonium chloride solution saturated at 23°. Sixty grams of copper ribbon (0.1 by 1 mm.) was immersed in the solution and air blown through the reagent until it became a dark blue in color. Nitrogen was then bubbled through the mixture for several hours so that much of the cupric ammonium complex was reduced to the cuprous form. This solution was siphoned into the absorption tube of the apparatus and the capacity of the absorbing reagent determined by titration against an acidified solution of potassium permanganate.

In experiments with this absorbent, the drops of 0.023 *N* chromous reagent added to the indicator solution varied from eleven to thirty. The minutes required to return the color to the indicator solution per drop of chromous reducing agent were 0.49, 0.36, 0.55, 0.57, 0.40, 0.55, 0.59. As in the other cases these data represent a series of successive experiments where the rate of nitrogen flow was 300 ml. per minute.

The chromous sulfate–sulfuric acid absorption solution was prepared in accordance with the recommendations of Stone and Beeson.[5] In this method the chromous sulfate is obtained by reducing a sulfuric acid solution of violet chrome alum with zinc amalgam in a Jones reductor.

Two series of determinations were made with this reagent in the absorbing tube. One series was carried out before any of the other reagents were tested and another series, with a fresh solution, after the other oxygen absorbents had been evaluated. The two series served as a check on the constancy of the technique used in conducting the experiments. The time interval required to color the indicator per drop of chromous reagent added was so long that only this one drop was used in these experiments. The series of experiments carried out before the other reagents were tested gave values of 13, 12, 12.5 minutes per drop of chromous to coloration of the indicator. The runs on the second solution, made after the other absorbents had been tested, gave 11.5, 13, 13.5, 14.25 minutes per drop.

The data obtained with the various reagents tested are summed up in the table.

A COMPARISON OF THE EFFICIENCIES OF VARIOUS OXYGEN ABSORBENTS, USING 300 ML. OF THE ABSORBING REAGENT, AND A RATE OF FLOW OF GAS OF 300 ML. PER MINUTE

Absorbent used	Normal capacity	Average drops of Cr^{++}	Average min. to coloration	Minutes per drop
Potassium pyrogallate	6.3	13.2	3.97	0.30
Quinone hyposulfite	4.8	10.2	5.0	.49
Cuprous chloride	1.2	19.3	9.39	.49
Chromous sulfate	0.4	1.0	12.82	12.82

The values under the heading "Normal Capacity" in the table present the maximum concentration in equivalents per liter with respect to the reaction with oxygen. For the pyrogallate solution, the normality is based on von Kovács-Zorkoczy's[6] statement as to the capacity of pyrogallol and the quantity of this reagent used. The concentration of the hyposulfite reagent is based on a determination of the purity of the reagent and the amount used. The ammoniacal cuprous ammonium chloride was titrated with permanganate before and after the data were taken and found to change from 1.16 to 0.98 *N*. The chromous sulfate value is based on the amount of chrome alum used in preparing the reagent, though titration before and after one series of runs showed a variation from 0.31 to 0.12 *N* during the experiment.

Discussion

A comparison of the values set forth in the last column of the table shows that, under these conditions, chromous sulfate is at least twenty-five times more rapid in absorbing oxygen than any of the other reagents used.

No difference was found between Fieser's reagent and the ammoniacal copper chloride. The difference between these reagents and the pyrogallate is sufficient to prove that pyrogallate solutions are slower in their absorption of oxygen. Moreover, this superiority of the hyposulfite reagent over the pyrogallate is in agreement with the work of Fieser which has been quoted previously.

No data are given concerning the precise changes in the concentrations of the absorbing agents during the time that their relative efficiencies were determined. This is because variations in the concentration were found to have no effect on the results within the limits of the experimental observations. 0.3 *N* chromous sulfate was no more effective in absorbing oxygen in the apparatus than a 0.1 *N* solution. In either case the reaction appeared to be as rapid as one between ions.

Experiments in this Laboratory[7] showed that the rate of absorption of oxygen by chromous sulfate solutions, in an apparatus such as Fieser used, is too rapid to be measured. The concentration of the chromous sulfate was varied from 0.4 to 0.01 *N* and the concentration of the sulfuric acid from 3.0 to 0.12 without obtaining any measurable change in rate of absorption.

Since each of the reagents used in a particular series of determinations yielded a nearly constant interval of time for coloring the indicator, rather than a decreasing interval, it is clear that the change in concentration of the reagent, due to oxygen absorbed, did not affect the data presented.

It is the writer's opinion that the rate of reaction of the dissolved oxygen with the absorbent is so much greater than the rate at which the oxygen is dissolved by the bubbling process that the former factor can be neglected entirely. This opinion leads one to conclude that the high relative efficiency of the chromous reagent, as compared to the other absorbents, may be at least partially explained by the fact that the physical properties of the chromous solution favor a more rapid solution of the oxygen in the chromous reagent than in the other solutions.

In addition to the advantage of absorbing the oxygen at a much faster rate than the other reagents, the chromous sulfate may be used to reduce the oxygen content of carbon dioxide and other acid gases which could not be treated by the reagents which are basic. The liberation of ammonia gas by the ammoniacal cuprous chloride, the clogging of the filter plate pores by the pyrogallate and hyposulfite reagents, the formation of a troublesome foam, and the evolution of gaseous decomposition products are disadvantages found in working with the other oxygen absorbents which were not met with when using the chromous sulfate.

The desirability of comparing the rates of oxygen absorption, by these reagents, over a wide range of conditions was recognized early in the work. Many experiments were conducted at widely varying rates of gas flow, with longer absorption columns, and with air in place of the commercial nitrogen. Though the results of these experiments indicated that relative rates similar to those reported in this paper held over a wide range of conditions, satisfactory comparisons were obtained only under the method and system described. Serious difficulties arising from fundamental differences in the properties of the absorption reagents and from the character of the indicator led to the abandonment of further attempts at quantitative comparisons.

Summary

1. A new oxidation–reduction indicator has been shown to be a satisfactory reagent for the detection of small amounts of oxygen.

2. A method of comparing the rates at which various reagents absorb oxygen from a stream of nitrogen has been described.

3. Chromous sulfate–sulfuric acid solutions have been shown to absorb oxygen from a stream of nitrogen at an unusually high rate under certain conditions. Adopting the results obtained with chromous sulfate reagents, as a standard, the relative oxygen-absorption rates as found in this same apparatus under similar conditions may be expressed as follows: potassium pyrogallate 2.3%, ammoniacal cuprous ammonium chloride 4%, alkaline sodium hyposulfite β-anthraquinone-sodium sulfonate 4%, and chromous sulfate–sulfuric acid reagent 100%.

A Study of Promoter Action. The Oxidation of Aniline Sulfate by Hot, Concentrated Sulfuric Acid in the Presence of Copper and Mercury Sulfates[1]

BY M. M. HARING AND H. H. KAVELER

Oxidation by hot, concentrated sulfuric acid has many applications, of which one of the more important is the analytical method of Kjeldahl.[2] Numerous modifications of the method have been published, the use of copper and mercuric sulfate catalysts being emphasized. However, only Bredig and Brown[3,4] have made a study of the kinetics of the reaction and of the relation between catalytic effect and amount of the catalyst. They observed, among other things, that mixed copper and mercuric sulfates exhibited a catalytic effect greater than the additive value. However, they published only one set of data on mixed catalysts. It was the primary purpose of this investigation to study a wide range of catalyst ratios and total amounts.

Reagents.—Mercuric oxide was prepared by adding the calculated amount of sodium hydroxide to a solution of c. p. mercuric chloride heated to 70°. The precipitated red oxide was washed free of alkali and chlorides and dried at 100°.

Reagent copper sulfate pentahydrate was used without further purification.

The sulfuric acid used was reagent quality (sp. gr. 1.83–1.84) and was demonstrated to be free of the heavy metals.

The aniline sulfate was the purest obtainable. Analysis by the Kjeldahl method gave 9.77% nitrogen as against 9.86% theoretical.

Apparatus.—The apparatus used was similar to that described by Bredig and Brown.[3,4] The thermostat was modified to accord with modern practice. It maintained the experimental temperature of 275° to ± 0.1°. The reaction vessel and gas measuring apparatus are shown in Fig. 1, the volume of the reaction bulb being about 75 cc.

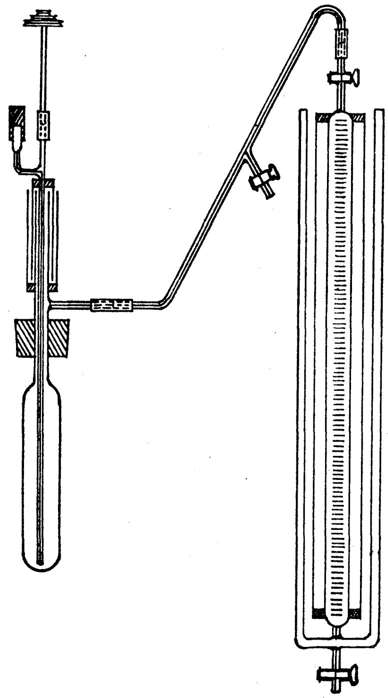

Fig. 1.

All weights and other measuring devices were checked for precision.

Procedure.—The desired quantity of the catalyst was introduced into the reaction flask through a long-stemmed funnel, followed by 50 cc. of sulfuric acid. After insertion in the bath, the mixture was stirred for one hour.

The stirring was stopped and the desired amount of a standard solution of aniline sulfate in sulfuric acid (about

8% by weight) was run from a weight buret into the well on the side-arm of the stirrer. This was followed immediately by 1.0–1.5 cc. of sulfuric acid and the run started. The pressure was maintained at the atmospheric value throughout a run. 0.05–0.09 g. of aniline sulfate was used in all experiments. The weights of catalyst used were always 0.0305 g. of mercuric oxide and 0.0351 g. of copper sulfate pentahydrate or integral multiples thereof. These unit weights are in the same ratio as the molecular weights. The maximum amount of catalyst used in any experiment was a very small fraction of the solubility in sulfuric acid.[5]

Data and Calculations

For comparison purpose, all gas volumes were reduced to a weight of 0.0500 g. of aniline sulfate by proportion. Bredig and Brown[3,4] showed this procedure to be valid. All volumes likewise were corrected to standard conditions. From two to nine runs (in most cases four) were made for each quantity of catalyst. The volumes for each case were averaged at corresponding times, plotted on a large scale and the best smooth curve drawn. All data given below, save Table I, were obtained in this manner. Table I shows all the data. The variation in volumes from the mean for corresponding times for the different members of a series was seldom in excess of 5% and usually much less. In the following tables t is for times in minutes, V is the average volume in cc. and K is the monomolecular reaction constant for times in minutes, as obtained from $K = (2.303/t) \log (C_0/C)$. Purity of the aniline sulfate was considered in calculating C_0. The amount of catalyst is expressed in terms of unit weights as defined previously. The average K is based on the values at 45, 60 and 90 minutes. Early values for K for catalyzed reactions are too unsteady to give a good comparison. All values of K are included in the average for the uncatalyzed reaction. K values in all tables are $\times 10^4$.

	Av.	45.6		70.4		64.3

The fact that the effect of mixed catalysts is more than additive is demonstrated by calculating the promotion factor. This is obtained by dividing the average *K* for a mixed catalyst (less *K* uncatalyzed) by the sum of the *K* values for the appropriate units of the pure catalysts (less 2 *K* uncatalyzed). Wherever these values had not been directly determined they were obtained by graphic interpolation. The promotion factors are given in Table VI.

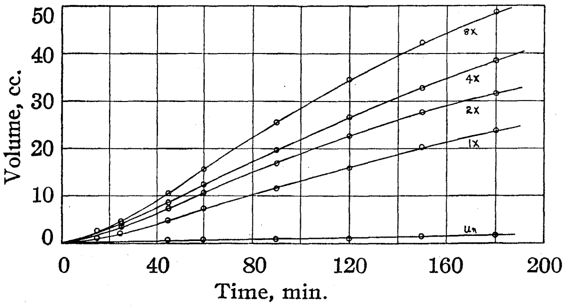

Fig. 3.—Copper sulfate pentahydrate catalyst, x, units of catalyst; Un, uncatalyzed.

TABLE VI

3Hg–3Cu	5Hg–1Cu	2Hg–4Cu	4Hg–2Cu
1.80	1.84	1.78	1.87
1Hg–1Cu	8Hg–8Cu	4Hg–1Cu	1Hg–4Cu
1.62	2.36	1.66	1.49
1Hg–8Cu	8Hg–1Cu	4.5Hg–4.5Cu	
1.95	2.52	2.22	

The effect is more apparent when graphically portrayed. This is given for the series containing six units of mixed catalyst. In Fig. 4 the volumes of gas liberated at 24, 45, 60 and 90 minutes are plotted against the Hg/Cu mole ratio. Values for six units of pure catalyst were obtained by graphic interpolation.

Discussion

The data of Tables II and III reveal that copper is a better catalyst than mercury at the lower concentrations but a poorer catalyst at the higher concentration, on a mole for mole basis. The catalytic effect increases with concentration of the catalyst, but is not directly proportional as claimed by Bredig and Brown.[3,4] However, examination of their data does not support their contention. Mixtures of the two catalysts show the same general proportionality. The mixtures with a high mercury content are better catalysts than those with a high copper content. Figure 4 shows that the most active mixture is approximately two moles of mercury to one of copper.

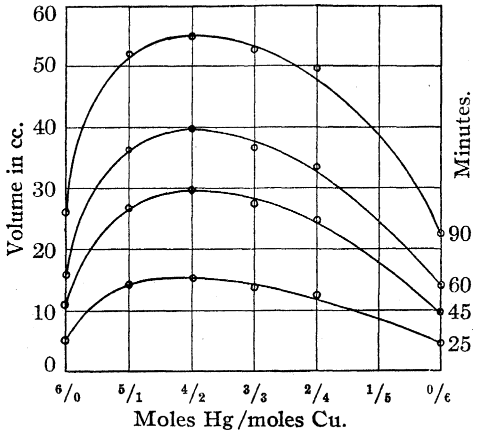

Fig. 4.—Variation of promoter effect with catalyst composition ratio and time.

Since both metals are good catalysts and all mixtures, as shown in Table VI, have activities far greater than the additive value, it is clear that this is a case of coactivation. A very interesting observation is that the promoter effect drops off with time.

Bredig and Brown[3,4] claimed this reaction to be monomolecular. The results of this study, particularly the data on the uncatalyzed reaction, support their contention. The values of K for the catalyzed reactions are far from constant, although they become more so, in most cases, after about an hour. Examination of Figs. 2 and 3 reveals that all curves have an inflection at about forty minutes. The curves of Bredig and Brown show the same inflection. This might be explained in four ways. (1) The cooling effect of introducing the sample might slow up the reaction for a brief interval. (2) The sample, due to inadequate stirring, might not be uniformly distributed immediately. (3) An undisturbed rate of gas evolution might not be obtained while the gas concentration in the mixture increased to saturation. (4) The inflection is real and due to a series of consecutive reactions of differing velocity. (1), (2) and (3) would be errors inherent in the method. As such they would be subject to variation. That two groups of investigators working entirely independently should duplicate these factors is highly improbable. Explanation (4) is almost certainly correct. Heated to 275°, a solution of aniline sulfate in sulfuric acid slowly darkens, going to green, then to black and finally to yellow, thus indicating numerous successive reactions. The equation for the reaction given by Bredig and Brown is

$$(C_6H_5NH_2)_2 \cdot H_2SO_4 + 28H_2SO_4 = 12CO_2 + 28SO_2 + (NH_4)_2SO_4 + 32H_2O$$

which is evidently only the sum of a series. Of course, with excess sulfuric acid this reaction would be pseudomonomolecular, but the evidence is against a single step. The data do not permit more than a guess at the probable path. Aniline blacks, sulfonated products and quinone are almost certainly produced. In fact the yellow needles of quinone were observed to crystallize out in several of the mixtures after cooling. However, the very good constancy of K uncatalyzed shows that, in the first stages, the reaction is monomolecular or at least pseudomonomolecular.

As to the mechanism of the catalysis and coactivation, the data afford little evidence. Aniline has been shown to form numerous complexes with mercuric and other metallic salts.[6,7,8]

Mercuriated aryls are also formed with aniline.[9]

The copper compounds are less easily prepared and are not as stable[9] (p. 774).

Such complexes might react to produce a compound more readily oxidized than aniline itself. A parallel case has been studied.[10]

The work of Bohnson and Robertson[11,12] on the decomposition of hydrogen peroxide by mixtures of copper and iron ions affords a possible explanation of the coactivation.

In this case it was shown that one metal continually regenerates the other in active form. Some support for this suggestion is found in the work of Germuth,[13] who showed that the rate of oxidation of mercurous to mercuric ion by atmospheric oxygen is appreciably increased by traces of cupric ion.

Summary

1. Copper and mercury sulfates are excellent

catalysts for the oxidation of aniline sulfate by sulfuric acid, mercury being the better. The effect is not strictly proportional to the amount of the catalyst.

2. Together the two catalysts give effects much greater than the additive value. This is, accordingly, a case of coactivation. Mercury and copper in the ratio of two moles to one give the most pronounced effect.

3. The reaction is monomolecular or pseudo-monomolecular in the first stages.

Condensations by Sodium. VIII. Solvent Exchange Reactions, Preparation of Phenylmalonic Acid, and Comments on Some Mechanisms of Reactions which Employ Sodium

BY AVERY A. MORTON AND INGENUIN HECHENBLEIKNER

When benzene or a mixture of benzene and ligroin was used as the solvent for the preparation of amylsodium from amyl chloride and sodium by the recently described[1] synthesis of organo-metallic compounds, the product after carbonation was benzoic instead of caproic acid. Exchange of phenyl for the amyl radical was complete and the yield of benzoic acid, calculated on the basis of a molecule of acid for every one of amyl chloride used, was as high as 78%. Toluene, dimethylaniline, anisole, diphenylmethane and fluorene, when used similarly either as solvents or as diluents in a ligroin solution, shared this interesting property so that the monocarboxylic acids formed as products of carbonation were phenylacetic, N-dimethylanthranilic, *o*-methoxybenzoic, diphenylacetic and diphenyleneacetic acids in yields of 40, 18, 20, 14 and 18.5%, respectively (see Table II). No attempt was made to obtain the maximum yields.

In order to illustrate the possibilities of extending this solvent exchange type of synthesis beyond the preparation of acids we have prepared phenylsodium by interaction of amyl chloride, sodium and benzene and then brought about its reaction with propyl chloride. Propylbenzene was found in substantial quantity. In a like manner phenylsodium was induced to react with ethylene oxide yielding β-phenylethyl alcohol as one of the products.

Syntheses of this type continued to show promise of use in the preparation of malonic acids. A notable example was the formation of phenylmalonic in addition to phenylacetic acid from the reaction in toluene solution. With amyl chloride in a mixture of toluene and ligroin a yield of 33% of phenylmalonic acid was obtained from the same run which yielded 40% of phenylacetic acid. With isobutyl chloride the yields were 20% of phenylmalonic and 11% of phenylacetic acid. When the addition of toluene was delayed until after all reactions between amyl chloride and sodium had ceased, the yields of phenylmalonic and phenylacetic acids were 28 and 5%, respectively. The method is therefore a far more convenient source of this compound than has hitherto been available. It is especially interesting to note that the yield of the malonic acid is often considerably in excess of that for the monocarboxylic acid.

Mechanism of Exchange Reactions.—Our work has now progressed to a point where we have assurance as to the manner in which some of the products are formed. The monosubstitution product, benzoic acid, arises from metathesis of the sodium compound with the hydrocarbon according to equation 1.

$$C_5H_{11}Na + C_6H_6 \longrightarrow C_5H_{12} + C_6H_5Na \quad (1)$$

Important evidence of the correctness of this view was furnished by (a) reserving the addition of benzene in experiments 3 and 4 until after the free radicals had disappeared and the formation of amylsodium had been completed, a condition which resulted in the entire replacement of caproic by benzoic acid among the products of carbonation and (b) by carrying out, as in experiment 6, an exchange reaction in the presence of carbon dioxide to remove amylsodium as fast as it was formed and thereupon failing to find any benzoic acid. Neither was this acid found in six experiments made under pressure of carbon dioxide. We therefore conclude that the free radi-

---

[1] Morton and Hechenbleikner, THIS JOURNAL, 58, 1697 (1936).

cal amyl did not react with benzene under the conditions of our experiments and that the occurrence of benzoic acid was due to the reaction of the monosodium compound with benzene according to equation 1. A mild form of acidity on the part of the hydrogen atom in benzene which permits the formation of a stable salt, sodium phenide, is thus suggested. The much higher yield of benzoic acid (78%) than was usually obtained for caproic acid in like experiments reported in the previous paper may be interpreted as indicating the greater stability of phenylsodium in a Wurtz synthesis.

Although the free radical amyl was without a role in the solvent exchange reactions, some evidence suggesting that the radical amylidene was in part responsible for the formation of iso- and terephthalic acids was uncovered. In the aforementioned experiments on the interaction of benzene, amyl chloride and sodium, under pressure of carbon dioxide, a mixture of the two phthalic acids was obtained in each instance. On the reasonable assumption that carbon dioxide would remove the organo-dimetallic compound before it could react with benzene as effectively as it had in the case of amylsodium, we conclude that free amylidene must have reacted with benzene according to equation 2, and that the phenylene so

$$C_5H_{10}< + C_6H_6 \longrightarrow C_5H_{12} + C_6H_4< \qquad (2)$$

formed then added two atoms of sodium yielding phenylene disodium which was promptly carbonated, producing the mixture of phthalic acids.

Iso- and terephthalic acids may also be formed because of a reaction of amylidene disodium with benzene according to equation 3. Although the likelihood of benzene reacting with two molecules

$$C_5H_{10}Na_2 + C_6H_6 \longrightarrow C_5H_{12} + C_6H_4Na_2 \qquad (3)$$

of amylsodium (equation 4) appeared to be very

$$C_6H_6 + 2C_5H_{11}Na \longrightarrow C_6H_4Na_2 + 2C_5H_{12} \qquad (4)$$

good, we have so far been unable to produce evidence which would point conclusively to such a chemical change. The facts bearing on this point can be stated briefly. (1) When benzene was present at a temperature below 5° during or after the reaction of amyl chloride with sodium the subsequent carbonation yielded benzoic and butylmalonic but no phthalic acids. Apparently amylidene disodium reacted more sluggishly with benzene than did amylsodium so that at this temperature a solvent exchange reaction occurred with amylsodium only. (2) When benzene was allowed to react at 65° with the products of the reaction between amyl chloride and sodium, phthalic acids appeared among the products and the amount of butylmalonic acid was decreased. These two facts suggested that under these conditions bimetallation of benzene may have occurred by reaction 3. With toluene, it is true, we did obtain evidence that disubstitution by means of amylsodium had taken place, for the yield of phenylmalonic acid in one experiment was 28% under conditions which had produced butylmalonic acid in yields no higher than 24% and usually near 17% (see previous paper).

Mechanism of Malonic Acid Formation.—As an explanation for the occurrence of butylmalonic acid we favor that which pictures an initial formation of the free radical amyl, its disproportionation to amylidene and pentane, the addition of sodium to the former and the carbonation of the disodium product shown in sequence below.

$$C_5H_{11}Cl \xrightarrow{Na} C_5H_{11}- \xrightarrow{C_5H_{11}-} C_5H_{12} + C_5H_{10}< \xrightarrow{Na} C_5H_{10}Na_2 \xrightarrow{CO_2} C_5H_{10}(COONa)_2 \qquad (5)$$

Our opinion is founded on (a) the agreement of the experimental facts with all the results which would be predicted on the free radical basis, and (b) the inability to find any evidence to bolster up alternative mechanisms, *viz.*, one involving amylsodium and another the splitting out of hydrogen chloride.

A full discussion of our efforts to connect amylsodium with the formation of butylmalonic acid was included in the previous paper. That evidence, coupled with additional information in this paper, is overwhelmingly against any such idea. To conserve space we are limiting our present discussion of this point to only one of the ways in which amylsodium could conceivably be responsible for the occurrence of the dicarboxylic acids. The following sequence assumes a certain lability of the hydrogen atom on the alpha carbon atom of sodium caproate so that it reacts with amylsodium.

$$C_5H_{11}Na \xrightarrow{CO_2} C_5H_{11}COONa \xrightarrow{C_5H_{11}Na} C_5H_{12} + C_5H_{10}Na(COONa) \xrightarrow{CO_2} C_5H_{10}(COONa)_2 \qquad (6)$$

Four points can be cited against this mechanism: (1) the failure as reported in the previous paper to get an increased yield of butylmalonic acid when sodium caproate, prepared *in situ* by partial carbonation, was present during the addition of amyl chloride to sodium; (2) the destruction of most of the amylsodium, prior to carbonation by fourteen hours of heating at 80° while leaving the yield of butylmalonic acid unchanged, a fact which we interpreted in the previous paper as illustrating the surprising stability of amylidene disodium, obviously formed prior to carbonation; (3) the reaction in benzene solution recorded in this paper in which amylsodium was removed by complete reaction with benzene below 5° but from which butylmalonic acid was isolated among the carbonation products, thereby showing again that sodium amyl could not be a source of butylmalonic acid and that amylidene disodium must have been present before carbonation; (4) the unlikelihood that amylsodium would react with sodium caproate in the manner above indicated since Schorigin[2] has already shown in the case of phenylsodium and Gilman and Van Ess[3] have found with alkyllithium that the secondary products in reactions with carboxyl containing compounds were ketones and tertiary carbinols. In short, organo-metallic compounds of this type, when they do react with alkali salts of carboxylic acid, show a tendency to react with the carboxyl group after the usual manner of an ester with the Grignard reagent rather than with a weakly acid hydrogen atom on the alpha carbon atom. The above facts confirm the view expressed in the previous paper that amylsodium is in nowise connected with the formation of butylmalonic acid.

Splitting out of hydrogen halide from an alkyl halide was initially proposed by Michael[4] as a first step in the Wurtz synthesis. Acree[5] in a study of the action of phenylsodium on ethyl bromide suggested a similar role for phenylsodium as a means of accounting for the presence of ethylene among the products of the reaction. Ethylidene was assumed to be the intermediate. These assumptions are adaptations of the well-known activity of sodium ethylate in double bond formation with the exception that hydrogen halide is taken from the same rather than from adjacent carbon atoms. The equation for the reaction is

$$C_5H_{11}Cl \xrightarrow{\text{Na (or NaR)}} HCl + C_5H_{10}< \quad (7)$$

The corresponding equation for the formation of amylidene in the reaction of sodium on diamyl mercury would require the splitting out of $HHgC_5H_{11}$ instead of HCl. Reference to the work in the fifth paper[6] on the formation of butylmalonic acid in the reactions under pressure of carbon dioxide is sufficient to dispose of the possibility that amylsodium had caused the eviction of hydrogen chloride in this manner, since carbon dioxide should remove the organometallic compound as fast as it was formed. Other agents commonly employed in forming ethylenic bonds are not available under all conditions in these reactions. Thus sodium ethylate or sodium hydroxide could not be present in the autoclave reactions[6] in the presence of an excess of carbon dioxide and sodium carbonate on the other hand was not present when the formation of organo-alkali compounds[1] was carried out in absence of carbon dioxide. Metallic sodium, therefore, remains as the sole agent which might function in this manner and be present in all cases. Such an opinion of the special activity of sodium would appear to require considerable tinkering in an endeavor to link the general mechanism of double bond formation with the Wurtz synthesis. We have thought it worth while, however, to make one more attempt under conditions which are ordinarily quite favorable for the splitting out of hydrogen halide. Since the formation of phenylmalonic acid occurred with considerable ease we elected to try the reaction of benzyl chloride with sodium in the presence of sodium alcoholate, formed *in situ* by the addition of a little alcohol. A vigorous reaction ensued and the product had the customary dark color but no phenylmalonic acid could be found upon carbonation. If a substituted methylene radical were formed under these conditions, as might be thought possible from the opinion of Bergmann and Hervey,[7] metallic sodium did not serve as an interceptor. Further investigations of this idea did not appear promising.

As stated before the favored explanation for the occurrence of malonic acids is that the free radical amyl undergoes disproportionation forming an idene radical which then adds two atoms of sodium. This view is in full accord with every fact which has been brought out by these studies. Thus the yields of carboxylic acids in all cases, whether in the autoclave reactions (fifth paper),[6]

the reactions with mercury diamyl (sixth paper),[8] the experiments in the isolation of the intermediate amylsodium (seventh paper),[1] or in the exchange reactions reported in this paper, have never been in excess of that which could be accounted for on this basis. Moreover, the amount of pentane recovered in the reaction of sodium with diamyl mercury[9] was close to that demanded by the theory. If we accept the view that the free radical mechanism pictures a correct outline of events, the isolation of butylmalonic acid means that in the disproportionation of free amyl an intermediate step is the formation of amylidene which then rearranges to amylene. Metallic sodium acted as an imperfect interceptor for the amylidene stage. The quantity of butylmalonic acid on this basis is actually a measure of the free radical known to have disproportionated.

Mechanism of the Wurtz Reaction.—In applying our data to the mechanism of the Wurtz–Fittig reaction we shall show that (a) free radicals are formed either before or simultaneously with the formation of alkylsodium, and (b) the free radical amyl undergoes disproportionation instead of dimerization to at least 92% (the true value may be even higher) from which it follows that decane is probably formed by the reaction of amylsodium with amyl chloride. Schlubach and Goes[10] represented the first step of the Wurtz–Fittig reaction as the formation of a free radical by the action of sodium on an alkyl halide according to equation 8. Subsequently the radical added sodium, dimerized or underwent disproportionation.

$$\mathrm{RX + Na \longrightarrow R— + NaX} \qquad (8)$$

See equations 9. In the final step the alkylsodium reacted with alkyl halide.

$$\mathrm{R—} + \begin{cases} \mathrm{Na \longrightarrow RNa} & (a) \\ \mathrm{R— \longrightarrow RR} & (b) \\ \mathrm{R— \longrightarrow R_{-H} + R_{+H}} & (c) \end{cases} \qquad (9)$$

Goldschmidt and Schön,[11] however, gave the first phase as shown in equation 10

$$\mathrm{RX + 2Na \longrightarrow + NaX} \qquad (10)$$

and have outlined the possibility of the occurrence of free radicals from the reaction

$$\mathrm{RNa + RX \longrightarrow R— + R— + NaX} \qquad (11)$$

Our experiments under pressure of carbon dioxide are equivalent to carrying out a Wurtz–Fittig reaction in the presence of an agent, carbon dioxide, which would trap the alkyl sodium but not the free radical. Since butylmalonic acid continued to be formed under these conditions, even when the pressure was as high as 900 pounds (60 atm), we conclude that free radicals must have been formed either prior to or simultaneously with the formation of alkylsodium as given in equation 8.

That the tendency of the amyl radical under these conditions was overwhelmingly toward disproportionation (equation 9c) rather than toward dimerization (equation 9b) can be seen by reference to one[12] of the experiments in which we were particularly successful in finding conditions under which metallic sodium acted as a nearly perfect trap for the amylidene. In this instance only 2%, calculated on the basis of the sodium, went to products[13] which were other than acids. When recalculated in terms of the amyl chloride consumed we find that 45.5% appeared as amyl sodium (caproic acid), 50% as a free radical which underwent disproportionation (butylmalonic acid) and only 4.5% as unknown (decane, pentane and pentene). The combined amount of free radical which was present and could either disproportionate or dimerize was therefore 54.5% and of this amount 92% is known to have taken the former path. Because of this great tendency for disporportionation it seems likely that decane, when synthesized from the action of sodium on amyl chloride, is formed largely by way of the amylsodium plus amyl chloride path. Particularly is this view made likely by reference to the 45.5% yield of amylsodium in the same reaction. As regards the formation of amylsodium by equation (9a) or (10) our data do not permit a differentiation.

Our conclusions on the mechanism of the Wurtz reaction can be summarized briefly. This synthesis occurs because of the reaction between amylsodium and amyl chloride, a view confirmed by (a) our isolation of the organo-metallic compound in quantity and (b) the evidence showing that the free radical amyl had scarcely any tendency to combine with itself forming decane. Having shown that free radicals are present either prior to or simultaneously with the formation of amylsodium, it is an entirely reasonable supposi-

[13] By the term Wurtz in the former paper we included all reactions possible in a Wurtz synthesis. The figure was arrived at by difference. Hence the column marked Wurtz referred to decane, pentane and pentene.

tion that amylsodium is a consequence of the addition of an atom of sodium to the free radical.

Experiments

General Direction.—The usual method of carrying out the reactions, unless otherwise specified, was the same as described in the previous paper,[1] *viz.*, addition of amyl chloride to fine sodium sand with gentle stirring in the desired solvent. Such changes as were made necessary by the use of a different solvent are indicated clearly. The separation of the products was in general made possible by the fact that the aliphatic monocarboxylic acids could be extracted with petroleum ether, the malonic acids were usually soluble in cold or hot water, but could be extracted with ether, the phthalic acids were insoluble in water or ligroin. The melting points of the products were compared with those in Beilstein. The sodium sand was made up in large batches so that the grade did not change through a series of experiments. This precaution was necessary because the yields of acids were affected by the fineness of the sand. The data for the experiments are given as far as possible in tables followed by supplementary notes on each reaction. In the paragraph immediately following that section attention is called to the significance of each experiment. The numbering is for convenience only. Yields are calculated on the basis of the sodium employed except in reaction 3 in which the value is referred to diamyl mercury.

TABLE I

EXCHANGE REACTIONS WITH BENZENE

Constant factors. Eastman Kodak Co. *n*-amyl chloride used in all experiments except in number 3, where diamyl mercury and in number 5 where isobutyl chloride were used. Mallinckrodt thiophene-free benzene used.

No.	Sodium, g.	Amyl chloride, ml.	Benzoic acid		Phthalic acids		Butylmalonic acid	
			G.	%	G.	%	G.	%
1	15	30	6.4	21.4			3.5	17.5
2	15	20	15.7	78			0.43	3.2
3	4	10[a]	2.2	32	0.2	4		
4	10	20	2.3	11.5	.9	6.5	1.1	8.2
5	10	15	5.3	32			Traces	
6	5	30	0.0					

[a] Quantity of diamyl mercury in grams instead of ml.

1. Sodium sand in 150 ml. of benzene with 50 ml. of pentane to keep the mixture from solidifying. Temperature below 5° during addition of the chloride which required two hours. Stirred for fifteen minutes after addition was completed.

2. Sodium in 80 ml. of benzene and 50 ml. of pentane. Amyl chloride in 50 ml. of benzene. Temperature below −2° during addition of amyl chloride solution which required one hour. Stirred for one hour longer at room temperature.

3. Diamyl mercury used in place of amyl chloride. Sodium sand in 100 ml. of pentane. Mixture stirred for two hours following mixing of reagents, after which 100 ml. of benzene was added.

4. Sodium sand in 50 ml. of ligroin; amyl chloride in 50 ml. of same solvent. Addition time one and one-half hours, temperature 18–22°. Stood one hour at room temperature. Benzene, 100 ml., then added and mixture heated to 65° for one hour. The phthalic acid mixture contained 0.054 g. of the iso- form which was separated by the solubility of the barium salt.

5. Isobutyl chloride dissolved in 50 ml. of benzene. Sodium sand in 50 ml. of benzene. Time of addition one and one-quarter hours; temperature 25–30°. Mixture allowed to stand for two hours before carbonation.

6. Sodium sand in 30 ml. of benzene; amyl chloride added undiluted; temperature 10–20°. Carbon dioxide passed in during the addition of the alkyl chloride; reaction time one hour. No benzoic acid was obtained. Caproic acid, 23%. No analysis was made for butylmalonic acid.

Special attention is directed to (a) the absence of phthalic acids in 1 and 2 where the temperature of the reaction was below 5° and the presence of these acids where the temperature was 65° (experiment 4); (b) the very high yield of benzoic acid in number 2 where the concentration of benzene was less and the rate of addition of amyl chloride was greater than in number 1; (c) the exchange reaction, experiment 5, with isobutyl chloride and the small quantity of dicarboxylic acids among the products; (d) the failure to find benzoic acid when carbon dioxide was bubbled through the reaction mixture (experiment 6) indicating the ease with which amylsodium could be removed from the reaction before the latter could react with benzene; (e) the combined yields of phthalic and butylmalonic acids in experiment 4 which amounted to 14.7%, a value within the range of 13–17% noted in the previous paper for the yield of butylmalonic acid under the same conditions and hence suggestive of the formation of phthalic acids at the expense of butylmalonic acid in the exchange reaction; (f) the delayed addition of benzene to the reaction mixture in experiments 3 and 4 which showed that an exchange reaction had occurred between benzene and the organometallic compound.

7. Sodium sand in 25 ml. of ligroin and 25 ml. of toluene. Amyl chloride dissolved in 25 ml. of ligroin and 25 ml. of toluene. Addition at 0–5° for two and one-half hours. Stirred three hours at 40–45° during which time 100 ml. more ligroin was added because the mixture became so thick it could not be stirred. At the end of this time the almost solid greenish-yellow mass was carbonated.

8. Solvent conditions the same as in experiment 7. Isobutyl chloride used instead of amyl chloride. Addition time three hours at 0–5°. Stirred two hours at 40–45°. Carbonated at 60°.

9. Sodium sand in 50 ml. of ligroin. Time of addition two hours at 0–10°. Stood at room temperature for three hours. 100 ml. of toluene added and the mixture heated to 50° for ten minutes.

TABLE II

EXCHANGE REACTION WITH COMPOUNDS OTHER THAN BENZENE

No.	Sodium, g.	Amyl chloride, ml.	Solvent or diluent	Ml.	Mono-acid		Di-acid		Butylmalonic acid	
					G.	%	G.	%	G.	%
7	15	20	Toluene	50	9	40	5.0	33		
8	15	15	Toluene	50	2	11	2.4	20		
9	10	20	Toluene	100	1.2	5.2	4.15	28		
10	10	20	Anisole	50	5	20			Trace	
11	10	20	Diphenylmethane	20	4.8	14	None		Trace	
12	10	20	Dimethylaniline	50	5	18				
13	15	20	Fluorene	10 (g.)	6.5	18.5			1	7

10. Sodium sand in ligroin–anisole mixture, 25 ml. of each. Amyl chloride dissolved in the same mixture was added at 20–25° during one hour. *o*-Methoxybenzoic acid obtained. Melting point 99°. Recorded value in literature 98.5°.

11. Sodium sand and diphenylmethane in 50 ml. of ligroin. Amyl chloride in 50 ml. of ligroin added at 25–30° during one hour. Mixture stood twelve hours at room temperature before carbonation. Diphenylacetic acid m. p. 145–146° obtained. Recorded values in the literature vary from 144 to 149°. The corresponding malonic acid is unstable.

12. Sodium sand in a mixture of 50 ml. each of ligroin and dimethylaniline. Amyl chloride dissolved in 50 ml. of ligroin added at 0–10° during 1.25 hours. The mixture was allowed to stand for four hours before carbonation. N-Dimethylanthranilic acid of m. p. 68–70° was found. Recorded value in the literature is 70°.

13. Sodium sand and amyl chloride separately contained in 50 ml. of ligroin. Addition time one hour at 0–15°. Stirred twenty minutes at room temperature. Fluorene, 10 g., in 100 ml. of ligroin then added. Diphenyleneacetic acid obtained. Melting point of ethyl ester 44–45°. Recorded value in literature 43–45°. The corresponding malonic acid is unstable.

Special attention is directed to (a) the formation of substituted malonic acids with an aromatic compound containing a methyl group illustrated in experiments 7, 8, 9 with toluene; (b) the addition of fluorene to the reaction mixture after the formation of the organo-alkali compounds from amyl chloride and sodium had been completed, a method found satisfactory after other attempts in which fluorene was present during the first stage of the reaction had failed to give products which could be isolated readily; (c) the occurrence of ortho substitution products with anisole and dimethylaniline.

Reaction of Benzyl Chloride and Sodium Ethylate.—To a mixture of 15 g. of sodium sand and 20 ml. of benzyl chloride in 100 ml. of ligroin was added slowly 5 ml. of anhydrous ethyl alcohol at room temperature. The reaction mixture evolved a gas and turned a dark red color characteristic of the color present in any of the reactions in the absence of alcohol. After carbonation, however, scarcely a trace of acid was found to be present.

Propylbenzene from Amyl Chloride, Benzene, Sodium and Propyl Chloride.—To 75 g. of sodium sand suspended with stirring in 350 ml. of benzene and contained in a three-necked flask protected by an atmosphere of nitrogen was added 180 ml. of technical *n*-amyl chloride at 18° over a period of three hours. The mixture was then allowed to stand fourteen hours after which 100 g. of *n*-propyl chloride was added. The mixture was heated to 80° for two hours, after which it was decomposed and the hydrocarbon layer distilled. Propylbenzene, b. p. 159°, was obtained in a yield of 23% (30 g.). Higher boiling fractions were present which were not investigated.

Phenylethyl Alcohol from Amyl Chloride, Benzene, Sodium and Ethylene Oxide.—In a similar apparatus 20 g. of sodium sand was suspended in a mixture of 150 ml. of benzene and 50 ml. of ligroin. Amyl chloride, 40 ml., was added at 0° during two hours. The mixture was stirred for four hours after which 8 g. of ethylene oxide was passed in at 0°. The yield of phenylethyl alcohol obtained from the process was 12.5% (5 g.). About 3 g. of heptyl alcohol was also obtained. Higher alcohols insoluble in benzene were also present.

Exchange Reactions with Benzene under Pressure of Carbon Dioxide.—Six experiments were carried out in the autoclave described in a previous publication in this series. The amount of sodium sand was varied from 10 to 15 g. and the quantity of benzene varied from 100 to 120 ml. Amyl chloride, 120 ml. and carbon dioxide, 200 lb. (13 atm.) were present in each case. The temperatures varied from 80 to 132°. In no case was benzoic acid found to be present among the acids isolated from the reaction mixture, although caproic, 1 to 2.5 g. of phthalic (iso and tere mixture), and butylmalonic acids were readily obtainable.

Summary

A yield as high as 78% of benzoic acid can be obtained in an exchange reaction between amyl chloride, sodium and benzene. In varying yields phenylacetic, N-dimethylanthranilic, *o*-methoxybenzoic, diphenylacetic and diphenyleneacetic acids have been obtained in a similar manner from amyl chloride and sodium with toluene, dimethylaniline, anisole, diphenylmethane and fluorene.

Phenylsodium, prepared from amyl chloride and sodium has been treated with propyl chloride and ethylene oxide to yield propylbenzene and phenylethyl alcohol, respectively.

Phenylmalonic acid has been prepared by reaction of toluene with amyl chloride and sodium or with the products of the reaction of this chloride and the metal.

Evidence is presented to show that the formation of phenylsodium occurs from the action of amylsodium, but not the free radical amyl, with benzene.

The formation of iso- and terephthalic acids in the interaction of benzene, amyl chloride and sodium has been shown to be due probably to reactions of either amylidene or amylidene disodium with benzene.

Further discussion of the mechanism of the formation of butylmalonic acid from the reaction of amyl chloride and sodium has been made and the probable path has been judged to be by disproportionation of the free radical amyl.

In the disproportionation of this free radical to pentane and pentene, the presence of the intermediate state, amylidene, which rearranges to pentene has been indicated.

Application of these studies to the mechanism of the Wurtz–Fittig reaction has shown that it proceeds by means of the reaction of an alkylsodium with the alkyl chloride and that free radicals are present during the early stages.

Reactions of Alkyl Sulfates, Tetraethyl Orthosilicate and Diethyl Carbonate in Friedel–Crafts Syntheses[1,2]

BY HOWARD L. KANE AND ALEXANDER LOWY

Alkylations by the method of Friedel and Crafts are generally carried out using the halides or olefins. Nevertheless, certain disadvantages, especially among the lower members, are inherent in both these methods (particularly the necessity for pressure apparatus or very high stirring speeds).

The use of esters other than the halides as alkylating agents also has been proposed. Among these esters are the alkyl chlorocarbonates,[3] ethyl toluene-*p*-sulfonate,[4] trialkyl or triaralkyl borates[5] and the esters of aliphatic acids such as ethyl acetate or ethyl valerate.[6] An apparent exception to this mode of behavior exists in the case of ethyl nitrate, which acts as a nitrating agent rather than an alkylating agent.[7]

The purpose of this investigation was to observe whether the alkyl esters of sulfuric, orthosilicic and carbonic acids were active in this type of synthesis. As was anticipated, these substances proved to be efficient alkylating agents. The conditions which influenced the yield of mono-alkylated benzenes were also observed, such as concentrations of reagents, duration of heating and reaction time.

It is probable that many other esters (such as the sulfites, phosphates, acid sulfates, etc.) can undergo this type of condensation. The exceptional case of the nitrate may likewise become normal under different experimental conditions. This generalization is in harmony with the observation of Slanina, Sowa and Nieuwland[8] that acidic substances promote the olefin–benzene condensation in the presence of boron fluoride, this probably occurring through the formation of alkyl esters.

In the present investigation it has been shown that dimethyl, diethyl, diisopropyl and dibutyl sulfates, tetraethyl orthosilicate and diethyl carbonate will condense with benzene in the presence of aluminum chloride. These reactions may be summarized by equations

$$3(RO)_2SO_2 + 6C_6H_6 + 2AlCl_3 \longrightarrow 6C_6H_5R + 6HCl + Al_2(SO_4)_3$$

$$3(RO)_2CO + 6C_6H_6 + 2AlCl_3 \longrightarrow 6C_6H_5R + 6HCl + Al_2(CO_3)_3$$

$$3(RO)_4Si + 12C_6H_6 + 4AlCl_3 \longrightarrow 12C_6H_5R + 12HCl + Al_4(SiO_4)_3$$

Experimental

The apparatus employed for the alkylations was the usual one-liter three-necked flask, into one neck of which extended a dropping funnel and thermometer. The cen-

tral neck was fitted with a glass stopper and mercury seal, through which extended a motor-driven glass stirrer. The third neck was connected to a modified Hopkins-type reflux condenser. This condenser could be cooled by water in the usual way, or it could be packed with solid carbon dioxide. This latter procedure was employed when methyl or ethyl esters were the reactants.

The aluminum chloride used throughout was of 99.5% purity. The benzene was dried over sodium and distilled at 80–81°. The various esters were purified by vacuum distillation before use.

Diethyl Sulfate.—The experiment which gave the highest yield of ethylbenzene from diethyl sulfate is described below (IIA).

Benzene (574 g.) was stirred (1000 r. p. m.) with aluminum chloride (96 g., 0.72 mole), and cooled in an ice-bath. Diethyl sulfate (77 g., 0.5 mole) mixed with 50 g. of benzene (making a total of eight moles) was then added during four hours. The ice-bath was removed an hour later, and the mixture warmed slowly. After five and one-half hours the temperature had reached 70°, where it was maintained for two more hours. After cooling for one-half hour the product was poured over cracked ice. The total reaction time was thus thirteen hours, during the whole of which the reflux condenser was cooled by packing with solid carbon dioxide.

The benzene layer, when hydrolysis of the aluminum chloride was complete, was washed with dilute sulfuric acid, aqueous sodium bicarbonate and water. It was then dried over calcium chloride for one day.

The dried benzene layer was then fractionally distilled, and yielded 75.7 g. of ethylbenzene, boiling at 133–137°. Three and one-half grams of a product boiling in the diethylbenzene range (175–185°), and four grams of residue were also obtained. Calculation of the theoretical yields was made on the assumption that all alkyl groups in the various esters were active. On this basis 0.5 mole of diethyl sulfate should form 1.0 mole of ethylbenzene (106 g.). The above yield of 75.7 g. is thus 71.4% of the theoretical.

The effects of variation in aluminum chloride concentration are summarized in Table I. Comparison of IA with IB shows that low concentrations of aluminum chloride result in incomplete reaction. Comparison of IIA with IIB, on the other hand, shows that excessive amounts of aluminum chloride also cause a reduction in yield of ethylbenzene; the yield of higher-boiling products is correspondingly increased. The amount of aluminum chloride employed in IB and IIA is 2.2 times the stoichiometrical quantity required by the above equation.

TABLE I

DIETHYL SULFATE—EFFECT OF $AlCl_3$ CONCENTRATION

No.	Diethyl sulfate, g.	$AlCl_3$, g.	Benzene, g.	Molar ratio of $AlCl_3$ to diethyl sulfate	Ethylbenzene (133–137°) % yield	Diethylbenzenes (175–185°) % yield	Residue, g.
IA	38.5	24	312	0.72	36.5	21	3.5
IB	38.5	48	312	1.44	62.5	21	1.5
IIA	77	96	624	1.44	71.4	5	4.0
IIB	77	146	624	2.20	31.6	12	12.0

The effects of variation in temperature were studied in a series of experiments summarized in Table II. Best yields were obtained by conducting the reaction for the first few hours at low temperatures, and then heating for a short time (IIIA). Heating at 50 or 70° for the entire experiment gave much reduced yields of ethylbenzene (IIIB, IIIC).

TABLE II

DIETHYL SULFATE—EFFECT OF HEATING

Diethyl sulfate, 38.5 g.; $AlCl_3$, 48 g.; benzene, 312 g.

No.	Time at 10°, hours	Time at higher temp., hours	Higher temp., °C.	Ethylbenzene (133–137°) % yield	Diethylbenzenes (175–185°) % yield	Residue, g.
IIIA	5	1	70	66.5	18	2.5
IIIB	0	5.5	50	40.5	6	3.0
IIIC	0	5.5	70	36.7	6	4.5

The addition of calcium carbonate to react with hydrochloric acid had very little effect on the reaction. When 100 g. of calcium carbonate, 96 g. of aluminum chloride, 77 g. of diethyl sulfate and 624 g. of benzene reacted under the usual conditions (similar to IIIA, Table II), the yield of ethylbenzene was still 63.7%. Even when 1 g. of water and 1 g. of concentrated ammonium hydroxide were also added, the yield was 64.2%. This is surprising in view of the usual sensitivity of Friedel–Crafts reactions to moisture.

Dimethyl Sulfate.—Benzene (624 g., 8 moles) was stirred (1000 r. p. m.) with $AlCl_3$ (48 g., 0.36 mole) for one hour. Dimethyl sulfate (31.5 g., 0.25 mole) was then added during a two-hour period. The flask was kept at 25° during this addition, and for three hours longer. The temperature was raised to 70° during the course of one hour and maintained at that temperature for another hour. During the entire experiment the reflux condenser was cooled with solid carbon dioxide. The mixture was hydrolyzed with cracked ice. The benzene layer was separated, washed with aqueous sodium bicarbonate and water and then dried over calcium chloride for twelve hours. Fractional distillation of the product through a 66-cm. Young column gave 27.5 g. of toluene (108–113°), 3 g. in the xylene range (135–145°) and 1.5 g. of residue. The yield of toluene was thus 59.8%, based on both methyl groups of dimethyl sulfate.

Other reactions in which dimethyl sulfate was employed confirmed the result of the diethyl sulfate reactions where aluminum chloride concentration was concerned. The best yields were obtained with a ratio of aluminum chloride to ester of 1.44 to 1. Small variations in the neighborhood of this value were not attempted.

Dimethyl sulfate was very slowly reactive below 20°.

Diisopropyl Sulfate.—This ester was prepared by the reaction of isopropyl alcohol with sulfuryl chloride.[9] Levaillant reports 34% yield by this method, but by allowing the crude carbon tetrachloride solution to stand for two to three days (until the cloudiness disappeared) a yield of 48.6% was obtained. The product distilling at 74–80° under 3–4 mm. was employed.

The usual procedure as described above was effective except that it was necessary to reflux the crude product with aqueous sodium bicarbonate before washing. The ester reacted freely at 0°. The reaction between 91 g. (0.5 mole) of diisopropyl sulfate, 96 g. (0.72 mole) of alu-

---

(9) Levaillant, *Compt. rend.*, **188**, 261 (1929).

minum chloride and 624 g. (8.0 moles) of benzene, gave 53.0 g. of isopropylbenzene (44.2%) boiling at 148–152°. Twenty-five grams of higher-boiling products was obtained.

Dibutyl Sulfate.—This ester was prepared by the method of Barkenbus and Owen[10] in 64% yield (b. p. 110–118° at 4–6 mm.).

Thirty-five grams (0.17 mole) of the dibutyl sulfate so prepared was treated in the usual way with 208 g. (2.67 moles) of benzene and 32 g. (0.24 mole) of aluminum chloride, except that heating was omitted. The reaction was conducted for six hours in an ice-bath, and then for fifteen hours at 30°. Stirring was continued at 1000 r. p. m. The product contained a bright cherry-red lower layer. After hydrolysis, refluxing with sodium bicarbonate, washing and drying, the entire mixture was fractionally distilled, yielding the following products: 165–175°, 19.5 g. (43.6% calculated as isomeric butylbenzenes); 175–185°, 5.5 g.; higher boiling products, 2.0 g.

Tetraethyl Orthosilicate.—Best yields of ethylbenzene were obtained when the ratio of aluminum chloride to tetraethyl orthosilicate was 2.88 moles to one. When 52 g. (0.25 mole) of the ester was treated with 624 g. of benzene and 96 g. of aluminum chloride, 56.5 g. of ethylbenzene (133–137°) was obtained (53.3% based on all ethyl groups of tetraethyl orthosilicate). The reaction was conducted for sixteen hours at 25° (reaction being slow at lower temperatures); the temperature was raised during five and one-half hours to 70°, and maintained there for four hours. Hydrolysis and fractionation were accomplished in the usual way, as with diethyl sulfate.

Diethyl Carbonate.—Fifty-nine grams of diethyl carbonate (0.5 mole), 96 g. of aluminum chloride (0.72 mole) and 624 g. of benzene (8.0 moles) were treated as described above for twenty-six hours at 25° and three hours at 70° (four hours were consumed in gradually raising the temperature from 25 to 70°). The reaction was slow at temperatures below 25°. After hydrolysis, washing, drying and fractionation as with diethyl sulfate, 59.8 g. of ethylbenzene (133–137°) or 56.4%, and 19.5 g. of higher boiling products were obtained.

Naphthalene.—Several experiments in which naphthalene reacted with diethyl sulfate in the presence of aluminum chloride and a solvent gave a product boiling in the ethylnaphthalene range, from which no pure compound could be isolated. The solvents used were carbon disulfide and *o*-dichlorobenzene.

In one experiment 128 g. of naphthalene (1.0 mole), 441 g. of *o*-dichlorobenzene (3.0 moles) and 77 g. of diethyl sulfate (0.5 mole) were stirred at 1000 r. p. m. for one hour. Then 147 g. of aluminum chloride (1.1 moles) was added in small portions during twenty-five and one-half hours. The temperature of an ice and salt bath was maintained at 0 ± 2° for the first fourteen and the last three hours, being permitted to warm up to 25° for the intervening time. Stirring was continued throughout the experiment. The black product was hydrolyzed and washed in the way described in the benzene experiments, and was then steam-distilled. The oil layer was separated, dried and fractionally distilled. Thirty-five grams of a hydrocarbon oil boiling at 240–270° was obtained along with 10 g. of higher boiling products. Redistillation of the 240–270° fraction gave 25 g. of a product boiling at 245–255°. β-Ethylnaphthalene boils at 251°, α-ethylnaphthalene at 258–259° corrected.

Flow Method.—An apparatus was devised in which the liquid reactants (benzene and diethyl sulfate, for example) could be made to flow over the aluminum chloride, contained in a long, narrow, inclined tube. The best yield obtained by this method was 25.7% of ethylbenzene.

Action of Aluminum Chloride on Alkyl Esters.—Aluminum chloride has been shown to react with tetraethyl orthosilicate in the absence of a solvent, the products being ethyl chloride and ether.[11] Dimethyl sulfate reacts with stannic chloride, forming methyl chloride and other products, also in the absence of a solvent.[12] To determine whether the course of these reactions would be altered at the dilutions employed in the alkylations described above, the following experiments were conducted.

38.5 g. of diethyl sulfate was treated with 48 g. of aluminum chloride in 300 g. of 90–100° olefin-free ligroin. The temperature was kept at 10–50°. The volatile products were condensed with solid carbon dioxide. Five grams of a product not ethyl chloride was obtained. Repetition of this experiment using 29.5 g. of diethyl carbonate in place of the sulfate, at temperatures below 50°, also gave 3 g. of a product, but no ethyl chloride.

That reaction of some kind did occur was evident from the fact that the aluminum chloride became gelatinous as the addition of ester proceeded. It is possible that the ligroin was not inactive, as had been supposed. Recent evidence shows that paraffin hydrocarbons are not inert in the presence of aluminum chloride, zirconium chloride and boron fluoride.[13]

Summary

1. The use of esters as alkylating agents in the Friedel–Crafts syntheses has been extended to include a number of new examples.

2. The best yields of mono-alkylated benzene obtained with the following esters were: dimethyl sulfate, 59.8%; diethyl sulfate, 71.4%; diisopropyl sulfate, 44.2%; dibutyl sulfate, 43.6%; tetraethyl orthosilicate, 53.3%; and diethyl carbonate, 56.4%.

3. The general conditions affecting the yield, such as reaction time, temperature and proportions of reagents have been studied. The best ratio of aluminum chloride to ester was 1.44 moles to one, except in the case of the silicate, where it was 2.88 to one.

4. Attempts to alkylate naphthalene with diethyl sulfate led to hydrocarbon oils which could not be fractionated into separate ethylated naphthalenes.

5. Attempts to use a flow method with diethyl sulfate gave much reduced yields.

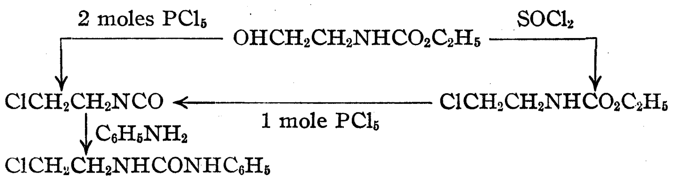
Syntheses from Ethanolamine. III. Synthesis of N-β-Chloroethyl Urethan and of β-Chloroethyl Isocyanate

BY HENRY WENKER

In extending a study of syntheses from enthanolamine, it has been found that N-β-oxyethyl urethan reacts with thionyl chloride to form N-β-chloroethyl urethan. Under the influence of phosphorus pentachloride, the latter compound yields β-chloroethyl isocyanate, which can also be prepared directly from the oxyurethan by using 2 moles of phosphorus pentachloride. The constitution of the isocyanate was confirmed by the preparation of the respective α-aryl-β-(β-chloroethyl) ureas from aniline and from *p*-phenetidine. The reactions involved are expressed by the formulas



Both compounds have not been described hitherto; their use for further syntheses is now being investigated.

Experimental

N-β-Chloroethyl Urethan.—One hundred and forty-three grams of thionyl chloride is added gradually to 133 g. of N-β-oxyethyl urethan. The reaction is finished by short heating on the water-bath and the product distilled *in vacuo*. With the exception of a small residue, all distilled from 128–130° at 13 mm. The yield was 138 g. or 91%.

Anal. Calcd. for $C_5H_{10}O_2NCl$: N, 9.3; Cl, 23.4. Found: N, 9.1; Cl, 23.2.

N-β-Chloroethyl urethan is a colorless, fairly mobile liquid possessing a slightly pungent odor. It dissolves readily in ethanol and ether, but not in water.

β-Chloroethyl Isocyanate.—Preparation from N-β-oxyethyl urethan: 133 g. of the urethan is dropped, under external cooling, on 420 g. of phosphorus pentachloride contained in a 2-liter flask. About one-half of the pentachloride remains undissolved, but heating on the water-bath soon produces a clear homogeneous solution. The product is then distilled very slowly, using an efficient fractionating column. Even so, there is a considerable intermediate fraction, until finally the pure isocyanate distils at 135°. The yield was 52 g. or 49%.

Anal. Calcd. for C_3H_4ONCl: N, 13.3; Cl, 33.6. Found: N, 13.0; Cl, 33.4.

The preparation from N-β-chloroethyl urethan is identical, except that for one mole of the urethan, or 151 g., one mole of pentachloride or 210 g. is used. The yield is the same as above.

β-Chloroethyl isocyanate is a colorless, mobile liquid, heavier than water and rapidly decomposed by it under evolution of carbon dioxide. The resulting solution is clear with silver nitrate, but on standing becomes cloudy. The isocyanate has an unpleasant odor and its vapor is very irritating on the eyes.

Ten and one-half grams of isocyanate was added to 9.3 g. of aniline dissolved in 50 ml. of ether. The solution boiled up spontaneously and a sludge of white crystals was formed. Crystallized from dilute ethanol, the product melted at 124°; the literature[1] gives 124° for α-phenyl-β-(β-chloroethyl) urea.

The isocyanate reacts similarly with *p*-phenetidine; the urea melts at 149°. It forms fine white crystals of silky luster.

Anal. Calcd. for $C_{11}H_{15}O_2N_2Cl$: N, 11.5; Cl, 17.9. Found: N, 11.2; Cl, 17.9.

Phosphorus pentoxide, which has been used successfully[2] for the preparation of phenyl isocyanate from phenyl urethan instead of the pentachloride,[3] was found to be unsuitable for the purpose of converting N-β-chloroethyl urethan into the isocyanate; upon heating decomposition with evolution of hydrogen chloride occurred.

Summary

N-β-Oxyethyl urethan reacts with thionyl chloride to form N-β-chloroethyl urethan; both urethans, the former with 2 moles, the latter with 1 mole of phosphorus pentachloride, yield β-chloroethyl isocyanate.

The Calcium Binding Power of Egg Albumin

BY JULIUS C. ABELS

Since Rona and Takahashi[1] demonstrated that the calcium in protein systems is for the most part non-ionic, the manner by which this calcium is bound has aroused much study. The modes of linkage which at first present themselves are through one or more of the common free groups of the protein molecule: probably the amino, carboxyl, aliphatic or phenyl hydroxyl. We therefore thought it of interest to make protein preparations which lack one or more of these functional groups and then to note their calcium binding power. We have not been able to block the carboxyl, but in view of the results obtained (see below) we did not feel that this was necessary.

Experimental

A. Preparations.—1. Crystalline egg albumin was prepared by the method of Kekwick and Cannan.[2] This was recrystallized three times, and was used as the parent material for the other preparations as well.

2. Deaminized egg albumin was made in the usual way with nitrous acid at 20° in very dilute solution in order to avoid premature precipitation. This was then dialyzed in cellophane bags against running tap water and distilled water, and left in the ice chest overnight, during which time a slight precipitate formed; this was dissolved by adjusting the *p*H of the solution to 8.4 and finally by the addition of hydrochloric acid the *p*H was lowered to 7.8. This protein solution was concentrated by ultrafiltration. Amino nitrogen (gasometric Van Slyke) on five such preparations showed that complete deamination had been accomplished.

3. Five separate preparations of acetylated albumin were made by the method of Freudenberg.[3] Ether-extracted albumin was dried and finely suspended in a mixture of equal volumes of glacial acetic acid and quinoline, and to this acetic anhydride and quinoline were added slowly at 5°, the *p*H of the system being kept at about 6.5. Aliquots were precipitated daily with 4 volumes of ether, filtered, washed with slightly acidified water, and suspended in water at *p*H 5.0. This was dialyzed overnight against running tap water and then distilled water with constant mechanical agitation; and finally dissolved in water at *p*H 8.2. Acetyl determinations were made on these solutions by the method of Herriott,[4] and when a constant value of 28 acetyl groups per molecule of albumin (molecular weight 34,500) had been obtained on the aliquots of three successive days, the main mass of the preparation was treated similarly and concentrated by ultrafiltration.

4. Gelatin, also employed in this study, was Eastman Kodak purified product. This, as well as the other proteins used, was calcium free.

B. Methods.—The method employed in determining the bound calcium was essentially that of R. Loeb[5] in his study of the effect of proteins on the diffusibility of the calcium ion. Ten to twenty cc. of protein solution was placed in a cellophane bag, and a rubber stopper was fitted into the filled bag to avoid subsequent dilution. The sac was then suspended in a large volume (300–400 cc.) of 0.80% sodium chloride brought to *p*H 7.6 with sodium bicarbonate and sodium carbonate, and to this latter solution was added calcium chloride in amounts from 1.0 to 12.0 mml./liter. The use of the sodium chloride in this instance serves to reduce the Donnan equilibrium. These systems were set aside for thirty hours at 20° (at 30° in the case of the gelatin experiments), after which time samples were withdrawn from both the protein solution and dialysate for calcium[6] and chloride[7] determinations.

Results

The results are perhaps best stated in a table of typical experiments.

The table is for the most part self-explanatory. From the amount of calcium in the dialysate (column 2) and from the ratio of chloride in dialysate to chloride in protein solution (3), the amount of calcium in the protein solution due to the Donnan effect may be calculated (4). When this value is subtracted from the observed amount of calcium in the protein solution (1), the remainder is that bound to some free group or groups of the protein molecule.

Discussion

The following points which Loeb[5] has noted for egg albumin have been confirmed: that on the alkaline side of its isoelectric point there is always a binding of calcium, and as the protein concentration is increased the total amount of bound calcium is increased. The same has also been noted for gelatin. The values found for groups of calcium to egg albumin molecule (about 1:1) agree fundamentally with those noted by other workers using serum proteins and serum.[8,9]

It is apparent immediately that the calcium is not bound through a carbamino linkage, for, if

[a] 34,500 was chosen arbitrarily as the molecular weight of gelatin to provide comparison with the ratios obtained for the egg albumin.

this were so, deamination of the albumin should result in a decrease of bound calcium instead of in an increase. These higher ratios might be interpreted as being due to (a) an increased calcium binding power of the protein resulting from the splitting of the chain in the course of deamination; (b) the substitution of functional hydroxyl groups for the amino, which is the result of a deamination in aqueous solutions; or (c) to both.

The substitution of hydroxyl groups was tested by using the acetylated albumin. Such experiments show that these proteins no longer have the calcium linkage; and since the acetylation has blocked the amino and hydroxyl groups, and not the carboxyls, we may conclude that the functional group is very probably the hydroxyl. This is further shown by the restoration of the calcium binding power of the protein when the acetyl groups are removed by treating the protein solution with alkali to *p*H 11.0, for two minutes, bringing back to *p*H 8.2, and removing the acetate by dialysis. That the hydroxyl group is not necessarily a phenolic one is seen from the fact that gelatin, with no phenyl groups, binds calcium to the same extent as does albumin. It would be interesting, however, to determine whether or not the phenolic radical plays any role; this might be done by correlating tyrosine values of partially acetylated proteins with their ability to bind calcium.

Summary

A study of protein derivatives seems to indicate that calcium is bound to albumin through an hydroxyl linkage.

The Spontaneous Stable Formation of Colloids from Crystals or from True Solution through the Presence of a Protective Colloid[1]

By J. W. McBain and M. E. Laing McBain

The subject of colloids has suffered greatly from the commonly accepted stigma that colloidal systems are inherently unstable and that they therefore show the effects of every chance incident in the history of each individual specimen. This discouraging view has probably arisen from the older habit of regarding colloids merely as fine dispersions without mention of any factor that should hold them in so unlikely a condition, much less cause them, when disturbed or destroyed, to revert spontaneously to that former state.

In 1926[2] one of us presented the argument that certain colloidal solutions, such as those of soap, must be regarded as stable in the strictest thermodynamic sense, because they exist in equilibrium with crystalloidal constituents and crystals, and hence must be as stable as these. This has been accepted by many leading colloid authori-

---

ties, such as Freundlich and von Weimarn, who agree that a large group of important colloids are as stably formed as ordinary solutions.

However, even now in 1936, according to von Buzágh's "Kolloidik,"[3] "eine sehr allgemein verbreitete Anschauung" is that colloidal sols cannot be stable.

Our explanation of true stability of a colloidal particle demands a spontaneous orientation of the molecules, with the soluble groups exposed to the solvent, such that the particle is self organizing and if disturbed would revert again to this equilibrium form. Thus soap solutions come to true reversible equilibrium and exhibit properties which become fully independent of their previous history just like any solution of sugar or salt.

In 1917 Pickering[4] stated that oils could dissolve in concentrated soap systems, as well as forming emulsions therein. However, his proof of this clear claim was doubtful, because he did not dissolve the oils directly but formed his systems by very indirect methods involving concentrated pastes of semi-solid soap and also mechanical working. Hence, his results were not definitely differentiated from those of von Weimarn who had specialized in producing admittedly unstable colloids by indirect methods.

In 1918 and 1921 McBain, Beedle, and Bolam[5] made the obvious suggestion that a water-soluble substance could be sorbed by a soap particle in aqueous solution. In 1932 Lester Smith, in a series of important and significant papers,[6] showed that the solubility of various liquids was much increased by the presence of 10% of soap, and, like Weichherz in 1929, he suggested that the increase was sorbed upon the soap micelles, possibly displacing water of hydration. The results depended upon the procedure and did not strictly demonstrate the existence of any true reversible equilibrium.

In Smith's second paper of 1932 he used a water-insoluble indicator dye, methyl yellow (0.32 part in 10^7 water), but (p. 1673) he first dissolved it in ether along with free fatty acids, and afterward produced soap by adding aqueous alkali and more ether (and usually methyl alcohol). This procedure too closely resembles von Weimarn's technique of forming unstable colloids *in situ* to carry any conviction as to the spontaneous formation of an inherently stable protected colloid.

We now make the definite suggestion that colloidal particles may be spontaneously and reversibly formed in solvents in which they are insoluble, provided that a suitable protective colloid is present to act as solubilizing or stable protective agent. For example, a true crystal insoluble in water can spontaneously pass into water containing a suitable stable colloid, and form colloidal particles in association with the stabilizing colloid.

Thus crystals of oil-soluble dyes, such as Yellow AB, Yellow OB, and Scarlet 9995X, pass directly into a 1% aqueous soap solution. Not only so, but such dilute soap solution will extract these dyes even from unsaturated solutions in kerosene, medicinal paraffin oil, paraffin wax, or benzene, etc. Conversely, equilibrium may be attained from the opposite direction, since each of these non-aqueous solvents will extract from the dye-containing soap solution a proportion of dye. Thus the two liquid layers, one a true solution, and the other a protected colloidal solution (incapable of existing without such protection) come into complete reversible equilibrium, the position of equilibrium being the same when approached from either side.

Therefore, we must conclude that a molecule in a crystalline space lattice or a molecule in true solution, saturated or unsaturated, is no more stable than a molecule in a colloidal particle suitably stabilized. The stabilizing force is that of adsorption within the particles of stabilizing colloids; in some extreme cases it may be direct chemical combination.

It appears likely that the colloidal particle is surrounded by the stable colloid rather than that according to the other extreme form of the previous suggestion of McBain and of Lester Smith the insoluble material coats the stable soluble colloid. Gurwitsch[7] likewise in showing that the amounts of oil which could be incorporated in soap solutions without turbidity were parallel to the known ease and extent of association of the soap molecules, had assumed that the oil molecules formed thick coatings around the soap micelles and made the micelles hydrophobic (that is, unstable).

Brintzinger and Beier[8] systematically studied the increase in solubility of a series of acids and bases in the presence of gelatine and of gum arabic in concentrations ranging from 0.5 to 6.0%. In most cases there was a marked increase in solubility, less in the case of gum arabic. In a few cases there was no effect and the solubility of anthranilic acid was actually lowered by the gum arabic. The authors considered that chemical combination, solution in and adsorption by the colloidal particles might all be involved. They also mentioned that urea is more soluble in blood or protein-containing liquids than in pure water. Similarly, in the well-known studies by Findlay and collaborators (1911–1914) the solubility of gases in water was sometimes increased and sometimes diminished by various colloids and mechanical suspensions.

To explain the continued existence of colloids requires some affinity between the solvent and the groups exposed on the outside of the particle. These groups may be supplied by part of the molecule of a stable colloid itself or by a sufficient amount of such exposed soluble groups supplied by a stable protective colloid.

Experimental

Experiments have been carried out both with commercial soap and sodium oleate, mostly 1% dissolved in water, but occasionally 0.5%. The non-aqueous phase has been benzene, toluene, kerosene, Nujol, xylene, soft paraffin wax, etc. Most of the experiments have been semi-quantitative, in addition to the significant qualitative observations mentioned in the text. A study of the partition coefficient in its dependence on concentration of dye and of stabilizing colloid is reserved for a later communication with T. M. Woo. Concentration of dye was determined colorimetrically against a reference solution of dichromate. For example, in four experiments the total system consisted of 40 g. of water, 2 g. of toluene, 0.4 g. of sodium oleate, and 0.001 g. of scarlet X; in two cases the dye was first dissolved in the toluene, and in the other two it was admixed with the aqueous soap. Thereupon, the two layers were brought into contact and placed upon a machine which imparted to the system an extremely slow swirling motion that avoided all breaking of the surface or emulsification. After twenty-four hours the colorimeter readings were 1.34, 1.3, 1.8 and 1.6, respectively, showing that within the somewhat large experimental error the same equilibrium was obtained from both sides. A typical result may be quoted from Mr. Woo's data for the system 0.5% potassium oleate, 40 g. of water, 0.04 *N* potassium hydroxide, 2 g. of toluene, and 0.1 g. of dye—the latter placed in two cases in the toluene and in two in the aqueous soap; the dye remaining in the soap layer after forty-eight hours was 0.0232, 0.0232 and 0.0237, 0.0237 g., respectively.

To avoid misunderstanding, it should be emphasized clearly that the processes pointed out above are different in kind from the familiar phenomena of peptization or of protective action on suspensions such as carbon black suspended in soap solution, or silver chloride in gelatine, or the peptizing of a gel to form a sol. In all cases of peptization it has been assumed that the peptizing agent merely separated already existing particles. Similarly, formation of ordinary (protected) colloid particles by the so-called condensation methods, whether physical or chemical, generate the colloid *in situ* from a high state of supersaturation. It is clear that both these processes differ from the extraction of a molecule from its stable space lattice or its unsaturated solution to create stable colloidal particles.

Likewise the processes here described differ from hydrotropy[9] where in general protective colloids are not involved. Doubtless however many examples there described may belong here, and in many cases the same forces, whether van der Waals or chemical, may be operative.

It is evident that if our conclusions are accepted there must already exist numerous unrecognized examples of such action. Many protected colloids containing a sufficient amount of truly stable protective agent may contain much more stable material than has hitherto been suspected.

Summary

Not only are many important colloids truly stable in that they form spontaneously and enter into reversible equilibrium with crystalloidal constituents and crystals, but otherwise unstable colloids may also exhibit similar properties characteristic of true stability if sufficient stable protective colloid is present.

The Resistance and Capacity Behavior of Strong Electrolytes in Dilute Aqueous Solution.[1] I. Method for the Simultaneous Observation of Conductance and Dielectric Constant at High Radio Frequencies

BY ORLAN M. ARNOLD AND JOHN WARREN WILLIAMS

The interionic attraction theory has been utilized by Debye and Hückel[2] and by Onsager[3] to demonstrate that a square root law is the correct one to explain the change in the electrical conductance of very dilute solutions of strong electrolytes with concentration. In such systems variations in the mobilities rather than in the number of the ions are responsible for the observed conductance changes. At the time Debye and Hückel first proposed their conductivity theory Sand[4] realized that if changes in the mobilities of the ions were caused by electrostatic forces, then measurements at very high frequencies and at very high field strengths should lead to enhanced conductances since in either event the effect of such forces would be reduced. At the present writing the existence of such increased conductances under these conditions has been established experimentally and elaborate theories have been worked out to describe them. The experiments to be discussed in the following article were designed to test further the validity of the theory of Debye and Falkenhagen[5] which describes the frequency variation of conductance in dilute solutions of strong electrolytes.

The ordinary bridge methods such as are used for the determination of resistance and capacity at audio frequencies are not generally satisfactory at the lower radio frequencies and they fail entirely when observations at the higher radio frequencies are required. At such high frequencies the standard resistance coils react inductively and capacitatively, changes in the position of the contact on a slide wire produce changes in the ratio of such inductances and capacities in an unknown way, and the arrangement and length of the lead wires can give rise to uncertainties. From time to time there have been proposed methods, making possible the observation of conductance and/or capacity change at the radio frequencies.[6-10] The method finally adopted by us resembled that of Sack and his collaborators, but it differed in so many important respects that we feel it necessary to devote this first article to a brief description of the apparatus itself and the theory upon which its use is based. This comparator-resonance method made possible the simultaneous observation of resistance and capacity change with frequency, at the same time it was flexible as regards frequency change. It did not permit absolute measurements to be made, but it did accomplish a comparison of conductance and dielectric constant of two solutions, a standard and an unknown.

Description of Apparatus

A schematic diagram of the apparatus is given in Fig. 1. As indicated, there are three distinct circuits, a generator, (I); an intermediate circuit (II); and a comparator circuit, (III). In use all parts of this apparatus were clamped in fixed position on a firm table.

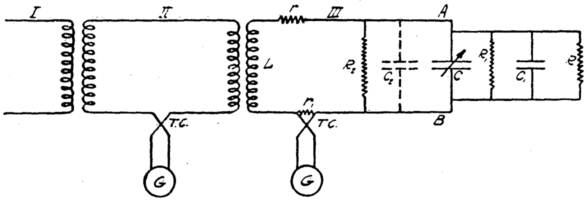

Fig. 1.—Schematic diagram of high frequency apparatus: L, inductance in the measuring circuit; C, capacitance of the variable precision condenser; R, resistance of the solution in the cell; R_1, resistance of the insulation of the precision condenser; R_2, resistance of the insulation of other parts of circuit; r, resistance of the leads in the measuring circuit; r_1 resistance of the heater in the thermocouple; C_1, capacitance of the measuring cell; C_2, capacitance between leads in the circuit; G, galvanometer; T. C., thermocouple.

A modified Hartley circuit, using an 01A tube, was found to be a satisfactory source of alternating current. In order to obtain uniform power output, good wave form and constant frequency at the high radio frequencies, it was

necessary to adjust inductance and capacity to one another, to adjust a variable grid leak resistance, and to maintain constant filament and plate supply. The wave length range used in the experiments was approximately 10 to 180 meters.

The intermediate circuit connected the generator with the comparator circuit. It consisted of two plug-in variable coupling coils and sensitive thermocouple connected in series. The indicating instrument used with the thermocouple was a Rawson multimeter. This intermediate circuit was not tuned to the oscillator for several reasons. First, too strong coupling, which causes unsteadiness of the power output and of the frequency in the oscillator and which results in greater fluctuation of current in the measuring circuit, may be thus avoided. Second, the disturbing effects due to the presence of harmonics are reduced. Third, greater possibility is afforded for more complete electrostatic shielding. The comparator circuit consisted of an inductance L, a thermocouple of high sensitivity (connected to a Leeds and Northrup Type R galvanometer), a precision condenser of low capacity C, a conductance cell C_1, or resistance R, connected as shown with very short leads. A beam of light reflected from the galvanometer mirror and focused on a curved scale of two meter radius and 4,140 divisions served to measure the energy in the circuit.

The thermocouples used were of the vacuum type, No. 22C, manufactured by the Western Electric Company. In each case they were placed directly in series with the circuit rather than in auxiliary detector circuits as is usually done. In a long series of experiments the ever present possibility of error due to slight mechanical displacement of primary and auxiliary circuits is thus avoided; in addition, the sensitivity of the current measurements is increased to the extent that very feeble currents can be used with success. The use of feeble currents is advantageous because heating effects in the conductance cells should be reduced as much as possible.

The shielding and grounding of the several circuits presented many difficulties and much attention was given to their solution. For the highest efficiency it was found necessary to shield separately the various parts of the apparatus. The generator, the thermocouples, the inductance of the comparator circuit with its coupling coil of the tank circuit and the precision condenser were enclosed in copper-lined boxes. An additional electrostatic shield was placed about the coupling coil of the intermediate circuit adjacent to the inductance of the comparator circuit in order to enhance the magnetic induction and reduce the electrostatic induction. Those parts of the circuits which were grounded were connected to a metal rod sunk in moist earth exterior to the building proper. All alternating current lines connected to single phase motors in the immediate vicinity of the apparatus were grounded or choked.

Theory of the Circuit and Measurements

The method of interpretation of precision condenser readings in terms of the dielectric constants of the solutions may be described as follows: For pure capacities connected as shown in Fig. 1, $\bar{C} = C' + C_1 + C_2$, when the cell is connected in parallel, and $\bar{C} = C'' + C_2$, when the cell is disconnected. Here C' and C'' are the precision condenser settings for the two observations and $\bar{C}$ is the total capacity of the circuit. It is further evident that $C'' - C' = C_1$. When dilute electrolyte solutions are introduced into the cells, the situation becomes much more complicated. Nevertheless, one may compare with reasonable correctness the susceptibilities of two solutions of the same electrical conductance, provided the latter is not too great, by making observations of the changes in the apparent capacity C_{1A}, defined as $C''_A - C'_A$. Thus, differences in C_{1A}, from solution to solution, using the same cell in identical position at the same wave length may be interpreted directly in terms of dielectric constant change when reference is made to the behavior of a standard solution of known dielectric constant and like electrical conductance. The capacity C_2 is small enough so that $\bar{C}$ may be considered equal to C'' when the cell is disconnected from the circuit.

Both galvanometer deflections and precision condenser settings are made use of for the evaluation of the conductances of the solutions. The mathematical treatment of the comparator circuit for the conductance problem is complicated. There will be considered a definition of the total impedance of the circuit and a definition of the impedance from point A to point B in the circuit; then there will be described the two specific cases, one in which the conductance cell or other resistance is removed from the circuit, and the other in which the cell or resistance is connected in the circuit. In all these considerations the resistance R_2 has been neglected, since $R_2 >> R$. In the equations I is the current in the comparator circuit, I' is the current in the intermediate circuit, E is the voltage in the comparator circuit, Z designates an impedance, D is a galvanometer deflection and k is a proportionality constant.

Definition of Total Impedance of Circuit.—We may begin our consideration with the following relations

$$kD = I^2$$

$$\bar{r} = r + r_1$$

$$z_1 = \bar{R}_0 + j\bar{X}_0$$

In these equations z_1, $\bar{R}_0$ and $\bar{X}_0$ symbolize total impedance, resistance and reactances from A to B, respectively. Now, by definition

$$(j\omega L + \bar{r} + z_1)I + j\omega MI' = 0 \qquad (1)$$

After substituting for z_1, rearranging the real and the imaginary terms, squaring and substituting E for MI', one obtains for the current I the expression

$$|I| = \frac{E}{\sqrt{(\bar{r} + \bar{R}_0)^2 + (\omega L + \bar{X}_0)^2}} = \frac{E}{z_T} \qquad (2)$$

in which z_T is the total impedance.

The current I is the root mean square of the current amplitude. Since one is concerned with the current amplitude only, the phase angle may be neglected.

From equation (2) the total impedance may be expressed by the relationship

$$z_T^2 = (\bar{r} + \bar{R}_0)^2 + (\omega L + \bar{X}_0)^2$$

The total impedance is treated in the form of its square since it eliminates the square root term, and since the galvanometer deflection expresses the square of the current.

By further definition

$$\bar{X}_0 = \omega L_1 - (1/\omega\bar{C}_0)$$

where L_1 is the inductance and $\bar{C}_0$ is the total capacity, both across AB. Since L_1 is nearly if not exactly zero, the reactance for the part of the circuit from A to B may be expressed as $\bar{X}_0 = -1/\omega\bar{C}_0$. Thus, the expression for the total impedance of the circuit becomes

$$z_T^2 = (\bar{r} + \bar{R}_0)^2 + (\omega L - (1/\omega\bar{C}_0))^2 \qquad (3)$$

Definition of Impedance from A to B.—The quantities $\bar{R}_0$ and $\bar{C}_0$ must be determined for substitution in equation (3).

The admittance, Y, from A to B may be written

$$Y = \frac{1}{\bar{R}} + j\omega\bar{C} = \frac{1 + j\omega\overline{CR}}{\bar{R}}$$

or

$$\bar{z}_1 = \frac{\bar{R}}{1 + j\omega\overline{RC}} = \frac{\bar{R}(1 - j\omega\overline{CR})}{1 + \omega^2\bar{C}^2\bar{R}^2}$$

in which $\bar{R}$ represents R_1, R_2, and R in parallel, $\bar{C}$ is the effective capacity across AB, and $\bar{z}_1$ is the effective impedance, also across AB.

Rewriting the expression for $\bar{z}_1$, we have

$$\bar{z}_1 = \frac{\bar{R}}{1 + \omega^2\bar{C}^2\bar{R}^2} - \frac{j\omega\overline{CR}^2}{1 + \omega^2\bar{C}^2\bar{R}^2} = \bar{R}_0 + j\bar{X}_0 = \bar{R}_0 - \frac{j}{\omega\bar{C}_0}$$

The evaluation of $\bar{z}_1$ makes it possible to express z_T in terms of more readily accessible quantities. Since

$$R_0 = \frac{\bar{R}}{1 + \omega^2\bar{C}^2\bar{R}^2} \text{ and } \frac{1}{\omega\bar{C}_0} = \frac{\omega\overline{CR}^2}{1 + \omega^2\bar{C}^2\bar{R}^2}$$

substitution for $\bar{R}_0$ and $\dfrac{1}{\omega\bar{C}_0}$ in equation (3) gives

$$z_T^2 = \left(\bar{r} + \frac{\bar{R}}{1 + \omega^2\bar{C}^2\bar{R}^2}\right)^2 + \left(\omega L - \frac{\omega\overline{CR}^2}{1 + \omega^2\bar{C}^2\bar{R}^2}\right)^2 \qquad (4)$$

Case 1. Cell Not Connected.—In this case $\bar{R}_1$ is the only resistance to be considered for the evaluation of $\bar{R}$. Equation (4) becomes

$$z_{T_1}^2 = \left(\bar{r}_1 + \frac{R_1}{1 + \omega^2\bar{C}^2R_1^2}\right)^2 + \left(\omega L - \frac{\omega\bar{C}R_1^2}{1 + \omega^2\bar{C}^2R_1^2}\right)^2 \qquad (5)$$

The subscript 1 is used for the total impedance of the circuit when the conductance cell or other resistance is not connected across AB. Since R_1 is high in magnitude, equation (5) reduces to

$$z_{T_1}^2 = \bar{r}_1^2 + \omega^2L^2 - \frac{2L}{\bar{C}} + \frac{1}{\omega^2\bar{C}^2} = \bar{r}_1^2 + \left(\omega L - \frac{1}{\omega\bar{C}}\right)^2$$

At resonance $\omega L = \dfrac{1}{\omega\bar{C}}$, and the impedance becomes

$$z_{T_1}^2 = \bar{r}_1^2 \qquad (6)$$

Case 2. Cell Connected in Parallel with Precision Condenser.—The resistances contained in $\bar{R}$ appearing in equation (4) are now R and R_1. Since R_1 is large and may be neglected ($R_1 >> R$), the expression for the impedance assumes the form

$$z_{T_2}^2 = \left(\bar{r}_2 + \frac{R}{1 + \omega^2\bar{C}^2R^2}\right)^2 + \left(\omega L - \frac{\omega\bar{C}R^2}{1 + \omega^2\bar{C}^2R^2}\right)^2$$

The subscript 2 indicates that the cell or resistance is now connected in the comparator circuit If the quantity $\omega^2\bar{C}^2R^2$ is large compared to 1, the expression reduces, at resonance, to

$$z_{T_2}^2 = \left(\bar{r}_2 + \frac{R}{1 + \omega^2\bar{C}^2R^2}\right)^2 \qquad (7)$$

Relationship between Galvanometer Deflection and Electrical Conductance.—From Ohm's law

$$I_1^2z_{T_1}^2 = E_1^2 \text{ and } I_2^2z_{T_2}^2 = E_2^2$$

Therefore

$$I_1^2z_{T_1}^2 = I_2^2z_{T_2}^2, \text{ since } E_1 = E_2 \qquad (8)$$

The voltage is maintained constant for any set of observations having to do with a given solution.

From equations (6), (7) and (8) we have

$$\frac{I_1^2}{I_2^2} = \frac{z_{T_2}^2}{z_{T_1}^2} = \frac{kD_1}{kD_2} = \frac{\left(\bar{r}_2 + \dfrac{R}{1 + \omega^2\bar{C}^2R^2}\right)^2}{\bar{r}_1^2} \qquad (9)$$

At any one frequency the total impedance of the circuit without the cell is always the same. Thus the numerical value for the resistance of any solution, as compared to that of a potassium chloride solution, may be obtained from the ratio which forms equation (9), provided the resistances of the two solutions are nearly of the same magnitude.

The solution of this expression for R in a series of measurements at any wave length is facilitated by the construction of an interpolation table for R and kD_2/kD_1, to be used at that wave length. The values of $\bar{r}$ and $\omega^2\bar{C}^2$ are constant for any wave length and may be obtained either by the proper calibration of the members of the circuit or by solving for one or the other by the substitution in the equation of known values of R and kD_2/kD_1. The latter known quantities must have been obtained from a series of measurements with a standard resistance. The quantities $\bar{r}$ and $\omega\bar{C}$ do not have to be precise for if approximate constant values are used throughout, the relative values of kD_2/kD_1 and R will be correct.

We wish to express our indebtedness to Professor Edward Bennett of the Department of Electrical Engineering of this University and to Dr. Ronold King of the Department of Physics of Lafayette College for their helpful advice.

Summary

A method is described which serves for the simultaneous observation of electrical conductance and dielectric constant of very dilute electrolyte solutions at high radio frequencies. The apparatus which was used may be described as being of the comparator-resonance type. It consists of three distinct units, a variable high frequency oscillator circuit, an intermediate circuit and a comparator circuit with thermocouple–galvanometer measuring system.

The mathematical theory of the circuits is considered. Dielectric constant change is calculated from a comparison of the resonance settings of the standard variable precision condenser in the comparator circuit with the conductance cell connected and disconnected. For the evaluation of electrical conductance change there are required observations of the comparator circuit galvanometer deflections, again at resonance and with the cell connected and disconnected. It is further pointed out that the method developed may be applied to the measurement of high frequency currents through other types of resistances.

The Resistance and Capacity Behavior of Strong Electrolytes in Dilute Aqueous Solution. II. The Dispersion of Electrical Conductance[1]

BY ORLAN M. ARNOLD AND JOHN WARREN WILLIAMS

Some years ago it was pointed out by Debye and Falkenhagen[2] that as a necessary consequence of the postulated existence about any central ion of an ionic atmosphere with a finite time of relaxation, there must result an electrical conductance which is dependent upon the frequency of the field which is used to measure it. If an alternating field is applied, each ion in the solution will acquire a periodic motion. If the frequency is low enough (1000 cycles, for example) there will be produced in each instant a dissymmetry in the ionic atmosphere which corresponds to the momentary velocity of the ion. But if this frequency is increased to a point where the period of oscillation of the ion becomes comparable with the time required for the formation of its atmosphere any dissymmetry of the latter, necessary for the existence of the electrical force of relaxation, will decrease. Thus, depending upon the time of relaxation of the atmosphere about any particular ion there will be a frequency at which the dissymmetry of the atmosphere no longer can be formed in the normal way, and as the frequency is increased above this value the electrical force of relaxation will diminish and the mobility of the central ion will increase until such time as the frequency has been made so high that the dissymmetry of the ionic atmosphere disappears entirely.

The results of the calculations of Debye and Hückel[3] and of Onsager[4] for the molar conductance of a solution at zero, or very low, frequency may be expressed in the form

$$\bar{\Lambda} = \bar{\Lambda}_0 - \bar{\Lambda}_{I_0} - \bar{\Lambda}_{II}$$

Here $\bar{\Lambda}$ is the molar conductance of the solution at a finite concentration, $\bar{\Lambda}_0$ is the molar conductance at infinite dilution, $\bar{\Lambda}_{I_0}$ is the electrical

(1) A preliminary and incomplete report of this work has appeared in another place [Williams and Arnold, *Acta Physicochim., U. R. S. S.*, **3**, 619 (1935)]. This report gives as well provisional data for the dielectric constants of very dilute electrolyte solutions at two high frequencies.

(2) Debye and Falkenhagen, *Physik. Z.*, **29**, 121, 401 (1928).

(3) Debye and Hückel, *Physik. Z.*, **24**, 305 (1923).

(4) Onsager, *ibid.*, **27**, 388 (1926); **28**, 277 (1927).

force of relaxation expressed in conductance units, and $\overline{\Lambda}_{\text{II}}$ is the electrophoretic force, again expressed in conductance units. The molar conductance of the solution as a function of the frequency ω, used to measure it may be written in similar fashion as

$$\overline{\Lambda} = \overline{\Lambda}_0 - \overline{\Lambda}_{\text{I}\omega} - \overline{\Lambda}_{\text{II}}$$

in which at zero frequency, $\overline{\Lambda}_{\text{I}\omega} = \overline{\Lambda}_{\text{I}_0}$. When at extremely high frequencies the dissymmetry of the ionic atmosphere has disappeared entirely, $\overline{\Lambda}_{\text{I}\omega} \longrightarrow 0$, and the molar conductance approaches the limiting value

$$\overline{\Lambda} = \overline{\Lambda}_0 - \overline{\Lambda}_{\text{II}}$$

The mathematical treatment of Debye and Falkenhagen has led to the following expression for the electrical force of relaxation expressed as conductance.

$$\overline{\Lambda}_{\text{I}\omega} = \frac{|e_1e_2|}{3DkT}\kappa\overline{\Lambda}_0\chi(\omega,\theta,q)$$

where

$$\chi(\omega,\theta,q) = \frac{\sqrt{q}}{\left(1-\frac{1}{q}\right)^2 + \omega^2\theta^2}\left[\left(1-\frac{1}{q}\right)\left(\overline{R}-\frac{1}{\sqrt{q}}\right) + \omega\theta\overline{Q}\right]$$

$$\overline{R} = \frac{1}{\sqrt{2}}\sqrt{\sqrt{1+\omega^2\theta^2}+1}$$

$$\overline{Q} = (1/\sqrt{2})\sqrt{\sqrt{1+\omega^2\theta^2}-1}$$

and the other symbols have the significance usually assigned to them in the discussion of the interionic attraction theories. Thus

$$Q = \frac{(\overline{L}_1z_1 + \overline{L}_2z_1)\,z_1z_2}{(z_1+z_2)(\overline{L}_1z_2^2 + \overline{L}_2z_1^2)}$$

$$\theta = \frac{z_1^2z_2^2}{z_2^2\overline{L}_1 + z_1^2\overline{L}_2} \times \frac{15.33 \times 10^{-8}}{kTq\kappa^2}$$

and

$$\kappa^2 = \frac{4\pi}{DkT}\frac{e^2N\gamma}{1000}\Sigma\nu_iz_i^2$$

In this article are recorded measurements of the electrical conductance of dilute aqueous solutions of potassium chloride, barium chloride, magnesium sulfate, lanthanum iodate, cerium sulfate, praseodymium sulfate and luteo chloride at the wave lengths 15, 30, 50, 75, 100, 130 and 170 meters.

High Frequency Conductance Measurements

The comparator-resonance method described in the first paper of this series[5] was employed for the measurement of the variation of conductance at the high frequencies. In order to ensure high precision the different members of the circuit were carefully calibrated as follows.

The precision condenser was calibrated by the substitution method in a heterodyne circuit for its absolute value in capacity at several different points. This condenser was calibrated twice for its linearity in capacity. The type R galvanometer was calibrated for its deflections on a circular scale by the ordinary differential direct current method. Known resistances were introduced in series with the galvanometer. From more than three hundred points over the whole range a smooth curve showing deviations from a linear relation between the current and the deflection was obtained. This curve gave the correction for the galvanometer deflections. The thermocouple in the measuring circuit and the Type R galvanometer connected to this thermocouple were calibrated for forty points on the galvanometer scale by reversing the several values of direct current through the heater of the thermocouple. This thermocouple was also calibrated in terms of microvolts in the Electrical Engineering Standards Laboratory of the University with the use of a White potentiometer. The thermocouple was twice again calibrated as located in the circuit, first with the White potentiometer and then with a microammeter. The procedure in each case was to reverse the direct current through the heater.

Careful physical measurements of size, length and position of wires in the circuit were made and independent determinations of ω, L and $\overline{C}$ showed that at resonance, $\omega L = 1/\omega\overline{C}$.

Audio Frequency Conductance Measurements

The conductance of the electrolytes at audio frequencies was determined by using the ordinary type of bridge arrangement. The measurements were accurate to 0.01% as shown by calibrations and results with standard solutions. The standard resistances were a set of Curtis-wound coils of resistance 100,000 to 1000 ohms and a dial box giving resistances from 1000 to 1 ohm. These resistances previously had been calibrated by the U. S. Bureau of Standards. Heavy connecting wire was used between members of the circuit. Careful shielding of leads was required. Two compensating condensers with capacity 3000 $\mu\mu F$ and 300 $\mu\mu F$ were used for balancing capacity in the different arms of the bridge. A Kohlrausch eleven-turn slide wire manufactured by the Leeds and Northrup Company was employed to obtain the balance point. The alternating current was furnished by a vacuum tube generator. A vacuum tube amplifier was used in the detection of the point of balance.

Design and Construction of Conductance Cells

In the selection of the conductance cells consideration had to be given to the magnitude of the resistance demanded at each of the several short wave lengths by the characteristics of the circuit. The range of values of resistance required for the highest sensitivity at each wave length was determined experimentally. Table I gives the approximate ranges at the wave lengths selected for measurements.

It has been demonstrated as well that these values are theoretically correct, using the other constants of the measuring circuit and the equation for the currents in the circuit. The ranges of the resistance for a particular wave length may be changed by variation of the characteristics of the circuit.

At the beginning of the work much attention was given to the construction and properties of the conductance cells.

TABLE I

MAGNITUDE OF RESISTANCES FOR CHOSEN WAVE LENGTHS

Wave length meters	Approximate range of resistances, ohms.
170	25,000 to 75,000
130	25,000 to 75,000
100	25,000 to 100,000
75	25,000 to 65,000
50	5,000 to 20,000
30	2,500 to 7,500
15	400 to 1,600

The conductance of standard potassium chloride solutions at audio frequencies was studied in cells constructed with different kinds of glass and electrode material in a variety of shapes. Many irregularities of conductance were observed. Several important observations, later found mentioned in a publication by Jones and Bollinger,[6] were made in this preliminary work.

Many of the cells which are used for the determination of low frequency conductance are not suited at all for work at high frequencies because of arrangement of electrodes and of the proximity of mercury contact arms and filling tubes. The closeness of these arms introduces serious errors at high frequencies.

The cells finally designed for the high frequency measurements were similar to the one shown in Fig. 1. The exterior dimensions, especially with respect to electrode position and filling arms, were kept constant. This uniformity of construction was essential, first, in order that the cells would fit a standard clamp in the thermostat bath to give reproducible position from experiment to experiment, and second, in order that any capacitative effects between the electrode leads and filling arms, if not entirely eliminated, be reduced to a minimum and be nearly the same from cell to cell.

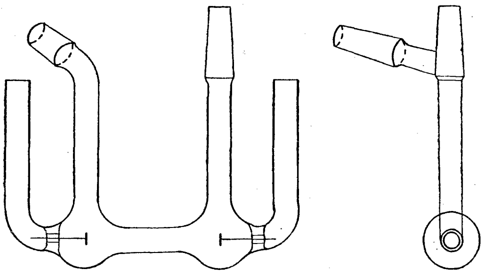

Fig. 1.—Conductance cell.

From conductance data found in standard tables, it was possible to compute the size and spacing of electrodes as well as the size of the body of a cell to be used with a given electrolyte at any of the wave lengths chosen. The cells were constructed with either Jena Geräte or Jena 16_{III} glass. Bright platinum electrodes were employed throughout. Eight cells were so constructed.

Special seasoning of the cells was accomplished by a carefully controlled steam-bath in which the cell was first brought gradually up to the temperature of steam, after which a current of steam was forced through the cell for several hours, then the cell was caused to cool slowly. At times when the cells did not contain a solution they were kept soaking with high grade conductivity water.

Calibration of Cells.—For the determination of the ordinary cell constants a 0.01 demal solution of potassium chloride served as electrolyte. Conductance values of Parker and Parker[7] were used in these calibrations.[8] The cell constants given in Table II, obtained by means of two different standard solutions, show a maximum deviation from the average of less than one part in ten thousand except in the case of cell number eight.

Temperature Control.—A thermally insulated thermostat bath of 23 liters capacity was filled with light oil in order to avoid electrostatic disturbances common to a water-bath and to ensure as complete electrical insulation as possible for the measuring cell. The container was grounded further to reduce electrical disturbances. It was possible to maintain the temperature of the bath to 0.001° for a considerable length of time. The maximum deviation allowed for a measurement was 0.002°.

Preparation and Purification of Materials.—One of the prime requisites of conductance measurements is that only pure materials be used since foreign substances are apt to give large errors from which indefinite or wrong conclusions will be drawn. This is especially true with the quantitative measurements of the small conductance effects at high frequencies. Since the frequency effect is a function of the valence of the ions involved, the presence, in small numbers, of foreign ions of the higher valence types would mask the effect of lower valence types.

Purification of Conductance Water.—The water was prepared by four or five distillations. Water, after having been distilled for general laboratory purposes, was distilled in a large block tin condenser. At the same time the steam and condensing liquid were washed by a stream of purified air. Only the middle portion of the distilled water was retained. The water was next distilled through a newly designed, all Pyrex, well-seasoned still which had a trap of direction reversing type and baffle domes for entrapping the spray. Glass dust shields protected the ground glass joints. Again only the middle portion of the water was retained. This water was then distilled in an all quartz distillation apparatus. The quartz condenser arm was air cooled. The receiver was always one of the transparent quartz flasks used in the work. The rate of distillation was maintained so that there was always an escape of steam which prevented foreign gases from diffusing back into the flask and which kept the distilled portion at nearly the boiling point. The first and last portions were always rejected. The process was sometimes repeated with the glass or quartz still. After cooling the water the quartz container was placed in a vacuum degassing tower and the evacuation was continued until the bubbling ceased. A stream of purified nitrogen was introduced into the chamber. The water, which was of exceptional quality, was found to depreciate readily in purity. Since considerable time was required to make the measurements it was decided to let the water "age" a part of a day before the solution was prepared. This procedure was followed in order that any unavoidable change of conduc-

Av.	.043462	1.0583	.57731	1.8264	11.498	1.1324	.25371	8.3156

tance of solvent would take place before, rather than during, the measurements. The specific conductance of the aged water when used was in the vicinity of 0.360×10^{-6}.

Potassium Chloride.—The potassium chloride (Mallinckrodt, "Reagent Quality") was recrystallized four times from aqueous solutions made with the best grade of conductance water obtainable. The salt, after drying in an oven at 110° and after standing for considerable time in a closed container, was analyzed for moisture content. The salt contained 0.15% water as shown by three determinations with a maximum deviation of 0.01%. Correction was made on this basis when a standard potassium chloride solution was prepared.

Magnesium Sulfate.—The magnesium sulfate (Mallinckrodt "Reagent Quality") was further purified by recrystallizing four times from the best grade of boiled conductance water. The salt was slowly dried by placing it in a desiccator above sulfuric acid and phosphorus pentoxide and by passing a stream of purified nitrogen over it. Several sets of analyses were performed. The water content at the beginning was not constant. After the salt had stood over the pentoxide for a year an analysis was again made by the pyrophosphate method. With three determinations the average of a salt in a sample was 74.23% with a maximum deviation of 0.04%.

Lanthanum Iodate.—The lanthanum iodate was obtained through the generosity of Professor V. K. La Mer of Columbia University who furnished a sample of the purified $La(IO_3)_3$ used in a study with Goldman.[9] At the time of the measurements an analysis was made for the water content of the salt. Three determinations by the thiosulfate method gave an average of 97.40% lanthanum iodate with a maximum deviation of 0.1%. The analytical reagents were either of reagent quality or they were further purified.

Cerium Sulfate and Praseodymium Sulfate.—Samples of these salts were procured from our Division of Analytical Chemistry. Further purification of the salts was accomplished by repeated crystallizations of the salts from the best grade of conductance water. Saturated solutions of the cerium and praseodymium sulfates were prepared at 0° and then the temperature was elevated to 80° for the former and to 75° for the latter. About five-sixths of the praseodymium salt precipitated out each time, but the amount was somewhat less in the case of the cerium sulfate. The purified samples were dried carefully. Due to the small quantity of the purified salts chemical analyses were omitted and the determination of the concentrations used in the measurements was made by using conductance data given in the "International Critical Tables."

Barium Chloride.—The barium chloride (Mallinckrodt "Reagent Quality") was not purified further. However, an analysis of the usual kind for the determination of water of hydration was carried out. The average percentage of barium chloride in a sample was found to be 85.27% with a maximum variation between the three determinations of 0.05%.

Luteo Chloride.—The luteo chloride was a Kahlbaum preparation. Due to the small quantity available further purification or chemical analysis was not attempted.

Technique Used in Measurements

Preparation of Solutions.—The solutions were prepared by the volumetric method in a 500-ml. calibrated Pyrex flask which had been well-seasoned by continued soaking with conductance water. The conductance water was transferred from the quartz container in the nitrogen filled degassing chamber through a siphon into the volumetric flask, placed in another chamber which was filled with purified nitrogen gas. The sample of salt was weighed on an analytical balance which had been adjusted to a sensitivity of 0.01 mg. The same calibrated set of weights was used for all weighings throughout the experimental work. After the addition of the sample of salt to the water in the volumetric flask the latter was placed in the bath at 25.000 ± 0.002°. After temperature equilibrium had been reached the total volume was brought to the 500-ml. mark.

The Filling and Handling of Cells.—The cells were first rinsed repeatedly with the solution to be used and then filled by siphon in a chamber filled with purified nitrogen gas. Contamination of the dilute solutions with foreign gases was thus eliminated. The filled cells used in an experiment were placed in the thermostat and the audio frequency resistance of the solution in each cell was determined.

High Frequency Procedure.—To carry out the measurements at any one of the higher frequencies, the cell adapted to that particular wave length was placed in the special holder in the thermostat. The zero position of the galvanometer light beam was noted. After all parts of the high frequency circuits were adjusted to the predetermined settings for that wave length, the oscillator was started and the circuits tuned so that the maximum deflection at resonance was approximately 400.0 on the galvanometer scale. The generator was always started two or more hours before the experiment began so that stability of power output could be maintained in all of the high frequency circuits. Any lack of stability could be detected by the shift of the galvanometer light on the scale. All of the observations at the high frequencies were made after midnight in order to avoid as far as possible external electrical disturbances.

The galvanometer deflection and the precision condenser reading were recorded. The cell was then connected in parallel with the precision condenser and the galvanometer deflection and precision condenser setting at resonance were again noted and recorded. Four to ten consecutive sets of such readings were taken for a particular solution at each wave length. Besides the observations for the

---

(9) La Mer and Goldman, THIS JOURNAL, 51, 2632 (1929).

solution, the same type of readings were made for two low inductive fixed resistances. The resistances were of the same order of magnitude as that for the cell with electrolyte. With any series of solutions these same fixed resistances were inserted repeatedly and observations were made at the time the solution was studied at that wave length. Thus these fixed resistances served as a check and reference for shift or disturbances from experiment to experiment. These fixed resistances were checked frequently by resistance determinations with the audio frequency bridge and were found to stay constant to well within 0.1%. It is imperative for such comparison measurements that the same cell be used for any particular wave length with a series of solutions.

Results

Conductance at Audio Frequency.—Although the determination of conductance at an audio frequency (1000 cycles), was not the chief object of the measurements being reported, it was part of the necessary procedure for each solution, since these data furnish a basis for reference. To illustrate the accuracy of these results data may be given for the reference potassium chloride solutions. For 0.005 normal potassium chloride the values of the observed molar conductance are 143.63 and 143.61 for two experiments as compared to Shedlovsky's[10] observed value 143.64 and his calculated value 143.65. For 0.002 normal potassium chloride in another experiment the observed value was 145.83 as compared to Shedlovsky's observed value 145.79 and calculated value 145.81.

Theoretical Values of High Frequency Change of Conductance.—In order to interpret the experimental observations it was necessary to calculate the changes in conductance of standard potassium chloride solutions at the different frequencies. It is assumed in the interpretation of the observations made with higher valence type salts that the small changes to which potassium chloride solutions are subject obey the Debye–Falkenhagen equation. This assumption has been made by other observers. The theoretical values were calculated for the other salts studied.

Because of the difficulty in adaptation and because of desire for greater accuracy the interpolation table given by Debye and Falkenhagen[2] for the ratio $\overline{\Lambda}_{I\omega}/\Lambda_{I_0}$ at definite values of q and $\omega\theta$ was not used.

The predicted conductance changes were calculated by using an equation given in the introduction. In addition to certain universal constants ($T = 298$, $e = 4.770 \times 10^{-10}$, $D = 78.54$, $k = 1.371 \times 10^{-16}$), it was necessary to have figures for the limiting molar conductances, $\overline{\Lambda}_0$ of the several salts. The following figures were obtained from standard sources of reference: KCl, 149.82; $BaCl_2$, 282.13; $MgSO_4$, 267.0; $La(IO_3)_3$, 336.8; $Ce_2(SO_4)_3$, 953.9; $Pr_2(SO_4)_3$, 945.5; $Co(NH_3)_6Cl_3$, 540.0. The mobility of the luteo ion, $Co(NH_3)_6^{+++}$, is somewhat uncertain.[11] The value 104.6 for $^1/_3$ $Co(NH_3)_6^{+++}$ was deduced from conductance data given by Harkins, Hall and Roberts.

The experimental work was arranged in three series of experiments, as shown in Table III. Here are presented theoretical and experimental values for the increase of molar conductance $\overline{\Lambda}_{I_0} - \overline{\Lambda}_{I\omega}$ of the different salts at the several high frequencies used in the measurements. Thus, these data indicate the amount by which the limiting molar conductance is changed due to changes in the electrical force of relaxation produced by the application of the fields of high frequency. It is also possible to obtain at once values for $\overline{\Lambda}_{I\omega}$, and $\overline{\Lambda}_{I\omega}/\overline{\Lambda}_{I_0}$ if it is desired to express the changes in this way.

Example of the Calculation of the Conductance from the Experimental Observations.—In order to illustrate the method by which the data of the foregoing tables have been obtained, the observations in the case of the 0.0006443 molar magnesium sulfate solution at 50 meter wave length are considered in detail. Galvanometer deflections with the cell in the circuit and with the cell out of the circuit are given in Table IV, Part A. Here the two columns at the right give the deflections corrected for the zero of the galvanometer as recorded in column two at the left. Part B of the same table gives average deflection values for the cell and fixed resistances.

In Part C are found the ratios of the galvanometer deflections with and without the cell or fixed resistance in the circuit for an experiment (14) with the standard potassium chloride solution and for an experiment (18) with the magnesium sulfate solution. The same cell and fixed resistances were used in both runs.

Any shift in the zero of the galvanometer after the beginning of the observations or any shift due to other disturbances from experiment to experiment should be detected through the ratios observed for the standard fixed resistances. Thus,

this added information obtained by using the fixed resistances R18 and R17 made it possible to correct the magnesium sulfate values for any deviation or shift taking place during an experiment. Part D of Table IV shows the ratios of the fixed resistances referred to the values obtained in experiment 14 as standard. The average ratio 1.0027 is the factor by which the magnesium sulfate ratio is corrected to 0.5303. It is to be regarded as a coincidence that the thermocouple correction exactly cancels the adjustment in opposite sense for the galvanometer. The thermocouple correction is determined from calibration curves in which the square of the current through the thermocouple heater is plotted as a function of the galvanometer deflection.

The next step is to evaluate these current ratios for the two solutions in terms of the relative ohmic resistances. The relative values of resistance are obtained from the relation[5]

$$\frac{I_2^2}{I_1^2} = \frac{\bar{r}_1^2}{\left(r_2 + \frac{R}{1 + \omega^2C^2R^2}\right)^2} = \frac{kD_2}{kD_1}$$

From the portion of the interpolation table which forms Part E of Table IV, the ratios for potassium chloride and magnesium sulfate (Part D) are identified with the relative resistances 12,792 and 12,504, respectively. By using the theory of Debye and Falkenhagen the actual resistance in the cell at 50 meters for the potassium chloride solution is calculated to be 13,422 ohms. By direct proportion, using this ohmic resistance

for the potassium chloride solution and the two relative values given in the table, the actual ohmic resistance for the magnesium sulfate solution is calculated to be 13,120 ohms. But the resistance of the magnesium sulfate solution in the same cell at the audio frequency was 13,235 ohms, therefore an increase in conductance has been observed. Interpreted in terms of molar conductance the quantities $\bar{\Lambda}_0$ and $\bar{\Lambda}_\omega$ are found to be 225.62 and 227.53, respectively. Then

$$\bar{\Lambda}_\omega - \bar{\Lambda}_0 = \bar{\Lambda}_{I_0} - \bar{\Lambda}_{I\omega} = 1.91$$

The theoretical value of $\bar{\Lambda}_{I_0}$ is 12.34. Thus $\bar{\Lambda}_{I\omega} = 12.34 - 1.91 = 10.43$. If the data for a given solution are referred to figures for several standard potassium chloride solutions the above procedure must be repeated.

Discussion

Since the appearance, in 1928, of the quantitative theory describing the dispersion of electrical conductance for dilute solutions of strong electrolytes there have been published the results of a number of experimental researches intended to test the validity of the theory. Reference may be made to important contributions in this field by Sack,[12] Zahn,[13] Rieckhoff,[14] Brendel,[15] Deubner,[16] M. Wien,[17] Malsch,[18] Gärtner,[19] and others. In some cases it was possible to measure only the order of magnitude of the conductance increase at a single high frequency, in others

complications served to render difficult any interpretation in terms of the theory, but in the main the results of these studies have been consistent with the requirements of the theory.

It has been our plan to make, in extremely dilute aqueous solutions of strong electrolytes, a more systematic study of the theory than has hitherto been attempted. Thus, instead of confining our attention to observations of the behavior of the solutions at one, or at most, several wave lengths, we have sought to make the measurements over a considerable frequency range. Again, we have been interested in a comparison of the magnitude of the conductance increase for electrolytes of as many different valence types and ion sizes as conveniently possible. To a lesser extent we have been able to study the effect of concentration changes in the solution of some of the salts. The results of the experimental work are compared with the requirements of the theory in Table III.

It is at once evident that the agreement between theory and the results of our experiments at each of the seven wave lengths is as good as can be expected when the difficult nature of the measurements is considered. The influence of variation in the valence type of the dissolved salt in changing the values of $\bar{\Lambda}_{I_0} - \bar{\Lambda}_{I_\omega}$ in the dilute solutions is consistent with the requirements of the theory. Thus, at any one wave length, barium chloride solutions show much less actual increase in conductance than do solutions of salts of higher valence types. The lanthanum iodate and luteo chloride solutions (3–1 valence type) show more significant increases and, when the relative concentration is taken into consideration, the magnesium sulfate solutions (2–2 valence type) show an even greater dispersion. The increased conductance is so pronounced in the case of the cerium sulfate and praseodymium sulfate in solution (3–2 valence type) that it can be measured with a very considerable degree of accuracy.

The measurements are much less complete as regards the effect of concentration change, but again, insofar as our experiments extend, this influence is entirely consistent with the predictions and requirements of the dispersion theory. The data for barium chloride and magnesium sulfate solutions are the only ones which are now involved. The change of conductance with frequency is very small at the higher concentrations in the wave length region in which these studies were made. The theory predicts that in order to observe large changes of conductance at the higher concentrations it will be necessary to measure the effects at much higher frequencies than were available to us. However, this shift of the critical frequency range toward the shorter wave lengths is indicated clearly by the experimental data for both barium chloride and magnesium sulfate solutions, with the more pronounced increases in conductance being observed in the solutions of lower concentration. For the study of the effect of changes in concentration measurements of Wien[17] with magnesium sulfate and barium ferricyanide solutions at 10, 20 and 40 meters are especially deserving of mention.

The significance of experiments of the type made by us now can be suggested. In the interionic attraction theories the fundamental idea is that the ions cannot be distributed at random in a solution, since, owing to the coulomb forces, there must be an excess of positive ions in the neighborhood of a negative ion and *vice versa*. Thus each ion is considered to be surrounded by a symmetrical ionic atmosphere with distribution of charge depending upon the square root of the concentration. It order to explain the ordinary conductance behavior of an electrolyte solution the number of the ions and their mobilities must be considered. The interionic attraction theory describes the effect of the electrical forces on the ionic mobilities by assuming the ionic atmosphere to have a definite time of formation and relaxation. On the basis of this assumption, if a constant current passes through such a solution the average distribution of ions is changed and the ionic atmosphere loses its central symmetry, but if a high frequency voltage, with time necessary for one vibration comparable to the time of relaxation, is applied, the dissymmetry of the atmosphere is greatly reduced and a conductance larger than that measured at ordinary low frequencies ought to result. If the experimentally observed conductances show satisfactory agreement with the requirements of the dispersion theory, as they do in the cases investigated by us, it can be claimed that the existence of such an atmosphere about each ion with finite time of relaxation, is definitely proved.

According to the theory the time of relaxation of the atmosphere (which is responsible for the dispersion effect) depends only on the mobilities of the ions and the forces between them. Thus, only the valence of the ions, the viscosity and dielectric constant of the solvent, and certain other physical factors are involved. If we wish to investigate whether or not in an ionic solution the chemical nature of the solvent and the affinities of ions play an important role, experiments of the type described above in which these factors are varied can give valuable information. In the experiments here reported a nearly ideal ionic behavior is observed, but it is probably accounted for because only extremely dilute aqueous solutions were considered. But even if the chemical nature of the solvent and the affinities of the ions are predominant factors, such experiments as these are still of significance because they explain and predict the behavior of ideal electrolytes and make possible a measure of the deviations from ideality in the actual solution.

Summary

1. A quantitative experimental study of the dispersions of the electrical conductance for strong electrolytes of several valence types in extremely dilute aqueous solutions has been made. The conductance of these solutions was observed at frequencies corresponding to the seven wave lengths, 15, 30, 50, 75, 100, 130 and 170 meters. In addition, observations were made at the frequency 1000 cycles.

2. The results of the experiments have been compared with the requirements of the dispersion theory. They are found to be in satisfactory quantitative agreement, indicating once more that in all probability the purely physical interionic attraction theory does adequately explain and describe the behavior of an ideal electrolyte.

The Thermodynamics of Cadmium Chloride in Aqueous Solution from Electromotive Force Measurements[1]

BY HERBERT S. HARNED AND MARGARET E. FITZGERALD

Measurements of the electromotive forces of the cell

$$\text{Cd–Cd}_x\text{Hg (11\%)} \mid \text{CdCl}_2(m) \mid \text{AgCl–Ag} \qquad (1)$$

have been made at 5° intervals from 0 to 40°, inclusive, and throughout a cadmium chloride concentration range of 0.0005 to 1 *M*. From the results, the standard potential of the cell, E_0, the activity coefficients and other thermodynamic properties of cadmium chloride have been computed.

Experimental Procedure

The silver–silver chloride electrodes of the kind designated by Harned[2] as type (2) were used. The cadmium amalgam was prepared from pure redistilled Kahlbaum cadmium and distilled mercury. The amalgam electrodes containing 11% of total cadmium were made individually in each cell vessel.

Mercury and an excess of cadmium were introduced in a suitable glass vessel which was then evacuated. This mixture was placed in a water-bath at 60° for fifteen minutes, and was shaken frequently. The saturated amalgam formed in this manner was allowed to flow through a sealed tube into the amalgam electrode compartments of four cells where it covered the sealed in platinum wires which made contact with the external leads. Since this operation was carried out *in vacuo*, the amalgam was free of oxide. In the case of cells containing dilute solutions ($m < 0.05$ *M*) the silver chloride electrode was immersed in the same compartment as the amalgam. On the other hand, with higher concentrations of solution the life of the cell was found to be considerably increased by separating the electrode compartments by means of a tube and a stopcock which was closed at times when actual measurements were not in progress.

A standard concentrated stock solution was made from a high-grade carefully purified cadmium chloride and conductivity water. Its strength was found by gravimetric determination of its chloride content. More dilute solutions were prepared by adding weighed amounts of the standard solution to water. The cell solu-

(2) Harned, THIS JOURNAL, **51**, 416 (1929).

tions were then boiled *in vacuo* to remove dissolved air, and kept under hydrogen. Corrections were made for the water boiled off during this process and vacuum corrections were made for all weighings.

The cells came to equilibrium in one to two hours after preparation. Four cells were measured at each concentration. The temperature control was within ±0.02°.

Experimental Results

Electromotive forces were determined at thirty-odd concentrations ranging from 0.0005 to 1 *M* and at 5° intervals from 0 to 40°. These were smoothed to round concentrations from a graph of *E versus* log *m*. The actual values may be expressed conveniently by means of the quadratic equation

$$E = E_{25} + a(t - 25) + b(t - 25)^2 \qquad (2)$$

Values of E_{25}, a and b are given in Table I. In the last column are given the average deviation between the observed results and those computed by the equation. In other words, Δ is the sum of the magnitudes of deviations at the nine temperatures divided by nine.

Similar cells have been measured at 25° by Horsch,[3] Lucasse[4] and from 0 to 45° by Quintin.[5] Since Horsch and Lucasse used amalgams of different compositions which were unsaturated, the absolute values of their electromotive forces are different from the present results. Graphs of the data of Horsch, Lucasse and the present results *versus* log *m* were found to be parallel, which indicated the same effect of change in concentration in all cases. Lucasse did not state the strength of the amalgam employed. The explanation of the difference between our results and those of Horsch is due not only to the difference in amalgam strength but also to the fact that Horsch employed silver–silver chloride electrodes prepared in the manner described by Lewis and Brighton.[6] These were found to be several millivolts different from the type of electrode employed by us. On the other hand, our results are in close agreement with those of Quintin who also employed the saturated amalgam.

The experimental accuracy was in general of the order of 0.1 mv. At the higher concentrations (>0.1 *M*), the experimental error was found to be somewhat greater than this.

Evaluation of the Standard Potential of the Cell

The electromotive force of the cell may be represented by the equation

$$E = E_0 - k \log 4m^3\gamma_{\pm}^3 \qquad (3)$$

where E_0 is the standard potential, m and $\gamma_{\pm}$ are the molality and stoichiometrical activity coefficient of cadmium chloride and k equals 2.303 $RT/2F$. By replacing $\log \gamma_{\pm}$ by $(-\mu\sqrt{m} + B'm)$ where μ is the limiting slope of the Debye and Hückel theory, we obtain

$$E + k \log 4m^3 = 3ku\sqrt{\mu} = E_0 - B'm = E_{\text{H}} \qquad (4)$$

The left-hand side, plotted against $\sqrt{m}$, was found to give a curve at all temperatures of which the slope increased with decreasing concentration. The data of Horsch in very dilute solutions at 25° was plotted in this way and although a fairly representative straight line could be drawn, the uncertainty of this method of extrapolation was great. Further, these graphs possessed slopes about twice that predicted by theory. This uncertainty is shown by earlier extrapolations. Getman[7] plotted this function against $\sqrt{\mu}$, using Horsch's data and found E_0 to be 0.6215. La Mer, Gronwall and Greiff[8] plotted the same data against $\sqrt{m}$ and obtained 0.5790 for E_0 but did not consider this a proper value. Instead they applied their extension of the Debye and Hückel

theory using an apparent ionic diameter "a" of 1 Å., and obtained 0.6230 for E_0.

According to equation (4), if cadmium chloride were a completely dissociated electrolyte, a plot of $E + k \log 4m^3 - 3k\mu\sqrt{m}$ should be linear with m in dilute solutions. That this is not the case confirms the view derived from conductance data that cadmium chloride is incompletely dissociated.

The dissociation mechanism which from the character of the data appears to be most suitable is

$$\text{CdCl}_2 = \text{Cl}^- + \text{CdCl}^+ \rightleftharpoons \text{Cd}^{++} + \text{Cl}^- \qquad (5)$$

according to which cadmium chloride is completely dissociated while the ion CdCl^+ is partially dissociated. It is probable that both cadmium chloride and CdCl^+ are incompletely dissociated. The above assumption neglects the first dissociation as having a negligible effect compared to the second in dilute solution. If α is the degree of dissociation of CdCl^+ and K the dissociation constant of this equilibrium, then the former is given by the equation

$$\alpha = \frac{1}{2}\left\{ -\left(1 + \frac{K}{m\gamma'_{\text{Cd}}}\right) + \sqrt{\left(1 + \frac{K}{m\gamma'_{\text{Cd}}}\right)^2 + 4\,\frac{K}{m\gamma'_{\text{Cd}}}} \right\} \qquad (6)$$

if γ^1_{Cl} is assumed to equal γ'_{CdCl}.

Some idea of the magnitude of K may be gained by considering the conductance data of Wershoven[9] at 18°, from which Noyes and Falk[10] calculated degrees of dissociation. These estimates place K between 0.007 and 0.02. From the same data, Reghellato and Davies[11] found, by means of Onsager's theory and by assuming a reasonable value for the mobility of the ion CdCl^+, an equilibrium constant of 0.0101 at 25°.

Our first step was to compute α by equation (6) for values of K in the neighborhood of 0.01 (0.005 to 0.015). γ'_{Cd} was computed from the Debye and Hückel equation

$$\log \gamma'_{\text{Cd}} = -2u\sqrt{\mu'}/(1 + A\sqrt{\mu'}) \qquad (7)$$

employing a value of the mean apparent diameter "a" of 5 Å. The primed quantities are real, while the unprimed quantities are stoichiometrical. Thus, μ' is $\Sigma m_i' z_i^2/2$ where m_i' represents the actual ionic concentrations. This required the following procedure. An initial value of α was assumed for values of K and m under consideration. From this, μ' was calculated from the relation

$$\mu' = (2\alpha + 1)m \qquad (8)$$

and γ'_{Cd} was obtained by equation (7). Then α was recalculated by equation (6) using this value of γ'_{Cd}. From this value of α another γ'_{Cd} and μ' were found, and equation (7) applied again. This process was repeated until the same value of α, to a few ten thousandths of a unit, was obtained twice. This procedure was carried out at 0, 25 and 40° to obtain values of α from 0.0005 to 0.5 M with various values of K.

Equation (3) is written in terms of the stoichiometric activity and coefficients and molality. It may also be written in terms of the real activity coefficient $\gamma'_\pm$ and actual ionic concentrations in the form

$$E = E_0 - k \log \alpha(1 + \alpha)^2 m^3 \gamma_\pm^3 \qquad (9)$$

From the definition of E_{H} in equation (4), we have

$$E_{\text{H}} - E_0 = E - E_0 + k \log 4m^3 - 3\,ku\sqrt{\mu} \qquad (10)$$

which combined with equation (9) gives

$$E_{\text{H}} - E_0 = k \log 4 - \log \alpha(\alpha + 1)^2 - 3k \log \gamma' - 3ku\sqrt{\mu} \qquad (11)$$

The right side of this latter equation was computed for various values of K and plotted against $\sqrt{m}$, using the activity coefficient of barium chloride obtained by Tippetts and Newton[12] for the real activity coefficient of cadmium chloride, $\gamma'_\pm$. This substitution is a reasonable one in dilute solutions and increases in validity with decreasing concentration. In Fig. 1 the general form of these curves are illustrated by the smooth lines.

The function, E_{H}, computed from E by equation (4) was then plotted for 0, 25 and 40° against $\sqrt{m}$ and compared to the curves calculated by equation (11) and for values of K varied by one thousandth unit. In Fig. 1 plots of this function are shown together with the curves which fitted them best. The values of the dissociation constants employed finally were 0.013, 0.011 and 0.010 at 0, 25 and 40°, respectively. The values of the right-hand member of equation (11) were read off the curves and subtracted from the original unsmoothed E_{H} functions. According to equations (10) and (11), this gave

$$E_0 = E + k \log \alpha(1 + \alpha)^2 m^3 \gamma'^3_\pm \qquad (12)$$

The values of E_0 obtained in this manner were averaged by drawing a straight line of zero slope through the points obtained by plotting against $\sqrt{m}$. The actual plots of these functions com-

puted from the unsmoothed electromotive forces are also shown in Fig. 1.

In order to obtain E_0 at the other temperatures, the correction factors, $E_H - E_0$, used for each concentration at 0, 25 and 40° were plotted against temperature and smoothed curves drawn through three points. The correction factors read from these curves at the intermediate temperatures were then applied in the manner previously described to E_H, and the values of E_0 so obtained were averaged. These standard potentials are given in the second column of Table II.

[a] This investigation.

These results may be represented by the equation

$$E_0 = E_{0(25)} + \alpha_0(t - 25) + b_0(t - 25)^2 \qquad (13)$$

similar in form to equation (2). Numerical values of the constants of this equation are given at the bottom of Table I.

The function computed by equation (11) is certainly of the same form in dilute solutions as when computed from the observed electromotive forces. This gives us confidence that the method of extrapolation here employed is reasonable and that the values obtained for E_0 are a close approach to the true values. We note that the dissociation constant seems to decrease with increasing temperature but do not regard this determination as an accurate evaluation of this quantity.

Standard Potential of the Electrode: Cd(s)|Cd^{++}

The standard potential of the two-phase amalgam electrode of 11% total cadmium content, E_0', can be computed readily from the values of E_0 by subtracting the standard potentials of the hydrogen silver–silver chloride cell given by Harned and Ehlers[13] at the corresponding temperatures. The potentials thus obtained for the electrode Cd–Cd_xHg (11%) / Cd^{++} are represented by E_0' and are given in the third column of Table II. Quintin[14] obtained 0.3491, 0.3521 and 0.3553 at 15, 25 and 35°, respectively, from an apparently identical cell by an application of the La Mer, Gronwall and Greiff[8] method. These values are in fair agreement with those obtained by us.

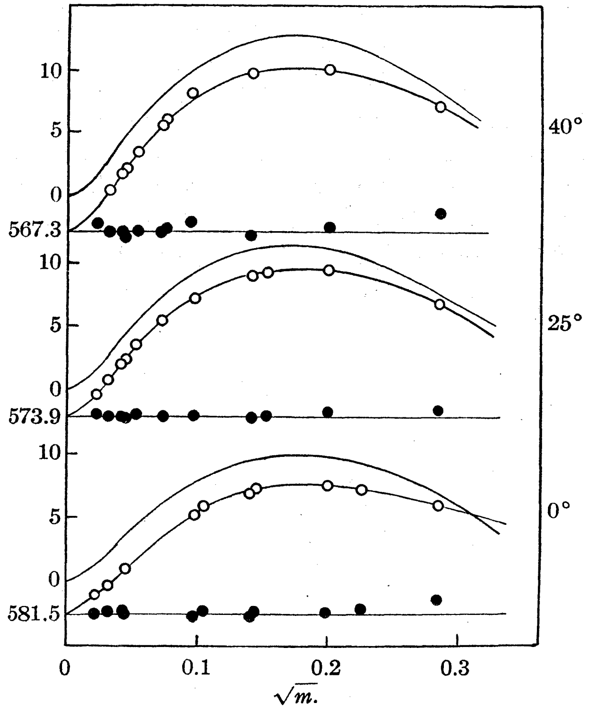

Fig. 1.—Extrapolation functions at 0, 25 and 40° (scale in millivolts, diameters of circles, 0.8 mv.): (1) Curves without points are theoretical according to Eq. (11). $E_H - E_0$ is plotted. (2) Circles represent plots of E_H according to Eq. (4). (3) Dots represent E_0 according to Eq. (12). (4) The dissociation constants were 0.010, 0.011 and 0.013 at 40, 25 and 0°, respectively.

Parks and La Mer[15] have measured the potential of cadmium amalgam of the same composition as that employed in the present investigation against cadmium. From their results and the values of E_0' in Table II, the values of the standard potential, E_0'', of the electrode Cd(s) / Cd^{++}, given in the fourth column of this table from 0 to 30° were computed. The values at 35 and 40° were computed from the results of Getman[16] for γ-cadmium. According to Cohen,[17] cadmium metal exists in three forms. Getman[16] measured cells of cadmium against cadmium amalgam over a time interval and found that only 10% main-

tained the original high value for the electromotive force which was due to γ-Cd, while the potentials of the other 90% dropped in value due to a change to α- or β-Cd. Parks and La Mer's results agreed with those obtained for γ-Cd by Getman, so that the values given by us in Table II are taken to refer to γ-Cd.

There have been many attempts to provide a sound extrapolation of the existing data on cadmium chloride at 25°. The last column of Table II contains values of E_0'' obtained by the investigators mentioned at the bottom of the table. The first four values were derived from Horsch's data, the fifth from Horsch's and Lucasse's and the remainder each used their own experimental results.

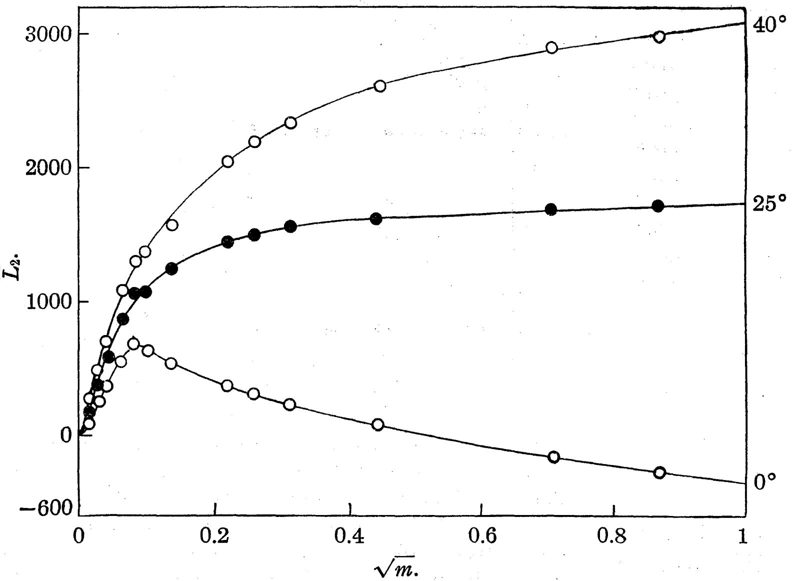

Fig. 2.—Relative partial molal heat content, $\bar{L}_2$, *versus* $\sqrt{m}$.

Brewster measured the potential of a cell with a liquid junction containing stick cadmium and calomel electrodes. German's second value was obtained from measurements of a cell containing cadmium in the form of a single crystal and a calomel electrode.

Some of the values have been changed. Horsch's[3] and Lewis and Randall's[18] values have been recalculated after correcting the silver chloride and calomel electrodes as indicated by the more recent values of the activity coefficient of hydrochloric acid. Quintin's silver chloride electrode was assumed to be the same as the type used by us. A correction of 0.0534 volt for the amalgam electrode used by Horsch was added to the value of E_0 obtained from his data, and one of 0.0505 volt to those obtained from amalgams of 11% total cadmium content. All results should refer to γ-Cd, although there remains some doubt regarding Getman's cell containing a single crystal. If this is α-Cd, a correction of 0.0031 volt should be added to Getman's second value.

The principal cause of the difference in values of these standard potentials is due to the methods of extrapolation. The first two determinations were made without the use of the limiting theoretical law of Debye and Hückel. This combined with giving too great weight to the determinations at extreme dilutions (<0.0004 *M*) tends to give results that are too low. Getman's extrapolation of Horsch's data and Brewster's[19] extrapolation of his own results were made by a plot suggested by equation (4). Again, the curve through the results in the concentration range available possesses a slope greater than the theoretical, and as a result intercepts the axis at zero molality at a value of E_0 which is too low. Getman's second value was computed by equation (3) from his results, and Horsch's activity coefficients. Activity coefficients computed from a low value of E_0 would be too large, which would make Getman's second value low also.

La Mer, Gronwall and Greiff could only fit the observed results with their equation upon the assumption of an apparent ionic diameter of 1 Å. Quintin's extrapolation seems reasonable, although the uncertainty is somewhat large because of the small number of points used. Scatchard and Tefft[20] used a function similar to equation (11) but made a rough application only and in our opinion placed too much weight on Horsch's results in very dilute solutions.

This critique of methods of extrapolation along with our experience indicates that the higher values of E_0'' (~ 0.402 volt) are more likely to be correct.

Activity Coefficient, Relative Partial Molal Heat Content and Specific Heat

The stoichiometric activity coefficient $\gamma_{\pm}$ may be computed from the values of E in Table I and

the values of E_0 in Table II by means of equation (3). Unfortunately, accurate freezing point and vapor pressure data have not been obtained for cadmium chloride solutions so that values of the activity coefficients derived from the different colligative properties are not available for comparison. Because of this, we have not tabulated activity coefficients.

The relative partial molal heat content, $\bar{L}_2$, has been computed from equations (2) and (13) by the method given by Harned and Thomas.[21] For a bi-univalent electrolyte, equation (17) of Harned and Thomas is

$$\bar{L}_2 = 2\alpha + 2\beta T^2 \tag{14}$$

where the constants α and β may be computed from the constants of equations (2) and (13). Equation (14) is a necessary consequence of the quadratic temperature variation of E and E_0, and should only be applied to the temperature range (0 to 40°) in which the experimental results were found to conform closely to the quadratic relationship. In Table III, values of α and β are given at the concentrations designated. Values of $\bar{L}_2$ at 25° are recorded in the table and plots of this quantity at 0, 25 and 40° are shown in Fig. 2. In the last column of the table, values of the relative partial molal specific heat, $\bar{C}_p - \bar{C}_{p_0}$, at 25° computed from the equation

$$\bar{C}_p - \bar{C}_{p_0} = 4\beta T \tag{15}$$

are also given. We have been unable to find accurate calorimetrically determined values of these quantities so that further confirmation or disproof of the accuracy of these results and calculations cannot be obtained at the present time.

Summary

1. Measurements of the cells Cd–Hg_xCd (11%) | CdCl_2 (m) | AgCl–Ag from 0 to 40° and at concentrations from 0.0005 to 1 M have been made.

2. The standard potential of the cell from 0 to 40° has been computed by a method which assumes incomplete dissociation of an intermediate ion, the dissociation constant of which was estimated to be 0.013, 0.011 and 0.010 at 0, 25 and 40° respectively.

3. The standard potential of the electrode: Cd_γ(s) | Cd^{++}, has been computed from 0 to 40°.

4. The relative partial molal heat content and specific heat of cadmium chloride in aqueous solution have been calculated.

The Nature of Electrode Reactions. I. Factors Affecting the Electrochemical Reduction of N-Nitrosomethylaniline[1]

BY JOHN E. WELLS, DONALD E. BABCOCK AND WESLEY G. FRANCE

Alpha methylphenylhydrazine was first prepared electrochemically by Backer[2] through the reduction of phenylmethylnitramine and later[3] from the corresponding methylphenylnitrosamine. Tinned copper cathodes were used in both instances but no detailed study of the reaction was made.

The present work consists of the investigation of the influence of the following factors on the electrochemical reduction of N-nitrosomethylaniline at copper, lead, cadmium, mercury and cadmium amalgam electrodes: (1) temperature, (2) current density, (3) acid concentration of the catholyte, (4) the extent to which the cathodes dissolve during the course of the reduction and the amount of chemical reduction produced thereby, (5) the magnitude of the potential drop at various current strengths resulting from the presence of the depolarizer.

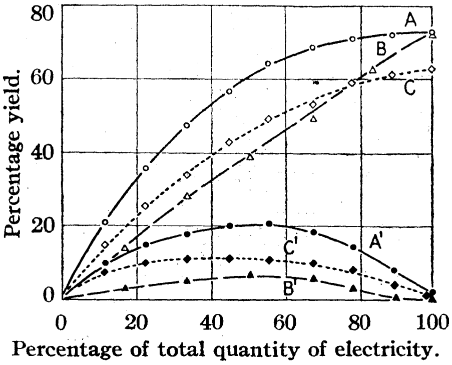

Fig. 1.—A and A′, 2 amp. per 2/3 dm.² at cadmium cathode; B and B′, 3 amp. per 2/3 dm.² at cadmium cathode; C and C′, 2 amp. per 2/3 dm.² at cadmium amalgam cathode.

The cell used was similar to that previously described.[4] The nitrosomethylaniline was specially prepared to ensure a high degree of purity by the method of Reverdin and de la Harpe.[5] A weighed sample of the nitrosamine was placed in the cathode compartment of the cell with 200 ml. of electrolyte of known acid concentration, a further portion of the same acid solution was added to the anode compartment and the cell placed in a thermostat. The electrolyte was rapidly stirred and a constant current was maintained until the theoretical quantity of electricity required for the reduction had passed. Throughout the course of the reduction small samples of the catholyte were removed at ten minute intervals and analyzed for cathode metal ions and hydrazine content. The hydrazine was determined by a modified method of Strache,[6] and the metal ion content by electrotitration. The collected data are contained in the accompanying table and curves.

In Fig. 1 curves A, B and C, indicate the yield of hydrazine at various time intervals corresponding to the passage of definite percentages of the total quantity of electricity theoretically required for the reduction. A′, B′ and C′ are plots of the concentrations of the metal ions present in the catholyte at these same intervals in terms of the chemical equivalents of methylphenylhydrazine based on the equation

$$C_6H_5(CH_3)NNO + 4H^+ + 2Cd = 2Cd^{++} + HOH + C_6H_5(CH_3)NNH_2$$

These data show that during the course of the reduction the cadmium at first dissolves but later redeposits on the cathode and at the higher current densities the dissolution of the electrode is diminished and the final yield of the hydrazine is increased. The curves in Fig. 2 in which the percentage yield is plotted against the current density show that the maximum yield for each electrode occurs at some definite current density. At current densities above or below this value the yields are smaller. The decreasing order for the optimum current densities of the electrodes is lead, cadmium, cadmium amalgam, mercury and copper. The same order was observed for the decreasing values of the maximum yields at the various electrodes.

From the curves in Fig. 3 in which the yields are plotted against the temperature it is clearly evident that a decrease in the temperature of the

reduction results in an increase in the yields at all electrodes. The temperature is of further importance in that it affects the velocity of the undesirable side reactions. The first and most important of these is the rearrangement of the N-nitrosomethylaniline into *p*-nitrosomethylaniline, from which the desired hydrazine cannot be obtained. At the higher temperatures at which this reaction is most rapid the yields for all electrodes were very low. The nitrosomethylaniline solidifies at a temperature of from 7–8° in 1.0 *N* hydrochloric acid, and therefore below this temperature all reductions drop to a negligible value. The maximum yields were obtained at temperatures just above the freezing point of the depolarizer.

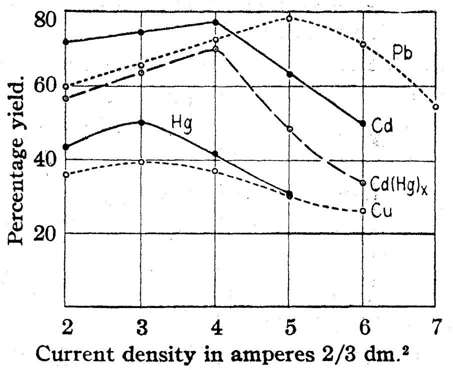

Fig. 2.

The data presented in Fig. 1 indicate conclusively that the electrochemical reduction is accompanied by a certain amount of purely chemical reduction when cadmium and cadmium amalgam electrodes are used. In order to study further the extent of the chemical reduction the following experiments were carried out over a selected range of temperatures and acid concentrations. The cells were set up exactly as before using the same quantity of depolarizer but without any current flowing. After a period of ninety minutes, the time required for the electrochemical reduction, the catholyte solution was analyzed for hydrazine content. These results are recorded in Table I.

These data together with those of Fig. 1 show that the dissolution of the electrode is a direct function of the temperature and acid concentration and an inverse function of the current density. It is interesting to note that whereas cadmium and the cadmium from the amalgam dissolved appreciably the other electrodes of copper, lead and mercury did not. However traces of these latter metals were usually found in the catholyte solutions. In the case of the cadmium amalgam the magnitude of the chemical reduction of the nitrosamine was diminished to a very small value. This decrease corresponded to the lowered concentration of cadmium in the amalgam relative to that of the pure metal.

TABLE I

REDUCTION BY PURELY CHEMICAL MEANS WITH THE SAME ELECTRODES USED IN THE ELECTROCHEMICAL REDUCTIONS

Current passed in this case is zero, for 90 minutes in each case with 200 ml. of electrolyte

1.00	Cd	5	0.0

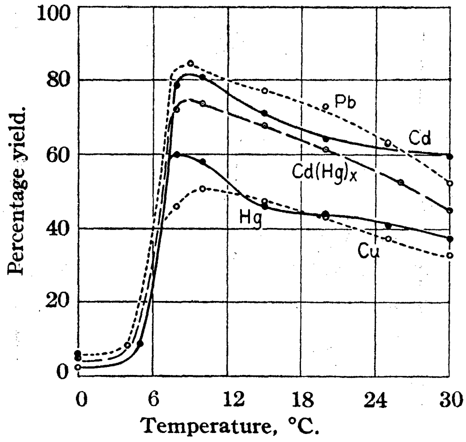

Fig. 3.

The copper cathodes appeared to be oxidized, presumably by the NO group of the nitrosamine. This fact together with the presence of the metal ions in the catholyte is strongly suggestive of the existence of a tendency on the part of the metal of the electrode to combine with the nitrosamine adsorbed on the surface of the electrode.

Liebreich considered the tendency of the metals[7] to dissolve or corrode as being a function of their overvoltage values. He regarded the hydrogen as acting in two ways, one to reduce the metal oxide or form hydrides and two to be evolved as

---

(7) Liebreich, *Korrosion Metalschutz*, **3**, 78–82 (1927).

gaseous hydrogen. The same conclusion was reached by Theil and Echell.[8]

The magnitude of the potential drop of the cathodes at various current strengths due to the presence of the depolarizer was determined and found to be appreciable in all cases, the decreasing order of magnitude being cadmium amalgam, lead, cadmium and copper. These results are expressed graphically in Fig. 4 in which the potential drop ($-\Delta E$ volts) due to the presence of the depolarizer is plotted against the corresponding current strengths (amperes) at which the electrode potentials were measured. When considered in relation to the dissolution of the cadmium amalgam electrodes, these results suggest the possibility that the loss in the overvoltage value of the electrode due to the depolarizer may be the direct cause of the dissolution. This view is given added support by the fact that at the higher current densities and hence higher overvoltage values, the concentrations of the metal ions in the catholyte solutions were lower.

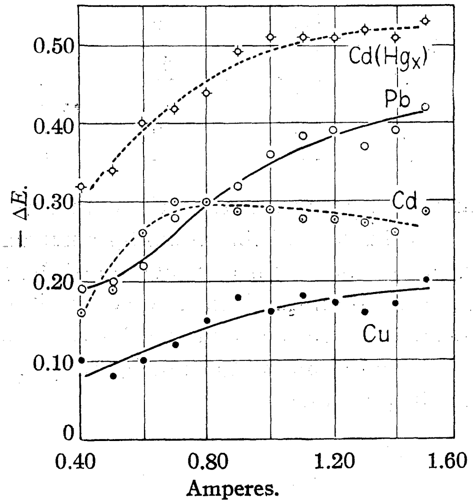

Fig. 4.

Summary

The results of this investigation may be summarized as follows.

1. The electrochemical reduction of N-nitrosomethylaniline proceeds most readily at a temperature slightly above the freezing point of the depolarizer.
2. For Cd, Cd(Hg)$_x$, Pb, Cu and Hg the optimum current density is a specific characteristic of the electrode material.
3. In the main electrochemical reactions the acid concentration is not a major factor; however, the kind and concentration of acid and also the temperature may determine the course and extent of undesirable side reactions.
4. Purely chemical reductions and associated side reactions may occur along with the electrochemical reductions at the active electrodes employed in this investigation.
5. The dissolution of the electrodes may be the result of the drop in the cathodic overvoltage due to the presence of the depolarizer.
6. The electrochemical reduction of N-nitrosomethylaniline provides a highly satisfactory way of preparing α-methylphenylhydrazine, giving yields as high as 85%.

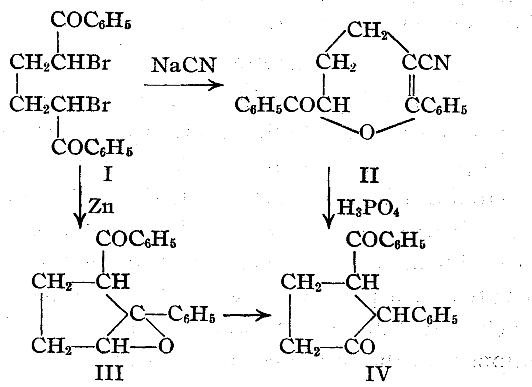
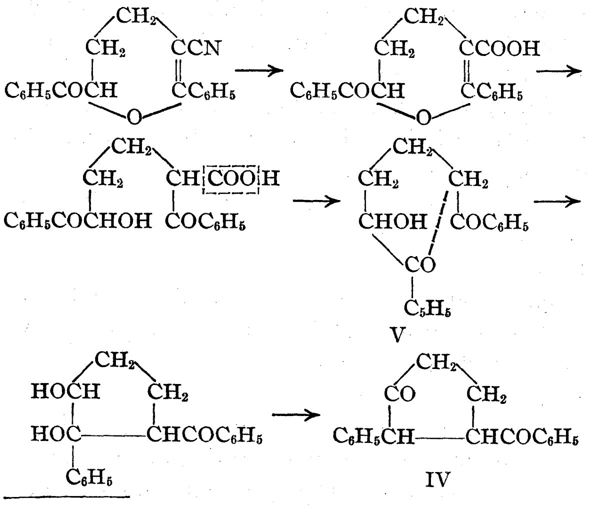
A Cyclopentane Derivative from 1,4-Dibromo-1,4-dibenzoylbutane

BY REYNOLD C. FUSON, ARNOLD LIPPERT, R. V. YOUNG AND H. H. HULLY

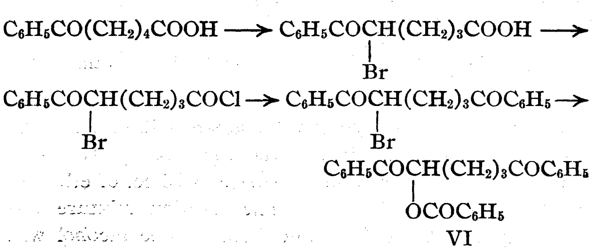
A cyclopentane derivative (IV) was obtained by rearrangement of the oxide (III), which is formed when 1,4-dibromo-1,4-dibenzoylbutane (I) is treated with zinc.[1] It has now been found that this transformation of the diketone (I) into the cyclopentanone can be effected in another way. The first step involves the action of sodium cyanide on the dibromo diketone, and gives a cyano dihydro-1,4-pyran (II).[2] When this nitrile is heated with sirupy phosphoric acid, it is converted to the cyclopentanone (IV).



This curious change of II into IV involves hydrolysis of the cyano group, opening of the dihydro-1,4-pyran ring, decarboxylation of the resulting acid and finally closure to the cyclopentanone. It seems probable that these reactions take place in the following sequence



In an effort to gain some insight into this complex change, we have prepared the benzoate of the hydroxy diketone (V) and subjected it to the action of phosphoric acid. The synthesis of the benzoate (VI) was accomplished by the following series of transformations



$$C_6H_5CO(CH_2)_4COOH \longrightarrow C_6H_5CO\underset{Br}{CH}(CH_2)_3COOH \longrightarrow$$
$$C_6H_5CO\underset{Br}{CH}(CH_2)_3COCl \longrightarrow C_6H_5CO\underset{Br}{CH}(CH_2)_3COC_6H_5 \longrightarrow$$
$$C_6H_5CO\underset{OCOC_6H_5}{CH}(CH_2)_3COC_6H_5$$

VI

This benzoate should be hydrolyzed by the hot 85% phosphoric acid to the hydroxy diketone (V), and the latter, if really an intermediate in the process, should yield the cyclopentanone. The result of the test was an 80% yield of the expected compound (IV). This lends support to the proposed mechanism.

Experimental

The transformation of the cyano compound (II) into the cyclopentanone (IV) can be effected by use of sulfuric acid or phosphoric acid. The best yields were obtained by use of the following procedure. Ten grams of the cyano compound was dissolved in 300 cc. of 85% phosphoric acid and 25 cc. of 95% ethyl alcohol. The mixture was stirred for eighteen hours and then heated under reflux on a hot-plate for eight hours. When the reaction mixture had cooled, it was placed in a 2-liter beaker and diluted to a volume of 1800 cc. by addition of water. The yellow solid which separated over a period of several hours was removed by filtration and recrystallized from ethyl alcohol. The melting point was 159–159.5° (corr.) and was not depressed by admixture with 2-phenyl-3-benzoylcyclopentanone. The yield was 40% of the theoretical amount.

The benzoate of 1-hydroxy-1,4-dibenzoylbutane was synthesized by the following series of reactions.

δ-Bromo-δ-benzoylvaleric Acid.—Thirty grams of δ-benzoylvaleric acid, prepared according to Hill,[3] was dissolved in 300 cc. of hot carbon tetrachloride. To this solution was added 25 g. of bromine through a capillary tube extending beneath the surface of the liquid. The reaction was complete in about ten minutes. Air was then drawn through the warm solution until the volume was about 150 cc. When cooled, the solution deposited crystals which were purified by precipitation from a cold ethyl acetate solution by the addition of petroleum ether (25–45°). The yield is 30 g. of product which melts at 109–110°,

Anal. Calcd. for $C_{12}H_{13}O_3Br$: C, 50.52; H, 4.60; Br, 28.04. Found: C, 50.63; H, 4.87; Br, 27.83.

1-Bromo-1,4-dibenzoylbutane.—Twenty grams of δ-bromo-δ-benzoylvaleric acid and 14 cc. of thionyl chloride were warmed gently on the steam-bath for one hour; then the excess thionyl chloride was removed by heating the reaction mixture to 60° under diminished pressure. The δ-benzoyl-δ-bromovaleryl chloride thus obtained was added dropwise to an ice-cold suspension of 18 g. of aluminum chloride in 100 cc. of benzene. After the addition of the acid chloride the reaction mixture was allowed to stand overnight at room temperature. Decomposition of the complex gave 13 g. of 1-bromo-1,4-dibenzoylbutane which melted at 62–63°.

Anal. Calcd. for $C_{18}H_{17}O_2Br$: Br, 23.16. Found: Br, 23.31.

The Benzoate of 1-Hydroxy-1,4-dibenzoylbutane.—Five grams of 1-bromo-1,4-dibenzoylbutane was dissolved in a solution of 1.2 g. of sodium benzoate in 75 cc. of ethyl alcohol and 10 cc. of water. The reaction mixture was heated under reflux for three hours. The alcohol was then removed from the solution and the residue was taken up in ethyl acetate. Addition of petroleum ether (b. p. 25–45°) to the solution precipitated crystals which melted at 110–111°. Three grams of the keto ester was obtained.

Anal. Calcd. for $C_{25}H_{22}O_4$: C, 77.75; H, 5.78. Found: C, 77.67; H, 5.89.

2-Phenyl-3-benzoylcyclopentanone.—A solution of 5 g. of the benzoate of 1-hydroxy-1,4-dibenzoylbutane in 60 cc. of alcohol was added to 200 cc. of 85% phosphoric acid and the mixture heated under reflux for twelve hours. At the end of this time, the reaction mixture was poured into 200 cc. of ice water and allowed to stand about thirty minutes. The precipitate was decolorized with norite and recrystallized from ethyl alcohol. There was obtained 3 g. of fine, colorless needles, melting at 156–158°. A mixed melting point with an authentic sample of 2-phenyl-3-benzoylcyclopentanone showed no depression.

Summary

Hot phosphoric acid converts 2-phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran (II) to a cyclopentanone derivative. A mechanism is postulated which involves the formation of 1-hydroxy-1,4-dibenzoylbutane as an intermediate. The benzoate of this compound has been prepared and treated with phosphoric acid; the product is the cyclopentanone in question. This result lends support to the proposed mechanism.

Dihydro-1,4-pyrans. V. The Structure of the 3-Cyano Derivatives

By H. H. Hully, F. H. Brock and Reynold C. Fuson

In a previous paper[1] the cyano compounds resulting from the action of sodium cyanide on certain 1,4-dibromo-1,4-diaroylbutanes were assigned tentatively a dihydro-1,4-pyran structure. Strong support for this structure was obtained by degradation of the cyano compound obtained from 1,4-dibromo-1,4-dibenzoylbutane. Use of the Beckmann rearrangement led to a series of derivatives whose properties were in accord with predictions based on the structure originally assigned (I).[2] The end-product of this degradation has subsequently been definitely identified as α-hydroxy-δ-benzoylvaleric acid (II).[3] In view of these results, it seems certain that the original cyano compound has the dihydro-1,4-pyran structure.

In the search for confirmatory evidence, we have studied the effects of certain oxidizing and reducing agents on this dihydro-1,4-pyran.

Concentrated nitric acid attacks the ethylenic bond and produces the nitric ester of a nitro alcohol. By analogy with similar cases[4] we have assigned structure III to this compound. Its formation was the first definite proof of the presence of the ethylenic bond in the parent substance.

Catalytic hydrogenation, however, did not affect the ethylenic bond. On the contrary, the carbonyl group was attacked preferentially. The resulting alcohol (IV) was found to yield a urethan when treated with phenyl isocyanate. Treatment with chromic acid oxidized the alcohol to the original ketone. Concentrated nitric acid converted the carbinol (IV) into the same derivative (III) which was obtained from the original cyano pyran (I).

Ozone attacked the ethylenic linkage and produced an ozonide which led to ring opening in the expected manner. The cleavage product (V), when treated with alkali, gave benzoic acid (one

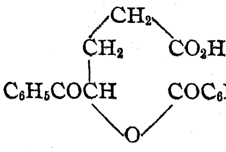
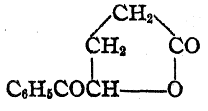
IV



V



VI

Attempts to synthesize this open-chain derivative were, however, unsuccessful.[3] To this end γ-bromo-γ-benzoylbutyric acid was prepared and treated with silver benzoate. The only product which could be obtained was the γ-benzoylbutyrolactone (VI).

Experimental

The Action of Nitric Acid on 2-Phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran.—One gram of 2-phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran was dissolved in 5 cc. of glacial acetic acid and a solution of 1 cc. of concentrated nitric acid (sp. gr., 1.42) in 3 cc. of glacial acetic acid was added slowly. The reaction mixture was heated at 100° for one hour. Oxides of nitrogen were evolved during this time. The solution was then poured into 200 cc. of ice water, the precipitate collected on a filter and crystallized from ethyl alcohol. There was obtained 1 g. of a product melting at 139.5–140°, with evolution of oxides of nitrogen.

Anal. Calcd. for $C_{19}H_{15}O_7N_3$: C, 57.43; H, 3.81. Found: C, 57.31, 57.29; H, 4.04, 3.93.

This compound, to which was assigned formula III, was also made by the action at 0° of fuming nitric acid on the carbinol (IV).

Reduction of 2-Phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran.—Seven and eighteen-hundredths grams of 2-phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran was dissolved in 300 cc. of ethyl acetate and treated with hydrogen under a pressure of three atmospheres for fourteen hours in the presence of a platinum oxide catalyst. The platinum was removed from the solution, and the ethyl acetate removed by distillation. The residue, after several recrystallizations from dilute alcohol, melted at 110–113°.

The carbinol could not be purified satisfactorily, since deposition of an oil always accompanied crystallization. Treatment of the carbinol with phenyl isocyanate, however, gave the corresponding urethan, which could be satisfactorily purified by crystallization from ethyl alcohol. The melting point is 137–138°.

Anal. Calcd. for $C_{26}H_{22}O_3N_2$: N, 6.83. Found: N, 6.92.

Oxidation of the Carbinol.—One gram of the carbinol was dissolved in 10 cc. of glacial acetic acid, and to this was added 0.2 g. of chromic anhydride in 40 cc. of acetic acid. The solution was warmed on the steam cone for ten minutes. The solution was then diluted with 200 cc. of water, neutralized with aqueous sodium hydroxide and extracted with ether. Evaporation of the ether left a residue which melted at 105–106° after recrystallization from ethyl acetate. A mixed melting point with 2-phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran gave no depression. The yield was practically quantitative.

Ozonolysis of 2-Phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran.—Two grams of 2-phenyl-3-cyano-6-benzoyl-5,6-dihydro-1,4-pyran was dissolved in 40 cc. of glacial acetic acid and a moderate stream of ozone was bubbled through the solution for seven hours. The ozonide was decomposed by the addition of water. After several hours crystals were deposited; these were dissolved in ethyl acetate and reprecipitated by the addition of petroleum ether (b. p. 25–45°). After several recrystallizations, the acid melted at 113°; yield 0.5 g.

Anal. Calcd. for $C_{18}H_{16}O_5$: C, 69.2; H, 5.14; neut. equiv., 312. Found: C, 69.39; H, 5.27; neut. equiv., 316.

The semicarbazone melted (from an alcohol–water mixture) at 190–195°, with decomposition.

Anal. Calcd. for $C_{19}H_{19}O_5N_3$: C, 61.8; H, 5.15. Found: C, 62.2; H, 5.4.

Hydrolysis of the Benzoate of γ-Hydroxy-γ-benzoylbutyric Acid (V).—Sixteen-hundredths of a gram of the benzoate of γ-hydroxy-γ-benzoylbutyric acid, which was produced by the ozonolysis just described, was treated with an excess of sodium hydroxide solution and allowed to stand overnight. The solution was then acidified and concentrated to a volume of 5 cc.; it was then extracted with ether. Evaporation of the ether left crystals which melted at 182–184°. A mixed melting point with succinic acid showed no depression.

Summary

Further evidence has been obtained in confirmation of the dihydro-1,4-pyran structure previously assigned to the cyano compound derived from 1,4-dibromo-1,4-dibenzoylbutane by the action of sodium cyanide.

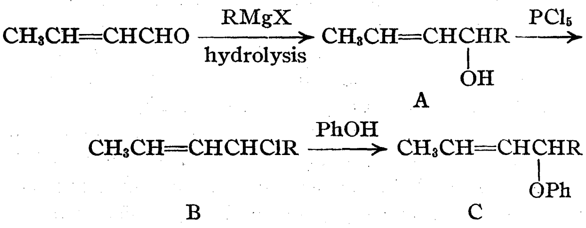
Rearrangements of α-Propylcrotyl Chloride and α-Propylcrotyl Phenyl Ether

BY CHARLES D. HURD AND JONATHAN W. WILLIAMS

The rearrangement of several α-alkylcrotyl phenyl ethers was studied by Hurd and Cohen.[1] The ethers were synthesized from crotonaldehyde by the following series of steps.



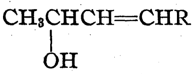
$$CH_3CH{=}CHCHO \xrightarrow[\text{hydrolysis}]{RMgX} CH_3CH{=}CH\underset{\displaystyle OH}{CHR} \xrightarrow{PCl_5}$$

A

$$CH_3CH{=}CHCHClR \xrightarrow{PhOH} CH_3CH{=}CH\underset{\displaystyle OPh}{CHR}$$

B C

Rearrangement of (C) by heating at 230° yielded the phenol (D), $C_6H_4{<}^{OH}_{CH(CH_3)CH=CHR}$. It was not established whether or not A, B and C were free from allylic isomers E, F and G, respectively.

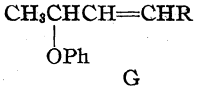


$$CH_3\underset{\displaystyle OH}{CH}CH{=}CHR$$

E

$CH_3CHClCH{=}CHR$

F



$$CH_3\underset{\displaystyle OPh}{CH}CH{=}CHR$$

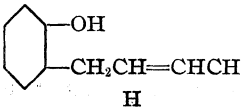
G

This question was significant since an allylic rearrangement of α-alkylallyl alcohols, $CH_2{=}CHCHOHR$, does occur during reaction with halogen acids. Until recently it was thought that the rearrangement into $CH_2XCH{=}CHR$ was complete. In the case of α-methylallyl alcohol, it has been established[2] that the related bromide is an equilibrium mixture of 1-bromo-2-butene and 3-bromo-1-butene, the former predominating. It would be reasonable to assume, therefore, that B (as prepared) would be a mixture of B and F, in which case C would be admixed with G.

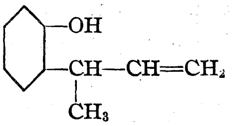
The R-groups in the α-alkylcrotyl compounds of Hurd and Cohen were methyl, ethyl and propyl. It was decided to study the last of these, although the second would have been equally appropriate. The first was inapplicable (since B = F). It was planned to test for the presence of isomeric pairs by ozonolysis. Compounds A to C would yield acetaldehyde or acetic acid, whereas E to G would produce butyraldehyde or butyric acid. Mixtures of isomeric pairs would produce corresponding mixtures of acetic and butyric acids.

It was found by this means that the propylcrotyl alcohol was practically pure A. Conversion to the chloride did cause some isomerization, but B predominated over F. About the same ratio (80:20) was observed in the case of the phenyl ether, showing that the latter was a mixture of C + G, with C in considerable excess.

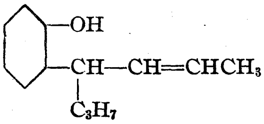
The rearrangement of C into D involves an inversion of the propylcrotyl group. Claisen[3] was the first to call attention to such an effect. He demonstrated that (H), which may be formed



H



I



J

from phenol by direct crotylation, differs from I, the chief product formed on pyrolysis of phenyl crotyl ether. Evidence in support of Claisen's viewpoint was obtained in the present work. Rearrangement of propylcrotyl phenyl ether (the mixture of C + G) yielded a mixture of phenols (D + J). Analysis showed that the ratio of phenols in the (D + J)-mixture corresponded within limits of experimental error to the ratio in (C + G).

Experimental Part

2-Heptene-4-ol, 4-chloro-2-heptene, α-propylcrotyl phenyl ether and α-methyl-δ-ethylcrotylphenol were prepared as described by Hurd and Cohen.[1] The boiling points taken, respectively, were 60–65° (23 mm.), 140–145°, 170–173° (35 mm.) and 190–195° (18 mm.). For ozonizations, 2 to 3 g. was dissolved in 150–250 cc. of carbon tetrachloride and a stream of ozonized oxygen was conducted through the solution. The solvent was then distilled off and 100 cc. of water added to the residue of oily ozonide. After ten hours, 0.5–1 g. of sodium hydroxide and silver oxide (from 10 g. of silver nitrate) were added and the mixture refluxed for three hours. It was then filtered, acidified with dilute sulfuric acid and the volatile acid distilled. The moist silver oxide served not only to oxidize the aldehydes to acids, but also to convert the α-chloroaldehydes (from B or F) to non-volatile α-hydroxy

acids. Analysis of the volatile acids was by Duclaux determinations[4] on 100-cc. specimens.

Duclaux values of 6.4, 6.9, 7.3 were obtained for the first three 10-cc. portions of distillate collected from the volatile acids from 2-heptene-4-ol. This represents nearly pure acetic acid. The slight deviation may be due to the presence of α-hydroxyvaleric acid, whose influence in this determination is unknown. Confirmation that the volatile acid was acetic was the conversion of 0.5 g. of the sodium salts to 0.5 g. of *p*-bromophenacyl acetate, m. p. 84–85°, by reaction in 50% alcohol with *p*-bromophenacyl bromide.

The volatile acids from the 4-chloro-2-heptene gave a Duclaux value of 23.3 for the first 30 cc. of distillate. From this, these simultaneous equations are applicable: $\text{Ac} + \text{Bu} = 100\%$; $0.197\ \text{Ac} + 0.448\ \text{Bu} = 23.3\%$. Solving, Ac (for acetic) = 86%; Bu (for butyric) = 14%. Hydrolysis of the chloride (3 g.) to the alcohol (1.6 g.; 62% yield), b. p. 60–65° at 23 mm. and subsequent ozonolysis of the alcohol as before gave confirmatory evidence that a mixture was involved. The value for 30 cc. of Duclaux distillate was 22.2, indicative of 90% Ac and 10% Bu.

Duclaux analysis of the volatile acids from α-propylcrotyl phenyl ether (after ozonolysis, etc.) gave 24.7 as the value for 30 cc. of distillate. This represents 80% Ac, 20% Bu and indicates that the ether is a mixture of C and G possibly in the ratio of 80:20. The assumption that the volatile acids are exclusively acetic and butyric may not be entirely correct in this case since a small portion of the volatile acid may come from the aromatic part of the molecule. The figures, however, seem fairly reliable.

The product of rearrangement, namely, α-methyl-δ-ethylcrotylphenol, was treated analogously. The Duclaux value for 30 cc. of distillate was 40.3. Calculation gives 18% Ac, 82% Bu, which indicates that the phenol is chiefly D together with a smaller amount of J. The preponderance of butyric acid in the volatile acids was witnessed by converting the acids to dry sodium salts (0.5 g.) and treating the latter with *p*-bromophenacyl bromide. *p*-Bromophenacyl butyrate, m. p. 63°, was formed abundantly.

Summary

Partial allylic rearrangement of 4-chloro-2-heptene into 2-chloro-3-heptene is encountered during synthesis of the former from 2-heptene-4-ol (α-propylcrotyl alcohol). α-Propylcrotyl phenyl ether and its rearrangement product were prepared and their structures determined by ozonolysis. The evidence obtained supports the contention that the allyl group undergoes inversion during rearrangement of allyl phenyl ether into *o*-allylphenol.

Adsorption by Dehydrated Chabasite as a Function of the Water Content

BY ARTHUR B. LAMB AND JOHN C. WOODHOUSE

Vom Rath[1] in 1876 demonstrated that crystals of chabasite, a hydrated calcium, sodium, aluminum silicate, on dehydration retain their original form and clarity unchanged even when the loss of water amounts to nearly one-fifth of their original weight and a still larger fraction of their original volume. Friedel[2] in 1896 found that these dehydrated crystals adsorb gases with marked avidity. Especially interesting is the more recent discovery made independently by several investigators[3] that such an adsorption does not take place with gases whose molecules are larger than a certain definite limiting size and so cannot enter the pores of uniform and atomic dimensions characteristic of this adsorbent.

Impressed by the interesting potentialities of these "crystallogenetic"[4] adsorbents as we have called them, we have now made a careful study of the development of the adsorptive activity of chabasite as it is progressively dehydrated. As a criterion of this activity we have used the adsorptions of hydrogen, oxygen and carbon dioxide upon it, since they represent gases which are, respectively, very slightly, moderately and largely adsorbed.

No similar study, so far as we are aware, has been made.

Apparatus

The samples of chabasite were dehydrated and the adsorption of the resultant product measured in the apparatus shown in Fig. 1.

The manometer C was of the constant-level type. The mercury level on the adsorbent side was kept exactly at (1) by the use of the mercury reservoir B, placed under any de-

(4) That is, adsorbents which owe their adsorptive activity to the crystal structure of the parent substance from which they have been prepared.

sired pressure by air supplied from a hand pump. B was connected by a valve to C. The side of C away from the adsorbent was evacuated through the stopcock A by a diffusion pump sealed to the system.

Purified and triply distilled mercury was then admitted to C from B, and as high a vacuum as possible obtained with the diffusion pump. The empty manometer tube had been previously cleaned, and dried, by the passage through the heated tube of dry air for long intervals. The mercury level was gradually raised by pressure from B, with the tube being kept hot, and under the low pressure provided by the diffusion pump. In about two hours it had risen to point (3) where the 7-mm. internal diameter tube joined a capillary tube 800 mm. long, leading downward and terminating in the stopcock. This downward tube was now likewise roasted, still under the low pressure, and any residual adsorbed gases removed. Mercury was boiled over from (3) to fill the heated downward tube with its vapor, the stopcock was closed and the capillary tube filled with mercury. Thus a high vacuum was ensured on this arm of the manometer. The arrangement was such that if by any chance gas entered the evacuated arm, the procedure of evacuation could be conveniently and quickly repeated. Pressures between 1000 and 1950 mm. were read to 1 mm. and between 100 and 1000 to 0.5 mm. on a calibrated millimeter scale. Pressures between 5 and 100 mm. were read to 0.1 mm. and below 5 mm. to 0.02 mm. by means of a cathetometer.

The adsorption cell D shown above in Fig. 2, usually of quartz but sometimes of Pyrex, was attached to the apparatus by interchangeable ground joints. Its volume (5–7 cc.) from (A) to (B) was first determined accurately; this volume was then charged with 10–14 mesh chabasite through the 5 mm. tube and this was sealed off flat at (C). Since the residual volume of the small tube could be computed accurately from its linear dimensions, the total volume of the cell could be ascertained to within 0.005 cc. The density of the undehydrated chabasite was determined to the second decimal place and using this value and taking the density of the water in the chabasite as unity, the free space in the cell containing wholly or partially dehydrated adsorbent was computed. The free space in the adsorption apparatus between 1 and 2 was also measured accurately by displacement of mercury. It amounted to only between 1.2 and 1.6 cc. in the several arrangements of apparatus used. The total free space in the apparatus ranged between 1.2 and 1.7 cc. per gram of anhydrous chabasite with a maximum uncertainty of ±0.1 cc.

During measurements the cell was surrounded by suitable constant temperature jackets employing transition points, and preferably boiling points of stable substances.

The mercury-operated gas buret, G, had a capacity of 103.47 cc. It was provided with a stirred water jacket and could be read to about ±0.01 cc., but readings usually were taken only to ±0.05 cc. Gases were thus measured to within 0.02 cc. or less per gram of anhydrous chabasite. By means of the leveling bulb gas volumes were measured at atmospheric pressure and at the temperature of the jacket. Corrections were made to standard conditions, taking account of individual deviations from the gas laws.

In order to be sure whether water and the several gases employed were really adsorbed reversibly, it was necessary to measure accurately the several temperatures of dehydration and gas adsorption. Up to 356° (the boiling point of mercury) jackets employing vapors from the refluxing of

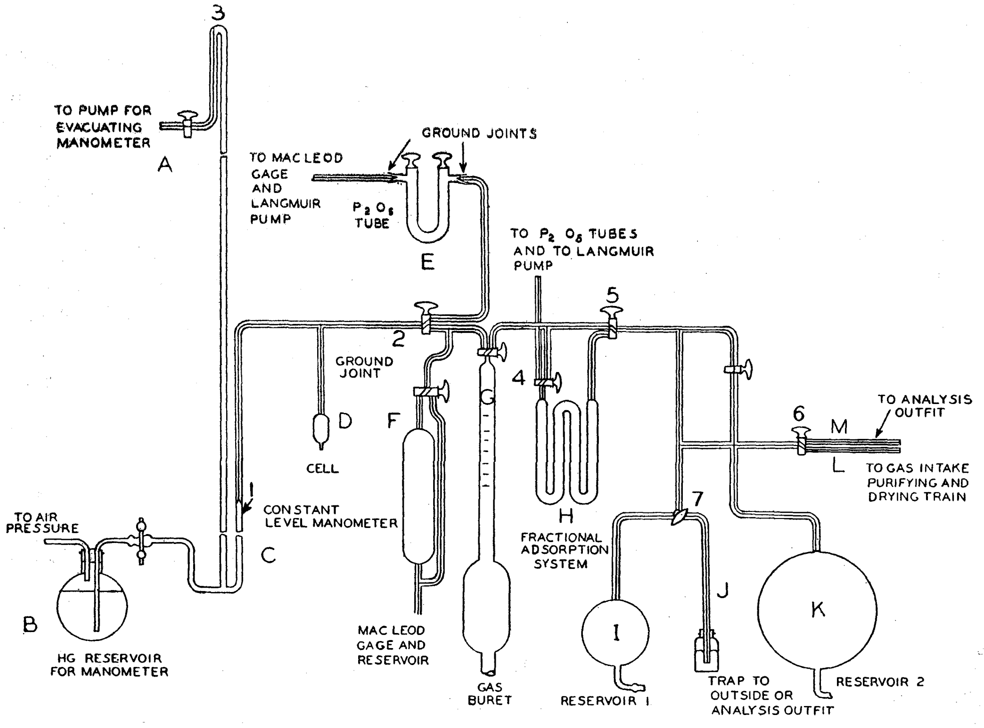

Fig. 1.—Apparatus.

stable compounds were employed. Above 356° there was used a closed tubular electric furnace.

Below 300°, temperatures were checked by a nitrogen-filled glass thermometer. From 300 to 750° they were measured by a nitrogen-filled quartz thermometer and above that by a thermoelectric pyrometer.

The vapor jackets gave all temperatures identical with the boiling points of the compounds used. When the electric furnace was employed, thermometers and cell were so placed that no part of the adsorbent was subjected to a temperature of more than ±5° from that recorded.

At higher temperatures, control was important also in order to prevent injury to the adsorbent through overheating. The observations of earlier experimenters[5] regarding the reversibility of hydration and dehydration below 600° were checked quantitatively.

Materials

Chabasite.—This consisted of six samples which so far as we know represent collections made in the vicinity of Aussig, Bohemia. The small crystals as received were removed from their rocky matrix, crushed sufficiently to pass a 10- and be retained on a 14-mesh-to-the-inch sieve and the fragments examined individually with a microscope and a polariscope to ensure the absence of any foreign material. Each sample thus secured, usually weighing from 75 to 100 grams, was then exposed in a desiccator over 24% aqueous sulfuric acid at about 20° (aqueous pressure 15 mm.) for at least two weeks, and during the last day as nearly as possible at exactly 20°. After this equilibration samples kept for an additional three months under the same conditions showed no further gain or loss in weight. The water contents of these samples were determined by heating 2–4 g. portions at 900–950° to constant weight. The following results, each representing the mean of two concordant duplicate analyses, were obtained for the six chabasite samples: 22.25, 22.23, 22.34, 22.27, 22.27 and 22.30; average 22.28% H_2O.

Hydrogen, Oxygen and Carbon Dioxide.—Selected samples of the compressed or liquefied commercial gases were analyzed carefully and found to be, respectively, 99.0–99.25, 99.5 and 99.88% pure as drawn from the cylinders. The gases were then dried over phosphorus pentoxide and introduced into the adsorption apparatus where they were further purified by means of fractional adsorption.

For this purpose they were allowed to enter the apparatus through L and to escape through J until the voided gas showed a constant and high degree of purity. Tube H charged with 50 g. of activated chabasite and highly evacuated was now chilled to −192° for hydrogen, −182° for oxygen and −78° for carbon dioxide and the gas adsorbed in it up to a pressure of about 1900 mm. A portion of this gas was then discarded, a large fraction of the remainder was drawn into the reservoirs I or K and the residue removed from H by evacuation at room temperature. This procedure was repeated one or more times and the finally purified gas stored in I or K. In the case of carbon dioxide the purification was also frequently carried out using the dehydrated chabasite itself in D. When enough of the gas had been added to raise the pressure there to the maximum desired, a small measured portion containing practically all of the impurities was removed and replaced by an equal volume of the pure original gas (99.88%). This was repeated (usually two repetitions were ample) until the first sample withdrawn showed a purity of 99.88%. We could then be certain that the residual gas was of a considerably higher purity.

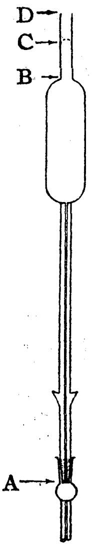

Fig. 2.—Adsorption cell.

Procedure

The water vapor was drawn off from the sample through stopcock 2 into the phosphorus pentoxide tube E, by means of a mercury diffusion pump backed by an oil pump. After suitable intervals of heating and pumping, tube E was disconnected and weighed. By the use of an identical counterpoise and by careful control of the humidity this could be done with an accuracy of ±0.2 mg. which corresponds to an uncertainty of only about 0.004% with the usual 5-g. sample of chabasite.

Adsorption Measurements.—The gas after final purification was transferred to the buret F and from there measured volumes of it were admitted to the evacuated cell D containing the suitably dehydrated adsorbent. Pressure readings were taken until no further change could be detected. This was usually the case within at most twenty minutes. Additional amounts of gas were then introduced until the limit of the manometer had been reached. The points thus obtained gave an "in-going" isotherm. The process was now reversed, measured volumes of gas being removed and an "out-going" isotherm obtained.

Experimental Results

A typical set of experimental data as obtained for a single "out-going" point on an oxygen isotherm is given in Table I in order to illustrate the application of the corrections and the methods of calculation.

TABLE I

Our experimental data are collected in Tables II–V and are shown graphically in Figs. 3–9.

---

[5] The most pertinent previous information appears to be the observations of Rothmund [*Rec. Trav. Chim.*, **44**, 329 (1925)] that chabasite dehydrated at a temperature of 400–600° loses most of its water but can regain it fully on exposure to water vapor at room temperature. At higher temperatures this reversibility becomes less complete and at 800° is wholly lost.

Since however a total of 30 isotherms for oxygen and 15 for carbon dioxide were measured at 0°, because of limitations of space only a part of these have been included in the tables.[6] The temperatures of dehydration given in the tables are the respective maximum temperatures attained during the dehydration which was usually continued for four to ten hours until no appreciable amount of water came off at pressures less than 0.1 mm. The volumes of gas adsorbed as given in the tables represent the number of cubic centimeters, corrected to standard temperature and pressure, adsorbed at the given pressure, per gram of anhydrous adsorbent.

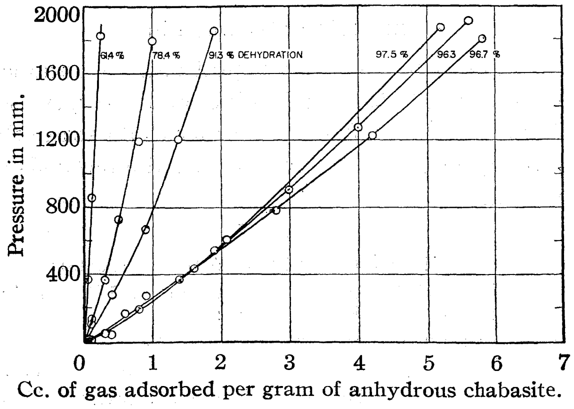

Fig. 3.—Adsorption isotherms at 0° of hydrogen by chabasite at various degrees of dehydration.

Incomplete results with ammonia, which so far as we know is the most highly adsorbed of all gases upon these adsorbents, show that it is somewhat adsorbed upon chabasite when even less than 5% of the total water is removed; and there is some evidence that ammonia actually drives water out of partially dehydrated chabasite. Moreover, ammonia when once adsorbed is held with extreme tenacity. It was found, for example, that all of the ammonia adsorbed on 90% dehydrated chabasite could only be removed by prolonged heating of the adsorbent above 400° at vacua obtainable by mercury diffusion pumps.

Under these conditions there was actual decomposition of the ammonia, and very probably a further removal of water. For these reasons no attempt has been made to treat the ammonia results quantitatively as has been done with hydrogen, oxygen and carbon dioxide.

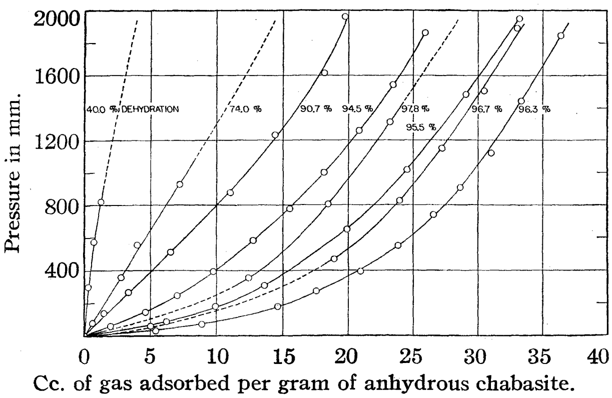

Fig. 4.—Adsorption isotherms at 0° of oxygen by chabasite at various degrees of dehydration.

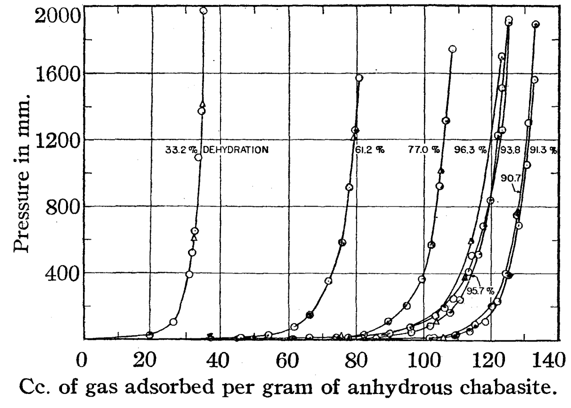

Fig. 5.—Adsorption isotherms at 0° of carbon dioxide by chabasite at various degrees of dehydration. Triangles represent "in-going" values.

The displacement of water by ammonia and the subsequent removal of the latter by evacuation at these relatively low temperatures does, however, facilitate the preparation of highly active adsorbents.

Reproducibility of the Measurements

In the measurements upon samples of chabasite which were only slightly dehydrated the adsorption equilibria adjusted themselves slowly, but in the measurements made with samples considerably dehydrated, for instance 50% or more, equilibrium was attained rapidly, usually in less than twenty minutes.

Hysteresis was also substantially absent, the "in-going" points corresponding closely to the "out-going." This has been indicated in the case of the data for the adsorption of carbon dioxide at 0° by labeling the "in-going" points in the Tables with a * and in the figures with a Δ. It can be seen that they agree closely with corre-

sponding "out-going" points. A similar reproducibility was obtained in the other measurements with carbon dioxide, oxygen and hydrogen.

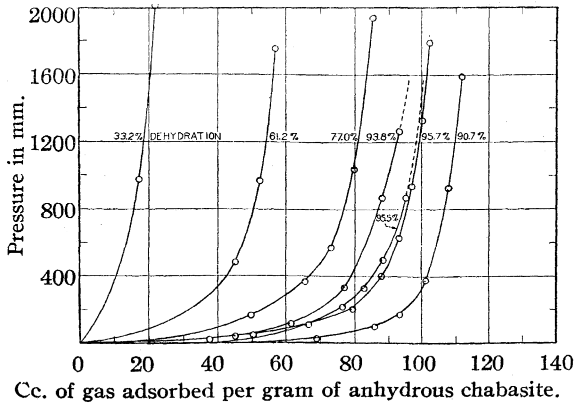

Fig. 7.—Adsorption isotherms for carbon dioxide at 61.2° by chabasite at various degrees of dehydration.

Isotherms obtained from different samples of chabasite of nearly the same degree of dehydration were also usually quite concordant. This is evidence not only of a still broader reproducibility of the phenomenon, but also of the absence of any displacement of water from the partially dehydrated chabasite during the adsorption and desorption of the gases within the range of temperatures and pressures employed. This fixity of the residual water was confirmed by passing the desorbed gases through weighed tubes containing phosphorus pentoxide and ascertaining that there was no increase in weight.

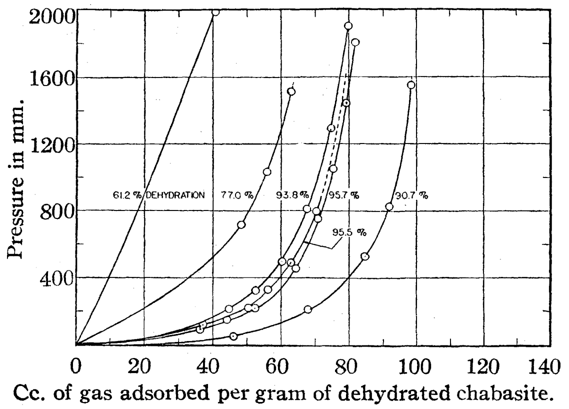

Fig. 8.—Adsorption isotherms of carbon dioxide at 100° by chabasite at various degrees of dehydration.

Utilizing large-scale plots for these isotherms, isobars were now constructed where the amounts adsorbed per gram of anhydrous chabasite were plotted against percentages of water removed. The resulting curves for hydrogen and oxygen on the same scale and for carbon dioxide on a four times smaller scale all at 0° are shown in Fig. 10. Those for carbon dioxide at successively higher temperatures are shown in Fig. 11.

These isobars are also indicative of the reproducibility of our results. The isotherms from which they are derived were obtained in some instances from as many as six different samples of chabasite. These samples not only were independent at the start but were independently dehydrated at somewhat different temperatures and pressures and according to different schedules. In spite of this, the resultant individual points lie smoothly on the isobaric curves. This shows that the adsorptive capacity of this variety of chabasite at a given degree of dehydration is definite and independent, within the limits tried, of the mode of dehydration.

It is also of interest that the adsorptive capacity of a highly dehydrated chabasite remains undiminished after repeated adsorptions and desorptions have occurred both with the same gas and other gases. Thus for example, using chabasite Sample 1, where 19.05% of water of the total of 22.25% originally present had been removed, a later isotherm with carbon dioxide checked closely an earlier isotherm made with this gas, although in the interim several other isotherms at other temperatures had been measured upon the same sample. Similarly chabasite Sample 11, where 21.41% of water had been removed, gave an isotherm substantially identical with an earlier one although in the meantime a dozen isotherms at other temperatures and with other gases had been measured upon it.

Discussion

It can be seen from Figs. 10–11 that the adsorption increases steadily as water is removed from the chabasite, but that ultimately a sharp maximum is reached at a point where only a little water remains. From there on the adsorption diminishes rapidly until at complete dehydration practically no gas is adsorbed. It should be pointed out also that while the adsorption equilibria up to the maximum are reversible, as noted above, after the maximum is passed the reversibility diminishes, and when the water has been largely removed, the equilibria are only slowly attained and are of somewhat doubtful reproducibility. Continued heating after the maximum activity has been developed lessens the activity even when no measurable loss of water occurs.

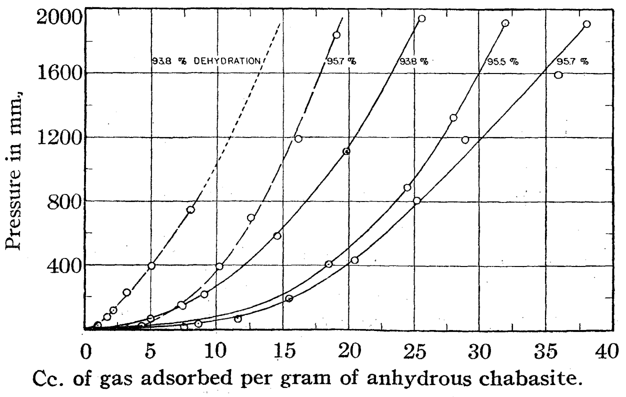

Fig. 9.—Adsorption isotherms at 218 and 306° of carbon dioxide by chabasite at various degrees of dehydration: broken lines, 306°; solid lines, −218°.

From Fig. 11 it can be seen that the same characteristic maximum adsorption at 93% dehydration observed at 0° persists at the higher temperatures. There is also a secondary maximum which is barely suggested in the curve for adsorption at 0° but becomes well marked in the curves for 34.5, 61.2 and 100°. Incomplete results at 218 and 300° show that this secondary maximum is also well marked at these temperatures. It is noteworthy that this secondary maximum occurs at nearly the same percentage dehydration (96%)

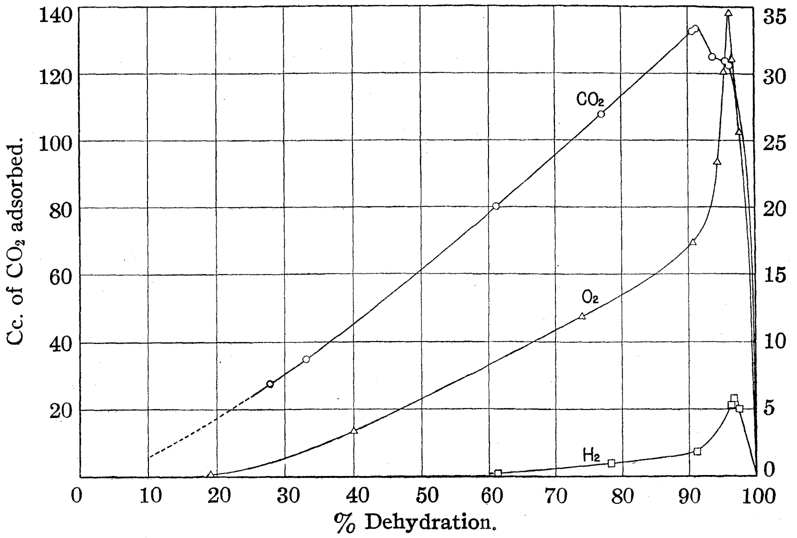

Fig. 10.—Adsorption at 0° and 1600 mm. of CO_2, O_2 and H_2 by chabasite at various degrees of dehydration: ○ = CO_2; △ = O_2; □ = H_2.

where the primary and sole maxima occur for oxygen and for hydrogen.

A reasonable interpretation of the general course of these curves is that the porosity of the adsorbent, and hence its inner surface and its adsorptive capacity, steadily increase as water is removed, so long as the original crystal lattice persists. At the high temperatures required to remove the last traces of water, the crystal lattice begins to collapse, with a consequent decrease in the adsorptive capacity. The sharp drop from the maximum is then to be attributed to a sintering that takes place at the high temperatures of dehydration.

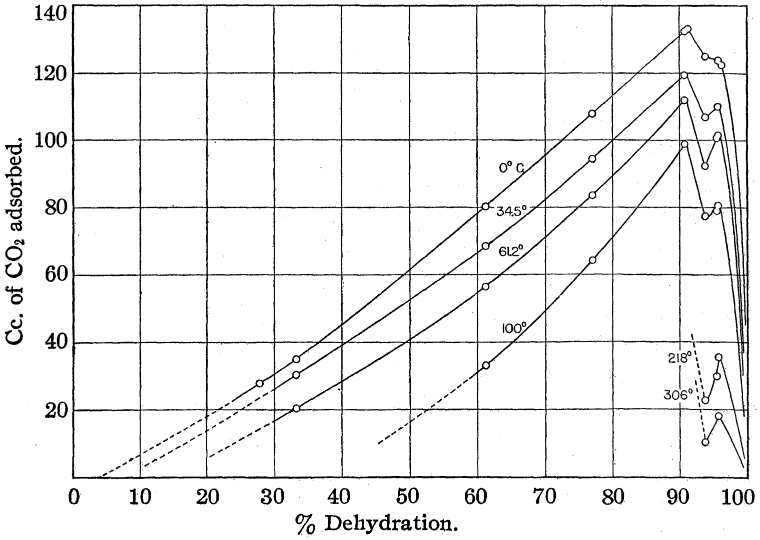

Fig. 11.—Adsorption isobars at 1600 mm. of carbon dioxide by chabasite at various degrees of dehydration.

Another feature of these curves is of great interest. They do not run linearly from the origin (no water removed), but appear to approach the horizontal axis rather abruptly at points at some distance to the right of the origin. In other words, significant quantities of the carbon dioxide, oxygen and hydrogen only appear to be adsorbed when, respectively, 5, 17 and 50% of the total water have been removed. It follows that chabasites dehydrated by these amounts exhibit an astonishing specificity in their behavior toward these gases. Our data in this range are too meager and too inaccurate to fix the exact ratios between the adsorptions of these gases under these conditions, but at 17% dehydration 15 cc. of carbon dioxide and less than 0.2 cc. of oxygen are adsorbed and at 50% dehydration 6 cc. of oxygen and less than 0.1 cc. of hydrogen are adsorbed. These amounts correspond to ratios at least of the order of 75:1 and 60:1, whereas the ratios between the volumes of these gases adsorbed under the same conditions on active charcoal are approximately 3:1 and 4:1, respectively. This remarkable specificity makes possible a simple and effective separation of such gases out of their mixtures.

A reasonable explanation of the negligible adsorption of these gases at and below these critical degrees of dehydration is as follows: The first 5% of the water removed appears to come from the "outer" surface of the crystals or crystallites and its removal provides only an insignificant increase in surface and a consequent insignificant increase in adsorption. The next water removed (up to 17%) opens up relatively coarse pores into which all three gases readily penetrate. The surface thus developed is sufficient to adsorb carbon dioxide largely but oxygen and hydrogen only in negligible amounts. When more water is removed (up to 50%), some additional coarse pores are produced into which carbon dioxide can enter, but the chief effect is to open up a great number of smaller pores into which only oxygen and hydrogen can enter. The resultant inner surface is sufficiently large to adsorb a significant amount of oxygen but is not large enough to adsorb more than a negligible amount of hydrogen. The removal of still more water (50–95%) not only increases the number of coarser and finer pores and thus increases the adsorption of carbon dioxide and oxygen, but it opens up a multitude of the very finest pores into which hydrogen alone can enter. This finest porosity provides a correspondingly great surface with a consequent considerable adsorption even of hydrogen.

This explanation does not, on first thought, seem to help in understanding the marked specificity exhibited by the chabasite dehydrated to 17 and 50% as compared, for instance, with the adsorption of these gases on active charcoal. The negligible adsorption of oxygen compared with that of carbon dioxide at 17% dehydration (1:60), or of hydrogen compared with that of oxygen, cannot be due to any difficulty in the access of the oxygen or the hydrogen, respectively, to the inner surface of the adsorbent, for the oxygen molecule is smaller than the carbon dioxide molecule and the hydrogen molecule in turn is smaller than the oxygen molecule.

On further thought, however, it is clear that this disparity between the ratio of 60:1 for these partially dehydrated chabasites and of 4:1 for charcoal is due to the marked difference in the nature of the porosity of the two types of adsorbent. Whereas in the former at this degree of dehydration the two gases compared both have ready access to all the porosity, in the latter there is a considerable porosity into which only the smaller and less adsorbable of the two gases can enter. Charcoal therefore appears to be a relatively better adsorbent for the less adsorbable gas than would otherwise be the case.

Stated somewhat differently, it may be said that since the same area of adsorbent surface in these specially dehydrated chabasites is available to both gases, the observed ratio between the amount of each gas adsorbed, though extreme, is nevertheless presumably normal.

Another interesting feature of these curves is the relative location of the point of maximum adsorption as disclosed by the data in Table VI.

TABLE VI

LOCATION OF THE MAXIMA

	Percentages		
	Water removed	residual water	Dehydration
Hydrogen	21.6	0.48	97.8
Oxygen	21.4	.68	96.9
Carbon dioxide	20.5	1.58	92.9

The maxima for hydrogen and oxygen are displaced slightly in the direction of more complete dehydration, the maximum for hydrogen being displaced somewhat farther than that for oxygen. These maxima clearly represent the resultant of two opposing effects of the dehydration, namely, the continuing exposure of additional inner surface which increases, and the accelerating collapse of the crystal structure which decreases the adsorption. If the second porosity to be developed is finer than the first and impenetrable by carbon dioxide while the third porosity is still finer and impenetrable by oxygen and if these porosities are correspondingly more extensive, it would be expected that with oxygen and even more with hydrogen the effect of the increase in porosity and inner surface would prevail over the progressive collapse of the crystal lattice to higher degrees of dehydration than in the case with carbon dioxide. This displacement then of the maxima is in full accord with the inference drawn from the other parts of the curves.

A final point of interest with regard to these curves is the very considerable volumes of gases adsorbed at the maxima as compared, for instance, with corresponding volumes for charcoal. Thus the most highly activated coconut charcoal adsorbs at 0° and under atmospheric pressure about 1.5 cc. H_2, 20 cc. O_2 and 87 cc. CO_2, while as can be seen from the above curves, dehydrated chabasite at the several maxima adsorbs, respectively, 2.7 cc. H_2, 27 cc. O_2 and 130 cc. CO_2.

Summary

Chabasite shows a maximum adsorption of hydrogen, oxygen and carbon dioxide at 0°, when 97.8, 96.9 and 92.9%, respectively, of its original water has been removed at suitable temperatures. It shows a similar maximum adsorp-

tion of carbon dioxide at the same percentage dehydration at temperatures of 34.5, 61.2 and 100°. This behavior is explained as due to the collapse of the crystal skeleton when the last fractions of the water are removed.

Slightly dehydrated chabasite exhibits a pronounced specificity of adsorption toward hydrogen, oxygen and carbon dioxide. This behavior is explained on the assumption of several limiting pore sizes and of differing extents of the corresponding inner surfaces.

CAMBRIDGE, MASS. RECEIVED AUGUST 19, 1936

NOTES

The Ethyl Esters of Triiodophenoxyacetic Acids and Potassium Triiodophenoxyacetate

BY T. C. DANIELS AND R. E. LYONS

Several hitherto undescribed triiodophenoxy substitution products of ethyl acetate have been prepared because of their possible opacity to x-rays. The procedure followed was similar to that used by Hewett, Johnson and Pope[1] in preparing tribromophenoxyacetic esters. A mixture of 0.05 mole of triiodophenol, with equivalent quantities of sodium and of ethyl mono-, di- or trichloroacetate, dissolved in 50 cc. of absolute alcohol, was heated on a water-bath for two, three and one-half, or seven hours, respectively, and then poured into 250 cc. of cold water. The monophenoxy derivative, after two recrystallizations from alcohol, was obtained in 40% yield as colorless silky crystals; the diphenoxy, after two recrystallizations from chloroform (in which iodine was liberated slowly) as colorless needles. Attempts to secure the triphenoxy derivative in crystalline form were unavailing, only a yellow, amorphous mass being obtained.

The mono-substituted ester was hydrolyzed incompletely by heating with 30% aqueous potassium hydroxide for several hours. The reaction mixture was poured into water, filtered and the free acid precipitated by dilute hydrochloric acid. Saponification of the di- and tri-substituted esters does not occur under similar conditions.

The Effect of Helium on the Kinetics of the Thermal Decomposition of Acetaldehyde

BY C. J. M. FLETCHER

The extent to which organic molecules decompose by way of a free radical and chain mechanism, or by a simple rearrangement, has been a matter of considerable debate. Although there is an increasing body of experimental evidence which indicates that free radicals and chain processes do exist in the decomposition of such molecules, there is still the alternative that molecular rearrangement can compete with the chain mechanism often to its virtual exclusion. Acetaldehyde is a substance for which a chain mechanism has been proposed,[1] and it has been suggested that the kinetics of its chain decomposition in the presence of free radicals produced either photochemically,[2] or by the thermal decomposition of azomethane,[3] support such a mechanism. However, the concentration of free radicals present,[4] the influence of small amounts of nitric oxide,[5] and the catalysis of acetaldehyde by diethyl ether[6] do not support this hypothesis.

[1] F. O. Rice and Herzfeld, THIS JOURNAL, **56**, 284 (1934).

[2] Leermakers, *ibid.*, **56**, 1537 (1934).

[3] Allen and Sickman, *ibid.*, **56**, 2031 (1934).

[4] Patet, *Z. physik. Chem.*, **B32**, 294 (1936).

[5] Staveley and Hinshelwood, *J. Chem. Soc.*, 812 (1936).

[6] Fletcher and Rollefson, THIS JOURNAL, **58**, 2129 (1936).

The effect of inert gases on the rate of reaction also indicates that the decomposition does not follow the chain mechanism:

$$\begin{array}{rlll} CH_3CHO \longrightarrow CH_3 + CHO & k_1 & E_1 & (1) \\ CH_3 + CH_3CHO \longrightarrow CH_4 + CH_3CO & k_2 & E_2 & (2) \\ CH_3.CO \longrightarrow CH_3 + CO & k_3 & E_3 & (3) \\ 2CH_3 \longrightarrow C_2H_6 & k_4 & E_4 & (4) \\ 2CH_3 + M \longrightarrow C_2H_6 + M & k_5 & E_5 & (5) \end{array}$$

but rather the direct rearrangement

$$CH_3CHO \longrightarrow CH_4 + CO \quad k_6 \quad E_6 \quad (6)$$

for whereas at temperatures above 440°, the recombination of methyl radicals is mainly a homogeneous reaction which takes place partially at ternary collisions so that the rate of the chain reaction is retarded by helium,[7] the thermal decomposition of acetaldehyde itself is accelerated by nitrogen,[8] and by helium (Table I).

TABLE I

TEMPERATURE 552°

$p_{Acet.}$, mm.	p_{He}, mm.	$t_{1/3}$, sec.	$t_{1/2}/t_{1/3}$	Increase in $1/t_{1/3}$, %
93.9	429	148	1.97	11
82.0	375	160	1.95	10
96.4	...	163	1.94	..
83.0	...	175	1.93	..

The last column of Table I gives the increase in rate (as determined from values of the time taken for the pressure to increase by one-third of the initial pressure of acetaldehyde) in the presence of helium compared to the rate for the same initial pressure of pure acetaldehyde.

The results with helium were obtained with the same experimental procedure as that for which it was found that the rate of the chain decomposition in the presence of ethylene oxide was retarded by about 10% at 441° for a 2:1 helium ratio.[7] As the heterogeneous recombination of methyl radicals decreases with temperature, the acceleration given in Table I cannot be accounted for by the inert gas preventing the diffusion of radicals to the walls. Neither can it be explained on the chain mechanism by an increase in the rate of production of methyl radicals such as might occur if reaction 1 were second order; for the initial rate of the chain mechanism is

$$-(dp/dt) = p^{(n/2)+1} k_2 \sqrt{k_1/[k_4 + k_5\,(M)]} \quad (1)$$

where n is the order of reaction 1, so that to explain the observed order of approximately 1.5, Reaction 1 has to be first order.

As the chain mechanism competes so ineffectively with the direct rearrangement, it may be assumed that its over-all energy of activation, $E_{ald.}$, is considerably higher. If the variation with temperature of the recombination of free radicals at ternary collisions can be neglected, then, from equation 1, $E_{ald.} = E_2 + {}^1/_2(E_1 - E_4)$. Values of $(E_2 - {}^1/_2E_4)$ may be obtained from the decompositions induced by azomethane and ethylene oxide; from the results with azomethane, Allen and Sickman[3] derived the value 13,800 cal. on the assumption, which is probably justified,[9] that all the azomethane decomposes to give free radicals. With ethylene oxide the fraction of molecules which gives free radicals is approximately 14%;[7] if the temperature independent factors are the same for both types of decomposition, such a proportion would be obtained if the energies of activation differ by about 3000 cal., *i. e.*, that for the production of free radicals would be approximately 56,000 cal. Making a calculation similar to that for azomethane, $(E_2 - {}^1/_2E_4)$ is therefore 13,500 cal., in good agreement with the value from azomethane. Thus $E_{ald.} \simeq {}^1/_2E_1 + 13{,}700$ cal., so that for the chain mechanism to have a larger energy of activation than that actually observed (50,000 cal.[10] or 45,700 cal.[11]), the energy of activation (E_1) for the breaking of the C–C bond must be closer to 80,000 cal. than to the value of 70,000 cal. assumed by Rice and Herzfeld.

The Standard Electrode Potential of Silver

BY J. J. LINGANE AND W. D. LARSON

The value for the standard potential of the silver electrode, $Ag \mid Ag^+ (a = 1)$, given by Lewis and Randall[1] is −0.7995 v., whereas the value given in the "International Critical Tables"[2] is −0.7978 v. Both of these values apparently are based on the measurements of Noyes and Brann[3] on cells involving liquid junction potentials. Evaluation of the standard potential of the silver electrode from these measurements

---

[1] Lewis and Randall, "Thermodynamics," McGraw Hill Book Co., Inc., New York, 1923, p. 414.

[2] "International Critical Tables," Vol. VI, p. 333.

[3] Noyes and Brann, THIS JOURNAL, **34**, 1016 (1912).

necessitates the use of the standard potential of the calomel electrode, and the difference between the two values given above apparently is due to the revision of the accepted value of the standard potential of the calomel electrode.

We wish to call attention to a simple unambiguous method by means of which the standard electrode potential of silver may be calculated from the standard potential of the silver–silver chloride electrode, $Ag\,|\,AgCl(s),\ Cl^-\ (a = 1)$, and the activity product of silver chloride. The relation between the standard potential of the silver–silver chloride electrode, E^0_{AgCl}, the activity product of silver chloride, K, and the standard potential of the silver electrode $E^0_{Ag,\,Ag^+}$, is given by the thermodynamic equation

$$E^0_{AgCl} = E^0_{Ag,\,Ag^+} - (RT/F)\ln K \qquad (1)$$

The value of E^0_{AgCl} has been determined by several investigators[4] from measurements of the cell $H_2\,|\,HCl,\ AgCl(s)\,|\,Ag$. A critical examination of the data of these authors has led us to believe that the measurements of Carmody, who used quartz cells and was the only one of these investigators who was able to obtain very concordant results in extremely dilute solutions, are the most reliable. By graphical extrapolation Carmody obtained the value −0.2223 v. for E^0_{AgCl}. We have recalculated the value of E^0_{AgCl} from Carmody's data for the three most dilute solutions (0.0007280, 0.0005518 and 0.0003288 *m*) by application of the limiting law of Debye and Hückel. This leads to the equation

$$E^0_{AgCl} = -E_{cell} - \frac{RT}{F}\ln m^2 + 2 \times 0.5045\,\frac{RT}{F}\,S^{1/2} \qquad (2)$$

in which S is the total ionic strength of the solution corrected for the solubility of silver chloride. This equation leads to the same value of E^0_{AgCl} for each of the three most dilute solutions, namely, −0.2222 v. at 25°. We consider this to be the most reliable value of E^0_{AgCl}, and it is in excellent agreement with the value −0.2221 v. estimated by Randall and Young.[5]

The activity product of silver chloride has been determined recently by Brown and MacInnes[6] by a highly precise electrometric titration method. They found a value of K equal to 1.721×10^{-10} at 25°, and this result is apparently reliable to a few tenths of one per cent.

By substituting these values into equation (1) we obtain for the standard electrode potential of silver at 25°

$$E^0_{Ag,\,Ag^+} = -0.2222 + 0.05913\log(1.721 \times 10^{-10}) = -0.7996\text{ v.}$$

The close agreement between this result and the value given by Lewis and Randall is remarkable in view of the fact that the value calculated above is based on entirely independent measurements by different investigators. This result therefore constitutes strong evidence in favor of accepting the value −0.7996 v. as the standard potential of the silver electrode, rather than the value −0.7978 v. given in the "International Critical Tables."

Beta-Octyl Thiocyanate

BY W. GORDON ROSE AND H. L. HALLER

In the course of studies on the relative toxicity to insects of optical isomers of secondary alkyl thiocyanates, the results of which will be reported elsewhere, occasion has been had to prepare the dextro and levo forms of beta-octyl thiocyanate (alpha-methylheptyl thiocyanate). By the action of phosphorus tribromide (138.0 g.) on dextro-beta-octanol (66.0 g.), $[\alpha]^{20}D$ +9.70° homogeneous, $[\alpha]^{20}D$ +11.88° in ethanol ($c = 5.67$), there was obtained 81.3 g. of beta-octyl bromide, $[\alpha]^{20}D$ −32.15° homogeneous, $[\alpha]^{20}D$ −45.30° in ethanol ($c = 5.99$). The latter (81.0 g.), on being refluxed in 100 cc. of methanol with 45.0 g. of potassium thiocyanate, yielded 51.7 g. of beta-octyl thiocyanate, b. p. 98.5–99.0° at 4 mm., d^{20} 0.919, $n^{20}D$ 1.4635, MR_D(obsd.) = 51.30, MR_D(calcd.) = 51.09, $[\alpha]^{20}D$ +51.7° homogeneous, $[\alpha]^{20}D$ +59.1° in ethanol ($c = 5.06$). *Anal.* Calcd. for $C_9H_{17}NS$: C, 63.08; H, 10.01; N, 8.18. Found: C, 63.14, 63.17; H, 10.02, 10.08; N, 8.44, 8.32.

Beta-octyl thiocyanate has been obtained previously by the interaction of beta-octyl-*p*-toluenesulfonate and potassium thiocyanate.[1] The beta-octyl sulfonate was obtained on oxidation of the corresponding sulfinate, which in turn

[6] Brown and MacInnes, *ibid.*, **57**, 459 (1935).

[1] Kenyon, Phillips and Pittman, *J. Chem. Soc.*, 1081 (1935).

was obtained from beta-octanol and *p*-toluenesulfinyl chloride. Starting with a dextro-beta-octanol, $[\alpha]^{20}_{5893}$ +9.48° homogeneous, $[\alpha]^{20}_{4359}$ +22.40° in ethanol (c = 4.992), Kenyon and his co-workers obtained, through this series of reactions, a levo-beta-octyl thiocyanate, $[\alpha]^{20}_{5893}$ −71.41° homogeneous, $[\alpha]^{20}_{5893}$ −64.68° in ethanol (c = 5.010), $n^{17°}_{D}$ 1.4651, $d^{20°}_{4}$ 0.795.

In the series of reactions used by the writers a dextrorotatory octanol yielded a dextrorotatory thiocyanate, while in the procedure used by Kenyon a levo-octyl thiocyanate was obtained from a dextrorotatory octanol. Since an asymmetric carbon atom is involved in both series of reactions, the difference in the results may be explained by the occurrence or absence of the Walden inversion.

The refractive index of the thiocyanate prepared by the writers agrees with that reported by Kenyon and his co-workers, indicating that the compounds are of the same degree of chemical purity. The density of the writers' compound, however, was 0.919, whereas Kenyon reported 0.795.

The molecular refraction of beta-octyl thiocyanate, calculated from the revised values of Eisenlohr for the atomic refractions[2] and employing 13.21 for the thiocyanate radical, is 51.09. The observed molecular refraction for the writers' compound, obtained with the Lorentz–Lorenz formula, is 51.31, whereas with the values for refractive index and density reported by Kenyon 59.31 is obtained.

These results indicate that the value for the density found by the writers is closer to the true value than is that found by Kenyon, *et al.* Since the specific refraction (homogeneous) is dependent on the density, this value is also subject to revision.

A Stopcock Substitute

By Walter C. Schumb and H. Irving Crane

In the course of a certain investigation in this Laboratory it was found necessary to devise a means of interrupting the flow of a benzene solution. A stopcock could not be used, since the ordinary organic stopcock lubricants are readily attacked by benzene, and the reactivity of the solute toward moisture or reactive hydrogen made the use of certain other types of lubricant, such as phosphoric acid, out of the question. The device shown in the diagram is an adaptation of Stock's stopcock for gases [*Ber.*, **58,** 2058 (1925)].

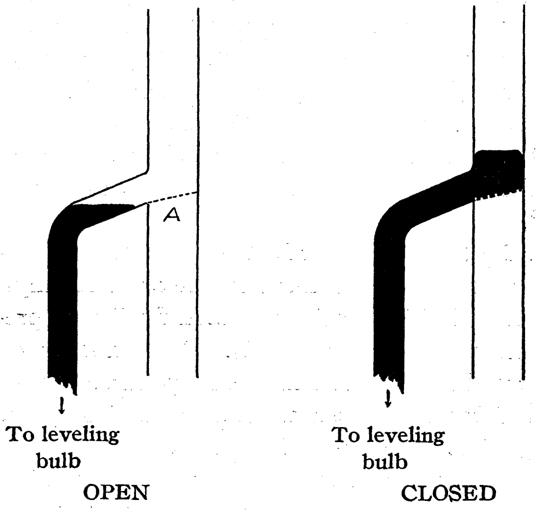

Fig. 1.

The device, constructed of Pyrex glass, consists essentially of a fritted glass plate (A) (80 mesh), so placed that mercury can be flowed over it at will by means of a suitable leveling bulb.

Obviously the device is applicable to any liquid of not too high viscosity, which does not attack mercury. The high surface tension of mercury prevents any of it passing through the fritted plate.

The Rearrangement of Alkyl Aryl Thioethers

By Wendell H. Taylor

In a recent study of the reaction between aromatic mercaptals and formaldehyde, the author[1] postulated a rearrangement of formaldehyde diaryl mercaptals involving the migration of the —CH_2 group from sulfur to the benzene nucleus, with regeneration of the —SH groups. Such a change would be essentially similar to the rearrangement of the alkyl aryl thioethers and it was therefore of interest to investigate such thioether rearrangements under conditions comparable to those under which the analogous oxygen com-

---

(1) W. H. Taylor, This Journal, **57,** 1065 (1935).

pounds isomerize, and comparable also to the conditions of the above-mentioned mercaptal reaction.

The rearrangement of two allyl aryl thioethers has previously been reported,[2] both, however, involving "pyrolysis" of the compounds at their rather high boiling points (215–264°) in the absence of solvents or rearranging agents. The present communication reports briefly on the rearrangement of allyl *p*-tolyl sulfide, *s*-butyl *p*-tolyl sulfide and *s*-butyl phenyl sulfide in the presence of zinc chloride–acetic acid reagent which has been found[3] a satisfactory rearranging medium for the oxygen ethers at temperatures as low as 112°.

In the three cases studied the thioether underwent partial rearrangement to one or more alkyl-substituted thiophenols, obtained finally by precipitation as lead mercaptides. Simultaneously a scission of the thioether molecule appeared to take place, fairly large amounts of allene and butylene being evolved. This is in sharp contrast to the non-production of unsaturated gases reported[4] in thioether and oxygen ether pyrolysis, but corresponds exactly to the observations of Sprung and Wallis. The presence of thiophenol and *p*-thiocresol as the other scission products was indicated by the high percentage of lead found by analysis of the total lead mercaptide precipitate, and by interpolation an approximate ratio of rearrangement product to decomposition product was obtained. Although a part of the thiophenols set free in the reaction suffered oxidation to disulfides and could not be weighed as lead mercaptides, thereby rendering an accurate estimate of the extent of the rearrangement impossible, the isomerization of $\text{—CH}_2\text{—S—R}$ to $\text{R(CH}_2\text{—)SH}$ was definitely established.

For assistance with a part of the experimental work the author wishes to thank Messrs. W. A. Bastedo, Jr., and R. W. Storer.

Experimental

The thioethers were prepared in good yields by heating the appropriate alkyl bromide for twenty-four hours at 110–120° with the sodium salt of thiophenol or *p*-thiocresol. Allyl *p*-tolyl sulfide had the properties described by Hurd; *s*-butyl phenyl sulfide, b. p. 104–105° (25 mm.); *s*-butyl *p*-tolyl sulfide b. p. 135–138° (22 mm.). All were colorless liquids of not unpleasant odor, giving no reaction with alcoholic lead acetate solution. The zinc chloride–acetic acid reagent contained 10 g. of fused zinc chloride in 26 cc. of solution.

In a typical experiment 20–30 cc. of the zinc chloride solution was heated for three hours at 135–150° in a flask provided with a dropping funnel and connected *via* a reflux condenser to a gas buret. After the air thus had been displaced partially, 2.5–10 g. of the thioether was run in and the heating continued for twenty-four hours more, by which time the evolution of gas had practically ceased. By passing steam into the reaction flask all remaining gas was easily driven over into the buret, the contents of which were tested from time to time during the reaction period. The heavy, brownish product which remained in the flask was extracted with ether, and the portion of this which then dissolved in warm 95% alcohol was treated immediately with a saturated alcoholic solution of lead acetate. The precipitate of lead mercaptides was filtered off, washed, dried and analyzed for lead by the usual method of gentle ignition followed by treatment with nitric and sulfuric acids to give lead sulfate.

In the rearrangement of allyl *p*-tolyl sulfide, the volume of gaseous product having the properties of allene—odor, inflammability with luminous flame, reaction with bromine water and with mercuric chloride, inertness toward ammoniacal silver nitrate—amounted to 30–60 cc. per gram of thioether originally taken, the yield decreasing as the reaction temperature was raised from 135 to 150°. The orange lead mercaptide precipitate, presumably a mixture of the lead salts of *p*-thiocresol and 2-allyl-4-methyl thiophenol, gave on analysis 40.2–40.8% Pb. Calcd. for $Pb(SC_6H_4CH_3)_2$: Pb, 43.4; calcd. for $Pb(S\cdot C_6H_3\cdot C_3H_5\cdot CH_3)_2$: Pb, 38.9. The value obtained by analysis would correspond to a mixed mercaptide precipitate containing from 57.5–71% of the lead salt of 2-allyl-4-methyl thiophenol.

In the case of the butyl aryl ethers similar results were obtained. The gaseous product had the properties of butylene but was produced in smaller quantity—from 25–37 cc./g. of the butyl phenyl sulfide, and from 10–15 cc./g. of the butyl *p*-tolyl sulfide. Only in the case of the former was a quantitative analysis of the mercaptide precipitate made. The heavy yellow powder was found to contain 41.8% Pb. Calcd. for $Pb(SC_6H_5)_2$: Pb, 48.7; calcd. for $Pb(SC_6H_4C_4H_9)_2$: Pb, 38.5. This would correspond to a mixture of the two mercaptides containing 69% of the lead salt of *s*-butyl thiophenol.

The Spinning Top Ultracentrifuge and the Sedimentation of Small Molecules

BY J. W. WILLIAMS AND C. C. WATSON

In recent articles McBain and O'Sullivan[1] have discussed their development of the air-driven spinning top as transparent ultracentrifuge. As we read these reports we cannot escape the feeling that a certain pronouncement in them requires further analysis. In the "Communication" a

---

[1] McBain and O'Sullivan, THIS JOURNAL, **57**, 780, 2631 (1935).

"fortunate accident" is mentioned which made it possible "to observe the sedimentation velocity of a boundary in aqueous solution of mercuric chloride: $s = 0.891 \times 10^{-13}$ cm./sec./dyne; theory $= 0.890 \times 10^{-13}$." Later, in the definitive article, McBain and O'Sullivan make the claim that they have recorded for the first time the sedimentation velocity of an ordinary molecule (mercuric chloride), this as a footnote to the statements "For sedimentation equilibrium of ordinary molecules, powers ranging from 100,000 to 1,000,000 times gravity are essential. Still higher powers will be required for observing their sedimentation velocity."

It has seemed worth while to examine this extremely important claim, which is made more striking because of the remarkable agreement between theory and observation (about 0.1%) which is reported. Such examination is extremely difficult because definite information is lacking as regards the speed at which the rotor was turning, how the position of the boundary was observed and located at the ends of the several intervals of time during the centrifuging, how the distances from the center of the cell were measured, how the absence of convection effects was proved, what was the concentration of the solution and the temperature of the cell used in the experiment, how long the centrifuging was continued, etc. However, by making calculations which involve the dimensions of the apparatus, the rotor speeds, and strengths of the materials of construction mentioned in other parts of the longer article, it is concluded that their sedimentation power was not over 350,000 times gravity. For a molecule of weight and density of mercuric chloride in water at ordinary temperatures, one may calculate that the actual sedimentation rate with such centrifugal force would be of the order of 1 mm. per hour.

With the apparatus as described and with the assumption of technique and evaluation of the data according to the methods developed by Svedberg, it is highly improbable that such a rate could be measured with the precision claimed. Also, a serious difficulty is that the back diffusion would so blur the boundary that the distance of travel of the latter in any ordinary interval of time would be hard to estimate. Experiments of Pedersen[2] made in the Svedberg laboratory may be cited in this connection. Working with aqueous solutions of mercuric chloride and at 350,000 times gravity, this investigator was able to establish equilibrium in a cell with liquid column about 5 mm. in height after something like seven hours of centrifuging. However, no mention is made by Pedersen of the observations of the velocity of the sedimentation.

Actually, in view of the very careful Pedersen experiments and several statements contained in the article in question, there may be some doubt that a true sedimentation velocity was observed. In addition to the two sentences quoted above, McBain and O'Sullivan define an ultracentrifuge as being "any centrifuge of low or high power in which convection does not occur, and in which it is possible to measure any redistribution of the contents." Again in referring to the behavior of a rotor which is described as having several advantages (speed, uniformity of temperature, strength) over the one in which the experiment in question took place, there is the statement "With the driving air arbitrarily thermostated to within ±0.02° and the room temperature controlled, the same rotor will sometimes sediment molecules as small as purified egg albumin (molecular weight about 35,000)."

It is a matter of some surprise to find the theoretical sedimentation velocity constant for mercuric chloride molecules in aqueous medium expressed to three significant figures when no temperature is specified. The value of the constant varies considerably with temperature because the viscosity of the solvent is involved. The variation amounts to approximately 2% per degree in aqueous solution at ordinary centrifuge temperatures. For mercuric chloride the theorectical sedimentation constant expressed to two significant figures is 0.73 at 20°, 0.82 at 25° and 0.89 at 30°. The temperature of the cell during the experiment was not determined with precision.

Since the records of the experiment and the calculation for the corresponding theoretical specific sedimentation velocity for mercuric chloride are so incomplete, we are impelled to suggest that a further account of the work be presented before it can be given serious consideration as the first measurement of the sedimentation velocity of an ordinary molecule.

Addendum to the Note of Williams and Watson

By James W. McBain

I do not consider that the note by Williams and Watson calls for any detailed comment. The two sentences published by McBain and O'Sullivan, one sentence in a preliminary communication and the other single sentence in a footnote in a paper of eleven printed pages entitled "The Development of the Air-Driven Spinning Top as a Transparent Ultracentrifuge," still appear to be ample notice of the physical phenomenon that was observed, on November 15, 1934, with the old circular cell whose use was discontinued that year. The cell contained pure water and a crystal of mercuric chloride. Sufficient of the latter dissolved in the lower portion of the cell and then through an accident of convection currents, the absorbing material ($HgCl_2$) was sedimented downward again with a fairly sharp boundary as shown by the photographs and microphotometer photographs, moving 0.102 cm. in 8400 seconds at 108,600 r. p. m. with an average radius of 1.054 cm., giving an observed $S = MD \times (1 - V)/RT = 0.890 \times 10^{-13}$, which, as a mere scientific curiosity, agreed with the value predicted. The precise agreement is of course fortuitous and should not have been expressed to three significant figures, as is obvious to anyone who has any knowledge of an ultracentrifuge.

Professor Williams has acknowledged Dr. O'Sullivan's statement that the sedimentation force was 138,000 times gravity, but Williams and Watson prefer to state "it is concluded that it was not over 350,000 times gravity."

McBain and O'Sullivan stated that this result was an accident and that in the ordinary course, where convection does not occur, a higher order of magnitude of centrifugal force than that in any existing ultracentrifuge anywhere today would be required to obtain sedimentation velocities of such small molecules regularly.

It is entirely a matter of individual opinion as to whether any significance whatsoever attaches to this photographed and microphotometered observation, and Williams and Watson are convinced on the basis of their experience that none does. We still think that it did offer an actual semi-quantitative measurement.

As regards the fourth paragraph of the note of Williams and Watson devoted to discussing the state of development of our air-driven ultracentrifuge as described at the April, 1935, meeting of the Society, it is only necessary to say that our statements were carefully made and stand accordingly as referring to the now superseded models as developed at that time; and that the appreciable modifications and the very simple temperature control in the later model referred to in the footnote by H. J. Fouts inserted at the end of that paper in the final proofs have resulted in uniform success in sedimenting smaller protein molecules such as carbon monoxide hemoglobin—as was, for example, demonstrated at the Western Protein Conference, June 6, 1936. There appears now to be no reason why any sedimentation velocity or equilibrium observable in the Svedberg ultracentrifuges, or the equally good air-driven models now developed, for example, at the Rockefeller Institute for Medical Research [see for example *J. Exptl. Medicine*, **64**, 39 (1936)], or the model supplied by the Sharples Specialty Company of Philadelphia should not also be capable of quantitative study in the McBain–O'Sullivan–Fouts transparent ultracentrifuge. All parts of this cell are easily kept at any desired *constant* measured temperature within 0.02°. All forms of the air-driven ultracentrifuge appear to be in process of still further rapid improvement.

Chemical Nature of δ-Follicular Hormone

By O. Wintersteiner, E. Schwenk, H. Hirschmann and B. Whitman

In 1932 Schwenk and Hildebrandt[1] reported the isolation from the urine of pregnant mares of a new oestrogenic substance, isomeric with oestrone (theelin), which they designated δ-follicular hormone. Wintersteiner, Schwenk and Whitman[2] subsequently showed that this substance (m. p. 209°) was not a ketone, but a dihydroxy compound. Recently larger amounts of crude phenolic fractions from mares' urine were separated in the laboratories of the Schering Corporation into ketones and alcohols. The alcoholic portion was worked up for δ-hormone at Columbia University. Our present experience with material of this type makes it appear doubtful whether the earlier preparations represented a chemical individual,

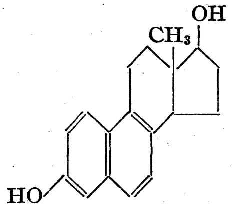
a possibility discussed in the first publication. Fractional crystallization yielded an apparently homogeneous product which did not change its melting point (226° corr.) on repeated recrystallization from various solvents. However, the analytical composition and specific rotation varied with different preparations ($[\alpha]_D$ +31 to +37°). The preponderant constituent of these mixtures appears to be a molecular compound consisting of two components. Only one component forms a picrate, and this property as well as its stronger acidic character enabled us to isolate this component in pure form.

The new compound melts at 215–217° and has the composition $C_{18}H_{20}O_2$ (calcd.: C, 80.55; H, 7.52; found: C, 80.53, 80.47; H, 7.61, 7.52); $[\alpha]^{25}_D$ −4.7° (0.7% in dioxane). A di-*p*-nitrobenzoate (m. p. 250–252° corr.) and a monobenzoate (m. p. 203–205° corr.) have been prepared. The compound gives the color reactions originally attributed to the δ-follicular hormone.[1,3] Its absorption spectrum coincides with that of equilenin. Our measurements on equilenin reveal two new bands in addition to those found by Dirscherl and Hanusch,[4] namely, at 2310 Å., log ε 4.78, and at 2920 Å., log ε 3.58.

The monobenzoate was oxidized with chromic acid to a ketone which gave no depression of its melting point (223° corr.) when mixed with equilenin benzoate. The dihydroxy compound (m. p. 217°) is therefore dihydroequilenin.



Contrary to the rule, established for other oestrogenic compounds, that reduction of the C_{17} keto group to carbinol enhances the physiological activity, the dihydroequilenin isolated from urine possesses only about one-half of the potency of equilenin. On the other hand, David[5] found that the oily product which he obtained by reduction of equilenin with sodium was about three times as potent as equilenin. The possibility that our diol differs from the potent oestrogenic diols, obtained by reduction, in the configuration of the C_{17} hydroxyl group will be investigated. Whether the high potency originally reported for the δ-hormone resides in the other, as yet unidentified, component of the molecular compound (m. p. 226°) or in other diols present in the impure preparations, remains to be determined.

We wish to express our sincere thanks to Dr. A. Girard of Paris for sending us samples of equilenin and its benzoate for comparison.

Phenylmercuric Fluoride

BY GEORGE F. WRIGHT[1]

The recent discovery[2] of mercuric fluoride as a new fluorinating agent recalls the investigation in this Laboratory of phenylmercuric fluoride. This preparation was incidental in the study of the relative strengths of C–Hg and Hg–X bonds in organomercuric halides. According to our knowledge of organomercurials the tendency toward the dissociation reaction $2RHgX \rightleftarrows R_2Hg + HgX_2$ decreases in the order HgI > HgBr > HgCl. It was hoped that the introduction of fluorine would so stabilize the Hg–X bond as to favor the primary reaction $RHgX \longrightarrow R— + HgX$ which, it is considered, accounts for the interconversion possible with compounds like furyl and thienylmercuric halides containing more reactive, though unfortunately less stable, radicals.[3] The compound did not, however, fulfil these expectations. Instead of reacting with acetyl chloride to give acetophenone, acetyl fluoride was formed as easily as from mercuric fluoride.[2] Likewise when the compound was pyrolyzed at a temperature lower than that required to decompose diphenylmercury, only the latter substance, and no diphenyl, was produced.

In connection with the assertion of Henne and Midgley that pure mercuric fluoride cannot be prepared by treating mercuric oxide with aqueous hydrofluoric acid it may be significant that treatment of such a solution with phenyldiazonium fluoride, and subsequent treatment with copper, produced no trace of phenylmercuric fluoride.

I wish to thank Professor E. P. Kohler for suggestions offered during this investigation.

Experimental

Phenylmercuric Fluoride.—A solution of 40.6 g. (0.17 mole) of freshly precipitated silver oxide and 14 g. (0.35 mole) of 50% hydrofluoric acid in 400 cc. of water was shaken for five hours with 78 g. (0.25 mole) of phenylmercuric chloride, previously moistened with ethanol. The solid was filtered off and extracted with 400 cc. of boiling ethanol. After a small amount of precipitation by cooling, the solution was decanted and concentrated *in vacuo.* The residue was extracted with boiling ethanol and filtered. The cooled solution yielded 32 g. of phenylmercuric fluoride, m. p. 170°, or 43% of the theoretical. The chlorine-free compound was soluble in hot alcohol, hot xylene and hot chloroform and was crystallized from the latter solvent for analysis (m. p. 171°). It was insoluble in carbon tetrachloride, ethyl acetate, ether and hot acetone. The extracted silver chloride from the reaction mixture contained much unreacted phenylmercuric chloride; no doubt the yield can be increased by a longer period of reaction.

Anal. Calcd. for C_6H_5HgF: C, 24.27; H, 1.70. Found: C, 24.25; H, 1.99.

Reaction with Acetyl Chloride.—When 2.96 g. (0.01 mole) of phenylmercuric fluoride was refluxed with 1.57 g. (0.02 mole) of acetyl chloride, the acetyl fluoride was evolved immediately through the reflux condenser. After five hours the reaction was poured into iced sodium carbonate solution. No mercuric oxide precipitated. The solid was filtered off and crystallized from xylene to weigh 2.80 g. and melt at 257°. This 90% yield of phenylmercuric chloride was substantiated by mixed melting point.

Diphenylmercury.—When phenylmercuric fluoride was slowly destructively distilled at 200° under 10 mm. only diphenylmercury, and no diphenyl, could be found in the distillate.

COMMUNICATIONS TO THE EDITOR

METAL ION ACTIVATION IN ENZYMATIC CATALYSIS. ARGINASE

Sir:

Recent investigations [Hellerman, Perkins, and Clark, *Proc. Nat. Acad. Sci.*, **19,** 855 (1933); Hellerman and Perkins, *J. Biol. Chem.*, **107,** 241 (1934); Bersin, *Z. physiol. Chem.*, **220,** 209 (1933)] support the idea that reversible chemical actions upon substituent thiol groups of certain enzymes (urease, papain, etc.) may account largely for their reversible inactivations by oxidation and by silver ion, phenylmercuric hydroxide, etc. However, the enzyme, arginase [Hellerman and Perkins, *J. Biol. Chem.*, **112,** 175 (1935)], was found to be little sensitive to phenylmercuric hydroxide, and most readily activated, not by reduction in the usual sense but rather by the use of reduced ions of the transition elements, manganese, cobalt or nickel, as well as ferrous ion, which had been associated previously with arginase activation. This, and other evidence cited, was considered to point strongly to metal coördination as a factor not merely in arginase activation but actually in the functioning of the enzyme itself. For example, dissociable, labile enzyme-substrate intermediates might be constructed by the "binding" to a metal ion of both enzyme and substrate through donor groupings of each. If so, an effective metal ion should alter the activity–*p*H curve of arginase in a characteristic way.

We have now studied the effect of such ions upon the arginase–arginine reaction in buffers of widely varying *p*H values but having approximately constant ionic strength ($\mu = 1$). Activity–*p*H curves constructed from the data clearly show characteristic differences. Liver-arginase action is enhanced greatly by nickelous and especially cobaltous ion from *p*H 5 to 7.7; activation by manganous ion is not significant below *p*H 6.7. The optima for cobaltous, nickelous and manganous ion are, respectively, *p*H 7.5 to 7.7, 6.7 to 7.7 and 10 as compared with the optimum for our arginase, without added metal, 7.7 to 9.0. The variations may be considered in relation to the corresponding stabilities of the coördination complexes of these ions with substituted ammonias. For example, we ascertained (by a potentiometric titration method) that the dissociation constants of the complex ions derived from *d*-arginine with cobaltous, nickelous and manganous ion, respectively, are approximately of the order, 2×10^{-10}, 4×10^{-11} and 1×10^{-6}. Manganous ion apparently cannot appreciably activate arginase in the more acid *p*H range where it coördinates only slightly.

A similar study has also been made with the new catalyst for *d*-arginine hydrolysis, which Hellerman and Perkins found was "elicited," in the presence of cobaltous, nickelous or manganous ion from some constituent of their preparations of jack bean urease. This "urease-metal" effect, in contrast to liver–arginase activity, is negligible below *p*H 7.0; "with Co^{++}" the curve relating activity (ordinate) with *p*H (abscissa) rises sharply from *p*H 7.1 to 7.7, the optimum. This practically proves the non-identity of the two catalysts. Nevertheless, the characteristics of the kinetics of arginine hydrolysis with either enzyme (plus Co^{++}) are similar (pseudounimolecular at *p*H 7.5). Moreover, the striking specificity of liver–arginase is retained in the new catalyst; this was tested with argininic acid, δ-guanidinovaleric acid, etc.

The results will be published in detail in another place.

AN ANTIRACHITIC SUBSTANCE FROM TUNA LIVER OIL

Sir:

Drummond and Haslewood [*Chem. & Ind.*, **55**, 598 (1936)] report the isolation of an antirachitic substance from tuna liver oil and indicate that their substance may not be identical with that of Brockman [*Z. physiol. Chem.*, **241**, 104 (1936)]. Our own findings may be of interest, particularly since we arrive at essentially the same end product as Brockman by a somewhat different route. We have not used the chromatographic technique which he deems essential.

Starting with an alcohol-soluble fraction from the non-saponifiable of tuna liver oil, the sterols were esterified with phthalic acid, leaving the hydrocarbons behind. This was followed by distribution of the sterol mixture between solvents in the manner described for a number of similar mixtures by various investigators. Removal of cholesterol by digitonin, freezing, treatment with decolorizing carbon and finally formation of the 3,5-dinitrobenzoic ester gave a crystalline product which melted sharply at 128.5°. The alcohol from this showed a narrow absorption band with a peak at 2650 Å. and an extinction coefficient $E^{1\%}_{1\text{cm.}} = 350$ in Normalbenzin (Kahlbaum). The dinitrobenzoic ester showed 4.94% of nitrogen; calcd. 4.83%. The biological activity was 30×10^6 international units per gram. No evidence of any considerable amount of biological activity residing in substances with other absorption peaks was obtained, although in the stages of lesser purity low absorption peaks at both longer (Drummond) and shorter wave lengths were very evident.

We agree with Brockman that the material he identified essentially characterizes the Vitamin D of this type of liver oil. Our slightly higher biological activity as well as our slightly but distinctly narrower absorption band (calculated to the same units as Brockman uses), cause a little hesitation in concluding that either Brockman's D_3 or our material is pure. The difference in absorption is not likely to be a solvent effect (hexane *vs.* Normalbenzin), particularly since the position of the peak is identical. All these findings have as yet no bearing on the question of multiplicity of forms of naturally occurring Vitamin D.

NEW BOOKS

Collateral Readings in Organic Chemistry. By L. A. Goldblatt, University of Pittsburgh. Edwards Brothers, Inc., Ann Arbor, Michigan, 1936. iii + 128 pp. 21.5 × 27.5 cm. Price, $1.00.

This book is an attempt, on the part of the author, to place at the disposal of students in Elementary Organic Chemistry, at a nominal expense, articles in the current literature. The articles have been taken from the journals sponsored by the American Chemical Society.

The author states in the preface that he desires to bring to the attention of the student of Elementary Organic Chemistry the existence of a literature in Organic Chemistry. The articles have been carefully chosen. The experiment is an interesting one and the book seems worth while.

Samuel T. Arnold

An Elementary Chemistry. By A. H. B. Bishop, Headmaster of Warwick School, and G. H. Locket, Assistant Master at Harrow School. Oxford University Press. 114 Fifth Ave., New York, N. Y., 1936. 398 pp. 133 figs. 13 × 19 cm. Price, $1.75.

This textbook of elementary chemistry, following the usual English method, presents more material than the ordinary American secondary school book, and rather less than most regular college texts. The topics and presentation in general are well adapted for a course emphasizing either general knowledge or college preparation. The authors have tried to avoid what they believe to be a fault of many texts, by offering more than the customary amount of information on the metallic elements and their metallurgy, and stressing the everyday and industrial uses of the elements and compounds described. The amount of chemical theory in the book has been minimized by careful presentation and judicious elimination, the latter perhaps having been carried too far for the best interests of college preparatory classes. Questions and problems are introduced frequently, many of them taken from various examination papers. One useful feature of the book is the directions for experiments which are inserted in the text at the proper places; many of them being suitable for desk demonstration. The book may well be chosen by instructors giving a thorough high school or brief college course.

Allen D. Bliss

Das Ausblühen der Salze. (The Efflorescence of Salts.) By Dr. Phil. Karl Schultze, Hygienisches Staatsinstitut zu Hamburg. Separate printing, from *Kolloid-Beiheften*, edited by Prof. Dr. Wo. Ostwald, Leipzig. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1936. 99 pp. 36 figs. 15.5 × 23.3 cm. Price, RM. 4.

The German word *ausblühen* refers usually to the shedding of blossoms; its intent is probably broader than that of the English, creeping of salts, and corresponds more nearly to that of efflorescence by which we are accustomed to designate both the loss of water from hydrated crystals with the consequent formation of powder and the deposition of dissolved salts in masses which resemble vegetation, as when we speak of the efflorescence upon a piece of masonry or the walls of a cellar. The phenomena in question are of interest to the colloid chemist, the geologist, the mineralogist, and others; they play an important part in the economy of nature and are of practical significance to the artist, the architect and the engineer.

The author of the present brochure has published extensively on the subject, and now presents an interesting, well-illustrated, and well-documented survey of the whole field. The seven sections of the monograph deal respectively with (1) the multiplicity of the names (for the phenomenon of efflorescence) and the first descriptions, (2) *Bodenausblühen* (creeping within deep masses of crystals), (3) climate and local conditions, (4) efflorescence of structural materials, (5) experiments toward an explanation of the mechanism of efflorescence, (6) capillary theory of efflorescence, and (7) influence of dispersion. The early work of Lemery on chemical vegetation, published with three handsome engravings in *Mem. Acad. Roy. des Sciences*, 1706, pp. 411–418; 1707, pp. 299–328, is not mentioned in the list of references.

Tenney L. Davis

Grundriss der chemischen Technik. (An Outline of Chemical Technology.) By Dr. F. A. Henglein, Professor and Director of the Institute of Chemical Technology, Technical College of Karlsruhe. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 35, Germany, 1936. viii + 470 pp. 435 figs. 19.5 × 27.5 cm. Price, RM. 16.80.

This book is the outgrowth of a series of lectures given at two well-known German universities and is based on the author's long practical experience in chemical industry. It is divided into two main parts, the first dealing with the general technology common to all branches of the industry and the second with the more specialized techniques of particular industries.

Part I opens with a brief review of some of the more important physicochemical laws governing chemical reaction, and some general observations on the economics of chemical processes and on the analysis of processes into unit operations. This is followed by a long section describing typical equipment for carrying out the more common unit operations—a purely descriptive and non-quantitative treatment, very well illustrated by diagrams and photographs.

The remaining sections of Part I deal with a number of matters which are of the utmost importance to the success of any chemical manufacturing enterprise, but which are frequently omitted or only casually mentioned in typical American texts on so-called "Industrial Chemistry." For example, such factors as power, water supply, storage, transportation, safety, shops and laboratories, organization of personnel, patents, buildings, etc., are treated briefly but with sufficient detail to emphasize their importance.

Part II, dealing with the more specialized procedures, has two main subdivisions, the first of which treats the more strictly chemical industries such as nitrogen fixation, acids, alkalies, dyestuffs, pharmaceuticals and the like, while the second is concerned with those industries producing consumption goods with the aid of chemicals and chemical control, but in which the products are not the direct result of chemical reactions. Examples are the rubber, textile, leather, perfume and photographic film industries. As an Introduction to Part II, there is a good general discussion of the raw materials of chemical industry.

The most outstanding feature of the book is the excellence of the illustrations of which there are more than 500. They contribute very greatly to its value, but even without them the reviewer believes that the book is a distinct contribution to the chemical engineering literature. It seems to him to give an unusually well balanced picture of chemical industry as a whole.

BARNETT F. DODGE

Colloid Symposium Monograph. Papers Presented at the Twelfth Symposium on Colloid Chemistry, Ithaca, New York, June, 1935. Edited by HARRY BOYER WEISER, Professor of Chemistry, The Rice Institute. The Williams and Wilkins Company, Mt. Royal and Guilford Avenues, Baltimore, Maryland, 1936. 156 pp. 18 × 26 cm. Price, $3.00.

This volume contains the papers presented at the Twelfth Symposium on Colloid Chemistry, held in June, 1935, at Ithaca, New York. All but two of these papers, namely, one entitled "The Adsorption of Water Vapor by the Growth Elements of the Sapwood and by the Heartwood of Southern Pine," by C. J. Frosch, and another, "A Hydrate Decomposition Mechanism," by V. R. Damerell and O. F. Tower, have already been published in Volume 40 of *The Journal of Physical Chemistry*. It is, however, a convenience to have them available in a separate volume, particularly for persons who have sets of Colloid Symposium Monographs and Colloid Symposium Annuals.

ARTHUR B. LAMB

The Thermochemistry of the Chemical Substances. By F. RUSSELL BICHOWSKY, Editor for Thermochemistry for the "International Critical Tables," and FREDERICK D. ROSSINI, Scientist in Physical Chemistry at the National Bureau of Standards. Reinhold Publishing Corporation, 330 West 42d Street, New York, N. Y., 1936. 460 pp. 15.5 × 23.5 cm. Price, $7.00.

The sub-title of this book "The Assembly of a Self Consistent Table of "Best" Values for the Heats of Formation of the Chemical Substances (Except Carbon Compounds Containing More Than Two Carbon Atoms), Including Heats of Transition, Fusion, and Vaporization" clearly defines the contents. The authors have retained the order of arrangement of the section of thermochemistry in the "International Critical Tables," of which this is essentially a revision and extension. Accurate descriptions of the electron configurations of many of the substances are added. The return to the calorie (1 defined calorie = 4.1850 absolute joules = 4.1833 International joules = 0.04337 absolute volt-electrons) is welcome.

In determining the best value, the authors first recalculated the experimental data to consistent units, molecular weights, etc., so far as possible. The values are tabulated as the heat evolved when the clearly indicated reaction takes place at a constant temperature of 18° and a constant pressure of 1 atm. Only the selected best value appears in the main table. There follows (pp. 171–405), arranged in the same "I. C. T." order as the main table, a discussion of the source and methods of measurement and sometimes the individual values from which the selection of the best value was made. This section is especially welcome to research workers in thermochemistry. The system of references to the original data is clear, concise, and is a great improvement over that used in the "I. C. T." or other tables of thermochemical data. The abbreviations used are clearly defined, and as the "I. C. T." order of arrangement is used the material is self indexed. But for those unfamiliar with the "I. C. T." standard arrangement, an index showing the locations of the elements in the table and text is given.

The authors are thoroughly familiar with the field and have succeeded in assembling, recalculating and tabulating the extensive data relating to heat of formation in a practical, accurate, and understandable way.

MERLE RANDALL

Experimental Enzyme Chemistry. By HENRY TAUBER, New York Medical College and Flower Hospital, New York City. Burgess Publishing Company, 426 South Sixth Street, Minneapolis, Minnesota, 1936. v + 118 pp. Illustrated. Price $3.50.

This mimeographed edition is a successful attempt to present certain of the more important advances in enzyme chemistry during the past few years. Experimental results, rather than theoretical considerations, are emphasized and no attempt is made to cover the material given in earlier monographs. At times the text is vague and shows haste in writing, and certain sections are rather sketchy due to the size of the book. However, this is in part offset by a well selected list of over 800 references.

The first chapter deals with the nature of enzymes and their mode of action as influenced by various factors. The protein nature of many enzyme systems, shown largely by American workers, is discussed. Such topics as buffers, "anti-enzyme," activators and inhibitors are either omitted or given too scant treatment. Then come chapters on the following specific systems: esterases, proteolytic enzymes and those acting upon related nitrogen compounds, carbohydrases, catalase, oxidizing enzymes and the flavine system, carbonic anhydrase, zymase and luciferase.

Especially in the cases of the proteases and the carbohydrases certain groupings are attacked by specific enzymes and these relationships are pointed out in this book. During the past ten years theories as to the role of cytochrome and the flavine pigment of Warburg and Christian in oxidizing enzyme systems have been developed; this difficult field is also well summarized.

Dr. Tauber has performed an excellent service in summarizing the latest material in several fields of enzyme chemistry and we can only wish that the manuscript were extended to cover more fully certain sections and to include other topics. An index would greatly increase the usefulness of the book. The monograph will scarcely serve as an introduction to the study of enzyme chemistry but it will be read with profit by those acquainted with the field.

W. M. SANDSTROM

Enzymologia. Vol. I, Nos. 1–2. Edited by CARL OPPENHEIMER. W. Junk Verlag, 74 Scheveningsche Weg, Den Haag, Holland. 160 pp. 20 × 28 cm. Price, per volume, Dutch florins, 15.00.

This journal, first issued in June, 1936, is devoted entirely to enzymes and will cover the whole range of enzyme research. Original articles and brief preliminary reports will be accepted, but summarizing reviews are to be accepted only when asked for by the editor. The manuscripts, which are to be as concise and comprehensive as possible, may be written in German, English, French and Italian. Publication will be prompt. Authors are to receive 120 free copies of their articles as honorarium. The editor, Dr. Oppenheimer, well known as the author of many authoritative volumes dealing with enzymes, will have the assistance of 101 collaborators from various countries who are recognized for their interest in enzyme chemistry and for past contributions in this field.

The first two numbers of the journal, containing seventeen research papers, have already appeared. These papers are of such quality that the reviewer believes that *Enzymologia* can be expected to deserve a place in every biochemical library. In view of the present high cost of German journals one wonders what the price will be per year. Because of the fact that *Enzymologia* will appear at indefinite intervals, it is difficult to make any positive statement, but it is probable that the cost per year will be inconsiderable.

In view of the present broadcast distribution of enzyme articles in so many different scientific publications it will be a distinct advantage to find a considerable number grouped together in one journal. The reviewer is of the opinion that *Enzymologia* deserves the support and interest of chemists and biologists, and that the existence of this new journal will raise the standards of enzyme research.

Page 69. Column 2, line 11 should read "$\alpha = K/[K + (H^+)]$." Line 17 should read "$[UO_2(C_2O_4)_2^=] = 0.0201$."—E. C. Pitzer.

George H. Tomlinson, 2nd, and Harold Hibbert. **Studies on Lignin and Related Compounds. XXIII. The Preparation and Methylation of Spruce Lignin Sulfonic Acids.**

Page 343. In column 2, line 12, for "100°" read "110°."—Harold Hibbert.

George H. Tomlinson, 2nd, and Harold Hibbert. **Studies on Lignin and Related Compounds. XXIV. The Formation of Vanillin from Waste Sulfite Liquor.**

Page 346. In Table I, column 4, item 5, for "Digest 100 cc. liquor ..." read "Digest 1000 cc. liquor ..."—Harold Hibbert.

B. Sullivan and C. H. Bailey. **The Lipids of the Wheat Embryo. I. The Fatty Acids.**

Page 386. In column 2 the third formula should read "$Ln = -(100 - G) + 1.104$ (thiocyanogen number)."—C. H. Bailey.

S. R. Benson and H. N. Calderwood. **The Chemical Examination of the Seed of Abies Balsamea (L) Miller.**

Pages 524–525. In item 7 of the Summary the second word should be "linolenic" instead of "linoleic," and in the last line for "9-octadecanoic" read "9-octadecenoic."—H. N. Calderwood.

Lee Irvin Smith and C. W. MacMullen. **The Reaction between Quinones and Sodium Enolates. IV. Pseudocumoquinone, Sodium Acetoacetic Ester and Sodium Malonic Ester.**

Page 630. "In formula I a methyl and hydroxyl group should be interchanged so that the hydroxyl will be para to the bridge oxygen and not meta."—Lee Irvin Smith.

Walter Fuchs. **Investigations Concerning Phenol Lignin and β-Methoxyethanol Lignin from Spruce Wood.**

Pages 673 ff. The compound described as "Methoxy Glycol" should have been named "β-Methoxyethanol."—The Editor.

William F. Bruce. **The Preparation of Platinum Oxide for Catalytic Hydrogenations.**

Page 688. In column 1, footnote 4 should read "(4) The addition of a trace of $FeSO_4$ served to promote the reaction."—William F. Bruce.

R. F. Miller and Roger Adams. **Contribution to the Multiplanar Isomerism of Cyclohexanes.**

Page 788, Column 2, line 18. The sentence, "On the basis of only one 'C' form, five isomers remain." should read, "On the basis of only two 'C' forms produced by interchange of a and b or c and d, six isomers remain."—R. F. Miller and Roger Adams.

Earl M. Bilger and Harold Hibbert. **Mechanism of Organic Reactions. IV. Pyrolysis of Esters and Acetals.**

Page 825. In the first column of the table, item 4 should read "Ethylene *n*-butyral" instead of "Ethyl *n*-butyral."—Harold Hibbert.

Samuel C. Hooker. **Condensation of Aldehydes with β-Hydroxy-α-naphthoquinone. Synthesis of Hydrolapachol.**

Page 1163. Note 1, Lines 10 and 11. The word "purification" should read "publication."

Henry E. Bent and N. B. Keevil. **The Electron Affinity of Free Radicals. X. A Potentiometric Method for Determining ΔF for the Addition of Sodium to an Organic Compound.**

Page 1230. Column 1, line 9 from the end, for "10^{12}" read "10^{10}."—Henry E. Bent.

P. C. Jurs and C. R. Noller. **Saponins and Sapogenins. IV. The Isolation of Amolonin and Determination of the Products of Hydrolysis.**

Page 1254. In the captions of Figs. 2 and 3 and at the bottom of column 1, for "polarigram" and "polarigraph" read "polarogram" and "polarograph."—C. R. Noller.

Henry E. Bent and Norman B. Keevil. **The Electron Affinity of Free Radicals. XI. The Free Energy of Addition of Sodium to Ketones and Unsaturated Hydrocarbons.**

Page 1371. Column 1, line 4, for "not" read "now."—Henry E. Bent.

Russell E. Marker, Oliver Kamm, Thomas S. Oakwood and Joseph F. Laucius. **Sterols. VI. Synthetic Preparation of Oestrone (Theelin).**

Page 1503. The authors write: "In the formulas for ergosterol, neoergosterol, dehydro-neoergosterol and tetrahydro-dehydro-neoergosterol, the radical attached to the 17-position should be C_9H_{17} instead of C_9H_{18}. The analysis formulas also should be changed accordingly."—Russell E. Marker, Oliver Kamm, Thomas S. Oakwood and Joseph F. Laucius.

Charles M. Mason, Roger D. Gray and Grace L. Ernst. **The Magnetic Rotation of Lanthanum and Neodymium Chlorides in Aqueous Solution.**

Page 1602. In column 2, lines 8 and 14, for "λ5460.8 Å," read "λ5460.7 Å."

Page 1604. In column 2, lines 12 and 24, for "λ5460.8 Å." read "λ5460.7 Å."—C. M. Mason.

James P. Danehy and J. A. Nieuwland. **The Reactions of Metal Halides with Acetylenic Grignard Reagents.** Charles A. Young, R. R. Vogt and J. A. Nieuwland. **The Reaction of Butylacetylene with Hydrogen Bromide.**

Pages 1609 and 1806. The first of these two papers should have been numbered XVI, and the second XV instead of XIV.—G. F. Hennion.

Theodore Soller, Seymore Goldwasser and Ralph A. Beebe. **A Sensitive Manostat for Low Pressures and its Application to the Adsorption of Hydrogen and Deuterium on Copper.**

Page 1706. In the Summary, paragraph 2, line 3, for "3.35" read "5.5."—Ralph A. Beebe.

G. H. Cartledge and W. P. Ericks. **Equilibrium between the Trioxalatomanganiate and Dioxalatodiaquomanganiate Ions.**

Page 2068. Footnote (6) should read "(6) Johnson, *Trans. Faraday Soc.*, [5] 28, 845 (1932)."—G. H. Cartledge.

Frank T. Gucker, Jr., Fred D. Ayres and T. Richard Rubin. **A Differential Method Employing Variable Heaters for the Determination of the Specific Heats of Solutions, with Results for Ammonium Nitrate at 25°.**

Page 2122. In column 1, the third line from the end should read "$= 1.24741 + [0.10(1.2471 - 1)]/79.6 = 1.24772 = x_1$."—Frank T. Gucker.

F. H. Norton and H. B. Hass. **The Action of Diethylmagnesium upon the Methyl Substituted Derivatives of Epoxyethane.**

Page 2150. In Table VIII, first part, after "Ref. cpd." insert a line reading "Et_2Mg 157.1 750 82.5 1.4390 0.8549 40.04 0."—H. B. Hass.

David E. Adelson and Marston Taylor Bogert. **Investigations in the Retene Field. VII. Certain Fluorenones and Phenanthridones from Retenediphenic Acid.**

Page 2236. Column 1, in formula (II) the "HOOC—" on the upper ring should be ortho to the bond connecting the rings instead of ortho to the "—$CH(CH_3)_2$."—Marston T. Bogert.

L. F. Fieser, M. Fieser and E. B. Hershberg. **The Synthesis of Phenanthrene and Hydrophenanthrene Derivatives. VI. 1′,3′-Diketocyclopentenophenanthrenes.**

Page 2323. In formula V the carbonyl groups should be at the 1′- and 3′-positions, rather than at 2′ and 3′.—L. F. Fieser.
